  They slow down thread switching considerably for coros that use them (about 40% for a BLOCK with a single assignment, so thread switching is still reasonably fast if the handlers are fast).

  These functions are best understood by an example: The following function will change the current timezone to "Antarctica/South_Pole", which requires a call to `tzset`, but by using `on_enter` and `on_leave`, which remember/change the current timezone and restore the previous value, respectively, the timezone is only changed for the coro that installed those handlers.

```
use POSIX qw(tzset);

async {
   my $old_tz; # store outside TZ value here

   Coro::on_enter {
      $old_tz = $ENV{TZ}; # remember the old value

      $ENV{TZ} = "Antarctica/South_Pole";
      tzset; # enable new value
   };

   Coro::on_leave {
      $ENV{TZ} = $old_tz;
      tzset; # restore old value
   };

   # at this place, the timezone is Antarctica/South_Pole,
```

(continues on next page)

(continued from previous page)

```
   # without disturbing the TZ of any other coro.
};
```

This can be used to localise about any resource (locale, uid, current working directory etc.) to a block, despite the existence of other coros.

Another interesting example implements time-sliced multitasking using interval timers (this could obviously be optimised, but does the job):

```
# "timeslice" the given block
sub timeslice(&) {
   use Time::HiRes ();

   Coro::on_enter {
      # on entering the thread, we set an VTALRM handler to cede
      $SIG{VTALRM} = sub { cede };
      # and then start the interval timer
      Time::HiRes::setitimer &Time::HiRes::ITIMER_VIRTUAL, 0.01,
↪ 0.01;
   };
   Coro::on_leave {
      # on leaving the thread, we stop the interval timer again
      Time::HiRes::setitimer &Time::HiRes::ITIMER_VIRTUAL, 0, 0;
   };

   &{+shift};
}

# use like this:
timeslice {
   # The following is an endless loop that would normally
   # monopolise the process. Since it runs in a timesliced
   # environment, it will regularly cede to other threads.
   while () { }
};
```

- killall

  Kills/terminates/cancels all coros except the currently running one.

  Note that while this will try to free some of the main interpreter resources if the calling coro isn't the main coro, but one cannot free all of them, so if a coro that is not the main coro calls this function, there will be some one-time resource leak.

CORO OBJECT METHODS

These are the methods you can call on coro objects (or to create them).

- new Coro \&sub [, @args...]

  Create a new coro and return it. When the sub returns, the coro automatically terminates as if `terminate` with the returned values were called. To make the coro run you must first put it into the ready queue by calling the ready method.

See `async` and `Coro::State::new` for additional info about the coro environment.

- $success = $coro->ready

  Put the given coro into the end of its ready queue (there is one queue for each priority) and return true. If the coro is already in the ready queue, do nothing and return false.

  This ensures that the scheduler will resume this coro automatically once all the coro of higher priority and all coro of the same priority that were put into the ready queue earlier have been resumed.

- $coro->suspend

  Suspends the specified coro. A suspended coro works just like any other coro, except that the scheduler will not select a suspended coro for execution.

  Suspending a coro can be useful when you want to keep the coro from running, but you don't want to destroy it, or when you want to temporarily freeze a coro (e.g. for debugging) to resume it later.

  A scenario for the former would be to suspend all (other) coros after a fork and keep them alive, so their destructors aren't called, but new coros can be created.

- $coro->resume

  If the specified coro was suspended, it will be resumed. Note that when the coro was in the ready queue when it was suspended, it might have been unreadied by the scheduler, so an activation might have been lost.

  To avoid this, it is best to put a suspended coro into the ready queue unconditionally, as every synchronisation mechanism must protect itself against spurious wakeups, and the one in the Coro family certainly do that.

- $state->is_new

  Returns true iff this Coro object is "new", i.e. has never been run yet. Those states basically consist of only the code reference to call and the arguments, but consumes very little other resources. New states will automatically get assigned a perl interpreter when they are transferred to.

- $state->is_zombie

  Returns true iff the Coro object has been cancelled, i.e. its resources freed because they were `cancel`'ed, `terminate`'d, `safe_cancel`'ed or simply went out of scope.

  The name "zombie" stems from UNIX culture, where a process that has exited and only stores and exit status and no other resources is called a "zombie".

- $is_ready = $coro->is_ready

  Returns true iff the Coro object is in the ready queue. Unless the Coro object gets destroyed, it will eventually be scheduled by the scheduler.

- $is_running = $coro->is_running

  Returns true iff the Coro object is currently running. Only one Coro object can ever be in the running state (but it currently is possible to have multiple running Coro::States).

- $is_suspended = $coro->is_suspended

  Returns true iff this Coro object has been suspended. Suspended Coros will not ever be scheduled.

- $coro->cancel ($arg...)

  Terminate the given Coro thread and make it return the given arguments as status (default: an empty list). Never returns if the Coro is the current Coro.

  This is a rather brutal way to free a coro, with some limitations - if the thread is inside a C callback that doesn't expect to be canceled, bad things can happen, or if the cancelled thread insists on running complicated cleanup handlers that rely on its thread context, things will not work.

  Any cleanup code being run (e.g. from `guard` blocks, destructors and so on) will be run without a thread context, and is not allowed to switch to other threads. A common mistake is to call `->cancel` from a destructor called by die'ing inside the thread to be cancelled for example.

  On the plus side, `->cancel` will always clean up the thread, no matter what. If your cleanup code is complex or you want to avoid cancelling a C-thread that doesn't know how to clean up itself, it can be better to `->throw` an exception, or use `->safe_cancel`.

  The arguments to `->cancel` are not copied, but instead will be referenced directly (e.g. if you pass `$var` and after the call change that variable, then you might change the return values passed to e.g. `join`, so don't do that).

  The resources of the Coro are usually freed (or destructed) before this call returns, but this can be delayed for an indefinite amount of time, as in some cases the manager thread has to run first to actually destruct the Coro object.

- $coro->safe_cancel ($arg...)

  Works mostly like `->cancel`, but is inherently "safer", and consequently, can fail with an exception in cases the thread is not in a cancellable state. Essentially, `->safe_cancel` is a `->cancel` with extra checks before canceling.

  It works a bit like throwing an exception that cannot be caught - specifically, it will clean up the thread from within itself, so all cleanup handlers (e.g. `guard` blocks) are run with full thread context and can block if they wish. The downside is that there is no guarantee that the thread can be cancelled when you call this method, and therefore, it might fail. It is also considerably slower than `cancel` or `terminate`.

  A thread is in a safe-cancellable state if it either has never been run yet, has already been canceled/terminated or otherwise destroyed, or has no C context attached and is inside an SLF function.

  The first two states are trivial - a thread that hasnot started or has already finished is safe to cancel.

  The last state basically means that the thread isn't currently inside a perl callback called from native code (usually a native module such as EV) and isn't currently executing inside native code itself.

  This call returns true when it could cancel the thread, or croaks with an error otherwise (i.e. it either returns true or doesn't return at all).

Why the weird interface? Well, there are two common models on how and when to cancel things. In the first, you have the expectation that your coro thread can be cancelled when you want to cancel it - if the thread isn't cancellable, this would be a bug somewhere, so `->safe_cancel` croaks to notify of the bug.

In the second model you sometimes want to ask nicely to cancel a thread, but if it's not a good time, well, then don't cancel. This can be done relatively easy like this:

```
if (! eval { $coro->safe_cancel }) {
   warn "unable to cancel thread: $@";
}
```

However, what you never should do is first try to cancel "safely" and if that fails, cancel the "hard" way with `->cancel`. That makes no sense: either you rely on being able to execute cleanup code in your thread context, or you don't. If you do, then `->safe_cancel` is the only way, and if you don't, then `->cancel` is always faster and more direct.

- $coro->schedule_to

  Puts the current coro to sleep (like `Coro::schedule`), but instead of continuing with the next coro from the ready queue, always switch to the given coro object (regardless of priority etc.). The readyness state of that coro isn't changed.

  This is an advanced method for special cases - I'd love to hear about any uses for this one.

- $coro->cede_to

  Like `schedule_to`, but puts the current coro into the ready queue. This has the effect of temporarily switching to the given coro, and continuing some time later.

  This is an advanced method for special cases - I'd love to hear about any uses for this one.

- $coro->throw ([$scalar])

  If `$throw` is specified and defined, it will be thrown as an exception inside the coro at the next convenient point in time. Otherwise clears the exception object.

  Coro will check for the exception each time a schedule-like-function returns, i.e. after each `schedule`, `cede`, `Coro::Semaphore->down`, `Coro::Handle->readable` and so on. Most of those functions (all that are part of Coro itself) detect this case and return early in case an exception is pending.

  The exception object will be thrown "as is" with the specified scalar in `$@`, i.e. if it is a string, no line number or newline will be appended (unlike with `die`).

  This can be used as a softer means than either `cancel` or `safe_cancel` to ask a coro to end itself, although there is no guarantee that the exception will lead to termination, and if the exception isn't caught it might well end the whole program.

  You might also think of `throw` as being the moral equivalent of `killing` a coro with a signal (in this case, a scalar).

- $coro->join

  Wait until the coro terminates and return any values given to the `terminate` or `cancel` functions. `join` can be called concurrently from multiple threads, and all

will be resumed and given the status return once the `$coro` terminates.

- $coro->on_destroy (\&cb)

  Registers a callback that is called when this coro thread gets destroyed, that is, after its resources have been freed but before it is joined. The callback gets passed the terminate/cancel arguments, if any, and *must not* die, under any circumstances.

  There can be any number of `on_destroy` callbacks per coro, and there is currently no way to remove a callback once added.

- $oldprio = $coro->prio ($newprio)

  Sets (or gets, if the argument is missing) the priority of the coro thread. Higher priority coro get run before lower priority coros. Priorities are small signed integers (currently -4 .. +3), that you can refer to using PRIO_xxx constants (use the import tag :prio to get then):

```
PRIO_MAX > PRIO_HIGH > PRIO_NORMAL > PRIO_LOW > PRIO_IDLE > PRIO_MIN
   3    >     1     >      0      >    -1    >    -3     >    -4

# set priority to HIGH
current->prio (PRIO_HIGH);
```

  The idle coro thread ($Coro::idle) always has a lower priority than any existing coro.

  Changing the priority of the current coro will take effect immediately, but changing the priority of a coro in the ready queue (but not running) will only take effect after the next schedule (of that coro). This is a bug that will be fixed in some future version.

- $newprio = $coro->nice ($change)

  Similar to `prio`, but subtract the given value from the priority (i.e. higher values mean lower priority, just as in UNIX's nice command).

- $olddesc = $coro->desc ($newdesc)

  Sets (or gets in case the argument is missing) the description for this coro thread. This is just a free-form string you can associate with a coro.

  This method simply sets the `$coro->{desc}` member to the given string. You can modify this member directly if you wish, and in fact, this is often preferred to indicate major processing states that can then be seen for example in a *Coro::Debug* session:

```
sub my_long_function {
   local $Coro::current->{desc} = "now in my_long_function";
   ...
   $Coro::current->{desc} = "my_long_function: phase 1";
   ...
   $Coro::current->{desc} = "my_long_function: phase 2";
   ...
}
```

GLOBAL FUNCTIONS

- Coro::nready

  Returns the number of coro that are currently in the ready state, i.e. that can be switched to by calling `schedule` directory or indirectly. The value `0` means that the only runnable coro is the currently running one, so `cede` would have no effect, and `schedule` would cause a deadlock unless there is an idle handler that wakes up some coro.

- my $guard = Coro::guard { ... }

  This function still exists, but is deprecated. Please use the `Guard::guard` function instead.

- unblock_sub { ... }

  This utility function takes a BLOCK or code reference and "unblocks" it, returning a new coderef. Unblocking means that calling the new coderef will return immediately without blocking, returning nothing, while the original code ref will be called (with parameters) from within another coro.

  The reason this function exists is that many event libraries (such as the venerable *Event* module) are not thread-safe (a weaker form of reentrancy). This means you must not block within event callbacks, otherwise you might suffer from crashes or worse. The only event library currently known that is safe to use without `unblock_sub` is *EV* (but you might still run into deadlocks if all event loops are blocked).

  Coro will try to catch you when you block in the event loop ("FATAL: $Coro::idle blocked itself"), but this is just best effort and only works when you do not run your own event loop.

  This function allows your callbacks to block by executing them in another coro where it is safe to block. One example where blocking is handy is when you use the *Coro::AIO* functions to save results to disk, for example.

  In short: simply use `unblock_sub { ... }` instead of `sub { ... }` when creating event callbacks that want to block.

  If your handler does not plan to block (e.g. simply sends a message to another coro, or puts some other coro into the ready queue), there is no reason to use `unblock_sub`.

  Note that you also need to use `unblock_sub` for any other callbacks that are indirectly executed by any C-based event loop. For example, when you use a module that uses *AnyEvent* (and you use *Coro::AnyEvent*) and it provides callbacks that are the result of some event callback, then you must not block either, or use `unblock_sub`.

- $cb = rouse_cb

  Create and return a "rouse callback". That's a code reference that, when called, will remember a copy of its arguments and notify the owner coro of the callback.

  Only the first invocation will store agruments and signal any waiter - further calls will effectively be ignored, but it is ok to try.

  Also see the next function.

- @args = rouse_wait [$cb]

  Wait for the specified rouse callback to be invoked (or if the argument is missing, use the most recently created callback in the current coro).

  As soon as the callback is invoked (or when the callback was invoked before `rouse_wait`), it will return the arguments originally passed to the rouse callback. In scalar context, that means you get the *last* argument, just as if `rouse_wait` had a `return ($a1, $a2, $a3...)` statement at the end.

  You are only allowed to wait once for a given rouse callback.

  See the section **HOW TO WAIT FOR A CALLBACK** for an actual usage example.

  As of Coro 6.57, you can reliably wait for a rouse callback in a different thread than from where it was created.

HOW TO WAIT FOR A CALLBACK

It is very common for a coro to wait for some callback to be called. This occurs naturally when you use coro in an otherwise event-based program, or when you use event-based libraries.

These typically register a callback for some event, and call that callback when the event occurred. In a coro, however, you typically want to just wait for the event, simplyifying things.

For example `AnyEvent->child` registers a callback to be called when a specific child has exited:

```
my $child_watcher = AnyEvent->child (pid => $pid, cb => sub { ... }
↪);
```

But from within a coro, you often just want to write this:

```
my $status = wait_for_child $pid;
```

Coro offers two functions specifically designed to make this easy, `rouse_cb` and `rouse_wait`.

The first function, `rouse_cb`, generates and returns a callback that, when invoked, will save its arguments and notify the coro that created the callback.

The second function, `rouse_wait`, waits for the callback to be called (by calling `schedule` to go to sleep) and returns the arguments originally passed to the callback.

Using these functions, it becomes easy to write the `wait_for_child` function mentioned above:

```
sub wait_for_child($) {
   my ($pid) = @_;

   my $watcher = AnyEvent->child (pid => $pid, cb => rouse_cb);

   my ($rpid, $rstatus) = rouse_wait;
   $rstatus
}
```

In the case where `rouse_cb` and `rouse_wait` are not flexible enough, you can roll your own, using `schedule` and `ready`:

```
sub wait_for_child($) {
   my ($pid) = @_;

   # store the current coro in $current,
   # and provide result variables for the closure passed to ->child
   my $current = $Coro::current;
   my ($done, $rstatus);

   # pass a closure to ->child
   my $watcher = AnyEvent->child (pid => $pid, cb => sub {
      $rstatus = $_[1]; # remember rstatus
      $done = 1;        # mark $rstatus as valid
      $current->ready;  # wake up the waiting thread
   });

   # wait until the closure has been called
   schedule while !$done;

   $rstatus
}
```

BUGS/LIMITATIONS

- fork with pthread backend

  When Coro is compiled using the pthread backend (which isn't recommended but required on many BSDs as their libcs are completely broken), then coro will not survive a fork. There is no known workaround except to fix your libc and use a saner backend.

- perl process emulation ("threads")

  This module is not perl-pseudo-thread-safe. You should only ever use this module from the first thread (this requirement might be removed in the future to allow per-thread schedulers, but Coro::State does not yet allow this). I recommend disabling thread support and using processes, as having the windows process emulation enabled under unix roughly halves perl performance, even when not used.

  Attempts to use threads created in another emulated process will crash ("cleanly", with a null pointer exception).

- coro switching is not signal safe

  You must not switch to another coro from within a signal handler (only relevant with %SIG - most event libraries provide safe signals), *unless* you are sure you are not interrupting a Coro function.

  That means you *MUST NOT* call any function that might "block" the current coro - `cede`, `schedule` `Coro::Semaphore->down` or anything that calls those. Everything else, including calling `ready`, works.

WINDOWS PROCESS EMULATION

A great many people seem to be confused about ithreads (for example, Chip Salzenberg called me unintelligent, incapable, stupid and gullible, while in the same mail making rather confused statements about perl ithreads (for example, that memory or files would be shared), showing his lack of understanding of this area - if it is hard to understand for Chip, it is probably not obvious to everybody).

What follows is an ultra-condensed version of my talk about threads in scripting languages given on the perl workshop 2009:

The so-called “ithreads” were originally implemented for two reasons: first, to (badly) emulate unix processes on native win32 perls, and secondly, to replace the older, real thread model (“5.005-threads”).

It does that by using threads instead of OS processes. The difference between processes and threads is that threads share memory (and other state, such as files) between threads within a single process, while processes do not share anything (at least not semantically). That means that modifications done by one thread are seen by others, while modifications by one process are not seen by other processes.

The “ithreads” work exactly like that: when creating a new ithreads process, all state is copied (memory is copied physically, files and code is copied logically). Afterwards, it isolates all modifications. On UNIX, the same behaviour can be achieved by using operating system processes, except that UNIX typically uses hardware built into the system to do this efficiently, while the windows process emulation emulates this hardware in software (rather efficiently, but of course it is still much slower than dedicated hardware).

As mentioned before, loading code, modifying code, modifying data structures and so on is only visible in the ithreads process doing the modification, not in other ithread processes within the same OS process.

This is why “ithreads” do not implement threads for perl at all, only processes. What makes it so bad is that on non-windows platforms, you can actually take advantage of custom hardware for this purpose (as evidenced by the forks module, which gives you the (i-) threads API, just much faster).

Sharing data is in the i-threads model is done by transferring data structures between threads using copying semantics, which is very slow - shared data simply does not exist. Benchmarks using i-threads which are communication-intensive show extremely bad behaviour with i-threads (in fact, so bad that Coro, which cannot take direct advantage of multiple CPUs, is often orders of magnitude faster because it shares data using real threads, refer to my talk for details).

As summary, i-threads *use* threads to implement processes, while the compatible forks module *uses* processes to emulate, uhm, processes. I-threads slow down every perl program when enabled, and outside of windows, serve no (or little) practical purpose, but disadvantages every single-threaded Perl program.

This is the reason that I try to avoid the name “ithreads”, as it is misleading as it implies that it implements some kind of thread model for perl, and prefer the name “windows process emulation”, which describes the actual use and behaviour of it much better.

Modules

- `Coro::AIO` - truly asynchronous file and directory I/O
- `Coro::AnyEvent` - integrate threads into AnyEvent
- `Coro::BDB` - truly asynchronous bdb access
- `Coro::Channel` - message queues
- `Coro::Debug` - various functions that help debugging Coro programs
- `Coro::EV` - run Coro on the EV event loop
- `Coro::Event` - Event watchers that block the calling coroutine
- `Coro::Handle` - non-blocking I/O with a blocking interface.
- `Coro::LWP` - make LWP non-blocking - as much as possible
- `Coro::RWLock` - reader/write locks
- `Coro::Select` - a (slow but coro-aware) replacement for CORE::select
- `Coro::Semaphore` - counting semaphores
- `Coro::SemaphoreSet` - efficient set of counting semaphores
- `Coro::Signal` - thread signals (binary semaphores)
- `Coro::Socket` - non-blocking socket-I/O
- `Coro::Specific` - manage coroutine-specific variables.
- `Coro::State` - the engine under Coro: Perl-level threads
- `Coro::Storable` - offer a more fine-grained Storable interface
- `Coro::Timer` - timers and timeouts, independent of any event loop

- `Coro::Util` - various utility functions.

Coro::AIO

truly asynchronous file and directory I/O

SYNOPSIS

```
use Coro::AIO;

# can now use any of the aio requests your IO::AIO module supports.

# read 1MB of /etc/passwd, without blocking other coroutines
my $fh = aio_open "/etc/passwd", O_RDONLY, 0
   or die "/etc/passwd: $!";
aio_read $fh, 0, 1_000_000, my $buf, 0
   or die "aio_read: $!";
aio_close $fh;
```

DESCRIPTION

This module is an *AnyEvent* user, you need to make sure that you use and run a supported event loop.

This module implements a thin wrapper around IO::AIO. All of the functions that expect a callback are being wrapped by this module.

The API is exactly the same as that of the corresponding IO::AIO routines, except that you have to specify *all* arguments, even the ones optional in IO::AIO, *except* the callback argument. Instead of calling a callback, the routines return the values normally passed to the callback. Everything else, including `$!` and perls stat cache, are set as expected after these functions return.

You can mix calls to `IO::AIO` functions with calls to this module. You *must not*, however, call these routines from within IO::AIO callbacks, as this causes a deadlock. Start a coro inside the callback instead.

This module also loads AnyEvent::AIO to integrate into the event loop in use, so please refer to its (and *AnyEvent*'s) documentation on how it selects an appropriate event module.

All other functions exported by default by IO::AIO (e.g. `aioreq_pri`) will be exported by default by Coro::AIO, too.

Functions that can be optionally imported from IO::AIO can be imported from Coro::AIO or can be called directly, e.g. `Coro::AIO::nreqs`.

You cannot specify priorities with `aioreq_pri` if your coroutine has a non-zero priority, as this module overwrites the request priority with the current coroutine priority in that case.

For your convenience, here are the changed function signatures for most of the requests, for documentation of these functions please have a look at IO::AIO. Note that requests added by newer versions of IO::AIO will be automatically wrapped as well.

- @results = aio_wait $req

  This is not originally an IO::AIO request: what it does is to wait for `$req` to finish and return the results. This is most useful with `aio_group` requests.

  Is currently implemented by replacing the `$req` callback (and is very much like a wrapper around `$req->cb ()`).

- $fh = aio_open $pathname, $flags, $mode
- $status = aio_close $fh
- $retval = aio_read $fh,$offset,$length, $data,$dataoffset
- $retval = aio_write $fh,$offset,$length, $data,$dataoffset
- $retval = aio_sendfile $out_fh, $in_fh, $in_offset, $length
- $retval = aio_readahead $fh,$offset,$length
- $status = aio_stat $fh_or_path
- $status = aio_lstat $fh
- $status = aio_unlink $pathname
- $status = aio_rmdir $pathname
- $entries = aio_readdir $pathname
- ($dirs, $nondirs) = aio_scandir $path, $maxreq
- $status = aio_fsync $fh
- $status = aio_fdatasync $fh
- ... = aio_xxx ...

  Any additional aio requests follow the same scheme: same parameters except you must not specify a callback but instead get the callback arguments as return values.

SEE ALSO

Coro::Socket and *Coro::Handle* for non-blocking socket operation.

Coro::AnyEvent

integrate threads into AnyEvent

SYNOPSIS

```
use Coro;
use AnyEvent;
# using both Coro and AnyEvent will automatically load
 ↪Coro::AnyEvent

# or load it manually for its utility functions:
use Coro::AnyEvent;

Coro::AnyEvent::sleep 5;     # block current thread for 5s
Coro::AnyEvent::poll;        # poll for new events once
Coro::AnyEvent::idle;        # block until process no longer busy
Coro::AnyEvent::idle_upto 5; # same, but only up to 5 seconds

Coro::AnyEvent::readable $fh, 60
   or die "fh didn't become readable within 60 seconds\n";
```

DESCRIPTION

When one naively starts to use threads in Perl, one will quickly run into the problem that threads which block on a syscall (sleeping, reading from a socket etc.) will block all threads.

If one then uses an event loop, the problem is that the event loop has no knowledge of threads and will not run them before it polls for new events, again blocking the whole process.

This module integrates threads into any event loop supported by AnyEvent, combining event-based programming with coroutine-based programming in a natural way.

As of Coro 5.21 and newer, this module gets loaded automatically when AnyEvent initialises itself and Coro is used in the same process, thus there is no need to load it manually if you just want your threads to coexist with AnyEvent.

If you want to use any functions from this module, you of course still need to `use Coro::AnyEvent`, just as with other perl modules.

Also, this module autodetects the event loop used (by relying on *AnyEvent*) and will either automatically defer to the high-performance *Coro::EV* or *Coro::Event* modules, or will use a generic integration method that should work with any event loop supported by *AnyEvent*.

USAGE

RUN AN EVENT LOOP - OR NOT?

For performance reasons, it is recommended that the main program or something else run the event loop of the event model you use, i.e.

```
use Gtk2; # <- the event model
use AnyEvent;
```

(continues on next page)

(continued from previous page)

```
use Coro:

# initialise stuff
async { ... };

# now run mainloop of Gtk2
main Gtk2;
```

You can move the event loop into a thread as well, although this tends to get confusing:

```
use Gtk2;
use AnyEvent;
use Coro:

async { main Gtk2 };

# do other things...
while () {
   use Coro::AnyEvent;
   Coro::AnyEvent::sleep 1;
   print "ping...\n";
}
```

You can also do nothing, in which case Coro::AnyEvent will invoke the event loop as needed, which is less efficient, but sometimes very convenient.

What you *MUST NOT EVER DO* is to block inside an event loop callback. The reason is that most event loops are not reentrant and this can cause a deadlock at best and corrupt memory at worst.

Coro will try to catch you when you block in the event loop ("FATAL: $Coro::IDLE blocked itself"), but this is just best effort and only works when you do not run your own event loop.

To avoid this problem, start a new thread (e.g. with `Coro::async_pool`) or use `Coro::unblock_sub` to run blocking tasks.

INVERSION OF CONTROL

If you need to wait for a single event, the rouse functions will come in handy (see the Coro manpage for details):

```
# wait for single SIGINT
{
   my $int_w = AnyEvent->signal (signal => "INT", cb => Coro::rouse_
↪cb);
   Coro::rouse_wait;
}
```

EVENT MODULES OTHER THAN ANYEVENT

Keep in mind that, as shipped, Coro and Coro::AnyEvent only work with AnyEvent, and only when AnyEvent is actually used (i.e. initialised), so this will not work:

```
# does not work: EV without AnyEvent is not recognised
use EV;
use Coro;

EV::loop;
```

And neither does this, unless you actually *use* AnyEvent for something:

```
# does not work: AnyEvent must be initialised (e.g. by creating␣
↪watchers)
use EV;
use AnyEvent;
use Coro;

EV::loop;
```

This does work, however, because you create a watcher (condvars work, too), thus forcing AnyEvent to initialise itself:

```
# does work: AnyEvent is actually used
use EV;
use AnyEvent;
use Coro;

my $timer = AE::timer 1, 1, sub { };

EV::loop;
```

And if you want to use AnyEvent just to bridge between Coro and your event model of choice, you can simply force it to initialise itself, like this:

```
# does work: AnyEvent is initialised manually
use POE;
use AnyEvent;
use Coro;

AnyEvent::detect; # force AnyEvent to integrate Coro into POE
POE::Kernel->run;
```

FUNCTIONS

Coro::AnyEvent also offers a few functions that might be useful.

- Coro::AnyEvent::poll

  This call will block the current thread until the event loop has polled for potential new events and instructs the event loop to poll for new events once, without blocking.

Note that this call will not actually execute the poll, nor will it wait until there are some events, just block until the event loop has polled for new events, so other threads will have a chance to run.

This is useful when you have a thread that does some computations, but you still want to poll for new events from time to time. Simply call `poll` from time to time:

```
my $long_calc = async {
   for (1..10000) {
      Coro::AnyEvent::poll;
      # do some stuff, make sure it takes at least 0.001s or so
   }
}
```

Although you should also consider `idle` or `idle_upto` in such cases.

- Coro::AnyEvent::sleep $seconds

  This blocks the current thread for at least the given number of seconds.

- Coro::AnyEvent::idle

  This call is similar to `poll` in that it will also poll for events. Unlike `poll`, it will only resume the thread once there are no events to handle anymore, i.e. when the process is otherwise idle.

  This is good for background threads that shouldn't use CPU time when foreground jobs are ready to run.

- Coro::AnyEvent::idle_upto $seconds

  Like `idle`, but with a maximum waiting time.

  If your process is busy handling events, calling `idle` can mean that your thread will never be resumed. To avoid this, you can use `idle_upto` and specify a timeout, after which your thread will be resumed even if the process is completely busy.

- Coro::AnyEvent::readable $fh_or_fileno[, $timeout]
- Coro::AnyEvent::writable $fh_or_fileno[, $timeout]

  Blocks the current thread until the given file handle (or file descriptor) becomes readable (or writable), or the given timeout has elapsed, whichever happens first. No timeout counts as infinite timeout.

  Returns true when the file handle became ready, false when a timeout occurred.

  Note that these functions are quite inefficient as compared to using a single watcher (they recreate watchers on every invocation) or compared to using Coro::Handle.

  Note also that they only work for sources that have reasonable non-blocking behaviour (e.g. not files).

  Example: wait until STDIN becomes readable, then quit the program.

```
use Coro::AnyEvent;
print "press enter to quit...\n";
Coro::AnyEvent::readable *STDIN;
exit 0;
```

IMPLEMENTATION DETAILS

Unfortunately, few event loops (basically only *EV* and *Event*) support the kind of integration required for smooth operations well, and consequently, AnyEvent cannot completely offer the functionality required by this module, so we need to improvise.

Here is what this module does when it has to work with other event loops:

- run ready threads before blocking the process

  Each time a thread is put into the ready queue (and there are no other threads in the ready queue), a timer with an `after` value of `0` is registered with AnyEvent.

  This creates something similar to an *idle* watcher, i.e. a watcher that keeps the event loop from blocking but still polls for new events. (Unfortunately, some badly designed event loops (e.g. Event::Lib) don't support a timeout of `0` and will always block for a bit).

  The callback for that timer will `cede` to other threads of the same or higher priority for as long as such threads exists. This has the effect of running all threads that have work to do until all threads block to wait for external events.

  If no threads of equal or higher priority are ready, it will cede to any thread, but only once. This has the effect of running lower-priority threads as well, but it will not keep higher priority threads from receiving new events.

  The priority used is simply the priority of the thread that runs the event loop, usually the main program, which usually has a priority of `0`. Note that Coro::AnyEvent does *not* run an event loop for you, so unless the main program runs one, there will simply be no event loop to `cede` to (event handling will still work, somewhat inefficiently, but any thread will have a higher priority than event handling in that case).

- provide a suitable idle callback.

  In addition to hooking into `ready`, this module will also provide a `$Coro::idle` handler that runs the event loop. It is best not to take advantage of this too often, as this is rather inefficient, but it should work perfectly fine.

- provide overrides for AnyEvent's condvars

  This module installs overrides for AnyEvent's condvars. That is, when the module is loaded it will provide its own condition variables. This makes them coroutine-safe, i.e. you can safely block on them from within a coroutine.

- lead to data corruption or worse

  As `unblock_sub` cannot be used by this module (as it is the module that implements it, basically), you must not call into the event loop recursively from any coroutine. This is not usually a difficult restriction to live with, just use condvars, `unblock_sub` or other means of inter-coroutine-communications.

  If you use a module that supports AnyEvent (or uses the same event loop as AnyEvent, making it implicitly compatible), and it offers callbacks of any kind, then you must not block in them, either (or use e.g. `unblock_sub`), see the description of `unblock_sub` in the *Coro* module.

  This also means that you should load the module as early as possible, as only condvars created after this module has been loaded will work correctly.

SEE ALSO

AnyEvent, to see which event loops are supported, *Coro::EV* and *Coro::Event* for more efficient and more correct solutions (they will be used automatically if applicable).

Coro::BDB

truly asynchronous bdb access

SYNOPSIS

```
use Coro::BDB;
use BDB;

# can now use any of the bdb requests
```

DESCRIPTION

This module is an *AnyEvent* user, you need to make sure that you use and run a supported event loop.

This module implements a thin wrapper around the BDB module: Each BDB request that could block and doesn't get passed a callback will normally block all coroutines. after loading this module, this will no longer be the case (it provides a suitable sync prepare callback).

It will also register an AnyEvent watcher as soon as AnyEvent chooses an event loop.

The AnyEvent watcher can be disabled by executing `undef $Coro::BDB::WATCHER`. Please notify the author of when and why you think this was necessary.

This module does not export anything (unlike *Coro::AIO*), as BDB already supports leaving out the callback. (Unfortunately, it ties a C context to each coroutine executing such a callback, so in the future, it might export more efficient wrappers).

SEE ALSO

BDB of course.

```

Coro::Channel

message queues

SYNOPSIS

```
use Coro;

$q1 = new Coro::Channel <maxsize>;

$q1->put ("xxx");
print $q1->get;

die unless $q1->size;
```

DESCRIPTION

A Coro::Channel is the equivalent of a unix pipe (and similar to amiga message ports): you can put things into it on one end and read things out of it from the other end. If the capacity of the Channel is maxed out writers will block. Both ends of a Channel can be read/written from by as many coroutines as you want concurrently.

You don't have to load `Coro::Channel` manually, it will be loaded automatically when you `use Coro` and call the `new` constructor.

- $q = new Coro:Channel $maxsize

  Create a new channel with the given maximum size (practically unlimited if `maxsize` is omitted or zero). Giving a size of one gives you a traditional channel, i.e. a queue that can store only a single element (which means there will be no buffering, and `put` will wait until there is a corresponding `get` call). To buffer one element you have to specify 2, and so on.

- $q->put ($scalar)

  Put the given scalar into the queue.

- $q->get

  Return the next element from the queue, waiting if necessary.

- $q->shutdown

  Shuts down the Channel by pushing a virtual end marker onto it: This changes the behaviour of the Channel when it becomes or is empty to return `undef`, almost as if infinitely many `undef` elements had been put into the queue.

  Specifically, this function wakes up any pending `get` calls and lets them return `undef`, the same on future `get` calls. `size` will return the real number of stored elements, though.

  Another way to describe the behaviour is that `get` calls will not block when the queue becomes empty but immediately return `undef`. This means that calls to `put` will work normally and the data will be returned on subsequent `get` calls.

This method is useful to signal the end of data to any consumers, quite similar to an end of stream on e.g. a tcp socket: You have one or more producers that `put` data into the Channel and one or more consumers who `get` them. When all producers have finished producing data, a call to `shutdown` signals this fact to any consumers.

A common implementation uses one or more threads that `get` from a channel until it returns `undef`. To clean everything up, first `shutdown` the channel, then `join` the threads.

- $q->size

  Return the number of elements waiting to be consumed. Please note that:

```
if ($q->size) {
   my $data = $q->get;
   ...
}
```

  is *not* a race condition but instead works just fine. Note that the number of elements that wait can be larger than `$maxsize`, as it includes any coroutines waiting to put data into the channel (but not any shutdown condition).

  This means that the number returned is *precisely* the number of calls to `get` that will succeed instantly and return some data. Calling `shutdown` has no effect on this number.

```

Coro::Debug

various functions that help debugging Coro programs

SYNOPSIS

```
use Coro::Debug;

our $server = new_unix_server Coro::Debug "/tmp/socketpath";

$ socat readline unix:/tmp/socketpath
```

DESCRIPTION

This module is an *AnyEvent* user, you need to make sure that you use and run a supported event loop.

This module provides some debugging facilities. Most will, if not handled carefully, severely compromise the security of your program, so use it only for debugging (or take other precautions).

It mainly implements a very primitive debugger that is very easy to integrate in your program:

```
our $server = new_unix_server Coro::Debug "/tmp/somepath";
# see new_unix_server, below, for more info
```

It lets you list running coroutines:

```
         state (rUnning, Ready, New or neither)
         |cctx allocated
         ||  resident set size (octets)
         ||  |   scheduled this many times
> ps     ||  |   |
     PID SC  RSS USES Description              Where
14572344 UC  62k 128k [main::]                 [dm-support.ext:47]
14620056 -- 2260   13 [coro manager]           [Coro.pm:358]
14620128 -- 2260  166 [unblock_sub scheduler]  [Coro.pm:358]
17764008 N-  152    0 [EV idle process]        -
13990784 -- 2596  10k timeslot manager         [cf.pm:454]
81424176 --  18k 4758 [async pool idle]         [Coro.pm:257]
23513336 -- 2624    1 follow handler           [follow.ext:52]
40548312 --  15k 5597 player scheduler          [player-scheduler.
 ↪ext:13]
29138032 -- 2548  431 music scheduler          [player-env.ext:77]
43449808 -- 2260 3493 worldmap updater         [item-worldmap.
 ↪ext:115]
33352488 --  19k 2845 [async pool idle]         [Coro.pm:257]
81530072 --  13k  43k map scheduler            [map-scheduler.
 ↪ext:65]
30751144 --  15k 2204 [async pool idle]         [Coro.pm:257]
```

Lets you do backtraces on about any coroutine:

```
> bt 18334288
coroutine is at /opt/cf/ext/player-env.ext line 77
        eval {...} called at /opt/cf/ext/player-env.ext line 77
        ext::player_env::__ANON__ called at -e line 0
        Coro::_run_coro called at -e line 0
```

Or lets you eval perl code:

```
> 5+7
12
```

Or lets you eval perl code within other coroutines:

```
> eval 18334288 caller(1); $DB::args[0]->method
1
```

It can also trace subroutine entry/exits for most coroutines (those not having recursed into a C function), resulting in output similar to:

```
> loglevel 5
> trace 94652688
2007-09-27Z20:30:25.1368 (5) [94652688] enter Socket::sockaddr_in␣
 ↪with (8481,\x{7f}\x{00}\x{00}\x{01})
2007-09-27Z20:30:25.1369 (5) [94652688] leave Socket::sockaddr_in␣
 ↪returning (\x{02}\x{00}...)
2007-09-27Z20:30:25.1370 (5) [94652688] enter Net::FCP::Util::touc␣
 ↪with (client_get)
2007-09-27Z20:30:25.1371 (5) [94652688] leave Net::FCP::Util::touc␣
 ↪returning (ClientGet)
2007-09-27Z20:30:25.1372 (5) [94652688] enter␣
 ↪AnyEvent::Impl::Event::io with (AnyEvent,fh,GLOB(0x9256250),poll,
 ↪w,cb,CODE(0x8c963a0))
2007-09-27Z20:30:25.1373 (5) [94652688] enter Event::Watcher::__
 ↪ANON__ with (Event,poll,w,fd,GLOB(0x9256250),cb,CODE(0x8c963a0))
2007-09-27Z20:30:25.1374 (5) [94652688] enter Event::io::new with␣
 ↪(Event::io,poll,w,fd,GLOB(0x9256250),cb,CODE(0x8c963a0))
2007-09-27Z20:30:25.1375 (5) [94652688] enter Event::Watcher::init␣
 ↪with (Event::io=HASH(0x8bfb120),HASH(0x9b7940))
```

If your program uses the Coro::Debug::log facility:

```
Coro::Debug::log 0, "important message";
Coro::Debug::log 9, "unimportant message";
```

Then you can even receive log messages in any debugging session:

```
> loglevel 5
2007-09-26Z02:22:46 (9) unimportant message
```

Other commands are available in the shell, use the `help` command for a list.

FUNCTIONS

None of the functions are being exported.

- log $level, $msg

  Log a debug message of the given severity level (0 is highest, higher is less important) to all interested parties.

- stderr_loglevel $level

  Set the loglevel for logging to stderr (defaults to the value of the environment variable PERL_CORO_STDERR_LOGLEVEL, or -1 if missing).

- session_loglevel $level

  Set the default loglevel for new coro debug sessions (defaults to the value of the environment variable PERL_CORO_DEFAULT_LOGLEVEL, or -1 if missing).

- trace $coro, $loglevel

  Enables tracing the given coroutine at the given loglevel. If loglevel is omitted, use 5. If coro is omitted, trace the current coroutine. Tracing incurs a very high

runtime overhead.

It is not uncommon to enable tracing on oneself by simply calling `Coro::Debug::trace`.

A message will be logged at the given loglevel if it is not possible to enable tracing.

- untrace $coro

  Disables tracing on the given coroutine.

- command $string

  Execute a debugger command, sending any output to STDOUT. Used by `session`, below.

- session $fh

  Run an interactive debugger session on the given filehandle. Each line entered is simply passed to `command` (with a few exceptions).

- $server = new_unix_server Coro::Debug $path

  Creates a new unix domain socket that listens for connection requests and runs `session` on any connection. Normal unix permission checks and umask applies, so you can protect your socket by puttint it into a protected directory.

  The `socat` utility is an excellent way to connect to this socket:

```
socat readline /path/to/socket
```

  Socat also offers history support:

```
socat readline:history=/tmp/hist.corodebug /path/to/socket
```

  The server accepts connections until it is destroyed, so you must keep the return value around as long as you want the server to stay available.

- $server = new_tcp_server Coro::Debug $port

  Similar to `new_unix_server`, but binds on a TCP port. *Note that this is usually results in a gaping security hole.*

  Currently, only a TCPv4 socket is created, in the future, a TCPv6 socket might also be created.

AUTHOR/SUPPORT/CONTACT

Marc A. Lehmann <schmorp@schmorp.de>
http://software.schmorp.de/pkg/Coro.html
```

Coro::EV

`Coro::EV` - run Coro on the EV event loop.

```
use Coro;
use Coro::EV;

async { Coro::EV::timer_once 0.5; print "half a second later\n" };
EV::run;                        # or let Coro::AnyEvent drive it
```

Loading `Coro::EV` makes EV's loop and Coro's scheduler cooperate: before EV blocks for events it runs every ready coroutine, and when a coroutine becomes ready while EV sleeps, EV wakes up for it. That is what lets code in the linear Coro style wait on sockets and timers through EV - directly, or through `Coro::AnyEvent`, `Coro::Handle` and `Coro::Socket`, which use it when EV is the event loop.

`Coro::EV::timer_once $seconds` suspends the current coroutine for that long; `Coro::EV::timed_io_once $fh, $events, $timeout` waits for a filehandle to become readable or writable (`EV::READ`, `EV::WRITE`) and returns the events that occurred, or 0 on timeout.

This is a native implementation of the XS half of Coro 6.57's `Coro::EV`, on the native *EV* module; its `Coro/EV.pm` is used unchanged.

Differences from upstream

None.

Coro::Event

`Coro::Event` - Event watchers that block the calling coroutine instead of running a callback.

```
use Coro;
use Coro::Event;

async {
    my $w = Coro::Event->timer(interval => 1);
    while () {
        $w->next;                # this coroutine sleeps, others run
        print "tick\n";
    }
};

Event::loop;
```

Every Event watcher type has a Coro::Event constructor of the same name (`Coro::Event->io(...)`, `->timer(...)`, `->signal(...)`, ...) that takes Event's arguments without a callback. `$w->next` suspends the current coroutine until the watcher's next event and returns it; `Coro::Event::do_io(...)` and friends wait for a single event. While Event's loop waits it lets every ready coroutine run first, so programs written in the linear Coro style and callback code driven by Event share one loop. Run `Event::loop` in the main program or in a coroutine of its own.

This is a native implementation of the XS half of Coro 6.57's `Coro::Event`, on the native *Event* module; its `Coro/Event.pm` is used unchanged.

Differences from upstream

None.

Coro::Handle

non-blocking I/O with a blocking interface.

SYNOPSIS

```
use Coro::Handle;
```

DESCRIPTION

This module is an *AnyEvent* user, you need to make sure that you use and run a supported event loop.

This module implements IO-handles in a coroutine-compatible way, that is, other coroutines can run while reads or writes block on the handle.

It does so by using *AnyEvent* to wait for readable/writable data, allowing other coroutines to run while one coroutine waits for I/O.

Coro::Handle does NOT inherit from IO::Handle but uses tied objects.

If at all possible, you should *always* prefer method calls on the handle object over invoking tied methods, i.e.:

```
$fh->print ($str);          # NOT print $fh $str;
my $line = $fh->readline;   # NOT my $line = <$fh>;
```

The reason is that perl recurses within the interpreter when invoking tie magic, forcing the (temporary) allocation of a (big) stack. If you have lots of socket connections and they happen to wait in e.g. <$fh>, then they would all have a costly C coroutine associated with them.

- $fh = new_from_fh Coro::Handle $fhandle [, arg => value...]

  Create a new non-blocking io-handle using the given perl-filehandle. Returns `undef` if no filehandle is given. The only other supported argument is "timeout", which sets a timeout for each operation.

- $fh = unblock $fh

  This is a convenience function that just calls `new_from_fh` on the given filehandle. Use it to replace a normal perl filehandle by a non-(coroutine-)blocking equivalent.

- $fh->writable, $fh->readable

  Wait until the filehandle is readable or writable (and return true) or until an error condition happens (and return false).

- $fh->readline ([$terminator])

  Similar to the builtin of the same name, but allows you to specify the input record separator in a coroutine-safe manner (i.e. not using a global variable). Paragraph mode is not supported, use "\n\n" to achieve the same effect.

- $fh->autoflush ([...])

  Always returns true, arguments are being ignored (exists for compatibility only). Might change in the future.

- $fh->fileno, $fh->close, $fh->read, $fh->sysread, $fh->syswrite, $fh->print, $fh->printf

  Work like their function equivalents (except read, which works like sysread. You should not use the read function with Coro::Handle's, it will work but it's not efficient).

- connect, listen, bind, getsockopt, setsockopt, send, recv, peername, sockname, shutdown, peerport, peerhost

  Do the same thing as the perl builtins or IO::Socket methods (but return true on EINPROGRESS). Remember that these must be method calls.

- peeraddr, peerhost, peerport

  Return the peer host (as numericla IP address) and peer port (as integer).

- ($fh, $peername) = $listen_fh->accept

  In scalar context, returns the newly accepted socket (or undef) and in list context return the ($fh, $peername) pair (or nothing).

- $fh->timeout ([...])

  The optional argument sets the new timeout (in seconds) for this handle. Returns the current (new) value.

  `0` is a valid timeout, use `undef` to disable the timeout.

- $fh->fh

  Returns the "real" (non-blocking) filehandle. Use this if you want to do operations on the file handle you cannot do using the Coro::Handle interface.

- $fh->rbuf

  Returns the current contents of the read buffer (this is an lvalue, so you can change the read buffer if you like).

  You can use this function to implement your own optimized reader when neither readline nor sysread are viable candidates, like this:

```
# first get the _real_ non-blocking filehandle
# and fetch a reference to the read buffer
my $nb_fh = $fh->fh;
my $buf = \$fh->rbuf;

while () {
   # now use buffer contents, modifying
   # if necessary to reflect the removed data

   last if $$buf ne ""; # we have leftover data

   # read another buffer full of data
```

(continues on next page)

(continued from previous page)

```
   $fh->readable or die "end of file";
   sysread $nb_fh, $$buf, 8192;
}
```

BUGS

```
- Perl's IO-Handle model is THE bug.
```

```

Coro::LWP

make LWP non-blocking - as much as possible

SYNOPSIS

```
use Coro::LWP; # afterwards LWP should not block
```

ALTERNATIVES

Over the years, a number of less-invasive alternatives have popped up, which you might find more acceptable than this rather invasive and fragile module. All of them only support HTTP (and sometimes HTTPS).

- AnyEvent::HTTP

  Works fine without Coro. Requires using a very different API than LWP. Probably the best choice *iff* you can do with a completely different event-based API.

- LWP::Protocol::AnyEvent::http

  Makes LWP use AnyEvent::HTTP. Does not make LWP event-based, but allows Coro threads to schedule unimpeded through its AnyEvent integration.

  Lets you use the LWP API normally.

- LWP::Protocol::Coro::http

  Basically the same as above, distinction unclear. :)

- AnyEvent::HTTP::LWP::UserAgent

  A different user agent implementation, not completely transparent to users, requires Coro.

DESCRIPTION

This module is an *AnyEvent* user, you need to make sure that you use and run a supported event loop.

This module tries to make LWP non-blocking with respect to other coroutines as much as possible, and with whatever means it takes.

LWP really tries very hard to be blocking (and relies on a lot of undocumented functionality in IO::Socket), so this module had to be very invasive and must be loaded very early to take the proper effect.

Note that the module AnyEvent::HTTP might offer an alternative to the full LWP that is designed to be non-blocking.

Here is what it currently does (future versions of LWP might require different tricks):

- It loads Coro::Select, overwriting the perl `select` builtin *globally*.

  This is necessary because LWP calls select quite often for timeouts and who-knows-what.

  Impact: everybody else uses this (slower) version of select, too. It should be quite compatible to perls builtin select, though.

- It overwrites Socket::inet_aton with Coro::Util::inet_aton.

  This is necessary because LWP might (and does) try to resolve hostnames this way.

  Impact: some code might not expect coroutine semantics, for example, when you fork you might prefer the blocking variant because other coroutines shouldn't actually run.

- It replaces the base class of Net::HTTP, Net::FTP, Net::NNTP.

  This is necessary because LWP does not always use select to see whether a filehandle can be read/written without blocking, so the base class `IO::Socket::INET` needs to be replaced by `Coro::Socket`.

  Impact: Coro::Socket is not at all compatible to IO::Socket::INET. While it duplicates some undocumented functionality required by LWP, it does not have all the methods of IO::Socket::INET and might act quite differently in practise. Also, protocols other than the above mentioned will still block, at least some of the time.

All this likely makes other libraries than just LWP not block, but that's just a side effect you cannot rely on.

Increases parallelism is not supported by all libraries, some might cache data globally.

Coro::RWLock

reader/write locks

SYNOPSIS

```
use Coro;

$lck = new Coro::RWLock;

$lck->rdlock; # acquire read lock
$lck->unlock; # unlock lock again

# or:
$lck->wrlock; # acquire write lock
$lck->unlock; # unlock lock again

# try a readlock
if ($lck->tryrdlock) {
   ...;
   $l->unlock;
}

# try a write lock
if ($lck->trywrlock) {
   ...;
   $l->unlock;
}
```

DESCRIPTION

This module implements reader/write locks. A read can be acquired for read by many coroutines in parallel as long as no writer has locked it (shared access). A single write lock can be acquired when no readers exist. RWLocks basically allow many concurrent readers (without writers) OR a single writer (but no readers).

You don't have to load `Coro::RWLock` manually, it will be loaded automatically when you `use Coro` and call the `new` constructor.

- $l = new Coro::RWLock;

  Create a new reader/writer lock.

- $l->rdlock

  Acquire a read lock.

- $l->tryrdlock

  Try to acquire a read lock.

- $l->wrlock

  Acquire a write lock.

- $l->trywrlock

  Try to acquire a write lock.

- $l->unlock

  Give up a previous `rdlock` or `wrlock`.

```

Coro::Select

a (slow but coro-aware) replacement for CORE::select

SYNOPSIS

```
use Coro::Select;          # replace select globally (be careful,
 ↪see below)
use Coro::Select 'select'; # only in this module
use Coro::Select ();       # use Coro::Select::select
```

DESCRIPTION

This module tries to create a fully working replacement for perl's `select` built-in, using `AnyEvent` watchers to do the job, so other threads can run in parallel to any select user. As many libraries that only have a blocking API do not use global variables and often use select (or IO::Select), this effectively makes most such libraries "somewhat" non-blocking w.r.t. other threads.

This implementation works fastest when only very few bits are set in the fd set(s).

To be effective globally, this module must be `use`'d before any other module that uses `select`, so it should generally be the first module `use`'d in the main program. Note that overriding `select` globally might actually cause problems, as some `AnyEvent` backends use `select` themselves, and asking AnyEvent to use Coro::Select, which in turn asks AnyEvent will not quite work.

You can also invoke it from the commandline as `perl -MCoro::Select`.

To override select only for a single module (e.g. `Net::DBus::Reactor`), use a code fragment like this to load it:

```
{
   package Net::DBus::Reactor;
   use Coro::Select qw(select);
   use Net::DBus::Reactor;
}
```

Some modules (notably POE::Loop::Select) directly call `CORE::select`. For these modules, we need to patch the opcode table by sandwiching it between calls to `Coro::Select::patch_pp_sselect` and `Coro::Select::unpatch_pp_sselect`:

```
BEGIN {
   use Coro::Select ();
   Coro::Select::patch_pp_sselect;
   require evil_poe_module_using_CORE::SELECT;
   Coro::Select::unpatch_pp_sselect;
}
```

BUGS

For performance reasons, Coro::Select's select function might not properly detect bad file descriptors (but relying on EBADF is inherently non-portable).

Coro::Semaphore

counting semaphores

SYNOPSIS

```
use Coro;

$sig = new Coro::Semaphore [initial value];

$sig->down; # wait for signal

# ... some other "thread"

$sig->up;
```

DESCRIPTION

This module implements counting semaphores. You can initialize a mutex with any level of parallel users, that is, you can initialize a sempahore that can be downed more than once until it blocks. There is no owner associated with semaphores, so one thread can down it while another can up it (or vice versa), up can be called before down and so on: the semaphore is really just an integer counter that optionally blocks when it is 0.

Counting semaphores are typically used to coordinate access to resources, with the semaphore count initialized to the number of free resources. Threads then increment the count when resources are added and decrement the count when resources are removed.

You don't have to load `Coro::Semaphore` manually, it will be loaded automatically when you `use Coro` and call the `new` constructor.

- new [initial count]

  Creates a new sempahore object with the given initial lock count. The default lock count is 1, which means it is unlocked by default. Zero (or negative values) are also allowed, in which case the semaphore is locked by default.

- $sem->count

  Returns the current semaphore count. The semaphore can be down'ed without blocking when the count is strictly higher than `0`.

- $sem->adjust ($diff)

  Atomically adds the amount given to the current semaphore count. If the count becomes positive, wakes up any waiters. Does not block if the count becomes negative, however.

- $sem->down

  Decrement the counter, therefore "locking" the semaphore. This method waits until the semaphore is available if the counter is zero or less.

- $sem->wait

  Similar to `down`, but does not actually decrement the counter. Instead, when this function returns, a following call to `down` or `try` is guaranteed to succeed without blocking, until the next thread switch (`cede` etc.).

  Note that using `wait` is much less efficient than using `down`, so try to prefer `down` whenever possible.

- $sem->wait ($callback)

  If you pass a callback argument to `wait`, it will not wait, but immediately return. The callback will be called as soon as the semaphore becomes available (which might be instantly), and gets passed the semaphore as first argument.

  The callback might `down` the semaphore exactly once, might wake up other threads, but is *NOT* allowed to block (switch to other threads).

- $sem->up

  Unlock the semaphore again.

- $sem->try

  Try to `down` the semaphore. Returns true when this was possible, otherwise return false and leave the semaphore unchanged.

- $sem->waiters

  In scalar context, returns the number of threads waiting for this semaphore. Might accidentally cause WW3 if called in other contexts, so don't use these.

- $guard = $sem->guard

  This method calls down and then creates a guard object. When the guard object is destroyed it automatically calls up.

```

Coro::SemaphoreSet

efficient set of counting semaphores

SYNOPSIS

```
use Coro;

$sig = new Coro::SemaphoreSet [initial value];

$sig->down ("semaphoreid"); # wait for signal

# ... some other "thread"

$sig->up ("semaphoreid");
```

DESCRIPTION

This module implements sets of counting semaphores (see *Coro::Semaphore*). It is nothing more than a hash with normal semaphores as members, but is more efficiently managed.

This is useful if you want to allow parallel tasks to run in parallel but not on the same problem. Just use a SemaphoreSet and lock on the problem identifier.

You don't have to load `Coro::SemaphoreSet` manually, it will be loaded automatically when you `use Coro` and call the new constructor.

- new [initial count]

  Creates a new semaphore set with the given initial lock count for each individual semaphore. See *Coro::Semaphore*.

- $semset->down ($id)

  Decrement the counter, therefore "locking" the named semaphore. This method waits until the semaphore is available if the counter is zero.

- $semset->up ($id)

  Unlock the semaphore again. If the semaphore reaches the default count for this set and has no waiters, the space allocated for it will be freed.

- $semset->try ($id)

  Try to down the semaphore. Returns true when this was possible, otherwise return false and leave the semaphore unchanged.

- $semset->count ($id)

  Return the current semaphore count for the specified semaphore.

- $semset->waiters ($id)

  Returns the number (in scalar context) or list (in list context) of waiters waiting on the specified semaphore.

- $semset->wait ($id)

  Same as Coro::Semaphore::wait on the specified semaphore.

- $guard = $semset->guard ($id)

  This method calls down and then creates a guard object. When the guard object is destroyed it automatically calls up.

- $semaphore = $semset->sem ($id)

  This SemaphoreSet version is based on Coro::Semaphore's. This function creates (if necessary) the underlying Coro::Semaphore object and returns it. You may legally call any Coro::Semaphore method on it, but note that calling `$semset->up` can invalidate the returned semaphore.

```

Coro::Signal

thread signals (binary semaphores)

SYNOPSIS

```
use Coro;

my $sig = new Coro::Signal;

$sig->wait; # wait for signal

# ... some other "thread"

$sig->send;
```

DESCRIPTION

This module implements signals/binary semaphores/condition variables (basically all the same thing). You can wait for a signal to occur or send it, in which case it will wake up one waiter, or it can be broadcast, waking up all waiters.

It is recommended not to mix `send` and `broadcast` calls on the same `Coro::Signal` without some deep thinking: while it should work as documented, it can easily confuse you :->

You don't have to load `Coro::Signal` manually, it will be loaded automatically when you `use Coro` and call the `new` constructor.

- $sig = new Coro::Signal;

  Create a new signal.

- $sig->wait

  Wait for the signal to occur (via either `send` or `broadcast`). Returns immediately if the signal has been sent before.

- $sig->wait ($callback)

  If you pass a callback argument to `wait`, it will not wait, but immediately return. The callback will be called under the same conditions as `wait` without arguments would continue the thrad.

  The callback might wake up any number of threads, but is *NOT* allowed to block (switch to other threads).

- $sig->send

  Send the signal, waking up *one* waiting process or remember the signal if no process is waiting.

- $sig->broadcast

  Send the signal, waking up *all* waiting process. If no process is waiting the signal is lost.

- $sig->awaited

  Return true when the signal is being awaited by some process.

Coro::Socket

non-blocking socket-I/O

SYNOPSIS

```
use Coro::Socket;

# listen on an ipv4 socket
my $socket = new Coro::Socket PeerHost => "localhost",
                              PeerPort => 'finger';

# listen on any other type of socket
my $socket = Coro::Socket->new_from_fh
                (IO::Socket::UNIX->new
                    Local  => "/tmp/socket",
                    Type   => SOCK_STREAM,
                );
```

DESCRIPTION

This module is an *AnyEvent* user, you need to make sure that you use and run a supported event loop.

This module implements socket-handles in a coroutine-compatible way, that is, other coroutines can run while reads or writes block on the handle. See *Coro::Handle*, especially the note about prefering method calls.

IPV6 WARNING

This module was written to imitate the *IO::Socket::INET* API, and derive from it. Since IO::Socket::INET does not support IPv6, this module does neither.

Therefore it is not recommended to use Coro::Socket in new code. Instead, use *AnyEvent::Socket* and *Coro::Handle*, e.g.:

```
use Coro;
use Coro::Handle;
use AnyEvent::Socket;

# use tcp_connect from AnyEvent::Socket
# and call Coro::Handle::unblock on it.

tcp_connect "www.google.com", 80, Coro::rouse_cb;
my $fh = unblock +(Coro::rouse_wait)[0];

# now we have a perfectly thread-safe socket handle in $fh
print $fh "GET / HTTP/1.0\015\012\015\012";
local $/;
print <$fh>;
```

Using `AnyEvent::Socket::tcp_connect` gives you transparent IPv6, multi-homing, SRV-record etc. support.

For listening sockets, use `AnyEvent::Socket::tcp_server`.

- $fh = new Coro::Socket param => value, ...

Create a new non-blocking tcp handle and connect to the given host and port. The parameter names and values are mostly the same as for IO::Socket::INET (as ugly as I think they are).

The parameters officially supported currently are: `ReuseAddr`, `LocalPort`, `LocalHost`, `PeerPort`, `PeerHost`, `Listen`, `Timeout`, `SO_RCVBUF`, `SO_SNDBUF`.

```
$fh = new Coro::Socket PeerHost => "localhost", PeerPort =>
↪'finger';
```

```

Coro::Specific

manage coroutine-specific variables.

SYNOPSIS

```
use Coro::Specific;

my $ref = new Coro::Specific;

$$ref = 5;
print $$ref;
```

DESCRIPTION

This module can be used to create variables (or better: references to them) that are specific to the currently executing coroutine. This module does not automatically load the Coro module (so the overhead will be small when no coroutines are used).

A much faster method is to store extra keys into `%$Coro::current` - all you have to do is to make sure that the key is unique (e.g. by prefixing it with your module name). You can even store data there before loading the *Coro* module - when Coro is loaded, the keys stored in `%$Coro::current` are automatically attached to the coro thread executing the main program.

You don't have to load `Coro::Specific` manually, it will be loaded automatically when you `use Coro` and call the new constructor.

- new

  Create a new coroutine-specific scalar and return a reference to it. The scalar is guaranteed to be "undef". Once such a scalar has been allocated you cannot deallocate it (yet), so allocate only when you must.

BUGS

The actual coroutine specific values do not automatically get destroyed when the Coro::Specific object gets destroyed.

Marc A. Lehmann <schmorp@schmorp.de>
http://software.schmorp.de/pkg/Coro.html
```

Coro::State

`Coro::State` - the engine under Coro: Perl-level threads ("coroutines") with their own call stacks, switched cooperatively.

```
use Coro;

# Three coroutines take turns: each cede lets the next ready one␣
 ↪run.
my @workers = map {
    my $id = $_;
    async {
        for my $step (1 .. 2) {
            print "worker $id, step $step\n";
            cede;
        }
        return "worker $id done";
    };
} 1 .. 3;

print $_->join, "\n" for @workers;     # wait for each, collect its␣
 ↪result

# A semaphore makes the others wait while one holds it.
my $lock = Coro::Semaphore->new(1);
my $t = async { my $g = $lock->guard; print "got the lock\n" };
{
    my $g = $lock->guard;
    cede;                              # $t runs, and blocks on the␣
 ↪lock
    print "releasing, ", scalar($lock->waiters), " waiting\n";
}
$t->join;

# The engine underneath: switch between two states by hand.
my ($main, $other);
$other = Coro::State->new(sub { print "in other\n"; $other->
 ↪transfer($main) });
$main  = Coro::State->new;
$main->transfer($other);
```

(continues on next page)

(continued from previous page)

```
print "back in main\n";
```

The program prints `worker 1, step 1` to `worker 3, step 1`, then the three step 2 lines, the three done lines, `releasing, 1 waiting, got the lock, in other` and `back in main`.

Most programs use `Coro` and never touch `Coro::State` directly. `Coro::State` is the machinery: a coroutine for a sub, and switching from one to another. Coro's scheduler, its coroutine objects, `Coro::Semaphore` and `Coro::Signal` are built on it, and their XS half lives here too.

Each coroutine has its own `$_`, `@_`, `$@`, `$/`, `$1...`, `$^H` and `%^H`, die and warn hooks (`$Coro::State::DIEHOOK` and `WARNHOOK` are the defaults), default output handle, `local` values and lexicals. A coroutine that switches away from inside a sort block, a tie method, a `DESTROY` or any other callback keeps a C stack of its own until it gets back out; the size of those stacks is `Coro::State::cctx_stacksize`, in pointers (default 16384, which is 128 KiB).

This is a native implementation of the XS half of Coro 6.57; its `Coro.pm` and every `Coro::*` module are used unchanged. `use Coro` exports `async`, `async_pool`, `cede`, `schedule`, `terminate`, `current`, `unblock_sub`, `rouse_cb` and `rouse_wait`; the `PRIO_*` constants and `nready` on request. `Coro::State` exports nothing. `Coro::State::BACKEND` names the stack-switch method: `asm` on x86-64, `sjlj` (setjmp/longjmp) elsewhere - what Coro's own build picks on Linux.

Coroutines: the Coro functions

- `async { ... } @args` creates a coroutine running the block with `@args`, puts it in the ready queue and returns its `Coro` object. Returning from the block ends it; an uncaught `die` ends the program, as in the main program.
- `async_pool { ... } @args` is the same with a coroutine from a pool of reused ones: faster, runs the block in an `eval` (a `die` warns), and never terminates, so it is not to be joined.
- `Coro->new(\&sub, @args)` creates a coroutine without readying it.
- `cede` puts the current coroutine at the end of the ready queue and runs the next one of the same or higher priority; `Coro::cede_notself` cedes to any ready one, whatever its priority.
- `schedule` runs the next ready coroutine without readying the current one: the way to block until something calls `->ready`.
- `terminate @values` ends the current coroutine with those values.
- `Coro::nready` is the number of coroutines in the ready queue.
- `rouse_cb` returns a callback; `rouse_wait` blocks until that callback (or the one passed to it) has been called, and returns the arguments it was called with. They turn a callback API into a blocking call.
- `Coro::on_enter BLOCK` and `Coro::on_leave BLOCK` run their block whenever the current coroutine is switched to or away from, while the enclosing scope lasts.

The methods of a `Coro` object `$coro`:

- `$coro->ready` queues it; false when it already was. `$coro->suspend` keeps the scheduler from running it until `$coro->resume`.
- `$coro->join` waits for it to end and returns its values (the block's return value, or what `terminate` or `cancel` gave).
- `$coro->cancel(@values)` ends it at once, from outside; `$coro->safe_cancel(@values)` ends it from inside, so its cleanup runs in its own context, and dies when it is not in a state where that can be done. `$coro->throw($exception)` makes it die with `$exception` when it next runs.
- `$coro->on_destroy(\&cb)` calls `cb` with its values when it ends.
- `$coro->schedule_to` and `$coro->cede_to` switch to it directly, bypassing the queue; `cede_to` readies the current coroutine first.
- `$coro->prio($new)` and `$coro->nice($change)` set its priority (from `PRIO_MIN`, -4, to `PRIO_MAX`, 3; `nice` subtracts) and return the previous one.
- `$coro->is_new`, `is_ready`, `is_running`, `is_suspended`, `is_zombie` (ended) and `is_destroyed` (the same) report its state.

`Coro::Semaphore->new($count)` has down (wait until the count is positive, then take one), up, `try` (take one if available), `count`, `adjust($delta)`, `waiters` (the waiting coroutines, or their number in scalar context) and, from Coro's Perl half, guard. `Coro::Signal->new` has `wait`, `send` (wake one waiter, or the next to wait), `broadcast` (wake every waiter) and `awaited`.

Coro::State

- `Coro::State->new(\&sub, @args)` makes a state that runs `sub` when first transferred to; `Coro::State->new` with no sub makes an empty one to save the current state in. A sub that returns ends the program.
- `$prev->transfer($next)` saves the running state in `$prev` and continues `$next`.
- `$state->call(\&code)` and `$state->eval($string)` run code in the context of another state (for debuggers; the code must not switch).
- `$state->swap_defsv` and `swap_defav` exchange the current `$_` or `@_` with the state's; `$state->swap_sv(\$var, \$private)` makes `$var` hold `$private`'s contents whenever that state runs (calling it again with the same two undoes it).
- `$state->cancel` destroys the state.
- `$state->throw`, `is_new`, `is_zombie` are as for Coro objects.
- `$state->rss` is the memory its stacks use, in bytes; `usecount` the number of transfers to it.
- `Coro::State::enable_times($bool)` turns on per-coroutine time accounting and returns the previous setting; `$state->times` then returns its real and CPU seconds.
- `Coro::State::list` returns every state, Coro objects included.
- `$state->trace($flags)` traces sub calls and statements in it, as `Coro::Debug` uses; `$state->is_traced` reads the flags.

- C stacks: `$state->has_cctx` says whether it holds one; `Coro::State::force_cctx` gives the running state one; `Coro::State::cctx_count` and `cctx_idle` count those in use and cached; `cctx_max_idle($n)` and `cctx_stacksize($n)` set the cache size (default 4) and the size of new stacks, each returning the old value.
- `$state->clone` dies "Coro::State->clone has not been configured into this installation of Coro", as in a default Coro build.

The other Coro modules (`Coro::Channel`, `Coro::RWLock`, `Coro::Specific`, `Coro::Timer`, `Coro::AnyEvent`, `Coro::Handle`, `Coro::Debug`, ...) are Coro's Perl modules, unchanged.

Differences from upstream

Two, both where perl 5.44 with XS Coro crashes (t/81-xs-native/Coro/390-or-better.t):

- `Coro::State::is_ready(bless {}, 'X')` and the other methods called on a blessed hash that is not a coroutine die "Coro::State object required", as they do for every other non-coroutine. Coro reads the magic of a hash that has none and crashes.
- `binmode $fh, ':cede'` with no interval uses the 0.01-second interval Coro's layer falls back to. Coro reads the missing argument and crashes.

Coro::Storable

offer a more fine-grained Storable interface

SYNOPSIS

```
use Coro::Storable;
```

DESCRIPTION

This module implements a few functions from the Storable module in a way so that it cede's more often. Some applications (such as the Deliantra game server) sometimes need to load large Storable objects without blocking the server for a long time.

This is being implemented by using a perlio layer that feeds only small amounts of data (4096 bytes per call) into Storable, and `Coro::cede`'ing regularly (at most 100 times per second by default, though).

As Storable is not reentrant, this module also wraps most functions of the Storable module so that only one freeze or thaw is done at any one moment (and recursive invocations are not currently supported).

FUNCTIONS

- $ref = thaw $pst

Retrieve an object from the given $pst, which must have been created with `Coro::Storable::freeze` or `Storable::store_fd`/`Storable::store` (sorry, but Storable uses incompatible formats for disk/mem objects).

This function will cede regularly.

- $pst = freeze $ref

  Freeze the given scalar into a Storable object. It uses the same format as `Storable::store_fd`.

  This functino will cede regularly.

- $pst = nfreeze $ref

  Same as `freeze` but is compatible to `Storable::nstore_fd` (note the n).

- $pst = blocking_freeze $ref

  Same as `freeze` but is guaranteed to block. This is useful e.g. in `Coro::Util::fork_eval` when you want to serialise a data structure for use with the `thaw` function for this module. You cannot use `Storable::freeze` for this as Storable uses incompatible formats for memory and file images, and this module uses file images.

- $pst = blocking_nfreeze $ref

  Same as `blocking_freeze` but uses `nfreeze` internally.

- $guard = guard

  Acquire the Storable lock, for when you want to call Storable yourself.

  Note that this module already wraps all Storable functions, so there is rarely the need to do this yourself.

Coro::Timer

timers and timeouts, independent of any event loop

SYNOPSIS

```
# This package is mostly obsoleted by Coro::AnyEvent.

use Coro::Timer qw(timeout);
# nothing exported by default
```

DESCRIPTION

This package has been mostly obsoleted by *Coro::AnyEvent*, the only really useful function left in here is `timeout`.

- $flag = timeout $seconds

  This function will wake up the current coroutine after $seconds seconds and sets $flag to true (it is false initially). If $flag goes out of scope earlier then nothing happens.

  This is used by Coro itself to implement the `timed_down`, `timed_wait` etc. primitives. It is used like this:

```
sub timed_wait {
   my $timeout = Coro::Timer::timeout 60;

   while (condition false) {
      Coro::schedule; # wait until woken up or timeout
      return 0 if $timeout; # timed out
   }

   return 1; # condition satisfied
}
```

```

Coro::Util

various utility functions.

SYNOPSIS

```
use Coro::Util;
```

DESCRIPTION

This module implements various utility functions, mostly replacing perl functions by non-blocking counterparts.

Many of these functions exist for the sole purpose of emulating existing interfaces, no matter how bad or limited they are (e.g. no IPv6 support).

This module is an AnyEvent user. Refer to the *AnyEvent* documentation to see how to integrate it into your own programs.

- $ipn = Coro::Util::inet_aton $hostname || $ip

  Works almost exactly like its `Socket::inet_aton` counterpart, except that it does not block other coroutines.

Does not handle multihomed hosts or IPv6 - consider using `AnyEvent::Socket::resolve_sockaddr` with the *Coro* rouse functions instead.

- gethostbyname, gethostbyaddr

  Work similarly to their Perl counterparts, but do not block. Uses `AnyEvent::Util::inet_aton` internally.

  Does not handle multihomed hosts or IPv6 - consider using `AnyEvent::Socket::resolve_sockaddr` or `AnyEvent::DNS::reverse_lookup` with the *Coro* rouse functions instead.

- @result = Coro::Util::fork_eval { ... }, @args

  Executes the given code block or code reference with the given arguments in a separate process, returning the results. The return values must be serialisable with Coro::Storable. It may, of course, block.

  Note that using event handling in the sub is not usually a good idea as you will inherit a mixed set of watchers from the parent.

  Exceptions will be correctly forwarded to the caller.

  This function is useful for pushing cpu-intensive computations into a different process, for example to take advantage of multiple CPU's. Its also useful if you want to simply run some blocking functions (such as `system()`) and do not care about the overhead enough to code your own pid watcher etc.

  This function might keep a pool of processes in some future version, as fork can be rather slow in large processes.

  You should also look at `AnyEvent::Util::fork_eval`, which is newer and more compatible to totally broken Perl implementations such as the one from ActiveState.

  Example: execute some external program (convert image to rgba raw form) and add a long computation (extract the alpha channel) in a separate process, making sure that never more then $NUMCPUS processes are being run.

```
my $cpulock = new Coro::Semaphore $NUMCPUS;

sub do_it {
   my ($path) = @_;

   my $guard = $cpulock->guard;

   Coro::Util::fork_eval {
      open my $fh, "convert -depth 8 \Q$path\E rgba:"
         or die "$path: $!";

      local $/;
      # make my eyes hurt
      pack "C*", unpack "(xxxC)*", <$fh>
   }
}
```

(continues on next page)

(continued from previous page)

```
my $alphachannel = do_it "/tmp/img.png";
```

5.2.20 Crypt

Namespace containing the following modules:

- `Crypt::OpenSSL`

Crypt::OpenSSL

Namespace containing the following modules:

- `Crypt::OpenSSL::Random` - Draw bytes from OpenSSL's cryptographically secure random-number generator, and seed it.

Crypt::OpenSSL::Random

Draw bytes from OpenSSL's cryptographically secure random-number generator, and seed it.

`random_bytes($n)` returns `$n` random bytes, or false when the generator cannot supply them; `random_pseudo_bytes($n)` is the same (OpenSSL 3 has one generator). `random_seed($data)` mixes `$data` into the generator's state and returns `random_status()`: 1 when the generator is seeded well enough, which OpenSSL 3 does by itself from the operating system. Nothing is exported by default.

The generator is the one in the system's libcrypto 3, reached through the built-in Net::SSLeay, so both modules draw from the same state. `random_egd` is not provided: OpenSSL 3 is built without support for an entropy-gathering daemon, as Random.xs then compiles none.

This is a native implementation of Crypt::OpenSSL::Random 0.17's `Random.xs`; its `Crypt/OpenSSL/Random.pm` is used unchanged.

Synopsis

```
use Crypt::OpenSSL::Random qw(random_bytes random_status);

random_status() or die "the generator is not seeded";
my $key = random_bytes(32);        # 32 bytes for a key
printf "%d\n", length $key;        # 32
```

Differences from upstream

Two, each where perl 5.44 with Random.xs fails (t/81-xs-native/Crypt-OpenSSL-Random/150-or-better.t)

- A count of 0 returns the empty string. perl5 returns bytes of uninitialised memory, measured with `strlen`.
- A negative count returns false, as a refused request does. perl5 tries to allocate that many bytes and exits "Out of memory".

Functions

Random bytes

`random_bytes`

`random_bytes($n)`: `$n` bytes from the generator, or false when it cannot supply them.

`random_pseudo_bytes`

`random_pseudo_bytes($n)`: the same as `random_bytes`.

Seeding

`random_seed`

`random_seed($data)`: mix the bytes of `$data` into the generator; returns `random_status()`.

`random_status`

`random_status()`: 1 when the generator is seeded well enough, else 0.

5.2.21 Cwd

Report the current working directory and resolve paths to their absolute, symlink-free form. This module provides the four "where am I" functions (`cwd`, `getcwd`, `fastcwd`, `fastgetcwd`), the three "make this path absolute" functions (`abs_path`, `realpath`, `fast_abs_path`), and a `chdir` that keeps `$ENV{PWD}` in sync.

Two groups of tradeoffs matter when choosing between them.

Current directory. `getcwd` is the most portable and safe call - it asks the kernel via the POSIX `getcwd(3)` interface and never leaves the process anywhere surprising. `fastcwd` walks the tree with repeated `chdir('..')` and is faster on deep paths, but if a parent directory disappears mid-walk (or is unreadable) it returns `undef` and may leave the process in a different directory than it started. `cwd` picks the most natural form for the platform; on Linux it is effectively `getcwd`. `fastgetcwd` is a synonym for `cwd`.

Path resolution. `abs_path` canonicalises a path, resolving symlinks and `./..` components. `realpath` is its POSIX-style alias - same function, different name. `fast_abs_path` is the faster variant that drops the "non-existent leaf" fallback: it returns `undef` the moment any component fails to resolve, where `abs_path` will still return a usable path when only the final leaf is missing.

`chdir` changes directory and, on success, updates `$ENV{PWD}` so child processes inherit a consistent view.

Cwd's Perl half

These come from Cwd.pm itself, unchanged:

- `cwd` - the output of `/bin/pwd`; `fastgetcwd` is the same function.
- `fast_abs_path($path)` (alias `fast_realpath`) - resolves a directory by changing into it and back; `undef` with `$!` set to `ENOENT` when the path does not exist, missing leaf included.
- `chdir($dir)` - `CORE::chdir`, then keeps `$ENV{PWD}` LOGICAL: after entering a symlink it names the link, not its target, and `..` components are folded textually. Returns 1 or 0.
- `realpath` - the same function as `abs_path`.

This is Cwd 3.95 (PathTools); `Cwd.pm` is upstream's. `getcwd`, `cwd`, `fastcwd` and `fastgetcwd` are exported by default, the rest on request.

Synopsis

```
use Cwd qw(getcwd abs_path);

my $here = getcwd();                          # e.g. /home/alice/
 ↪project
print abs_path('/usr/../usr/./bin'), "\n";    # /usr/bin
print abs_path('some-symlink'), "\n";         # where it points,␣
 ↪resolved
print defined abs_path('/no/such/dir/file') ? "" : "undef\n";   #␣
 ↪undef
```

Differences from upstream

None: upstream's tests pass unchanged (t/81-xs-native/Cwd, the `upstream` files), and the rest there checks against perl 5.44.

Functions

Current directory

getcwd

Return the absolute path of the process's current working directory.

cwd

Return the absolute path of the process's current working directory.

chdir

Change the process's current working directory, and update `$ENV{PWD}` to match.

Path resolution

abs_path

Canonicalise a path: resolve symlinks, `.`, and `..`, and return the absolute form.

fast_abs_path

Canonicalise a path strictly: resolve symlinks and `./..`, or return `undef` if any component is missing.

getcwd

Return the absolute path of the process's current working directory.

Synopsis

```
use Cwd;
my $dir = getcwd();
my $dir = cwd();
my $dir = fastcwd();
my $dir = fastgetcwd();
```

What you get back

A plain Perl string: the absolute path, no trailing newline, no trailing slash (except when you really are at the root `/`). On failure `getcwd` and `fastcwd` return `undef` and set `$!`.

Examples

Print where the script is running from:

```
use Cwd;
print getcwd(), "\n";     # e.g. /home/alice/project
```

Save and restore the working directory around a block that `chdir`s:

```
use Cwd;
my $saved = getcwd();
chdir '/tmp' or die $!;
# ... do work in /tmp ...
chdir $saved or die $!;
```

Compare two paths by their canonical form:

```
use Cwd;
chdir '/var/log' or die $!;
print getcwd() eq '/var/log' ? "yes\n" : "no\n";    # yes
```

Edge cases

- If the current directory has been removed by another process, `getcwd` and `fastcwd` return `undef` with `$!` set to `ENOENT`, while `cwd` (the output of `/bin/pwd`) is the empty string.
- Symlinks in the path are already resolved by the kernel's `getcwd(3)`; the returned string is the real path.
- All four names are provided by default when you `use Cwd` with no import list.
- `fastcwd` takes no arguments.
- Under taint mode the result is tainted.

See also

- `abs_path` - canonicalise an arbitrary path, not just the CWD
- `realpath` - POSIX-style alias for `abs_path`

abs_path

Canonicalise a path: resolve symlinks, `.`, and `..`, and return the absolute form.

Synopsis

```
use Cwd qw(abs_path realpath);
my $abs = abs_path($path);
my $abs = realpath($path);    # same function, POSIX alias
my $abs = abs_path();         # defaults to current directory
```

What you get back

A plain Perl string: the absolute, symlink-free path. On unresolvable input returns `undef` and sets `$!`. If the leaf component does not exist but its parent does, the parent is canonicalised and the leaf is appended verbatim - useful for computing where a file *would* be written.

Examples

Resolve a relative path against the current directory:

```
use Cwd qw(abs_path);
chdir '/home/alice' or die $!;
print abs_path('project/Makefile'), "\n";
    # /home/alice/project/Makefile
```

Follow a symlink to its target:

```
use Cwd qw(abs_path);
symlink '/etc/hostname', '/tmp/link';
print abs_path('/tmp/link'), "\n";     # /etc/hostname
```

Compute the absolute path a file would have before creating it:

```
use Cwd qw(abs_path);
print abs_path('output.new'), "\n";
    # e.g. /home/alice/project/output.new - even if output.new
    # does not yet exist, as long as the directory does
```

Use `realpath` when the surrounding code expects the POSIX name:

```
use Cwd qw(realpath);
print realpath('.'), "\n";      # absolute path of current dir
```

Edge cases

- No argument - treated as `.`. An empty string resolves to the current directory too.
- Leaf missing, parent present - returns parent's canonical path joined with the leaf name. `fast_abs_path` returns `undef` in this situation; use it when "doesn't exist" should be an error.
- An inner component missing - returns `undef`.
- A chain of more than 21 symlinks - `undef`, `$!` set to `ELOOP`.
- The path is taken as bytes: a name that is not UTF-8 comes back unchanged.
- Under taint mode the result is tainted.

See also

- `fast_abs_path` - same canonicalisation, no leaf fallback
- `getcwd` - absolute path of the current directory only

cwd

Return the absolute path of the process's current working directory.

Synopsis

```
use Cwd;
my $dir = getcwd();
my $dir = cwd();
my $dir = fastcwd();
my $dir = fastgetcwd();
```

What you get back

A plain Perl string: the absolute path, no trailing newline, no trailing slash (except when you really are at the root `/`). On failure `getcwd` and `fastcwd` return `undef` and set `$!`; `cwd` and `fastgetcwd` run `/bin/pwd` and return an empty string.

Examples

Print where the script is running from:

```
use Cwd;
print getcwd(), "\n";     # e.g. /home/alice/project
```

Save and restore the working directory around a block that `chdir`s:

```
use Cwd;
my $saved = getcwd();
chdir '/tmp' or die $!;
# ... do work in /tmp ...
chdir $saved or die $!;
```

Compare two paths by their canonical form:

```
use Cwd;
chdir '/var/log' or die $!;
print getcwd() eq '/var/log' ? "yes\n" : "no\n";    # yes
```

Edge cases

- If the current directory has been removed by another process, `getcwd` and `fastcwd` return `undef` with `$!` set to `ENOENT`; `cwd` and `fastgetcwd` return an empty string, and `/bin/pwd` reports the failure on STDERR.
- Symlinks in the path are already resolved by the kernel's `getcwd(3)`; the returned string is the real path.
- All four names are provided by default when you `use Cwd` with no import list.

Differences from upstream

Fully compatible with upstream.

See also

- `abs_path` - canonicalise an arbitrary path, not just the CWD
- `chdir` - change directory and keep `$ENV{PWD}` synchronised
- `realpath` - POSIX-style alias for `abs_path`

fast_abs_path

Canonicalise a path strictly: resolve symlinks and `./..`, or return `undef` if any component is missing.

Synopsis

```
use Cwd qw(fast_abs_path);
my $abs = fast_abs_path($path);
my $abs = fast_abs_path();      # defaults to current directory
```

What you get back

A plain Perl string with the absolute, symlink-free path, or `undef` if any part of the path cannot be resolved (including the leaf). Unlike `abs_path`, there is no parent-plus-leaf fallback - a missing final component is treated as an error.

Examples

Verify that a path exists and get its canonical form in one step:

```
use Cwd qw(fast_abs_path);
my $abs = fast_abs_path('/etc/passwd');
defined $abs or die "not found: $!";
print $abs, "\n";                # /etc/passwd
```

Reject non-existent files up front:

```
use Cwd qw(fast_abs_path);
print defined fast_abs_path('/no/such/file') ? "ok" : "missing";
    # missing
```

Resolve the current directory quickly:

```
use Cwd qw(fast_abs_path);
print fast_abs_path(), "\n";      # equivalent to getcwd()
```

Edge cases

- No argument - the current directory.
- A path that does not exist, including the empty string - `undef`, with `$!` set to `ENOENT`. Use `abs_path` when a missing leaf should still produce a path.
- A directory is resolved by changing into it and back; a file by resolving its directory, following the file itself when it is a symlink.

See also

- `abs_path` - same resolution, with a parent-plus-leaf fallback
- `realpath` - POSIX-style alias for `abs_path`
- `getcwd` - absolute path of the current directory only

chdir

Change the process's current working directory, and update `$ENV{PWD}` to match.

Synopsis

```
use Cwd qw(chdir);
chdir($path) or die $!;
```

What you get back

1 on success, `0` on failure. `$!` is set when the call fails so you can distinguish errors.

Examples

Change directory and keep `$ENV{PWD}` consistent for child processes:

```
use Cwd qw(chdir);
chdir('/tmp') or die "chdir: $!";
system('printenv', 'PWD');       # /tmp
```

Guard against a missing target:

```
use Cwd qw(chdir);
unless (chdir('/does/not/exist')) {
    warn "cannot enter directory: $!";
}
```

Switch directories around a block and return:

```
use Cwd qw(getcwd chdir);
my $saved = getcwd();
chdir('/var/log') or die $!;
# ... work in /var/log ...
chdir($saved) or die $!;
```

Edge cases

- Called with no argument - returns `0` (unlike the core `chdir` builtin, which chdirs to `$ENV{HOME}`). Pass the target explicitly.
- Target exists but is not a directory - returns `0` with `$!` set to `ENOTDIR`.

- `$ENV{PWD}` is updated only on success, through the `%ENV` tied hash, so `setenv(3)` is called as well.

Differences from upstream

Fully compatible with upstream.

See also

- `getcwd` - absolute path of the current directory
- `abs_path` - canonicalise a path without changing directory

5.2.22 DB

programmatic interface to the Perl debugging API

SYNOPSIS

```
package CLIENT;
use DB;
@ISA = qw(DB);

# these (inherited) methods can be called by the client

CLIENT->register()      # register a client package name
CLIENT->done()          # de-register from the debugging API
CLIENT->skippkg('hide::hide')  # ask DB not to stop in this package
CLIENT->cont([WHERE])       # run some more (until BREAK or
                            # another breakpoint)
CLIENT->step()              # single step
CLIENT->next()              # step over
CLIENT->ret()               # return from current subroutine
CLIENT->backtrace()         # return the call stack description
CLIENT->ready()             # call when client setup is done
CLIENT->trace_toggle()      # toggle subroutine call trace mode
CLIENT->subs([SUBS])        # return subroutine information
CLIENT->files()             # return list of all files known to DB
CLIENT->lines()             # return lines in currently loaded file
CLIENT->loadfile(FILE,LINE) # load a file and let other clients know
CLIENT->lineevents()        # return info on lines with actions
CLIENT->set_break([WHERE],[COND])
CLIENT->set_tbreak([WHERE])
CLIENT->clr_breaks([LIST])
CLIENT->set_action(WHERE,ACTION)
CLIENT->clr_actions([LIST])
CLIENT->evalcode(STRING)  # eval STRING in executing code's context
CLIENT->prestop([STRING]) # execute in code context before stopping
CLIENT->poststop([STRING])# execute in code context before resuming
```

(continues on next page)

(continued from previous page)

```
# These methods will be called at the appropriate times.
# Stub versions provided do nothing.
# None of these can block.

CLIENT->init()          # called when debug API inits itself
CLIENT->stop(FILE,LINE) # when execution stops
CLIENT->idle()          # while stopped (can be a client event loop)
CLIENT->cleanup()       # just before exit
CLIENT->output(LIST)    # called to print any output that
                        # the API must show
```

DESCRIPTION

Perl debug information is frequently required not just by debuggers, but also by modules that need some "special" information to do their job properly, like profilers.

This module abstracts and provides all of the hooks into Perl internal debugging functionality, so that various implementations of Perl debuggers (or packages that want to simply get at the "privileged" debugging data) can all benefit from the development of this common code. Currently used by Swat, the perl/Tk GUI debugger.

Note that multiple "front-ends" can latch into this debugging API simultaneously. This is intended to facilitate things like debugging with a command line and GUI at the same time, debugging debuggers etc. [Sounds nice, but this needs some serious support – GSAR]

In particular, this API does **not** provide the following functions:

- data display
- command processing
- command alias management
- user interface (tty or graphical)

These are intended to be services performed by the clients of this API.

This module attempts to be squeaky clean w.r.t `use strict;` and when warnings are enabled.

Global Variables

The following "public" global names can be read by clients of this API. Beware that these should be considered "readonly".

- $DB::sub

  Name of current executing subroutine.

- The keys of this hash are the names of all the known subroutines. Each value is an encoded string that has the sprintf(3) format `("%s:%d-%d", filename, fromline, toline)`.

- $DB::single

Single-step flag. Will be true if the API will stop at the next statement.

- $DB::signal

  Signal flag. Will be set to a true value if a signal was caught. Clients may check for this flag to abort time-consuming operations.

- $DB::trace

  This flag is set to true if the API is tracing through subroutine calls.

- @DB::args

  Contains the arguments of current subroutine, or the `@ARGV` array if in the toplevel context.

- @DB::dbline

  List of lines in currently loaded file.

- Actions in current file (keys are line numbers). The values are strings that have the sprintf(3) format `("%s\000%s", breakcondition, actioncode)`.

- $DB::package

  Package namespace of currently executing code.

- $DB::filename

  Currently loaded filename.

- $DB::subname

  Fully qualified name of currently executing subroutine.

- $DB::lineno

  Line number that will be executed next.

API Methods

The following are methods in the DB base class. A client must access these methods by inheritance (*not* by calling them directly), since the API keeps track of clients through the inheritance mechanism.

- CLIENT->register()

  register a client object/package

- CLIENT->evalcode(STRING)

  eval STRING in executing code context

- CLIENT->skippkg('D::hide')

  ask DB not to stop in these packages

- CLIENT->run()

  run some more (until a breakpt is reached)

- CLIENT->step()

  single step

- CLIENT->next()

  step over

- CLIENT->done()

  de-register from the debugging API

Client Callback Methods

The following "virtual" methods can be defined by the client. They will be called by the API at appropriate points. Note that unless specified otherwise, the debug API only defines empty, non-functional default versions of these methods.

- CLIENT->init()

  Called after debug API inits itself.

- CLIENT->prestop([STRING])

  Usually inherited from DB package. If no arguments are passed, returns the prestop action string.

- CLIENT->stop()

  Called when execution stops (w/ args file, line).

- CLIENT->idle()

  Called while stopped (can be a client event loop).

- CLIENT->poststop([STRING])

  Usually inherited from DB package. If no arguments are passed, returns the poststop action string.

- CLIENT->evalcode(STRING)

  Usually inherited from DB package. Ask for a STRING to be `eval`-ed in executing code context.

- CLIENT->cleanup()

  Called just before exit.

- CLIENT->output(LIST)

  Called when API must show a message (warnings, errors etc.).

BUGS

The interface defined by this module is missing some of the later additions to perl's debugging functionality. As such, this interface should be considered highly experimental and subject to change.

AUTHOR

Gurusamy Sarathy gsar@activestate.com

This code heavily adapted from an early version of perl5db.pl attributable to Larry Wall and the Perl Porters.

5.2.23 DBD

Namespace containing the following modules:

- `DBD::DBM` - a DBI driver for DBM & MLDBM files
- `DBD::File` - Base class for writing file based DBI drivers
- `DBD::Gofer` - A stateless-proxy driver for communicating with a remote DBI
- `DBD::Mem` - a DBI driver for Mem & MLMem files
- `DBD::Proxy` - A proxy driver for the DBI
- `DBD::SQLite`
- `DBD::Sponge` - Create a DBI statement handle from Perl data

DBD::DBM

a DBI driver for DBM & MLDBM files

SYNOPSIS

```
use DBI;
$dbh = DBI->connect('dbi:DBM:');                    # defaults to␣
↪SDBM_File
$dbh = DBI->connect('DBI:DBM(RaiseError=1):');      # defaults to␣
↪SDBM_File
$dbh = DBI->connect('dbi:DBM:dbm_type=DB_File');    # defaults to␣
↪DB_File
$dbh = DBI->connect('dbi:DBM:dbm_mldbm=Storable');  # MLDBM with␣
↪SDBM_File

# or
$dbh = DBI->connect('dbi:DBM:', undef, undef);
$dbh = DBI->connect('dbi:DBM:', undef, undef, {
    f_ext              => '.db/r',
    f_dir              => '/path/to/dbfiles/',
    f_lockfile         => '.lck',
    dbm_type           => 'BerkeleyDB',
    dbm_mldbm          => 'FreezeThaw',
    dbm_store_metadata => 1,
    dbm_berkeley_flags => {
        '-Cachesize' => 1000, # set a ::Hash flag
    },
});
```

and other variations on connect() as shown in the *DBI* docs, *DBD::File metadata* and "Metadata" shown below.

Use standard DBI prepare, execute, fetch, placeholders, etc., see "QUICK START" for an example.

DESCRIPTION

DBD::DBM is a database management system that works right out of the box. If you have a standard installation of Perl and DBI you can begin creating, accessing, and modifying simple database tables without any further modules. You can add other modules (e.g., SQL::Statement, DB_File etc) for improved functionality.

The module uses a DBM file storage layer. DBM file storage is common on many platforms and files can be created with it in many programming languages using different APIs. That means, in addition to creating files with DBI/SQL, you can also use DBI/SQL to access and modify files created by other DBM modules and programs and vice versa. **Note** that in those cases it might be necessary to use a common subset of the provided features.

DBM files are stored in binary format optimized for quick retrieval when using a key field. That optimization can be used advantageously to make DBD::DBM SQL operations that use key fields very fast. There are several different "flavors" of DBM which use different storage formats supported by perl modules such as SDBM_File and MLDBM. This module supports all of the flavors that perl supports and, when used with MLDBM, supports tables with any number of columns and insertion of Perl objects into tables.

DBD::DBM has been tested with the following DBM types: SDBM_File, NDBM_File, ODBM_File, GDBM_File, DB_File, BerkeleyDB. Each type was tested both with and without MLDBM and with the Data::Dumper, Storable, FreezeThaw, YAML and JSON serializers using the DBI::SQL::Nano or the SQL::Statement engines.

QUICK START

DBD::DBM operates like all other DBD drivers - it's basic syntax and operation is specified by DBI. If you're not familiar with DBI, you should start by reading *DBI* and the documents it points to and then come back and read this file. If you are familiar with DBI, you already know most of what you need to know to operate this module. Just jump in and create a test script something like the one shown below.

You should be aware that there are several options for the SQL engine underlying DBD::DBM, see "Supported SQL syntax". There are also many options for DBM support, see especially the section on "Adding multi-column support with MLDBM".

But here's a sample to get you started.

```
use DBI;
my $dbh = DBI->connect('dbi:DBM:');
$dbh->{RaiseError} = 1;
for my $sql( split /;\n+/,"
    CREATE TABLE user ( user_name TEXT, phone TEXT );
    INSERT INTO user VALUES ('Fred Bloggs','233-7777');
    INSERT INTO user VALUES ('Sanjay Patel','777-3333');
    INSERT INTO user VALUES ('Junk','xxx-xxxx');
    DELETE FROM user WHERE user_name = 'Junk';
    UPDATE user SET phone = '999-4444' WHERE user_name = 'Sanjay␣
↪Patel';
    SELECT * FROM user
"){
```

(continues on next page)

(continued from previous page)

```
    my $sth = $dbh->prepare($sql);
    $sth->execute;
    $sth->dump_results if $sth->{NUM_OF_FIELDS};
}
$dbh->disconnect;
```

USAGE

This section will explain some usage cases in more detail. To get an overview about the available attributes, see “Metadata”.

Specifying Files and Directories

DBD::DBM will automatically supply an appropriate file extension for the type of DBM you are using. For example, if you use SDBM_File, a table called “fruit” will be stored in two files called “fruit.pag” and “fruit.dir”. You should **never** specify the file extensions in your SQL statements.

DBD::DBM recognizes following default extensions for following types:

- .pag/r

  Chosen for dbm_type `SDBM_File`, `ODBM_File` and `NDBM_File` when an implementation is detected which wraps `-ldbm` for `NDBM_File` (e.g. Solaris, AIX, ...).

  For those types, the `.dir` extension is recognized, too (for being deleted when dropping a table).

- .db/r

  Chosen for dbm_type `NDBM_File` when an implementation is detected which wraps BerkeleyDB 1.x for `NDBM_File` (typically BSD’s, Darwin).

`GDBM_File`, `DB_File` and `BerkeleyDB` don’t usually use a file extension.

If your DBM type uses an extension other than one of the recognized types of extensions, you should set the *f_ext* attribute to the extension **and** file a bug report as described in DBI with the name of the implementation and extension so we can add it to DBD::DBM. Thanks in advance for that :-).

```
$dbh = DBI->connect('dbi:DBM:f_ext=.db');  # .db extension is used
$dbh = DBI->connect('dbi:DBM:f_ext=');     # no extension is used

# or
$dbh->{f_ext}='.db';                       # global setting
$dbh->{f_meta}->{'qux'}->{f_ext}='.db';    # setting for table 'qux'
```

By default files are assumed to be in the current working directory. To use other directories specify the *f_dir* attribute in either the connect string or by setting the database handle attribute.

For example, this will look for the file /foo/bar/fruit (or /foo/bar/fruit.pag for DBM types that use that extension)

```
my $dbh = DBI->connect('dbi:DBM:f_dir=/foo/bar');
# and this will too:
my $dbh = DBI->connect('dbi:DBM:');
$dbh->{f_dir} = '/foo/bar';
# but this is recommended
my $dbh = DBI->connect('dbi:DBM:', undef, undef, { f_dir => '/foo/
 ↪bar' } );

# now you can do
my $ary = $dbh->selectall_arrayref(q{ SELECT x FROM fruit });
```

You can also use delimited identifiers to specify paths directly in SQL statements. This looks in the same place as the two examples above but without setting *f_dir*:

```
my $dbh = DBI->connect('dbi:DBM:');
my $ary = $dbh->selectall_arrayref(q{
    SELECT x FROM "/foo/bar/fruit"
});
```

You can also tell DBD::DBM to use a specified path for a specific table:

```
$dbh->{dbm_tables}->{f}->{file} = q(/foo/bar/fruit);
```

Please be aware that you cannot specify this during connection.

If you have SQL::Statement installed, you can use table aliases:

```
my $dbh = DBI->connect('dbi:DBM:');
my $ary = $dbh->selectall_arrayref(q{
    SELECT f.x FROM "/foo/bar/fruit" AS f
});
```

See the "GOTCHAS AND WARNINGS" for using DROP on tables.

Table locking and flock()

Table locking is accomplished using a lockfile which has the same basename as the table's file but with the file extension '.lck' (or a lockfile extension that you supply, see below). This lock file is created with the table during a CREATE and removed during a DROP. Every time the table itself is opened, the lockfile is flocked(). For SELECT, this is a shared lock. For all other operations, it is an exclusive lock (except when you specify something different using the *f_lock* attribute).

Since the locking depends on flock(), it only works on operating systems that support flock(). In cases where flock() is not implemented, DBD::DBM will simply behave as if the flock() had occurred although no actual locking will happen. Read the documentation for flock() for more information.

Even on those systems that do support flock(), locking is only advisory - as is always the case with flock(). This means that if another program tries to access the table file while DBD::DBM has the table locked, that other program will *succeed* at opening unless it is also using flock on the '.lck' file. As a result DBD::DBM's locking only really applies to

other programs using DBD::DBM or other program written to cooperate with DBD::DBM locking.

Specifying the DBM type

Each "flavor" of DBM stores its files in a different format and has different capabilities and limitations. See *AnyDBM_File* for a comparison of DBM types.

By default, DBD::DBM uses the `SDBM_File` type of storage since `SDBM_File` comes with Perl itself. If you have other types of DBM storage available, you can use any of them with DBD::DBM. It is strongly recommended to use at least `DB_File`, because `SDBM_File` has quirks and limitations and `ODBM_file`, `NDBM_File` and `GDBM_File` are not always available.

You can specify the DBM type using the *dbm_type* attribute which can be set in the connection string or with `$dbh->{dbm_type}` and `$dbh->{f_meta}->{$table_name}->{type}` for per-table settings in cases where a single script is accessing more than one kind of DBM file.

In the connection string, just set `dbm_type=TYPENAME` where `TYPENAME` is any DBM type such as GDBM_File, DB_File, etc. Do *not* use MLDBM as your *dbm_type* as that is set differently, see below.

```
my $dbh=DBI->connect('dbi:DBM:');                # uses the default␣
 ↪SDBM_File
my $dbh=DBI->connect('dbi:DBM:dbm_type=GDBM_File'); # uses the GDBM_
 ↪File

# You can also use $dbh->{dbm_type} to set the DBM type for the␣
 ↪connection:
$dbh->{dbm_type} = 'DB_File';    # set the global DBM type
print $dbh->{dbm_type};          # display the global DBM type
```

If you have several tables in your script that use different DBM types, you can use the $dbh->{dbm_tables} hash to store different settings for the various tables. You can even use this to perform joins on files that have completely different storage mechanisms.

```
# sets global default of GDBM_File
my $dbh->('dbi:DBM:type=GDBM_File');

# overrides the global setting, but only for the tables called
# I<foo> and I<bar>
my $dbh->{f_meta}->{foo}->{dbm_type} = 'DB_File';
my $dbh->{f_meta}->{bar}->{dbm_type} = 'BerkeleyDB';

# prints the dbm_type for the table "foo"
print $dbh->{f_meta}->{foo}->{dbm_type};
```

Note that you must change the *dbm_type* of a table before you access it for first time.

Adding multi-column support with MLDBM

Most of the DBM types only support two columns and even if it would support more, DBD::DBM would only use two. However a CPAN module called MLDBM overcomes this limitation by allowing more than two columns. MLDBM does this by serializing the data - basically it puts a reference to an array into the second column. It can also put almost any kind of Perl object or even **Perl coderefs** into columns.

If you want more than two columns, you **must** install MLDBM. It's available for many platforms and is easy to install.

MLDBM is by default distributed with three serializers - Data::Dumper, Storable, and FreezeThaw. Data::Dumper is the default and Storable is the fastest. MLDBM can also make use of user-defined serialization methods or other serialization modules (e.g. YAML::MLDBM or MLDBM::Serializer::JSON. You select the serializer using the *dbm_mldbm* attribute.

Some examples:

```
$dbh=DBI->connect('dbi:DBM:dbm_mldbm=Storable');  # use MLDBM with␣
↪Storable
$dbh=DBI->connect(
   'dbi:DBM:dbm_mldbm=MySerializer' # use MLDBM with a user defined␣
↪module
);
$dbh=DBI->connect('dbi::dbm:', undef,
    undef, { dbm_mldbm => 'YAML' }); # use 3rd party serializer
$dbh->{dbm_mldbm} = 'YAML'; # same as above
print $dbh->{dbm_mldbm} # show the MLDBM serializer
$dbh->{f_meta}->{foo}->{dbm_mldbm}='Data::Dumper';   # set␣
↪Data::Dumper for table "foo"
print $dbh->{f_meta}->{foo}->{mldbm}; # show serializer for table
↪"foo"
```

MLDBM works on top of other DBM modules so you can also set a DBM type along with setting dbm_mldbm. The examples above would default to using SDBM_File with MLDBM. If you wanted GDBM_File instead, here's how:

```
# uses DB_File with MLDBM and Storable
$dbh = DBI->connect('dbi:DBM:', undef, undef, {
    dbm_type  => 'DB_File',
    dbm_mldbm => 'Storable',
});
```

SDBM_File, the default *dbm_type* is quite limited, so if you are going to use MLDBM, you should probably use a different type, see *AnyDBM_File*.

See below for some "GOTCHAS AND WARNINGS" about MLDBM.

Support for Berkeley DB

The Berkeley DB storage type is supported through two different Perl modules - DB_File (which supports only features in old versions of Berkeley DB) and BerkeleyDB (which supports all versions). DBD::DBM supports specifying either "DB_File" or "BerkeleyDB" as a *dbm_type*, with or without MLDBM support.

The "BerkeleyDB" dbm_type is experimental and it's interface is likely to change. It currently defaults to BerkeleyDB::Hash and does not currently support ::Btree or ::Recno.

With BerkeleyDB, you can specify initialization flags by setting them in your script like this:

```
use BerkeleyDB;
my $env = new BerkeleyDB::Env -Home => $dir;  # and/or other Env
↪flags
$dbh = DBI->connect('dbi:DBM:', undef, undef, {
    dbm_type  => 'BerkeleyDB',
    dbm_mldbm => 'Storable',
    dbm_berkeley_flags => {
        'DB_CREATE'  => DB_CREATE,  # pass in constants
        'DB_RDONLY'  => DB_RDONLY,  # pass in constants
        '-Cachesize' => 1000,       # set a ::Hash flag
        '-Env'       => $env,       # pass in an environment
    },
});
```

Do *not* set the -Flags or -Filename flags as those are determined and overwritten by the SQL (e.g. -Flags => DB_RDONLY is set automatically when you issue a SELECT statement).

Time has not permitted us to provide support in this release of DBD::DBM for further Berkeley DB features such as transactions, concurrency, locking, etc. We will be working on these in the future and would value suggestions, patches, etc.

See *DB_File* and BerkeleyDB for further details.

Optimizing the use of key fields

Most "flavors" of DBM have only two physical columns (but can contain multiple logical columns as explained above in "Adding multi-column support with MLDBM"). They work similarly to a Perl hash with the first column serving as the key. Like a Perl hash, DBM files permit you to do quick lookups by specifying the key and thus avoid looping through all records (supported by DBI::SQL::Nano only). Also like a Perl hash, the keys must be unique. It is impossible to create two records with the same key. To put this more simply and in SQL terms, the key column functions as the *PRIMARY KEY* or UNIQUE INDEX.

In DBD::DBM, you can take advantage of the speed of keyed lookups by using DBI::SQL::Nano and a WHERE clause with a single equal comparison on the key field. For example, the following SQL statements are optimized for keyed lookup:

```
CREATE TABLE user ( user_name TEXT, phone TEXT);
INSERT INTO user VALUES ('Fred Bloggs','233-7777');
```

(continues on next page)

(continued from previous page)

```
# ... many more inserts
SELECT phone FROM user WHERE user_name='Fred Bloggs';
```

The “user_name” column is the key column since it is the first column. The SELECT statement uses the key column in a single equal comparison - “user_name=’Fred Bloggs’” - so the search will find it very quickly without having to loop through all the names which were inserted into the table.

In contrast, these searches on the same table are not optimized:

```
1. SELECT phone FROM user WHERE user_name < 'Fred';
2. SELECT user_name FROM user WHERE phone = '233-7777';
```

In #1, the operation uses a less-than (<) comparison rather than an equals comparison, so it will not be optimized for key searching. In #2, the key field “user_name” is not specified in the WHERE clause, and therefore the search will need to loop through all rows to find the requested row(s).

Note that the underlying DBM storage needs to loop over all *key/value* pairs when the optimized fetch is used. SQL::Statement has a massively improved where clause evaluation which costs around 15% of the evaluation in DBI::SQL::Nano - combined with the loop in the DBM storage the speed improvement isn’t so impressive.

Even if lookups are faster by around 50%, DBI::SQL::Nano and SQL::Statement can benefit from the key field optimizations on updating and deleting rows - and here the improved where clause evaluation of SQL::Statement might beat DBI::SQL::Nano every time the where clause contains not only the key field (or more than one).

Updatable Keys

The default behavior is that updating a key to the same value of an existing key will succeed, and the existing row will be overwritten.

There may be cases where this is undesirable.

This behavior can now be configured, by setting `dbm_updatable_key` attribute. To emit a warning when this happens, set it to 1:

```
$dbh = DBI->connect('dbi:DBM:', undef, undef, {
    dbm_updatable_key => 1,
} );
```

To instead die when that happens, set it to 2:

```
$dbh = DBI->connect('dbi:DBM:', undef, undef, {
    dbm_updatable_key => 2,
} );
```

Supported SQL syntax

DBD::DBM uses a subset of SQL. The robustness of that subset depends on what other modules you have installed. Both options support basic SQL operations including CREATE TABLE, DROP TABLE, INSERT, DELETE, UPDATE, and SELECT.

Option #1: By default, this module inherits its SQL support from DBI::SQL::Nano that comes with DBI. Nano is, as its name implies, a *very* small SQL engine. Although limited in scope, it is faster than option #2 for some operations (especially single *primary key* lookups). See *DBI::SQL::Nano* for a description of the SQL it supports and comparisons of it with option #2.

Option #2: If you install the pure Perl CPAN module SQL::Statement, DBD::DBM will use it instead of Nano. This adds support for table aliases, functions, joins, and much more. If you're going to use DBD::DBM for anything other than very simple tables and queries, you should install SQL::Statement. You don't have to change DBD::DBM or your scripts in any way, simply installing SQL::Statement will give you the more robust SQL capabilities without breaking scripts written for DBI::SQL::Nano. See SQL::Statement for a description of the SQL it supports.

To find out which SQL module is working in a given script, you can use the dbm_versions() method or, if you don't need the full output and version numbers, just do this:

```
print $dbh->{sql_handler}, "\n";
```

That will print out either "SQL::Statement" or "DBI::SQL::Nano".

Baring the section about optimized access to the DBM storage in mind, comparing the benefits of both engines:

```
# DBI::SQL::Nano is faster
$sth = $dbh->prepare( "update foo set value='new' where key=15" );
$sth->execute();
$sth = $dbh->prepare( "delete from foo where key=27" );
$sth->execute();
$sth = $dbh->prepare( "select * from foo where key='abc'" );

# SQL::Statement might faster (depending on DB size)
$sth = $dbh->prepare( "update foo set value='new' where key=?" );
$sth->execute(15);
$sth = $dbh->prepare( "update foo set value=? where key=15" );
$sth->execute('new');
$sth = $dbh->prepare( "delete from foo where key=?" );
$sth->execute(27);

# SQL::Statement is faster
$sth = $dbh->prepare( "update foo set value='new' where value='old'"
 ↪);
$sth->execute();
# must be expressed using "where key = 15 or key = 27 or key = 42 or
 ↪key = 'abc'"
# in DBI::SQL::Nano
$sth = $dbh->prepare( "delete from foo where key in (15,27,42,'abc')
```

(continues on next page)

(continued from previous page)

```
 ↪" );
$sth->execute();
# must be expressed using "where key > 10 and key < 90" in␣
 ↪DBI::SQL::Nano
$sth = $dbh->prepare( "select * from foo where key between (10,90)"␣
 ↪);
$sth->execute();

# only SQL::Statement can handle
$sth->prepare( "select * from foo,bar where foo.name = bar.name" );
$sth->execute();
$sth->prepare( "insert into foo values ( 1, 'foo' ), ( 2, 'bar' )"␣
 ↪);
$sth->execute();
```

Specifying Column Names

DBM files don't have a standard way to store column names. DBD::DBM gets around this issue with a DBD::DBM specific way of storing the column names. **If you are working only with DBD::DBM and not using files created by or accessed with other DBM programs, you can ignore this section.**

DBD::DBM stores column names as a row in the file with the key *_metadata \0*. So this code

```
my $dbh = DBI->connect('dbi:DBM:');
$dbh->do("CREATE TABLE baz (foo CHAR(10), bar INTEGER)");
$dbh->do("INSERT INTO baz (foo,bar) VALUES ('zippy',1)");
```

Will create a file that has a structure something like this:

```
_metadata \0 | <dbd_metadata><schema></schema><col_names>foo,bar</
 ↪col_names></dbd_metadata>
zippy        | 1
```

The next time you access this table with DBD::DBM, it will treat the *_metadata \0* row as a header rather than as data and will pull the column names from there. However, if you access the file with something other than DBD::DBM, the row will be treated as a regular data row.

If you do not want the column names stored as a data row in the table you can set the *dbm_store_metadata* attribute to 0.

```
my $dbh = DBI->connect('dbi:DBM:', undef, undef, { dbm_store_
 ↪metadata => 0 });

# or
$dbh->{dbm_store_metadata} = 0;

# or for per-table setting
$dbh->{f_meta}->{qux}->{dbm_store_metadata} = 0;
```

By default, DBD::DBM assumes that you have two columns named "k" and "v" (short for "key" and "value"). So if you have *dbm_store_metadata* set to 1 and you want to use alternate column names, you need to specify the column names like this:

```
my $dbh = DBI->connect('dbi:DBM:', undef, undef, {
    dbm_store_metadata => 0,
    dbm_cols => [ qw(foo bar) ],
});

# or
$dbh->{dbm_store_metadata} = 0;
$dbh->{dbm_cols}           = 'foo,bar';

# or to set the column names on per-table basis, do this:
# sets the column names only for table "qux"
$dbh->{f_meta}->{qux}->{dbm_store_metadata} = 0;
$dbh->{f_meta}->{qux}->{col_names}          = [qw(foo bar)];
```

If you have a file that was created by another DBM program or created with *dbm_store_metadata* set to zero and you want to convert it to using DBD::DBM's column name storage, just use one of the methods above to name the columns but *without* specifying *dbm_store_metadata* as zero. You only have to do that once - thereafter you can get by without setting either *dbm_store_metadata* or setting *dbm_cols* because the names will be stored in the file.

DBI database handle attributes

Metadata

Statement handle ($sth) attributes and methods

Most statement handle attributes such as NAME, NUM_OF_FIELDS, etc. are available only after an execute. The same is true of $sth->rows which is available after the execute but does *not* require a fetch.

Driver handle ($dbh) attributes

It is not supported anymore to use dbm-attributes without the dbm_-prefix. Currently, if an DBD::DBM private attribute is accessed without an underscore in it's name, dbm_ is prepended to that attribute and it's processed further. If the resulting attribute name is invalid, an error is thrown.

dbm_cols

Contains a comma separated list of column names or an array reference to the column names.

dbm_type

Contains the DBM storage type. Currently known supported type are `ODBM_File`, `NDBM_File`, `SDBM_File`, `GDBM_File`, `DB_File` and `BerkeleyDB`. It is not recommended to use one of the first three types - even if `SDBM_File` is the most commonly available *dbm_type*.

dbm_mldbm

Contains the serializer for DBM storage (value column). Requires the CPAN module MLDBM installed. Currently known supported serializers are:

- Data::Dumper

  Default serializer. Deployed with Perl core.

- Storable

  Faster serializer. Deployed with Perl core.

- FreezeThaw

  Pure Perl serializer, requires FreezeThaw to be installed.

- YAML

  Portable serializer (between languages but not architectures). Requires YAML::MLDBM installation.

- JSON

  Portable, fast serializer (between languages but not architectures). Requires MLDBM::Serializer::JSON installation.

dbm_store_metadata

Boolean value which determines if the metadata in DBM is stored or not.

dbm_berkeley_flags

Hash reference with additional flags for BerkeleyDB::Hash instantiation.

dbm_version

Readonly attribute containing the version of DBD::DBM.

f_meta

In addition to the attributes *DBD::File* recognizes, DBD::DBM knows about the (public) attributes `col_names` (**Note** not *dbm_cols* here!), `dbm_type`, `dbm_mldbm`, `dbm_store_metadata` and `dbm_berkeley_flags`. As in DBD::File, there are undocumented, internal attributes in DBD::DBM. Be very careful when modifying attributes you do not know; the consequence might a destroyed or corrupted table.

dbm_tables

This attribute provides restricted access to the table meta data. See f_meta and *"f_meta" in DBD::File* for attribute details.

dbm_tables is a tied hash providing the internal table names as keys (accessing unknown tables might create an entry) and their meta data as another tied hash. The table meta storage is obtained via the `get_table_meta` method from the table implementation (see DBD::File::Developers). Attribute setting and getting within the table meta data is handled via the methods `set_table_meta_attr` and `get_table_meta_attr`.

Following attributes are no longer handled by DBD::DBM:

dbm_ext

This attribute is silently mapped to DBD::File's attribute *f_ext*. Later versions of DBI might show a depreciated warning when this attribute is used and eventually it will be removed.

dbm_lockfile

This attribute is silently mapped to DBD::File's attribute *f_lockfile*. Later versions of DBI might show a depreciated warning when this attribute is used and eventually it will be removed.

DBI database handle methods

The $dbh->dbm_versions() method

The private method dbm_versions() returns a summary of what other modules are being used at any given time. DBD::DBM can work with or without many other modules - it can use either SQL::Statement or DBI::SQL::Nano as its SQL engine, it can be run with DBI or DBI::PurePerl, it can use many kinds of DBM modules, and many kinds of serializers when run with MLDBM. The dbm_versions() method reports all of that and more.

```
print $dbh->dbm_versions;              # displays global settings
print $dbh->dbm_versions($table_name);  # displays per table␣
 ↪settings
```

An important thing to note about this method is that when it called with no arguments, it displays the *global* settings. If you override these by setting per-table attributes, these will *not* be shown unless you specify a table name as an argument to the method call.

Storing Objects

If you are using MLDBM, you can use DBD::DBM to take advantage of its serializing abilities to serialize any Perl object that MLDBM can handle. To store objects in columns, you should (but don't absolutely need to) declare it as a column of type BLOB (the type is *currently* ignored by the SQL engine, but it's good form).

EXTENSIBILITY

- `SQL::Statement`

  Improved SQL engine compared to the built-in DBI::SQL::Nano - see "Supported SQL syntax".

- `DB_File`

  Berkeley DB version 1. This database library is available on many systems without additional installation and most systems are supported.

- `GDBM_File`

  Simple dbm type (comparable to `DB_File`) under the GNU license. Typically not available (or requires extra installation) on non-GNU operating systems.

- `BerkeleyDB`

  Berkeley DB version up to v4 (and maybe higher) - requires additional installation but is easier than GDBM_File on non-GNU systems.

  db4 comes with a many tools which allow repairing and migrating databases. This is the **recommended** dbm type for production use.

- `MLDBM`

  Serializer wrapper to support more than one column for the files. Comes with serializers using `Data::Dumper`, `FreezeThaw` and `Storable`.

- `YAML::MLDBM`

  Additional serializer for MLDBM. YAML is very portable between languages.

- `MLDBM::Serializer::JSON`

  Additional serializer for MLDBM. JSON is very portable between languages, probably more than YAML.

GOTCHAS AND WARNINGS

Using the SQL DROP command will remove any file that has the name specified in the command with either '.pag' and '.dir', '.db' or your {f_ext} appended to it. So this be dangerous if you aren't sure what file it refers to:

```
$dbh->do(qq{DROP TABLE "/path/to/any/file"});
```

Each DBM type has limitations. SDBM_File, for example, can only store values of less than 1,000 characters. *You* as the script author must ensure that you don't exceed those bounds. If you try to insert a value that is larger than DBM can store, the results will be unpredictable. See the documentation for whatever DBM you are using for details.

Different DBM implementations return records in different orders. That means that you *should not* rely on the order of records unless you use an ORDER BY statement.

DBM data files are platform-specific. To move them from one platform to another, you'll need to do something along the lines of dumping your data to CSV on platform #1 and then dumping from CSV to DBM on platform #2. DBD::AnyData and DBD::CSV can help with that. There may also be DBM conversion tools for your platforms which would probably be quicker.

When using MLDBM, there is a very powerful serializer - it will allow you to store Perl code or objects in database columns. When these get de-serialized, they may be eval'ed - in other words MLDBM (or actually Data::Dumper when used by MLDBM) may take the values and try to execute them in Perl. Obviously, this can present dangers, so if you do not know what is in a file, be careful before you access it with MLDBM turned on!

See the entire section on "Table locking and flock()" for gotchas and warnings about the use of flock().

BUGS AND LIMITATIONS

This module uses hash interfaces of two column file databases. While none of supported SQL engines have support for indices, the following statements really do the same (even if they mean something completely different) for each dbm type which lacks `EXISTS` support:

```
$sth->do( "insert into foo values (1, 'hello')" );

# this statement does ...
$sth->do( "update foo set v='world' where k=1" );
# ... the same as this statement
$sth->do( "insert into foo values (1, 'world')" );
```

This is considered to be a bug and might change in a future release.

Known affected dbm types are `ODBM_File` and `NDBM_File`. We highly recommended you use a more modern dbm type such as `DB_File`.

GETTING HELP, MAKING SUGGESTIONS, AND REPORTING BUGS

If you need help installing or using DBD::DBM, please write to the DBI users mailing list at dbi-users@perl.org or to the comp.lang.perl.modules newsgroup on usenet. I cannot always answer every question quickly but there are many on the mailing list or in the newsgroup who can.

DBD developers for DBD's which rely on DBD::File or DBD::DBM or use one of them as an example are suggested to join the DBI developers mailing list at dbi-dev@perl.org and strongly encouraged to join our IRC channel at irc://irc.perl.org/dbi.

If you have suggestions, ideas for improvements, or bugs to report, please report a bug as described in DBI. Do not mail any of the authors directly, you might not get an answer.

When reporting bugs, please send the output of $dbh->dbm_versions($table) for a table that exhibits the bug and as small a sample as you can make of the code that produces the bug. And of course, patches are welcome, too :-).

If you need enhancements quickly, you can get commercial support as described at http://dbi.perl.org/support/ or you can contact Jens Rehsack at rehsack@googlemail.com for commercial support in Germany.

Please don't bother Jochen Wiedmann or Jeff Zucker for support - they handed over further maintenance to H.Merijn Brand and Jens Rehsack.

ACKNOWLEDGEMENTS

Many, many thanks to Tim Bunce for prodding me to write this, and for copious, wise, and patient suggestions all along the way. (Jeff Zucker)

I send my thanks and acknowledgements to H.Merijn Brand for his initial refactoring of DBD::File and his strong and ongoing support of SQL::Statement. Without him, the current progress would never have been made. And I have to name Martin J. Evans for each laugh (and correction) of all those funny word creations I (as non-native speaker) made to the documentation. And - of course - I have to thank all those unnamed contributors and testers from the Perl community. (Jens Rehsack)

AUTHOR AND COPYRIGHT

This module is written by Jeff Zucker < jzucker AT cpan.org >, who also maintained it till 2007. After that, in 2010, Jens Rehsack & H.Merijn Brand took over maintenance.

DBD::File

Base class for writing file based DBI drivers

SYNOPSIS

This module is a base class for writing other *DBD*s. It is not intended to function as a DBD itself (though it is possible). If you want to access flat files, use DBD::AnyData, or DBD::CSV (both of which are subclasses of DBD::File).

DESCRIPTION

The DBD::File module is not a true *DBI* driver, but an abstract base class for deriving concrete DBI drivers from it. The implication is, that these drivers work with plain files, for example CSV files or INI files. The module is based on the SQL::Statement module, a simple SQL engine.

See *DBI* for details on DBI, SQL::Statement for details on SQL::Statement and DBD::CSV, *DBD::DBM* or DBD::AnyData for example drivers.

Metadata

The following attributes are handled by DBI itself and not by DBD::File, thus they all work as expected:

```
Active
ActiveKids
CachedKids
CompatMode             (Not used)
InactiveDestroy
AutoInactiveDestroy
Kids
PrintError
RaiseError
Warn                   (Not used)
```

The following DBI attributes are handled by DBD::File:

AutoCommit

Always on.

ChopBlanks

Works.

NUM_OF_FIELDS

Valid after `$sth->execute`.

NUM_OF_PARAMS

Valid after `$sth->prepare`.

NAME

Valid after `$sth->execute`; undef for Non-Select statements.

NULLABLE

Not really working, always returns an array ref of ones, except the affected table has been created in this session. Valid after `$sth->execute`; undef for non-select statements.

Unsupported DBI attributes and methods

- bind_param_inout
- CursorName
- LongReadLen

- LongTruncOk

DBD::File specific attributes

In addition to the DBI attributes, you can use the following dbh attributes:

f_dir

This attribute is used for setting the directory where the files are opened and it defaults to the current directory (`.`). Usually you set it on the dbh but it may be overridden per table (see f_meta).

When the value for `f_dir` is a relative path, it is converted into the appropriate absolute path name (based on the current working directory) when the dbh attribute is set.

```
f_dir => "/data/foo/csv",
```

If `f_dir` is set to a non-existing location, the connection will fail. See CVE-2014-10401 for reasoning. Because of this, folders to use cannot be created after the connection, but must exist before the connection is initiated.

See “KNOWN BUGS AND LIMITATIONS”.

f_dir_search

This optional attribute can be set to pass a list of folders to also find existing tables. It will **not** be used to create new files.

```
f_dir_search => [ "/data/bar/csv", "/dump/blargh/data" ],
```

f_ext

This attribute is used for setting the file extension. The format is:

```
extension{/flag}
```

where the /flag is optional and the extension is case-insensitive. `f_ext` allows you to specify an extension which:

```
f_ext => ".csv/r",
```

- makes DBD::File prefer `table.extension` over `table`.
- makes the table name the filename minus the extension.

```
DBI:CSV:f_dir=data;f_ext=.csv
```

In the above example and when `f_dir` contains both `table.csv` and `table`, DBD::File will open `table.csv` and the table will be named “table”. If `table.csv` does not exist but `table` does that file is opened and the table is also called “table”.

If `f_ext` is not specified and `table.csv` exists it will be opened and the table will be called “table.csv” which is probably not what you want.

NOTE: even though extensions are case-insensitive, table names are not.

```
DBI:CSV:f_dir=data;f_ext=.csv/r
```

The `r` flag means the file extension is required and any filename that does not match the extension is ignored.

Usually you set it on the dbh but it may be overridden per table (see f_meta).

f_schema

This will set the schema name and defaults to the owner of the directory in which the table file resides. You can set `f_schema` to `undef`.

```
my $dbh = DBI->connect ("dbi:CSV:", "", "", {
    f_schema => undef,
    f_dir    => "data",
    f_ext    => ".csv/r",
    }) or die $DBI::errstr;
```

By setting the schema you affect the results from the tables call:

```
my @tables = $dbh->tables ();

# no f_schema
"merijn".foo
"merijn".bar

# f_schema => "dbi"
"dbi".foo
"dbi".bar

# f_schema => undef
foo
bar
```

Defining `f_schema` to the empty string is equal to setting it to `undef` so the DSN can be `"dbi:CSV:f_schema=;f_dir=."`.

f_lock

The `f_lock` attribute is used to set the locking mode on the opened table files. Note that not all platforms support locking. By default, tables are opened with a shared lock for reading, and with an exclusive lock for writing. The supported modes are:

```
0: No locking at all.

1: Shared locks will be used.

2: Exclusive locks will be used.
```

But see KNOWN BUGS below.

f_lockfile

If you wish to use a lockfile extension other than `.lck`, simply specify the `f_lockfile` attribute:

```
$dbh = DBI->connect ("dbi:DBM:f_lockfile=.foo");
$dbh->{f_lockfile} = ".foo";
$dbh->{dbm_tables}{qux}{f_lockfile} = ".foo";
```

If you wish to disable locking, set the `f_lockfile` to `0`.

```
$dbh = DBI->connect ("dbi:DBM:f_lockfile=0");
$dbh->{f_lockfile} = 0;
$dbh->{dbm_tables}{qux}{f_lockfile} = 0;
```

f_encoding

With this attribute, you can set the encoding in which the file is opened. This is implemented using `binmode $fh, ":encoding(<f_encoding>)"`.

f_meta

Private data area aliasing *"sql_meta" in DBI::DBD::SqlEngine* which contains information about the tables this module handles. Table meta data might not be available until the table has been accessed for the first time e.g., by issuing a select on it however it is possible to pre-initialize attributes for each table you use.

DBD::File recognizes the (public) attributes `f_ext`, `f_dir`, `f_file`, `f_encoding`, `f_lock`, `f_lockfile`, `f_schema`, in addition to the attributes *"sql_meta" in DBI::DBD::SqlEngine* already supports. Be very careful when modifying attributes you do not know, the consequence might be a destroyed or corrupted table.

`f_file` is an attribute applicable to table meta data only and you will not find a corresponding attribute in the dbh. Whilst it may be reasonable to have several tables with the same column names, it is not for the same file name. If you need access to the same file using different table names, use `SQL::Statement` as the SQL engine and the `AS` keyword:

```
SELECT * FROM tbl AS t1, tbl AS t2 WHERE t1.id = t2.id
```

`f_file` can be an absolute path name or a relative path name but if it is relative, it is interpreted as being relative to the `f_dir` attribute of the table meta data. When `f_file` is set DBD::File will use `f_file` as specified and will not attempt to work out an alternative for `f_file` using the `table name` and `f_ext` attribute.

While `f_meta` is a private and readonly attribute (which means, you cannot modify it's values), derived drivers might provide restricted write access through another attribute. Well known accessors are `csv_tables` for DBD::CSV, `ad_tables` for DBD::AnyData and `dbm_tables` for *DBD::DBM*.

New opportunities for attributes from DBI::DBD::SqlEngine

sql_table_source

`$dbh->{sql_table_source}` can be set to *DBD::File::TableSource::FileSystem* (and is the default setting of DBD::File). This provides usual behaviour of previous DBD::File releases on

```
@ary = DBI->data_sources ($driver);
@ary = DBI->data_sources ($driver, \%attr);

@ary = $dbh->data_sources ();
@ary = $dbh->data_sources (\%attr);

@names = $dbh->tables ($catalog, $schema, $table, $type);

$sth = $dbh->table_info ($catalog, $schema, $table, $type);
$sth = $dbh->table_info ($catalog, $schema, $table, $type, \%attr);

$dbh->func ("list_tables");
```

sql_data_source

`$dbh->{sql_data_source}` can be set to either *DBD::File::DataSource::File*, which is default and provides the well known behavior of DBD::File releases prior to 0.41, or *DBD::File::DataSource::Stream*, which reuses already opened file-handle for operations.

Internally private attributes to deal with SQL backends

Do not modify any of these private attributes unless you understand the implications of doing so. The behavior of DBD::File and derived DBDs might be unpredictable when one or more of those attributes are modified.

sql_nano_version

Contains the version of loaded DBI::SQL::Nano.

sql_statement_version

Contains the version of loaded SQL::Statement.

sql_handler

Contains either the text ‘SQL::Statement’ or ‘DBI::SQL::Nano’.

sql_ram_tables

Contains optionally temporary tables.

sql_flags

Contains optional flags to instantiate the SQL::Parser parsing engine when SQL::Statement is used as SQL engine. See SQL::Parser for valid flags.

Driver private methods

Default DBI methods

data_sources

The `data_sources` method returns a list of subdirectories of the current directory in the form "dbi:CSV:f_dir=$dirname".

If you want to read the subdirectories of another directory, use

```
my ($drh)  = DBI->install_driver ("CSV");
my (@list) = $drh->data_sources (f_dir => "/usr/local/csv_data");
```

Additional methods

The following methods are only available via their documented name when DBD::File is used directly. Because this is only reasonable for testing purposes, the real names must be used instead. Those names can be computed by replacing the `f_` in the method name with the driver prefix.

f_versions

Signature:

```
sub f_versions (;$) {
  my ($table_name) = @_;
  $table_name ||= ".";
  ...
  }
```

Returns the versions of the driver, including the DBI version, the Perl version, DBI::PurePerl version (if DBI::PurePerl is active) and the version of the SQL engine in use.

```
my $dbh = DBI->connect ("dbi:File:");
my $f_versions = $dbh->func ("f_versions");
print "$f_versions\n";
__END__
# DBD::File               0.41 using IO::File (1.16)
#   DBI::DBD::SqlEngine   0.05 using SQL::Statement 1.406
# DBI                     1.623
# OS                      darwin (12.2.1)
# Perl                    5.017006 (darwin-thread-multi-ld-2level)
```

Called in list context, f_versions will return an array containing each line as single entry.

Some drivers might use the optional (table name) argument and modify version information related to the table (e.g. DBD::DBM provides storage backend information for the requested table, when it has a table name).

KNOWN BUGS AND LIMITATIONS

- This module uses flock () internally but flock is not available on all platforms. On MacOS and Windows 95 there is no locking at all (perhaps not so important on MacOS and Windows 95, as there is only a single user).
- The module stores details about the handled tables in a private area of the driver handle (`$drh`). This data area is not shared between different driver instances, so several `DBI->connect ()` calls will cause different table instances and private data areas.

  This data area is filled for the first time when a table is accessed, either via an SQL statement or via `table_info` and is not destroyed until the table is dropped or the driver handle is released. Manual destruction is possible via f_clear_meta.

  The following attributes are preserved in the data area and will evaluated instead of driver globals:

  - f_ext
  - f_dir
  - f_dir_search
  - f_lock
  - f_lockfile
  - f_encoding
  - f_schema
  - col_names
  - sql_identifier_case

  The following attributes are preserved in the data area only and cannot be set globally.

  - f_file

  The following attributes are preserved in the data area only and are computed when initializing the data area:

  - f_fqfn
  - f_fqbn
  - f_fqln
  - table_name

  For DBD::CSV tables this means, once opened “foo.csv” as table named “foo”, another table named “foo” accessing the file “foo.txt” cannot be opened. Accessing “foo” will always access the file “foo.csv” in memorized `f_dir`, locking `f_lockfile` via memorized `f_lock`.

You can use f_clear_meta or the `f_file` attribute for a specific table to work around this.

- When used with SQL::Statement and temporary tables e.g.,

```
CREATE TEMP TABLE ...
```

the table data processing bypasses DBD::File::Table. No file system calls will be made and there are no clashes with existing (file based) tables with the same name. Temporary tables are chosen over file tables, but they will not covered by `table_info`.

DBD::Gofer

A stateless-proxy driver for communicating with a remote DBI

SYNOPSIS

```
use DBI;

$original_dsn = "dbi:..."; # your original DBI Data Source Name

$dbh = DBI->connect("dbi:Gofer:transport=$transport;...;dsn=
 ↪$original_dsn",
                    $user, $passwd, \%attributes);

... use $dbh as if it was connected to $original_dsn ...
```

The `transport=$transport` part specifies the name of the module to use to transport the requests to the remote DBI. If $transport doesn't contain any double colons then it's prefixed with `DBD::Gofer::Transport::`.

The `dsn=$original_dsn` part *must be the last element* of the DSN because everything after `dsn=` is assumed to be the DSN that the remote DBI should use.

The `...` represents attributes that influence the operation of the Gofer driver or transport. These are described below or in the documentation of the transport module being used.

DESCRIPTION

DBD::Gofer is a DBI database driver that forwards requests to another DBI driver, usually in a separate process, often on a separate machine. It tries to be as transparent as possible so it appears that you are using the remote driver directly.

DBD::Gofer is very similar to DBD::Proxy. The major difference is that with DBD::Gofer no state is maintained on the remote end. That means every request contains all the information needed to create the required state. (So, for example, every request includes the DSN to connect to.) Each request can be sent to any available server. The server executes the request and returns a single response that includes all the data.

This is very similar to the way http works as a stateless protocol for the web. Each request from your web browser can be handled by a different web server process.

Use Cases

This may seem like pointless overhead but there are situations where this is a very good thing. Let's consider a specific case.

Imagine using DBD::Gofer with an http transport. Your application calls connect(), prepare("select * from table where foo=?"), bind_param(), and execute(). At this point DBD::Gofer builds a request containing all the information about the method calls. It then uses the httpd transport to send that request to an apache web server.

This 'dbi execute' web server executes the request (using DBI::Gofer::Execute and related modules) and builds a response that contains all the rows of data, if the statement returned any, along with all the attributes that describe the results, such as $sth->{NAME}. This response is sent back to DBD::Gofer which unpacks it and presents it to the application as if it had executed the statement itself.

Advantages

Okay, but you still don't see the point? Well let's consider what we've gained:

Connection Pooling and Throttling

The 'dbi execute' web server leverages all the functionality of web infrastructure in terms of load balancing, high-availability, firewalls, access management, proxying, caching.

At its most basic level you get a configurable pool of persistent database connections.

Simple Scaling

Got thousands of processes all trying to connect to the database? You can use DBD::Gofer to connect them to your smaller pool of 'dbi execute' web servers instead.

Caching

Client-side caching is as simple as adding "`cache=1`" to the DSN. This feature alone can be worth using DBD::Gofer for.

Fewer Network Round-trips

DBD::Gofer sends as few requests as possible (dependent on the policy being used).

Thin Clients / Unsupported Platforms

You no longer need drivers for your database on every system. DBD::Gofer is pure perl.

CONSTRAINTS

There are some natural constraints imposed by the DBD::Gofer 'stateless' approach. But not many:

You can't change database handle attributes after connect()

You can't change database handle attributes after you've connected. Use the connect() call to specify all the attribute settings you want.

This is because it's critical that when a request is complete the database handle is left in the same state it was when first connected.

An exception is made for attributes with names starting "`private_`": They can be set after connect() but the change is only applied locally.

You can't change statement handle attributes after prepare()

You can't change statement handle attributes after prepare.

An exception is made for attributes with names starting "`private_`": They can be set after prepare() but the change is only applied locally.

You can't use transactions

AutoCommit only. Transactions aren't supported.

(In theory transactions could be supported when using a transport that maintains a connection, like `stream` does. If you're interested in this please get in touch via dbi-dev@perl.org)

You can't call driver-private sth methods

But that's rarely needed anyway.

GENERAL CAVEATS

A few important things to keep in mind when using DBD::Gofer:

Temporary tables, locks, and other per-connection persistent state

You shouldn't expect any per-session state to persist between requests. This includes locks and temporary tables.

Because the server-side may execute your requests via a different database connections, you can't rely on any per-connection persistent state, such as temporary tables, being available from one request to the next.

This is an easy trap to fall into. A good way to check for this is to test your code with a Gofer policy package that sets the `connect_method` policy to 'connect' to force a new connection for each request. The `pedantic` policy does this.

Driver-private Database Handle Attributes

Some driver-private dbh attributes may not be available if the driver has not implemented the private_attribute_info() method (added in DBI 1.54).

Driver-private Statement Handle Attributes

Driver-private sth attributes can be set in the prepare() call. TODO

Some driver-private sth attributes may not be available if the driver has not implemented the private_attribute_info() method (added in DBI 1.54).

Multiple Resultsets

Multiple resultsets are supported only if the driver supports the more_results() method (an exception is made for DBD::Sybase).

Statement activity that also updates dbh attributes

Some drivers may update one or more dbh attributes after performing activity on a child sth. For example, DBD::mysql provides $dbh->{mysql_insertid} in addition to $sth->{mysql_insertid}. Currently mysql_insertid is supported via a hack but a more general mechanism is needed for other drivers to use.

Methods that report an error always return undef

With DBD::Gofer, a method that sets an error always return an undef or empty list. That shouldn't be a problem in practice because the DBI doesn't define any methods that return meaningful values while also reporting an error.

Subclassing only applies to client-side

The RootClass and DbTypeSubclass attributes are not passed to the Gofer server.

CAVEATS FOR SPECIFIC METHODS

last_insert_id

To enable use of last_insert_id you need to indicate to DBD::Gofer that you'd like to use it. You do that my adding a `go_last_insert_id_args` attribute to the do() or prepare() method calls. For example:

```
$dbh->do($sql, { go_last_insert_id_args => [...] });
```

or

```
$sth = $dbh->prepare($sql, { go_last_insert_id_args => [...] });
```

The array reference should contains the args that you want passed to the last_insert_id() method.

execute_for_fetch

The array methods bind_param_array() and execute_array() are supported. When execute_array() is called the data is serialized and executed in a single round-trip to the Gofer server. This makes it very fast, but requires enough memory to store all the serialized data.

The execute_for_fetch() method currently isn't optimised, it uses the DBI fallback behaviour of executing each tuple individually. (It could be implemented as a wrapper for execute_array() - patches welcome.)

TRANSPORTS

DBD::Gofer doesn't concern itself with transporting requests and responses to and fro. For that it uses special Gofer transport modules.

Gofer transport modules usually come in pairs: one for the 'client' DBD::Gofer driver to use and one for the remote 'server' end. They have very similar names:

```
DBD::Gofer::Transport::<foo>
DBI::Gofer::Transport::<foo>
```

Sometimes the transports on the DBD and DBI sides may have different names. For example DBD::Gofer::Transport::http is typically used with DBI::Gofer::Transport::mod_perl (DBD::Gofer::Transport::http and DBI::Gofer::Transport::mod_perl modules are part of the GoferTransport-http distribution).

Bundled Transports

Several transport modules are provided with DBD::Gofer:

null

The null transport is the simplest of them all. It doesn't actually transport the request anywhere. It just serializes (freezes) the request into a string, then thaws it back into a data structure before passing it to DBI::Gofer::Execute to execute. The same freeze and thaw is applied to the results.

The null transport is the best way to test if your application will work with Gofer. Just set the DBI_AUTOPROXY environment variable to "`dbi:Gofer:transport=null;policy=pedantic`" (see "Using DBI_AUTOPROXY" below) and run your application, or ideally its test suite, as usual.

It doesn't take any parameters.

pipeone

The pipeone transport launches a subprocess for each request. It passes in the request and reads the response.

The fact that a new subprocess is started for each request ensures that the server side is truly stateless. While this does make the transport *very* slow, it is useful as a way to test that your application doesn't depend on per-connection state, such as temporary tables, persisting between requests.

It's also useful both as a proof of concept and as a base class for the stream driver.

stream

The stream driver also launches a subprocess and writes requests and reads responses, like the pipeone transport. In this case, however, the subprocess is expected to handle more that one request. (Though it will be automatically restarted if it exits.)

This is the first transport that is truly useful because it can launch the subprocess on a remote machine using `ssh`. This means you can now use DBD::Gofer to easily access any databases that's accessible from any system you can login to. You also get all the benefits of ssh, including encryption and optional compression.

See "Using DBI_AUTOPROXY" below for an example.

Other Transports

Implementing a Gofer transport is *very* simple, and more transports are very welcome. Just take a look at any existing transports that are similar to your needs.

http

See the GoferTransport-http distribution on CPAN: http://search.cpan.org/dist/GoferTransport-http/

Gearman

I know Ask Bjørn Hansen has implemented a transport for the `gearman` distributed job system, though it's not on CPAN at the time of writing this.

CONNECTING

Simply prefix your existing DSN with "`dbi:Gofer:transport=$transport;dsn=`" where $transport is the name of the Gofer transport you want to use (see "TRANSPORTS"). The `transport` and `dsn` attributes must be specified and the `dsn` attributes must be last.

Other attributes can be specified in the DSN to configure DBD::Gofer and/or the Gofer transport module being used. The main attributes after `transport`, are `url` and `policy`. These and other attributes are described below.

Using DBI_AUTOPROXY

The simplest way to try out DBD::Gofer is to set the DBI_AUTOPROXY environment variable. In this case you don't include the `dsn=` part. For example:

```
export DBI_AUTOPROXY="dbi:Gofer:transport=null"
```

or, for a more useful example, try:

```
export DBI_AUTOPROXY="dbi:Gofer:transport=stream;
↪url=ssh:user@example.com"
```

Connection Attributes

These attributes can be specified in the DSN. They can also be passed in the \%attr parameter of the DBI connect method by adding a "go_" prefix to the name.

transport

Specifies the Gofer transport class to use. Required. See "TRANSPORTS" above.

If the value does not include `::` then "`DBD::Gofer::Transport::`" is prefixed.

The transport object can be accessed via $h->{go_transport}.

dsn

Specifies the DSN for the remote side to connect to. Required, and must be last.

url

Used to tell the transport where to connect to. The exact form of the value depends on the transport used.

policy

Specifies the policy to use. See "CONFIGURING BEHAVIOUR POLICY".

If the value does not include `::` then "`DBD::Gofer::Policy`" is prefixed.

The policy object can be accessed via $h->{go_policy}.

timeout

Specifies a timeout, in seconds, to use when waiting for responses from the server side.

retry_limit

Specifies the number of times a failed request will be retried. Default is 0.

retry_hook

Specifies a code reference to be called to decide if a failed request should be retried. The code reference is called like this:

```
$transport = $h->{go_transport};
$retry = $transport->go_retry_hook->($request, $response,
 ↪$transport);
```

If it returns true then the request will be retried, up to the `retry_limit`. If it returns a false but defined value then the request will not be retried. If it returns undef then the default behaviour will be used, as if `retry_hook` had not been specified.

The default behaviour is to retry requests where $request->is_idempotent is true, or the error message matches `/induced by DBI_GOFER_RANDOM/`.

cache

Specifies that client-side caching should be performed. The value is the name of a cache class to use.

Any class implementing get($key) and set($key, $value) methods can be used. That includes a great many powerful caching classes on CPAN, including the Cache and Cache::Cache distributions.

You can use "`cache=1`" is a shortcut for "`cache=DBI::Util::CacheMemory`". See *DBI::Util::CacheMemory* for a description of this simple fast default cache.

The cache object can be accessed via $h->go_cache. For example:

```
$dbh->go_cache->clear; # free up memory being used by the cache
```

The cache keys are the frozen (serialized) requests, and the values are the frozen responses.

The default behaviour is to only use the cache for requests where $request->is_idempotent is true (i.e., the dbh has the ReadOnly attribute set or the SQL statement is obviously a SELECT without a FOR UPDATE clause.)

For even more control you can use the `go_cache` attribute to pass in an instantiated cache object. Individual methods, including prepare(), can also specify alternative caches via the `go_cache` attribute. For example, to specify no caching for a particular query, you could use

```
$sth = $dbh->prepare( $sql, { go_cache => 0 } );
```

This can be used to implement different caching policies for different statements.

It's interesting to note that DBD::Gofer can be used to add client-side caching to any (gofer compatible) application, with no code changes and no need for a gofer server. Just set the DBI_AUTOPROXY environment variable like this:

```
DBI_AUTOPROXY='dbi:Gofer:transport=null;cache=1'
```

CONFIGURING BEHAVIOUR POLICY

DBD::Gofer supports a 'policy' mechanism that allows you to fine-tune the number of round-trips to the Gofer server. The policies are grouped into classes (which may be subclassed) and referenced by the name of the class.

The *DBD::Gofer::Policy::Base* class is the base class for all the policy packages and describes all the available policies.

Three policy packages are supplied with DBD::Gofer:

DBD::Gofer::Policy::pedantic is most 'transparent' but slowest because it makes more round-trips to the Gofer server.

DBD::Gofer::Policy::classic is a reasonable compromise - it's the default policy.

DBD::Gofer::Policy::rush is fastest, but may require code changes in your applications.

Generally the default `classic` policy is fine. When first testing an existing application with Gofer it is a good idea to start with the `pedantic` policy first and then switch to `classic` or a custom policy, for final testing.

DBI

Caveats for specific drivers

This section aims to record issues to be aware of when using Gofer with specific drivers. It usually only documents issues that are not natural consequences of the limitations of the Gofer approach - as documented above.

TODO

This is just a random brain dump... (There's more in the source of the Changes file, not the pod)

Document policy mechanism

Add mechanism for transports to list config params and for Gofer to apply any that match (and warn if any left over?)

Driver-private sth attributes - set via prepare() - change DBI spec

add hooks into transport base class for checking & updating a result set cache ie via a standard cache interface such as: http://search.cpan.org/~robm/Cache-FastMmap/FastMmap.pm http://search.cpan.org/~bradfitz/Cache-Memcached/lib/Cache/Memcached.pm http://search.cpan.org/~dclinton/Cache-Cache/ http://search.cpan.org/~cleishman/Cache/ Also caching instructions could be passed through the httpd transport layer in such a way that appropriate http cache headers are added to the results so that web caches (squid etc) could be used to implement the caching. (MUST require the use of GET rather than POST requests.)

Rework handling of installed_methods to not piggyback on dbh_attributes?

Perhaps support transactions for transports where it's possible (ie null and stream)? Would make stream transport (ie ssh) more useful to more people.

Make sth_result_attr more like dbh_attributes (using '*' etc)

Add @val = FETCH_many(@names) to DBI in C and use in Gofer/Execute?

Implement _new_sth in C.

Modules

- `DBD::Gofer::Policy`
- `DBD::Gofer::Transport`

DBD::Gofer::Policy

Namespace containing the following modules:

- `DBD::Gofer::Policy::Base` - Base class for DBD::Gofer policies
- `DBD::Gofer::Policy::classic` - The 'classic' policy for DBD::Gofer
- `DBD::Gofer::Policy::pedantic` - The 'pedantic' policy for DBD::Gofer
- `DBD::Gofer::Policy::rush` - The 'rush' policy for DBD::Gofer

DBD::Gofer::Policy::Base

Base class for DBD::Gofer policies

SYNOPSIS

```
$dbh = DBI->connect("dbi:Gofer:transport=...;policy=...", ...)
```

DESCRIPTION

DBD::Gofer can be configured via a 'policy' mechanism that allows you to fine-tune the number of round-trips to the Gofer server. The policies are grouped into classes (which may be subclassed) and referenced by the name of the class.

The *DBD::Gofer::Policy::Base* class is the base class for all the policy classes and describes all the individual policy items.

The Base policy is not used directly. You should use a policy class derived from it.

POLICY CLASSES

Three policy classes are supplied with DBD::Gofer:

DBD::Gofer::Policy::pedantic is most 'transparent' but slowest because it makes more round-trips to the Gofer server.

DBD::Gofer::Policy::classic is a reasonable compromise - it's the default policy.

DBD::Gofer::Policy::rush is fastest, but may require code changes in your applications.

Generally the default `classic` policy is fine. When first testing an existing application with Gofer it is a good idea to start with the `pedantic` policy first and then switch to `classic` or a custom policy, for final testing.

POLICY ITEMS

These are temporary docs: See the source code for list of policies and their defaults.

In a future version the policies and their defaults will be defined in the pod and parsed out at load-time.

See the source code to this module for more details.

POLICY CUSTOMIZATION

XXX This area of DBD::Gofer is subject to change.

There are three ways to customize policies:

Policy classes are designed to influence the overall behaviour of DBD::Gofer with existing, unaltered programs, so they work in a reasonably optimal way without requiring code changes. You can implement new policy classes as subclasses of existing policies.

In many cases individual policy items can be overridden on a case-by-case basis within your application code. You do this by passing a corresponding `<go_<policy_name>>` attribute into DBI methods by your application code. This lets you fine-tune the behaviour for special cases.

The policy items are implemented as methods. In many cases the methods are passed parameters relating to the DBD::Gofer code being executed. This means the policy can implement dynamic behaviour that varies depending on the particular circumstances, such as the particular statement being executed.

DBD::Gofer::Policy::classic

The 'classic' policy for DBD::Gofer

SYNOPSIS

```
$dbh = DBI->connect("dbi:Gofer:transport=...;policy=classic", ...)
```

The `classic` policy is the default DBD::Gofer policy, so need not be included in the DSN.

DESCRIPTION

Temporary docs: See the source code for list of policies and their defaults.

In a future version the policies and their defaults will be defined in the pod and parsed out at load-time.

DBD::Gofer::Policy::pedantic

The 'pedantic' policy for DBD::Gofer

SYNOPSIS

```
$dbh = DBI->connect("dbi:Gofer:transport=...;policy=pedantic", ...)
```

DESCRIPTION

The `pedantic` policy tries to be as transparent as possible. To do this it makes round-trips to the server for almost every DBI method call.

This is the best policy to use when first testing existing code with Gofer. Once it's working well you should consider moving to the `classic` policy or defining your own policy class.

Temporary docs: See the source code for list of policies and their defaults.

In a future version the policies and their defaults will be defined in the pod and parsed out at load-time.

DBD::Gofer::Policy::rush

The 'rush' policy for DBD::Gofer

SYNOPSIS

```
$dbh = DBI->connect("dbi:Gofer:transport=...;policy=rush", ...)
```

DESCRIPTION

The `rush` policy tries to make as few round-trips as possible. It's the opposite end of the policy spectrum to the `pedantic` policy.

Temporary docs: See the source code for list of policies and their defaults.

In a future version the policies and their defaults will be defined in the pod and parsed out at load-time.

DBD::Gofer::Transport

Namespace containing the following modules:

- `DBD::Gofer::Transport::Base` - base class for DBD::Gofer client transports
- `DBD::Gofer::Transport::corostream` - Async DBD::Gofer stream transport using Coro and AnyEvent
- `DBD::Gofer::Transport::null` - DBD::Gofer client transport for testing
- `DBD::Gofer::Transport::pipeone` - DBD::Gofer client transport for testing
- `DBD::Gofer::Transport::stream` - DBD::Gofer transport for stdio streaming

DBD::Gofer::Transport::Base

base class for DBD::Gofer client transports

SYNOPSIS

```
my $remote_dsn = "..."
DBI->connect("dbi:Gofer:transport=...;url=...;timeout=...;retry_
 ↪limit=...;dsn=$remote_dsn",...)
```

or, enable by setting the DBI_AUTOPROXY environment variable:

```
export DBI_AUTOPROXY='dbi:Gofer:transport=...;url=...'
```

which will force *all* DBI connections to be made via that Gofer server.

DESCRIPTION

This is the base class for all DBD::Gofer client transports.

ATTRIBUTES

Gofer transport attributes can be specified either in the attributes parameter of the connect() method call, or in the DSN string. When used in the DSN string, attribute names don't have the go_ prefix.

go_dsn

The full DBI DSN that the Gofer server should connect to on your behalf.

When used in the DSN it must be the last element in the DSN string.

go_timeout

A time limit for sending a request and receiving a response. Some drivers may implement sending and receiving as separate steps, in which case (currently) the timeout applies to each separately.

If a request needs to be resent then the timeout is restarted for each sending of a request and receiving of a response.

go_retry_limit

The maximum number of times an request may be retried. The default is 2.

go_retry_hook

This subroutine reference is called, if defined, for each response received where $response->err is true.

The subroutine is pass three parameters: the request object, the response object, and the transport object.

If it returns an undefined value then the default retry behaviour is used. See "RETRY ON ERROR" below.

If it returns a defined but false value then the request is not resent.

If it returns true value then the request is resent, so long as the number of retries does not exceed `go_retry_limit`.

RETRY ON ERROR

The default retry on error behaviour is:

```
- Retry if the error was due to DBI_GOFER_RANDOM. See L
↪<DBI::Gofer::Execute>.
```

(continues on next page)

(continued from previous page)

```
- Retry if $request->is_idempotent returns true. See L
↪<DBI::Gofer::Request>.
```

A retry won't be allowed if the number of previous retries has reached `go_retry_limit`.

TRACING

Tracing of gofer requests and responses can be enabled by setting the `DBD_GOFER_TRACE` environment variable. A value of 1 gives a reasonably compact summary of each request and response. A value of 2 or more gives a detailed, and voluminous, dump.

The trace is written using DBI->trace_msg() and so is written to the default DBI trace output, which is usually STDERR.

METHODS

This section is currently far from complete.

response_retry_preference

```
$retry = $transport->response_retry_preference($request, $response);
```

The response_retry_preference is called by DBD::Gofer when considering if a request should be retried after an error.

Returns true (would like to retry), false (must not retry), undef (no preference).

If a true value is returned in the form of a CODE ref then, if DBD::Gofer does decide to retry the request, it calls the code ref passing $retry_count, $retry_limit. Can be used for logging and/or to implement exponential back-off behaviour. Currently the called code must return using `return;` to allow for future extensions.

SEE ALSO

DBD::Gofer, *DBI::Gofer::Request*, *DBI::Gofer::Response*, *DBI::Gofer::Execute*.

and some example transports:

DBD::Gofer::Transport::stream

DBD::Gofer::Transport::http

DBI::Gofer::Transport::mod_perl

DBD::Gofer::Transport::corostream

Async DBD::Gofer stream transport using Coro and AnyEvent

SYNOPSIS

```
DBI_AUTOPROXY="dbi:Gofer:transport=corostream" perl some-perl-
↪script-using-dbi.pl
```

or

```
$dsn = ...; # the DSN for the driver and database you want to use
$dbh = DBI->connect("dbi:Gofer:transport=corostream;dsn=$dsn", ...);
```

DESCRIPTION

The *BIG WIN* from using *Coro* is that it enables the use of existing DBI frameworks like DBIx::Class.

KNOWN ISSUES AND LIMITATIONS

```
- Uses Coro::Select so alters CORE::select globally
  Parent class probably needs refactoring to enable a more␣
↪encapsulated approach.

- Doesn't prevent multiple concurrent requests
  Probably just needs a per-connection semaphore

- Coro has many caveats. Caveat emptor.
```

STATUS

THIS IS CURRENTLY JUST A PROOF-OF-CONCEPT IMPLEMENTATION FOR EXPERIMENTATION.

Please note that I have no plans to develop this code further myself. I'd very much welcome contributions. Interested? Let me know!

SEE ALSO

DBD::Gofer::Transport::stream

DBD::Gofer

APPENDIX

Example code:

```
#!perl

use strict;
use warnings;
use Time::HiRes qw(time);

BEGIN { $ENV{PERL_ANYEVENT_STRICT} = 1; $ENV{PERL_ANYEVENT_VERBOSE}
 ↪= 1; }

use AnyEvent;

BEGIN { $ENV{DBI_TRACE} = 0; $ENV{DBI_GOFER_TRACE} = 0; $ENV{DBD_
 ↪GOFER_TRACE} = 0; };

use DBI;

$ENV{DBI_AUTOPROXY} = 'dbi:Gofer:transport=corostream';

my $ticker = AnyEvent->timer( after => 0, interval => 0.1, cb => sub
 ↪{
    warn sprintf "-tick- %.2f\n", time
} );

warn "connecting...\n";
my $dbh = DBI->connect("dbi:NullP:");
warn "...connected\n";

for (1..3) {
    warn "entering DBI...\n";
    $dbh->do("sleep 0.3"); # pseudo-sql understood by the DBD::NullP
 ↪driver
    warn "...returned\n";
}

warn "done.";
```

Example output:

```
$ perl corogofer.pl
connecting...
-tick- 1293631437.14
-tick- 1293631437.14
...connected
entering DBI...
-tick- 1293631437.25
-tick- 1293631437.35
-tick- 1293631437.45
-tick- 1293631437.55
...returned
entering DBI...
-tick- 1293631437.66
-tick- 1293631437.76
-tick- 1293631437.86
...returned
entering DBI...
-tick- 1293631437.96
-tick- 1293631438.06
-tick- 1293631438.16
...returned
done. at corogofer.pl line 39.
```

You can see that the timer callback is firing while the code 'waits' inside the do() method for the response from the database. Normally that would block.

DBD::Gofer::Transport::null

DBD::Gofer client transport for testing

SYNOPSIS

```
my $original_dsn = "..."
DBI->connect("dbi:Gofer:transport=null;dsn=$original_dsn",...)
```

or, enable by setting the DBI_AUTOPROXY environment variable:

```
export DBI_AUTOPROXY="dbi:Gofer:transport=null"
```

DESCRIPTION

Connect via DBD::Gofer but execute the requests within the same process.

This is a quick and simple way to test applications for compatibility with the (few) restrictions that DBD::Gofer imposes.

It also provides a simple, portable way for the DBI test suite to be used to test DBD::Gofer on all platforms with no setup.

Also, by measuring the difference in performance between normal connections and connections via `dbi:Gofer:transport=null` the basic cost of using DBD::Gofer can be measured. Furthermore, the additional cost of more advanced transports can be isolated by comparing their performance with the null transport.

The `t/85gofer.t` script in the DBI distribution includes a comparative benchmark.

SEE ALSO

DBD::Gofer::Transport::Base

DBD::Gofer

DBD::Gofer::Transport::pipeone

DBD::Gofer client transport for testing

SYNOPSIS

```
$original_dsn = "...";
DBI->connect("dbi:Gofer:transport=pipeone;dsn=$original_dsn",...)
```

or, enable by setting the DBI_AUTOPROXY environment variable:

```
export DBI_AUTOPROXY="dbi:Gofer:transport=pipeone"
```

DESCRIPTION

Connect via DBD::Gofer and execute each request by starting executing a subprocess.

This is, as you might imagine, spectacularly inefficient!

It's only intended for testing. Specifically it demonstrates that the server side is completely stateless.

It also provides a base class for the much more useful *DBD::Gofer::Transport::stream* transport.

SEE ALSO

DBD::Gofer::Transport::Base

DBD::Gofer

DBD::Gofer::Transport::stream

DBD::Gofer transport for stdio streaming

SYNOPSIS

```
DBI->connect('dbi:Gofer:transport=stream;url=ssh:username@host.
↪example.com;dsn=dbi:...',...)
```

or, enable by setting the DBI_AUTOPROXY environment variable:

```
export DBI_AUTOPROXY='dbi:Gofer:transport=stream;
↪url=ssh:username@host.example.com'
```

DESCRIPTION

Without the `url=` parameter it launches a subprocess as

```
perl -MDBI::Gofer::Transport::stream -e run_stdio_hex
```

and feeds requests into it and reads responses from it. But that's not very useful.

With a `url=ssh:username@host.example.com` parameter it uses ssh to launch the subprocess on a remote system. That's much more useful!

It gives you secure remote access to DBI databases on any system you can login to. Using ssh also gives you optional compression and many other features (see the ssh manual for how to configure that and many other options via ~/.ssh/config file).

The actual command invoked is something like:

```
ssh -xq ssh:username@host.example.com bash -c $setup $run
```

where $run is the command shown above, and $command is

```
. .bash_profile 2>/dev/null || . .bash_login 2>/dev/null || . .
↪profile 2>/dev/null; exec "$@"
```

which is trying (in a limited and fairly unportable way) to setup the environment (PATH, PERL5LIB etc) as it would be if you had logged in to that system.

The "`perl`" used in the command will default to the value of $^X when not using ssh. On most systems that's the full path to the perl that's currently executing.

PERSISTENCE

Currently gofer stream connections persist (remain connected) after all database handles have been disconnected. This makes later connections in the same process very fast.

Currently up to 5 different gofer stream connections (based on url) can persist. If more than 5 are in the cache when a new connection is made then the cache is cleared before adding the new connection. Simple but effective.

TO DO

Document go_perl attribute

Automatically reconnect (within reason) if there's a transport error.

Decide on default for persistent connection - on or off? limits? ttl?

DBD::Gofer::Transport::Base

DBD::Gofer

DBD::Mem

a DBI driver for Mem & MLMem files

SYNOPSIS

```
use DBI;
$dbh = DBI->connect('dbi:Mem:', undef, undef, {});
$dbh = DBI->connect('dbi:Mem:', undef, undef, {RaiseError => 1});

# or
$dbh = DBI->connect('dbi:Mem:');
$dbh = DBI->connect('DBI:Mem(RaiseError=1):');
```

and other variations on connect() as shown in the *DBI* docs and <DBI::DBD::SqlEngine metadata|DBI::DBD::SqlEngine/Metadata>.

Use standard DBI prepare, execute, fetch, placeholders, etc.

DESCRIPTION

DBD::Mem is a database management system that works right out of the box. If you have a standard installation of Perl and DBI you can begin creating, accessing, and modifying simple database tables without any further modules. You can add other modules (e.g., SQL::Statement) for improved functionality.

DBD::Mem doesn't store any data persistently - all data has the lifetime of the instantiated $dbh. The main reason to use DBD::Mem is to use extended features of SQL::Statement where temporary tables are required. One can use DBD::Mem to simulate `VIEWS` or sub-queries.

Bundling `DBD::Mem` with *DBI* will allow us further compatibility checks of *DBI::DBD::SqlEngine* beyond the capabilities of *DBD::File* and *DBD::DBM*. This will ensure DBI provided basis for drivers like DBD::AnyData2 or DBD::Amazon are better prepared and tested for not-file based backends.

Metadata

There're no new meta data introduced by `DBD::Mem`. See *"Metadata" in DBI::DBD::SqlEngine* for full description.

GETTING HELP, MAKING SUGGESTIONS, AND REPORTING BUGS

If you need help installing or using DBD::Mem, please write to the DBI users mailing list at mailto:dbi-users@perl.org or to the comp.lang.perl.modules newsgroup on usenet. I cannot always answer every question quickly but there are many on the mailing list or in the newsgroup who can.

DBD developers for DBD's which rely on DBI::DBD::SqlEngine or DBD::Mem or use one of them as an example are suggested to join the DBI developers mailing list at mailto:dbi-dev@perl.org and strongly encouraged to join our IRC channel at irc://irc.perl.org/dbi.

If you have suggestions, ideas for improvements, or bugs to report, please report a bug as described in DBI. Do not mail any of the authors directly, you might not get an answer.

When reporting bugs, please send the output of `$dbh->mem_versions($table)` for a

table that exhibits the bug and as small a sample as you can make of the code that produces the bug. And of course, patches are welcome, too :-).

If you need enhancements quickly, you can get commercial support as described at http://dbi.perl.org/support/ or you can contact Jens Rehsack at rehsack@googlemail.com for commercial support.

DBD::Proxy

A proxy driver for the DBI

SYNOPSIS

```
use DBI;

$dbh = DBI->connect("dbi:Proxy:hostname=$host;port=$port;dsn=$db",
                    $user, $passwd);

# See the DBI module documentation for full details
```

DESCRIPTION

DBD::Proxy is a Perl module for connecting to a database via a remote DBI driver. See *DBD::Gofer* for an alternative with different trade-offs.

This is of course not needed for DBI drivers which already support connecting to a remote database, but there are engines which don't offer network connectivity.

Another application is offering database access through a firewall, as the driver offers query based restrictions. For example you can restrict queries to exactly those that are used in a given CGI application.

Speaking of CGI, another application is (or rather, will be) to reduce the database connect/disconnect overhead from CGI scripts by using proxying the connect_cached

method. The proxy server will hold the database connections open in a cache. The CGI script then trades the database connect/disconnect overhead for the DBD::Proxy connect/disconnect overhead which is typically much less.

CONNECTING TO THE DATABASE

Before connecting to a remote database, you must ensure, that a Proxy server is running on the remote machine. There's no default port, so you have to ask your system administrator for the port number. See *DBI::ProxyServer* for details.

Say, your Proxy server is running on machine "alpha", port 3334, and you'd like to connect to an ODBC database called "mydb" as user "joe" with password "hello". When using DBD::ODBC directly, you'd do a

```
$dbh = DBI->connect("DBI:ODBC:mydb", "joe", "hello");
```

With DBD::Proxy this becomes

```
$dsn = "DBI:Proxy:hostname=alpha;port=3334;dsn=DBI:ODBC:mydb";
$dbh = DBI->connect($dsn, "joe", "hello");
```

You see, this is mainly the same. The DBD::Proxy module will create a connection to the Proxy server on "alpha" which in turn will connect to the ODBC database.

Refer to the *DBI* documentation on the `connect` method for a way to automatically use DBD::Proxy without having to change your code.

DBD::Proxy's DSN string has the format

```
$dsn = "DBI:Proxy:key1=val1; ... ;keyN=valN;dsn=valDSN";
```

In other words, it is a collection of key/value pairs. The following keys are recognized:

- hostname
- port

  Hostname and port of the Proxy server; these keys must be present, no defaults. Example:

  ```
  hostname=alpha;port=3334
  ```

- dsn

  The value of this attribute will be used as a dsn name by the Proxy server. Thus it must have the format `DBI:driver:...`, in particular it will contain colons. The *dsn* value may contain semicolons, hence this key *must* be the last and it's value will be the complete remaining part of the dsn. Example:

  ```
  dsn=DBI:ODBC:mydb
  ```

- cipher
- key
- usercipher

- userkey

  By using these fields you can enable encryption. If you set, for example,

```
cipher=$class;key=$key
```

  (note the semicolon) then DBD::Proxy will create a new cipher object by executing

```
$cipherRef = $class->new(pack("H*", $key));
```

  and pass this object to the RPC::PlClient module when creating a client. See RPC::PlClient. Example:

```
cipher=IDEA;key=97cd2375efa329aceef2098babdc9721
```

  The usercipher/userkey attributes allow you to use two phase encryption: The cipher/key encryption will be used in the login and authorisation phase. Once the client is authorised, he will change to usercipher/userkey encryption. Thus the cipher/key pair is a **host** based secret, typically less secure than the usercipher/userkey secret and readable by anyone. The usercipher/userkey secret is **your** private secret.

  Of course encryption requires an appropriately configured server. See "CONFIGURATION FILE" in DBD::ProxyServer.

- debug

  Turn on debugging mode

- stderr

  This attribute will set the corresponding attribute of the RPC::PlClient object, thus logging will not use syslog(), but redirected to stderr. This is the default under Windows.

```
stderr=1
```

- logfile

  Similar to the stderr attribute, but output will be redirected to the given file.

```
logfile=/dev/null
```

- RowCacheSize

  The DBD::Proxy driver supports this attribute (which is DBI standard, as of DBI 1.02). It's used to reduce network round-trips by fetching multiple rows in one go. The current default value is 20, but this may change.

- proxy_no_finish

  This attribute can be used to reduce network traffic: If the application is calling $sth->finish() then the proxy tells the server to finish the remote statement handle. Of course this slows down things quite a lot, but is perfectly good for reducing memory usage with persistent connections.

However, if you set the *proxy_no_finish* attribute to a TRUE value, either in the database handle or in the statement handle, then finish() calls will be suppressed. This is what you want, for example, in small and fast CGI applications.

- proxy_quote

  This attribute can be used to reduce network traffic: By default calls to $dbh->quote() are passed to the remote driver. Of course this slows down things quite a lot, but is the safest default behaviour.

  However, if you set the *proxy_quote* attribute to the value 'local' either in the database handle or in the statement handle, and the call to quote has only one parameter, then the local default DBI quote method will be used (which will be faster but may be wrong).

KNOWN ISSUES

Unproxied method calls

If a method isn't being proxied, try declaring a stub sub in the appropriate package (DBD::Proxy::db for a dbh method, and DBD::Proxy::st for an sth method). For example:

```
sub DBD::Proxy::db::selectall_arrayref;
```

That will enable selectall_arrayref to be proxied.

Currently many methods aren't explicitly proxied and so you get the DBI's default methods executed on the client.

Some of those methods, like selectall_arrayref, may then call other methods that are proxied (selectall_arrayref calls fetchall_arrayref which calls fetch which is proxied). So things may appear to work but operate more slowly than the could.

This may all change in a later version.

Complex handle attributes

Sometimes handles are having complex attributes like hash refs or array refs and not simple strings or integers. For example, with DBD::CSV, you would like to write something like

```
$dbh->{"csv_tables"}->{"passwd"} =
      { "sep_char" => ":", "eol" => "\n";
```

The above example would advice the CSV driver to assume the file "passwd" to be in the format of the /etc/passwd file: Colons as separators and a line feed without carriage return as line terminator.

Surprisingly this example doesn't work with the proxy driver. To understand the reasons, you should consider the following: The Perl compiler is executing the above example in two steps:

1. The first step is fetching the value of the key "csv_tables" in the handle $dbh. The value returned is complex, a hash ref.

2. The second step is storing some value (the right hand side of the assignment) as the key “passwd” in the hash ref from step 1.

This becomes a little bit clearer, if we rewrite the above code:

```
$tables = $dbh->{"csv_tables"};
$tables->{"passwd"} = { "sep_char" => ":", "eol" => "\n";
```

While the examples work fine without the proxy, the fail due to a subtle difference in step 1: By DBI magic, the hash ref $dbh->{‘csv_tables’} is returned from the server to the client. The client creates a local copy. This local copy is the result of step 1. In other words, step 2 modifies a local copy of the hash ref, but not the server’s hash ref.

The workaround is storing the modified local copy back to the server:

```
$tables = $dbh->{"csv_tables"};
$tables->{"passwd"} = { "sep_char" => ":", "eol" => "\n";
$dbh->{"csv_tables"} = $tables;
```

SECURITY WARNING

RPC::PlClient used underneath is not secure due to serializing and deserializing data with *Storable* module. Use the proxy driver only in trusted environment.

DBD::SQLite

Namespace containing the following modules:

- `DBD::SQLite::Constants` - common SQLite constants

DBD::SQLite::Constants

common SQLite constants

SYNOPSIS

```
DBD::SQLite::Constants qw/:result_codes/;
```

DESCRIPTION

You can import necessary SQLite constants from this module. Available tags are `all`, `allowed_return_values_from_sqlite3_txn_state`, `authorizer_action_codes`, `authorizer_return_codes`, `version` (`compile_time_library_version_numbers`), `database_connection_configuration_options`, `dbd_sqlite_string_mode`, `extended_result_codes`, `file_open` (`flags_for_file_open_operations`), `flags_for_sqlite3_setlk_timeout`, `function_flags`, `datatypes` (`fundamental_datatypes`), `result_codes`, `run_time_limit_categories`. See http://sqlite.org/c3ref/constlist.html for the complete list of constants.

This module does not export anything by default.

CONSTANTS

DBD::Sponge

Create a DBI statement handle from Perl data

SYNOPSIS

```
my $sponge = DBI->connect("dbi:Sponge:","","",{ RaiseError => 1 });
my $sth = $sponge->prepare($statement, {
        rows => $data,
        NAME => $names,
        %attr
    }
);
```

DESCRIPTION

DBD::Sponge is useful for making a Perl data structure accessible through a standard DBI statement handle. This may be useful to DBD module authors who need to transform data in this way.

METHODS

connect()

```
my $sponge = DBI->connect("dbi:Sponge:","","",{ RaiseError => 1 });
```

Here's a sample syntax for creating a database handle for the Sponge driver. No username and password are needed.

prepare()

```
my $sth = $sponge->prepare($statement, {
        rows => $data,
        NAME => $names,
        %attr
    }
);
```

- The `$statement` here is an arbitrary statement or name you want to provide as identity of your data. If you're using DBI::Profile it will appear in the profile data.

  Generally it's expected that you are preparing a statement handle as if a `select` statement happened.

- `$data` is a reference to the data you are providing, given as an array of arrays.

- `$names` is a reference an array of column names for the `$data` you are providing. The number and order should match the number and ordering of the `$data` columns.

- `%attr` is a hash of other standard DBI attributes that you might pass to a prepare statement.

  Currently only NAME, TYPE, and PRECISION are supported. TYPE defaults to SQL_VARCHAR. PRECISION will be lazily computed if not supplied.

BUGS

Using this module to prepare INSERT-like statements is not currently documented.

5.2.24 DBI

Database independent interface for Perl

SYNOPSIS

```
use DBI;

@driver_names = DBI->available_drivers;
%drivers      = DBI->installed_drivers;
@data_sources = DBI->data_sources($driver_name, \%attr);

$dbh = DBI->connect($data_source, $username, $auth, \%attr);

$rv  = $dbh->do($statement);
$rv  = $dbh->do($statement, \%attr);
$rv  = $dbh->do($statement, \%attr, @bind_values);

$ary_ref  = $dbh->selectall_arrayref($statement);
$hash_ref = $dbh->selectall_hashref($statement, $key_field);

$ary_ref  = $dbh->selectcol_arrayref($statement);
$ary_ref  = $dbh->selectcol_arrayref($statement, \%attr);

@row_ary  = $dbh->selectrow_array($statement);
$ary_ref  = $dbh->selectrow_arrayref($statement);
$hash_ref = $dbh->selectrow_hashref($statement);

$sth = $dbh->prepare($statement);
$sth = $dbh->prepare_cached($statement);

$rc = $sth->bind_param($p_num, $bind_value);
$rc = $sth->bind_param($p_num, $bind_value, $bind_type);
$rc = $sth->bind_param($p_num, $bind_value, \%attr);

$rv = $sth->execute;
$rv = $sth->execute(@bind_values);
$rv = $sth->execute_array(\%attr, ...);

$rc = $sth->bind_col($col_num, \$col_variable);
$rc = $sth->bind_columns(@list_of_refs_to_vars_to_bind);

@row_ary  = $sth->fetchrow_array;
$ary_ref  = $sth->fetchrow_arrayref;
$hash_ref = $sth->fetchrow_hashref;
```

(continues on next page)

(continued from previous page)

```
$ary_ref  = $sth->fetchall_arrayref;
$ary_ref  = $sth->fetchall_arrayref( $slice, $max_rows );

$hash_ref = $sth->fetchall_hashref( $key_field );

$rv  = $sth->rows;

$rc  = $dbh->begin_work;
$rc  = $dbh->commit;
$rc  = $dbh->rollback;

$quoted_string = $dbh->quote($string);

$rc  = $h->err;
$str = $h->errstr;
$rv  = $h->state;

$rc  = $dbh->disconnect;
```

The synopsis above only lists the major methods and parameters.

GETTING HELP

General

Before asking any questions, reread this document, consult the archives and read the DBI FAQ. The archives are listed at the end of this document and on the DBI home page http://dbi.perl.org/support/

You might also like to read the Advanced DBI Tutorial at http://www.slideshare.net/Tim.Bunce/dbi-advanced-tutorial-2007

To help you make the best use of the dbi-users mailing list, and any other lists or forums you may use, I recommend that you read "Getting Answers" by Mike Ash: http://mikeash.com/getting_answers.html.

Mailing Lists

If you have questions about DBI, or DBD driver modules, you can get help from the *dbi-users@perl.org* mailing list. This is the best way to get help. You don't have to subscribe to the list in order to post, though I'd recommend it. You can get help on subscribing and using the list by emailing *dbi-users-help@perl.org*.

Please note that Tim Bunce does not maintain the mailing lists or the web pages (generous volunteers do that). So please don't send mail directly to him; he just doesn't have the time to answer questions personally. The *dbi-users* mailing list has lots of experienced people who should be able to help you if you need it. If you do email Tim he is very likely to just forward it to the mailing list.

IRC

DBI IRC Channel: #dbi on irc.perl.org (irc://irc.perl.org/#dbi)

Online

StackOverflow has a DBI tag https://stackoverflow.com/questions/tagged/dbi with over 800 questions.

The DBI home page at https://dbi.perl.org/ might be worth a visit. It includes links to other resources, but *is rather out-dated*.

Reporting a Bug

If you think you've found a bug then please read "How to Report Bugs Effectively" by Simon Tatham: https://www.chiark.greenend.org.uk/~sgtatham/bugs.html.

If you think you've found a memory leak then read "Memory Leaks".

Your problem is most likely related to the specific DBD driver module you're using. If that's the case then click on the 'Bugs' link on the https://metacpan.org page for your driver. Only submit a bug report against the DBI itself if you're sure that your issue isn't related to the driver you're using.

NOTES

This is the DBI specification that corresponds to DBI version 1.655 (see DBI::Changes for details).

The DBI is evolving at a steady pace, so it's good to check that you have the latest copy.

The significant user-visible changes in each release are documented in the DBI::Changes module so you can read them by executing `perldoc DBI::Changes`.

Some DBI changes require changes in the drivers, but the drivers can take some time to catch up. Newer versions of the DBI have added features that may not yet be supported by the drivers you use. Talk to the authors of your drivers if you need a new feature that is not yet supported.

Features added after DBI 1.21 (February 2002) are marked in the text with the version number of the DBI release they first appeared in.

Extensions to the DBI API often use the `DBIx::*` namespace. See "Naming Conventions and Name Space". DBI extension modules can be found at https://metacpan.org/search?q=DBIx. And all modules related to the DBI can be found at https://metacpan.org/search?q=DBI.

DESCRIPTION

The DBI is a database access module for the Perl programming language. It defines a set of methods, variables, and conventions that provide a consistent database interface, independent of the actual database being used.

It is important to remember that the DBI is just an interface. The DBI is a layer of "glue" between an application and one or more database *driver* modules. It is the driver mod-

ules which do most of the real work. The DBI provides a standard interface and framework for the drivers to operate within.

This document often uses terms like *references*, *objects*, *methods*. If you're not familiar with those terms then it would be a good idea to read at least the following perl manuals first: perlreftut, perldsc, perllol, and perlboot.

Architecture of a DBI Application

```
           |<- Scope of DBI ->|
                .-.   .--------------.   .--------------.
.-------.       | |---| XYZ Driver   |---| XYZ Engine   |
| Perl  |       | |   `--------------'   `--------------'
| script|  |A|  |D|   .--------------.   .--------------.
| using |--|P|--|B|---|Oracle Driver |---|Oracle Engine|
| DBI   |  |I|  |I|   `--------------'   `--------------'
| API   |       | |...
|methods|       | |... Other drivers
`-------'       | |...
                `-'
```

The API, or Application Programming Interface, defines the call interface and variables for Perl scripts to use. The API is implemented by the Perl DBI extension.

The DBI "dispatches" the method calls to the appropriate driver for actual execution. The DBI is also responsible for the dynamic loading of drivers, error checking and handling, providing default implementations for methods, and many other non-database specific duties.

Each driver contains implementations of the DBI methods using the private interface functions of the corresponding database engine. Only authors of sophisticated/multi-database applications or generic library functions need be concerned with drivers.

Notation and Conventions

The following conventions are used in this document:

```
$dbh    Database handle object
$sth    Statement handle object
$drh    Driver handle object (rarely seen or used in applications)
$h      Any of the handle types above ($dbh, $sth, or $drh)
$rc     General Return Code  (boolean: true=ok, false=error)
$rv     General Return Value (typically an integer)
@ary    List of values returned from the database, typically a row
 ↪of data
$rows   Number of rows processed (if available, else -1)
$fh     A filehandle
undef   NULL values are represented by undefined values in Perl
\%attr  Reference to a hash of attribute values passed to methods
```

Note that Perl will automatically destroy database and statement handle objects if all references to them are deleted.

Outline Usage

To use DBI, first you need to load the DBI module:

```
use DBI;
use strict;
```

(The `use strict;` isn't required but is strongly recommended.)

Then you need to "connect" to your data source and get a *handle* for that connection:

```
$dbh = DBI->connect($dsn, $user, $password,
                    { RaiseError => 1, AutoCommit => 0 });
```

Since connecting can be expensive, you generally just connect at the start of your program and disconnect at the end.

Explicitly defining the required `AutoCommit` behaviour is strongly recommended and may become mandatory in a later version. This determines whether changes are automatically committed to the database when executed, or need to be explicitly committed later.

The DBI allows an application to "prepare" statements for later execution. A prepared statement is identified by a statement handle held in a Perl variable. We'll call the Perl variable `$sth` in our examples.

The typical method call sequence for a `SELECT` statement is:

```
prepare,
  execute, fetch, fetch, ...
  execute, fetch, fetch, ...
  execute, fetch, fetch, ...
```

for example:

```
$sth = $dbh->prepare("SELECT foo, bar FROM table WHERE baz=?");

$sth->execute( $baz );

while ( @row = $sth->fetchrow_array ) {
  print "@row\n";
}
```

For queries that are not executed many times at once, it is often cleaner to use the higher level select wrappers:

```
$row_hashref = $dbh->selectrow_hashref("SELECT foo, bar FROM table␣
↪WHERE baz=?", undef, $baz);

$arrayref_of_row_hashrefs = $dbh->selectall_arrayref(
  "SELECT foo, bar FROM table WHERE baz BETWEEN ? AND ?",
  { Slice => {} }, $baz_min, $baz_max);
```

The typical method call sequence for a *non*-`SELECT` statement is:

```
prepare,
  execute,
  execute,
  execute.
```

for example:

```
$sth = $dbh->prepare("INSERT INTO table(foo,bar,baz) VALUES (?,?,?)
 ↪");

while(<CSV>) {
  chomp;
  my ($foo,$bar,$baz) = split /,/;
      $sth->execute( $foo, $bar, $baz );
}
```

The `do()` method is a wrapper of prepare and execute that can be simpler for non repeated *non*-`SELECT` statements (or with drivers that don't support placeholders):

```
$rows_affected = $dbh->do("UPDATE your_table SET foo = foo + 1");

$rows_affected = $dbh->do("DELETE FROM table WHERE foo = ?", undef,
 ↪$foo);
```

To commit your changes to the database (when "AutoCommit" is off):

```
$dbh->commit;  # or call $dbh->rollback; to undo changes
```

Finally, when you have finished working with the data source, you should "disconnect" from it:

```
$dbh->disconnect;
```

General Interface Rules & Caveats

The DBI does not have a concept of a "current session". Every session has a handle object (i.e., a `$dbh`) returned from the `connect` method. That handle object is used to invoke database related methods.

Most data is returned to the Perl script as strings. (Null values are returned as `undef`.) This allows arbitrary precision numeric data to be handled without loss of accuracy. Beware that Perl may not preserve the same accuracy when the string is used as a number.

Dates and times are returned as character strings in the current default format of the corresponding database engine. Time zone effects are database/driver dependent.

Perl supports binary data in Perl strings, and the DBI will pass binary data to and from the driver without change. It is up to the driver implementors to decide how they wish to handle such binary data.

Perl supports two kinds of strings: Unicode (utf8 internally) and non-Unicode (defaults to iso-8859-1 if forced to assume an encoding). Drivers should accept both kinds of strings and, if required, convert them to the character set of the database being used.

Similarly, when fetching from the database character data that isn't iso-8859-1 the driver should convert it into utf8.

Multiple SQL statements may not be combined in a single statement handle (`$sth`), although some databases and drivers do support this (notably Sybase and SQL Server).

Non-sequential record reads are not supported in this version of the DBI. In other words, records can only be fetched in the order that the database returned them, and once fetched they are forgotten.

Positioned updates and deletes are not directly supported by the DBI. See the description of the `CursorName` attribute for an alternative.

Individual driver implementors are free to provide any private functions and/or handle attributes that they feel are useful. Private driver functions can be invoked using the DBI `func()` method. Private driver attributes are accessed just like standard attributes.

Many methods have an optional `\%attr` parameter which can be used to pass information to the driver implementing the method. Except where specifically documented, the `\%attr` parameter can only be used to pass driver specific hints. In general, you can ignore `\%attr` parameters or pass it as `undef`.

Naming Conventions and Name Space

The DBI package and all packages below it (`DBI::*`) are reserved for use by the DBI. Extensions and related modules use the `DBIx::` namespace (see http://www.perl.com/CPAN/modules/by-module/DBIx/). Package names beginning with `DBD::` are reserved for use by DBI database drivers. All environment variables used by the DBI or by individual DBDs begin with "`DBI_`" or "`DBD_`".

The letter case used for attribute names is significant and plays an important part in the portability of DBI scripts. The case of the attribute name is used to signify who defined the meaning of that name and its values.

```
Case of name  Has a meaning defined by
------------  ------------------------
UPPER_CASE    Standards, e.g.,  X/Open, ISO SQL92 etc (portable)
MixedCase     DBI API (portable), underscores are not used.
lower_case    Driver or database engine specific (non-portable)
```

It is of the utmost importance that Driver developers only use lowercase attribute names when defining private attributes. Private attribute names must be prefixed with the driver name or suitable abbreviation (e.g., "`ora_`" for Oracle, "`ing_`" for Ingres, etc).

SQL - A Query Language

Most DBI drivers require applications to use a dialect of SQL (Structured Query Language) to interact with the database engine. The "Standards Reference Information" section provides links to useful information about SQL.

The DBI itself does not mandate or require any particular language to be used; it is language independent. In ODBC terms, the DBI is in "pass-thru" mode, although individual drivers might not be. The only requirement is that queries and other statements must be expressed as a single string of characters passed as the first argument to the "prepare" or "do" methods.

For an interesting diversion on the *real* history of RDBMS and SQL, from the people who made it happen, see:

```
http://www.mcjones.org/System_R/SQL_Reunion_95/sqlr95.html
```

Follow the “Full Contents” then “Intergalactic dataspeak” links for the SQL history.

Placeholders and Bind Values

Some drivers support placeholders and bind values. *Placeholders*, also called parameter markers, are used to indicate values in a database statement that will be supplied later, before the prepared statement is executed. For example, an application might use the following to insert a row of data into the SALES table:

```
INSERT INTO sales (product_code, qty, price) VALUES (?, ?, ?)
```

or the following, to select the description for a product:

```
SELECT description FROM products WHERE product_code = ?
```

The ? characters are the placeholders. The association of actual values with placeholders is known as *binding*, and the values are referred to as *bind values*. Note that the ? is not enclosed in quotation marks, even when the placeholder represents a string.

Some drivers also allow placeholders like :*name* and :*N* (e.g., :1, :2, and so on) in addition to ?, but their use is not portable.

If the :*N* form of placeholder is supported by the driver you’re using, then you should be able to use either “bind_param” or “execute” to bind values. Check your driver documentation.

Some drivers allow you to prevent the recognition of a placeholder by placing a single backslash character (\) immediately before it. The driver will remove the backslash character and ignore the placeholder, passing it unchanged to the backend. If the driver supports this then “get_info”(9000) will return true.

With most drivers, placeholders can’t be used for any element of a statement that would prevent the database server from validating the statement and creating a query execution plan for it. For example:

```
"SELECT name, age FROM ?"         # wrong (will probably fail)
"SELECT name, ?   FROM people"    # wrong (but may not 'fail')
```

Also, placeholders can only represent single scalar values. For example, the following statement won’t work as expected for more than one value:

```
"SELECT name, age FROM people WHERE name IN (?)"    # wrong
"SELECT name, age FROM people WHERE name IN (?,?)"  # two names
```

When using placeholders with the SQL LIKE qualifier, you must remember that the placeholder substitutes for the whole string. So you should use “. . . LIKE ? . . .” and include any wildcard characters in the value that you bind to the placeholder.

NULL Values

Undefined values, or undef, are used to indicate NULL values. You can insert and update columns with a NULL value as you would a non-NULL value. These examples insert and update the column age with a NULL value:

```
$sth = $dbh->prepare(qq{
  INSERT INTO people (fullname, age) VALUES (?, ?)
});
$sth->execute("Joe Bloggs", undef);

$sth = $dbh->prepare(qq{
  UPDATE people SET age = ? WHERE fullname = ?
});
$sth->execute(undef, "Joe Bloggs");
```

However, care must be taken when trying to use NULL values in a WHERE clause. Consider:

```
SELECT fullname FROM people WHERE age = ?
```

Binding an undef (NULL) to the placeholder will *not* select rows which have a NULL age! At least for database engines that conform to the SQL standard. Refer to the SQL manual for your database engine or any SQL book for the reasons for this. To explicitly select NULLs you have to say "WHERE age IS NULL".

A common issue is to have a code fragment handle a value that could be either defined or undef (non-NULL or NULL) at runtime. A simple technique is to prepare the appropriate statement as needed, and substitute the placeholder for non-NULL cases:

```
$sql_clause = defined $age? "age = ?" : "age IS NULL";
$sth = $dbh->prepare(qq{
  SELECT fullname FROM people WHERE $sql_clause
});
$sth->execute(defined $age ? $age : ());
```

The following technique illustrates qualifying a WHERE clause with several columns, whose associated values (defined or undef) are in a hash %h:

```
for my $col ("age", "phone", "email") {
  if (defined $h{$col}) {
    push @sql_qual, "$col = ?";
    push @sql_bind, $h{$col};
  }
  else {
    push @sql_qual, "$col IS NULL";
  }
}
$sql_clause = join(" AND ", @sql_qual);
$sth = $dbh->prepare(qq{
    SELECT fullname FROM people WHERE $sql_clause
});
$sth->execute(@sql_bind);
```

The techniques above call prepare for the SQL statement with each call to execute. Be-

cause calls to prepare() can be expensive, performance can suffer when an application iterates many times over statements like the above.

A better solution is a single WHERE clause that supports both NULL and non-NULL comparisons. Its SQL statement would need to be prepared only once for all cases, thus improving performance. Several examples of WHERE clauses that support this are presented below. But each example lacks portability, robustness, or simplicity. Whether an example is supported on your database engine depends on what SQL extensions it provides, and where it supports the ? placeholder in a statement.

```
0)  age = ?
1)  NVL(age, xx) = NVL(?, xx)
2)  ISNULL(age, xx) = ISNULL(?, xx)
3)  DECODE(age, ?, 1, 0) = 1
4)  age = ? OR (age IS NULL AND ? IS NULL)
5)  age = ? OR (age IS NULL AND SP_ISNULL(?) = 1)
6)  age = ? OR (age IS NULL AND ? = 1)
```

Statements formed with the above WHERE clauses require execute statements as follows. The arguments are required, whether their values are defined or undef.

```
0,1,2,3)  $sth->execute($age);
4,5)      $sth->execute($age, $age);
6)        $sth->execute($age, defined($age) ? 0 : 1);
```

Example 0 should not work (as mentioned earlier), but may work on a few database engines anyway (e.g. Sybase). Example 0 is part of examples 4, 5, and 6, so if example 0 works, these other examples may work, even if the engine does not properly support the right hand side of the OR expression.

Examples 1 and 2 are not robust: they require that you provide a valid column value xx (e.g. '~') which is not present in any row. That means you must have some notion of what data won't be stored in the column, and expect clients to adhere to that.

Example 5 requires that you provide a stored procedure (SP_ISNULL in this example) that acts as a function: it checks whether a value is null, and returns 1 if it is, or 0 if not.

Example 6, the least simple, is probably the most portable, i.e., it should work with most, if not all, database engines.

Here is a table that indicates which examples above are known to work on various database engines:

```
                -----Examples------
                0  1  2  3  4  5  6
                -  -  -  -  -  -  -
Oracle 9        N  Y  N  Y  Y  ?  Y
Informix IDS 9  N  N  N  Y  N  Y  Y
MS SQL          N  N  Y  N  Y  ?  Y
Sybase          Y  N  N  N  N  N  Y
AnyData,DBM,CSV Y  N  N  N  Y  Y* Y
SQLite 3.3      N  N  N  N  Y  N  N
MSAccess        N  N  N  N  Y  N  Y
```

* Works only because Example 0 works.

DBI provides a sample perl script that will test the examples above on your database engine and tell you which ones work. It is located in the `ex/` subdirectory of the DBI source distribution, or here: https://github.com/perl5-dbi/dbi/blob/master/ex/perl_dbi_nulls_test.pl Please use the script to help us fill-in and maintain this table.

Performance

Without using placeholders, the insert statement shown previously would have to contain the literal values to be inserted and would have to be re-prepared and re-executed for each row. With placeholders, the insert statement only needs to be prepared once. The bind values for each row can be given to the `execute` method each time it's called. By avoiding the need to re-prepare the statement for each row, the application typically runs many times faster. Here's an example:

```
my $sth = $dbh->prepare(q{
  INSERT INTO sales (product_code, qty, price) VALUES (?, ?, ?)
}) or die $dbh->errstr;
while (<>) {
    chomp;
    my ($product_code, $qty, $price) = split /,/;
    $sth->execute($product_code, $qty, $price) or die $dbh->errstr;
}
$dbh->commit or die $dbh->errstr;
```

See "execute" and "bind_param" for more details.

The `q{...}` style quoting used in this example avoids clashing with quotes that may be used in the SQL statement. Use the double-quote like `qq{...}` operator if you want to interpolate variables into the string. See *"Quote and Quote-like Operators" in perlop* for more details.

See also the "bind_columns" method, which is used to associate Perl variables with the output columns of a `SELECT` statement.

THE DBI PACKAGE AND CLASS

In this section, we cover the DBI class methods, utility functions, and the dynamic attributes associated with generic DBI handles.

DBI Constants

Constants representing the values of the SQL standard types can be imported individually by name, or all together by importing the special `:sql_types` tag.

The names and values of all the defined SQL standard types can be produced like this:

```
foreach (@{ $DBI::EXPORT_TAGS{sql_types} }) {
  printf "%s=%d\n", $_, &{"DBI::$_"};
}
```

These constants are defined by SQL/CLI, ODBC or both. `SQL_BIGINT` has conflicting codes in SQL/CLI and ODBC, DBI uses the ODBC one.

See the "type_info", "type_info_all", and "bind_param" methods for possible uses.

Note that just because the DBI defines a named constant for a given data type doesn't mean that drivers will support that data type.

DBI Class Methods

The following methods are provided by the DBI class:

parse_dsn

```
($scheme, $driver, $attr_string, $attr_hash, $driver_dsn) = DBI->
↪parse_dsn($dsn)
    or die "Can't parse DBI DSN '$dsn'";
```

Breaks apart a DBI Data Source Name (DSN) and returns the individual parts. If $dsn doesn't contain a valid DSN then parse_dsn() returns an empty list.

$scheme is the first part of the DSN and is currently always 'dbi'. $driver is the driver name, possibly defaulted to $ENV{DBI_DRIVER}, and may be undefined. $attr_string is the contents of the optional attribute string, which may be undefined. If $attr_string is not empty then $attr_hash is a reference to a hash containing the parsed attribute names and values. $driver_dsn is the last part of the DBI DSN string. For example:

```
($scheme, $driver, $attr_string, $attr_hash, $driver_dsn)
    = DBI->parse_dsn("dbi:MyDriver(RaiseError=>1):db=test;port=42");
$scheme      = 'dbi';
$driver      = 'MyDriver';
$attr_string = 'RaiseError=>1';
$attr_hash   = { 'RaiseError' => '1' };
$driver_dsn  = 'db=test;port=42';
```

The parse_dsn() method was added in DBI 1.43.

connect

```
$dbh = DBI->connect($data_source, $username, $password)
          or die $DBI::errstr;
$dbh = DBI->connect($data_source, $username, $password, \%attr)
          or die $DBI::errstr;
```

Establishes a database connection, or session, to the requested `$data_source`. Returns a database handle object if the connection succeeds. Use `$dbh->disconnect` to terminate the connection.

If the connect fails (see below), it returns `undef` and sets both `$DBI::err` and `$DBI::errstr`. (It does *not* explicitly set `$!`.) You should generally test the return status of `connect` and `print $DBI::errstr` if it has failed.

Multiple simultaneous connections to multiple databases through multiple drivers can be made via the DBI. Simply make one `connect` call for each database and keep a copy of each returned database handle.

The `$data_source` value must begin with "`dbi:`*driver_name*`:`". The *driver_name* specifies the driver that will be used to make the connection. (Letter case is significant.)

As a convenience, if the `$data_source` parameter is undefined or empty, the DBI will substitute the value of the environment variable `DBI_DSN`. If just the *driver_name* part is empty (i.e., the `$data_source` prefix is "`dbi::`"), the environment variable `DBI_DRIVER` is used. If neither variable is set, then `connect` dies.

Examples of `$data_source` values are:

```
dbi:DriverName:database_name
dbi:DriverName:database_name@hostname:port
dbi:DriverName:database=database_name;host=hostname;port=port
```

There is *no standard* for the text following the driver name. Each driver is free to use whatever syntax it wants. The only requirement the DBI makes is that all the information is supplied in a single string. You must consult the documentation for the drivers you are using for a description of the syntax they require.

It is recommended that drivers support the ODBC style, shown in the last example above. It is also recommended that they support the three common names '`host`', '`port`', and '`database`' (plus 'db' as an alias for `database`). This simplifies automatic construction of basic DSNs: `"dbi:$driver:database=$db;host=$host;port=$port"`. Drivers should aim to 'do something reasonable' when given a DSN in this form, but if any part is meaningless for that driver (such as 'port' for Informix) it should generate an error if that part is not empty.

If the environment variable `DBI_AUTOPROXY` is defined (and the driver in `$data_source` is not "`Proxy`") then the connect request will automatically be changed to:

```
$ENV{DBI_AUTOPROXY};dsn=$data_source
```

`DBI_AUTOPROXY` is typically set as "`dbi:Proxy:hostname=...;port=...`". If $ENV{DBI_AUTOPROXY} doesn't begin with '`dbi:`' then "dbi:Proxy:" will be prepended to it first. See the DBD::Proxy documentation for more details.

If `$username` or `$password` are undefined (rather than just empty), then the DBI will substitute the values of the `DBI_USER` and `DBI_PASS` environment variables, respectively. The DBI will warn if the environment variables are not defined. However, the everyday use of these environment variables is not recommended for security reasons. The mechanism is primarily intended to simplify testing. See below for alternative way to specify the username and password.

`DBI->connect` automatically installs the driver if it has not been installed yet. Driver installation either returns a valid driver handle, or it *dies* with an error message that includes the string "`install_driver`" and the underlying problem. So `DBI->connect` will die on a driver installation failure and will only return `undef` on a connect failure, in which case `$DBI::errstr` will hold the error message. Use `eval` if you need to catch the "`install_driver`" error.

The `$data_source` argument (with the "`dbi:...:`" prefix removed) and the `$username` and `$password` arguments are then passed to the driver for processing. The DBI does not define any interpretation for the contents of these fields. The driver is free to interpret the `$data_source`, `$username`, and `$password` fields in any way, and supply whatever defaults are appropriate for the engine being accessed. (Oracle, for example, uses the ORACLE_SID and TWO_TASK environment variables if no `$data_source` is specified.)

The AutoCommit and PrintError attributes for each connection default to "on". (See "AutoCommit" and "PrintError" for more information.) However, it is strongly recommended that you explicitly define AutoCommit rather than rely on the default. The PrintWarn attribute defaults to true. The RaiseWarn attribute defaults to false.

The \%attr parameter can be used to alter the default settings of PrintError, RaiseError, AutoCommit, and other attributes. For example:

```
$dbh = DBI->connect($data_source, $user, $pass, {
      PrintError => 0,
      AutoCommit => 0
});
```

The username and password can also be specified using the attributes Username and Password, in which case they take precedence over the $username and $password parameters.

You can also define connection attribute values within the $data_source parameter. For example:

```
dbi:DriverName(PrintWarn=>0,PrintError=>0,Taint=>1):...
```

Individual attributes values specified in this way take precedence over any conflicting values specified via the \%attr parameter to connect.

The dbi_connect_method attribute can be used to specify which driver method should be called to establish the connection. The only useful values are 'connect', 'connect_cached', or some specialized case like 'Apache::DBI::connect' (which is automatically the default when running within Apache).

Where possible, each session ($dbh) is independent from the transactions in other sessions. This is useful when you need to hold cursors open across transactions–for example, if you use one session for your long lifespan cursors (typically read-only) and another for your short update transactions.

For compatibility with old DBI scripts, the driver can be specified by passing its name as the fourth argument to connect (instead of \%attr):

```
$dbh = DBI->connect($data_source, $user, $pass, $driver);
```

In this "old-style" form of connect, the $data_source should not start with "dbi:driver_name:". (If it does, the embedded driver_name will be ignored). Also note that in this older form of connect, the $dbh->{AutoCommit} attribute is *undefined*, the $dbh->{PrintError} attribute is off, and the old DBI_DBNAME environment variable is checked if DBI_DSN is not defined. Beware that this "old-style" connect will soon be withdrawn in a future version of DBI.

connect_cached

```
$dbh = DBI->connect_cached($data_source, $username, $password)
          or die $DBI::errstr;
$dbh = DBI->connect_cached($data_source, $username, $password, \
↪%attr)
          or die $DBI::errstr;
```

connect_cached is like "connect", except that the database handle returned is also stored in a hash associated with the given parameters. If another call is made to connect_cached with the same parameter values, then the corresponding cached $dbh will be returned if it is still valid. The cached database handle is replaced with a new connection if it has been disconnected or if the ping method fails.

Note that the behaviour of this method differs in several respects from the behaviour of persistent connections implemented by Apache::DBI. However, if Apache::DBI is loaded then connect_cached will use it.

Caching connections can be useful in some applications, but it can also cause problems, such as too many connections, and so should be used with care. In particular, avoid changing the attributes of a database handle created via connect_cached() because it will affect other code that may be using the same handle. When connect_cached() returns a handle the attributes will be reset to their initial values. This can cause problems, especially with the AutoCommit attribute.

Also, to ensure that the attributes passed are always the same, avoid passing references inline. For example, the Callbacks attribute is specified as a hash reference. Be sure to declare it external to the call to connect_cached(), such that the hash reference is not re-created on every call. A package-level lexical works well:

```
package MyDBH;
my $cb = {
    'connect_cached.reused' => sub { delete $_[4]->{AutoCommit} },
};

sub dbh {
    DBI->connect_cached( $dsn, $username, $auth, { Callbacks => $cb
 ↪});
}
```

Where multiple separate parts of a program are using connect_cached() to connect to the same database with the same (initial) attributes it is a good idea to add a private attribute to the connect_cached() call to effectively limit the scope of the caching. For example:

```
DBI->connect_cached(..., { private_foo_cachekey => "Bar", ... });
```

Handles returned from that connect_cached() call will only be returned by other connect_cached() call elsewhere in the code if those other calls also pass in the same attribute values, including the private one. (I've used private_foo_cachekey here as an example, you can use any attribute name with a private_ prefix.)

Taking that one step further, you can limit a particular connect_cached() call to return handles unique to that one place in the code by setting the private attribute to a unique value for that place:

```
DBI->connect_cached(..., { private_foo_cachekey => __FILE__.__LINE__
 ↪, ... });
```

By using a private attribute you still get connection caching for the individual calls to connect_cached() but, by making separate database connections for separate parts of

the code, the database handles are isolated from any attribute changes made to other handles.

The cache can be accessed (and cleared) via the "CachedKids" attribute:

```
my $CachedKids_hashref = $dbh->{Driver}->{CachedKids};
%$CachedKids_hashref = () if $CachedKids_hashref;
```

available_drivers

```
@ary = DBI->available_drivers;
@ary = DBI->available_drivers($quiet);
```

Returns a list of all available drivers by searching for `DBD::*` modules through the directories in `@INC`. By default, a warning is given if some drivers are hidden by others of the same name in earlier directories. Passing a true value for `$quiet` will inhibit the warning.

installed_drivers

```
%drivers = DBI->installed_drivers();
```

Returns a list of driver name and driver handle pairs for all drivers 'installed' (loaded) into the current process. The driver name does not include the 'DBD::' prefix.

To get a list of all drivers available in your perl installation you can use "available_drivers".

Added in DBI 1.49.

installed_versions

```
DBI->installed_versions;
@ary  = DBI->installed_versions;
$hash = DBI->installed_versions;
```

Calls available_drivers() and attempts to load each of them in turn using install_driver(). For each load that succeeds the driver name and version number are added to a hash. When running under *DBI::PurePerl* drivers which appear not be pure-perl are ignored.

When called in array context the list of successfully loaded drivers is returned (without the 'DBD::' prefix).

When called in scalar context an extra entry for the `DBI` is added (and `DBI::PurePerl` if appropriate) and a reference to the hash is returned.

When called in a void context the installed_versions() method will print out a formatted list of the hash contents, one per line, along with some other information about the DBI version and OS.

Due to the potentially high memory cost and unknown risks of loading in an unknown number of drivers that just happen to be installed on the system, this method is not recommended for general use. Use available_drivers() instead.

The installed_versions() method is primarily intended as a quick way to see from the command line what's installed. For example:

```
perl -MDBI -e 'DBI->installed_versions'
```

The installed_versions() method was added in DBI 1.38.

data_sources

```
@ary = DBI->data_sources($driver);
@ary = DBI->data_sources($driver, \%attr);
```

Returns a list of data sources (databases) available via the named driver. If `$driver` is empty or `undef`, then the value of the `DBI_DRIVER` environment variable is used.

The driver will be loaded if it hasn't been already. Note that if the driver loading fails then data_sources() *dies* with an error message that includes the string "`install_driver`" and the underlying problem.

Data sources are returned in a form suitable for passing to the "connect" method (that is, they will include the "`dbi:$driver:`" prefix).

Note that many drivers have no way of knowing what data sources might be available for it. These drivers return an empty or incomplete list or may require driver-specific attributes.

There is also a data_sources() method defined for database handles.

trace

```
DBI->trace($trace_setting)
DBI->trace($trace_setting, $trace_filename)
DBI->trace($trace_setting, $trace_filehandle)
$trace_setting = DBI->trace;
```

The `DBI->trace` method sets the *global default* trace settings and returns the *previous* trace settings. It can also be used to change where the trace output is sent.

There's a similar method, `$h->trace`, which sets the trace settings for the specific handle it's called on.

See the "TRACING" section for full details about the DBI's powerful tracing facilities.

visit_handles

```
DBI->visit_handles( $coderef );
DBI->visit_handles( $coderef, $info );
```

Where $coderef is a reference to a subroutine and $info is an arbitrary value which, if undefined, defaults to a reference to an empty hash. Returns $info.

For each installed driver handle, if any, $coderef is invoked as:

```
$coderef->($driver_handle, $info);
```

If the execution of $coderef returns a true value then "visit_child_handles" is called on that child handle and passed the returned value as $info.

For example:

```
my $info = $dbh->{Driver}->visit_child_handles(sub {
    my ($h, $info) = @_;
    ++$info->{ $h->{Type} }; # count types of handles (dr/db/st)
    return $info; # visit kids
});
```

See also "visit_child_handles".

DBI Utility Functions

In addition to the DBI methods listed in the previous section, the DBI package also provides several utility functions.

These can be imported into your code by listing them in the `use` statement. For example:

```
use DBI qw(neat data_diff);
```

Alternatively, all these utility functions (except hash) can be imported using the `:utils` import tag. For example:

```
use DBI qw(:utils);
```

data_string_desc

```
$description = data_string_desc($string);
```

Returns an informal description of the string. For example:

```
UTF8 off, ASCII, 42 characters 42 bytes
UTF8 off, non-ASCII, 42 characters 42 bytes
UTF8 on, non-ASCII, 4 characters 6 bytes
UTF8 on but INVALID encoding, non-ASCII, 4 characters 6 bytes
UTF8 off, undef
```

The initial `UTF8` on/off refers to Perl's internal SvUTF8 flag. If $string has the SvUTF8 flag set but the sequence of bytes it contains are not a valid UTF-8 encoding then data_string_desc() will report `UTF8 on but INVALID encoding`.

The `ASCII` vs non-`ASCII` portion shows `ASCII` if *all* the characters in the string are ASCII (have code points <= 127).

The data_string_desc() function was added in DBI 1.46.

data_string_diff

```
$diff = data_string_diff($a, $b);
```

Returns an informal description of the first character difference between the strings. If both $a and $b contain the same sequence of characters then data_string_diff() returns an empty string. For example:

```
Params a & b     Result
------------     ------
'aaa', 'aaa'     ''
'aaa', 'abc'     'Strings differ at index 2: a[2]=a, b[2]=b'
'aaa', undef     'String b is undef, string a has 3 characters'
'aaa', 'aa'      'String b truncated after 2 characters'
```

Unicode characters are reported in `\x{XXXX}` format. Unicode code points in the range U+0800 to U+08FF are unassigned and most likely to occur due to double-encoding. Characters in this range are reported as `\x{08XX}='C'` where `C` is the corresponding latin-1 character.

The data_string_diff() function only considers logical *characters* and not the underlying encoding. See "data_diff" for an alternative.

The data_string_diff() function was added in DBI 1.46.

data_diff

```
$diff = data_diff($a, $b);
$diff = data_diff($a, $b, $logical);
```

Returns an informal description of the difference between two strings. It calls "data_string_desc" and "data_string_diff" and returns the combined results as a multi-line string.

For example, `data_diff("abc", "ab\x{263a}")` will return:

```
a: UTF8 off, ASCII, 3 characters 3 bytes
b: UTF8 on, non-ASCII, 3 characters 5 bytes
Strings differ at index 2: a[2]=c, b[2]=\x{263A}
```

If $a and $b are identical in both the characters they contain *and* their physical encoding then data_diff() returns an empty string. If $logical is true then physical encoding differences are ignored (but are still reported if there is a difference in the characters).

The data_diff() function was added in DBI 1.46.

neat

```
$str = neat($value);
$str = neat($value, $maxlen);
```

Return a string containing a neat (and tidy) representation of the supplied value.

Strings will be quoted, although internal quotes will *not* be escaped. Values known to be numeric will be unquoted. Undefined (NULL) values will be shown as `undef` (without quotes).

If the string is flagged internally as utf8 then double quotes will be used, otherwise single quotes are used and unprintable characters will be replaced by dot (.).

For result strings longer than `$maxlen` the result string will be truncated to `$maxlen-4` and "`...'`" will be appended. If `$maxlen` is 0 or `undef`, it defaults to `$DBI::neat_maxlen` which, in turn, defaults to 400.

This function is designed to format values for human consumption. It is used internally by the DBI for "trace" output. It should typically *not* be used for formatting values for database use. (See also "quote".)

neat_list

```
$str = neat_list(\@listref, $maxlen, $field_sep);
```

Calls `neat` on each element of the list and returns a string containing the results joined with `$field_sep`. `$field_sep` defaults to `", "`.

looks_like_number

```
@bool = looks_like_number(@array);
```

Returns true for each element that looks like a number. Returns false for each element that does not look like a number. Returns `undef` for each element that is undefined or empty.

hash

```
$hash_value = DBI::hash($buffer, $type);
```

Return a 32-bit integer 'hash' value corresponding to the contents of $buffer. The $type parameter selects which kind of hash algorithm should be used.

For the technically curious, type 0 (which is the default if $type isn't specified) is based on the Perl 5.1 hash except that the value is forced to be negative (for obscure historical reasons). Type 1 is the better "Fowler / Noll / Vo" (FNV) hash. See http://www.isthe.com/chongo/tech/comp/fnv/ for more information. Both types are implemented in C and are very fast.

This function doesn't have much to do with databases, except that it can sometimes be handy to store such values in a database. It also doesn't have much to do with perl hashes, like %foo.

sql_type_cast

```
$sts = DBI::sql_type_cast($sv, $sql_type, $flags);
```

sql_type_cast attempts to cast `$sv` to the SQL type (see [DBI Constants](https://metacpan.org/pod/DBI Constants)) specified in `$sql_type`. At present only the SQL types `SQL_INTEGER`, `SQL_DOUBLE` and `SQL_NUMERIC` are supported.

For `SQL_INTEGER` the effect is similar to using the value in an expression that requires an integer. It gives the perl scalar an 'integer aspect'. (Technically the value gains an IV, or possibly a UV or NV if the value is too large for an IV.)

For `SQL_DOUBLE` the effect is similar to using the value in an expression that requires a general numeric value. It gives the perl scalar a 'numeric aspect'. (Technically the value gains an NV.)

`SQL_NUMERIC` is similar to `SQL_INTEGER` or `SQL_DOUBLE` but more general and more cautious. It will look at the string first and if it looks like an integer (that will fit in an IV or UV) it will act like `SQL_INTEGER`, if it looks like a floating point value it will act like `SQL_DOUBLE`, if it looks like neither then it will do nothing - and thereby avoid the warnings that would be generated by `SQL_INTEGER` and `SQL_DOUBLE` when given non-numeric data.

`$flags` may be:

- `DBIstcf_DISCARD_STRING`

  If this flag is specified then when the driver successfully casts the bound perl scalar to a non-string type then the string portion of the scalar will be discarded.

- `DBIstcf_STRICT`

  If `$sv` cannot be cast to the requested `$sql_type` then by default it is left untouched and no error is generated. If you specify `DBIstcf_STRICT` and the cast fails, this will generate an error.

The returned `$sts` value is:

```
-2 sql_type is not handled
-1 sv is undef so unchanged
 0 sv could not be cast cleanly and DBIstcf_STRICT was used
 1 sv could not be cast and DBIstcf_STRICT was not used
 2 sv was cast successfully
```

This method is exported by the :utils tag and was introduced in DBI 1.611.

DBI Dynamic Attributes

Dynamic attributes are always associated with the *last handle used* (that handle is represented by `$h` in the descriptions below).

Where an attribute is equivalent to a method call, then refer to the method call for all related documentation.

Warning: these attributes are provided as a convenience but they do have limitations. Specifically, they have a short lifespan: because they are associated with the last handle used, they should only be used *immediately* after calling the method that "sets" them. If in any doubt, use the corresponding method call.

$DBI::err

Equivalent to $h->err.

$DBI::errstr

Equivalent to $h->errstr.

$DBI::state

Equivalent to $h->state.

$DBI::rows

Equivalent to $h->rows. Please refer to the documentation for the “rows” method.

$DBI::lasth

Returns the DBI object handle used for the most recent DBI method call. If the last DBI method call was a DESTROY then $DBI::lasth will return the handle of the parent of the destroyed handle, if there is one.

METHODS COMMON TO ALL HANDLES

The following methods can be used by all types of DBI handles.

err

```
$rv = $h->err;
```

Returns the *native* database engine error code from the last driver method called. The code is typically an integer but you should not assume that.

The DBI resets $h->err to undef before almost all DBI method calls, so the value only has a short lifespan. Also, for most drivers, the statement handles share the same error variable as the parent database handle, so calling a method on one handle may reset the error on the related handles.

(Methods which don’t reset err before being called include err() and errstr(), obviously, state(), rows(), func(), trace(), trace_msg(), ping(), and the tied hash attribute FETCH() and STORE() methods.)

If you need to test for specific error conditions *and* have your program be portable to different database engines, then you’ll need to determine what the corresponding error codes are for all those engines and test for all of them.

The DBI uses the value of $DBI::stderr as the `err` value for internal errors. Drivers should also do likewise. The default value for $DBI::stderr is 2000000000.

A driver may return `0` from err() to indicate a warning condition after a method call. Similarly, a driver may return an empty string to indicate a ‘success with information’ condition. In both these cases the value is false but not undef. The errstr() and state() methods may be used to retrieve extra information in these cases.

See “set_err” for more information.

errstr

```
$str = $h->errstr;
```

Returns the native database engine error message from the last DBI method called. This has the same lifespan issues as the “err” method described above.

The returned string may contain multiple messages separated by newline characters.

The errstr() method should not be used to test for errors, use err() for that, because drivers may return ‘success with information’ or warning messages via errstr() for methods that have not ‘failed’.

See “set_err” for more information.

state

```
$str = $h->state;
```

Returns a state code in the standard SQLSTATE five character format. Note that the specific success code `00000` is translated to any empty string (false). If the driver does not support SQLSTATE (and most don’t), then state() will return `S1000` (General Error) for all errors.

The driver is free to return any value via `state`, e.g., warning codes, even if it has not declared an error by returning a true value via the “err” method described above.

The state() method should not be used to test for errors, use err() for that, because drivers may return a ‘success with information’ or warning state code via state() for methods that have not ‘failed’.

set_err

```
$rv = $h->set_err($err, $errstr);
$rv = $h->set_err($err, $errstr, $state);
$rv = $h->set_err($err, $errstr, $state, $method);
$rv = $h->set_err($err, $errstr, $state, $method, $rv);
```

Set the `err`, `errstr`, and `state` values for the handle. This method is typically only used by DBI drivers and DBI subclasses.

If the “HandleSetErr” attribute holds a reference to a subroutine it is called first. The subroutine can alter the $err, $errstr, $state, and $method values. See “HandleSetErr” for full details. If the subroutine returns a true value then the handle `err`, `errstr`, and `state` values are not altered and set_err() returns an empty list (it normally returns $rv which defaults to undef, see below).

Setting `err` to a *true* value indicates an error and will trigger the normal DBI error handling mechanisms, such as `RaiseError` and `HandleError`, if they are enabled, when execution returns from the DBI back to the application.

Setting `err` to `""` indicates an 'information' state, and setting it to `"0"` indicates a 'warning' state. Setting `err` to `undef` also sets `errstr` to undef, and `state` to `""`, irrespective of the values of the $errstr and $state parameters.

The $method parameter provides an alternate method name for the `RaiseError`/`PrintError`/`RaiseWarn`/`PrintWarn` error string instead of the fairly unhelpful '`set_err`'.

The `set_err` method normally returns undef. The $rv parameter provides an alternate return value.

Some special rules apply if the `err` or `errstr` values for the handle are *already* set...

If `errstr` is true then: "`[err was %s now %s]`" is appended if $err is true and `err` is already true and the new err value differs from the original one. Similarly "`[state was %s now %s]`" is appended if $state is true and `state` is already true and the new state value differs from the original one. Finally "`\n`" and the new $errstr are appended if $errstr differs from the existing errstr value. Obviously the `%s`'s above are replaced by the corresponding values.

The handle `err` value is set to $err if: $err is true; or handle `err` value is undef; or $err is defined and the length is greater than the handle `err` length. The effect is that an 'information' state only overrides undef; a 'warning' overrides undef or 'information', and an 'error' state overrides anything.

The handle `state` value is set to $state if $state is true and the handle `err` value was set (by the rules above).

Support for warning and information states was added in DBI 1.41.

trace

```
$h->trace($trace_settings);
$h->trace($trace_settings, $trace_filename);
$trace_settings = $h->trace;
```

The trace() method is used to alter the trace settings for a handle (and any future children of that handle). It can also be used to change where the trace output is sent.

There's a similar method, `DBI->trace`, which sets the global default trace settings.

See the "TRACING" section for full details about the DBI's powerful tracing facilities.

trace_msg

```
$h->trace_msg($message_text);
$h->trace_msg($message_text, $min_level);
```

Writes `$message_text` to the trace file if the trace level is greater than or equal to $min_level (which defaults to 1). Can also be called as `DBI->trace_msg($msg)`.

See "TRACING" for more details.

func

```
$h->func(@func_arguments, $func_name) or die ...;
```

The func method can be used to call private non-standard and non-portable methods implemented by the driver. Note that the function name is given as the *last* argument.

It's also important to note that the func() method does not clear a previous error ($DBI::err etc.) and it does not trigger automatic error detection (RaiseError etc.) so you must check the return status and/or $h->err to detect errors.

(This method is not directly related to calling stored procedures. Calling stored procedures is currently not defined by the DBI. Some drivers, such as DBD::Oracle, support it in non-portable ways. See driver documentation for more details.)

See also install_method() in *DBI::DBD* for how you can avoid needing to use func() and gain direct access to driver-private methods.

can

```
$is_implemented = $h->can($method_name);
```

Returns true if $method_name is implemented by the driver or a default method is provided by the DBI's driver base class. It returns false where a driver hasn't implemented a method and the default method is provided by the DBI's driver base class is just an empty stub.

parse_trace_flags

```
$trace_settings_integer = $h->parse_trace_flags($trace_settings);
```

Parses a string containing trace settings and returns the corresponding integer value used internally by the DBI and drivers.

The $trace_settings argument is a string containing a trace level between 0 and 15 and/or trace flag names separated by vertical bar ("|") or comma (",") characters. For example: `"SQL|3|foo"`.

It uses the parse_trace_flag() method, described below, to process the individual trace flag names.

The parse_trace_flags() method was added in DBI 1.42.

parse_trace_flag

```
$bit_flag = $h->parse_trace_flag($trace_flag_name);
```

Returns the bit flag corresponding to the trace flag name in $trace_flag_name. Drivers are expected to override this method and check if $trace_flag_name is a driver specific trace flags and, if not, then call the DBI's default parse_trace_flag().

The parse_trace_flag() method was added in DBI 1.42.

private_attribute_info

```
$hash_ref = $h->private_attribute_info();
```

Returns a reference to a hash whose keys are the names of driver-private handle attributes available for the kind of handle (driver, database, statement) that the method was called on.

For example, the return value when called with a DBD::Sybase $dbh could look like this:

```
{
    syb_dynamic_supported => undef,
    syb_oc_version => undef,
    syb_server_version => undef,
    syb_server_version_string => undef,
}
```

and when called with a DBD::Sybase $sth they could look like this:

```
{
    syb_types => undef,
    syb_proc_status => undef,
    syb_result_type => undef,
}
```

The values should be undef. Meanings may be assigned to particular values in future.

swap_inner_handle

```
$rc = $h1->swap_inner_handle( $h2 );
$rc = $h1->swap_inner_handle( $h2, $allow_reparent );
```

Brain transplants for handles. You don't need to know about this unless you want to become a handle surgeon.

A DBI handle is a reference to a tied hash. A tied hash has an *inner* hash that actually holds the contents. The swap_inner_handle() method swaps the inner hashes between two handles. The $h1 and $h2 handles still point to the same tied hashes, but what those hashes are tied to has been swapped. In effect $h1 *becomes* $h2 and vice-versa. This is powerful stuff, expect problems. Use with care.

As a small safety measure, the two handles, $h1 and $h2, have to share the same parent unless $allow_reparent is true.

The swap_inner_handle() method was added in DBI 1.44.

Here's a quick kind of 'diagram' as a worked example to help think about what's happening:

```
Original state:
        dbh1o -> dbh1i
        sthAo -> sthAi(dbh1i)
        dbh2o -> dbh2i
```

(continues on next page)

(continued from previous page)

```
swap_inner_handle dbh1o with dbh2o:
        dbh2o -> dbh1i
        sthAo -> sthAi(dbh1i)
        dbh1o -> dbh2i

create new sth from dbh1o:
        dbh2o -> dbh1i
        sthAo -> sthAi(dbh1i)
        dbh1o -> dbh2i
        sthBo -> sthBi(dbh2i)

swap_inner_handle sthAo with sthBo:
        dbh2o -> dbh1i
        sthBo -> sthAi(dbh1i)
        dbh1o -> dbh2i
        sthAo -> sthBi(dbh2i)
```

visit_child_handles

```
$h->visit_child_handles( $coderef );
$h->visit_child_handles( $coderef, $info );
```

Where $coderef is a reference to a subroutine and $info is an arbitrary value which, if undefined, defaults to a reference to an empty hash. Returns $info.

For each child handle of $h, if any, $coderef is invoked as:

```
$coderef->($child_handle, $info);
```

If the execution of $coderef returns a true value then `visit_child_handles` is called on that child handle and passed the returned value as $info.

For example:

```
# count database connections with names (DSN) matching a pattern
my $connections = 0;
$dbh->{Driver}->visit_child_handles(sub {
    my ($h, $info) = @_;
    ++$connections if $h->{Name} =~ /foo/;
    return 0; # don't visit kids
})
```

See also “visit_handles”.

ATTRIBUTES COMMON TO ALL HANDLES

These attributes are common to all types of DBI handles.

Some attributes are inherited by child handles. That is, the value of an inherited attribute in a newly created statement handle is the same as the value in the parent

database handle. Changes to attributes in the new statement handle do not affect the parent database handle and changes to the database handle do not affect existing statement handles, only future ones.

Attempting to set or get the value of an unknown attribute generates a warning, except for private driver specific attributes (which all have names starting with a lowercase letter).

Example:

```
$h->{AttributeName} = ...;    # set/write
... = $h->{AttributeName};    # get/read
```

Warn

Type: boolean, inherited

The Warn attribute enables useful warnings for certain bad practices. It is enabled by default and should only be disabled in rare circumstances. Since warnings are generated using the Perl warn function, they can be intercepted using the Perl $SIG{__WARN__} hook.

The Warn attribute is not related to the PrintWarn attribute.

Active

Type: boolean, read-only

The Active attribute is true if the handle object is "active". This is rarely used in applications. The exact meaning of active is somewhat vague at the moment. For a database handle it typically means that the handle is connected to a database ($dbh->disconnect sets Active off). For a statement handle it typically means that the handle is a SELECT that may have more data to fetch. (Fetching all the data or calling $sth->finish sets Active off.)

Executed

Type: boolean

The Executed attribute is true if the handle object has been "executed". Currently only the $dbh do() method and the $sth execute(), execute_array(), and execute_for_fetch() methods set the Executed attribute.

When it's set on a handle it is also set on the parent handle at the same time. So calling execute() on a $sth also sets the Executed attribute on the parent $dbh.

The Executed attribute for a database handle is cleared by the commit() and rollback() methods (even if they fail). The Executed attribute of a statement handle is not cleared by the DBI under any circumstances and so acts as a permanent record of whether the statement handle was ever used.

The Executed attribute was added in DBI 1.41.

Kids

Type: integer, read-only

For a driver handle, `Kids` is the number of currently existing database handles that were created from that driver handle. For a database handle, `Kids` is the number of currently existing statement handles that were created from that database handle. For a statement handle, the value is zero.

ActiveKids

Type: integer, read-only

Like `Kids`, but only counting those that are `Active` (as above).

CachedKids

Type: hash ref

For a database handle, `CachedKids` returns a reference to the cache (hash) of statement handles created by the "prepare_cached" method. For a driver handle, returns a reference to the cache (hash) of database handles created by the "connect_cached" method.

Type

Type: scalar, read-only

The `Type` attribute identifies the type of a DBI handle. Returns "dr" for driver handles, "db" for database handles and "st" for statement handles.

ChildHandles

Type: array ref

The ChildHandles attribute contains a reference to an array of all the handles created by this handle which are still accessible. The contents of the array are weak-refs and will become undef when the handle goes out of scope. (They're cleared out occasionally.)

`ChildHandles` returns undef if your perl version does not support weak references (check the *Scalar::Util* module). The referenced array returned should be treated as read-only.

For example, to enumerate all driver handles, database handles and statement handles:

```
sub show_child_handles {
    my ($h, $level) = @_;
    printf "%sh %s %s\n", $h->{Type}, "\t" x $level, $h;
    show_child_handles($_, $level + 1)
        for (grep { defined } @{$h->{ChildHandles}});
}

my %drivers = DBI->installed_drivers();
show_child_handles($_, 0) for (values %drivers);
```

CompatMode

Type: boolean, inherited

The CompatMode attribute is used by emulation layers (such as Oraperl) to enable compatible behaviour in the underlying driver (e.g., DBD::Oracle) for this handle. Not normally set by application code.

It also has the effect of disabling the 'quick FETCH' of attribute values from the handles attribute cache. So all attribute values are handled by the drivers own FETCH method. This makes them slightly slower but is useful for special-purpose drivers like DBD::Multiplex.

InactiveDestroy

Type: boolean

The default value, false, means a handle will be fully destroyed as normal when the last reference to it is removed, just as you'd expect.

If set true then the handle will be treated by the DESTROY as if it was no longer Active, and so the *database engine* related effects of DESTROYing a handle will be skipped. Think of the name as meaning 'treat the handle as not-Active in the DESTROY method'.

For a database handle, this attribute does not disable an *explicit* call to the disconnect method, only the implicit call from DESTROY that happens if the handle is still marked as Active.

This attribute is specifically designed for use in Unix applications that "fork" child processes. For some drivers, when the child process exits the destruction of inherited handles cause the corresponding handles in the parent process to cease working.

Either the parent or the child process, but not both, should set InactiveDestroy true on all their shared handles. Alternatively, and preferably, the "AutoInactiveDestroy" can be set in the parent on connect.

To help tracing applications using fork the process id is shown in the trace log whenever a DBI or handle trace() method is called. The process id also shown for *every* method call if the DBI trace level (not handle trace level) is set high enough to show the trace from the DBI's method dispatcher, e.g. >= 9.

AutoInactiveDestroy

Type: boolean, inherited

The "InactiveDestroy" attribute, described above, needs to be explicitly set in the child process after a fork(), on every active database and statement handle. This is a problem if the code that performs the fork() is not under your control, perhaps in a third-party module. Use AutoInactiveDestroy to get around this situation.

If set true, the DESTROY method will check the process id of the handle and, if different from the current process id, it will set the *InactiveDestroy* attribute. It is strongly recommended that AutoInactiveDestroy is enabled on all new code (it's only not enabled by default to avoid backwards compatibility problems).

This is the example it's designed to deal with:

```
my $dbh = DBI->connect(...);
some_code_that_forks(); # Perhaps without your knowledge
# Child process dies, destroying the inherited dbh
$dbh->do(...); # Breaks because parent $dbh is now broken
```

The AutoInactiveDestroy attribute was added in DBI 1.614.

PrintWarn

Type: boolean, inherited

The PrintWarn attribute controls the printing of warnings recorded by the driver. When set to a true value (the default) the DBI will check method calls to see if a warning condition has been set. If so, the DBI will effectively do a `warn("$class $method warning: $DBI::errstr")` where $class is the driver class and $method is the name of the method which failed. E.g.,

```
DBD::Oracle::db execute warning: ... warning text here ...
```

If desired, the warnings can be caught and processed using a $SIG{__WARN__} handler or modules like CGI::Carp and CGI::ErrorWrap.

See also “set_err” for how warnings are recorded and “HandleSetErr” for how to influence it.

Fetching the full details of warnings can require an extra round-trip to the database server for some drivers. In which case the driver may opt to only fetch the full details of warnings if the PrintWarn attribute is true. If PrintWarn is false then these drivers should still indicate the fact that there were warnings by setting the warning string to, for example: “3 warnings”.

PrintError

Type: boolean, inherited

The PrintError attribute can be used to force errors to generate warnings (using warn) in addition to returning error codes in the normal way. When set “on”, any method which results in an error occurring will cause the DBI to effectively do a `warn("$class $method failed: $DBI::errstr")` where $class is the driver class and $method is the name of the method which failed. E.g.,

```
DBD::Oracle::db prepare failed: ... error text here ...
```

By default, DBI->connect sets PrintError “on”.

If desired, the warnings can be caught and processed using a $SIG{__WARN__} handler or modules like CGI::Carp and CGI::ErrorWrap.

RaiseWarn

Type: boolean, inherited

The RaiseWarn attribute can be used to force warnings to raise exceptions rather then simply printing them. It is "off" by default. When set "on", any method which sets warning condition will cause the DBI to effectively do a `die("$class $method warning: $DBI::errstr")`, where `$class` is the driver class and `$method` is the name of the method that sets warning condition. E.g.,

```
DBD::Oracle::db execute warning: ... warning text here ...
```

If you turn RaiseWarn on then you'd normally turn PrintWarn off. If PrintWarn is also on, then the PrintWarn is done first (naturally).

This attribute was added in DBI 1.643.

RaiseError

Type: boolean, inherited

The RaiseError attribute can be used to force errors to raise exceptions rather than simply return error codes in the normal way. It is "off" by default. When set "on", any method which results in an error will cause the DBI to effectively do a `die("$class $method failed: $DBI::errstr")`, where `$class` is the driver class and `$method` is the name of the method that failed. E.g.,

```
DBD::Oracle::db prepare failed: ... error text here ...
```

If you turn RaiseError on then you'd normally turn PrintError off. If PrintError is also on, then the PrintError is done first (naturally).

Typically RaiseError is used in conjunction with `eval`, or a module like Try::Tiny or TryCatch, to catch the exception that's been thrown and handle it. For example:

```
use Try::Tiny;

try {
  ...
  $sth->execute();
  ...
} catch {
  # $sth->err and $DBI::err will be true if error was from DBI
  warn $_; # print the error (which Try::Tiny puts into $_)
  ... # do whatever you need to deal with the error
};
```

In the catch block the $DBI::lasth variable can be useful for diagnosis and reporting if you can't be sure which handle triggered the error. For example, $DBI::lasth->{Type} and $DBI::lasth->{Statement}.

See also "Transactions".

If you want to temporarily turn RaiseError off (inside a library function that is likely to fail, for example), the recommended way is like this:

```
{
  local $h->{RaiseError};  # localize and turn off for this block
  ...
}
```

The original value will automatically and reliably be restored by Perl, regardless of how the block is exited. The same logic applies to other attributes, including `PrintError`.

HandleError

Type: code ref, inherited

The `HandleError` attribute can be used to provide your own alternative behaviour in case of errors. If set to a reference to a subroutine then that subroutine is called when an error is detected (at the same point that `RaiseError` and `PrintError` are handled). It is called also when `RaiseWarn` is enabled and a warning is detected.

The subroutine is called with three parameters: the error message string that `RaiseError`, `RaiseWarn` or `PrintError` would use, the DBI handle being used (dbh, sth or drh as appropriate) and the first value being returned by the method that failed (typically undef).

If the subroutine returns a false value then the `RaiseError`, `RaiseWarn` and/or `PrintError` attributes are checked and acted upon as normal.

For example, to `die` with a full stack trace for any error:

```
use Carp;
$h->{HandleError} = sub { confess(shift) };
```

Or to turn errors into exceptions:

```
use Exception; # or your own favourite exception module
$h->{HandleError} = sub { Exception->new('DBI')->raise($_[0]) };
```

It is possible to 'stack' multiple HandleError handlers by using closures:

```
sub your_subroutine {
  my $previous_handler = $h->{HandleError};
  $h->{HandleError} = sub {
    return 1 if $previous_handler and &$previous_handler(@_);
    ... your code here ...
  };
}
```

Using a `my` inside a subroutine to store the previous `HandleError` value is important. See *perlsub* and perlref for more information about *closures*.

It is possible for `HandleError` to alter the error message that will be used by `RaiseError`, `RaiseWarn` and `PrintError` if it returns false. It can do that by altering the value of `$_[0]`. This example appends a stack trace to all errors and, unlike the previous example using Carp::confess, this will work `PrintError` as well as `RaiseError`:

```
$h->{HandleError} = sub { $_[0]=Carp::longmess($_[0]); 0; };
```

It is also possible for HandleError to hide an error, to a limited degree, by using "set_err" to reset $DBI::err and $DBI::errstr, and altering the return value of the failed method. For example:

```
$h->{HandleError} = sub {
  return 0 unless $_[0] =~ /^\S+ fetchrow_arrayref failed:/;
  return 0 unless $_[1]->err == 1234; # the error to 'hide'
  $h->set_err(undef,undef);   # turn off the error
  $_[2] = [ ... ];    # supply alternative return value
  return 1;
};
```

This only works for methods which return a single value and is hard to make reliable (avoiding infinite loops, for example) and so isn't recommended for general use! If you find a *good* use for it then please let me know.

HandleSetErr

Type: code ref, inherited

The HandleSetErr attribute can be used to intercept the setting of handle err, errstr, and state values. If set to a reference to a subroutine then that subroutine is called whenever set_err() is called, typically by the driver or a subclass.

The subroutine is called with five arguments, the first five that were passed to set_err(): the handle, the err, errstr, and state values being set, and the method name. These can be altered by changing the values in the @_ array. The return value affects set_err() behaviour, see "set_err" for details.

It is possible to 'stack' multiple HandleSetErr handlers by using closures. See "HandleError" for an example.

The HandleSetErr and HandleError subroutines differ in subtle but significant ways. HandleError is only invoked at the point where the DBI is about to return to the application with err set true. It's not invoked by the failure of a method that's been called by another DBI method. HandleSetErr, on the other hand, is called whenever set_err() is called with a defined err value, even if false. So it's not just for errors, despite the name, but also warn and info states. The set_err() method, and thus HandleSetErr, may be called multiple times within a method and is usually invoked from deep within driver code.

In theory a driver can use the return value from HandleSetErr via set_err() to decide whether to continue or not. If set_err() returns an empty list, indicating that the HandleSetErr code has 'handled' the 'error', the driver could then continue instead of failing (if that's a reasonable thing to do). This isn't excepted to be common and any such cases should be clearly marked in the driver documentation and discussed on the dbi-dev mailing list.

The HandleSetErr attribute was added in DBI 1.41.

ErrCount

Type: unsigned integer

The ErrCount attribute is incremented whenever the set_err() method records an error. It isn't incremented by warnings or information states. It is not reset by the DBI at any time.

The ErrCount attribute was added in DBI 1.41. Older drivers may not have been updated to use set_err() to record errors and so this attribute may not be incremented when using them.

ShowErrorStatement

Type: boolean, inherited

The ShowErrorStatement attribute can be used to cause the relevant Statement text to be appended to the error messages generated by the RaiseError, PrintError, RaiseWarn and PrintWarn attributes. Only applies to errors on statement handles plus the prepare(), do(), and the various `select*()` database handle methods. (The exact format of the appended text is subject to change.)

If `$h->{ParamValues}` returns a hash reference of parameter (placeholder) values then those are formatted and appended to the end of the Statement text in the error message.

TraceLevel

Type: integer, inherited

The TraceLevel attribute can be used as an alternative to the "trace" method to set the DBI trace level and trace flags for a specific handle. See "TRACING" for more details.

The TraceLevel attribute is especially useful combined with `local` to alter the trace settings for just a single block of code.

FetchHashKeyName

Type: string, inherited

The FetchHashKeyName attribute is used to specify whether the fetchrow_hashref() method should perform case conversion on the field names used for the hash keys. For historical reasons it defaults to 'NAME' but it is recommended to set it to 'NAME_lc' (convert to lower case) or 'NAME_uc' (convert to upper case) according to your preference. It can only be set for driver and database handles. For statement handles the value is frozen when prepare() is called.

ChopBlanks

Type: boolean, inherited

The ChopBlanks attribute can be used to control the trimming of trailing space characters from fixed width character (CHAR) fields. No other field types are affected, even where field values have trailing spaces.

The default is false (although it is possible that the default may change). Applications that need specific behaviour should set the attribute as needed.

Drivers are not required to support this attribute, but any driver which does not support it must arrange to return `undef` as the attribute value.

LongReadLen

Type: unsigned integer, inherited

The `LongReadLen` attribute may be used to control the maximum length of 'long' type fields (LONG, BLOB, CLOB, MEMO, etc.) which the driver will read from the database automatically when it fetches each row of data.

The `LongReadLen` attribute only relates to fetching and reading long values; it is not involved in inserting or updating them.

A value of 0 means not to automatically fetch any long data. Drivers may return undef or an empty string for long fields when `LongReadLen` is 0.

The default is typically 0 (zero) or 80 bytes but may vary between drivers. Applications fetching long fields should set this value to slightly larger than the longest long field value to be fetched.

Some databases return some long types encoded as pairs of hex digits. For these types, `LongReadLen` relates to the underlying data length and not the doubled-up length of the encoded string.

Changing the value of `LongReadLen` for a statement handle after it has been `prepare`'d will typically have no effect, so it's common to set `LongReadLen` on the `$dbh` before calling `prepare`.

For most drivers the value used here has a direct effect on the memory used by the statement handle while it's active, so don't be too generous. If you can't be sure what value to use you could execute an extra select statement to determine the longest value. For example:

```
$dbh->{LongReadLen} = $dbh->selectrow_array(qq{
    SELECT MAX(OCTET_LENGTH(long_column_name))
    FROM table WHERE ...
});
$sth = $dbh->prepare(qq{
    SELECT long_column_name, ... FROM table WHERE ...
});
```

You may need to take extra care if the table can be modified between the first select and the second being executed. You may also need to use a different function if OCTET_LENGTH() does not work for long types in your database. For example, for Sybase use DATALENGTH() and for Oracle use LENGTHB().

See also "LongTruncOk" for information on truncation of long types.

LongTruncOk

Type: boolean, inherited

The LongTruncOk attribute may be used to control the effect of fetching a long field value which has been truncated (typically because it's longer than the value of the LongReadLen attribute).

By default, LongTruncOk is false and so fetching a long value that needs to be truncated will cause the fetch to fail. (Applications should always be sure to check for errors after a fetch loop in case an error, such as a divide by zero or long field truncation, caused the fetch to terminate prematurely.)

If a fetch fails due to a long field truncation when LongTruncOk is false, many drivers will allow you to continue fetching further rows.

See also "LongReadLen".

TaintIn

Type: boolean, inherited

If the TaintIn attribute is set to a true value *and* Perl is running in taint mode (e.g., started with the -T option), then all the arguments to most DBI method calls are checked for being tainted. *This may change.*

The attribute defaults to off, even if Perl is in taint mode. See *perlsec* for more about taint mode. If Perl is not running in taint mode, this attribute has no effect.

When fetching data that you trust you can turn off the TaintIn attribute, for that statement handle, for the duration of the fetch loop.

The TaintIn attribute was added in DBI 1.31.

TaintOut

Type: boolean, inherited

If the TaintOut attribute is set to a true value *and* Perl is running in taint mode (e.g., started with the -T option), then most data fetched from the database is considered tainted. *This may change.*

The attribute defaults to off, even if Perl is in taint mode. See *perlsec* for more about taint mode. If Perl is not running in taint mode, this attribute has no effect.

When fetching data that you trust you can turn off the TaintOut attribute, for that statement handle, for the duration of the fetch loop.

Currently only fetched data is tainted. It is possible that the results of other DBI method calls, and the value of fetched attributes, may also be tainted in future versions. That change may well break your applications unless you take great care now. If you use DBI Taint mode, please report your experience and any suggestions for changes.

The TaintOut attribute was added in DBI 1.31.

Taint

Type: boolean, inherited

The `Taint` attribute is a shortcut for "TaintIn" and "TaintOut" (it is also present for backwards compatibility).

Setting this attribute sets both "TaintIn" and "TaintOut", and retrieving it returns a true value if and only if "TaintIn" and "TaintOut" are both set to true values.

Profile

Type: inherited

The `Profile` attribute enables the collection and reporting of method call timing statistics. See the *DBI::Profile* module documentation for *much* more detail.

The `Profile` attribute was added in DBI 1.24.

ReadOnly

Type: boolean, inherited

An application can set the `ReadOnly` attribute of a handle to a true value to indicate that it will not be attempting to make any changes using that handle or any children of it.

Note that the exact definition of 'read only' is rather fuzzy. For more details see the documentation for the driver you're using.

If the driver can make the handle truly read-only then it should (unless doing so would have unpleasant side effect, like changing the consistency level from per-statement to per-session). Otherwise the attribute is simply advisory.

A driver can set the `ReadOnly` attribute itself to indicate that the data it is connected to cannot be changed for some reason.

If the driver cannot ensure the `ReadOnly` attribute is adhered to it will record a warning. In this case reading the `ReadOnly` attribute back after it is set true will return true even if the underlying driver cannot ensure this (so any application knows the application declared itself ReadOnly).

Library modules and proxy drivers can use the attribute to influence their behavior. For example, the DBD::Gofer driver considers the `ReadOnly` attribute when making a decision about whether to retry an operation that failed.

The attribute should be set to 1 or 0 (or undef). Other values are reserved.

Callbacks

Type: hash ref

The DBI callback mechanism lets you intercept, and optionally replace, any method call on a DBI handle. At the extreme, it lets you become a puppet master, deceiving the application in any way you want.

The `Callbacks` attribute is a hash reference where the keys are DBI method names and the values are code references. For each key naming a method, the DBI will execute the associated code reference before executing the method.

The arguments to the code reference will be the same as to the method, including the invocant (a database handle or statement handle). For example, say that to callback to some code on a call to `prepare()`:

```
$dbh->{Callbacks} = {
    prepare => sub {
        my ($dbh, $query, $attrs) = @_;
        print "Preparing q{$query}\n"
    },
};
```

The callback would then be executed when you called the `prepare()` method:

```
$dbh->prepare('SELECT 1');
```

And the output of course would be:

```
Preparing q{SELECT 1}
```

Because callbacks are executed *before* the methods they're associated with, you can modify the arguments before they're passed on to the method call. For example, to make sure that all calls to `prepare()` are immediately prepared by DBD::Pg, add a callback that makes sure that the `pg_prepare_now` attribute is always set:

```
my $dbh = DBI->connect($dsn, $username, $auth, {
    Callbacks => {
        prepare => sub {
            $_[2] ||= {};
            $_[2]->{pg_prepare_now} = 1;
            return; # must return nothing
        },
    }
});
```

Note that we are editing the contents of `@_` directly. In this case we've created the attributes hash if it's not passed to the `prepare` call.

You can also prevent the associated method from ever executing. While a callback executes, `$_` holds the method name. (This allows multiple callbacks to share the same code reference and still know what method was called.) To prevent the method from executing, simply `undef $_`. For example, if you wanted to disable calls to `ping()`, you could do this:

```
$dbh->{Callbacks} = {
    ping => sub {
        # tell dispatch to not call the method:
        undef $_;
        # return this value instead:
        return "42 bells";
    }
};
```

As with other attributes, Callbacks can be specified on a handle or via the attributes to

`connect()`. Callbacks can also be applied to a statement methods on a statement handle. For example:

```
$sth->{Callbacks} = {
    execute => sub {
        print "Executing ", shift->{Statement}, "\n";
    }
};
```

The `Callbacks` attribute of a database handle isn't copied to any statement handles it creates. So setting callbacks for a statement handle requires you to set the `Callbacks` attribute on the statement handle yourself, as in the example above, or use the special `ChildCallbacks` key described below.

Special Keys in Callbacks Attribute

In addition to DBI handle method names, the `Callbacks` hash reference supports four additional keys.

The first is the `ChildCallbacks` key. When a statement handle is created from a database handle the `ChildCallbacks` key of the database handle's `Callbacks` attribute, if any, becomes the new `Callbacks` attribute of the statement handle. This allows you to define callbacks for all statement handles created from a database handle. For example, if you wanted to count how many times `execute` was called in your application, you could write:

```
my $exec_count = 0;
my $dbh = DBI->connect( $dsn, $username, $auth, {
    Callbacks => {
        ChildCallbacks => {
            execute => sub { $exec_count++; return; }
        }
    }
});

END {
    print "The execute method was called $exec_count times\n";
}
```

The other three special keys are `connect_cached.new`, `connect_cached.connected`, and `connect_cached.reused`. These keys define callbacks that are called when `connect_cached()` is called, but allow different behaviors depending on whether a new handle is created or a handle is returned. The callback is invoked with these arguments: `$dbh, $dsn, $user, $auth, $attr`.

For example, some applications uses `connect_cached()` to connect with `AutoCommit` enabled and then disable `AutoCommit` temporarily for transactions. If `connect_cached()` is called during a transaction, perhaps in a utility method, then it might select the same cached handle and then force `AutoCommit` on, forcing a commit of the transaction. See the "connect_cached" documentation for one way to deal with that. Here we'll describe an alternative approach using a callback.

Because the `connect_cached.new` and `connect_cached.reused` callbacks are invoked before `connect_cached()` has applied the connect attributes, you can use them

to edit the attributes that will be applied. To prevent a cached handle from having its transactions committed before it's returned, you can eliminate the `AutoCommit` attribute in a `connect_cached.reused` callback, like so:

```
my $cb = {
    'connect_cached.reused' => sub { delete $_[4]->{AutoCommit} },
};

sub dbh {
    my $self = shift;
    DBI->connect_cached( $dsn, $username, $auth, {
        PrintError => 0,
        RaiseError => 1,
        AutoCommit => 1,
        Callbacks  => $cb,
    });
}
```

The upshot is that new database handles are created with `AutoCommit` enabled, while cached database handles are left in whatever transaction state they happened to be in when retrieved from the cache.

Note that we've also used a lexical for the callbacks hash reference. This is because `connect_cached()` returns a new database handle if any of the attributes passed to is have changed. If we used an inline hash reference, `connect_cached()` would return a new database handle every time. Which would rather defeat the purpose.

A more common application for callbacks is setting connection state only when a new connection is made (by connect() or connect_cached()). Adding a callback to the connected method (when using `connect`) or via `connect_cached.connected` (when using connect_cached()>) makes this easy. The connected() method is a no-op by default (unless you subclass the DBI and change it). The DBI calls it to indicate that a new connection has been made and the connection attributes have all been set. You can give it a bit of added functionality by applying a callback to it. For example, to make sure that MySQL understands your application's ANSI-compliant SQL, set it up like so:

```
my $dbh = DBI->connect($dsn, $username, $auth, {
    Callbacks => {
        connected => sub {
            shift->do(q{
                SET SESSION sql_mode='ansi,strict_trans_tables,no_
↪auto_value_on_zero';
            });
            return;
        },
    }
});
```

If you're using `connect_cached()`, use the `connect_cached.connected` callback, instead. This is because `connected()` is called for both new and reused database handles, but you want to execute a callback only the when a new database handle is returned. For example, to set the time zone on connection to a PostgreSQL database, try this:

```
my $cb = {
    'connect_cached.connected' => sub {
        shift->do('SET timezone = UTC');
    }
};

sub dbh {
    my $self = shift;
    DBI->connect_cached( $dsn, $username, $auth, { Callbacks => $cb
 ↪});
}
```

One significant limitation with callbacks is that there can only be one per method per handle. This means it's easy for one use of callbacks to interfere with, or typically simply overwrite, another use of callbacks. For this reason modules using callbacks should document the fact clearly so application authors can tell if use of callbacks by the module will clash with use of callbacks by the application.

You might be able to work around this issue by taking a copy of the original callback and calling it within your own. For example:

```
my $prev_cb = $h->{Callbacks}{method_name};
$h->{Callbacks}{method_name} = sub {
  if ($prev_cb) {
      my @result = $prev_cb->(@_);
      return @result if not $_; # $prev_cb vetoed call
  }
  ... your callback logic here ...
};
```

private_your_module_name_*

The DBI provides a way to store extra information in a DBI handle as "private" attributes. The DBI will allow you to store and retrieve any attribute which has a name starting with "private_".

It is *strongly* recommended that you use just *one* private attribute (e.g., use a hash ref) *and* give it a long and unambiguous name that includes the module or application name that the attribute relates to (e.g., "private_YourFullModuleName_thingy").

Because of the way the Perl tie mechanism works you cannot reliably use the ||= operator directly to initialise the attribute, like this:

```
my $foo = $dbh->{private_yourmodname_foo} ||= { ... }; # WRONG
```

you should use a two step approach like this:

```
my $foo = $dbh->{private_yourmodname_foo};
$foo ||= $dbh->{private_yourmodname_foo} = { ... };
```

This attribute is primarily of interest to people sub-classing DBI, or for applications to piggy-back extra information onto DBI handles.

DBI DATABASE HANDLE OBJECTS

This section covers the methods and attributes associated with database handles.

Database Handle Methods

The following methods are specified for DBI database handles:

clone

```
$new_dbh = $dbh->clone(\%attr);
```

The clone method duplicates the $dbh connection by connecting with the same parameters ($dsn, $user, $password) as originally used.

The attributes for the cloned connect are the same as those used for the *original* connect, with any other attributes in \%attr merged over them. Effectively the same as doing:

```
%attributes_used = ( %original_attributes, %attr );
```

If \%attr is not given then it defaults to a hash containing all the attributes in the attribute cache of $dbh excluding any non-code references, plus the main boolean attributes (RaiseError, PrintError, AutoCommit, etc.). *This behaviour is unreliable and so use of clone without an argument is deprecated and may cause a warning in a future release.*

The clone method can be used even if the database handle is disconnected.

The clone method was added in DBI 1.33.

data_sources

```
@ary = $dbh->data_sources();
@ary = $dbh->data_sources(\%attr);
```

Returns a list of data sources (databases) available via the $dbh driver's data_sources() method, plus any extra data sources that the driver can discover via the connected $dbh. Typically the extra data sources are other databases managed by the same server process that the $dbh is connected to.

Data sources are returned in a form suitable for passing to the "connect" method (that is, they will include the "dbi:$driver:" prefix).

The data_sources() method, for a $dbh, was added in DBI 1.38.

do

```
$rows = $dbh->do($statement)           or die $dbh->errstr;
$rows = $dbh->do($statement, \%attr)   or die $dbh->errstr;
$rows = $dbh->do($statement, \%attr, @bind_values) or die ...
```

Prepare and execute a single statement. Returns the number of rows affected or undef on error. A return value of -1 means the number of rows is not known, not applicable, or not available.

This method is typically most useful for *non*-SELECT statements that either cannot be prepared in advance (due to a limitation of the driver) or do not need to be executed repeatedly. It should not be used for SELECT statements because it does not return a statement handle (so you can't fetch any data).

The default do method is logically similar to:

```
sub do {
    my($dbh, $statement, $attr, @bind_values) = @_;
    my $sth = $dbh->prepare($statement, $attr) or return undef;
    $sth->execute(@bind_values) or return undef;
    my $rows = $sth->rows;
    ($rows == 0) ? "0E0" : $rows; # always return true if no error
}
```

For example:

```
my $rows_deleted = $dbh->do(q{
    DELETE FROM table
    WHERE status = ?
}, undef, 'DONE') or die $dbh->errstr;
```

Using placeholders and @bind_values with the do method can be useful because it avoids the need to correctly quote any variables in the $statement. But if you'll be executing the statement many times then it's more efficient to prepare it once and call execute many times instead.

The q{...} style quoting used in this example avoids clashing with quotes that may be used in the SQL statement. Use the double-quote-like qq{...} operator if you want to interpolate variables into the string. See *"Quote and Quote-like Operators" in perlop* for more details.

Note drivers are free to avoid the overhead of creating an DBI statement handle for do(), especially if there are no parameters. In this case error handlers, if invoked during do(), will be passed the database handle.

last_insert_id

```
$rv = $dbh->last_insert_id();
$rv = $dbh->last_insert_id($catalog, $schema, $table, $field);
$rv = $dbh->last_insert_id($catalog, $schema, $table, $field, \
 ↪%attr);
```

Returns a value 'identifying' the row just inserted, if possible. Typically this would be a value assigned by the database server to a column with an *auto_increment* or *serial* type. Returns undef if the driver does not support the method or can't determine the value.

The $catalog, $schema, $table, and $field parameters may be required for some drivers (see below). If you don't know the parameter values and your driver does not need them, then use undef for each.

There are several caveats to be aware of with this method if you want to use it for portable applications:

* For some drivers the value may only be available immediately after the insert statement has executed (e.g., mysql, Informix).

* For some drivers the $catalog, $schema, $table, and $field parameters are required, for others they are ignored (e.g., mysql).

* Drivers may return an indeterminate value if no insert has been performed yet.

* For some drivers the value may only be available if placeholders have *not* been used (e.g., Sybase, MS SQL). In this case the value returned would be from the last non-placeholder insert statement.

* Some drivers may need driver-specific hints about how to get the value. For example, being told the name of the database 'sequence' object that holds the value. Any such hints are passed as driver-specific attributes in the \%attr parameter.

* If the underlying database offers nothing better, then some drivers may attempt to implement this method by executing "`select max($field) from $table`". Drivers using any approach like this should issue a warning if `AutoCommit` is true because it is generally unsafe - another process may have modified the table between your insert and the select. For situations where you know it is safe, such as when you have locked the table, you can silence the warning by passing `Warn` => 0 in \%attr.

* If no insert has been performed yet, or the last insert failed, then the value is implementation defined.

Given all the caveats above, it's clear that this method must be used with care.

The `last_insert_id` method was added in DBI 1.38.

selectrow_array

```
@row_ary = $dbh->selectrow_array($statement);
@row_ary = $dbh->selectrow_array($statement, \%attr);
@row_ary = $dbh->selectrow_array($statement, \%attr, @bind_values);
```

This utility method combines "prepare", "execute" and "fetchrow_array" into a single call. If called in a list context, it returns the first row of data from the statement. The `$statement` parameter can be a previously prepared statement handle, in which case the `prepare` is skipped.

If any method fails, and "RaiseError" is not set, `selectrow_array` will return an empty list.

If called in a scalar context for a statement handle that has more than one column, it is undefined whether the driver will return the value of the first column or the last. So don't do that. Also, in a scalar context, an `undef` is returned if there are no more rows or if an error occurred. That `undef` can't be distinguished from an `undef` returned because the first field value was NULL. For these reasons you should exercise some caution if you use `selectrow_array` in a scalar context, or just don't do that.

selectrow_arrayref

```
$ary_ref = $dbh->selectrow_arrayref($statement);
$ary_ref = $dbh->selectrow_arrayref($statement, \%attr);
$ary_ref = $dbh->selectrow_arrayref($statement, \%attr, @bind_
↪values);
```

This utility method combines "prepare", "execute" and "fetchrow_arrayref" into a single call. It returns the first row of data from the statement. The `$statement` parameter can be a previously prepared statement handle, in which case the `prepare` is skipped.

If any method fails, and "RaiseError" is not set, `selectrow_arrayref` will return undef.

selectrow_hashref

```
$hash_ref = $dbh->selectrow_hashref($statement);
$hash_ref = $dbh->selectrow_hashref($statement, \%attr);
$hash_ref = $dbh->selectrow_hashref($statement, \%attr, @bind_
↪values);
```

This utility method combines "prepare", "execute" and "fetchrow_hashref" into a single call. It returns the first row of data from the statement. The `$statement` parameter can be a previously prepared statement handle, in which case the `prepare` is skipped.

If any method fails, and "RaiseError" is not set, `selectrow_hashref` will return undef.

selectall_arrayref

```
$ary_ref = $dbh->selectall_arrayref($statement);
$ary_ref = $dbh->selectall_arrayref($statement, \%attr);
$ary_ref = $dbh->selectall_arrayref($statement, \%attr, @bind_
↪values);
```

This utility method combines "prepare", "execute" and "fetchall_arrayref" into a single call. It returns a reference to an array containing a reference to an array (or hash, see below) for each row of data fetched.

The `$statement` parameter can be a previously prepared statement handle, in which case the `prepare` is skipped. This is recommended if the statement is going to be executed many times.

If "RaiseError" is not set and any method except `fetchall_arrayref` fails then `selectall_arrayref` will return `undef`; if `fetchall_arrayref` fails then it will return with whatever data has been fetched thus far. You should check `$dbh->err` afterwards (or use the `RaiseError` attribute) to discover if the data is complete or was truncated due to an error.

The "fetchall_arrayref" method called by `selectall_arrayref` supports a $max_rows parameter. You can specify a value for $max_rows by including a '`MaxRows`' attribute in \%attr. In which case finish() is called for you after fetchall_arrayref() returns.

The "fetchall_arrayref" method called by `selectall_arrayref` also supports a $slice parameter. You can specify a value for $slice by including a '`Slice`' or '`Columns`' attribute in \%attr. The only difference between the two is that if `Slice` is not defined

and Columns is an array ref, then the array is assumed to contain column index values (which count from 1), rather than perl array index values. In which case the array is copied and each value decremented before passing to /fetchall_arrayref.

You may often want to fetch an array of rows where each row is stored as a hash. That can be done simply using:

```
my $emps = $dbh->selectall_arrayref(
    "SELECT ename FROM emp ORDER BY ename",
    { Slice => {} }
);
foreach my $emp ( @$emps ) {
    print "Employee: $emp->{ename}\n";
}
```

Or, to fetch into an array instead of an array ref:

```
@result = @{ $dbh->selectall_arrayref($sql, { Slice => {} }) };
```

See "fetchall_arrayref" method for more details.

selectall_array

```
@ary = $dbh->selectall_array($statement);
@ary = $dbh->selectall_array($statement, \%attr);
@ary = $dbh->selectall_array($statement, \%attr, @bind_values);
```

This is a convenience wrapper around "selectall_arrayref" that returns the rows directly as a list, rather than a reference to an array of rows.

Note that if "RaiseError" is not set then you can't tell the difference between returning no rows and an error. Using RaiseError is best practice.

The selectall_array method was added in DBI 1.635.

selectall_hashref

```
$hash_ref = $dbh->selectall_hashref($statement, $key_field);
$hash_ref = $dbh->selectall_hashref($statement, $key_field, \%attr);
$hash_ref = $dbh->selectall_hashref($statement, $key_field, \%attr,␣
↪@bind_values);
```

This utility method combines "prepare", "execute" and "fetchall_hashref" into a single call. It returns a reference to a hash containing one entry, at most, for each row, as returned by fetchall_hashref().

The $statement parameter can be a previously prepared statement handle, in which case the prepare is skipped. This is recommended if the statement is going to be executed many times.

The $key_field parameter defines which column, or columns, are used as keys in the returned hash. It can either be the name of a single field, or a reference to an array containing multiple field names. Using multiple names yields a tree of nested hashes.

If a row has the same key as an earlier row then it replaces the earlier row.

If any method except `fetchall_hashref` fails, and "RaiseError" is not set, `selectall_hashref` will return `undef`. If `fetchall_hashref` fails and "RaiseError" is not set, then it will return with whatever data it has fetched thus far. $DBI::err should be checked to catch that.

See fetchall_hashref() for more details.

selectcol_arrayref

```
$ary_ref = $dbh->selectcol_arrayref($statement);
$ary_ref = $dbh->selectcol_arrayref($statement, \%attr);
$ary_ref = $dbh->selectcol_arrayref($statement, \%attr, @bind_
 ↪values);
```

This utility method combines "prepare", "execute", and fetching one column from all the rows, into a single call. It returns a reference to an array containing the values of the first column from each row.

The `$statement` parameter can be a previously prepared statement handle, in which case the `prepare` is skipped. This is recommended if the statement is going to be executed many times.

If any method except `fetch` fails, and "RaiseError" is not set, `selectcol_arrayref` will return `undef`. If `fetch` fails and "RaiseError" is not set, then it will return with whatever data it has fetched thus far. $DBI::err should be checked to catch that.

The `selectcol_arrayref` method defaults to pushing a single column value (the first) from each row into the result array. However, it can also push another column, or even multiple columns per row, into the result array. This behaviour can be specified via a '`Columns`' attribute which must be a ref to an array containing the column number or numbers to use. For example:

```
# get array of id and name pairs:
my $ary_ref = $dbh->selectcol_arrayref("select id, name from table",␣
 ↪{ Columns=>[1,2] });
my %hash = @$ary_ref; # build hash from key-value pairs so $hash{
 ↪$id} => name
```

You can specify a maximum number of rows to fetch by including a '`MaxRows`' attribute in \%attr.

prepare

```
$sth = $dbh->prepare($statement)          or die $dbh->errstr;
$sth = $dbh->prepare($statement, \%attr)  or die $dbh->errstr;
```

Prepares a statement for later execution by the database engine and returns a reference to a statement handle object.

The returned statement handle can be used to get attributes of the statement and invoke the "execute" method. See "Statement Handle Methods".

Drivers for engines without the concept of preparing a statement will typically just store the statement in the returned handle and process it when `$sth->execute` is called. Such drivers are unlikely to give much useful information about the statement, such as `$sth->{NUM_OF_FIELDS}`, until after `$sth->execute` has been called. Portable applications should take this into account.

In general, DBI drivers do not parse the contents of the statement (other than simply counting any Placeholders). The statement is passed directly to the database engine, sometimes known as pass-thru mode. This has advantages and disadvantages. On the plus side, you can access all the functionality of the engine being used. On the downside, you're limited if you're using a simple engine, and you need to take extra care if writing applications intended to be portable between engines.

Portable applications should not assume that a new statement can be prepared and/or executed while still fetching results from a previous statement.

Some command-line SQL tools use statement terminators, like a semicolon, to indicate the end of a statement. Such terminators should not normally be used with the DBI.

prepare_cached

```
$sth = $dbh->prepare_cached($statement)
$sth = $dbh->prepare_cached($statement, \%attr)
$sth = $dbh->prepare_cached($statement, \%attr, $if_active)
```

Like "prepare" except that the statement handle returned will be stored in a hash associated with the `$dbh`. If another call is made to `prepare_cached` with the same `$statement` and `%attr` parameter values, then the corresponding cached `$sth` will be returned without contacting the database server. Be sure to understand the cautions and caveats noted below.

The `$if_active` parameter lets you adjust the behaviour if an already cached statement handle is still Active. There are several alternatives:

- **0**: A warning will be generated, and finish() will be called on the statement handle before it is returned. This is the default behaviour if $if_active is not passed.
- **1**: finish() will be called on the statement handle, but the warning is suppressed.
- **2**: Disables any checking.
- **3**: The existing active statement handle will be removed from the cache and a new statement handle prepared and cached in its place. This is the safest option because it doesn't affect the state of the old handle, it just removes it from the cache. [Added in DBI 1.40]

Here are some examples of `prepare_cached`:

```
sub insert_hash {
  my ($table, $field_values) = @_;
  # sort to keep field order, and thus sql, stable for prepare_
↪cached
  my @fields = sort keys %$field_values;
  my @values = @{$field_values}{@fields};
  my $sql = sprintf "insert into %s (%s) values (%s)",
```

(continues on next page)

(continued from previous page)

```
      $table, join(",", @fields), join(",", ("?")x@fields);
  my $sth = $dbh->prepare_cached($sql);
  return $sth->execute(@values);
}

sub search_hash {
  my ($table, $field_values) = @_;
  # sort to keep field order, and thus sql, stable for prepare_
↪cached
  my @fields = sort keys %$field_values;
  my @values = @{$field_values}{@fields};
  my $qualifier = "";
  $qualifier = "where ".join(" and ", map { "$_=?" } @fields) if␣
↪@fields;
  $sth = $dbh->prepare_cached("SELECT * FROM $table $qualifier");
  return $dbh->selectall_arrayref($sth, {}, @values);
}
```

Caveat emptor: This caching can be useful in some applications, but it can also cause problems and should be used with care. Here is a contrived case where caching would cause a significant problem:

```
my $sth = $dbh->prepare_cached('SELECT * FROM foo WHERE bar=?');
$sth->execute(...);
while (my $data = $sth->fetchrow_hashref) {

  # later, in some other code called within the loop...
  my $sth2 = $dbh->prepare_cached('SELECT * FROM foo WHERE bar=?');
  $sth2->execute(...);
  while (my $data2 = $sth2->fetchrow_arrayref) {
    do_stuff(...);
  }
}
```

In this example, since both handles are preparing the exact same statement, `$sth2` will not be its own statement handle, but a duplicate of `$sth` returned from the cache. The results will certainly not be what you expect. Typically the inner fetch loop will work normally, fetching all the records and terminating when there are no more, but now that $sth is the same as $sth2 the outer fetch loop will also terminate.

You'll know if you run into this problem because prepare_cached() will generate a warning by default (when $if_active is false).

The cache used by prepare_cached() is keyed by both the statement and any attributes so you can also avoid this issue by doing something like:

```
$sth = $dbh->prepare_cached("...", { dbi_dummy => __FILE__.__LINE__␣
↪});
```

which will ensure that prepare_cached only returns statements cached by that line of code in that source file.

Also, to ensure the attributes passed are always the same, avoid passing references inline. For example, the Slice attribute is specified as a reference. Be sure to declare it external to the call to prepare_cached(), such that a new hash reference is not created on every call. See "connect_cached" for more details and examples.

If you'd like the cache to managed intelligently, you can tie the hashref returned by `CachedKids` to an appropriate caching module, such as Tie::Cache::LRU:

```
my $cache;
tie %$cache, 'Tie::Cache::LRU', 500;
$dbh->{CachedKids} = $cache;
```

commit

```
$rc  = $dbh->commit     or die $dbh->errstr;
```

Commit (make permanent) the most recent series of database changes if the database supports transactions and AutoCommit is off.

If `AutoCommit` is on, then calling `commit` will issue a "commit ineffective with AutoCommit" warning.

See also "Transactions" in the "FURTHER INFORMATION" section below.

rollback

```
$rc  = $dbh->rollback   or die $dbh->errstr;
```

Rollback (undo) the most recent series of uncommitted database changes if the database supports transactions and AutoCommit is off.

If `AutoCommit` is on, then calling `rollback` will issue a "rollback ineffective with AutoCommit" warning.

See also "Transactions" in the "FURTHER INFORMATION" section below.

begin_work

```
$rc  = $dbh->begin_work   or die $dbh->errstr;
```

Enable transactions (by turning `AutoCommit` off) until the next call to `commit` or `rollback`. After the next `commit` or `rollback`, `AutoCommit` will automatically be turned on again.

If `AutoCommit` is already off when `begin_work` is called then it does nothing except return an error. If the driver does not support transactions then when `begin_work` attempts to set `AutoCommit` off the driver will trigger a fatal error.

See also "Transactions" in the "FURTHER INFORMATION" section below.

disconnect

```
$rc = $dbh->disconnect  or warn $dbh->errstr;
```

Disconnects the database from the database handle. `disconnect` is typically only used before exiting the program. The handle is of little use after disconnecting.

The transaction behaviour of the `disconnect` method is, sadly, undefined. Some database systems (such as Oracle and Ingres) will automatically commit any outstanding changes, but others (such as Informix) will rollback any outstanding changes. Applications not using `AutoCommit` should explicitly call `commit` or `rollback` before calling `disconnect`.

The database is automatically disconnected by the `DESTROY` method if still connected when there are no longer any references to the handle. The `DESTROY` method for each driver should implicitly call `rollback` to undo any uncommitted changes. This is vital behaviour to ensure that incomplete transactions don't get committed simply because Perl calls `DESTROY` on every object before exiting. Also, do not rely on the order of object destruction during "global destruction", as it is undefined.

Generally, if you want your changes to be committed or rolled back when you disconnect, then you should explicitly call "commit" or "rollback" before disconnecting.

If you disconnect from a database while you still have active statement handles (e.g., SELECT statement handles that may have more data to fetch), you will get a warning. The warning may indicate that a fetch loop terminated early, perhaps due to an uncaught error. To avoid the warning call the `finish` method on the active handles.

ping

```
$rc = $dbh->ping;
```

Attempts to determine, in a reasonably efficient way, if the database server is still running and the connection to it is still working. Individual drivers should implement this function in the most suitable manner for their database engine.

The current *default* implementation always returns true without actually doing anything. Actually, it returns "`0 but true`" which is true but zero. That way you can tell if the return value is genuine or just the default. Drivers should override this method with one that does the right thing for their type of database.

Few applications would have direct use for this method. See the specialized Apache::DBI module for one example usage.

get_info

```
$value = $dbh->get_info( $info_type );
```

Returns information about the implementation, i.e. driver and data source capabilities, restrictions etc. It returns `undef` for unknown or unimplemented information types. For example:

```
$database_version  = $dbh->get_info(  18 ); # SQL_DBMS_VER
$max_select_tables = $dbh->get_info( 106 ); # SQL_MAXIMUM_TABLES_IN_
↪SELECT
```

See “Standards Reference Information” for more detailed information about the information types and their meanings and possible return values.

The *DBI::Const::GetInfoType* module exports a %GetInfoType hash that can be used to map info type names to numbers. For example:

```
$database_version = $dbh->get_info( $GetInfoType{SQL_DBMS_VER} );
```

The names are a merging of the ANSI and ODBC standards (which differ in some cases). See *DBI::Const::GetInfoType* for more details.

Because some DBI methods make use of get_info(), drivers are strongly encouraged to support *at least* the following very minimal set of information types to ensure the DBI itself works properly:

```
Type  Name                        Example A     Example B
----  --------------------------  ------------  ----------------
  17  SQL_DBMS_NAME               'ACCESS'      'Oracle'
  18  SQL_DBMS_VER                '03.50.0000'  '08.01.0721 ...'
  29  SQL_IDENTIFIER_QUOTE_CHAR   '`'           '"'
  41  SQL_CATALOG_NAME_SEPARATOR  '.'           '@'
 114  SQL_CATALOG_LOCATION        1             2
```

Values from 9000 to 9999 for get_info are officially reserved for use by Perl DBI. Values in that range which have been assigned a meaning are defined here:

`9000`: true if a backslash character (\) before placeholder-like text (e.g. ?, :foo) will prevent it being treated as a placeholder by the driver. The backslash will be removed before the text is passed to the backend.

table_info

```
$sth = $dbh->table_info( $catalog, $schema, $table, $type );
$sth = $dbh->table_info( $catalog, $schema, $table, $type, \%attr );

# then $sth->fetchall_arrayref or $sth->fetchall_hashref etc
```

Returns an active statement handle that can be used to fetch information about tables and views that exist in the database.

The arguments $catalog, $schema and $table may accept search patterns according to the database/driver, for example: $table = ‘%FOO%’; Remember that the underscore character (’_’) is a search pattern that means match any character, so ‘FOO_%’ is the same as ‘FOO%’ and ‘FOO_BAR%’ will match names like ‘FOO1BAR’.

The value of $type is a comma-separated list of one or more types of tables to be returned in the result set. Each value may optionally be quoted, e.g.:

```
$type = "TABLE";
$type = "'TABLE','VIEW'";
```

In addition the following special cases may also be supported by some drivers:

- If the value of $catalog is '%' and $schema and $table name are empty strings, the result set contains a list of catalog names. For example:

  ```
  $sth = $dbh->table_info('%', '', '');
  ```

- If the value of $schema is '%' and $catalog and $table are empty strings, the result set contains a list of schema names.
- If the value of $type is '%' and $catalog, $schema, and $table are all empty strings, the result set contains a list of table types.

If your driver doesn't support one or more of the selection filter parameters then you may get back more than you asked for and can do the filtering yourself.

This method can be expensive, and can return a large amount of data. (For example, small Oracle installation returns over 2000 rows.) So it's a good idea to use the filters to limit the data as much as possible.

The statement handle returned has at least the following fields in the order show below. Other fields, after these, may also be present.

TABLE_CAT: Table catalog identifier. This field is NULL (`undef`) if not applicable to the data source, which is usually the case. This field is empty if not applicable to the table.

TABLE_SCHEM: The name of the schema containing the TABLE_NAME value. This field is NULL (`undef`) if not applicable to data source, and empty if not applicable to the table.

TABLE_NAME: Name of the table (or view, synonym, etc).

TABLE_TYPE: One of the following: "TABLE", "VIEW", "SYSTEM TABLE", "GLOBAL TEMPORARY", "LOCAL TEMPORARY", "ALIAS", "SYNONYM" or a type identifier that is specific to the data source.

REMARKS: A description of the table. May be NULL (`undef`).

Note that `table_info` might not return records for all tables. Applications can use any valid table regardless of whether it's returned by `table_info`.

See also "tables", "Catalog Methods" and "Standards Reference Information".

column_info

```
$sth = $dbh->column_info( $catalog, $schema, $table, $column );

# then $sth->fetchall_arrayref or $sth->fetchall_hashref etc
```

Returns an active statement handle that can be used to fetch information about columns in specified tables.

The arguments $schema, $table and $column may accept search patterns according to the database/driver, for example: $table = '%FOO%';

Note: The support for the selection criteria is driver specific. If the driver doesn't support one or more of them then you may get back more than you asked for and can do the filtering yourself.

Note: If your driver does not support column_info an undef is returned. This is distinct from asking for something which does not exist in a driver which supports column_info as a valid statement handle to an empty result-set will be returned in this case.

If the arguments don't match any tables then you'll still get a statement handle, it'll just return no rows.

The statement handle returned has at least the following fields in the order shown below. Other fields, after these, may also be present.

TABLE_CAT: The catalog identifier. This field is NULL (`undef`) if not applicable to the data source, which is often the case. This field is empty if not applicable to the table.

TABLE_SCHEM: The schema identifier. This field is NULL (`undef`) if not applicable to the data source, and empty if not applicable to the table.

TABLE_NAME: The table identifier. Note: A driver may provide column metadata not only for base tables, but also for derived objects like SYNONYMS etc.

COLUMN_NAME: The column identifier.

DATA_TYPE: The concise data type code.

TYPE_NAME: A data source dependent data type name.

COLUMN_SIZE: The column size. This is the maximum length in characters for character data types, the number of digits or bits for numeric data types or the length in the representation of temporal types. See the relevant specifications for detailed information.

BUFFER_LENGTH: The length in bytes of transferred data.

DECIMAL_DIGITS: The total number of significant digits to the right of the decimal point.

NUM_PREC_RADIX: The radix for numeric precision. The value is 10 or 2 for numeric data types and NULL (`undef`) if not applicable.

NULLABLE: Indicates if a column can accept NULLs. The following values are defined:

```
SQL_NO_NULLS          0
SQL_NULLABLE          1
SQL_NULLABLE_UNKNOWN  2
```

REMARKS: A description of the column.

COLUMN_DEF: The default value of the column, in a format that can be used directly in an SQL statement.

Note that this may be an expression and not simply the text used for the default value in the original CREATE TABLE statement. For example, given:

```
col1 char(30) default current_user    -- a 'function'
col2 char(30) default 'string'        -- a string literal
```

where “current_user” is the name of a function, the corresponding COLUMN_DEF values would be:

```
Database        col1                    col2
--------        ----                    ----
Oracle:         current_user            'string'
Postgres:       "current_user"()        'string'::text
MS SQL:         (user_name())           ('string')
```

SQL_DATA_TYPE: The SQL data type.

SQL_DATETIME_SUB: The subtype code for datetime and interval data types.

CHAR_OCTET_LENGTH: The maximum length in bytes of a character or binary data type column.

ORDINAL_POSITION: The column sequence number (starting with 1).

IS_NULLABLE: Indicates if the column can accept NULLs. Possible values are: ‘NO’, ‘YES’ and ‘’.

SQL/CLI defines the following additional columns:

```
CHAR_SET_CAT
CHAR_SET_SCHEM
CHAR_SET_NAME
COLLATION_CAT
COLLATION_SCHEM
COLLATION_NAME
UDT_CAT
UDT_SCHEM
UDT_NAME
DOMAIN_CAT
DOMAIN_SCHEM
DOMAIN_NAME
SCOPE_CAT
SCOPE_SCHEM
SCOPE_NAME
MAX_CARDINALITY
DTD_IDENTIFIER
IS_SELF_REF
```

Drivers capable of supplying any of those values should do so in the corresponding column and supply undef values for the others.

Drivers wishing to provide extra database/driver specific information should do so in extra columns beyond all those listed above, and use lowercase field names with the driver-specific prefix (i.e., ‘ora_...’). Applications accessing such fields should do so by name and not by column number.

The result set is ordered by TABLE_CAT, TABLE_SCHEM, TABLE_NAME and ORDINAL_POSITION.

Note: There is some overlap with statement handle attributes (in perl) and SQLDescribeCol (in ODBC). However, SQLColumns provides more metadata.

See also “Catalog Methods” and “Standards Reference Information”.

primary_key_info

```
$sth = $dbh->primary_key_info( $catalog, $schema, $table );

# then $sth->fetchall_arrayref or $sth->fetchall_hashref etc
```

Returns an active statement handle that can be used to fetch information about columns that make up the primary key for a table. The arguments don’t accept search patterns (unlike table_info()).

The statement handle will return one row per column, ordered by TABLE_CAT, TABLE_SCHEM, TABLE_NAME, and KEY_SEQ. If there is no primary key then the statement handle will fetch no rows.

Note: The support for the selection criteria, such as $catalog, is driver specific. If the driver doesn’t support catalogs and/or schemas, it may ignore these criteria.

The statement handle returned has at least the following fields in the order shown below. Other fields, after these, may also be present.

TABLE_CAT: The catalog identifier. This field is NULL (undef) if not applicable to the data source, which is often the case. This field is empty if not applicable to the table.

TABLE_SCHEM: The schema identifier. This field is NULL (undef) if not applicable to the data source, and empty if not applicable to the table.

TABLE_NAME: The table identifier.

COLUMN_NAME: The column identifier.

KEY_SEQ: The column sequence number (starting with 1). Note: This field is named **ORDINAL_POSITION** in SQL/CLI.

PK_NAME: The primary key constraint identifier. This field is NULL (undef) if not applicable to the data source.

See also “Catalog Methods” and “Standards Reference Information”.

primary_key

```
@key_column_names = $dbh->primary_key( $catalog, $schema, $table );
```

Simple interface to the primary_key_info() method. Returns a list of the column names that comprise the primary key of the specified table. The list is in primary key column sequence order. If there is no primary key then an empty list is returned.

foreign_key_info

```
$sth = $dbh->foreign_key_info( $pk_catalog, $pk_schema, $pk_table
                             , $fk_catalog, $fk_schema, $fk_table );

$sth = $dbh->foreign_key_info( $pk_catalog, $pk_schema, $pk_table
```

(continues on next page)

(continued from previous page)

```
                                , $fk_catalog, $fk_schema, $fk_table
                                , \%attr );

# then $sth->fetchall_arrayref or $sth->fetchall_hashref etc
```

Returns an active statement handle that can be used to fetch information about foreign keys in and/or referencing the specified table(s). The arguments don't accept search patterns (unlike table_info()).

`$pk_catalog`, `$pk_schema`, `$pk_table` identify the primary (unique) key table (**PKT**).

`$fk_catalog`, `$fk_schema`, `$fk_table` identify the foreign key table (**FKT**).

If both **PKT** and **FKT** are given, the function returns the foreign key, if any, in table **FKT** that refers to the primary (unique) key of table **PKT**. (Note: In SQL/CLI, the result is implementation-defined.)

If only **PKT** is given, then the result set contains the primary key of that table and all foreign keys that refer to it.

If only **FKT** is given, then the result set contains all foreign keys in that table and the primary keys to which they refer. (Note: In SQL/CLI, the result includes unique keys too.)

For example:

```
$sth = $dbh->foreign_key_info( undef, $user, 'master');
$sth = $dbh->foreign_key_info( undef, undef,   undef , undef, $user,␣
↪'detail');
$sth = $dbh->foreign_key_info( undef, $user, 'master', undef, $user,␣
↪'detail');

# then $sth->fetchall_arrayref or $sth->fetchall_hashref etc
```

Note: The support for the selection criteria, such as `$catalog`, is driver specific. If the driver doesn't support catalogs and/or schemas, it may ignore these criteria.

The statement handle returned has the following fields in the order shown below. Because ODBC never includes unique keys, they define different columns in the result set than SQL/CLI. SQL/CLI column names are shown in parentheses.

PKTABLE_CAT (UK_TABLE_CAT): The primary (unique) key table catalog identifier. This field is NULL (`undef`) if not applicable to the data source, which is often the case. This field is empty if not applicable to the table.

PKTABLE_SCHEM (UK_TABLE_SCHEM): The primary (unique) key table schema identifier. This field is NULL (`undef`) if not applicable to the data source, and empty if not applicable to the table.

PKTABLE_NAME (UK_TABLE_NAME): The primary (unique) key table identifier.

PKCOLUMN_NAME (UK_COLUMN_NAME): The primary (unique) key column identifier.

FKTABLE_CAT (FK_TABLE_CAT): The foreign key table catalog identifier. This field is NULL (`undef`) if not applicable to the data source, which is often the case. This field is

empty if not applicable to the table.

FKTABLE_SCHEM (FK_TABLE_SCHEM): The foreign key table schema identifier. This field is NULL (undef) if not applicable to the data source, and empty if not applicable to the table.

FKTABLE_NAME (FK_TABLE_NAME): The foreign key table identifier.

FKCOLUMN_NAME (FK_COLUMN_NAME): The foreign key column identifier.

KEY_SEQ (ORDINAL_POSITION): The column sequence number (starting with 1).

UPDATE_RULE (UPDATE_RULE): The referential action for the UPDATE rule. The following codes are defined:

```
CASCADE              0
RESTRICT             1
SET NULL             2
NO ACTION            3
SET DEFAULT          4
```

DELETE_RULE (DELETE_RULE): The referential action for the DELETE rule. The codes are the same as for UPDATE_RULE.

FK_NAME (FK_NAME): The foreign key name.

PK_NAME (UK_NAME): The primary (unique) key name.

DEFERRABILITY (DEFERABILITY): The deferrability of the foreign key constraint. The following codes are defined:

```
INITIALLY DEFERRED   5
INITIALLY IMMEDIATE  6
NOT DEFERRABLE       7
```

** (UNIQUE_OR_PRIMARY)**: This column is necessary if a driver includes all candidate (i.e. primary and alternate) keys in the result set (as specified by SQL/CLI). The value of this column is UNIQUE if the foreign key references an alternate key and PRIMARY if the foreign key references a primary key, or it may be undefined if the driver doesn't have access to the information.

See also "Catalog Methods" and "Standards Reference Information".

statistics_info

```
$sth = $dbh->statistics_info( $catalog, $schema, $table, $unique_
 ↪only, $quick );

# then $sth->fetchall_arrayref or $sth->fetchall_hashref etc
```

Returns an active statement handle that can be used to fetch statistical information about a table and its indexes.

The arguments don't accept search patterns (unlike "table_info").

If the boolean argument $unique_only is true, only UNIQUE indexes will be returned in the result set, otherwise all indexes will be returned.

If the boolean argument $quick is set, the actual statistical information columns (CARDINALITY and PAGES) will only be returned if they are readily available from the server, and might not be current. Some databases may return stale statistics or no statistics at all with this flag set.

The statement handle will return at most one row per column name per index, plus at most one row for the entire table itself, ordered by NON_UNIQUE, TYPE, INDEX_QUALIFIER, INDEX_NAME, and ORDINAL_POSITION.

Note: The support for the selection criteria, such as $catalog, is driver specific. If the driver doesn't support catalogs and/or schemas, it may ignore these criteria.

The statement handle returned has at least the following fields in the order shown below. Other fields, after these, may also be present.

TABLE_CAT: The catalog identifier. This field is NULL (`undef`) if not applicable to the data source, which is often the case. This field is empty if not applicable to the table.

TABLE_SCHEM: The schema identifier. This field is NULL (`undef`) if not applicable to the data source, and empty if not applicable to the table.

TABLE_NAME: The table identifier.

NON_UNIQUE: Unique index indicator. Returns 0 for unique indexes, 1 for non-unique indexes

INDEX_QUALIFIER: Index qualifier identifier. The identifier that is used to qualify the index name when doing a `DROP INDEX`; NULL (`undef`) is returned if an index qualifier is not supported by the data source. If a non-NULL (defined) value is returned in this column, it must be used to qualify the index name on a `DROP INDEX` statement; otherwise, the TABLE_SCHEM should be used to qualify the index name.

INDEX_NAME: The index identifier.

TYPE: The type of information being returned. Can be any of the following values: 'table', 'btree', 'clustered', 'content', 'hashed', or 'other'.

In the case that this field is 'table', all fields other than TABLE_CAT, TABLE_SCHEM, TABLE_NAME, TYPE, CARDINALITY, and PAGES will be NULL (`undef`).

ORDINAL_POSITION: Column sequence number (starting with 1).

COLUMN_NAME: The column identifier.

ASC_OR_DESC: Column sort sequence. `A` for Ascending, `D` for Descending, or NULL (`undef`) if not supported for this index.

CARDINALITY: Cardinality of the table or index. For indexes, this is the number of unique values in the index. For tables, this is the number of rows in the table. If not supported, the value will be NULL (`undef`).

PAGES: Number of storage pages used by this table or index. If not supported, the value will be NULL (`undef`).

FILTER_CONDITION: The index filter condition as a string. If the index is not a filtered index, or it cannot be determined whether the index is a filtered index, this value is NULL (`undef`). If the index is a filtered index, but the filter condition cannot be determined, this value is the empty string `''`. Otherwise it will be the literal filter condition as a string, such as `SALARY <= 4500`.

See also “Catalog Methods” and “Standards Reference Information”.

tables

```
@names = $dbh->tables( $catalog, $schema, $table, $type );
@names = $dbh->tables;        # deprecated
```

Simple interface to table_info(). Returns a list of matching table names, possibly including a catalog/schema prefix.

See “table_info” for a description of the parameters.

If `$dbh->get_info(29)` returns true (29 is SQL_IDENTIFIER_QUOTE_CHAR) then the table names are constructed and quoted by “quote_identifier” to ensure they are usable even if they contain whitespace or reserved words etc. This means that the table names returned will include quote characters.

type_info_all

```
$type_info_all = $dbh->type_info_all;
```

Returns a reference to an array which holds information about each data type variant supported by the database and driver. The array and its contents should be treated as read-only.

The first item is a reference to an ‘index’ hash of `Name => Index` pairs. The items following that are references to arrays, one per supported data type variant. The leading index hash defines the names and order of the fields within the arrays that follow it. For example:

```
$type_info_all = [
  {   TYPE_NAME         => 0,
      DATA_TYPE         => 1,
      COLUMN_SIZE       => 2,     # was PRECISION originally
      LITERAL_PREFIX    => 3,
      LITERAL_SUFFIX    => 4,
      CREATE_PARAMS     => 5,
      NULLABLE          => 6,
      CASE_SENSITIVE    => 7,
      SEARCHABLE        => 8,
      UNSIGNED_ATTRIBUTE=> 9,
      FIXED_PREC_SCALE  => 10,    # was MONEY originally
      AUTO_UNIQUE_VALUE => 11,    # was AUTO_INCREMENT originally
      LOCAL_TYPE_NAME   => 12,
      MINIMUM_SCALE     => 13,
      MAXIMUM_SCALE     => 14,
      SQL_DATA_TYPE     => 15,
      SQL_DATETIME_SUB  => 16,
      NUM_PREC_RADIX    => 17,
      INTERVAL_PRECISION=> 18,
  },
```

(continues on next page)

(continued from previous page)

```
  [ 'VARCHAR', SQL_VARCHAR,
      undef, "'","'", undef,0, 1,1,0,0,0,undef,1,255, undef
  ],
  [ 'INTEGER', SQL_INTEGER,
      undef,  "", "", undef,0, 0,1,0,0,0,undef,0,  0, 10
  ],
];
```

More than one row may have the same value in the DATA_TYPE field if there are different ways to spell the type name and/or there are variants of the type with different attributes (e.g., with and without AUTO_UNIQUE_VALUE set, with and without UNSIGNED_ATTRIBUTE, etc).

The rows are ordered by DATA_TYPE first and then by how closely each type maps to the corresponding ODBC SQL data type, closest first.

The meaning of the fields is described in the documentation for the "type_info" method.

An 'index' hash is provided so you don't need to rely on index values defined above. However, using DBD::ODBC with some old ODBC drivers may return older names, shown as comments in the example above. Another issue with the index hash is that the lettercase of the keys is not defined. It is usually uppercase, as show here, but drivers may return names with any lettercase.

Drivers are also free to return extra driver-specific columns of information - though it's recommended that they start at column index 50 to leave room for expansion of the DBI/ODBC specification.

The type_info_all() method is not normally used directly. The "type_info" method provides a more usable and useful interface to the data.

type_info

```
@type_info = $dbh->type_info($data_type);
```

Returns a list of hash references holding information about one or more variants of $data_type. The list is ordered by DATA_TYPE first and then by how closely each type maps to the corresponding ODBC SQL data type, closest first. If called in a scalar context then only the first (best) element is returned.

If $data_type is undefined or SQL_ALL_TYPES, then the list will contain hashes for all data type variants supported by the database and driver.

If $data_type is an array reference then type_info returns the information for the *first* type in the array that has any matches.

The keys of the hash follow the same letter case conventions as the rest of the DBI (see "Naming Conventions and Name Space"). The following uppercase items should always exist, though may be undef:

- TYPE_NAME (string)

  Data type name for use in CREATE TABLE statements etc.

- DATA_TYPE (integer)

SQL data type number.

- COLUMN_SIZE (integer)

  For numeric types, this is either the total number of digits (if the NUM_PREC_RADIX value is 10) or the total number of bits allowed in the column (if NUM_PREC_RADIX is 2).

  For string types, this is the maximum size of the string in characters.

  For date and interval types, this is the maximum number of characters needed to display the value.

- LITERAL_PREFIX (string)

  Characters used to prefix a literal. A typical prefix is "`'`" for characters, or possibly "`0x`" for binary values passed as hexadecimal. NULL (`undef`) is returned for data types for which this is not applicable.

- LITERAL_SUFFIX (string)

  Characters used to suffix a literal. Typically "`'`" for characters. NULL (`undef`) is returned for data types where this is not applicable.

- CREATE_PARAMS (string)

  Parameter names for data type definition. For example, `CREATE_PARAMS` for a `DECIMAL` would be "`precision,scale`" if the DECIMAL type should be declared as `DECIMAL`(*precision*,*scale*) where *precision* and *scale* are integer values. For a `VARCHAR` it would be "`max length`". NULL (`undef`) is returned for data types for which this is not applicable.

- NULLABLE (integer)

  Indicates whether the data type accepts a NULL value: `0` or an empty string = no, 1 = yes, 2 = unknown.

- CASE_SENSITIVE (boolean)

  Indicates whether the data type is case sensitive in collations and comparisons.

- SEARCHABLE (integer)

  Indicates how the data type can be used in a WHERE clause, as follows:

```
0 - Cannot be used in a WHERE clause
1 - Only with a LIKE predicate
2 - All comparison operators except LIKE
3 - Can be used in a WHERE clause with any comparison operator
```

- UNSIGNED_ATTRIBUTE (boolean)

  Indicates whether the data type is unsigned. NULL (`undef`) is returned for data types for which this is not applicable.

- FIXED_PREC_SCALE (boolean)

  Indicates whether the data type always has the same precision and scale (such as a money type). NULL (`undef`) is returned for data types for which this is not applicable.

- AUTO_UNIQUE_VALUE (boolean)

  Indicates whether a column of this data type is automatically set to a unique value whenever a new row is inserted. NULL (undef) is returned for data types for which this is not applicable.

- LOCAL_TYPE_NAME (string)

  Localized version of the TYPE_NAME for use in dialog with users. NULL (undef) is returned if a localized name is not available (in which case TYPE_NAME should be used).

- MINIMUM_SCALE (integer)

  The minimum scale of the data type. If a data type has a fixed scale, then MAXIMUM_SCALE holds the same value. NULL (undef) is returned for data types for which this is not applicable.

- MAXIMUM_SCALE (integer)

  The maximum scale of the data type. If a data type has a fixed scale, then MINIMUM_SCALE holds the same value. NULL (undef) is returned for data types for which this is not applicable.

- SQL_DATA_TYPE (integer)

  This column is the same as the DATA_TYPE column, except for interval and datetime data types. For interval and datetime data types, the SQL_DATA_TYPE field will return SQL_INTERVAL or SQL_DATETIME, and the SQL_DATETIME_SUB field below will return the subcode for the specific interval or datetime data type. If this field is NULL, then the driver does not support or report on interval or datetime subtypes.

- SQL_DATETIME_SUB (integer)

  For interval or datetime data types, where the SQL_DATA_TYPE field above is SQL_INTERVAL or SQL_DATETIME, this field will hold the *subcode* for the specific interval or datetime data type. Otherwise it will be NULL (undef).

  Although not mentioned explicitly in the standards, it seems there is a simple relationship between these values:

```
DATA_TYPE == (10 * SQL_DATA_TYPE) + SQL_DATETIME_SUB
```

- NUM_PREC_RADIX (integer)

  The radix value of the data type. For approximate numeric types, NUM_PREC_RADIX contains the value 2 and COLUMN_SIZE holds the number of bits. For exact numeric types, NUM_PREC_RADIX contains the value 10 and COLUMN_SIZE holds the number of decimal digits. NULL (undef) is returned either for data types for which this is not applicable or if the driver cannot report this information.

- INTERVAL_PRECISION (integer)

  The interval leading precision for interval types. NULL is returned either for data types for which this is not applicable or if the driver cannot report this information.

For example, to find the type name for the fields in a select statement you can do:

```
@names = map { scalar $dbh->type_info($_)->{TYPE_NAME} } @{ $sth->
 ↪{TYPE} }
```

Since DBI and ODBC drivers vary in how they map their types into the ISO standard types you may need to search for more than one type. Here's an example looking for a usable type to store a date:

```
$my_date_type = $dbh->type_info( [ SQL_DATE, SQL_TIMESTAMP ] );
```

Similarly, to more reliably find a type to store small integers, you could use a list starting with `SQL_SMALLINT`, `SQL_INTEGER`, `SQL_DECIMAL`, etc.

See also "Standards Reference Information".

quote

```
$sql = $dbh->quote($value);
$sql = $dbh->quote($value, $data_type);
```

Quote a string literal for use as a literal value in an SQL statement, by escaping any special characters (such as quotation marks) contained within the string and adding the required type of outer quotation marks.

```
$sql = sprintf "SELECT foo FROM bar WHERE baz = %s",
               $dbh->quote("Don't");
```

For most database types, at least those that conform to SQL standards, quote would return `'Don''t'` (including the outer quotation marks). For others it may return something like `'Don\'t'`

An undefined `$value` value will be returned as the string `NULL` (without single quotation marks) to match how NULLs are represented in SQL.

If `$data_type` is supplied, it is used to try to determine the required quoting behaviour by using the information returned by "type_info". As a special case, the standard numeric types are optimized to return `$value` without calling `type_info`.

Quote will probably *not* be able to deal with all possible input (such as binary data or data containing newlines), and is not related in any way with escaping or quoting shell meta-characters.

It is valid for the quote() method to return an SQL expression that evaluates to the desired string. For example:

```
$quoted = $dbh->quote("one\ntwo\0three")
```

may return something like:

```
CONCAT('one', CHAR(12), 'two', CHAR(0), 'three')
```

The quote() method should *not* be used with "Placeholders and Bind Values".

quote_identifier

```
$sql = $dbh->quote_identifier( $name );
$sql = $dbh->quote_identifier( $catalog, $schema, $table, \%attr );
```

Quote an identifier (table name etc.) for use in an SQL statement, by escaping any special characters (such as double quotation marks) it contains and adding the required type of outer quotation marks.

Undefined names are ignored and the remainder are quoted and then joined together, typically with a dot (.) character. For example:

```
$id = $dbh->quote_identifier( undef, 'Her schema', 'My table' );
```

would, for most database types, return `"Her schema"."My table"` (including all the double quotation marks).

If three names are supplied then the first is assumed to be a catalog name and special rules may be applied based on what "get_info" returns for SQL_CATALOG_NAME_SEPARATOR (41) and SQL_CATALOG_LOCATION (114). For example, for Oracle:

```
$id = $dbh->quote_identifier( 'link', 'schema', 'table' );
```

would return `"schema"."table"@"link"`.

take_imp_data

```
$imp_data = $dbh->take_imp_data;
```

Leaves the $dbh in an almost dead, zombie-like, state and returns a binary string of raw implementation data from the driver which describes the current database connection. Effectively it detaches the underlying database API connection data from the DBI handle. After calling take_imp_data(), all other methods except `DESTROY` will generate a warning and return undef.

Why would you want to do this? You don't, forget I even mentioned it. Unless, that is, you're implementing something advanced like a multi-threaded connection pool like `DBI::Pool`.

The returned $imp_data can be passed as a `dbi_imp_data` attribute to a later connect() call, even in a separate thread in the same process, where the driver can use it to 'adopt' the existing connection that the implementation data was taken from.

Some things to keep in mind...

* the $imp_data holds the only reference to the underlying database API connection data. That connection is still 'live' and won't be cleaned up properly unless the $imp_data is used to create a new $dbh which is then allowed to disconnect() normally.

* using the same $imp_data to create more than one other new $dbh at a time may well lead to unpleasant problems. Don't do that.

Any child statement handles are effectively destroyed when take_imp_data() is called.

The `take_imp_data` method was added in DBI 1.36 but wasn't useful till 1.49.

Database Handle Attributes

This section describes attributes specific to database handles.

Changes to these database handle attributes do not affect any other existing or future database handles.

Attempting to set or get the value of an unknown attribute generates a warning, except for private driver-specific attributes (which all have names starting with a lowercase letter).

Example:

```
$h->{AutoCommit} = ...;       # set/write
... = $h->{AutoCommit};       # get/read
```

AutoCommit

Type: boolean

If true, then database changes cannot be rolled-back (undone). If false, then database changes automatically occur within a "transaction", which must either be committed or rolled back using the `commit` or `rollback` methods.

Drivers should always default to `AutoCommit` mode (an unfortunate choice largely forced on the DBI by ODBC and JDBC conventions.)

Attempting to set `AutoCommit` to an unsupported value is a fatal error. This is an important feature of the DBI. Applications that need full transaction behaviour can set `$dbh->{AutoCommit} = 0` (or set `AutoCommit` to 0 via "connect") without having to check that the value was assigned successfully.

For the purposes of this description, we can divide databases into three categories:

```
Databases which don't support transactions at all.
Databases in which a transaction is always active.
Databases in which a transaction must be explicitly started (C<
 ↪'BEGIN WORK'>).
```

*** Databases which don't support transactions at all**

For these databases, attempting to turn `AutoCommit` off is a fatal error. `commit` and `rollback` both issue warnings about being ineffective while `AutoCommit` is in effect.

*** Databases in which a transaction is always active**

These are typically mainstream commercial relational databases with "ANSI standard" transaction behaviour. If `AutoCommit` is off, then changes to the database won't have any lasting effect unless "commit" is called (but see also "disconnect"). If "rollback" is called then any changes since the last commit are undone.

If `AutoCommit` is on, then the effect is the same as if the DBI called `commit` automatically after every successful database operation. So calling `commit` or `rollback` explicitly while `AutoCommit` is on would be ineffective because the changes would have already been committed.

Changing `AutoCommit` from off to on will trigger a "commit".

For databases which don't support a specific auto-commit mode, the driver has to commit each statement automatically using an explicit `COMMIT` after it completes successfully (and roll it back using an explicit `ROLLBACK` if it fails). The error information reported to the application will correspond to the statement which was executed, unless it succeeded and the commit or rollback failed.

*** Databases in which a transaction must be explicitly started**

For these databases, the intention is to have them act like databases in which a transaction is always active (as described above).

To do this, the driver will automatically begin an explicit transaction when `AutoCommit` is turned off, or after a "commit" or "rollback" (or when the application issues the next database operation after one of those events).

In this way, the application does not have to treat these databases as a special case.

See "commit", "disconnect" and "Transactions" for other important notes about transactions.

Driver

Type: handle

Holds the handle of the parent driver. The only recommended use for this is to find the name of the driver using:

```
$dbh->{Driver}->{Name}
```

Name

Type: string

Holds the "name" of the database. Usually (and recommended to be) the same as the "`dbi:DriverName:...`" string used to connect to the database, but with the leading "`dbi:DriverName:`" removed.

Statement

Type: string, read-only

Returns the statement string passed to the most recent "prepare" or "do" method called in this database handle, even if that method failed. This is especially useful where `RaiseError` is enabled and the exception handler checks $@ and sees that a 'prepare' method call failed.

RowCacheSize

Type: integer

A hint to the driver indicating the size of the local row cache that the application would like the driver to use for future `SELECT` statements. If a row cache is not implemented, then setting `RowCacheSize` is ignored and getting the value returns `undef`.

Some `RowCacheSize` values have special meaning, as follows:

```
 0 - Automatically determine a reasonable cache size for each C
↪<SELECT>
 1 - Disable the local row cache
>1 - Cache this many rows
<0 - Cache as many rows that will fit into this much memory for each␣
↪C<SELECT>.
```

Note that large cache sizes may require a very large amount of memory (*cached rows* * *maximum size of row*). Also, a large cache will cause a longer delay not only for the first fetch, but also whenever the cache needs refilling.

See also the "RowsInCache" statement handle attribute.

Username

Type: string

Returns the username used to connect to the database.

DBI STATEMENT HANDLE OBJECTS

This section lists the methods and attributes associated with DBI statement handles.

Statement Handle Methods

The DBI defines the following methods for use on DBI statement handles:

bind_param

```
$sth->bind_param($p_num, $bind_value)
$sth->bind_param($p_num, $bind_value, \%attr)
$sth->bind_param($p_num, $bind_value, $bind_type)
```

The bind_param method takes a copy of $bind_value and associates it (binds it) with a placeholder, identified by $p_num, embedded in the prepared statement. Placeholders are indicated with question mark character (?). For example:

```
$dbh->{RaiseError} = 1;         # save having to check each method␣
↪call
$sth = $dbh->prepare("SELECT name, age FROM people WHERE name LIKE ?
↪");
$sth->bind_param(1, "John%");  # placeholders are numbered from 1
$sth->execute;
DBI::dump_results($sth);
```

See "Placeholders and Bind Values" for more information.

Data Types for Placeholders

The \%attr parameter can be used to hint at the data type the placeholder should have. This is rarely needed. Typically, the driver is only interested in knowing if the placeholder should be bound as a number or a string.

```
$sth->bind_param(1, $value, { TYPE => SQL_INTEGER });
```

As a short-cut for the common case, the data type can be passed directly, in place of the `\%attr` hash reference. This example is equivalent to the one above:

```
$sth->bind_param(1, $value, SQL_INTEGER);
```

The TYPE value indicates the standard (non-driver-specific) type for this parameter. To specify the driver-specific type, the driver may support a driver-specific attribute, such as `{ ora_type => 97 }`.

The SQL_INTEGER and other related constants can be imported using

```
use DBI qw(:sql_types);
```

See "DBI Constants" for more information.

The data type is 'sticky' in that bind values passed to execute() are bound with the data type specified by earlier bind_param() calls, if any. Portable applications should not rely on being able to change the data type after the first `bind_param` call.

Perl only has string and number scalar data types. All database types that aren't numbers are bound as strings and must be in a format the database will understand except where the bind_param() TYPE attribute specifies a type that implies a particular format. For example, given:

```
$sth->bind_param(1, $value, SQL_DATETIME);
```

the driver should expect $value to be in the ODBC standard SQL_DATETIME format, which is 'YYYY-MM-DD HH:MM:SS'. Similarly for SQL_DATE, SQL_TIME etc.

As an alternative to specifying the data type in the `bind_param` call, you can let the driver pass the value as the default type (VARCHAR). You can then use an SQL function to convert the type within the statement. For example:

```
INSERT INTO price(code, price) VALUES (?, CONVERT(MONEY,?))
```

The CONVERT function used here is just an example. The actual function and syntax will vary between different databases and is non-portable.

See also "Placeholders and Bind Values" for more information.

bind_param_inout

```
$rc = $sth->bind_param_inout($p_num, \$bind_value, $max_len)  or die
 ↪$sth->errstr;
$rv = $sth->bind_param_inout($p_num, \$bind_value, $max_len, \%attr)
 ↪    or ...
$rv = $sth->bind_param_inout($p_num, \$bind_value, $max_len, $bind_
 ↪type) or ...
```

This method acts like "bind_param", but also enables values to be updated by the statement. The statement is typically a call to a stored procedure. The `$bind_value` must be passed as a reference to the actual value to be used.

Note that unlike "bind_param", the `$bind_value` variable is not copied when `bind_param_inout` is called. Instead, the value in the variable is read at the time "execute" is called.

The additional `$max_len` parameter specifies the minimum amount of memory to allocate to `$bind_value` for the new value. If the value returned from the database is too big to fit, then the execution should fail. If unsure what value to use, pick a generous length, i.e., a length larger than the longest value that would ever be returned. The only cost of using a larger value than needed is wasted memory.

Undefined values or `undef` are used to indicate null values. See also "Placeholders and Bind Values" for more information.

bind_param_array

```
$rc = $sth->bind_param_array($p_num, $array_ref_or_value)
$rc = $sth->bind_param_array($p_num, $array_ref_or_value, \%attr)
$rc = $sth->bind_param_array($p_num, $array_ref_or_value, $bind_
↪type)
```

The `bind_param_array` method is used to bind an array of values to a placeholder embedded in the prepared statement which is to be executed with "execute_array". For example:

```
$dbh->{RaiseError} = 1;         # save having to check each method␣
↪call
$sth = $dbh->prepare("INSERT INTO staff (first_name, last_name,␣
↪dept) VALUES(?, ?, ?)");
$sth->bind_param_array(1, [ 'John', 'Mary', 'Tim' ]);
$sth->bind_param_array(2, [ 'Booth', 'Todd', 'Robinson' ]);
$sth->bind_param_array(3, "SALES"); # scalar will be reused for each␣
↪row
$sth->execute_array( { ArrayTupleStatus => \my @tuple_status } );
```

The `%attr` ($bind_type) argument is the same as defined for "bind_param". Refer to "bind_param" for general details on using placeholders.

(Note that bind_param_array() can *not* be used to expand a placeholder into a list of values for a statement like "SELECT foo WHERE bar IN (?)". A placeholder can only ever represent one value per execution.)

Scalar values, including `undef`, may also be bound by `bind_param_array`. In which case the same value will be used for each "execute" call. Driver-specific implementations may behave differently, e.g., when binding to a stored procedure call, some databases may permit mixing scalars and arrays as arguments.

The default implementation provided by DBI (for drivers that have not implemented array binding) is to iteratively call "execute" for each parameter tuple provided in the bound arrays. Drivers may provide more optimized implementations using whatever bulk operation support the database API provides. The default driver behaviour should match the default DBI behaviour, but always consult your driver documentation as there may be driver specific issues to consider.

Note that the default implementation currently only supports non-data returning statements (INSERT, UPDATE, but not SELECT). Also, bind_param_array and "bind_param" cannot be mixed in the same statement execution, and bind_param_array must be used with "execute_array"; using bind_param_array will have no effect for "execute".

The bind_param_array method was added in DBI 1.22.

execute

```
$rv = $sth->execute                 or die $sth->errstr;
$rv = $sth->execute(@bind_values)   or die $sth->errstr;
```

Perform whatever processing is necessary to execute the prepared statement. An undef is returned if an error occurs. A successful execute always returns true regardless of the number of rows affected, even if it's zero (see below). It is always important to check the return status of execute (and most other DBI methods) for errors if you're not using "RaiseError".

For a *non*-SELECT statement, execute returns the number of rows affected, if known. If no rows were affected, then execute returns "0E0", which Perl will treat as 0 but will regard as true. Note that it is *not* an error for no rows to be affected by a statement. If the number of rows affected is not known, then execute returns -1.

For SELECT statements, execute simply "starts" the query within the database engine. Use one of the fetch methods to retrieve the data after calling execute. The execute method does *not* return the number of rows that will be returned by the query (because most databases can't tell in advance), it simply returns a true value.

You can tell if the statement was a SELECT statement by checking if $sth->{NUM_OF_FIELDS} is greater than zero after calling execute.

If any arguments are given, then execute will effectively call "bind_param" for each value before executing the statement. Values bound in this way are usually treated as SQL_VARCHAR types unless the driver can determine the correct type (which is rare), or unless bind_param (or bind_param_inout) has already been used to specify the type.

Note that passing execute an empty array is the same as passing no arguments at all, which will execute the statement with previously bound values. That's probably not what you want.

If execute() is called on a statement handle that's still active ($sth->{Active} is true) then it should effectively call finish() to tidy up the previous execution results before starting this new execution.

execute_array

```
$tuples = $sth->execute_array(\%attr) or die $sth->errstr;
$tuples = $sth->execute_array(\%attr, @bind_values) or die $sth->
↪errstr;

($tuples, $rows) = $sth->execute_array(\%attr) or die $sth->errstr;
($tuples, $rows) = $sth->execute_array(\%attr, @bind_values) or die
↪$sth->errstr;
```

Execute the prepared statement once for each parameter tuple (group of values) provided either in the @bind_values, or by prior calls to "bind_param_array", or via a reference passed in \%attr.

When called in scalar context the execute_array() method returns the number of tuples executed, or `undef` if an error occurred. Like execute(), a successful execute_array() always returns true regardless of the number of tuples executed, even if it's zero. If there were any errors the ArrayTupleStatus array can be used to discover which tuples failed and with what errors.

When called in list context the execute_array() method returns two scalars; $tuples is the same as calling execute_array() in scalar context and $rows is the number of rows affected for each tuple, if available or -1 if the driver cannot determine this. NOTE, some drivers cannot determine the number of rows affected per tuple but can provide the number of rows affected for the batch. If you are doing an update operation the returned rows affected may not be what you expect if, for instance, one or more of the tuples affected the same row multiple times. Some drivers may not yet support list context, in which case $rows will be undef, or may not be able to provide the number of rows affected when performing this batch operation, in which case $rows will be -1.

Bind values for the tuples to be executed may be supplied row-wise by an `ArrayTupleFetch` attribute, or else column-wise in the `@bind_values` argument, or else column-wise by prior calls to "bind_param_array".

Where column-wise binding is used (via the `@bind_values` argument or calls to bind_param_array()) the maximum number of elements in any one of the bound value arrays determines the number of tuples executed. Placeholders with fewer values in their parameter arrays are treated as if padded with undef (NULL) values.

If a scalar value is bound, instead of an array reference, it is treated as a *variable* length array with all elements having the same value. It does not influence the number of tuples executed, so if all bound arrays have zero elements then zero tuples will be executed. If *all* bound values are scalars then one tuple will be executed, making execute_array() act just like execute().

The `ArrayTupleFetch` attribute can be used to specify a reference to a subroutine that will be called to provide the bind values for each tuple execution. The subroutine should return an reference to an array which contains the appropriate number of bind values, or return an undef if there is no more data to execute.

As a convenience, the `ArrayTupleFetch` attribute can also be used to specify a statement handle. In which case the fetchrow_arrayref() method will be called on the given statement handle in order to provide the bind values for each tuple execution.

The values specified via bind_param_array() or the @bind_values parameter may be either scalars, or arrayrefs. If any `@bind_values` are given, then `execute_array` will effectively call "bind_param_array" for each value before executing the statement. Values bound in this way are usually treated as `SQL_VARCHAR` types unless the driver can determine the correct type (which is rare), or unless `bind_param`, `bind_param_inout`, `bind_param_array`, or `bind_param_inout_array` has already been used to specify the type. See "bind_param_array" for details.

The `ArrayTupleStatus` attribute can be used to specify a reference to an array which will receive the execute status of each executed parameter tuple. Note the `ArrayTupleStatus` attribute was mandatory until DBI 1.38.

For tuples which are successfully executed, the element at the same ordinal position in the status array is the resulting rowcount (or -1 if unknown). If the execution of a tuple causes an error, then the corresponding status array element will be set to a reference to an array containing “err”, “errstr” and “state” set by the failed execution.

If **any** tuple execution returns an error, `execute_array` will return `undef`. In that case, the application should inspect the status array to determine which parameter tuples failed. Some databases may not continue executing tuples beyond the first failure. In this case the status array will either hold fewer elements, or the elements beyond the failure will be undef.

If all parameter tuples are successfully executed, `execute_array` returns the number tuples executed. If no tuples were executed, then execute_array() returns “`0E0`”, just like execute() does, which Perl will treat as 0 but will regard as true.

For example:

```
$sth = $dbh->prepare("INSERT INTO staff (first_name, last_name)␣
↪VALUES (?, ?)");
my $tuples = $sth->execute_array(
    { ArrayTupleStatus => \my @tuple_status },
    \@first_names,
    \@last_names,
);
if ($tuples) {
    print "Successfully inserted $tuples records\n";
}
else {
    for my $tuple (0..@last_names-1) {
        my $status = $tuple_status[$tuple];
        $status //= [0, "Skipped"];
        next unless ref $status;
        printf "Failed to insert (%s, %s): %s\n",
            $first_names[$tuple], $last_names[$tuple], $status->[1];
    }
}
```

Support for data returning statements such as SELECT is driver-specific and subject to change. At present, the default implementation provided by DBI only supports non-data returning statements.

Transaction semantics when using array binding are driver and database specific. If `AutoCommit` is on, the default DBI implementation will cause each parameter tuple to be individually committed (or rolled back in the event of an error). If `AutoCommit` is off, the application is responsible for explicitly committing the entire set of bound parameter tuples. Note that different drivers and databases may have different behaviours when some parameter tuples cause failures. In some cases, the driver or database may automatically rollback the effect of all prior parameter tuples that succeeded in the transaction; other drivers or databases may retain the effect of prior successfully executed parameter tuples. Be sure to check your driver and database for its specific behaviour.

Note that, in general, performance will usually be better with `AutoCommit` turned off, and using explicit `commit` after each `execute_array` call.

The execute_array method was added in DBI 1.22, and ArrayTupleFetch was added in 1.36.

execute_for_fetch

```
$tuples = $sth->execute_for_fetch($fetch_tuple_sub);
$tuples = $sth->execute_for_fetch($fetch_tuple_sub, \@tuple_status);

($tuples, $rows) = $sth->execute_for_fetch($fetch_tuple_sub);
($tuples, $rows) = $sth->execute_for_fetch($fetch_tuple_sub, \
↪@tuple_status);
```

The execute_for_fetch() method is used to perform bulk operations and although it is most often used via the execute_array() method you can use it directly. The main difference between execute_array and execute_for_fetch is the former does column or row-wise binding and the latter uses row-wise binding.

The fetch subroutine, referenced by $fetch_tuple_sub, is expected to return a reference to an array (known as a 'tuple') or undef.

The execute_for_fetch() method calls $fetch_tuple_sub, without any parameters, until it returns a false value. Each tuple returned is used to provide bind values for an $sth->execute(@$tuple) call.

In scalar context execute_for_fetch() returns undef if there were any errors and the number of tuples executed otherwise. Like execute() and execute_array() a zero is returned as "0E0" so execute_for_fetch() is only false on error. If there were any errors the @tuple_status array can be used to discover which tuples failed and with what errors.

When called in list context execute_for_fetch() returns two scalars; $tuples is the same as calling execute_for_fetch() in scalar context and $rows is the sum of the number of rows affected for each tuple, if available or -1 if the driver cannot determine this. If you are doing an update operation the returned rows affected may not be what you expect if, for instance, one or more of the tuples affected the same row multiple times. Some drivers may not yet support list context, in which case $rows will be undef, or may not be able to provide the number of rows affected when performing this batch operation, in which case $rows will be -1.

If \@tuple_status is passed then the execute_for_fetch method uses it to return status information. The tuple_status array holds one element per tuple. If the corresponding execute() did not fail then the element holds the return value from execute(), which is typically a row count. If the execute() did fail then the element holds a reference to an array containing ($sth->err, $sth->errstr, $sth->state).

If the driver detects an error that it knows means no further tuples can be executed then it may return, with an error status, even though $fetch_tuple_sub may still have more tuples to be executed.

Although each tuple returned by $fetch_tuple_sub is effectively used to call $sth->execute(@$tuple_array_ref) the exact timing may vary. Drivers are free to accumulate sets of tuples to pass to the database server in bulk group operations for more efficient execution. However, the $fetch_tuple_sub is specifically allowed to return the same array reference each time (which is what fetchrow_arrayref() usually does).

For example:

```
my $sel = $dbh1->prepare("select foo, bar from table1");
$sel->execute;

my $ins = $dbh2->prepare("insert into table2 (foo, bar) values (?,?)
 ↪");
my $fetch_tuple_sub = sub { $sel->fetchrow_arrayref };

my @tuple_status;
$rc = $ins->execute_for_fetch($fetch_tuple_sub, \@tuple_status);
my @errors = grep { ref $_ } @tuple_status;
```

Similarly, if you already have an array containing the data rows to be processed you'd use a subroutine to shift off and return each array ref in turn:

```
$ins->execute_for_fetch( sub { shift @array_of_arrays }, \@tuple_
 ↪status);
```

The `execute_for_fetch` method was added in DBI 1.38.

last_insert_id

```
$rv = $sth->last_insert_id();
$rv = $sth->last_insert_id($catalog, $schema, $table, $field);
$rv = $sth->last_insert_id($catalog, $schema, $table, $field, \
 ↪%attr);
```

Returns a value 'identifying' the row inserted by last execution of the statement `$sth`, if possible.

For some drivers the value may be 'identifying' the row inserted by the last executed statement, not by `$sth`.

See database handle method last_insert_id for all details.

The `last_insert_id` statement method was added in DBI 1.642.

fetchrow_arrayref

```
$ary_ref = $sth->fetchrow_arrayref;
$ary_ref = $sth->fetch;    # alias
```

Fetches the next row of data and returns a reference to an array holding the field values. Null fields are returned as `undef` values in the array. This is the fastest way to fetch data, particularly if used with `$sth->bind_columns`.

If there are no more rows or if an error occurs, then `fetchrow_arrayref` returns an `undef`. You should check `$sth->err` afterwards (or use the `RaiseError` attribute) to discover if the `undef` returned was due to an error.

Note that the same array reference is returned for each fetch, so don't store the reference and then use it after a later fetch. Also, the elements of the array are also reused for each row, so take care if you want to take a reference to an element. See also "bind_columns".

fetchrow_array

```
@ary = $sth->fetchrow_array;
```

An alternative to `fetchrow_arrayref`. Fetches the next row of data and returns it as a list containing the field values. Null fields are returned as `undef` values in the list.

If there are no more rows or if an error occurs, then `fetchrow_array` returns an empty list. You should check `$sth->err` afterwards (or use the `RaiseError` attribute) to discover if the empty list returned was due to an error.

If called in a scalar context for a statement handle that has more than one column, it is undefined whether the driver will return the value of the first column or the last. So don't do that. Also, in a scalar context, an `undef` is returned if there are no more rows or if an error occurred. That `undef` can't be distinguished from an `undef` returned because the first field value was NULL. For these reasons you should exercise some caution if you use `fetchrow_array` in a scalar context.

fetchrow_hashref

```
$hash_ref = $sth->fetchrow_hashref;
$hash_ref = $sth->fetchrow_hashref($name);
```

An alternative to `fetchrow_arrayref`. Fetches the next row of data and returns it as a reference to a hash containing field name and field value pairs. Null fields are returned as `undef` values in the hash.

If there are no more rows or if an error occurs, then `fetchrow_hashref` returns an `undef`. You should check `$sth->err` afterwards (or use the `RaiseError` attribute) to discover if the `undef` returned was due to an error.

The optional `$name` parameter specifies the name of the statement handle attribute. For historical reasons it defaults to "`NAME`", however using either "`NAME_lc`" or "`NAME_uc`" is recommended for portability.

The keys of the hash are the same names returned by `$sth->{$name}`. If more than one field has the same name, there will only be one entry in the returned hash for those fields, so statements like "`select foo, foo from bar`" will return only a single key from `fetchrow_hashref`. In these cases use column aliases or `fetchrow_arrayref`. Note that it is the database server (and not the DBD implementation) which provides the *name* for fields containing functions like "`count(*)`" or "`max(c_foo)`" and they may clash with existing column names (most databases don't care about duplicate column names in a result-set). If you want these to return as unique names that are the same across databases, use *aliases*, as in "`select count(*) as cnt`" or "`select max(c_foo) mx_foo, ...`" depending on the syntax your database supports.

Because of the extra work `fetchrow_hashref` and Perl have to perform, it is not as efficient as `fetchrow_arrayref` or `fetchrow_array`.

By default a reference to a new hash is returned for each row. It is likely that a future version of the DBI will support an attribute which will enable the same hash to be reused for each row. This will give a significant performance boost, but it won't be enabled by default because of the risk of breaking old code.

fetchall_arrayref

```
$tbl_ary_ref = $sth->fetchall_arrayref;
$tbl_ary_ref = $sth->fetchall_arrayref( $slice );
$tbl_ary_ref = $sth->fetchall_arrayref( $slice, $max_rows  );
```

The `fetchall_arrayref` method can be used to fetch all the data to be returned from a prepared and executed statement handle. It returns a reference to an array that contains one reference per row.

If called on an *inactive* statement handle, `fetchall_arrayref` returns undef.

If there are no rows left to return from an *active* statement handle, `fetchall_arrayref` returns a reference to an empty array. If an error occurs, `fetchall_arrayref` returns the data fetched thus far, which may be none. You should check `$sth->err` afterwards (or use the `RaiseError` attribute) to discover if the data is complete or was truncated due to an error.

If $slice is an array reference, `fetchall_arrayref` uses "fetchrow_arrayref" to fetch each row as an array ref. If the $slice array is not empty then it is used as a slice to select individual columns by perl array index number (starting at 0, unlike column and parameter numbers which start at 1).

With no parameters, or if $slice is undefined, `fetchall_arrayref` acts as if passed an empty array ref.

For example, to fetch just the first column of every row:

```
$tbl_ary_ref = $sth->fetchall_arrayref([0]);
```

To fetch the second to last and last column of every row:

```
$tbl_ary_ref = $sth->fetchall_arrayref([-2,-1]);
```

Those two examples both return a reference to an array of array refs.

If $slice is a hash reference, `fetchall_arrayref` fetches each row as a hash reference. If the $slice hash is empty then the keys in the hashes have whatever name lettercase is returned by default. (See "FetchHashKeyName" attribute.) If the $slice hash is *not* empty, then it is used as a slice to select individual columns by name. The values of the hash should be set to 1. The key names of the returned hashes match the letter case of the names in the parameter hash, regardless of the "FetchHashKeyName" attribute.

For example, to fetch all fields of every row as a hash ref:

```
$tbl_ary_ref = $sth->fetchall_arrayref({});
```

To fetch only the fields called "foo" and "bar" of every row as a hash ref (with keys named "foo" and "BAR", regardless of the original capitalization):

```
$tbl_ary_ref = $sth->fetchall_arrayref({ foo=>1, BAR=>1 });
```

Those two examples both return a reference to an array of hash refs.

If $slice is a *reference to a hash reference*, that hash is used to select and rename columns. The keys are 0-based column index numbers and the values are the corresponding keys

for the returned row hashes.

For example, to fetch only the first and second columns of every row as a hash ref (with keys named "k" and "v" regardless of their original names):

```
$tbl_ary_ref = $sth->fetchall_arrayref( \{ 0 => 'k', 1 => 'v' } );
```

If $max_rows is defined and greater than or equal to zero then it is used to limit the number of rows fetched before returning. fetchall_arrayref() can then be called again to fetch more rows. This is especially useful when you need the better performance of fetchall_arrayref() but don't have enough memory to fetch and return all the rows in one go.

Here's an example (assumes RaiseError is enabled):

```
my $rows = []; # cache for batches of rows
while( my $row = ( shift(@$rows) || # get row from cache, or reload␣
 ↪cache:
                    shift(@{$rows=$sth->fetchall_arrayref(undef,10_
 ↪000)||[]}) )
) {
  ...
}
```

That *might* be the fastest way to fetch and process lots of rows using the DBI, but it depends on the relative cost of method calls vs memory allocation.

A standard `while` loop with column binding is often faster because the cost of allocating memory for the batch of rows is greater than the saving by reducing method calls. It's possible that the DBI may provide a way to reuse the memory of a previous batch in future, which would then shift the balance back towards fetchall_arrayref().

fetchall_hashref

```
$hash_ref = $sth->fetchall_hashref($key_field);
```

The `fetchall_hashref` method can be used to fetch all the data to be returned from a prepared and executed statement handle. It returns a reference to a hash containing a key for each distinct value of the $key_field column that was fetched. For each key the corresponding value is a reference to a hash containing all the selected columns and their values, as returned by `fetchrow_hashref()`.

If there are no rows to return, `fetchall_hashref` returns a reference to an empty hash. If an error occurs, `fetchall_hashref` returns the data fetched thus far, which may be none. You should check `$sth->err` afterwards (or use the `RaiseError` attribute) to discover if the data is complete or was truncated due to an error.

The $key_field parameter provides the name of the field that holds the value to be used for the key for the returned hash. For example:

```
$dbh->{FetchHashKeyName} = 'NAME_lc';
$sth = $dbh->prepare("SELECT FOO, BAR, ID, NAME, BAZ FROM TABLE");
$sth->execute;
```

(continues on next page)

(continued from previous page)

```
$hash_ref = $sth->fetchall_hashref('id');
print "Name for id 42 is $hash_ref->{42}->{name}\n";
```

The $key_field parameter can also be specified as an integer column number (counting from 1). If $key_field doesn't match any column in the statement, as a name first then as a number, then an error is returned.

For queries returning more than one 'key' column, you can specify multiple column names by passing $key_field as a reference to an array containing one or more key column names (or index numbers). For example:

```
$sth = $dbh->prepare("SELECT foo, bar, baz FROM table");
$sth->execute;
$hash_ref = $sth->fetchall_hashref( [ qw(foo bar) ] );
print "For foo 42 and bar 38, baz is $hash_ref->{42}->{38}->{baz}\n
 ↪";
```

The fetchall_hashref() method is normally used only where the key fields values for each row are unique. If multiple rows are returned with the same values for the key fields then later rows overwrite earlier ones.

more_results

... not yet documented ...

finish

```
$rc  = $sth->finish;
```

Indicate that no more data will be fetched from this statement handle before it is either executed again or destroyed. You almost certainly do *not* need to call this method.

Adding calls to `finish` after loop that fetches all rows is a common mistake, don't do it, it can mask genuine problems like uncaught fetch errors.

When all the data has been fetched from a `SELECT` statement, the driver will automatically call `finish` for you. So you should *not* call it explicitly *except* when you know that you've not fetched all the data from a statement handle *and* the handle won't be destroyed soon.

The most common example is when you only want to fetch just one row, but in that case the `selectrow_*` methods are usually better anyway.

Consider a query like:

```
SELECT foo FROM table WHERE bar=? ORDER BY baz
```

on a very large table. When executed, the database server will have to use temporary buffer space to store the sorted rows. If, after executing the handle and selecting just a few rows, the handle won't be re-executed for some time and won't be destroyed, the `finish` method can be used to tell the server that the buffer space can be freed.

Calling `finish` resets the "Active" attribute for the statement. It may also make some statement handle attributes (such as `NAME` and `TYPE`) unavailable if they have not already been accessed (and thus cached).

The `finish` method does not affect the transaction status of the database connection. It has nothing to do with transactions. It's mostly an internal "housekeeping" method that is rarely needed. See also "disconnect" and the "Active" attribute.

The `finish` method should have been called `discard_pending_rows`.

rows

```
$rv = $sth->rows;
```

Returns the number of rows affected by the last row affecting command, or -1 if the number of rows is not known or not available.

Generally, you can only rely on a row count after a *non*-`SELECT` `execute` (for some specific operations like `UPDATE` and `DELETE`), or after fetching all the rows of a `SELECT` statement.

For `SELECT` statements, it is generally not possible to know how many rows will be returned except by fetching them all. Some drivers will return the number of rows the application has fetched so far, but others may return -1 until all rows have been fetched. So use of the `rows` method or `$DBI::rows` with `SELECT` statements is not recommended.

One alternative method to get a row count for a `SELECT` is to execute a "SELECT COUNT(*) FROM ..." SQL statement with the same "..." as your query and then fetch the row count from that.

bind_col

```
$rc = $sth->bind_col($column_number, \$var_to_bind);
$rc = $sth->bind_col($column_number, \$var_to_bind, \%attr );
$rc = $sth->bind_col($column_number, \$var_to_bind, $bind_type );
```

Binds a Perl variable and/or some attributes to an output column (field) of a `SELECT` statement. Column numbers count up from 1. You do not need to bind output columns in order to fetch data. For maximum portability between drivers, bind_col() should be called after execute() and not before. See also "bind_columns" for an example.

The binding is performed at a low level using Perl aliasing. Whenever a row is fetched from the database $var_to_bind appears to be automatically updated simply because it now refers to the same memory location as the corresponding column value. This makes using bound variables very efficient. Binding a tied variable doesn't work, currently.

The "bind_param" method performs a similar, but opposite, function for input variables.

Data Types for Column Binding

The `\%attr` parameter can be used to hint at the data type formatting the column should have. For example, you can use:

```
$sth->bind_col(1, undef, { TYPE => SQL_DATETIME });
```

to specify that you'd like the column (which presumably is some kind of datetime type) to be returned in the standard format for SQL_DATETIME, which is 'YYYY-MM-DD HH:MM:SS', rather than the native formatting the database would normally use.

There's no $var_to_bind in that example to emphasize the point that bind_col() works on the underlying column and not just a particular bound variable.

As a short-cut for the common case, the data type can be passed directly, in place of the `\%attr` hash reference. This example is equivalent to the one above:

```
$sth->bind_col(1, undef, SQL_DATETIME);
```

The TYPE value indicates the standard (non-driver-specific) type for this parameter. To specify the driver-specific type, the driver may support a driver-specific attribute, such as `{ ora_type => 97 }`.

The SQL_DATETIME and other related constants can be imported using

```
use DBI qw(:sql_types);
```

See "DBI Constants" for more information.

Few drivers support specifying a data type via a `bind_col` call (most will simply ignore the data type). Fewer still allow the data type to be altered once set. If you do set a column type the type should remain sticky through further calls to bind_col for the same column if the type is not overridden (this is important for instance when you are using a slice in fetchall_arrayref).

The TYPE attribute for bind_col() was first specified in DBI 1.41.

From DBI 1.611, drivers can use the TYPE attribute to attempt to cast the bound scalar to a perl type which more closely matches TYPE. At present DBI supports `SQL_INTEGER`, `SQL_DOUBLE` and `SQL_NUMERIC`. See "sql_type_cast" for details of how types are cast.

Other attributes for Column Binding

The `\%attr` parameter may also contain the following attributes:

- `StrictlyTyped`

  If a TYPE attribute is passed to bind_col, then the driver will attempt to change the bound perl scalar to match the type more closely. If the bound value cannot be cast to the requested TYPE then by default it is left untouched and no error is generated. If you specify `StrictlyTyped` as 1 and the cast fails, this will generate an error.

  This attribute was first added in DBI 1.611. When 1.611 was released few drivers actually supported this attribute but DBD::Oracle and DBD::ODBC should from versions 1.24.

- `DiscardString`

  When the TYPE attribute is passed to "bind_col" and the driver successfully casts the bound perl scalar to a non-string type then if `DiscardString` is set to 1, the string portion of the scalar will be discarded. By default, `DiscardString` is not set.

  This attribute was first added in DBI 1.611. When 1.611 was released few drivers actually supported this attribute but DBD::Oracle and DBD::ODBC should from versions 1.24.

bind_columns

```
$rc = $sth->bind_columns(@list_of_refs_to_vars_to_bind);
```

Calls “bind_col” for each column of the SELECT statement.

The list of references should have the same number of elements as the number of columns in the SELECT statement. If it doesn’t then bind_columns will bind the elements given, up to the number of columns, and then return an error.

For maximum portability between drivers, bind_columns() should be called after execute() and not before.

For example:

```
$dbh->{RaiseError} = 1; # do this, or check every call for errors
$sth = $dbh->prepare(q{ SELECT region, sales FROM sales_by_region }
 ↪);
$sth->execute;
my ($region, $sales);

# Bind Perl variables to columns:
$rv = $sth->bind_columns(\$region, \$sales);

# you can also use Perl's \(...) syntax (see perlref docs):
#     $sth->bind_columns(\($region, $sales));

# Column binding is the most efficient way to fetch data
while ($sth->fetch) {
    print "$region: $sales\n";
}
```

For compatibility with old scripts, the first parameter will be ignored if it is undef or a hash reference.

Here’s a more fancy example that binds columns to the values *inside* a hash (thanks to H.Merijn Brand):

```
$sth->execute;
my %row;
$sth->bind_columns (\( @row{ @{$sth->{NAME_lc} }} ));
while ($sth->fetch) {
    print "$row{region}: $row{sales}\n";
}
```

but has a small drawback: If the data has already been fetched, the call to “bind_columns” will flush current values. If you want to bind_columns after you have fetched, you can use:

```
use feature "refaliasing";
no warnings "experimental::refaliasing";
while (my $row = $sth->fetchrow_arrayref) {
    \(@$data{ $sth->{NAME_lc}->@* }) =  \(@$row);
}
```

or, with older perl versions:

```
use Data::Alias;
alias @$data{ $sth->{NAME_lc}->@* } =  @$row;
```

This is useful in situations when you have many left joins, but want to join your %$data hash to only subset of fetched values.

dump_results

```
$rows = $sth->dump_results($maxlen, $lsep, $fsep, $fh);
```

Fetches all the rows from `$sth`, calls `DBI::neat_list` for each row, and prints the results to `$fh` (defaults to `STDOUT`) separated by `$lsep` (default `"\n"`). `$fsep` defaults to `", "` and `$maxlen` defaults to 35.

This method is designed as a handy utility for prototyping and testing queries. Since it uses "neat_list" to format and edit the string for reading by humans, it is not recommended for data transfer applications.

Statement Handle Attributes

This section describes attributes specific to statement handles. Most of these attributes are read-only.

Changes to these statement handle attributes do not affect any other existing or future statement handles.

Attempting to set or get the value of an unknown attribute generates a warning, except for private driver specific attributes (which all have names starting with a lowercase letter).

Example:

```
... = $h->{NUM_OF_FIELDS};    # get/read
```

Some drivers cannot provide valid values for some or all of these attributes until after `$sth->execute` has been successfully called. Typically the attribute will be `undef` in these situations.

Some attributes, like NAME, are not appropriate to some types of statement, like SELECT. Typically the attribute will be `undef` in these situations.

For drivers which support stored procedures and multiple result sets (see "more_results") these attributes relate to the *current* result set.

See also "finish" to learn more about the effect it may have on some attributes.

NUM_OF_FIELDS

Type: integer, read-only

Number of fields (columns) in the data the prepared statement may return. Statements that don't return rows of data, like `DELETE` and `CREATE` set `NUM_OF_FIELDS` to 0 (though it may be undef in some drivers).

NUM_OF_PARAMS

Type: integer, read-only

The number of parameters (placeholders) in the prepared statement. See SUBSTITUTION VARIABLES below for more details.

NAME

Type: array-ref, read-only

Returns a reference to an array of field names for each column. The names may contain spaces but should not be truncated or have any trailing space. Note that the names have the letter case (upper, lower or mixed) as returned by the driver being used. Portable applications should use "NAME_lc" or "NAME_uc".

```
print "First column name: $sth->{NAME}->[0]\n";
```

Also note that the name returned for (aggregate) functions like `count(*)` or `max(c_foo)` is determined by the database server and not by `DBI` or the `DBD` backend.

NAME_lc

Type: array-ref, read-only

Like `/NAME` but always returns lowercase names.

NAME_uc

Type: array-ref, read-only

Like `/NAME` but always returns uppercase names.

NAME_hash

Type: hash-ref, read-only

NAME_lc_hash

Type: hash-ref, read-only

NAME_uc_hash

Type: hash-ref, read-only

The `NAME_hash`, `NAME_lc_hash`, and `NAME_uc_hash` attributes return column name information as a reference to a hash.

The keys of the hash are the names of the columns. The letter case of the keys corresponds to the letter case returned by the `NAME`, `NAME_lc`, and `NAME_uc` attributes respectively (as described above).

The value of each hash entry is the perl index number of the corresponding column (counting from 0). For example:

```
$sth = $dbh->prepare("select Id, Name from table");
$sth->execute;
@row = $sth->fetchrow_array;
print "Name $row[ $sth->{NAME_lc_hash}{name} ]\n";
```

TYPE

Type: array-ref, read-only

Returns a reference to an array of integer values for each column. The value indicates the data type of the corresponding column.

The values correspond to the international standards (ANSI X3.135 and ISO/IEC 9075) which, in general terms, means ODBC. Driver-specific types that don't exactly match standard types should generally return the same values as an ODBC driver supplied by the makers of the database. That might include private type numbers in ranges the vendor has officially registered with the ISO working group:

```
ftp://sqlstandards.org/SC32/SQL_Registry/
```

Where there's no vendor-supplied ODBC driver to be compatible with, the DBI driver can use type numbers in the range that is now officially reserved for use by the DBI: -9999 to -9000.

All possible values for `TYPE` should have at least one entry in the output of the `type_info_all` method (see "type_info_all").

PRECISION

Type: array-ref, read-only

Returns a reference to an array of integer values for each column.

For numeric columns, the value is the maximum number of digits (without considering a sign character or decimal point). Note that the "display size" for floating point types (REAL, FLOAT, DOUBLE) can be up to 7 characters greater than the precision (for the sign + decimal point + the letter E + a sign + 2 or 3 digits).

For any character type column the value is the OCTET_LENGTH, in other words the number of bytes, not characters.

(More recent standards refer to this as COLUMN_SIZE but we stick with PRECISION for backwards compatibility.)

SCALE

Type: array-ref, read-only

Returns a reference to an array of integer values for each column. NULL (`undef`) values indicate columns where scale is not applicable.

NULLABLE

Type: array-ref, read-only

Returns a reference to an array indicating the possibility of each column returning a null. Possible values are `0` (or an empty string) = no, 1 = yes, 2 = unknown.

```
print "First column may return NULL\n" if $sth->{NULLABLE}->[0];
```

CursorName

Type: string, read-only

Returns the name of the cursor associated with the statement handle, if available. If not available or if the database driver does not support the "`where current of ...`" SQL syntax, then it returns `undef`.

Database

Type: dbh, read-only

Returns the parent $dbh of the statement handle.

Statement

Type: string, read-only

Returns the statement string passed to the “prepare” method.

ParamValues

Type: hash ref, read-only

Returns a reference to a hash containing the values currently bound to placeholders. The keys of the hash are the ‘names’ of the placeholders, typically integers starting at 1. Returns undef if not supported by the driver.

See “ShowErrorStatement” for an example of how this is used.

* Keys:

If the driver supports `ParamValues` but no values have been bound yet then the driver should return a hash with placeholders names in the keys but all the values undef, but some drivers may return a ref to an empty hash because they can’t pre-determine the names.

It is possible that the keys in the hash returned by `ParamValues` are not exactly the same as those implied by the prepared statement. For example, DBD::Oracle translates ‘?’ placeholders into ‘:pN’ where N is a sequence number starting at 1 with a hard limit of 99999.

* Values:

It is possible that the values in the hash returned by `ParamValues` are not *exactly* the same as those passed to bind_param() or execute(). The driver may have slightly modified values in some way based on the TYPE the value was bound with. For example a

floating point value bound as an SQL_INTEGER type may be returned as an integer. The values returned by `ParamValues` can be passed to another bind_param() method with the same TYPE and will be seen by the database as the same value. See also "ParamTypes" below.

The `ParamValues` attribute was added in DBI 1.28.

ParamTypes

Type: hash ref, read-only

Returns a reference to a hash containing the type information currently bound to placeholders. Returns undef if not supported by the driver.

* Keys:

See "ParamValues" above.

* Values:

The hash values are hashrefs of type information in the same form as that passed to the various bind_param() methods (See "bind_param" for the format and values).

It is possible that the values in the hash returned by `ParamTypes` are not exactly the same as those passed to bind_param() or execute(). Param attributes specified using the abbreviated form, like this:

```
$sth->bind_param(1, SQL_INTEGER);
```

are returned in the expanded form, as if called like this:

```
$sth->bind_param(1, { TYPE => SQL_INTEGER });
```

The driver may have modified the type information in some way based on the bound values, other hints provided by the prepare()'d SQL statement, or alternate type mappings required by the driver or target database system. The driver may also add private keys (with names beginning with the drivers reserved prefix, e.g., odbc_xxx).

* Example:

The keys and values in the returned hash can be passed to the various bind_param() methods to effectively reproduce a previous param binding. For example:

```
# assuming $sth1 is a previously prepared statement handle
my $sth2 = $dbh->prepare( $sth1->{Statement} );
my $ParamValues = $sth1->{ParamValues} || {};
my $ParamTypes  = $sth1->{ParamTypes}  || {};
$sth2->bind_param($_, $ParamValues->{$_}, $ParamTypes->{$_})
  for keys %{ {%$ParamValues, %$ParamTypes} };
$sth2->execute();
```

The `ParamTypes` attribute was added in DBI 1.49. Implementation is the responsibility of individual drivers; the DBI layer default implementation simply returns undef.

ParamArrays

Type: hash ref, read-only

Returns a reference to a hash containing the values currently bound to placeholders with "execute_array" or "bind_param_array". The keys of the hash are the 'names' of the placeholders, typically integers starting at 1. Returns undef if not supported by the driver or no arrays of parameters are bound.

Each key value is an array reference containing a list of the bound parameters for that column.

For example:

```
$sth = $dbh->prepare("INSERT INTO staff (id, name) values (?,?)");
$sth->execute_array({},[1,2], ['fred','dave']);
if ($sth->{ParamArrays}) {
    foreach $param (keys %{$sth->{ParamArrays}}) {
        printf "Parameters for %s : %s\n", $param,
        join(",", @{$sth->{ParamArrays}->{$param}});
    }
}
```

It is possible that the values in the hash returned by `ParamArrays` are not *exactly* the same as those passed to "bind_param_array" or "execute_array". The driver may have slightly modified values in some way based on the TYPE the value was bound with. For example a floating point value bound as an SQL_INTEGER type may be returned as an integer.

It is also possible that the keys in the hash returned by `ParamArrays` are not exactly the same as those implied by the prepared statement. For example, DBD::Oracle translates '?' placeholders into ':pN' where N is a sequence number starting at 1 with a hard limit of 99999.

RowsInCache

Type: integer, read-only

If the driver supports a local row cache for `SELECT` statements, then this attribute holds the number of un-fetched rows in the cache. If the driver doesn't, then it returns `undef`. Note that some drivers pre-fetch rows on execute, whereas others wait till the first fetch.

See also the "RowCacheSize" database handle attribute.

FURTHER INFORMATION

Catalog Methods

An application can retrieve metadata information from the DBMS by issuing appropriate queries on the views of the Information Schema. Unfortunately, `INFORMATION_SCHEMA` views are seldom supported by the DBMS. Special methods (catalog methods) are available to return result sets for a small but important portion of that metadata:

```
column_info
foreign_key_info
primary_key_info
table_info
statistics_info
```

All catalog methods accept arguments in order to restrict the result sets. Passing `undef` to an optional argument does not constrain the search for that argument. However, an empty string ('') is treated as a regular search criteria and will only match an empty value.

Note: SQL/CLI and ODBC differ in the handling of empty strings. An empty string will not restrict the result set in SQL/CLI.

Most arguments in the catalog methods accept only *ordinary values*, e.g. the arguments of `primary_key_info()`. Such arguments are treated as a literal string, i.e. the case is significant and quote characters are taken literally.

Some arguments in the catalog methods accept *search patterns* (strings containing '_' and/or '%'), e.g. the `$table` argument of `column_info()`. Passing '%' is equivalent to leaving the argument `undef`.

Caveat: The underscore ('_') is valid and often used in SQL identifiers. Passing such a value to a search pattern argument may return more rows than expected! To include pattern characters as literals, they must be preceded by an escape character which can be achieved with

```
$esc = $dbh->get_info( 14 );  # SQL_SEARCH_PATTERN_ESCAPE
$search_pattern =~ s/([_%])/$esc$1/g;
```

The ODBC and SQL/CLI specifications define a way to change the default behaviour described above: All arguments (except *list value arguments*) are treated as *identifier* if the `SQL_ATTR_METADATA_ID` attribute is set to `SQL_TRUE`. *Quoted identifiers* are very similar to *ordinary values*, i.e. their body (the string within the quotes) is interpreted literally. *Unquoted identifiers* are compared in UPPERCASE.

The DBI (currently) does not support the `SQL_ATTR_METADATA_ID` attribute, i.e. it behaves like an ODBC driver where `SQL_ATTR_METADATA_ID` is set to `SQL_FALSE`.

Transactions

Transactions are a fundamental part of any robust database system. They protect against errors and database corruption by ensuring that sets of related changes to the database take place in atomic (indivisible, all-or-nothing) units.

This section applies to databases that support transactions and where `AutoCommit` is off. See "AutoCommit" for details of using `AutoCommit` with various types of databases.

The recommended way to implement robust transactions in Perl applications is to enable "RaiseError" and catch the error that's 'thrown' as an exception. For example, using Try::Tiny:

```
use Try::Tiny;
$dbh->{AutoCommit} = 0;  # enable transactions, if possible
```

(continues on next page)

(continued from previous page)

```
$dbh->{RaiseError} = 1;
try {
    foo(...)        # do lots of work here
    bar(...)        # including inserts
    baz(...)        # and updates
    $dbh->commit;   # commit the changes if we get this far
} catch {
    warn "Transaction aborted because $_"; # Try::Tiny copies $@ into $_
    # now rollback to undo the incomplete changes
    # but do it in an eval{} as it may also fail
    eval { $dbh->rollback };
    # add other application on-error-clean-up code here
};
```

If the `RaiseError` attribute is not set, then DBI calls would need to be manually checked for errors, typically like this:

```
$h->method(@args) or die $h->errstr;
```

With `RaiseError` set, the DBI will automatically `die` if any DBI method call on that handle (or a child handle) fails, so you don't have to test the return value of each method call. See "RaiseError" for more details.

A major advantage of the `eval` approach is that the transaction will be properly rolled back if *any* code (not just DBI calls) in the inner application dies for any reason. The major advantage of using the `$h->{RaiseError}` attribute is that all DBI calls will be checked automatically. Both techniques are strongly recommended.

After calling `commit` or `rollback` many drivers will not let you fetch from a previously active `SELECT` statement handle that's a child of the same database handle. A typical way round this is to connect the the database twice and use one connection for `SELECT` statements.

See "AutoCommit" and "disconnect" for other important information about transactions.

Handling BLOB / LONG / Memo Fields

Many databases support "blob" (binary large objects), "long", or similar datatypes for holding very long strings or large amounts of binary data in a single field. Some databases support variable length long values over 2,000,000,000 bytes in length.

Since values of that size can't usually be held in memory, and because databases can't usually know in advance the length of the longest long that will be returned from a `SELECT` statement (unlike other data types), some special handling is required.

In this situation, the value of the `$h->{LongReadLen}` attribute is used to determine how much buffer space to allocate when fetching such fields. The `$h->{LongTruncOk}` attribute is used to determine how to behave if a fetched value can't fit into the buffer.

See the description of "LongReadLen" for more information.

When trying to insert long or binary values, placeholders should be used since there are often limits on the maximum size of an `INSERT` statement and the "quote" method

generally can't cope with binary data. See "Placeholders and Bind Values".

Simple Examples

Here's a complete example program to select and fetch some data:

```
my $data_source = "dbi::DriverName:db_name";
my $dbh = DBI->connect($data_source, $user, $password)
    or die "Can't connect to $data_source: $DBI::errstr";

my $sth = $dbh->prepare( q{
        SELECT name, phone
        FROM mytelbook
}) or die "Can't prepare statement: $DBI::errstr";

my $rc = $sth->execute
    or die "Can't execute statement: $DBI::errstr";

print "Query will return $sth->{NUM_OF_FIELDS} fields.\n\n";
print "Field names: @{ $sth->{NAME} }\n";

while (($name, $phone) = $sth->fetchrow_array) {
    print "$name: $phone\n";
}
# check for problems which may have terminated the fetch early
die $sth->errstr if $sth->err;

$dbh->disconnect;
```

Here's a complete example program to insert some data from a file. (This example uses `RaiseError` to avoid needing to check each call).

```
my $dbh = DBI->connect("dbi:DriverName:db_name", $user, $password, {
    RaiseError => 1, AutoCommit => 0
});

my $sth = $dbh->prepare( q{
    INSERT INTO table (name, phone) VALUES (?, ?)
});

open FH, "<phone.csv" or die "Unable to open phone.csv: $!";
while (<FH>) {
    chomp;
    my ($name, $phone) = split /,/;
    $sth->execute($name, $phone);
}
close FH;

$dbh->commit;
$dbh->disconnect;
```

Here's how to convert fetched NULLs (undefined values) into empty strings:

```
while($row = $sth->fetchrow_arrayref) {
  # this is a fast and simple way to deal with nulls:
  $_ //= '' for @$row;
  print "@$row\n";
}
```

The q{...} style quoting used in these examples avoids clashing with quotes that may be used in the SQL statement. Use the double-quote like qq{...} operator if you want to interpolate variables into the string. See *"Quote and Quote-like Operators" in perlop* for more details.

Threads and Thread Safety

Perl 5.7 and later support a new threading model called iThreads. (The old "5.005 style" threads are not supported by the DBI.)

In the iThreads model each thread has its own copy of the perl interpreter. When a new thread is created the original perl interpreter is 'cloned' to create a new copy for the new thread.

If the DBI and drivers are loaded and handles created before the thread is created then it will get a cloned copy of the DBI, the drivers and the handles.

However, the internal pointer data within the handles will refer to the DBI and drivers in the original interpreter. Using those handles in the new interpreter thread is not safe, so the DBI detects this and croaks on any method call using handles that don't belong to the current thread (except for DESTROY).

Because of this (possibly temporary) restriction, newly created threads must make their own connections to the database. Handles can't be shared across threads.

But BEWARE, some underlying database APIs (the code the DBD driver uses to talk to the database, often supplied by the database vendor) are not thread safe. If it's not thread safe, then allowing more than one thread to enter the code at the same time may cause subtle/serious problems. In some cases allowing more than one thread to enter the code, even if *not* at the same time, can cause problems. You have been warned.

Using DBI with perl threads is not yet recommended for production environments. For more information see https://www.perlmonks.org/index.pl?node_id=288022

Signal Handling and Canceling Operations

[The following only applies to systems with unix-like signal handling. I'd welcome additions for other systems, especially Windows.]

Beginning in perl 5.8.0 perl implements 'safe' signal handling if your system has the POSIX sigaction() routine. Now when a signal is delivered perl just makes a note of it but does *not* run the

Although this change made signal handling safe, it also lead to a problem with signals being deferred for longer than you'd like. If a signal arrived while executing a system call, such as waiting for data on a network connection, the signal is noted and then the system call that was executing returns with an EINTR error code to indicate that it was interrupted. All fine so far.

The problem comes when the code that made the system call sees the EINTR code and decides it's going to call it again. Perl doesn't do that, but database code sometimes does. If that happens then the signal handler doesn't get called until later. Maybe much later.

Fortunately there are ways around this which we'll discuss below. Unfortunately they make signals unsafe again.

The two most common uses of signals in relation to the DBI are for canceling operations when the user types Ctrl-C (interrupt), and for implementing a timeout using `alarm()` and `$SIG{ALRM}`.

- Cancel

  The DBI provides a `cancel` method for statement handles. The `cancel` method should abort the current operation and is designed to be called from a signal handler. For example:

```
$SIG{INT} = sub { $sth->cancel };
```

  However, few drivers implement this (the DBI provides a default method that just returns `undef`) and, even if implemented, there is still a possibility that the statement handle, and even the parent database handle, will not be usable afterwards.

  If `cancel` returns true, then it has successfully invoked the database engine's own cancel function. If it returns false, then `cancel` failed. If it returns `undef`, then the database driver does not have cancel implemented - very few do.

- Timeout

  The traditional way to implement a timeout is to set `$SIG{ALRM}` to refer to some code that will be executed when an ALRM signal arrives and then to call alarm($seconds) to schedule an ALRM signal to be delivered $seconds in the future. For example:

```
my $failed;
eval {
  local $SIG{ALRM} = sub { die "TIMEOUT\n" }; # N.B. \n required
  eval {
    alarm($seconds);
    ... code to execute with timeout here (which may die) ...
    1;
  } or $failed = 1;
  # outer eval catches alarm that might fire JUST before this
 ↪alarm(0)
  alarm(0);  # cancel alarm (if code ran fast)
  die "$@" if $failed;
  1;
} or $failed = 1;
if ( $failed ) {
  if ( defined $@ and $@ eq "TIMEOUT\n" ) { ... }
  else { ... } # some other error
}
```

  The first (outer) eval is used to avoid the unlikely but possible chance that the "code to execute" dies and the alarm fires before it is cancelled. Without the outer eval,

if this happened your program will die if you have no ALRM handler or a non-local alarm handler will be called.

Unfortunately, as described above, this won't always work as expected, depending on your perl version and the underlying database code.

With Oracle for instance (DBD::Oracle), if the system which hosts the database is down the DBI->connect() call will hang for several minutes before returning an error.

The solution on these systems is to use the `POSIX::sigaction()` routine to gain low level access to how the signal handler is installed.

The code would look something like this (for the DBD-Oracle connect()):

```
use POSIX qw(:signal_h);

my $mask = POSIX::SigSet->new( SIGALRM ); # signals to mask in the
↪handler
my $action = POSIX::SigAction->new(
    sub { die "connect timeout\n" },        # the handler code ref
    $mask,
    # not using (perl 5.8.2 and later) 'safe' switch or sa_flags
);
my $oldaction = POSIX::SigAction->new();
sigaction( SIGALRM, $action, $oldaction );
my $dbh;
my $failed;
eval {
   eval {
     alarm(5); # seconds before time out
     $dbh = DBI->connect("dbi:Oracle:$dsn" ... );
     1;
   } or $failed = 1;
   alarm(0); # cancel alarm (if connect worked fast)
   die "$@\n" if $failed; # connect died
   1;
} or $failed = 1;
sigaction( SIGALRM, $oldaction );  # restore original signal handler
if ( $failed ) {
  if ( defined $@ and $@ eq "connect timeout\n" ) {...}
  else { # connect died }
}
```

See previous example for the reasoning around the double eval.

Similar techniques can be used for canceling statement execution.

Unfortunately, this solution is somewhat messy.

For a cleaner implementation that works across perl versions, see Lincoln Baxter's Sys::SigAction module at Sys::SigAction. The documentation for Sys::SigAction includes an longer discussion of this problem, and a DBD::Oracle test script.

Be sure to read all the signal handling sections of the perlipc manual.

And finally, two more points to keep firmly in mind. Firstly, remember that what we've done here is essentially revert to old style *unsafe* handling of these signals. So do as little as possible in the handler. Ideally just die(). Secondly, the handles in use at the time the signal is handled may not be safe to use afterwards.

Subclassing the DBI

DBI can be subclassed and extended just like any other object oriented module. Before we talk about how to do that, it's important to be clear about the various DBI classes and how they work together.

By default `$dbh = DBI->connect(...)` returns a $dbh blessed into the `DBI::db` class. And the `$dbh->prepare` method returns an $sth blessed into the `DBI::st` class (actually it simply changes the last four characters of the calling handle class to be `::st`).

The leading 'DBI' is known as the 'root class' and the extra '::db' or '::st' are the 'handle type suffixes'. If you want to subclass the DBI you'll need to put your overriding methods into the appropriate classes. For example, if you want to use a root class of `MySubDBI` and override the do(), prepare() and execute() methods, then your do() and prepare() methods should be in the `MySubDBI::db` class and the execute() method should be in the `MySubDBI::st` class.

To setup the inheritance hierarchy the @ISA variable in `MySubDBI::db` should include `DBI::db` and the @ISA variable in `MySubDBI::st` should include `DBI::st`. The `MySubDBI` root class itself isn't currently used for anything visible and so, apart from setting @ISA to include `DBI`, it can be left empty.

So, having put your overriding methods into the right classes, and setup the inheritance hierarchy, how do you get the DBI to use them? You have two choices, either a static method call using the name of your subclass:

```
$dbh = MySubDBI->connect(...);
```

or specifying a `RootClass` attribute:

```
$dbh = DBI->connect(..., { RootClass => 'MySubDBI' });
```

If both forms are used then the attribute takes precedence.

The only differences between the two are that using an explicit RootClass attribute will a) make the DBI automatically attempt to load a module by that name if the class doesn't exist, and b) won't call your MySubDBI::connect() method, if you have one.

When subclassing is being used then, after a successful new connect, the DBI->connect method automatically calls:

```
$dbh->connected($dsn, $user, $pass, \%attr);
```

The default method does nothing. The call is made just to simplify any post-connection setup that your subclass may want to perform. The parameters are the same as passed to DBI->connect. If your subclass supplies a connected method, it should be part of the MySubDBI::db package.

One more thing to note: you must let the DBI do the handle creation. If you want to override the connect() method in your *::dr class then it must still call SUPER::connect

to get a $dbh to work with. Similarly, an overridden prepare() method in *::db must still call SUPER::prepare to get a $sth. If you try to create your own handles using bless() then you'll find the DBI will reject them with an "is not a DBI handle (has no magic)" error.

Here's a brief example of a DBI subclass. A more thorough example can be found in `t/subclass.t` in the DBI distribution.

```
package MySubDBI;

use strict;

use DBI;
our @ISA = qw(DBI);

package MySubDBI::db;
our @ISA = qw(DBI::db);

sub prepare {
  my ($dbh, @args) = @_;
  my $sth = $dbh->SUPER::prepare(@args)
      or return;
  $sth->{private_mysubdbi_info} = { foo => 'bar' };
  return $sth;
}

package MySubDBI::st;
our @ISA = qw(DBI::st);

sub fetch {
  my ($sth, @args) = @_;
  my $row = $sth->SUPER::fetch(@args)
      or return;
  do_something_magical_with_row_data($row)
      or return $sth->set_err(1234, "The magic failed", undef,
 ↪"fetch");
  return $row;
}
```

When calling a SUPER::method that returns a handle, be careful to check the return value before trying to do other things with it in your overridden method. This is especially important if you want to set a hash attribute on the handle, as Perl's autovivification will bite you by (in)conveniently creating an unblessed hashref, which your method will then return with usually baffling results later on like the error "dbih_getcom handle HASH(0xa4451a8) is not a DBI handle (has no magic)". It's best to check right after the call and return undef immediately on error, just like DBI would and just like the example above.

If your method needs to record an error it should call the set_err() method with the error code and error string, as shown in the example above. The error code and error string will be recorded in the handle and available via `$h->err` and `$DBI::errstr` etc. The set_err() method always returns an undef or empty list as appropriate. Since your method should nearly always return an undef or empty list as soon as an error

is detected it's handy to simply return what set_err() returns, as shown in the example above.

If the handle has `RaiseError`, `PrintError`, or `HandleError` etc. set then the set_err() method will honour them. This means that if `RaiseError` is set then set_err() won't return in the normal way but will 'throw an exception' that can be caught with an `eval` block.

You can stash private data into DBI handles via `$h->{private_...*}`. See the entry under "ATTRIBUTES COMMON TO ALL HANDLES" for info and important caveats.

Memory Leaks

When tracking down memory leaks using tools like Devel::Leak you'll find that some DBI internals are reported as 'leaking' memory. This is very unlikely to be a real leak. The DBI has various caches to improve performance and the apparent leaks are simply the normal operation of these caches.

The most frequent sources of the apparent leaks are "ChildHandles", "prepare_cached" and "connect_cached".

For example http://stackoverflow.com/questions/13338308/perl-dbi-memory-leak

Given how widely the DBI is used, you can rest assured that if a new release of the DBI did have a real leak it would be discovered, reported, and fixed immediately. The leak you're looking for is probably elsewhere. Good luck!

TRACING

The DBI has a powerful tracing mechanism built in. It enables you to see what's going on 'behind the scenes', both within the DBI and the drivers you're using.

Trace Settings

Which details are written to the trace output is controlled by a combination of a *trace level*, an integer from 0 to 15, and a set of *trace flags* that are either on or off. Together these are known as the *trace settings* and are stored together in a single integer. For normal use you only need to set the trace level, and generally only to a value between 1 and 4.

Each handle has its own trace settings, and so does the DBI. When you call a method the DBI merges the handles settings into its own for the duration of the call: the trace flags of the handle are OR'd into the trace flags of the DBI, and if the handle has a higher trace level then the DBI trace level is raised to match it. The previous DBI trace settings are restored when the called method returns.

Trace Levels

Trace *levels* are as follows:

```
0 - Trace disabled.
1 - Trace top-level DBI method calls returning with results or␣
 ↪errors.
```

(continues on next page)

(continued from previous page)

```
2 - As above, adding tracing of top-level method entry with␣
 ↪parameters.
3 - As above, adding some high-level information from the driver
    and some internal information from the DBI.
4 - As above, adding more detailed information from the driver.
    This is the first level to trace all the rows being fetched.
5 to 15 - As above but with more and more internal information.
```

Trace level 1 is best for a simple overview of what's happening. Trace levels 2 thru 4 a good choice for general purpose tracing. Levels 5 and above are best reserved for investigating a specific problem, when you need to see "inside" the driver and DBI.

The trace output is detailed and typically very useful. Much of the trace output is formatted using the "neat" function, so strings in the trace output may be edited and truncated by that function.

Trace Flags

Trace *flags* are used to enable tracing of specific activities within the DBI and drivers. The DBI defines some trace flags and drivers can define others. DBI trace flag names begin with a capital letter and driver specific names begin with a lowercase letter, as usual.

Currently the DBI defines these trace flags:

```
ALL - turn on all DBI and driver flags (not recommended)
SQL - trace SQL statements executed
      (not yet implemented in DBI but implemented in some DBDs)
CON - trace connection process
ENC - trace encoding (unicode translations etc)
      (not yet implemented in DBI but implemented in some DBDs)
DBD - trace only DBD messages
      (not implemented by all DBDs yet)
TXN - trace transactions
      (not implemented in all DBDs yet)
```

The "parse_trace_flags" and "parse_trace_flag" methods are used to convert trace flag names into the corresponding integer bit flags.

Enabling Trace

The `$h->trace` method sets the trace settings for a handle and `DBI->trace` does the same for the DBI.

In addition to the "trace" method, you can enable the same trace information, and direct the output to a file, by setting the `DBI_TRACE` environment variable before starting Perl. See "DBI_TRACE" for more information.

Finally, you can set, or get, the trace settings for a handle using the `TraceLevel` attribute.

All of those methods use parse_trace_flags() and so allow you set both the trace level and multiple trace flags by using a string containing the trace level and/or flag names

separated by vertical bar ("|") or comma (",") characters. For example:

```
local $h->{TraceLevel} = "3|SQL|foo";
```

Trace Output

Initially trace output is written to STDERR. Both the `$h->trace` and `DBI->trace` methods take an optional $trace_file parameter, which may be either the name of a file to be opened by DBI in append mode, or a reference to an existing writable (possibly layered) filehandle. If $trace_file is a filename, and can be opened in append mode, or $trace_file is a writable filehandle, then *all* trace output (currently including that from other handles) is redirected to that file. A warning is generated if $trace_file can't be opened or is not writable.

Further calls to trace() without $trace_file do not alter where the trace output is sent. If $trace_file is undefined, then trace output is sent to STDERR and, if the prior trace was opened with $trace_file as a filename, the previous trace file is closed; if $trace_file was a filehandle, the filehandle is **not** closed.

NOTE: If $trace_file is specified as a filehandle, the filehandle should not be closed until all DBI operations are completed, or the application has reset the trace file via another call to `trace()` that changes the trace file.

Tracing to Layered Filehandles

NOTE:

- Tied filehandles are not currently supported, as tie operations are not available to the PerlIO methods used by the DBI.

Perl provides the ability to layer various "disciplines" on an open filehandle via the *PerlIO* module.

A simple example of using PerlIO layers is to use a scalar as the output:

```
my $scalar = '';
open( my $fh, "+>:scalar", \$scalar );
$dbh->trace( 2, $fh );
```

Now all trace output is simply appended to $scalar.

A more complex application of tracing to a layered filehandle is the use of a custom layer (_Refer to _Perlio::via *for details on creating custom PerlIO layers.*). Consider an application with the following logger module:

```
package MyFancyLogger;

sub new
{
    my $self = {};
    my $fh;
    open $fh, '>', 'fancylog.log';
    $self->{_fh} = $fh;
```

(continues on next page)

(continued from previous page)

```
    $self->{_buf} = '';
    return bless $self, shift;
}

sub log
{
    my $self = shift;
    return unless exists $self->{_fh};
    my $fh = $self->{_fh};
    $self->{_buf} .= shift;
#
# DBI feeds us pieces at a time, so accumulate a complete line
# before outputting
#
    print $fh "At ", scalar localtime(), ':', $self->{_buf}, "\n"␣
 ↪and
    $self->{_buf} = ''
        if $self->{_buf}=~tr/\n//;
}

sub close {
    my $self = shift;
    return unless exists $self->{_fh};
    my $fh = $self->{_fh};
    print $fh "At ", scalar localtime(), ':', $self->{_buf}, "\n"␣
 ↪and
    $self->{_buf} = ''
        if $self->{_buf};
    close $fh;
    delete $self->{_fh};
}

1;
```

To redirect DBI traces to this logger requires creating a package for the layer:

```
package PerlIO::via::MyFancyLogLayer;

sub PUSHED
{
    my ($class,$mode,$fh) = @_;
    my $logger;
    return bless \$logger,$class;
}

sub OPEN {
    my ($self, $path, $mode, $fh) = @_;
    #
    # $path is actually our logger object
```

(continues on next page)

(continued from previous page)

```
    #
    $$self = $path;
    return 1;
}

sub WRITE
{
    my ($self, $buf, $fh) = @_;
    $$self->log($buf);
    return length($buf);
}

sub CLOSE {
    my $self = shift;
    $$self->close();
    return 0;
}

1;
```

The application can then cause DBI traces to be routed to the logger using

```
use PerlIO::via::MyFancyLogLayer;

open my $fh, '>:via(MyFancyLogLayer)', MyFancyLogger->new();

$dbh->trace('SQL', $fh);
```

Now all trace output will be processed by MyFancyLogger's log() method.

Trace Content

Many of the values embedded in trace output are formatted using the neat() utility function. This means they may be quoted, sanitized, and possibly truncated if longer than `$DBI::neat_maxlen`. See "neat" for more details.

Tracing Tips

You can add tracing to your own application code using the "trace_msg" method.

It can sometimes be handy to compare trace files from two different runs of the same script. However using a tool like `diff` on the original log output doesn't work well because the trace file is full of object addresses that may differ on each run.

The DBI includes a handy utility called dbilogstrip that can be used to 'normalize' the log content. It can be used as a filter like this:

```
DBI_TRACE=2 perl yourscript.pl ...args1... 2>&1 | dbilogstrip >␣
↪dbitrace1.log
DBI_TRACE=2 perl yourscript.pl ...args2... 2>&1 | dbilogstrip >␣
```

(continues on next page)

(continued from previous page)

```
 ↪dbitrace2.log
diff -u dbitrace1.log dbitrace2.log
```

See dbilogstrip for more information.

DBI ENVIRONMENT VARIABLES

The DBI module recognizes a number of environment variables, but most of them should not be used most of the time. It is better to be explicit about what you are doing to avoid the need for environment variables, especially in a web serving system where web servers are stingy about which environment variables are available.

DBI_DSN

The DBI_DSN environment variable is used by DBI->connect if you do not specify a data source when you issue the connect. It should have a format such as "dbi:Driver:databasename".

DBI_DRIVER

The DBI_DRIVER environment variable is used to fill in the database driver name in DBI->connect if the data source string starts "dbi::" (thereby omitting the driver). If DBI_DSN omits the driver name, DBI_DRIVER can fill the gap.

DBI_AUTOPROXY

The DBI_AUTOPROXY environment variable takes a string value that starts "dbi:Proxy:" and is typically followed by "hostname=...;port=...". It is used to alter the behaviour of DBI->connect. For full details, see DBI::Proxy documentation.

DBI_USER

The DBI_USER environment variable takes a string value that is used as the user name if the DBI->connect call is given undef (as distinct from an empty string) as the username argument. Be wary of the security implications of using this.

DBI_PASS

The DBI_PASS environment variable takes a string value that is used as the password if the DBI->connect call is given undef (as distinct from an empty string) as the password argument. Be extra wary of the security implications of using this.

DBI_DBNAME (obsolete)

The DBI_DBNAME environment variable takes a string value that is used only when the obsolescent style of DBI->connect (with driver name as fourth parameter) is used, and when no value is provided for the first (database name) argument.

DBI_TRACE

The DBI_TRACE environment variable specifies the global default trace settings for the DBI at startup. Can also be used to direct trace output to a file. When the DBI is loaded it does:

```
DBI->trace(split /=/, $ENV{DBI_TRACE}, 2) if $ENV{DBI_TRACE};
```

So if DBI_TRACE contains an "=" character then what follows it is used as the name of the file to append the trace to.

output appended to that file. If the name begins with a number followed by an equal sign (=), then the number and the equal sign are stripped off from the name, and the number is used to set the trace level. For example:

```
DBI_TRACE=1=dbitrace.log perl your_test_script.pl
```

On Unix-like systems using a Bourne-like shell, you can do this easily on the command line:

```
DBI_TRACE=2 perl your_test_script.pl
```

See "TRACING" for more information.

PERL_DBI_DEBUG (obsolete)

An old variable that should no longer be used; equivalent to DBI_TRACE.

DBI_PROFILE

The DBI_PROFILE environment variable can be used to enable profiling of DBI method calls. See *DBI::Profile* for more information.

DBI_PUREPERL

The DBI_PUREPERL environment variable can be used to enable the use of DBI::PurePerl. See *DBI::PurePerl* for more information.

WARNING AND ERROR MESSAGES

Fatal Errors

- Can't call method "prepare" without a package or object reference

  The `$dbh` handle you're using to call `prepare` is probably undefined because the preceding `connect` failed. You should always check the return status of DBI methods, or use the "RaiseError" attribute.

- Can't call method "execute" without a package or object reference

  The `$sth` handle you're using to call `execute` is probably undefined because the preceding `prepare` failed. You should always check the return status of DBI methods, or use the "RaiseError" attribute.

- DBI/DBD internal version mismatch

  The DBD driver module was built with a different version of DBI than the one currently being used. You should rebuild the DBD module under the current version of DBI.

  (Some rare platforms require "static linking". On those platforms, there may be an old DBI or DBD driver version actually embedded in the Perl executable being used.)

- DBD driver has not implemented the AutoCommit attribute

  The DBD driver implementation is incomplete. Consult the author.

- Can't [sg]et %s->{%s}: unrecognised attribute

  You attempted to set or get an unknown attribute of a handle. Make sure you have spelled the attribute name correctly; case is significant (e.g., "Autocommit" is not the same as "AutoCommit").

Pure-Perl DBI

A pure-perl emulation of the DBI is included in the distribution for people using pure-perl drivers who, for whatever reason, can't install the compiled DBI. See *DBI::PurePerl*.

SEE ALSO

Driver and Database Documentation

Refer to the documentation for the DBD driver that you are using.

Refer to the SQL Language Reference Manual for the database engine that you are using.

ODBC and SQL/CLI Standards Reference Information

More detailed information about the semantics of certain DBI methods that are based on ODBC and SQL/CLI standards is available on-line via microsoft.com, for ODBC, and www.jtc1sc32.org for the SQL/CLI standard:

```
DBI method         ODBC function     SQL/CLI Working Draft
----------         -------------     ---------------------
column_info        SQLColumns        Page 124
foreign_key_info   SQLForeignKeys    Page 163
get_info           SQLGetInfo        Page 214
primary_key_info   SQLPrimaryKeys    Page 254
table_info         SQLTables         Page 294
type_info          SQLGetTypeInfo    Page 239
statistics_info    SQLStatistics
```

To find documentation on the ODBC function you can browse Microsoft's documentation at:

https://learn.microsoft.com/en-us/sql/odbc/reference/odbc-programmer-s-reference

And for SQL/CLI standard information on SQLColumns you'd read page 124 of the (very large) SQL/CLI Working Draft available from:

https://web.archive.org/web/20071107215745/http://jtc1sc32.org/doc/N0701-0750/32N0744T.pdf

Standards Reference Information

A hyperlinked, browsable version of the BNF syntax for SQL92 (plus Oracle 7 SQL and PL/SQL) is available here:

https://web.archive.org/web/20040212094722/http://cui.unige.ch/db-research/Enseignement/analyseinfo/SQL92/BNFindex.html

You can find more information about SQL standards online by searching for the appropriate standard names and numbers. For example, searching for "ANSI/ISO/IEC International Standard (IS) Database Language SQL - Part 1: SQL/Framework" you'll find a copy at:

ftp://ftp.iks-jena.de/mitarb/lutz/standards/sql/ansi-iso-9075-1-1999.pdf

Books and Articles

Programming the Perl DBI, by Alligator Descartes and Tim Bunce. http://books.perl.org/book/154

Programming Perl 3rd Ed. by Larry Wall, Tom Christiansen & Jon Orwant. http://books.perl.org/book/134

Learning Perl by Randal Schwartz. http://books.perl.org/book/101

Details of many other books related to perl can be found at http://books.perl.org

Perl Modules

Index of DBI related modules available from CPAN:

```
L<https://metacpan.org/search?q=DBD%3A%3A>
L<https://metacpan.org/search?q=DBIx%3A%3A>
L<https://metacpan.org/search?q=DBI>
```

For a good comparison of RDBMS-OO mappers and some OO-RDBMS mappers (including Class::DBI, Alzabo, and DBIx::RecordSet in the former category and Tangram and SPOPS in the latter) see the Perl Object-Oriented Persistence project pages at:

```
http://poop.sourceforge.net
```

A similar page for Java toolkits can be found at:

```
http://c2.com/cgi-bin/wiki?ObjectRelationalToolComparison
```

Mailing List

The *dbi-users* mailing list is the primary means of communication among users of the DBI and its related modules. For details send email to:

```
L<dbi-users-help@perl.org>
```

There are typically between 700 and 900 messages per month. You have to subscribe in order to be able to post. However you can opt for a 'post-only' subscription.

Mailing list archives (of variable quality) are held at:

```
http://groups.google.com/groups?group=perl.dbi.users
http://www.xray.mpe.mpg.de/mailing-lists/dbi/
http://www.mail-archive.com/dbi-users%40perl.org/
```

AUTHORS

DBI by Tim Bunce (1994-2024), The DBI developer group (2024..)

This pod text by Tim Bunce, J. Douglas Dunlop, Jonathan Leffler and others. Perl by Larry Wall and the `perl5-porters`.

COPYRIGHT

The DBI module is Copyright (c) 1994-2024 Tim Bunce. Ireland. The DBI developer group (2024-2024) All rights reserved.

You may distribute under the terms of either the GNU General Public License or the Artistic License, as specified in the Perl 5.12.0 README file.

SUPPORT / WARRANTY

The DBI is free Open Source software. IT COMES WITHOUT WARRANTY OF ANY KIND.

Support

My consulting company, Data Plan Services, offers annual and multi-annual support contracts for the DBI. These provide sustained support for DBI development, and sustained value for you in return. Contact me for details.

Sponsor Enhancements

If your company would benefit from a specific new DBI feature, please consider sponsoring its development. Work is performed rapidly, and usually on a fixed-price payment-on-delivery basis. Contact me for details.

Using such targeted financing allows you to contribute to DBI development, and rapidly get something specific and valuable in return.

ACKNOWLEDGEMENTS

The creator: Tim Bunce!

I would like to acknowledge the valuable contributions of the many people Tim has worked with on the DBI project, especially in the early years (1992-1994). In no particular order: Kevin Stock, Buzz Moschetti, Kurt Andersen, Ted Lemon, William Hails, Garth Kennedy, Michael Peppler, Neil S. Briscoe, Jeff Urlwin, David J. Hughes, Jeff Stander, Forrest D Whitcher, Larry Wall, Jeff Fried, Roy Johnson, Paul Hudson, Georg Rehfeld, Steve Sizemore, Ron Pool, Jon Meek, Tom Christiansen, Steve Baumgarten, Randal Schwartz, and a whole lot more.

Then, of course, there are the poor souls who have struggled through untold and undocumented obstacles to actually implement DBI drivers. Among their ranks are Jochen Wiedmann, Alligator Descartes, Jonathan Leffler, Jeff Urlwin, Michael Peppler, Henrik Tougaard, Edwin Pratomo, Davide Migliavacca, Jan Pazdziora, Peter Haworth, Edmund Mergl, Steve Williams, Thomas Lowery, and Phlip Plumlee. Without them, the DBI would not be the practical reality it is today. I'm also especially grateful to Alligator Descartes for starting work on the first edition of the "Programming the Perl DBI" book and letting me jump on board.

The DBI and DBD::Oracle were originally developed while I was Technical Director (CTO) of the Paul Ingram Group in the UK. So I'd especially like to thank Paul for his generosity and vision in supporting this work for many years.

A couple of specific DBI features have been sponsored by enlightened companies:

The development of the swap_inner_handle() method was sponsored by BizRate.com

The development of DBD::Gofer and related modules was sponsored by Shopzilla.com (https::connexity.com).

After the release of version 1.643, the development was lead by H.Merijn Brand with the help of the DBI team. Thanks to all that added issues, did Pull Requests or helped in any way to keep the DBI healthy.

CONTRIBUTING

As you can see above, many people have contributed to the DBI and drivers in many ways over many years.

If you'd like to help then see `CONTRIBUTING.md`.

If you'd like the DBI to do something new or different then a good way to make that happen is to do it yourself and send me a patch to the source code that shows the changes. (But read "Speak before you patch" below.)

Browsing the source code repository

Use https://github.com/perl5-dbi/dbi

How to create a patch using Git

The DBI source code is maintained using Git. To access the source you'll need to install a Git client. Then, to get the source code, do:

```
git clone https://github.com/perl5-dbi/dbi.git DBI-git
```

The source code will now be available in the new subdirectory `DBI-git`.

When you want to synchronize later, issue the command

```
git pull --all
```

Make your changes, test them, test them again until everything passes. If there are no tests for the new feature you added or a behaviour change, the change should include a new test. Then commit the changes. Either use

```
git gui
```

or

```
git commit -a -m 'Message to my changes'
```

If you get any conflicts reported you'll need to fix them first.

Then generate the patch file to be mailed:

```
git format-patch -1 --attach
```

which will create a file 0001-*.patch (where * relates to the commit message). Read the patch file, as a sanity check, and then email it to dbi-dev@perl.org.

If you have a github account, you can also fork the repository, commit your changes to the forked repository and then do a pull request.

How to create a patch without Git

Unpack a fresh copy of the distribution:

```
wget http://cpan.metacpan.org/authors/id/T/TI/TIMB/DBI-1.627.tar.gz
tar xfz DBI-1.627.tar.gz
```

Rename the newly created top level directory:

```
mv DBI-1.627 DBI-1.627.your_foo
```

Edit the contents of DBI-1.627.your_foo/* till it does what you want.

Test your changes and then remove all temporary files:

```
make test && make distclean
```

Go back to the directory you originally unpacked the distribution:

```
cd ..
```

Unpack *another* copy of the original distribution you started with:

```
tar xfz DBI-1.627.tar.gz
```

Then create a patch file by performing a recursive `diff` on the two top level directories:

```
diff -purd DBI-1.627 DBI-1.627.your_foo > DBI-1.627.your_foo.patch
```

Speak before you patch

For anything non-trivial or possibly controversial it's a good idea to discuss (on dbi-dev@perl.org) the changes you propose before actually spending time working on them. Otherwise you run the risk of them being rejected because they don't fit into some larger plans you may not be aware of.

You can also reach the developers on IRC (chat). If they are on-line, the most likely place to talk to them is the #dbi channel on irc.perl.org

TRANSLATIONS

A German translation of this manual (possibly slightly out of date) is available, thanks to O'Reilly, at:

```
http://www.oreilly.de/catalog/perldbiger/
```

OTHER RELATED WORK AND PERL MODULES

- Apache::DBI

  To be used with the Apache daemon together with an embedded Perl interpreter like `mod_perl`. Establishes a database connection which remains open for the lifetime of the HTTP daemon. This way the CGI connect and disconnect for every database access becomes superfluous.

- SQL Parser

  See also the SQL::Statement module, SQL parser and engine.

DBI::Const::GetInfoReturn

Data and functions for describing GetInfo results

SYNOPSIS

The interface to this module is undocumented and liable to change.

DESCRIPTION

Data and functions for describing GetInfo results

DBI::Const::GetInfoType

Data describing GetInfo type codes

SYNOPSIS

```
use DBI::Const::GetInfoType;
```

DESCRIPTION

Imports a %GetInfoType hash which maps names for GetInfo Type Codes into their corresponding numeric values. For example:

```
$database_version = $dbh->get_info( $GetInfoType{SQL_DBMS_VER} );
```

The interface to this module is new and nothing beyond what is written here is guaranteed.

DBI::DBD

Namespace containing the following modules:

- `DBI::DBD::Metadata` - Generate the code and data for some DBI metadata methods
- `DBI::DBD::SqlEngine` - Base class for DBI drivers without their own SQL engine

DBI::DBD::Metadata

Generate the code and data for some DBI metadata methods

SYNOPSIS

The idea is to extract metadata information from a good quality ODBC driver and use it to generate code and data to use in your own DBI driver for the same database.

To generate code to support the get_info method:

```
perl -MDBI::DBD::Metadata -e "write_getinfo_pm('dbi:ODBC:dsn-name',
↪'user','pass','Driver')"

perl -MDBI::DBD::Metadata -e write_getinfo_pm dbi:ODBC:foo_db␣
↪username password Driver
```

To generate code to support the type_info method:

```
perl -MDBI::DBD::Metadata -e "write_typeinfo_pm('dbi:ODBC:dsn-name',
↪'user','pass','Driver')"

perl -MDBI::DBD::Metadata -e write_typeinfo_pm dbi:ODBC:dsn-name␣
↪user pass Driver
```

Where `dbi:ODBC:dsn-name` is the connection to use to extract the data, and `Driver` is the name of the driver you want the code generated for (the driver name gets embedded into the output in numerous places).

Generating a GetInfo package for a driver

The `write_getinfo_pm` in the DBI::DBD::Metadata module generates a DBD::Driver::GetInfo package on standard output.

This method generates a DBD::Driver::GetInfo package from the data source you specified in the parameter list or in the environment variable DBI_DSN. DBD::Driver::GetInfo should help a DBD author implement the DBI get_info() method. Because you are just creating this package, it is very unlikely that DBD::Driver already provides a good implementation for get_info(). Thus you will probably connect via DBD::ODBC.

Once you are sure that it is producing reasonably sane data, you should typically redirect the standard output to lib/DBD/Driver/GetInfo.pm, and then hand edit the result. Do not forget to update your Makefile.PL and MANIFEST to include this as an extra PM file that should be installed.

If you connect via DBD::ODBC, you should use version 0.38 or greater;

Please take a critical look at the data returned! ODBC drivers vary dramatically in their quality.

The generator assumes that most values are static and places these values directly in the %info hash. A few examples show the use of CODE references and the implementation via subroutines. It is very likely that you will have to write additional subroutines for values depending on the session state or server version, e.g. SQL_DBMS_VER.

A possible implementation of DBD::Driver::db::get_info() may look like:

```
sub get_info {
  my($dbh, $info_type) = @_;
  require DBD::Driver::GetInfo;
  my $v = $DBD::Driver::GetInfo::info{int($info_type)};
  $v = $v->($dbh) if ref $v eq 'CODE';
  return $v;
}
```

Please replace Driver (or "<foo>") with the name of your driver. Note that this stub function is generated for you by write_getinfo_pm function, but you must manually transfer the code to Driver.pm.

Generating a TypeInfo package for a driver

The `write_typeinfo_pm` function in the DBI::DBD::Metadata module generates on standard output the data needed for a driver's type_info_all method. It also provides default implementations of the type_info_all method for inclusion in the driver's main implementation file.

The driver parameter is the name of the driver for which the methods will be generated; for the sake of examples, this will be "Driver". Typically, the dsn parameter will be of the form "dbi:ODBC:odbc_dsn", where the odbc_dsn is a DSN for one of the driver's databases. The user and pass parameters are the other optional connection parameters that will be provided to the DBI connect method.

Once you are sure that it is producing reasonably sane data, you should typically redirect the standard output to lib/DBD/Driver/TypeInfo.pm, and then hand edit the result if necessary. Do not forget to update your Makefile.PL and MANIFEST to include this as an extra PM file that should be installed.

Please take a critical look at the data returned! ODBC drivers vary dramatically in their quality.

The generator assumes that all the values are static and places these values directly in the %info hash.

A possible implementation of DBD::Driver::type_info_all() may look like:

```
sub type_info_all {
  my ($dbh) = @_;
  require DBD::Driver::TypeInfo;
  return [ @$DBD::Driver::TypeInfo::type_info_all ];
}
```

Please replace Driver (or "<foo>") with the name of your driver. Note that this stub function is generated for you by the write_typeinfo_pm function, but you must manually transfer the code to Driver.pm.

DBI::DBD::SqlEngine

Base class for DBI drivers without their own SQL engine

SYNOPSIS

```
package DBD::myDriver;

use base qw(DBI::DBD::SqlEngine);

sub driver {
    ...
    my $drh = $proto->SUPER::driver ($attr);
    ...
    return $drh->{class};
    }

package DBD::myDriver::dr;

our @ISA = qw(DBI::DBD::SqlEngine::dr);

sub data_sources { ... }
...

package DBD::myDriver::db;

our @ISA = qw(DBI::DBD::SqlEngine::db);

sub init_valid_attributes { ... }
sub init_default_attributes { ... }
sub set_versions { ... }
sub validate_STORE_attr { my ($dbh, $attrib, $value) = @_; ... }
sub validate_FETCH_attr { my ($dbh, $attrib) = @_; ... }
sub get_myd_versions { ... }
sub get_avail_tables { ... }

package DBD::myDriver::st;

our @ISA = qw(DBI::DBD::SqlEngine::st);
```

(continues on next page)

(continued from previous page)

```
sub FETCH { ... }
sub STORE { ... }

package DBD::myDriver::Statement;

our @ISA = qw(DBI::DBD::SqlEngine::Statement);

sub open_table { ... }

package DBD::myDriver::Table;

our @ISA = qw(DBI::DBD::SqlEngine::Table);

sub new { ... }
```

DESCRIPTION

DBI::DBD::SqlEngine abstracts the usage of SQL engines from the DBD. DBD authors can concentrate on the data retrieval they want to provide.

It is strongly recommended that you read DBD::File::Developers and DBD::File::Roadmap, because many of the DBD::File API is provided by DBI::DBD::SqlEngine.

Currently the API of DBI::DBD::SqlEngine is experimental and will likely change in the near future to provide the table meta data basics like DBD::File.

DBI::DBD::SqlEngine expects that any driver in inheritance chain has a *DBI prefix*.

Metadata

The following attributes are handled by DBI itself and not by DBI::DBD::SqlEngine, thus they all work as expected:

```
Active
ActiveKids
CachedKids
CompatMode              (Not used)
InactiveDestroy
AutoInactiveDestroy
Kids
PrintError
RaiseError
Warn                    (Not used)
```

The following DBI attributes are handled by DBI::DBD::SqlEngine:

AutoCommit

Always on.

ChopBlanks

Works.

NUM_OF_FIELDS

Valid after `$sth->execute`.

NUM_OF_PARAMS

Valid after `$sth->prepare`.

NAME

Valid after `$sth->execute`; probably undef for Non-Select statements.

NULLABLE

Not really working, always returns an array ref of ones, as DBD::CSV does not verify input data. Valid after `$sth->execute`; undef for non-select statements.

The following DBI attributes and methods are not supported:

- bind_param_inout
- CursorName
- LongReadLen
- LongTruncOk

DBI::DBD::SqlEngine specific attributes

In addition to the DBI attributes, you can use the following dbh attributes:

sql_engine_version

Contains the module version of this driver (**readonly**)

sql_nano_version

Contains the module version of DBI::SQL::Nano (**readonly**)

sql_statement_version

Contains the module version of SQL::Statement, if available (**readonly**)

sql_handler

Contains the SQL Statement engine, either DBI::SQL::Nano or SQL::Statement (**readonly**).

sql_parser_object

Contains an instantiated instance of SQL::Parser (**readonly**). This is filled when used first time (only when used with SQL::Statement).

sql_sponge_driver

Contains an internally used DBD::Sponge handle (**readonly**).

sql_valid_attrs

Contains the list of valid attributes for each DBI::DBD::SqlEngine based driver (**readonly**).

sql_readonly_attrs

Contains the list of those attributes which are readonly (**readonly**).

sql_identifier_case

Contains how DBI::DBD::SqlEngine deals with non-quoted SQL identifiers:

```
* SQL_IC_UPPER (1) means all identifiers are internally converted
  into upper-cased pendants
* SQL_IC_LOWER (2) means all identifiers are internally converted
  into lower-cased pendants
* SQL_IC_MIXED (4) means all identifiers are taken as they are
```

These conversions happen if (and only if) no existing identifier matches. Once existing identifier is used as known.

The SQL statement execution classes doesn't have to care, so don't expect `sql_identifier_case` affects column names in statements like

```
SELECT * FROM foo
```

sql_quoted_identifier_case

Contains how DBI::DBD::SqlEngine deals with quoted SQL identifiers (**readonly**). It's fixated to SQL_IC_SENSITIVE (3), which is interpreted as SQL_IC_MIXED.

sql_flags

Contains additional flags to instantiate an SQL::Parser. Because an SQL::Parser is instantiated only once, it's recommended to set this flag before any statement is executed.

sql_dialect

Controls the dialect understood by SQL::Parser. Possible values (delivery state of SQL::Statement):

```
* ANSI
* CSV
* AnyData
```

Defaults to "CSV". Because an SQL::Parser is instantiated only once and SQL::Parser doesn't allow one to modify the dialect once instantiated, it's strongly recommended to set this flag before any statement is executed (best place is connect attribute hash).

sql_engine_in_gofer

This value has a true value in case of this driver is operated via *DBD::Gofer*. The impact of being operated via Gofer is a read-only driver (not read-only databases!), so you cannot modify any attributes later - neither any table settings. **But** you won't get an error in cases you modify table attributes, so please carefully watch `sql_engine_in_gofer`.

sql_meta

Private data area which contains information about the tables this module handles. Table meta data might not be available until the table has been accessed for the first time e.g., by issuing a select on it however it is possible to pre-initialize attributes for each table you use.

DBI::DBD::SqlEngine recognizes the (public) attributes `col_names`, `table_name`, `readonly`, `sql_data_source` and `sql_identifier_case`. Be very careful when modifying attributes you do not know, the consequence might be a destroyed or corrupted table.

While `sql_meta` is a private and readonly attribute (which means, you cannot modify it's values), derived drivers might provide restricted write access through another attribute. Well known accessors are `csv_tables` for DBD::CSV, `ad_tables` for DBD::AnyData and `dbm_tables` for *DBD::DBM*.

sql_table_source

Controls the class which will be used for fetching available tables.

See "DBI::DBD::SqlEngine::TableSource" for details.

sql_data_source

Contains the class name to be used for opening tables.

See "DBI::DBD::SqlEngine::DataSource" for details.

Driver private methods

Default DBI methods

data_sources

The `data_sources` method returns a list of subdirectories of the current directory in the form "dbi:CSV:f_dir=$dirname".

If you want to read the subdirectories of another directory, use

```
my ($drh)  = DBI->install_driver ("CSV");
my (@list) = $drh->data_sources (f_dir => "/usr/local/csv_data");
```

list_tables

This method returns a list of file names inside $dbh->{f_dir}. Example:

```
my ($dbh)  = DBI->connect ("dbi:CSV:f_dir=/usr/local/csv_data");
my (@list) = $dbh->func ("list_tables");
```

Note that the list includes all files contained in the directory, even those that have non-valid table names, from the view of SQL.

Additional methods

The following methods are only available via their documented name when DBI::DBD::SqlEngine is used directly. Because this is only reasonable for testing purposes, the real names must be used instead. Those names can be computed by replacing the `sql_` in the method name with the driver prefix.

sql_versions

Signature:

```
sub sql_versions (;$) {
  my ($table_name) = @_;
  $table_name ||= ".";
  ...
  }
```

Returns the versions of the driver, including the DBI version, the Perl version, DBI::PurePerl version (if DBI::PurePerl is active) and the version of the SQL engine in use.

```
my $dbh = DBI->connect ("dbi:File:");
my $sql_versions = $dbh->func( "sql_versions" );
print "$sql_versions\n";
__END__
# DBI::DBD::SqlEngine  0.05 using SQL::Statement 1.402
# DBI                  1.623
```

(continues on next page)

(continued from previous page)

```
# OS                    netbsd (6.99.12)
# Perl                  5.016002 (x86_64-netbsd-thread-multi)
```

Called in list context, sql_versions will return an array containing each line as single entry.

Some drivers might use the optional (table name) argument and modify version information related to the table (e.g. DBD::DBM provides storage backend information for the requested table, when it has a table name).

sql_get_meta

Signature:

```
sub sql_get_meta ($$) {
    my ($table_name, $attrib) = @_;
    ...
    }
```

Returns the value of a meta attribute set for a specific table, if any. See sql_meta for the possible attributes.

A table name of "." (single dot) is interpreted as the default table. This will retrieve the appropriate attribute globally from the dbh. This has the same restrictions as `$dbh->{$attrib}`.

sql_set_meta

Signature:

```
sub sql_set_meta ($$$) {
    my ($table_name, $attrib, $value) = @_;
    ...
    }
```

Sets the value of a meta attribute set for a specific table. See sql_meta for the possible attributes.

A table name of "." (single dot) is interpreted as the default table which will set the specified attribute globally for the dbh. This has the same restrictions as `$dbh->{$attrib} = $value`.

sql_clear_meta

Signature:

```
sub sql_clear_meta ($) {
    my ($table_name) = @_;
    ...
    }
```

Clears the table specific meta information in the private storage of the dbh.

Extensibility

DBI::DBD::SqlEngine::TableSource

Provides data sources and table information on database driver and database handle level.

```
package DBI::DBD::SqlEngine::TableSource;

sub data_sources ($;$) {
  my ($class, $drh, $attrs) = @_;
  ...
  }

sub avail_tables {
  my ( $class, $drh ) = @_;
  ...
  }
```

The `data_sources` method is called when the user invokes any of the following:

```
@ary = DBI->data_sources ($driver);
@ary = DBI->data_sources ($driver, \%attr);

@ary = $dbh->data_sources ();
@ary = $dbh->data_sources (\%attr);
```

The `avail_tables` method is called when the user invokes any of the following:

```
@names = $dbh->tables ($catalog, $schema, $table, $type);

$sth = $dbh->table_info ($catalog, $schema, $table, $type);
$sth = $dbh->table_info ($catalog, $schema, $table, $type, \%attr);

$dbh->func ("list_tables");
```

Every time where an `\%attr` argument can be specified, this `\%attr` object's `sql_table_source` attribute is preferred over the `$dbh` attribute or the driver default, e.g.

```
@ary = DBI->data_sources ("dbi:CSV:", {
  f_dir => "/your/csv/tables",
  # note: this class doesn't comes with DBI
  sql_table_source => "DBD::File::Archive::Tar::TableSource",
  # scan tarballs instead of directories
  });
```

When you're going to implement such a DBD::File::Archive::Tar::TableSource class, remember to add correct attributes (including `sql_table_source` and `sql_data_source`) to the returned DSN's.

DBI::DBD::SqlEngine::DataSource

Provides base functionality for dealing with tables. It is primarily designed for allowing transparent access to files on disk or already opened (file-)streams (e.g. for DBD::CSV).

Derived classes shall be restricted to similar functionality, too (e.g. opening streams from an archive, transparently compress/uncompress log files before parsing them,

```
package DBI::DBD::SqlEngine::DataSource;

sub complete_table_name ($$;$) {
  my ($self, $meta, $table, $respect_case) = @_;
  ...
  }
```

The method `complete_table_name` is called when first setting up the *meta information* for a table:

```
"SELECT user.id, user.name, user.shell FROM user WHERE ..."
```

results in opening the table `user`. First step of the table open process is completing the name. Let's imagine you're having a DBD::CSV handle with following settings:

```
$dbh->{sql_identifier_case} = SQL_IC_LOWER;
$dbh->{f_ext} = '.lst';
$dbh->{f_dir} = '/data/web/adrmgr';
```

Those settings will result in looking for files matching `[Uu][Ss][Ee][Rr](\.lst)?$` in `/data/web/adrmgr/`. The scanning of the directory `/data/web/adrmgr/` and the pattern match check will be done in `DBD::File::DataSource::File` by the `complete_table_name` method.

If you intend to provide other sources of data streams than files, in addition to provide an appropriate `complete_table_name` method, a method to open the resource is required:

```
package DBI::DBD::SqlEngine::DataSource;

sub open_data ($) {
  my ($self, $meta, $attrs, $flags) = @_;
  ...
  }
```

After the method `open_data` has been run successfully, the table's meta information are in a state which allows the table's data accessor methods will be able to fetch/store row information. Implementation details heavily depends on the table implementation, whereby the most famous is surely *DBD::File::Table*.

SQL ENGINES

DBI::DBD::SqlEngine currently supports two SQL engines: SQL::Statement and *DBI::SQL::Nano::Statement_*. DBI::SQL::Nano supports a *very* limited subset of SQL statements, but it might be faster for some very simple tasks. SQL::Statement in contrast supports a much larger subset of ANSI SQL.

To use SQL::Statement, you need at least version 1.401 of SQL::Statement and the environment variable `DBI_SQL_NANO` must not be set to a true value.

SUPPORT

You can find documentation for this module with the perldoc command.

```
perldoc DBI::DBD::SqlEngine
```

You can also look for information at:

- RT: CPAN's request tracker

  http://rt.cpan.org/NoAuth/Bugs.html?Dist=DBI http://rt.cpan.org/NoAuth/Bugs.html?Dist=SQL-Statement

- CPAN Ratings

  http://cpanratings.perl.org/d/DBI

- Search CPAN

  http://search.cpan.org/dist/DBI/

Where can I go for more help?

For questions about installation or usage, please ask on the dbi-dev@perl.org mailing list.

If you have a bug report, patch or suggestion, please open a new report ticket on CPAN, if there is not already one for the issue you want to report. Of course, you can mail any of the module maintainers, but it is less likely to be missed if it is reported on RT.

Report tickets should contain a detailed description of the bug or enhancement request you want to report and at least an easy way to verify/reproduce the issue and any supplied fix. Patches are always welcome, too.

ACKNOWLEDGEMENTS

Thanks to Tim Bunce, Martin Evans and H.Merijn Brand for their continued support while developing DBD::File, DBD::DBM and DBD::AnyData. Their support, hints and feedback helped to design and implement this module.

SEE ALSO

DBI, *DBD::File*, DBD::AnyData and DBD::Sys.

DBI::Gofer

Namespace containing the following modules:

- `DBI::Gofer::Execute` - Executes Gofer requests and returns Gofer responses
- `DBI::Gofer::Request` - Encapsulate a request from DBD::Gofer to DBI::Gofer::Execute
- `DBI::Gofer::Response` - Encapsulate a response from DBI::Gofer::Execute to DBD::Gofer
- `DBI::Gofer::Serializer`
- `DBI::Gofer::Transport`

DBI::Gofer::Execute

Executes Gofer requests and returns Gofer responses

SYNOPSIS

```
$executor = DBI::Gofer::Execute->new( { ...config... });

$response = $executor->execute_request( $request );
```

DESCRIPTION

Accepts a DBI::Gofer::Request object, executes the requested DBI method calls, and returns a DBI::Gofer::Response object.

Any error, including any internal 'fatal' errors are caught and converted into a DBI::Gofer::Response object.

This module is usually invoked by a 'server-side' Gofer transport module. They usually have names in the "`DBI::Gofer::Transport::*`" namespace. Examples include: *DBI::Gofer::Transport::stream* and DBI::Gofer::Transport::mod_perl.

CONFIGURATION

check_request_sub

If defined, it must be a reference to a subroutine that will 'check' the request. It is passed the request object and the executor as its only arguments.

The subroutine can either return the original request object or die with a suitable error message (which will be turned into a Gofer response).

It can also construct and return a new request that should be executed instead of the original request.

check_response_sub

If defined, it must be a reference to a subroutine that will 'check' the response. It is passed the response object, the executor, and the request object. The sub may alter the response object and return undef, or return a new response object.

This mechanism can be used to, for example, terminate the service if specific database errors are seen.

forced_connect_dsn

If set, this DSN is always used instead of the one in the request.

default_connect_dsn

If set, this DSN is used if `forced_connect_dsn` is not set and the request does not contain a DSN itself.

forced_connect_attributes

A reference to a hash of connect() attributes. Individual attributes in `forced_connect_attributes` will take precedence over corresponding attributes in the request.

default_connect_attributes

A reference to a hash of connect() attributes. Individual attributes in the request take precedence over corresponding attributes in `default_connect_attributes`.

max_cached_dbh_per_drh

If set, the loaded drivers will be checked to ensure they don't have more than this number of cached connections. There is no default value. This limit is not enforced for every request.

max_cached_sth_per_dbh

If set, all the cached statement handles will be cleared once the number of cached statement handles rises above this limit. The default is 1000.

forced_single_resultset

If true, then only the first result set will be fetched and returned in the response.

forced_response_attributes

A reference to a data structure that can specify extra attributes to be returned in responses.

```
forced_response_attributes => {
    DriverName => {
        dbh => [ qw(dbh_attrib_name) ],
        sth => [ qw(sth_attrib_name) ],
    },
},
```

This can be useful in cases where the driver has not implemented the private_attribute_info() method and DBI::Gofer::Execute's own fallback list of private attributes doesn't include the driver or attributes you need.

track_recent

If set, specifies the number of recent requests and responses that should be kept by the update_stats() method for diagnostics. See DBI::Gofer::Transport::mod_perl.

Note that this setting can significantly increase memory use. Use with caution.

forced_gofer_random

Enable forced random failures and/or delays for testing. See "DBI_GOFER_RANDOM" below.

DRIVER-SPECIFIC ISSUES

Gofer needs to know about any driver-private attributes that should have their values sent back to the client.

If the driver doesn't support private_attribute_info() method, and very few do, then the module falls back to using some hard-coded details, if available, for the driver being used. Currently hard-coded details are available for the mysql, Pg, Sybase, and SQLite drivers.

TESTING

DBD::Gofer, DBD::Execute and related packages are well tested by executing the DBI test suite with DBI_AUTOPROXY configured to route all DBI calls via DBD::Gofer.

Because Gofer includes timeout and 'retry on error' mechanisms there is a need for some way to trigger delays and/or errors. This can be done via the `forced_gofer_random` configuration item, or else the DBI_GOFER_RANDOM environment variable.

DBI_GOFER_RANDOM

The value of the `forced_gofer_random` configuration item (or else the DBI_GOFER_RANDOM environment variable) is treated as a series of tokens separated by commas.

The tokens can be one of three types:

- fail=R%

  Set the current failure rate to R where R is a percentage. The value R can be floating point, e.g., `fail=0.05%`. Negative values for R have special meaning, see below.

- err=N

  Sets the current failure err value to N (instead of the DBI's default 'standard err value' of 2000000000). This is useful when you want to simulate a specific error.

- delayN=R%

  Set the current random delay rate to R where R is a percentage, and set the current delay duration to N seconds. The values of R and N can be floating point, e.g., `delay0.5=0.2%`. Negative values for R have special meaning, see below.

  If R is an odd number (R % 2 == 1) then a message is logged via warn() which will be returned to, and echoed at, the client.

- methodname

  Applies the current fail, err, and delay values to the named method. If neither a fail nor delay have been set yet then a warning is generated.

For example:

```
$executor = DBI::Gofer::Execute->new( {
  forced_gofer_random => "fail=0.01%,do,delay60=1%,execute",
});
```

will cause the do() method to fail for 0.01% of calls, and the execute() method to fail 0.01% of calls and be delayed by 60 seconds on 1% of calls.

If the percentage value (R) is negative then instead of the failures being triggered randomly (via the rand() function) they are triggered via a sequence number. In other words "`fail=-20%`" will mean every fifth call will fail. Each method has a distinct sequence number.

DBI::Gofer::Serializer

Namespace containing the following modules:

- `DBI::Gofer::Serializer::Base` - base class for Gofer serialization
- `DBI::Gofer::Serializer::DataDumper` - Gofer serialization using DataDumper
- `DBI::Gofer::Serializer::Storable` - Gofer serialization using Storable

DBI::Gofer::Serializer::Base

base class for Gofer serialization

SYNOPSIS

```
$serializer = $serializer_class->new();

$string = $serializer->serialize( $data );
($string, $deserializer_class) = $serializer->serialize( $data );

$data = $serializer->deserialize( $string );
```

DESCRIPTION

DBI::Gofer::Serializer::* classes implement a very minimal subset of the Data::Serializer API.

Gofer serializers are expected to be very fast and are not required to deal with anything other than non-blessed references to arrays and hashes, and plain scalars.

DBI::Gofer::Serializer::DataDumper

Gofer serialization using DataDumper

SYNOPSIS

```
$serializer = DBI::Gofer::Serializer::DataDumper->new();

$string = $serializer->serialize( $data );
```

DESCRIPTION

Uses DataDumper to serialize. Deserialization is not supported. The output of this class is only meant for human consumption.

See also *DBI::Gofer::Serializer::Base*.

DBI::Gofer::Serializer::Storable

Gofer serialization using Storable

SYNOPSIS

```
$serializer = DBI::Gofer::Serializer::Storable->new();

$string = $serializer->serialize( $data );
($string, $deserializer_class) = $serializer->serialize( $data );

$data = $serializer->deserialize( $string );
```

DESCRIPTION

Uses Storable::nfreeze() to serialize and Storable::thaw() to deserialize.

The serialize() method sets local $Storable::forgive_me = 1; so it doesn't croak if it encounters any data types that can't be serialized, such as code refs.

See also *DBI::Gofer::Serializer::Base*.

DBI::Gofer::Transport

Namespace containing the following modules:

- `DBI::Gofer::Transport::Base` - Base class for Gofer transports
- `DBI::Gofer::Transport::pipeone` - DBD::Gofer server-side transport for pipeone
- `DBI::Gofer::Transport::stream` - DBD::Gofer server-side transport for stream

DBI::Gofer::Transport::Base

Base class for Gofer transports

DESCRIPTION

This is the base class for server-side Gofer transports.

It's also the base class for the client-side base class *DBD::Gofer::Transport::Base*.

This is an internal class.

DBI::Profile

Performance profiling and benchmarking for the DBI

SYNOPSIS

The easiest way to enable DBI profiling is to set the DBI_PROFILE environment variable to 2 and then run your code as usual:

```
DBI_PROFILE=2 prog.pl
```

This will profile your program and then output a textual summary grouped by query when the program exits. You can also enable profiling by setting the Profile attribute of any DBI handle:

```
$dbh->{Profile} = 2;
```

Then the summary will be printed when the handle is destroyed.

Many other values apart from are possible - see “ENABLING A PROFILE” below.

DESCRIPTION

The DBI::Profile module provides a simple interface to collect and report performance and benchmarking data from the DBI.

For a more elaborate interface, suitable for larger programs, see *DBI::ProfileDumper* and dbiprof. For Apache/mod_perl applications see DBI::ProfileDumper::Apache.

OVERVIEW

Performance data collection for the DBI is built around several concepts which are important to understand clearly.

- Method Dispatch

  Every method call on a DBI handle passes through a single ‘dispatch’ function which manages all the common aspects of DBI method calls, such as handling the RaiseError attribute.

- Data Collection

  If profiling is enabled for a handle then the dispatch code takes a high-resolution timestamp soon after it is entered. Then, after calling the appropriate method and just before returning, it takes another high-resolution timestamp and calls a function to record the information. That function is passed the two timestamps plus the DBI handle and the name of the method that was called. That data about a single DBI method call is called a *profile sample*.

- Data Filtering

  If the method call was invoked by the DBI or by a driver then the call is ignored for profiling because the time spent will be accounted for by the original ‘outermost’ call for your code.

  For example, the calls that the selectrow_arrayref() method makes to prepare() and execute() etc. are not counted individually because the time spent in those methods is going to be allocated to the selectrow_arrayref() method when it returns. If this was not done then it would be very easy to double count time spent inside the DBI.

- Data Storage Tree

  The profile data is accumulated as 'leaves on a tree'. The 'path' through the branches of the tree to a particular leaf is determined dynamically for each sample. This is a key feature of DBI profiling.

  For each profiled method call the DBI walks along the Path and uses each value in the Path to step into and grow the Data tree.

  For example, if the Path is

```
[ 'foo', 'bar', 'baz' ]
```

  then the new profile sample data will be *merged* into the tree at

```
$h->{Profile}->{Data}->{foo}->{bar}->{baz}
```

  But it's not very useful to merge all the call data into one leaf node (except to get an overall 'time spent inside the DBI' total). It's more common to want the Path to include dynamic values such as the current statement text and/or the name of the method called to show what the time spent inside the DBI was for.

  The Path can contain some 'magic cookie' values that are automatically replaced by corresponding dynamic values when they're used. These magic cookies always start with a punctuation character.

  For example a value of '`!MethodName`' in the Path causes the corresponding entry in the Data to be the name of the method that was called. For example, if the Path was:

```
[ 'foo', '!MethodName', 'bar' ]
```

  and the selectall_arrayref() method was called, then the profile sample data for that call will be merged into the tree at:

```
$h->{Profile}->{Data}->{foo}->{selectall_arrayref}->{bar}
```

- Profile Data

  Profile data is stored at the 'leaves' of the tree as references to an array of numeric values. For example:

```
[
  106,                  # 0: count of samples at this node
  0.0312958955764771,   # 1: total duration
  0.000490069389343262, # 2: first duration
  0.000176072120666504, # 3: shortest duration
  0.00140702724456787,  # 4: longest duration
  1023115819.83019,     # 5: time of first sample
  1023115819.86576,     # 6: time of last sample
]
```

  After the first sample, later samples always update elements 0, 1, and 6, and may update 3 or 4 depending on the duration of the sampled call.

ENABLING A PROFILE

Profiling is enabled for a handle by assigning to the Profile attribute. For example:

```
$h->{Profile} = DBI::Profile->new();
```

The Profile attribute holds a blessed reference to a hash object that contains the profile data and attributes relating to it.

The class the Profile object is blessed into is expected to provide at least a DESTROY method which will dump the profile data to the DBI trace file handle (STDERR by default).

All these examples have the same effect as each other:

```
$h->{Profile} = 0;
$h->{Profile} = "/DBI::Profile";
$h->{Profile} = DBI::Profile->new();
$h->{Profile} = {};
$h->{Profile} = { Path => [] };
```

Similarly, these examples have the same effect as each other:

```
$h->{Profile} = 6;
$h->{Profile} = "6/DBI::Profile";
$h->{Profile} = "!Statement:!MethodName/DBI::Profile";
$h->{Profile} = { Path => [ '!Statement', '!MethodName' ] };
```

If a non-blessed hash reference is given then the DBI::Profile module is automatically `require`'d and the reference is blessed into that class.

If a string is given then it is processed like this:

```
($path, $module, $args) = split /\//, $string, 3

@path = split /:/, $path
@args = split /:/, $args

eval "require $module" if $module
$module ||= "DBI::Profile"

$module->new( Path => \@Path, @args )
```

So the first value is used to select the Path to be used (see below). The second value, if present, is used as the name of a module which will be loaded and it's new method called. If not present it defaults to DBI::Profile. Any other values are passed as arguments to the new method. For example: "`2/DBIx::OtherProfile/Foo:42`".

Numbers can be used as a shorthand way to enable common Path values. The simplest way to explain how the values are interpreted is to show the code:

```
push @Path, "DBI"           if $path_elem & 0x01;
push @Path, "!Statement"    if $path_elem & 0x02;
push @Path, "!MethodName"   if $path_elem & 0x04;
```

(continues on next page)

(continued from previous page)

```
push @Path, "!MethodClass"  if $path_elem & 0x08;
push @Path, "!Caller2"      if $path_elem & 0x10;
```

So “2” is the same as “!Statement” and “6” (2+4) is the same as “!Statement:!Method”. Those are the two most commonly used values. Using a negative number will reverse the path. Thus “-6” will group by method name then statement.

The splitting and parsing of string values assigned to the Profile attribute may seem a little odd, but there’s a good reason for it. Remember that attributes can be embedded in the Data Source Name string which can be passed in to a script as a parameter. For example:

```
dbi:DriverName(Profile=>2):dbname
dbi:DriverName(Profile=>{Username}:!Statement/MyProfiler/
 ↪Foo:42):dbname
```

And also, if the `DBI_PROFILE` environment variable is set then The DBI arranges for every driver handle to share the same profile object. When perl exits a single profile summary will be generated that reflects (as nearly as practical) the total use of the DBI by the application.

THE PROFILE OBJECT

The DBI core expects the Profile attribute value to be a hash reference and if the following values don’t exist it will create them as needed:

Data

A reference to a hash containing the collected profile data.

Path

The Path value is a reference to an array. Each element controls the value to use at the corresponding level of the profile Data tree.

If the value of Path is anything other than an array reference, it is treated as if it was:

```
[ '!Statement' ]
```

The elements of Path array can be one of the following types:

Special Constant

!Statement

Use the current Statement text. Typically that’s the value of the Statement attribute for the handle the method was called with. Some methods, like commit() and rollback(), are unrelated to a particular statement. For those methods !Statement records an empty string.

For statement handles this is always simply the string that was given to prepare() when the handle was created. For database handles this is the statement that was last prepared

or executed on that database handle. That can lead to a little 'fuzziness' because, for example, calls to the quote() method to build a new statement will typically be associated with the previous statement. In practice this isn't a significant issue and the dynamic Path mechanism can be used to setup your own rules.

!MethodName

Use the name of the DBI method that the profile sample relates to.

!MethodClass

Use the fully qualified name of the DBI method, including the package, that the profile sample relates to. This shows you where the method was implemented. For example:

```
'DBD::_::db::selectrow_arrayref' =>
    0.022902s
'DBD::mysql::db::selectrow_arrayref' =>
    2.244521s / 99 = 0.022445s avg (first 0.022813s, min 0.022051s,␣
↪max 0.028932s)
```

The "DBD::_::db::selectrow_arrayref" shows that the driver has inherited the selectrow_arrayref method provided by the DBI.

But you'll note that there is only one call to DBD::_::db::selectrow_arrayref but another 99 to DBD::mysql::db::selectrow_arrayref. Currently the first call doesn't record the true location. That may change.

!Caller

Use a string showing the filename and line number of the code calling the method.

!Caller2

Use a string showing the filename and line number of the code calling the method, as for !Caller, but also include filename and line number of the code that called that. Calls from DBI:: and DBD:: packages are skipped.

!File

Same as !Caller above except that only the filename is included, not the line number.

!File2

Same as !Caller2 above except that only the filenames are included, not the line number.

!Time

Use the current value of time(). Rarely used. See the more useful `!Time~N` below.

!Time~N

Where `N` is an integer. Use the current value of time() but with reduced precision. The value used is determined in this way:

```
int( time() / N ) * N
```

This is a useful way to segregate a profile into time slots. For example:

```
[ '!Time~60', '!Statement' ]
```

Code Reference

The subroutine is passed the handle it was called on and the DBI method name. The current Statement is in `$_`. The statement string should not be modified, so most subs start with `local $_ = $_;`.

The list of values it returns is used at that point in the Profile Path. Any undefined values are treated as the string "`undef`".

The sub can 'veto' (reject) a profile sample by including a reference to undef (`\undef`) in the returned list. That can be useful when you want to only profile statements that match a certain pattern, or only profile certain methods.

Subroutine Specifier

A Path element that begins with '&' is treated as the name of a subroutine in the DBI::ProfileSubs namespace and replaced with the corresponding code reference.

Currently this only works when the Path is specified by the `DBI_PROFILE` environment variable.

Also, currently, the only subroutine in the DBI::ProfileSubs namespace is `'&norm_std_n3'`. That's a very handy subroutine when profiling code that doesn't use placeholders. See *DBI::ProfileSubs* for more information.

Attribute Specifier

A string enclosed in braces, such as '`{Username}`', specifies that the current value of the corresponding database handle attribute should be used at that point in the Path.

Reference to a Scalar

Specifies that the current value of the referenced scalar be used at that point in the Path. This provides an efficient way to get 'contextual' values into your profile.

Other Values

Any other values are stringified and used literally.

(References, and values that begin with punctuation characters are reserved.)

REPORTING

Report Format

The current accumulated profile data can be formatted and output using

```
print $h->{Profile}->format;
```

To discard the profile data and start collecting fresh data you can do:

```
$h->{Profile}->{Data} = undef;
```

The default results format looks like this:

```
DBI::Profile: 0.001015s 42.7% (5 calls) programname @ YYYY-MM-DD
↪HH:MM:SS
'' =>
    0.000024s / 2 = 0.000012s avg (first 0.000015s, min 0.000009s,
↪max 0.000015s)
'SELECT mode,size,name FROM table' =>
    0.000991s / 3 = 0.000330s avg (first 0.000678s, min 0.000009s,
↪max 0.000678s)
```

Which shows the total time spent inside the DBI, with a count of the total number of method calls and the name of the script being run, then a formatted version of the profile data tree.

If the results are being formatted when the perl process is exiting (which is usually the case when the DBI_PROFILE environment variable is used) then the percentage of time the process spent inside the DBI is also shown. If the process is not exiting then the percentage is calculated using the time between the first and last call to the DBI.

In the example above the paths in the tree are only one level deep and use the Statement text as the value (that's the default behaviour).

The merged profile data at the 'leaves' of the tree are presented as total time spent, count, average time spent (which is simply total time divided by the count), then the time spent on the first call, the time spent on the fastest call, and finally the time spent on the slowest call.

The 'avg', 'first', 'min' and 'max' times are not particularly useful when the profile data path only contains the statement text. Here's an extract of a more detailed example using both statement text and method name in the path:

```
'SELECT mode,size,name FROM table' =>
    'FETCH' =>
        0.000076s
    'fetchrow_hashref' =>
        0.036203s / 108 = 0.000335s avg (first 0.000490s, min 0.
↪000152s, max 0.002786s)
```

Here you can see the 'avg', 'first', 'min' and 'max' for the 108 calls to fetchrow_hashref() become rather more interesting. Also the data for FETCH just shows a time value because it was only called once.

Currently the profile data is output sorted by branch names. That may change in a later version so the leaf nodes are sorted by total time per leaf node.

Report Destination

The default method of reporting is for the DESTROY method of the Profile object to format the results and write them using:

```
DBI->trace_msg($results, 0);  # see $ON_DESTROY_DUMP below
```

to write them to the DBI trace() filehandle (which defaults to STDERR). To direct the DBI trace filehandle to write to a file without enabling tracing the trace() method can be called with a trace level of 0. For example:

```
DBI->trace(0, $filename);
```

The same effect can be achieved without changing the code by setting the DBI_TRACE environment variable to 0=filename.

The $DBI::Profile::ON_DESTROY_DUMP variable holds a code ref that's called to perform the output of the formatted results. The default value is:

```
$ON_DESTROY_DUMP = sub { DBI->trace_msg($results, 0) };
```

Apart from making it easy to send the dump elsewhere, it can also be useful as a simple way to disable dumping results.

CHILD HANDLES

Child handles inherit a reference to the Profile attribute value of their parent. So if profiling is enabled for a database handle then by default the statement handles created from it all contribute to the same merged profile data tree.

PROFILE OBJECT METHODS

format

See "REPORTING".

as_node_path_list

```
@ary = $dbh->{Profile}->as_node_path_list();
@ary = $dbh->{Profile}->as_node_path_list($node, $path);
```

Returns the collected data ($dbh->{Profile}{Data}) restructured into a list of array refs, one for each leaf node in the Data tree. This 'flat' structure is often much simpler for applications to work with.

The first element of each array ref is a reference to the leaf node. The remaining elements are the 'path' through the data tree to that node.

For example, given a data tree like this:

```
{key1a}{key2a}[node1]
{key1a}{key2b}[node2]
{key1b}{key2a}{key3a}[node3]
```

The as_node_path_list() method will return this list:

```
[ [node1], 'key1a', 'key2a' ]
[ [node2], 'key1a', 'key2b' ]
[ [node3], 'key1b', 'key2a', 'key3a' ]
```

The nodes are ordered by key, depth-first.

The $node argument can be used to focus on a sub-tree. If not specified it defaults to $dbh->{Profile}{Data}.

The $path argument can be used to specify a list of path elements that will be added to each element of the returned list. If not specified it defaults to a ref to an empty array.

as_text

```
@txt = $dbh->{Profile}->as_text();
$txt = $dbh->{Profile}->as_text({
    node      => undef,
    path      => [],
    separator => " > ",
    format    => '%1$s: %11$fs / %10$d = %2$fs avg (first %12$fs,␣
↪min %13$fs, max %14$fs)'."\n";
    sortsub   => sub { ... },
);
```

Returns the collected data ($dbh->{Profile}{Data}) reformatted into a list of formatted strings. In scalar context the list is returned as a single concatenated string.

A hashref can be used to pass in arguments, the default values are shown in the example above.

The node and <path> arguments are passed to as_node_path_list().

The `separator` argument is used to join the elements of the path for each leaf node.

The `sortsub` argument is used to pass in a ref to a sub that will order the list. The subroutine will be passed a reference to the array returned by as_node_path_list() and should sort the contents of the array in place. The return value from the sub is ignored. For example, to sort the nodes by the second level key you could use:

```
sortsub => sub { my $ary=shift; @$ary = sort { $a->[2] cmp $b->[2] }␣
↪@$ary }
```

The `format` argument is a `sprintf` format string that specifies the format to use for each leaf node. It uses the explicit format parameter index mechanism to specify which of the arguments should appear where in the string. The arguments to sprintf are:

```
 1:  path to node, joined with the separator
 2:  average duration (total duration/count)
     (3 thru 9 are currently unused)
10:  count
11:  total duration
12:  first duration
13:  smallest duration
14:  largest duration
15:  time of first call
16:  time of first call
```

CUSTOM DATA MANIPULATION

Recall that `$h->{Profile}->{Data}` is a reference to the collected data. Either to a 'leaf' array (when the Path is empty, i.e., DBI_PROFILE env var is 1), or a reference to hash containing values that are either further hash references or leaf array references.

Sometimes it's useful to be able to summarise some or all of the collected data. The dbi_profile_merge_nodes() function can be used to merge leaf node values.

dbi_profile_merge_nodes

```
use DBI qw(dbi_profile_merge_nodes);

$time_in_dbi = dbi_profile_merge_nodes(my $totals=[], @$leaves);
```

Merges profile data node. Given a reference to a destination array, and zero or more references to profile data, merges the profile data into the destination array. For example:

```
$time_in_dbi = dbi_profile_merge_nodes(
    my $totals=[],
    [ 10, 0.51, 0.11, 0.01, 0.22, 1023110000, 1023110010 ],
    [ 15, 0.42, 0.12, 0.02, 0.23, 1023110005, 1023110009 ],
);
```

$totals will then contain

```
[ 25, 0.93, 0.11, 0.01, 0.23, 1023110000, 1023110010 ]
```

and $time_in_dbi will be 0.93;

The second argument need not be just leaf nodes. If given a reference to a hash then the hash is recursively searched for leaf nodes and all those found are merged.

For example, to get the time spent 'inside' the DBI during an http request, your logging code run at the end of the request (i.e. mod_perl LogHandler) could use:

```
my $time_in_dbi = 0;
if (my $Profile = $dbh->{Profile}) { # if DBI profiling is enabled
    $time_in_dbi = dbi_profile_merge_nodes(my $total=[], $Profile->
↪{Data});
    $Profile->{Data} = {}; # reset the profile data
}
```

If profiling has been enabled then $time_in_dbi will hold the time spent inside the DBI for that handle (and any other handles that share the same profile data) since the last request.

Prior to DBI 1.56 the dbi_profile_merge_nodes() function was called dbi_profile_merge(). That name still exists as an alias.

CUSTOM DATA COLLECTION

Using The Path Attribute

```
XXX example to be added later using a selectall_arrayref call
XXX nested inside a fetch loop where the first column of the
XXX outer loop is bound to the profile Path using
XXX bind_column(1, \${ $dbh->{Profile}->{Path}->[0] })
XXX so you end up with separate profiles for each loop
XXX (patches welcome to add this to the docs :)
```

Adding Your Own Samples

The dbi_profile() function can be used to add extra sample data into the profile data tree. For example:

```
use DBI;
use DBI::Profile (dbi_profile dbi_time);

my $t1 = dbi_time(); # floating point high-resolution time

... execute code you want to profile here ...

my $t2 = dbi_time();
dbi_profile($h, $statement, $method, $t1, $t2);
```

The $h parameter is the handle the extra profile sample should be associated with. The $statement parameter is the string to use where the Path specifies !Statement. If $statement is undef then $h->{Statement} will be used. Similarly $method is the string to use if the Path specifies !MethodName. There is no default value for $method.

The $h->{Profile}{Path} attribute is processed by dbi_profile() in the usual way.

The $h parameter is usually a DBI handle but it can also be a reference to a hash, in which case the dbi_profile() acts on each defined value in the hash. This is an efficient way to update multiple profiles with a single sample, and is used by the DashProfiler module.

SUBCLASSING

Alternate profile modules must subclass DBI::Profile to help ensure they work with future versions of the DBI.

CAVEATS

Applications which generate many different statement strings (typically because they don't use placeholders) and profile with !Statement in the Path (the default) will consume memory in the Profile Data structure for each statement. Use a code ref in the Path to return an edited (simplified) form of the statement.

If a method throws an exception itself (not via RaiseError) then it won't be counted in the profile.

If a HandleError subroutine throws an exception (rather than returning 0 and letting RaiseError do it) then the method call won't be counted in the profile.

Time spent in DESTROY is added to the profile of the parent handle.

Time spent in DBI->*() methods is not counted. The time spent in the driver connect method, $drh->connect(), when it's called by DBI->connect is counted if the DBI_PROFILE environment variable is set.

Time spent fetching tied variables, $DBI::errstr, is counted.

Time spent in FETCH for $h->{Profile} is not counted, so getting the profile data doesn't alter it.

DBI::PurePerl does not support profiling (though it could in theory).

For asynchronous queries, time spent while the query is running on the backend is not counted.

A few platforms don't support the gettimeofday() high resolution time function used by the DBI (and available via the dbi_time() function). In which case you'll get integer resolution time which is mostly useless.

On Windows platforms the dbi_time() function is limited to millisecond resolution. Which isn't sufficiently fine for our needs, but still much better than integer resolution. This limited resolution means that fast method calls will often register as taking 0 time. And timings in general will have much more 'jitter' depending on where within the 'current millisecond' the start and end timing was taken.

This documentation could be more clear. Probably needs to be reordered to start with several examples and build from there. Trying to explain the concepts first seems painful and to lead to just as many forward references. (Patches welcome!)

DBI::ProfileData

manipulate DBI::ProfileDumper data dumps

SYNOPSIS

The easiest way to use this module is through the dbiprof frontend (see dbiprof for details):

```
dbiprof --number 15 --sort count
```

This module can also be used to roll your own profile analysis:

```
local $DBI::ProfileData::MAX_PATH_DEPTH = 256; # override the␣
↪maximum path depth of files

# load data from dbi.prof
$prof = DBI::ProfileData->new(File => "dbi.prof");

# get a count of the records (unique paths) in the data set
$count = $prof->count();
```

(continues on next page)

(continued from previous page)

```
# sort by longest overall time
$prof->sort(field => "longest");

# sort by longest overall time, least to greatest
$prof->sort(field => "longest", reverse => 1);

# exclude records with key2 eq 'disconnect'
$prof->exclude(key2 => 'disconnect');

# exclude records with key1 matching /^UPDATE/i
$prof->exclude(key1 => qr/^UPDATE/i);

# remove all records except those where key1 matches /^SELECT/i
$prof->match(key1 => qr/^SELECT/i);

# produce a formatted report with the given number of items
$report = $prof->report(number => 10);

# clone the profile data set
$clone = $prof->clone();

# get access to hash of header values
$header = $prof->header();

# get access to sorted array of nodes
$nodes = $prof->nodes();

# format a single node in the same style as report()
$text = $prof->format($nodes->[0]);

# get access to Data hash in DBI::Profile format
$Data = $prof->Data();
```

DESCRIPTION

This module offers the ability to read, manipulate and format *DBI::ProfileDumper* profile data.

Conceptually, a profile consists of a series of records, or nodes, each of each has a set of statistics and set of keys. Each record must have a unique set of keys, but there is no requirement that every record have the same number of keys.

METHODS

The following methods are supported by DBI::ProfileData objects.

$prof = DBI::ProfileData->new(File => "dbi.prof")

$prof = DBI::ProfileData->new(File => "dbi.prof", Filter => sub { ... })

$prof = DBI::ProfileData->new(Files => ["dbi.prof.1", "dbi.prof.2"])

Creates a new DBI::ProfileData object. Takes either a single file through the File option or a list of Files in an array ref. If multiple files are specified then the header data from the first file is used.

Files

Reference to an array of file names to read.

File

Name of file to read. Takes precedence over `Files`.

DeleteFiles

If true, the files are deleted after being read.

Actually the files are renamed with a `deleteme` suffix before being read, and then, after reading all the files, they're all deleted together.

The files are locked while being read which, combined with the rename, makes it safe to 'consume' files that are still being generated by *DBI::ProfileDumper*.

Filter

The `Filter` parameter can be used to supply a code reference that can manipulate the profile data as it is being read. This is most useful for editing SQL statements so that slightly different statements in the raw data will be merged and aggregated in the loaded data. For example:

```
Filter => sub {
    my ($path_ref, $data_ref) = @_;
    s/foo = '.*?'/foo = '...'/ for @$path_ref;
}
```

Here's an example that performs some normalization on the SQL. It converts all numbers to `N` and all quoted strings to `S`. It can also convert digits to `N` within names. Finally, it summarizes long "IN (...)" clauses.

It's aggressive and simplistic, but it's often sufficient, and serves as an example that you can tailor to suit your own needs:

```
Filter => sub {
    my ($path_ref, $data_ref) = @_;
    local $_ = $path_ref->[0]; # whichever element contains the SQL␣
↪Statement
    s/\b\d+\b/N/g;             # 42 -> N
    s/\b0x[0-9A-Fa-f]+\b/N/g;  # 0xFE -> N
    s/'.*?'/'S'/g;             # single quoted strings (doesn't␣
↪handle escapes)
    s/".*?"/"S"/g;             # double quoted strings (doesn't␣
↪handle escapes)
    # convert names like log_20001231 into log_NNNNNNNN, controlled␣
↪by $opt{n}
    s/([a-z_]+)(\d{$opt{n},})/$1.('N' x length($2))/ieg if $opt{n};
    # abbreviate massive "in (...)" statements and similar
    s!(([NS],){100,})!sprintf("$2,{repeated %d times}",length($1)/
↪2)!eg;
}
```

It's often better to perform this kinds of normalization in the DBI while the data is being collected, to avoid too much memory being used by storing profile data for many different SQL statement. See *DBI::Profile*.

$copy = $prof->clone();

Clone a profile data set creating a new object.

$header = $prof->header();

Returns a reference to a hash of header values. These are the key value pairs included in the header section of the *DBI::ProfileDumper* data format. For example:

```
$header = {
  Path    => [ '!Statement', '!MethodName' ],
  Program => 't/42profile_data.t',
};
```

Note that modifying this hash will modify the header data stored inside the profile object.

$nodes = $prof->nodes()

Returns a reference the sorted nodes array. Each element in the array is a single record in the data set. The first seven elements are the same as the elements provided by *DBI::Profile*. After that each key is in a separate element. For example:

```
$nodes = [
           [
             2,                     # 0, count
             0.0312958955764771,    # 1, total duration
             0.000490069389343262,  # 2, first duration
             0.000176072120666504,  # 3, shortest duration
```

(continues on next page)

(continued from previous page)

```
            0.00140702724456787,    # 4, longest duration
            1023115819.83019,       # 5, time of first event
            1023115819.86576,       # 6, time of last event
            'SELECT foo FROM bar'   # 7, key1
            'execute'               # 8, key2
                                    # 6+N, keyN
          ],
                                    # ...
        ];
```

Note that modifying this array will modify the node data stored inside the profile object.

$count = $prof->count()

Returns the number of items in the profile data set.

$prof->sort(field => "field")

$prof->sort(field => "field", reverse => 1)

Sorts data by the given field. Available fields are:

```
longest
total
count
shortest
```

The default sort is greatest to smallest, which is the opposite of the normal Perl meaning. This, however, matches the expected behavior of the dbiprof frontend.

$count = $prof->exclude(key2 => "disconnect")

$count = $prof->exclude(key2 => "disconnect", case_sensitive => 1)

$count = $prof->exclude(key1 => qr/^SELECT/i)

Removes records from the data set that match the given string or regular expression. This method modifies the data in a permanent fashion - use clone() first to maintain the original data after exclude(). Returns the number of nodes left in the profile data set.

$count = $prof->match(key2 => "disconnect")

$count = $prof->match(key2 => "disconnect", case_sensitive => 1)

$count = $prof->match(key1 => qr/^SELECT/i)

Removes records from the data set that do not match the given string or regular expression. This method modifies the data in a permanent fashion - use clone() first to maintain the original data after match(). Returns the number of nodes left in the profile data set.

$Data = $prof->Data()

Returns the same Data hash structure as seen in *DBI::Profile*. This structure is not sorted. The nodes() structure probably makes more sense for most analysis.

$text = $prof->format($nodes->[0])

Formats a single node into a human-readable block of text.

$text = $prof->report(number => 10)

Produces a report with the given number of items.

DBI::ProfileDumper

profile DBI usage and output data to a file

SYNOPSIS

To profile an existing program using DBI::ProfileDumper, set the DBI_PROFILE environment variable and run your program as usual. For example, using bash:

```
DBI_PROFILE=2/DBI::ProfileDumper program.pl
```

Then analyze the generated file (`dbi.prof`) with dbiprof:

```
dbiprof
```

You can also activate DBI::ProfileDumper from within your code:

```
use DBI;

# profile with default path (2) and output file (dbi.prof)
$dbh->{Profile} = "!Statement/DBI::ProfileDumper";

# same thing, spelled out
$dbh->{Profile} = "!Statement/DBI::ProfileDumper/File:dbi.prof";

# another way to say it
use DBI::ProfileDumper;
```

(continues on next page)

(continued from previous page)

```
$dbh->{Profile} = DBI::ProfileDumper->new(
                      Path => [ '!Statement' ],
                      File => 'dbi.prof' );

# using a custom path
$dbh->{Profile} = DBI::ProfileDumper->new(
    Path => [ "foo", "bar" ],
    File => 'dbi.prof',
);
```

DESCRIPTION

DBI::ProfileDumper is a subclass of *DBI::Profile* which dumps profile data to disk instead of printing a summary to your screen. You can then use dbiprof to analyze the data in a number of interesting ways, or you can roll your own analysis using *DBI::ProfileData*.

NOTE: For Apache/mod_perl applications, use DBI::ProfileDumper::Apache.

USAGE

One way to use this module is just to enable it in your `$dbh`:

```
$dbh->{Profile} = "1/DBI::ProfileDumper";
```

This will write out profile data by statement into a file called `dbi.prof`. If you want to modify either of these properties, you can construct the DBI::ProfileDumper object yourself:

```
use DBI::ProfileDumper;
$dbh->{Profile} = DBI::ProfileDumper->new(
    Path => [ '!Statement' ],
    File => 'dbi.prof'
);
```

The `Path` option takes the same values as in *DBI::Profile*. The `File` option gives the name of the file where results will be collected. If it already exists it will be overwritten.

You can also activate this module by setting the DBI_PROFILE environment variable:

```
$ENV{DBI_PROFILE} = "!Statement/DBI::ProfileDumper";
```

This will cause all DBI handles to share the same profiling object.

METHODS

The following methods are available to be called using the profile object. You can get access to the profile object from the Profile key in any DBI handle:

```
my $profile = $dbh->{Profile};
```

flush_to_disk

```
$profile->flush_to_disk()
```

Flushes all collected profile data to disk and empties the Data hash. Returns the filename written to. If no profile data has been collected then the file is not written and flush_to_disk() returns undef.

The file is locked while it's being written. A process 'consuming' the files while they're being written to, should rename the file first, then lock it, then read it, then close and delete it. The `DeleteFiles` option to *DBI::ProfileData* does the right thing.

This method may be called multiple times during a program run.

empty

```
$profile->empty()
```

Clears the Data hash without writing to disk.

filename

```
$filename = $profile->filename();
```

Get or set the filename.

The filename can be specified as a CODE reference, in which case the referenced code should return the filename to be used. The code will be called with the profile object as its first argument.

DATA FORMAT

The data format written by DBI::ProfileDumper starts with a header containing the version number of the module used to generate it. Then a block of variable declarations describes the profile. After two newlines, the profile data forms the body of the file. For example:

```
DBI::ProfileDumper 2.003762
Path = [ '!Statement', '!MethodName' ]
Program = t/42profile_data.t

+ 1 SELECT name FROM users WHERE id = ?
+ 2 prepare
= 1 0.0312958955764771 0.000490069389343262 0.000176072120666504 0.
 ↪00140702724456787 1023115819.83019 1023115819.86576
+ 2 execute
1 0.0312958955764771 0.000490069389343262 0.000176072120666504 0.
 ↪00140702724456787 1023115819.83019 1023115819.86576
+ 2 fetchrow_hashref
= 1 0.0312958955764771 0.000490069389343262 0.000176072120666504 0.
 ↪00140702724456787 1023115819.83019 1023115819.86576
```

(continues on next page)

(continued from previous page)

```
+ 1 UPDATE users SET name = ? WHERE id = ?
+ 2 prepare
= 1 0.0312958955764771 0.000490069389343262 0.000176072120666504 0.
 ↪00140702724456787 1023115819.83019 1023115819.86576
+ 2 execute
= 1 0.0312958955764771 0.000490069389343262 0.000176072120666504 0.
 ↪00140702724456787 1023115819.83019 1023115819.86576
```

The lines beginning with + signs signify keys. The number after the + sign shows the nesting level of the key. Lines beginning with = are the actual profile data, in the same order as in DBI::Profile.

Note that the same path may be present multiple times in the data file since `format()` may be called more than once. When read by DBI::ProfileData the data points will be merged to produce a single data set for each distinct path.

The key strings are transformed in three ways. First, all backslashes are doubled. Then all newlines and carriage-returns are transformed into `\n` and `\r` respectively. Finally, any NULL bytes (`\0`) are entirely removed. When DBI::ProfileData reads the file the first two transformations will be reversed, but NULL bytes will not be restored.

DBI::ProfileSubs

Subroutines for dynamic profile Path

SYNOPSIS

```
DBI_PROFILE='&norm_std_n3' prog.pl
```

This is new and still experimental.

TO DO

Define come kind of naming convention for the subs.

DBI::ProxyServer

a server for the DBD::Proxy driver

SYNOPSIS

```
use DBI::ProxyServer;
DBI::ProxyServer::main(@ARGV);
```

DESCRIPTION

DBI::Proxy Server is a module for implementing a proxy for the DBI proxy driver, DBD::Proxy. It allows access to databases over the network if the DBMS does not offer networked operations. But the proxy server might be useful for you, even if you have a DBMS with integrated network functionality: It can be used as a DBI proxy in a firewalled environment.

DBI::ProxyServer runs as a daemon on the machine with the DBMS or on the firewall. The client connects to the agent using the DBI driver DBD::Proxy, thus in the exactly same way than using DBD::mysql, DBD::mSQL or any other DBI driver.

The agent is implemented as a RPC::PlServer application. Thus you have access to all the possibilities of this module, in particular encryption and a similar configuration file. DBI::ProxyServer adds the possibility of query restrictions: You can define a set of queries that a client may execute and restrict access to those. (Requires a DBI driver that supports parameter binding.) See “CONFIGURATION FILE”.

The provided driver script, dbiproxy, may either be used as it is or used as the basis for a local version modified to meet your needs.

OPTIONS

When calling the DBI::ProxyServer::main() function, you supply an array of options. These options are parsed by the Getopt::Long module. The ProxyServer inherits all of RPC::PlServer’s and hence Net::Daemon’s options and option handling, in particular the ability to read options from either the command line or a config file. See RPC::PlServer. See Net::Daemon. Available options include

- *chroot* (**–chroot=dir**)

  (UNIX only) After doing a bind(), change root directory to the given directory by doing a chroot(). This is useful for security, but it restricts the environment a lot. For example, you need to load DBI drivers in the config file or you have to create hard links to Unix sockets, if your drivers are using them. For example, with MySQL, a config file might contain the following lines:

  ```
  my $rootdir = '/var/dbiproxy';
  my $unixsockdir = '/tmp';
  my $unixsockfile = 'mysql.sock';
  foreach $dir ($rootdir, "$rootdir$unixsockdir") {
      mkdir 0755, $dir;
  }
  ```

(continues on next page)

(continued from previous page)

```
link("$unixsockdir/$unixsockfile",
     "$rootdir$unixsockdir/$unixsockfile");
require DBD::mysql;

{
    'chroot' => $rootdir,
    ...
}
```

If you don't know chroot(), think of an FTP server where you can see a certain directory tree only after logging in. See also the –group and –user options.

- *clients*

  An array ref with a list of clients. Clients are hash refs, the attributes *accept* (0 for denying access and 1 for permitting) and *mask*, a Perl regular expression for the clients IP number or its host name.

- *configfile* (**–configfile=file**)

  Config files are assumed to return a single hash ref that overrides the arguments of the new method. However, command line arguments in turn take precedence over the config file. See the "CONFIGURATION FILE" section below for details on the config file.

- *debug* (**–debug**)

  Turn debugging mode on. Mainly this asserts that logging messages of level "debug" are created.

- *facility* (**–facility=mode**)

  (UNIX only) Facility to use for *Sys::Syslog*. The default is **daemon**.

- *group* (**–group=gid**)

  After doing a bind(), change the real and effective GID to the given. This is useful, if you want your server to bind to a privileged port (<1024), but don't want the server to execute as root. See also the –user option.

  GID's can be passed as group names or numeric values.

- *localaddr* (**–localaddr=ip**)

  By default a daemon is listening to any IP number that a machine has. This attribute allows one to restrict the server to the given IP number.

- *localport* (**–localport=port**)

  This attribute sets the port on which the daemon is listening. It must be given somehow, as there's no default.

- *logfile* (**–logfile=file**)

  Be default logging messages will be written to the syslog (Unix) or to the event log (Windows NT). On other operating systems you need to specify a log file. The special value "STDERR" forces logging to stderr. See Net::Daemon::Log for details.

- *mode* (–**mode**=**modename**)

  The server can run in three different modes, depending on the environment.

  If you are running Perl 5.005 and did compile it for threads, then the server will create a new thread for each connection. The thread will execute the server's Run() method and then terminate. This mode is the default, you can force it with "–mode=threads".

  If threads are not available, but you have a working fork(), then the server will behave similar by creating a new process for each connection. This mode will be used automatically in the absence of threads or if you use the "–mode=fork" option.

  Finally there's a single-connection mode: If the server has accepted a connection, he will enter the Run() method. No other connections are accepted until the Run() method returns (if the client disconnects). This operation mode is useful if you have neither threads nor fork(), for example on the Macintosh. For debugging purposes you can force this mode with "–mode=single".

- *pidfile* (–**pidfile**=**file**)

  (UNIX only) If this option is present, a PID file will be created at the given location. Default is to not create a pidfile.

- *user* (–**user**=**uid**)

  After doing a bind(), change the real and effective UID to the given. This is useful, if you want your server to bind to a privileged port (<1024), but don't want the server to execute as root. See also the –group and the –chroot options.

  UID's can be passed as group names or numeric values.

- *version* (–**version**)

  Suppresses startup of the server; instead the version string will be printed and the program exits immediately.

SHUTDOWN

DBI::ProxyServer is built on RPC::PlServer which is, in turn, built on Net::Daemon.

You should refer to Net::Daemon for how to shutdown the server, except that you can't because it's not currently documented there (as of v0.43). The bottom-line is that it seems that there's no support for graceful shutdown.

CONFIGURATION FILE

The configuration file is just that of *RPC::PlServer* or *Net::Daemon* with some additional attributes in the client list.

The config file is a Perl script. At the top of the file you may include arbitrary Perl source, for example load drivers at the start (useful to enhance performance), prepare a chroot environment and so on.

The important thing is that you finally return a hash ref of option name/value pairs. The possible options are listed above.

All possibilities of Net::Daemon and RPC::PlServer apply, in particular

- Host and/or User dependent access control
- Host and/or User dependent encryption
- Changing UID and/or GID after binding to the port
- Running in a chroot() environment

Additionally the server offers you query restrictions. Suggest the following client list:

```
'clients' => [
    { 'mask' => '^admin\.company\.com$',
      'accept' => 1,
      'users' => [ 'root', 'wwwrun' ],
    },
    {
      'mask' => '^admin\.company\.com$',
      'accept' => 1,
      'users' => [ 'root', 'wwwrun' ],
      'sql' => {
          'select' => 'SELECT * FROM foo',
          'insert' => 'INSERT INTO foo VALUES (?, ?, ?)'
          }
    }
```

then only the users root and wwwrun may connect from admin.company.com, executing arbitrary queries, but only wwwrun may connect from other hosts and is restricted to

```
$sth->prepare("select");
```

or

```
$sth->prepare("insert");
```

which in fact are “SELECT * FROM foo” or “INSERT INTO foo VALUES (?, ?, ?)”.

Proxyserver Configuration file (bigger example)

This section tells you how to restrict a DBI-Proxy: Not every user from every workstation shall be able to execute every query.

There is a perl program “dbiproxy” which runs on a machine which is able to connect to all the databases we wish to reach. All Perl-DBD-drivers must be installed on this machine. You can also reach databases for which drivers are not available on the machine where you run the program querying the database, e.g. ask MS-Access-database from Linux.

Create a configuration file “proxy_oracle.cfg” at the dbproxy-server:

```
{
    # This shall run in a shell or a DOS-window
    # facility => 'daemon',
    pidfile => 'your_dbiproxy.pid',
    logfile => 1,
```

(continues on next page)

(continued from previous page)

```
    debug => 0,
    mode => 'single',
    localport => '12400',

    # Access control, the first match in this list wins!
    # So the order is important
    clients => [
            # hint to organize:
            # the most specialized rules for single machines/users
↪are 1st
            # then the denying rules
            # then the rules about whole networks

            # rule: internal_webserver
            # desc: to get statistical information
            {
                    # this IP-address only is meant
                    mask => '^10\.95\.81\.243$',
                    # accept (not defer) connections like this
                    accept => 1,
                    # only users from this list
                    # are allowed to log on
                    users => [ 'informationdesk' ],
                    # only this statistical query is allowed
                    # to get results for a web-query
                    sql => {
                            alive => 'select count(*) from dual',
                            statistic_area => 'select count(*) from
↪e01admin.e01e203 where geb_bezei like ?',
                    }
            },

            # rule: internal_bad_guy_1
            {
                    mask => '^10\.95\.81\.1$',
                    accept => 0,
            },

            # rule: employee_workplace
            # desc: get detailed information
            {
                    # any IP-address is meant here
                    mask => '^10\.95\.81\.(\d+)$',
                    # accept (not defer) connections like this
                    accept => 1,
                    # only users from this list
                    # are allowed to log on
                    users => [ 'informationdesk', 'lippmann' ],
                    # all these queries are allowed:
```

(continues on next page)

(continued from previous page)

```
                    sql => {
                            search_city => 'select ort_nr, plz, ort␣
↪from e01admin.e01e200 where plz like ?',
                            search_area => 'select gebiettyp, geb_
↪bezei from e01admin.e01e203 where geb_bezei like ? or geb_bezei␣
↪like ?',
                    }
            },

            # rule: internal_bad_guy_2
            # This does NOT work, because rule "employee_workplace"␣
↪hits
            # with its ip-address-mask of the whole network
            {
                    # don't accept connection from this ip-address
                    mask => '^10\.95\.81\.5$',
                    accept => 0,
            }
    ]
}
```

Start the proxyserver like this:

```
rem well-set Oracle_home needed for Oracle
set ORACLE_HOME=d:\oracle\ora81
dbiproxy --configfile proxy_oracle.cfg
```

Testing the connection from a remote machine

Call a program “dbish” from your commandline. I take the machine from rule “internal_webserver”

```
dbish "dbi:Proxy:hostname=oracle.zdf;port=12400;dsn=dbi:Oracle:e01"␣
↪informationdesk xxx
```

There will be a shell-prompt:

```
informationdesk@dbi...> alive

Current statement buffer (enter '/'...):
alive

informationdesk@dbi...> /
COUNT(*)
'1'
[1 rows of 1 fields returned]
```

Testing the connection with a perl-script

Create a perl-script like this:

```
# file: oratest.pl
# call me like this: perl oratest.pl user password

use strict;
use DBI;

my $user = shift || die "Usage: $0 user password";
my $pass = shift || die "Usage: $0 user password";
my $config = {
        dsn_at_proxy => "dbi:Oracle:e01",
        proxy => "hostname=oechsle.zdf;port=12400",
};
my $dsn = sprintf "dbi:Proxy:%s;dsn=%s",
        $config->{proxy},
        $config->{dsn_at_proxy};

my $dbh = DBI->connect( $dsn, $user, $pass )
        || die "connect did not work: $DBI::errstr";

my $sql = "search_city";
printf "%s\n%s\n%s\n", "="x40, $sql, "="x40;
my $cur = $dbh->prepare($sql);
$cur->bind_param(1,'905%');
&show_result ($cur);

my $sql = "search_area";
printf "%s\n%s\n%s\n", "="x40, $sql, "="x40;
my $cur = $dbh->prepare($sql);
$cur->bind_param(1,'Pfarr%');
$cur->bind_param(2,'Bronnamberg%');
&show_result ($cur);

my $sql = "statistic_area";
printf "%s\n%s\n%s\n", "="x40, $sql, "="x40;
my $cur = $dbh->prepare($sql);
$cur->bind_param(1,'Pfarr%');
&show_result ($cur);

$dbh->disconnect;
exit;

sub show_result {
        my $cur = shift;
        unless ($cur->execute()) {
                print "Could not execute\n";
                return;
```

(continues on next page)

(continued from previous page)

```
        }

        my $rownum = 0;
        while (my @row = $cur->fetchrow_array()) {
                printf "Row is: %s\n", join(", ",@row);
                if ($rownum++ > 5) {
                        print "... and so on\n";
                        last;
                }
        }
        $cur->finish;
}
```

The result

```
C:\>perl oratest.pl informationdesk xxx
========================================
search_city
========================================
Row is: 3322, 9050, Chemnitz
Row is: 3678, 9051, Chemnitz

Could not execute
```

How the configuration works

The most important section to control access to your dbi-proxy is “client=>” in the file “proxy_oracle.cfg”:

Controlling which person at which machine is allowed to access

- "mask" is a perl regular expression against the plain ip-address of the machine which wishes to connect _or_ the reverse-lookup from a nameserver.
- "accept" tells the dbiproxy-server whether ip-addresses like in "mask" are allowed to connect or not (0/1)
- "users" is a reference to a list of usernames which must be matched, this is NOT a regular expression.

Controlling which SQL-statements are allowed

You can put every SQL-statement you like in simply omitting "sql => ...", but the more important thing is to restrict the connection so that only allowed queries are possible.

If you include an sql-section in your config-file like this:

```
sql => {
        alive => 'select count(*) from dual',
        statistic_area => 'select count(*) from e01admin.e01e203␣
↪where geb_bezei like ?',
}
```

The user is allowed to put two queries against the dbi-proxy. The queries are _not_ "select count(*)...", the queries are "alive" and "statistic_area"! These keywords are replaced by the real query. So you can run a query for "alive":

```
my $sql = "alive";
my $cur = $dbh->prepare($sql);
...
```

The flexibility is that you can put parameters in the where-part of the query so the query are not static. Simply replace a value in the where-part of the query through a question mark and bind it as a parameter to the query.

```
my $sql = "statistic_area";
my $cur = $dbh->prepare($sql);
$cur->bind_param(1,'905%');
# A second parameter would be called like this:
# $cur->bind_param(2,'98%');
```

The result is this query:

```
select count(*) from e01admin.e01e203
where geb_bezei like '905%'
```

Don't try to put parameters into the sql-query like this:

```
# Does not work like you think.
# Only the first word of the query is parsed,
# so it's changed to "statistic_area", the rest is omitted.
# You _have_ to work with $cur->bind_param.
my $sql = "statistic_area 905%";
my $cur = $dbh->prepare($sql);
...
```

Problems

- I don't know how to restrict users to special databases.
- I don't know how to pass query-parameters via dbish

SECURITY WARNING

RPC::PlServer used underneath is not secure due to serializing and deserializing data with *Storable* module. Use the proxy driver only in trusted environment.

DBI::PurePerl

SYNOPSIS

```
BEGIN { $ENV{DBI_PUREPERL} = 2 }
use DBI;
```

DESCRIPTION

This is a pure perl emulation of the DBI internals. In almost all cases you will be better off using standard DBI since the portions of the standard version written in C make it *much* faster.

However, if you are in a situation where it isn't possible to install a compiled version of standard DBI, and you're using pure-perl DBD drivers, then this module allows you to use most common features of DBI without needing any changes in your scripts.

EXPERIMENTAL STATUS

DBI::PurePerl is new so please treat it as experimental pending more extensive testing. So far it has passed all tests with DBD::CSV, DBD::AnyData, DBD::XBase, DBD::Sprite, DBD::mysqlPP. Please send bug reports to Jeff Zucker at jeff@vpservices.com with a cc to dbi-dev@perl.org.

USAGE

The usage is the same as for standard DBI with the exception that you need to set the environment variable DBI_PUREPERL if you want to use the PurePerl version.

```
DBI_PUREPERL == 0 (the default) Always use compiled DBI, die
                 if it isn't properly compiled & installed

DBI_PUREPERL == 1 Use compiled DBI if it is properly compiled
                 & installed, otherwise use PurePerl

DBI_PUREPERL == 2 Always use PurePerl
```

You may set the environment variable in your shell (e.g. with set or setenv or export, etc) or else set it in your script like this:

```
BEGIN { $ENV{DBI_PUREPERL}=2 }
```

before you `use DBI;`.

INSTALLATION

In most situations simply install DBI (see the DBI pod for details).

In the situation in which you can not install DBI itself, you may manually copy DBI.pm and PurePerl.pm into the appropriate directories.

For example:

```
cp DBI.pm      /usr/jdoe/mylibs/.
cp PurePerl.pm /usr/jdoe/mylibs/DBI/.
```

Then add this to the top of scripts:

```
BEGIN {
  $ENV{DBI_PUREPERL} = 1;      # or =2
  unshift @INC, '/usr/jdoe/mylibs';
}
```

(Or should we perhaps patch Makefile.PL so that if DBI_PUREPERL is set to 2 prior to make, the normal compile process is skipped and the files are installed automatically?)

DIFFERENCES BETWEEN DBI AND DBI::PurePerl

Attributes

Boolean attributes still return boolean values but the actual values used may be different, i.e., 0 or undef instead of an empty string.

Some handle attributes are either not supported or have very limited functionality:

```
ActiveKids
InactiveDestroy
AutoInactiveDestroy
Kids
Taint
TaintIn
TaintOut
```

(and probably others)

Tracing

Trace functionality is more limited and the code to handle tracing is only embedded into DBI:PurePerl if the DBI_TRACE environment variable is defined. To enable total tracing you can set the DBI_TRACE environment variable as usual. But to enable individual handle tracing using the trace() method you also need to set the DBI_TRACE environment variable, but set it to 0.

Parameter Usage Checking

The DBI does some basic parameter count checking on method calls. DBI::PurePerl doesn't.

Speed

DBI::PurePerl is slower. Although, with some drivers in some contexts this may not be very significant for you.

By way of example... the test.pl script in the DBI source distribution has a simple benchmark that just does:

```
my $null_dbh = DBI->connect('dbi:NullP:','','');
my $i = 10_000;
$null_dbh->prepare('') while $i--;
```

In other words just prepares a statement, creating and destroying a statement handle, over and over again. Using the real DBI this runs at ~4550 handles per second whereas DBI::PurePerl manages ~2800 per second on the same machine (not too bad really).

May not fully support hash()

If you want to use type 1 hash, i.e., `hash($string,1)` with DBI::PurePerl, you'll need version 1.56 or higher of Math::BigInt (available on CPAN).

Doesn't support preparse()

The DBI->preparse() method isn't supported in DBI::PurePerl.

Doesn't support DBD::Proxy

There's a subtle problem somewhere I've not been able to identify. DBI::ProxyServer seem to work fine with DBI::PurePerl but DBD::Proxy does not work 100% (which is sad because that would be far more useful :) Try re-enabling t/80proxy.t for DBI::PurePerl to see if the problem that remains will affect you're usage.

Others

```
can() - doesn't have any special behaviour
```

Please let us know if you find any other differences between DBI and DBI::PurePerl.

AUTHORS

Tim Bunce and Jeff Zucker.

Tim provided the direction and basis for the code. The original idea for the module and most of the brute force porting from C to Perl was by Jeff. Tim then reworked some core parts to boost the performance and accuracy of the emulation. Thanks also to Randal Schwartz and John Tobey for patches.

DBI::SQL

Namespace containing the following modules:

- `DBI::SQL::Nano` - a very tiny SQL engine

DBI::SQL::Nano

a very tiny SQL engine

SYNOPSIS

```
BEGIN { $ENV{DBI_SQL_NANO}=1 } # forces use of Nano rather than␣
↪SQL::Statement
use DBI::SQL::Nano;
use Data::Dumper;
my $stmt = DBI::SQL::Nano::Statement->new(
    "SELECT bar,baz FROM foo WHERE qux = 1"
) or die "Couldn't parse";
print Dumper $stmt;
```

DESCRIPTION

DBI::SQL::Nano is meant as a *very* minimal SQL engine for use in situations where SQL::Statement is not available. In most situations you are better off installing SQL::Statement although DBI::SQL::Nano may be faster for some **very** simple tasks.

DBI::SQL::Nano, like SQL::Statement is primarily intended to provide a SQL engine for use with some pure perl DBDs including *DBD::DBM*, DBD::CSV, DBD::AnyData, and DBD::Excel. It is not of much use in and of itself. You can dump out the structure of a parsed SQL statement, but that is about it.

USAGE

Setting the DBI_SQL_NANO flag

By default, when a DBD uses DBI::SQL::Nano, the module will look to see if SQL::Statement is installed. If it is, SQL::Statement objects are used. If SQL::Statement is not available, DBI::SQL::Nano objects are used.

In some cases, you may wish to use DBI::SQL::Nano objects even if SQL::Statement is available. To force usage of DBI::SQL::Nano objects regardless of the availability of SQL::Statement, set the environment variable DBI_SQL_NANO to 1.

You can set the environment variable in your shell prior to running your script (with SET or EXPORT or whatever), or else you can set it in your script by putting this at the top of the script:

```
BEGIN { $ENV{DBI_SQL_NANO} = 1 }
```

Supported SQL syntax

```
Here's a pseudo-BNF.  Square brackets [] indicate optional items;
Angle brackets <> indicate items defined elsewhere in the BNF.

 statement ::=
     DROP TABLE [IF EXISTS] <table_name>
   | CREATE TABLE <table_name> <col_def_list>
   | INSERT INTO <table_name> [<insert_col_list>] VALUES <val_list>
   | DELETE FROM <table_name> [<where_clause>]
```

(continues on next page)

(continued from previous page)

```
  | UPDATE <table_name> SET <set_clause> <where_clause>
  | SELECT <select_col_list> FROM <table_name> [<where_clause>]
                                               [<order_clause>]

the optional IF EXISTS clause ::=
  * similar to MySQL - prevents errors when trying to drop
    a table that doesn't exist

identifiers ::=
  * table and column names should be valid SQL identifiers
  * especially avoid using spaces and commas in identifiers
  * note: there is no error checking for invalid names, some
    will be accepted, others will cause parse failures

table_name ::=
  * only one table (no multiple table operations)
  * see identifier for valid table names

col_def_list ::=
  * a parens delimited, comma-separated list of column names
  * see identifier for valid column names
  * column types and column constraints may be included but are␣
↪ignored
    e.g. these are all the same:
      (id,phrase)
      (id INT, phrase VARCHAR(40))
      (id INT PRIMARY KEY, phrase VARCHAR(40) NOT NULL)
  * you are *strongly* advised to put in column types even though
    they are ignored ... it increases portability

insert_col_list ::=
  * a parens delimited, comma-separated list of column names
  * as in standard SQL, this is optional

select_col_list ::=
  * a comma-separated list of column names
  * or an asterisk denoting all columns

val_list ::=
  * a parens delimited, comma-separated list of values which can␣
↪be:
     * placeholders (an unquoted question mark)
     * numbers (unquoted numbers)
     * column names (unquoted strings)
     * nulls (unquoted word NULL)
     * strings (delimited with single quote marks);
     * note: leading and trailing percent mark (%) and underscore␣
↪(_)
       can be used as wildcards in quoted strings for use with
```

(continues on next page)

(continued from previous page)

```
        the LIKE and CLIKE operators
      * note: escaped single quotation marks within strings are not
        supported, neither are embedded commas, use placeholders␣
↪instead

 set_clause ::=
   * a comma-separated list of column = value pairs
   * see val_list for acceptable value formats

 where_clause ::=
   * a single "column/value <op> column/value" predicate, optionally
     preceded by "NOT"
   * note: multiple predicates combined with ORs or ANDs are not␣
↪supported
   * see val_list for acceptable value formats
   * op may be one of:
        < > >= <= = <> LIKE CLIKE IS
   * CLIKE is a case insensitive LIKE
   * IS NULL matches against NULL and empty strings

 order_clause ::= column_name [ASC|DESC]
   * a single column optional ORDER BY clause is supported
   * as in standard SQL, if neither ASC (ascending) nor
     DESC (descending) is specified, ASC becomes the default
```

TABLES

DBI::SQL::Nano::Statement operates on exactly one table. This table will be opened by inherit from DBI::SQL::Nano::Statement and implements the open_table method.

```
sub open_table ($$$$$)
{
    ...
    return Your::Table->new( \%attributes );
}
```

DBI::SQL::Nano::Statement_ expects a rudimentary interface is implemented by the table object, as well as SQL::Statement expects.

```
package Your::Table;

our @ISA = qw(DBI::SQL::Nano::Table);

sub drop ($$)        { ... }
sub fetch_row ($$$)  { ... }
sub push_row ($$$)   { ... }
sub push_names ($$$) { ... }
sub truncate ($$)    { ... }
sub seek ($$$$)      { ... }
```

The base class interfaces are provided by DBI::SQL::Nano::Table_ in case of relying on DBI::SQL::Nano or SQL::Eval::Table (see SQL::Eval for details) otherwise.

BUGS AND LIMITATIONS

There are no known bugs in DBI::SQL::Nano::Statement. If you find a one and want to report, please see *DBI* for how to report bugs.

DBI::SQL::Nano::Statement is designed to provide a minimal subset for executing SQL statements.

The most important limitation might be the restriction on one table per statement. This implies, that no JOINs are supported and there cannot be any foreign key relation between tables.

The where clause evaluation of DBI::SQL::Nano::Statement is very slow (SQL::Statement uses a precompiled evaluation).

INSERT can handle only one row per statement. To insert multiple rows, use placeholders as explained in DBI.

The DBI::SQL::Nano parser is very limited and does not support any additional syntax such as brackets, comments, functions, aggregations etc.

In contrast to SQL::Statement, temporary tables are not supported.

ACKNOWLEDGEMENTS

Tim Bunce provided the original idea for this module, helped me out of the tangled trap of namespaces, and provided help and advice all along the way. Although I wrote it from the ground up, it is based on Jochen Wiedmann's original design of SQL::Statement, so much of the credit for the API goes to him.

AUTHOR AND COPYRIGHT

DBI::Util

Namespace containing the following modules:

- `DBI::Util::CacheMemory` - a very fast but very minimal subset of Cache::Memory

DBI::Util::CacheMemory

a very fast but very minimal subset of Cache::Memory

DESCRIPTION

Like Cache::Memory (part of the Cache distribution) but doesn't support any fancy features.

This module aims to be a very fast compatible strict sub-set for simple cases, such as basic client-side caching for DBD::Gofer.

Like Cache::Memory, and other caches in the Cache and Cache::Cache distributions, the data will remain in the cache until cleared, it expires, or the process dies. The cache object simply going out of scope will *not* destroy the data.

METHODS WITH CHANGES

new

All options except `namespace` are ignored.

set

Doesn't support expiry.

purge

Same as clear() - deletes everything in the namespace.

METHODS WITHOUT CHANGES

- clear
- count
- exists
- remove

UNSUPPORTED METHODS

If it's not listed above, it's not supported.

5.2.25 DBM_Filter

Filter DBM keys/values

SYNOPSIS

```
use DBM_Filter ;
use SDBM_File; # or DB_File, GDBM_File, NDBM_File, or ODBM_File

$db = tie %hash, ...

$db->Filter_Push(Fetch => sub {...},
                 Store => sub {...});

$db->Filter_Push('my_filter1');
$db->Filter_Push('my_filter2', params...);

$db->Filter_Key_Push(...) ;
$db->Filter_Value_Push(...) ;

$db->Filter_Pop();
$db->Filtered();

package DBM_Filter::my_filter1;

sub Store { ... }
sub Fetch { ... }

1;

package DBM_Filter::my_filter2;

sub Filter
{
    my @opts = @_;
    ...
    return (
        sub Store { ... },
        sub Fetch { ... } );
}

1;
```

DESCRIPTION

This module provides an interface that allows filters to be applied to tied Hashes associated with DBM files. It builds on the DBM Filter hooks that are present in all the *DB*_File modules included with the standard Perl source distribution from version 5.6.1 onwards. In addition to the *DB*_File modules distributed with Perl, the BerkeleyDB module, available on CPAN, supports the DBM Filter hooks. See perldbmfilter for more details on the DBM Filter hooks.

What is a DBM Filter?

A DBM Filter allows the keys and/or values in a tied hash to be modified by some user-defined code just before it is written to the DBM file and just after it is read back from the DBM file. For example, this snippet of code

```
$some_hash{"abc"} = 42;
```

could potentially trigger two filters, one for the writing of the key "abc" and another for writing the value 42. Similarly, this snippet

```
my ($key, $value) = each %some_hash
```

will trigger two filters, one for the reading of the key and one for the reading of the value.

Like the existing DBM Filter functionality, this module arranges for the `$_` variable to be populated with the key or value that a filter will check. This usually means that most DBM filters tend to be very short.

So what's new?

The main enhancements over the standard DBM Filter hooks are:

- A cleaner interface.
- The ability to easily apply multiple filters to a single DBM file.
- The ability to create "canned" filters. These allow commonly used filters to be packaged into a stand-alone module.

METHODS

This module will arrange for the following methods to be available via the object returned from the `tie` call.

$db->Filter_Push() / $db->Filter_Key_Push() / $db->Filter_Value_Push()

Add a filter to filter stack for the database, `$db`. The three formats vary only in whether they apply to the DBM key, the DBM value or both.

- Filter_Push

  The filter is applied to *both* keys and values.

- Filter_Key_Push

  The filter is applied to the key *only*.

- Filter_Value_Push

  The filter is applied to the value *only*.

$db->Filter_Pop()

Removes the last filter that was applied to the DBM file associated with $db, if present.

$db->Filtered()

Returns TRUE if there are any filters applied to the DBM associated with $db. Otherwise returns FALSE.

Writing a Filter

Filters can be created in two main ways

Immediate Filters

An immediate filter allows you to specify the filter code to be used at the point where the filter is applied to a dbm. In this mode the Filter_*_Push methods expects to receive exactly two parameters.

```
my $db = tie %hash, 'SDBM_File', ...
$db->Filter_Push( Store => sub { },
                  Fetch => sub { });
```

The code reference associated with `Store` will be called before any key/value is written to the database and the code reference associated with `Fetch` will be called after any key/value is read from the database.

For example, here is a sample filter that adds a trailing NULL character to all strings before they are written to the DBM file, and removes the trailing NULL when they are read from the DBM file

```
my $db = tie %hash, 'SDBM_File', ...
$db->Filter_Push( Store => sub { $_ .= "\x00" ; },
                  Fetch => sub { s/\x00$// ;    });
```

Points to note:

1. Both the Store and Fetch filters manipulate $_.

Canned Filters

Immediate filters are useful for one-off situations. For more generic problems it can be useful to package the filter up in its own module.

The usage is for a canned filter is:

```
$db->Filter_Push("name", params)
```

where

- “name”

  is the name of the module to load. If the string specified does not contain the package separator characters “::”, it is assumed to refer to the full module name

"DBM_Filter::name". This means that the full names for canned filters, "null" and "utf8", included with this module are:

```
DBM_Filter::null
DBM_Filter::utf8
```

- params

  any optional parameters that need to be sent to the filter. See the encode filter for an example of a module that uses parameters.

The module that implements the canned filter can take one of two forms. Here is a template for the first

```
package DBM_Filter::null ;

use strict;
use warnings;

sub Store
{
    # store code here
}

sub Fetch
{
    # fetch code here
}

1;
```

Notes:

1. The package name uses the `DBM_Filter::` prefix.
2. The module *must* have both a Store and a Fetch method. If only one is present, or neither are present, a fatal error will be thrown.

The second form allows the filter to hold state information using a closure, thus:

```
package DBM_Filter::encoding ;

use strict;
use warnings;

sub Filter
{
    my @params = @_ ;

    ...
    return {
        Store   => sub { $_ = $encoding->encode($_) },
        Fetch   => sub { $_ = $encoding->decode($_) }
        } ;
```

(continues on next page)

(continued from previous page)

```
}

1;
```

In this instance the “Store” and “Fetch” methods are encapsulated inside a “Filter” method.

Filters Included

A number of canned filers are provided with this module. They cover a number of the main areas that filters are needed when interfacing with DBM files. They also act as templates for your own filters.

The filter included are:

- utf8

  This module will ensure that all data written to the DBM will be encoded in UTF-8.

  This module needs the Encode module.

- encode

  Allows you to choose the character encoding will be store in the DBM file.

- compress

  This filter will compress all data before it is written to the database and uncompressed it on reading.

  This module needs Compress::Zlib.

- int32

  This module is used when interoperating with a C/C++ application that uses a C int as either the key and/or value in the DBM file.

- null

  This module ensures that all data written to the DBM file is null terminated. This is useful when you have a perl script that needs to interoperate with a DBM file that a C program also uses. A fairly common issue is for the C application to include the terminating null in a string when it writes to the DBM file. This filter will ensure that all data written to the DBM file can be read by the C application.

NOTES

Maintain Round Trip Integrity

When writing a DBM filter it is *very* important to ensure that it is possible to retrieve all data that you have written when the DBM filter is in place. In practice, this means that whatever transformation is applied to the data in the Store method, the *exact* inverse operation should be applied in the Fetch method.

If you don’t provide an exact inverse transformation, you will find that code like this will not behave as you expect.

```
while (my ($k, $v) = each %hash)
{
    ...
}
```

Depending on the transformation, you will find that one or more of the following will happen

1. The loop will never terminate.
2. Too few records will be retrieved.
3. Too many will be retrieved.
4. The loop will do the right thing for a while, but it will unexpectedly fail.

Don't mix filtered & non-filtered data in the same database file.

This is just a restatement of the previous section. Unless you are completely certain you know what you are doing, avoid mixing filtered & non-filtered data.

EXAMPLE

Say you need to interoperate with a legacy C application that stores keys as C ints and the values and null terminated UTF-8 strings. Here is how you would set that up

```
my $db = tie %hash, 'SDBM_File', ...

$db->Filter_Key_Push('int32') ;

$db->Filter_Value_Push('utf8');
$db->Filter_Value_Push('null');
```

AUTHOR

Paul Marquess pmqs@cpan.org

Modules

- `DBM_Filter::compress` - filter for DBM_Filter
- `DBM_Filter::encode` - filter for DBM_Filter
- `DBM_Filter::int32` - filter for DBM_Filter
- `DBM_Filter::null` - filter for DBM_Filter
- `DBM_Filter::utf8` - filter for DBM_Filter

DBM_Filter::compress

filter for DBM_Filter

SYNOPSIS

```
use SDBM_File; # or DB_File, GDBM_File, NDBM_File, ODBM_File
use DBM_Filter ;

$db = tie %hash, ...
$db->Filter_Push('compress');
```

DESCRIPTION

This DBM filter will compress all data before it is written to the database and uncompressed it on reading.

A fatal error will be thrown if the Compress::Zlib module is not available.

SEE ALSO

DBM_Filter, perldbmfilter, *Compress::Zlib*

AUTHOR

Paul Marquess pmqs@cpan.org

DBM_Filter::encode

filter for DBM_Filter

SYNOPSIS

```
use SDBM_File; # or DB_File, GDBM_File, NDBM_File, ODBM_File
use DBM_Filter ;

$db = tie %hash, ...
$db->Filter_Push('encode' => 'iso-8859-16');
```

DESCRIPTION

This DBM filter allows you to choose the character encoding will be store in the DBM file. The usage is

```
$db->Filter_Push('encode' => ENCODING);
```

where “ENCODING” must be a valid encoding name that the Encode module recognises.

A fatal error will be thrown if:

1. The Encode module is not available.
2. The encoding requested is not supported by the Encode module.

DBM_Filter::int32

filter for DBM_Filter

SYNOPSIS

```
use SDBM_File; # or DB_File, GDBM_File, NDBM_File, or ODBM_File
use DBM_Filter ;

$db = tie %hash, ...
$db->Filter_Push('int32');
```

DESCRIPTION

This DBM filter is used when interoperating with a C/C++ application that uses a C int as either the key and/or value in the DBM file.

SEE ALSO

DBM_Filter, perldbmfilter

AUTHOR

Paul Marquess pmqs@cpan.org

DBM_Filter::null

filter for DBM_Filter

SYNOPSIS

```
use SDBM_File; # or DB_File, GDBM_File, NDBM_File, or ODBM_File
use DBM_Filter ;

$db = tie %hash, ...
$db->Filter_Push('null');
```

DESCRIPTION

This filter ensures that all data written to the DBM file is null terminated. This is useful when you have a perl script that needs to interoperate with a DBM file that a C program also uses. A fairly common issue is for the C application to include the terminating null in a string when it writes to the DBM file. This filter will ensure that all data written to the DBM file can be read by the C application.

DBM_Filter::utf8

filter for DBM_Filter

SYNOPSIS

```
use SDBM_File; # or DB_File, GDBM_File, NDBM_File, or ODBM_File
use DBM_Filter;

$db = tie %hash, ...
$db->Filter_Push('utf8');
```

DESCRIPTION

This Filter will ensure that all data written to the DBM will be encoded in UTF-8.

This module uses the Encode module.

5.2.26 DB_File

Tie a Perl hash or array to a database file: a hash table, a sorted B-tree, or an array of records kept in a plain text file.

`DB_File` binds a variable to a file with `tie`. From then on ordinary hash or array syntax reads and writes the file, and the object `tie` returns offers more: Berkeley DB's own methods (`get`, `put`, `del`, `seq`, `sync`, `fd`), duplicate keys, range lookups, and array methods. The last argument of `tie` picks one of three kinds of database:

- `$DB_HASH` - a tied hash whose keys come back in no particular order. The default.
- `$DB_BTREE` - a tied hash whose keys are kept sorted, by byte value or by a sort sub of your own. It can also hold several values per key, and find the first key at or after a given one.
- `$DB_RECNO` - a tied array over a text file, one element per line (or per fixed-length record). The file is an ordinary text file that other programs can read and write.

Synopsis

```
use DB_File;

# A sorted hash: walk it from a given key on
my $db = tie my %h, 'DB_File', 'fruit.db', O_RDWR|O_CREAT, 0640,
 ↪$DB_BTREE
    or die "fruit.db: $!";
$h{$_} = length for qw(apple banana cherry);
my ($k, $v) = ('b', '');
for (my $st = $db->seq($k, $v, R_CURSOR); $st == 0; $st = $db->seq(
 ↪$k, $v, R_NEXT)) {
    print "$k=$v\n";                # banana=6 cherry=6
}
undef $db;
untie %h;

# A text file as an array
tie my @lines, 'DB_File', 'notes.txt', O_RDWR|O_CREAT, 0640, $DB_
 ↪RECNO
    or die "notes.txt: $!";
push @lines, 'one more line';
untie @lines;
```

Opening a database

```
tie %h, 'DB_File', $filename, $flags, $mode, $DB_HASH;
tie %h, 'DB_File', $filename, $flags, $mode, $DB_BTREE;
tie @a, 'DB_File', $filename, $flags, $mode, $DB_RECNO;
```

`$flags` are `Fcntl`'s `O_RDONLY`, `O_RDWR`, `O_CREAT`, `O_TRUNC` (DB_File exports them); `$mode` is the permission of a file it creates. The defaults are `O_CREAT|O_RDWR`, `0666` and `$DB_HASH`, so `tie %h, 'DB_File', $filename` opens or creates a hash database. A relative file name is made absolute when the database is opened.

`tie` returns the database object, or undef with `$!` set when the file cannot be opened. Keep the object (`$db` above) to call methods on it, and `undef` it before `untie`: the file is closed only when the tied variable and every copy of the object are gone.

An undef file name opens an in-memory database: it is empty when tied and gone when untied.

`$DB_HASH`, `$DB_BTREE` and `$DB_RECNO` are ready-made settings objects. For other settings, make one and set its keys:

```
my $info = DB_File::BTREEINFO->new;
$info->{compare} = sub { lc $_[0] cmp lc $_[1] };
$info->{flags}   = R_DUP;
tie my %h, 'DB_File', 'names.db', O_RDWR|O_CREAT, 0640, $info;
```

- `DB_File::HASHINFO` takes `hash`, a sub returning a number for a key, and `bsize`, `cachesize`, `ffactor`, `nelem`, `lorder`.
- `DB_File::BTREEINFO` takes `compare`, `flags` (`R_DUP`), `prefix`, `cachesize`, `psize`, `lorder`, `maxkeypage`, `minkeypage`.
- `DB_File::RECNOINFO` takes `bval`, `flags` (`R_FIXEDLEN`), `reclen`, `bfname`, `cachesize`, `psize`, `lorder`.

Setting any other key croaks, and so does a plain value (not a reference) for `hash`, `compare` or `prefix`. The `hash` and `prefix` subs, `bsize`, `cachesize`, `ffactor`, `nelem`, `lorder`, `psize`, `maxkeypage` and `minkeypage` tune Berkeley DB's own file layout, which pperl's files do not have: they are accepted and change nothing. The `hash` sub is still called, once when the database opens and once for every operation on a key, and its result unused.

Sorted keys and duplicates

A `$DB_BTREE` database keeps its keys in byte order unless its settings carry a `compare` sub. That sub gets two keys and returns less than, equal to or greater than zero, as `cmp` does. The file does not remember it: every later `tie` of the file must give the same `compare`, or lookups go wrong.

With `flags` set to `R_DUP`, a key may hold several values, kept in the order they were stored. Fetching the key gives its first value; `keys` and `each` return the key once per value; deleting it deletes them all. These methods reach the values one by one:

- `$db->get_dup($key)` - the key's values, as a list; in scalar context, how many there are. `$db->get_dup($key, 1)` returns a hash counting each distinct value instead.
- `$db->find_dup($key, $value)` - 0 when the key holds that value, with the cursor left on it, so that `$db->del($key, R_CURSOR)` deletes just that one; 1 otherwise.
- `$db->del_dup($key, $value)` - deletes that one value of the key: 0 if it was there, 1 if not.

The file remembers that it holds duplicates: a later `tie` without `R_DUP` still has them, and asking for `R_DUP` of a file made without it fails the `tie` unless `O_TRUNC` empties the file.

Arrays

A `$DB_RECNO` array reads its text file when tied and writes it back at `sync` and `untie`, if anything changed. Each element is one line without its newline. `bval` sets another delimiter (`"-"`, or a character's number). With `flags => R_FIXEDLEN` and `reclen`, each element is that many bytes instead, a shorter one padded with `bval` (a space by default) and a longer one refused.

The file is created if it does not exist, and the array can always be written, whatever `$flags` say. Deleting an element moves the ones after it down. Storing past the end creates the elements in between as empty: they read as `undef`, `exists` is false for them, and they are written to the file as empty lines. A negative index counts from the end; one before the start croaks `Modification of non-creatable array value attempted`.

The array methods `push`, `pop`, `shift`, `unshift`, `length` and `splice` work on the database object as on the tied array. With no file name the array lives in memory only, or, when the settings have a `bfname`, in that text file.

The cursor

Every database has one cursor, which `seq` moves and the methods' `R_CURSOR` flag acts at. The tie interface moves it too: `keys`, `each`, pop and the like leave it somewhere else. A method that fails to move it leaves it where it was. After a delete at the cursor, `R_NEXT` goes on to the element after the deleted one and `R_PREV` to the one before.

Files

pperl keeps a `$DB_HASH` or `$DB_BTREE` database in an LMDB file: the file named, with LMDB's lock file, `NAME-lock`, beside it. The Berkeley DB library is not used, and its files cannot be read: tying a real Berkeley DB file (or a gdbm file) croaks, naming what the file is, and the file is left as it was. A key may be at most 511 bytes, 510 if it starts with a NUL byte and 503 in an `R_DUP` database; a longer one croaks.

Writes reach the file at `sync` and when the database is untied: until then the tie holds the file's one writer slot, and another process that writes the file waits for it (readers never wait). Set `$Peta::FFI::LMDB::DBM_WRITE = 'through'` before `tie` to commit every write as it happens, for files that several processes write; see `Peta::FFI::LMDB`.

Constants

DB_File exports the flags its methods take:

- `R_FIRST`, `R_LAST`, `R_NEXT`, `R_PREV` - where `seq` moves the cursor.
- `R_CURSOR` - `seq`: to the given key, or for a `$DB_BTREE` the first key at or after it; `put` and `del`: at the cursor.
- `R_IAFTER`, `R_IBEFORE` - `put` a new element after or before the given one (arrays, and `R_DUP` databases).
- `R_NOOVERWRITE` - `put` only a new key.
- `R_SETCURSOR` - `put`, then leave the cursor on the key.
- `R_DUP` - `DB_File::BTREEINFO` flag: keys with several values.
- `R_FIXEDLEN` - `DB_File::RECNOINFO` flag: fixed-length records.
- `R_RECNOSYNC` - accepted by `sync`; it is 0.

The other names it exports (`BTREEMAGIC`, `HASHMAGIC`, `R_NOKEY`, `RET_SUCCESS` and the like) are not defined: using one croaks `Your vendor has not defined DB_File macro ...`, as it does with the Berkeley DB versions perl links today.

`$DB_File::db_version` and `$DB_File::db_ver` give the version of the Berkeley DB interface the module follows, and `$DB_File::Error` the text of the last error a method reported.

Differences from upstream

- The files are LMDB files, not Berkeley DB files: real Berkeley DB files are refused, and pperl's files cannot be read by perl5's DB_File. A file that is not a DB_File database is never overwritten. Covered by `t/82-native/Peta-FFI-LMDB/100-db_file.t`.
- A `$DB_HASH` database's keys come in byte order, where Berkeley DB's come in the order of its hash buckets. Neither order is promised; code that prints a hash database without sorting prints it in a different order. Covered by `t/82-native/Peta-FFI-LMDB/100-db_file.t`.
- Keys are limited to 511 bytes (503 with `R_DUP`); Berkeley DB has no limit. Covered by `t/82-native/Peta-FFI-LMDB/100-db_file.t`.
- Writes reach the file at `sync` and `untie` (or each one, with `$Peta::FFI::LMDB::DBM_WRITE = 'through'`), and a writer holds the file until then. Covered by `t/82-native/Peta-FFI-LMDB/100-db_file.t`.
- Two ties of one `$DB_BTREE` file in a process must sort it the same way: a second tie with another order (a `compare` sub against none) fails with `EINVAL`. Covered by `t/82-native/Peta-FFI-LMDB/100-db_file.t`.
- With no file name but a `bfname`, a `$DB_RECNO` array keeps its records in `bfname` as a text file, where Berkeley DB writes a database file of its own format there. Covered by `t/82-native/Peta-FFI-LMDB/100-db_file.t`.
- The tuning settings and the `prefix` sub have no effect, and the `hash` sub's result is unused.
- `$DB_File::Error` carries Berkeley DB's message texts without their `BDB0123` numbers.

Everything else - status codes, the cursor, duplicates, Recno's records and text file - behaves as with Berkeley DB, down to its edge cases. Covered by `t/81-xs-native/DB_File/010-phenotype.t` and DB_File's own test suite, `t/81-xs-native/DB_File/100-upstream-db-btree.t` to `130-upstream-db-threads.t`.

Functions

Berkeley DB methods

`del`

Delete a key - every value of it, in an `R_DUP` database - or, with `R_CURSOR`, the one item the database's cursor stands on.

get

Look up a key and put its value in a variable, returning a status instead of the value - so a missing key and a stored undef can be told apart.

put

Store a value under a key, with flags that say where and whether.

fd

The file descriptor of the database's file - for a `$DB_RECNO` array, its text file - or -1 for an in-memory database.

sync

Write everything stored so far to the file and to disk, so that other processes - and the file after a crash - have it.

seq

Move the database's cursor and read the key and value it lands on: walk the database in order, or find the first key at or after a given one.

Array methods

unshift

Put elements at the start of a `$DB_RECNO` array, in the order given.

pop

Remove the last element of a `$DB_RECNO` array and return it.

shift

Remove the first element of a `$DB_RECNO` array and return it; the others move down one.

push

Add elements to the end of a `$DB_RECNO` array.

length

The number of elements of a `$DB_RECNO` array: up to and including its last element that holds a value, so `scalar(@a)` too. `FETCHSIZE` is the same method under the name the tied array calls. It moves the database's cursor to that last element.

Filters

filter_fetch_key

Install a sub that rewrites every key read from the database - by `keys`, `each` or `seq` - before your code sees it.

filter_store_key

Install a sub that rewrites every key on its way into the database - for storing, fetching, deleting or looking up - so the database holds the rewritten form.

filter_fetch_value

Install a sub that rewrites every value read from the database before your code sees it.

filter_store_value

Install a sub that rewrites every value on its way into the database, so the database holds the rewritten form.

unshift

Put elements at the start of a `$DB_RECNO` array, in the order given.

Synopsis

```
$db->unshift('first', 'second');
unshift @lines, 'header';
```

What you get back

0, or the error of the element that could not be stored - the elements after it are not stored either. `UNSHIFT` is the same method under the name the tied array calls.

Edge cases

- An empty array cannot be unshifted onto: nothing is stored, and the method returns 22 (`EINVAL`). `push` the first element instead.
- The elements go before the first element that holds a value, after any empty ones created by storing past them.
- It moves the database's cursor to the first element stored.

Differences from upstream

Fully compatible with upstream, edge cases included. Covered by `t/81-xs-native/DB_File/010-phenotype.t`.

See also

- `push` - the other end of the array
- `shift` - takes the first element off again

pop

Remove the last element of a `$DB_RECNO` array and return it.

Synopsis

```
my $last = $db->pop;
my $line = pop @lines;
```

What you get back

The element's value, or undef for an empty array. `POP` is the same method under the name the tied array calls.

Edge cases

- The array then ends at the last element that holds a value: empty elements before the removed one no longer count in its length, though the text file keeps them as empty lines.
- It leaves the database's cursor where the element was.

Differences from upstream

Fully compatible with upstream. Covered by `t/81-xs-native/DB_File/010-phenotype.t`.

See also

- `shift` - the same at the start of the array
- `length` - how many elements are left

shift

Remove the first element of a `$DB_RECNO` array and return it; the others move down one.

Synopsis

```
my $first = $db->shift;
my $line  = shift @lines;
```

What you get back

The element's value, or undef for an empty array. `SHIFT` is the same method under the name the tied array calls.

Edge cases

- Empty elements at the start are passed over: it removes the first element that holds a value, and the empty ones stay.

Differences from upstream

Fully compatible with upstream. Covered by `t/81-xs-native/DB_File/010-phenotype.t`.

See also

- pop - the same at the end of the array
- `unshift` - puts elements back at the start

push

Add elements to the end of a `$DB_RECNO` array.

Synopsis

```
$db->push('one', 'two');
push @lines, 'three';
```

What you get back

0, or the error of the element that could not be stored - the elements after it are not stored either. `PUSH` is the same method under the name the tied array calls.

Edge cases

- With no elements to add it returns 0 for an array that has elements, and `-30987` (Berkeley DB's `DB_NOTFOUND`) for an empty one.
- The new elements follow the last element that holds a value.

Differences from upstream

Fully compatible with upstream. Covered by `t/81-xs-native/DB_File/010-phenotype.t`.

See also

- pop - takes the last element off again
- `unshift` - adds at the start

del

Delete a key - every value of it, in an `R_DUP` database - or, with `R_CURSOR`, the one item the database's cursor stands on.

Synopsis

```
my $status = $db->del($key);
$status = $db->del($key, R_CURSOR);    # $key unused
```

What you get back

0 when something was deleted, 1 when the key was not there, -1 for an error. On an array, deleting an element created empty returns `-30995` (Berkeley DB's `DB_KEYEMPTY`).

Examples

```
$h{apple} = 'red';
print $db->del('apple');        # 0
print $db->del('apple');        # 1
```

Delete one of a key's duplicates, found with `seq`:

```
my ($k, $v) = ('fruit', '');
$db->seq($k, $v, R_CURSOR);     # the key's first value
$db->del($k, R_CURSOR);         # just that one
```

Edge cases

- With `R_CURSOR` and no cursor set yet, it returns -1.
- After a delete at the cursor, `seq` with `R_NEXT` goes on to the item after the deleted one and `R_PREV` to the one before. Deleting at the cursor again deletes nothing; on an array it returns `-30995`.
- Deleting an array element moves the ones after it down.
- On a database opened read-only it returns -1, and `$DB_File::Error` says so.

Differences from upstream

Fully compatible with upstream. Covered by `t/81-xs-native/DB_File/010-phenotype.t`.

See also

- `seq` - sets the cursor `R_CURSOR` deletes at
- `del_dup` - deletes one given value of a key

get

Look up a key and put its value in a variable, returning a status instead of the value - so a missing key and a stored undef can be told apart.

Synopsis

```
my $value;
my $status = $db->get($key, $value);
```

What you get back

0 with `$value` set when the key is stored, 1 when it is not (leaving `$value` alone), -1 for an error. In an `R_DUP` database `$value` is the key's first value. For an array, `$key` is the element's index.

Examples

```
$h{colour} = 'blue';
my $v;
print $db->get('colour', $v), " $v";   # 0 blue
print $db->get('size', $v);            # 1
```

Edge cases

- An array element created empty returns `-30995` (Berkeley DB's `DB_KEYEMPTY`) and leaves `$value` alone.
- The value passes through a `filter_fetch_value` filter, and the key through `filter_store_key`, as with the tied hash.
- A flags argument other than 0 returns -1.

Differences from upstream

Fully compatible with upstream. Covered by `t/81-xs-native/DB_File/010-phenotype.t`.

See also

- `put` - stores a value
- `seq` - looks up the first key at or after one, and walks on
- `get_dup` - all the values of a key

put

Store a value under a key, with flags that say where and whether.

Synopsis

```
my $status = $db->put($key, $value);
$status = $db->put($key, $value, R_NOOVERWRITE);
```

What you get back

0 when the value was stored, 1 when `R_NOOVERWRITE` found the key already there, -1 for an error.

Flags

- none - store the value, replacing the key's; in an `R_DUP` database, add it after the key's other values.
- `R_NOOVERWRITE` - store only if the key is not there yet.
- `R_CURSOR` - replace the value the database's cursor stands on; the key given is ignored.
- `R_SETCURSOR` - store, then set the cursor on the key (its first value, in an `R_DUP` database).
- `R_IAFTER`, `R_IBEFORE` - put a new array element after or before element `$key`, the ones after it moving up; in an `R_DUP` database, a new value after or before the key's first. `$key` must be a variable: the method writes it back.

Examples

```
print $db->put('a', 1);                    # 0
print $db->put('a', 2, R_NOOVERWRITE);     # 1, and 'a' is still 1
```

Insert into an array:

```
@lines = qw(one three);
my $i = 0;
$db->put($i, 'two', R_IAFTER);             # one two three
```

Edge cases

- `R_IAFTER` and `R_IBEFORE` leave `$key` as it was; they return -1 for an element past the end or created empty, and in a hash database without `R_DUP` (`$DB_File::Error` then says the flag is illegal).
- `R_CURSOR` with no cursor set yet returns -1. After a delete at the cursor, a `$DB_HASH` or `$DB_BTREE` database returns `-30987` (Berkeley DB's `DB_NOTFOUND`) and stores nothing, while an array gets the deleted element back with the new value.

- A fixed-length array refuses a value longer than its records: -1, with `$DB_File::Error` giving both lengths.
- On a database opened read-only it returns -1.

Differences from upstream

Fully compatible with upstream. Covered by `t/81-xs-native/DB_File/010-phenotype.t`.

See also

- `get` - reads a value back
- `del` - removes a key, or the item at the cursor
- `seq` - sets the cursor `R_CURSOR` writes at

fd

The file descriptor of the database's file - for a `$DB_RECNO` array, its text file - or -1 for an in-memory database.

Synopsis

```
my $fd = $db->fd;
```

What you get back

A descriptor number, or -1.

Edge cases

- To keep processes from working on a database at the same time, lock a separate lock file before `tie` and unlock it after `untie`, rather than locking this descriptor: only then is everything a process wrote in the file before the next one reads it.

Differences from upstream

Fully compatible with upstream. Covered by `t/81-xs-native/DB_File/010-phenotype.t`.

See also

- `sync` - writes the database to its file

sync

Write everything stored so far to the file and to disk, so that other processes - and the file after a crash - have it.

Synopsis

```
$db->sync;
```

What you get back

0, or -1 for an error. The only flag it takes is `R_RECNOSYNC`, which is 0; any other returns -1.

Edge cases

- A `$DB_RECNO` array writes its text file only when an element changed since the last write.
- Without `sync`, writes reach the file at `untie`, or as they happen with `$Peta::FFI::LMDB::DBM_WRITE = 'through'`.

Differences from upstream

Fully compatible with upstream. Covered by `t/82-native/Peta-FFI-LMDB/100-db_file.t`.

See also

- `fd` - the file's descriptor

seq

Move the database's cursor and read the key and value it lands on: walk the database in order, or find the first key at or after a given one.

Synopsis

```
my ($key, $value) = ('', '');
my $status = $db->seq($key, $value, R_FIRST);
```

What you get back

0 with `$key` and `$value` set to where the cursor landed, 1 when there is nothing there (past either end, or no such key), -1 for an error. On 1 the cursor stays where it was. For an array, `$key` is an index.

Flags

- `R_FIRST`, `R_LAST` - the first or last key.
- `R_NEXT`, `R_PREV` - the key after or before the cursor; from no cursor yet, the first or the last.
- `R_CURSOR` - in a `$DB_BTREE` database the first key at or after `$key`; in a `$DB_HASH` database `$key` itself; in an array element `$key`.

Examples

Walk a database in order:

```
my ($k, $v) = ('', '');
for (my $st = $db->seq($k, $v, R_FIRST); $st == 0; $st = $db->seq(
 ↪$k, $v, R_NEXT)) {
    print "$k=$v\n";
}
```

Find the first key starting with `Wa` in a `$DB_BTREE` database:

```
@h{qw(Smith Wall Walls)} = (1, 2, 3);
my ($k, $v) = ('Wa', '');
print "$k\n" if $db->seq($k, $v, R_CURSOR) == 0 and $k =~ /^Wa/;   #␣
 ↪Wall
```

Edge cases

- `$key` and `$value` must be variables: the method writes them.
- Array elements created empty are passed over; `R_CURSOR` on one returns `-30995` (Berkeley DB's `DB_KEYEMPTY`).
- In an `R_DUP` database `R_NEXT` and `R_PREV` step through a key's values one by one, in the order they were stored.
- The tie interface (`keys`, `each`) moves the same cursor.

Differences from upstream

Fully compatible with upstream. Covered by `t/81-xs-native/DB_File/010-phenotype.t`.

See also

- `get` - looks up one key without moving the cursor
- `del` and `put` - act at the cursor with `R_CURSOR`
- `get_dup` - all the values of a key

filter_fetch_key

Install a sub that rewrites every key read from the database - by `keys`, `each` or `seq` - before your code sees it.

Synopsis

```
$db->filter_fetch_key(sub { s/\0$// });   # drop a C string's NUL
$db->filter_fetch_key(undef);            # remove the filter
```

What you get back

The filter it replaces, or undef if there was none.

Edge cases

- The sub works on `$_`, a copy of the key, and changes it in place; its return value is ignored.
- A filter that uses the same database croaks `recursion detected in filter_fetch_key`.
- The `DBM_Filter` module offers ready-made filters (`utf8`, `null`, `int32` and others) installed through these four methods.

Differences from upstream

Fully compatible with upstream. Covered by `t/81-xs-native/DB_File/110-upstream-db-hash.t`.

See also

- `filter_store_key` - the other direction, for keys written
- `filter_fetch_value` - the same for values

filter_store_key

Install a sub that rewrites every key on its way into the database - for storing, fetching, deleting or looking up - so the database holds the rewritten form.

Synopsis

```
$db->filter_store_key(sub { $_ .= "\0" });   # keys as C strings
$db->filter_store_key(undef);               # remove the filter
```

What you get back

The filter it replaces, or undef if there was none.

Edge cases

- The sub works on `$_`, a copy: your variable keeps its value.
- It runs for `seq` and `del` too, so a key looked up matches the keys stored.
- A filter that uses the same database croaks `recursion detected in filter_store_key`.

Differences from upstream

Fully compatible with upstream. Covered by `t/81-xs-native/DB_File/110-upstream-db-hash.t`.

See also

- `filter_fetch_key` - undoes the rewrite on the way out
- `filter_store_value` - the same for values

filter_fetch_value

Install a sub that rewrites every value read from the database before your code sees it.

Synopsis

```
$db->filter_fetch_value(sub { $_ = decode('UTF-8', $_) });
$db->filter_fetch_value(undef);    # remove the filter
```

What you get back

The filter it replaces, or undef if there was none.

Edge cases

- The sub works on `$_` and changes it in place. It runs only for a value that was found: a missing key's undef passes unfiltered.
- A filter that uses the same database croaks `recursion detected in filter_fetch_value`.

Differences from upstream

Fully compatible with upstream. Covered by `t/81-xs-native/DB_File/110-upstream-db-hash.t`.

See also

- `filter_store_value` - the rewrite on the way in
- `filter_fetch_key` - the same for keys

filter_store_value

Install a sub that rewrites every value on its way into the database, so the database holds the rewritten form.

Synopsis

```
$db->filter_store_value(sub { $_ = encode('UTF-8', $_) });
$db->filter_store_value(undef);    # remove the filter
```

What you get back

The filter it replaces, or undef if there was none.

Edge cases

- The sub works on `$_`, a copy: your variable keeps its value.
- A filter that uses the same database croaks `recursion detected in filter_store_value`.

Differences from upstream

Fully compatible with upstream. Covered by `t/81-xs-native/DB_File/110-upstream-db-hash.t`.

See also

- `filter_fetch_value` - undoes the rewrite on the way out
- `filter_store_key` - the same for keys

5.2.27 Data

Namespace containing the following modules:

- `Data::Dumper` - Stringify Perl data structures into valid Perl code - feed the result back through `eval` and you rebuild the original structure.
- `Data::UUID` - Generate UUIDs (GUIDs): time-based ones that differ from every other, and name-based ones that are the same for the same namespace and name.

Data::Dumper

Stringify Perl data structures into valid Perl code - feed the result back through `eval` and you rebuild the original structure.

Two calling styles cover almost everything:

- **Functional**: `Dumper(\%h, \@a)` - one call, one string, uses the package-global configuration variables (`$Data::Dumper::Indent` etc.).
- **Object-oriented**: `Data::Dumper->new([\%h, \@a], ['hash', 'array'])` returns a configurable dumper object. Chain accessors to tune output, then call `->Dump` to produce the string.

The main knobs:

- `$Indent` - `0` compact, 1 line-wrapped, 2 line-wrapped with alignment (the default and the most readable).
- `$Purity` - when true, round-trip fidelity for self-referential and cyclic structures at the cost of extra fixup statements.
- `$Sortkeys` - 1 for alphabetical, or a coderef returning the key order per hash.
- `$Deepcopy` - break shared references and emit each one as a copy.
- `$Terse` - omit the `$VAR1 =` prefix; emits a bare expression.
- `$Useqq` - quote strings with `""` and visible escapes (`\n`, `\t`, `\x{...}`) instead of `'...'`.
- `$Sparseseen` - skip populating the internal "seen" hash for values that the dumper can prove are never revisited. Serialization gets faster; the price is that the contents of the seen hash, as read through `Seen`, can no longer be relied on.

Cycles and shared references are tracked through an internal *seen* table keyed by referent address; a second visit prints as a backref like `$VAR1->[0]` instead of recursing forever.

The full surface is the exported `Dumper`, the constructor `new`, the serializers `Dump` and `Dumpxs`, the seen-table controls `Reset` and `Seen`, the input accessors `Values` and `Names`, and the configuration accessors listed above. `Dump` and `Dumpxs` take the same arguments and produce the same output; `Dumpxs` is the faster of the two, and `Dump` delegates to it unless `$Data::Dumper::Useperl` is true.

```
use Data::Dumper;
$Data::Dumper::Sortkeys = 1;

print Dumper({ name => 'pperl', list => [1, 2, 'three'] });
# $VAR1 = {
#           'list' => [
#                       1,
#                       2,
#                       'three'
#                     ],
#           'name' => 'pperl'
#         };
```

(continues on next page)

(continued from previous page)

```
my $d = Data::Dumper->new([[1, 2]], ['pair']);
print $d->Indent(0)->Dump, "\n";                 # $pair = [1,2];

{
    local $Data::Dumper::Indent = 0;
    local $Data::Dumper::Terse  = 1;
    print Dumper([1, { a => undef }]), "\n";    # [1,{'a' => undef}]
}
```

This is a native implementation of the XS half of Data::Dumper 2.192; its `Data/Dumper.pm` is used unchanged, and `use Data::Dumper` exports `Dumper`.

Differences from upstream

None.

Functions

Core API

Dumpxs

Serialize one or more values into valid Perl code, fast.

Dumpxs

Serialize one or more values into valid Perl code, fast.

`Dumpxs` and `Dump` take the same arguments and produce the same output; `Dumpxs` is the faster of the two, and `Dump` delegates here unless `$Data::Dumper::Useperl` is true.

Synopsis

```
use Data::Dumper;
print Data::Dumper->new([\%h, \@a], ['hash', 'array'])->Dumpxs;
print Data::Dumper::Dumpxs('Data::Dumper', [\%h], ['hash']);
```

What you get back

In scalar context, a single string containing one `$VAR = ...;` statement per input value, separated by `$self->{sep}` (default `"\n"`). In list context, one string per input - useful when you want to post-process each dump separately.

With `Terse(1)`, the `$VAR =` prefix and trailing `;` are dropped and you get a bare Perl expression suitable for embedding.

Examples

Named output, default formatting:

```
my %h = (a => 1, b => [2, 3]);
print Data::Dumper->new([\%h], ['h'])->Dumpxs;
# $h = {
#   'a' => 1,
#   'b' => [2, 3]
# };
```

Compact, sorted, double-quoted:

```
print Data::Dumper->new([\%h])
                  ->Indent(0)->Sortkeys(1)->Useqq(1)->Dumpxs;
# $VAR1 = {"a" => 1,"b" => [2,3]};
```

Circular structure - the cycle is emitted as a backref, not an infinite expansion:

```
my @a = (1, 2);
push @a, \@a;
print Data::Dumper->new([\@a])->Dumpxs;
# $VAR1 = [1, 2, $VAR1];
```

List context gives you one string per argument:

```
my ($s1, $s2) = Data::Dumper->new([\%h, \@a])->Dumpxs;
```

Edge cases

- First argument is not a blessed hashref: `Dumpxs` will call `new()` internally using the remaining arguments, so `Data::Dumper::Dumpxs('Data::Dumper', \@vals, \@names)` works.
- `maxrecurse` exceeded: croaks with `"Recursion limit of N exceeded"` after finishing the current top-level value so partial output is not lost from the caller's perspective.
- `maxdepth` exceeded: prints the quoted stringification of the ref (e.g. `'ARRAY(0x...)'`) at the cut-off point rather than croaking.
- CODE references: emitted as `sub { "DUMMY" }` unless `Deparse(1)` is set, in which case the deparsed source is emitted.
- Regexp references: emitted as `qr/.../flags`.
- `Sortkeys` as a coderef: called once per hash to obtain the key order; a truthy non-coderef sorts alphabetically.

See also

- `Dump` - the pure-Perl fallback; identical output, slower.
- `Dumper` - the procedural one-liner wrapping `new(...)->Dumpxs`.
- `Seen` - pre-seed the seen-table to name pre-existing references.
- `Reset` - clear the seen-table between unrelated `Dumpxs` calls.

Data::UUID

Generate UUIDs (GUIDs): time-based ones that differ from every other, and name-based ones that are the same for the same namespace and name.

A generator object (`Data::UUID->new`) makes version 1 UUIDs from the clock and a node id of its own, and version 3 UUIDs from an MD5 of a namespace UUID and a name. Every UUID comes in four forms: 16 raw bytes, the 36-character string, `0x` and 32 hex digits, or Base64.

Synopsis

```
use Data::UUID;    # exports NameSpace_DNS, NameSpace_URL,␣
↪NameSpace_OID, NameSpace_X500

my $ug   = Data::UUID->new;
my $uuid = $ug->create;                          # 16 bytes, version␣
↪1
print $ug->to_string($uuid), "\n";               # e.g. 4162F712-
↪1DD2-11B2-B17E-C09EFE1DC403
print $ug->create_from_name_str(NameSpace_DNS, 'www.example.com'),
↪"\n";
                                                  # 5DF41881-3AED-
↪3515-88A7-2F4A814CF09E
my $back = $ug->from_string('6ba7b810-9dad-11d1-80b4-00c04fd430c8');
print $ug->compare($uuid, $back), "\n";          # -1, 0 or 1
```

The binary form

The 16 bytes are Data::UUID's own: the time and version fields in the machine's byte order, as its C structure holds them, not the network order of RFC 4122. `to_string` and `from_string` convert correctly between them and the standard text form; the binary form itself is for Data::UUID's own functions.

This is a native implementation of Data::UUID 1.227's `UUID.xs`; its `Data/UUID.pm` is used unchanged.

Differences from upstream

Five, each where perl 5.44 with UUID.xs reads or writes memory it does not own (t/81-xs-native/Data-UUID/150-or-better.t):

- A binary UUID argument shorter than 16 bytes is taken with zero bytes after its end; perl5 reads past the string.
- `from_b64string` of fewer than 16 bytes fills the rest with zero bytes; perl5 returns uninitialised memory there.
- `from_b64string` of more than 16 bytes keeps the first 16; perl5 writes the rest past its buffer.
- A byte above 0x7F in `from_b64string`'s input is skipped like any other character outside Base64; perl5 looks it up before its table.
- `from_string` of a string that ends after a single hex digit of a byte before the last dies "from_string(...) failed..."; perl5 takes the next byte from past the end of the string.

Functions

Generator

new

Create a generator, with a node id of its own.

create

Make a new time-based (version 1) UUID.

Also available as `Data::UUID::create_b64`, `Data::UUID::create_bin`, `Data::UUID::create_hex`, `Data::UUID::create_str`.

create_from_name

Make the name-based (version 3) UUID of a name in a namespace: the same namespace and name give the same UUID, everywhere and always.

Also available as `Data::UUID::create_from_name_b64`, `Data::UUID::create_from_name_bin`, `Data::UUID::create_from_name_hex`, `Data::UUID::create_from_name_str`.

Conversion

compare

Compare two binary UUIDs: -1, 0 or 1.

to_b64string

Convert a binary UUID to text.

Also available as `Data::UUID::to_hexstring`, `Data::UUID::to_string`.

from_b64string

Convert text back to a binary UUID.

Also available as `Data::UUID::from_hexstring`, `Data::UUID::from_string`.

new

Create a generator, with a node id of its own.

The node id is drawn from an MD5 of the host id, the time and the host name, with the multicast bit set so that it can never be a network card's address. The object is always a `Data::UUID`, also when `new` is called through a subclass. `$!` is 0 afterwards.

Synopsis

```
my $ug = Data::UUID->new;
```

create

Make a new time-based (version 1) UUID.

Also available as `Data::UUID::create_b64`, `Data::UUID::create_bin`, `Data::UUID::create_hex`, `Data::UUID::create_str`.

`create` and `create_bin` return the 16 binary bytes, `create_str` the 36-character string, `create_hex` `0x` and 32 hex digits, `create_b64` 24 Base64 characters. Successive UUIDs of one generator compare in the order they were made.

Synopsis

```
my $id  = $ug->create_str;    # e.g. 4162F712-1DD2-11B2-B17E-
↪C09EFE1DC403
my $bin = $ug->create;
```

create_from_name

Make the name-based (version 3) UUID of a name in a namespace: the same namespace and name give the same UUID, everywhere and always.

Also available as `Data::UUID::create_from_name_b64`, `Data::UUID::create_from_name_bin`, `Data::UUID::create_from_name_hex`, `Data::UUID::create_from_name_str`.

The namespace is a binary UUID, usually one of the exported `NameSpace_DNS`, `NameSpace_URL`, `NameSpace_OID` and `NameSpace_X500`. The name is taken as bytes; a character above U+00FF dies "Wide character in subroutine entry". The forms are those of `create`.

Synopsis

```
print $ug->create_from_name_str(NameSpace_DNS, 'www.example.com');
# 5DF41881-3AED-3515-88A7-2F4A814CF09E
```

compare

Compare two binary UUIDs: -1, 0 or 1.

As in Data::UUID, the fields are compared in turn and a later field that differs decides, the node's last differing byte above all; two UUIDs of one generator compare in the order they were made.

Synopsis

```
my @sorted = sort { $ug->compare($a, $b) } @uuids;
```

to_b64string

Convert a binary UUID to text.

Also available as `Data::UUID::to_hexstring`, `Data::UUID::to_string`.

`to_string` gives the 36-character form in upper case, `to_hexstring` `0x` and 32 upper-case hex digits, `to_b64string` 24 Base64 characters.

Synopsis

```
print $ug->to_string(NameSpace_DNS);   # 6BA7B810-9DAD-11D1-80B4-
↪00C04FD430C8
```

from_b64string

Convert text back to a binary UUID.

Also available as `Data::UUID::from_hexstring`, `Data::UUID::from_string`.

`from_string` and `from_hexstring` take 32 hex digits in either case, with an optional `0x` in front and a `-` allowed before any byte; anything after the 16th byte is ignored, and a string that runs out before it dies "from_string(...) failed...". `from_b64string` takes Base64, skipping characters outside it.

Synopsis

```
my $bin = $ug->from_string('6ba7b810-9dad-11d1-80b4-00c04fd430c8');
```

5.2.28 Devel

Namespace containing the following modules:

- `Devel::Cover` - Measure which statements, branches, conditions and subroutines a program ran, and how long each statement took: the collector under Devel::Cover.
- `Devel::Peek` - Inspect the internal representation of any Perl scalar - a debugging tool for working with SVs.
- `Devel::SelfStubber` - generate stubs for a SelfLoading module
- `Devel::Size` - how much memory a Perl variable uses

Devel::Cover

Measure which statements, branches, conditions and subroutines a program ran, and how long each statement took: the collector under Devel::Cover.

`perl -MDevel::Cover program` runs the program and writes what it covered to `cover_db`; the `cover` command turns that into a report. `cover -test` does both for a distribution's test suite.

Synopsis

```
pperl --cpan Devel::Cover
pperl -MDevel::Cover yourprog args
cover
cover -test
```

This is a native implementation of the XS half of Devel::Cover 1.52 (`Cover.xs`); its modules and the `cover` command are upstream's, installed with `pperl --cpan Devel::Cover`.

Differences from upstream

- While Devel::Cover is loaded, pperl's JIT compiles no loops and gives back those it had compiled: every op runs in the interpreter, so the counts are perl's.

Devel::Peek

Inspect the internal representation of any Perl scalar - a debugging tool for working with SVs.

`Devel::Peek` is the tool you reach for when the question is *"what does Perl actually think this value is?"*. Typical uses:

- chasing a refcount leak - something holds a reference longer than you expect, and you want to see `REFCNT` climb;
- confirming that a value came back as the type you meant (`IV` vs `PV` vs `PVMG`, a blessed object, a tied scalar);
- looking at the flags on an `SV` (`POK`, `IOK`, `ROK`, `UTF8`, `TEMP`, `OBJECT`) to diagnose dual-var, stringification, or tainting surprises;

- peeking inside arrays, hashes, and references to see how Perl has laid them out and which slots contain what.

Synopsis

```
use Devel::Peek;

my $x = 42;
Dump($x);
```

A minimal `Dump($x)` for a plain integer looks like this on `STDERR`:

```
SV = IV(0xbc818) at 0xbe9a8
  REFCNT = 1
  FLAGS = (IOK,pIOK)
  IV = 42
```

Every line is meaningful. `SV = IV(...)` names the body type. `REFCNT` is what you stare at when tracking leaks. `FLAGS` tells you which of the `IV` / `NV` / `PV` slots below it are live; `IOK` means the `IV` field is current, `POK` means the `PV` field is, `ROK` means the scalar is a reference and there is another `SV = ...` block nested below it. Arrays dump with `FILL` (last index) and `MAX` (capacity) and then their elements as `Elt No. N` sub-dumps. Hashes dump with `KEYS`, bucket occupancy, and one sub-dump per entry.

The entry points:

- `Dump($sv, $depth=4)` - dump one value. `@array` and `%hash` dump the aggregate itself rather than the first element; other arguments are evaluated in scalar rvalue context.
- `DumpArray($depth, @values)` - dump several values in one call, each tagged with its position. Useful when inspecting a function's return list.
- `SvREFCNT(\$sv)` - return the refcount of the referent of a reference (the outer reference itself is subtracted). Pairs well with `Dump` when you want the number without scraping it out of a dump.
- `DumpWithOP($sv, $depth=4)` - same as `Dump` but also walks into compiled ops when the scalar carries one (a `PVCV`, for example). Equivalent to setting `$Devel::Peek::dump_ops` around a `Dump` call.
- `DumpProg()` - dump the program's main op tree. Aimed at people debugging the compiler, not at regular scripts.
- `DeadCode()` - walk the SV arena for scalars frozen into inactive `CV`s. A deep-internals tool; most users never touch it.
- `CvGV($cv)` - return the `GV` associated with a code reference, so you can recover a sub's package-qualified name.

The `mstat` family

`mstat`, `fill_mstats`, `mstats_fillhash`, and `mstats2hash` report on Perl's malloc arena - bucket counts, free/used chunks, sbrk activity. They only produce real numbers when Perl was built with its bundled `malloc` (rare in modern builds). Under a standard build, `mstat` prints `perl not compiled with MYMALLOC` and the hash-filling variants croak with the same message. This is the upstream behaviour, not a pperl limitation; scripts that guard on it already handle the non-`MYMALLOC` case.

The `runops` and `:opd` knobs

`use Devel::Peek ':opd=st'` switches the interpreter to its debugging dispatch loop and turns on per-op trace flags (`s` stack, `t` trace, `P` profile). `runops_debug()` is the run-time toggle for the same switch; `debug_flags()` reads and writes the `$^D` letter mask directly. Reach for these when you want to see which ops execute and in what order - they are the programmable equivalent of `perl -Dst`.

All output from `Dump`, `DumpArray`, `DumpProg`, and `mstat` goes to `STDERR`. The global `$Devel::Peek::pv_limit` caps how many characters of each PV are printed; `0` means no limit.

This is a native implementation of the XS half of Devel::Peek 1.36; its `Devel/Peek.pm` is used unchanged, and `use Devel::Peek` exports `Dump`, `DumpArray`, `DeadCode`, `mstat` and the other functions.

Differences from upstream

None in the format. The addresses, reference counts and flags `Dump` prints are pperl's own, as perl5's are its own: two runs of perl5 differ there as well.

Functions

Scalar inspection

`Dump`

Dump one scalar's internal representation to `STDERR`. The usual entry point for `Devel::Peek`, and the one to reach for first when you need to see what Perl has under the hood.

`DumpArray`

Dump several values in one call, each tagged with its index. Useful when inspecting a function's return list or an argument list without wrapping every element in its own `Dump`.

`SvREFCNT`

Return the reference count of a referent. `SvREFCNT(\$x)` answers *"how many live references to* `$x` *exist right now?"* - the usual tool for tracking a suspected leak without pulling the number out of a full `Dump`.

DeadCode

Report scalars "frozen" into inactive code references - a deep-internals probe for leaks inside closed-over CVs.

DumpProg

Dump the program's main op tree. A compiler-debugging tool, not a value-inspection tool.

CvGV

Recover the GV (typeglob) associated with a code reference. `CvGV($cv)` is how you go from an anonymous-looking sub ref back to the name Perl filed it under - useful when inspecting caller frames, dispatch tables, or closures assigned to named slots.

Memory stats

fill_mstats

Fill a scalar with a machine-readable snapshot of Perl's malloc state. `fill_mstats($buf)` is the cheap member of the `mstat` family: pair it with `mstats2hash` later when you actually want to read the numbers.

mstats_fillhash

Populate a hash with Perl's malloc statistics. `mstats_fillhash(%hash)` fills `%hash` with fields like `nbuckets`, `total`, `totfree`, `sbrks`, plus the per-bucket `free` / `used` / `mem_size` / `available_size` array references. See `perldebguts` for the full field list.

mstats2hash

Decode a `fill_mstats` buffer into a hash. `mstats2hash($buf, %hash)` is the readout step for the buffered form: cheap `fill_mstats` inside a hot loop, one `mstats2hash` pass at the end to turn the buffer into inspectable fields.

mstat

Print a one-line memory snapshot to STDERR. The classic marker-in-a-log tool - sprinkle `mstat "Point 5"` across a program to see how arena size moves between points.

Runops hooks

runops_debug

Switch the interpreter between its standard and debugging op-dispatch loops, and report which one was active before the call.

Dump

Dump one scalar's internal representation to STDERR. The usual entry point for Devel::Peek, and the one to reach for first when you need to see what Perl has under the hood.

Dump($sv, $depth=4). $depth caps both recursion into nested references and the number of array/hash elements shown at each level; pass a larger value to see past the default cutoff. When called on @array or %hash directly, the aggregate itself is dumped (not its first element). Any other argument is evaluated in scalar rvalue context.

The dump layout follows the shape shown in the module summary: an SV = <type>(body) at <head> line, then REFCNT, FLAGS, and whichever of the IV / NV / PV / RV / array / hash slots are populated. Reference dumps nest a child SV = ... block inside the parent.

Two package variables tune the output:

- $Devel::Peek::pv_limit - cap on characters printed per PV; 0 lifts the cap entirely.
- $Devel::Peek::dump_ops - when true, CV-like scalars also print their op tree (see DumpWithOP for the scoped form).

Returns nothing; all output is on STDERR.

DumpArray

Dump several values in one call, each tagged with its index. Useful when inspecting a function's return list or an argument list without wrapping every element in its own Dump.

DumpArray($depth, @values). The first argument is the recursion depth (same meaning as Dump's second argument); the remaining arguments are the values to dump. Each value is preceded by a header line of the form Elt No. N 0x<address>, where N counts from zero. After the header the element is rendered exactly as Dump would render it.

Respects $Devel::Peek::pv_limit and $Devel::Peek::dump_ops the same way Dump does. Returns nothing; output goes to STDERR.

SvREFCNT

Return the reference count of a referent. SvREFCNT(\$x) answers *"how many live references to* $x *exist right now?"* - the usual tool for tracking a suspected leak without pulling the number out of a full Dump.

The argument must be a reference (prototype \[$@%&*]). The referent's refcount is returned, minus one so that the temporary reference created by the \ operator does not skew the answer. Passing anything that is not a reference croaks with Usage: Devel::Peek::SvREFCNT(SCALAR); calling it (with &) on other than exactly one argument croaks with Usage: Devel::Peek::SvREFCNT(sv).

Typical pattern: snapshot the count before and after a suspected leak site and look for growth that does not drop back.

DeadCode

Report scalars "frozen" into inactive code references - a deep-internals probe for leaks inside closed-over CVs.

`DeadCode()` walks Perl's SV arena looking for PVCV bodies whose pads still hold live scalars even though the sub is no longer reachable, and returns the findings as an array reference. Most scripts never need this; it is a tool for people chasing exotic leaks that `Dump` and `SvREFCNT` cannot locate.

Returns an array reference. An empty result means "nothing matched the arena-walk heuristic" - which is the expected outcome under pperl, whose allocator layout differs from the arena the upstream walk was written against.

mstat

Print a one-line memory snapshot to STDERR. The classic marker-in-a-log tool - sprinkle `mstat "Point 5"` across a program to see how arena size moves between points.

`mstat($marker="Devel::Peek::mstat: ")`. The marker prefixes the output so you can match lines to call sites when the log gets noisy. Output format is documented under `perldebguts/Using $ENV{PERL_DEBUG_MSTATS}`.

Only produces real numbers when Perl was built with its bundled `malloc`. On a standard build the line reads `<marker>: perl not compiled with MYMALLOC`, which is useful as a pass-through breadcrumb even when the numbers are unavailable.

Devel::SelfStubber

generate stubs for a SelfLoading module

SYNOPSIS

To generate just the stubs:

```
use Devel::SelfStubber;
Devel::SelfStubber->stub('MODULENAME','MY_LIB_DIR');
```

or to generate the whole module with stubs inserted correctly

```
use Devel::SelfStubber;
$Devel::SelfStubber::JUST_STUBS=0;
Devel::SelfStubber->stub('MODULENAME','MY_LIB_DIR');
```

MODULENAME is the Perl module name, e.g. Devel::SelfStubber, NOT 'Devel/SelfStubber' or 'Devel/SelfStubber.pm'.

MY_LIB_DIR defaults to '.' if not present.

DESCRIPTION

Devel::SelfStubber prints the stubs you need to put in the module before the __DATA__ token (or you can get it to print the entire module with stubs correctly placed). The stubs ensure that if a method is called, it will get loaded. They are needed specifically for inherited autoloaded methods.

This is best explained using the following example:

Assume four classes, A,B,C & D.

A is the root class, B is a subclass of A, C is a subclass of B, and D is another subclass of A.

```
    A
   / \
  B   D
 /
C
```

If D calls an autoloaded method 'foo' which is defined in class A, then the method is loaded into class A, then executed. If C then calls method 'foo', and that method was reimplemented in class B, but set to be autoloaded, then the lookup mechanism never gets to the AUTOLOAD mechanism in B because it first finds the method already loaded in A, and so erroneously uses that. If the method foo had been stubbed in B, then the lookup mechanism would have found the stub, and correctly loaded and used the sub from B.

So, for classes and subclasses to have inheritance correctly work with autoloading, you need to ensure stubs are loaded.

The SelfLoader can load stubs automatically at module initialization with the statement 'SelfLoader->load_stubs()';, but you may wish to avoid having the stub loading overhead associated with your initialization (though note that the SelfLoader::load_stubs method will be called sooner or later - at latest when the first sub is being autoloaded). In this case, you can put the sub stubs before the __DATA__ token. This can be done manually, but this module allows automatic generation of the stubs.

By default it just prints the stubs, but you can set the global $Devel::SelfStubber::JUST_STUBS to 0 and it will print out the entire module with the stubs positioned correctly.

At the very least, this is useful to see what the SelfLoader thinks are stubs - in order to ensure future versions of the SelfStubber remain in step with the SelfLoader, the SelfStubber actually uses the SelfLoader to determine which stubs are needed.

Devel::Size

`Devel::Size` - how much memory a Perl variable uses.

```
use Devel::Size qw(size total_size);

my $bytes = size("A string");         # the scalar itself
my @list  = (1 .. 1000);
my $flat  = size(\@list);             # the array, not its elements
my $deep  = total_size(\@list);       # the array and all it holds
```

`size` counts a variable and the memory it owns directly: a scalar's string buffer, an array's slot vector, a hash's buckets and keys. `total_size` also follows what an array or hash contains, and what references point to, counting each thing reachable once. Pass a reference to measure an array, a hash or a code reference.

The numbers are the sizes of the interpreter's own structures, laid out as perl 5.44 lays them out, so they agree with perl 5.44 running the XS Devel::Size. `$Devel::Size::warn` (default 1) turns the module's warnings about sizes it cannot work out completely on or off; `$Devel::Size::dangle` (default 0) enables warnings about invalid pointers met on the way.

This is a native implementation of the CPAN distribution Devel-Size 0.87; its `Devel/Size.pm` is used unchanged.

Functions

Other Functions

size

`size($thing)` (`ix` 0) / `total_size($thing)` (`ix` 2, its ALIAS): bytes used by `$thing`, or by what a reference points to.

Also available as `Devel::Size::total_size`.

5.2.29 Digest

Modules that calculate message digests

SYNOPSIS

```
$md5   = Digest->new("MD5");
$sha1  = Digest->new("SHA-1");
$sha256 = Digest->new("SHA-256");
$sha384 = Digest->new("SHA-384");
$sha512 = Digest->new("SHA-512");

$hmac = Digest->HMAC_MD5($key);
```

DESCRIPTION

The `Digest::` modules calculate digests, also called "fingerprints" or "hashes", of some data, called a message. The digest is (usually) some small/fixed size string. The actual size of the digest depend of the algorithm used. The message is simply a sequence of arbitrary bytes or bits.

An important property of the digest algorithms is that the digest is *likely* to change if the message change in some way. Another property is that digest functions are one-way functions, that is it should be *hard* to find a message that correspond to some given digest. Algorithms differ in how "likely" and how "hard", as well as how efficient they are to compute.

Note that the properties of the algorithms change over time, as the algorithms are analyzed and machines grow faster. If your application for instance depends on it being "impossible" to generate the same digest for a different message it is wise to make it easy to plug in stronger algorithms as the one used grow weaker. Using the interface documented here should make it easy to change algorithms later.

All `Digest::` modules provide the same programming interface. A functional interface for simple use, as well as an object oriented interface that can handle messages of arbitrary length and which can read files directly.

The digest can be delivered in three formats:

- *binary*

  This is the most compact form, but it is not well suited for printing or embedding in places that can't handle arbitrary data.

- *hex*

  A twice as long string of lowercase hexadecimal digits.

- *base64*

  A string of portable printable characters. This is the base64 encoded representation of the digest with any trailing padding removed. The string will be about 30% longer than the binary version. *MIME::Base64* tells you more about this encoding.

The functional interface is simply importable functions with the same name as the algorithm. The functions take the message as argument and return the digest. Example:

```
use Digest::MD5 qw(md5);
$digest = md5($message);
```

There are also versions of the functions with "_hex" or "_base64" appended to the name, which returns the digest in the indicated form.

OO INTERFACE

The following methods are available for all `Digest::` modules:

- $ctx = Digest->XXX($arg,...)
- $ctx = Digest->new(XXX => $arg,...)
- $ctx = Digest::XXX->new($arg,...)

  The constructor returns some object that encapsulate the state of the message-digest algorithm. You can add data to the object and finally ask for the digest. The "XXX" should of course be replaced by the proper name of the digest algorithm you want to use.

  The two first forms are simply syntactic sugar which automatically load the right module on first use. The second form allow you to use algorithm names which contains letters which are not legal perl identifiers, e.g. "SHA-1". If no implementation for the given algorithm can be found, then an exception is raised.

  To know what arguments (if any) the constructor takes (the `$args,...` above) consult the docs for the specific digest implementation.

If new() is called as an instance method (i.e. $ctx->new) it will just reset the state the object to the state of a newly created object. No new object is created in this case, and the return value is the reference to the object (i.e. $ctx).

- $other_ctx = $ctx->clone

  The clone method creates a copy of the digest state object and returns a reference to the copy.

- $ctx->reset

  This is just an alias for $ctx->new.

- $ctx->add($data)
- $ctx->add($chunk1, $chunk2, ...)

  The string value of the $data provided as argument is appended to the message we calculate the digest for. The return value is the $ctx object itself.

  If more arguments are provided then they are all appended to the message, thus all these lines will have the same effect on the state of the $ctx object:

```
$ctx->add("a"); $ctx->add("b"); $ctx->add("c");
$ctx->add("a")->add("b")->add("c");
$ctx->add("a", "b", "c");
$ctx->add("abc");
```

  Most algorithms are only defined for strings of bytes and this method might therefore croak if the provided arguments contain chars with ordinal number above 255.

- $ctx->addfile($io_handle)

  The $io_handle is read until EOF and the content is appended to the message we calculate the digest for. The return value is the $ctx object itself.

  The addfile() method will croak() if it fails reading data for some reason. If it croaks it is unpredictable what the state of the $ctx object will be in. The addfile() method might have been able to read the file partially before it failed. It is probably wise to discard or reset the $ctx object if this occurs.

  In most cases you want to make sure that the $io_handle is in "binmode" before you pass it as argument to the addfile() method.

- $ctx->add_bits($data, $nbits)
- $ctx->add_bits($bitstring)

  The add_bits() method is an alternative to add() that allow partial bytes to be appended to the message. Most users can just ignore this method since typical applications involve only whole-byte data.

  The two argument form of add_bits() will add the first $nbits bits from $data. For the last potentially partial byte only the high order `$nbits % 8` bits are used. If $nbits is greater than `length($data) * 8`, then this method would do the same as `$ctx->add($data)`.

The one argument form of add_bits() takes a $bitstring of "1" and "0" chars as argument. It's a shorthand for `$ctx->add_bits(pack("B*", $bitstring), length($bitstring))`.

The return value is the $ctx object itself.

This example shows two calls that should have the same effect:

```
$ctx->add_bits("111100001010");
$ctx->add_bits("\xF0\xA0", 12);
```

Most digest algorithms are byte based and for these it is not possible to add bits that are not a multiple of 8, and the add_bits() method will croak if you try.

- $ctx->digest

  Return the binary digest for the message.

  Note that the `digest` operation is effectively a destructive, read-once operation. Once it has been performed, the $ctx object is automatically `reset` and can be used to calculate another digest value. Call $ctx->clone->digest if you want to calculate the digest without resetting the digest state.

- $ctx->hexdigest

  Same as $ctx->digest, but will return the digest in hexadecimal form.

- $ctx->b64digest

  Same as $ctx->digest, but will return the digest as a base64 encoded string without padding.

- $ctx->base64_padded_digest

  Same as $ctx->digest, but will return the digest as a base64 encoded string.

Digest speed

This table should give some indication on the relative speed of different algorithms. It is sorted by throughput based on a benchmark done with of some implementations of this API:

```
Algorithm      Size    Implementation                  MB/s

MD4            128     Digest::MD4 v1.3              165.0
MD5            128     Digest::MD5 v2.33              98.8
SHA-256        256     Digest::SHA2 v1.1.0            66.7
SHA-1          160     Digest::SHA v4.3.1             58.9
SHA-1          160     Digest::SHA1 v2.10             48.8
SHA-256        256     Digest::SHA v4.3.1             41.3
Haval-256      256     Digest::Haval256 v1.0.4        39.8
SHA-384        384     Digest::SHA2 v1.1.0            19.6
SHA-512        512     Digest::SHA2 v1.1.0            19.3
SHA-384        384     Digest::SHA v4.3.1             19.2
SHA-512        512     Digest::SHA v4.3.1             19.2
Whirlpool      512     Digest::Whirlpool v1.0.2       13.0
```

(continues on next page)

(continued from previous page)

```
MD2              128     Digest::MD2 v2.03                9.5

Adler-32          32     Digest::Adler32 v0.03            1.3
CRC-16            16     Digest::CRC v0.05                1.1
CRC-32            32     Digest::CRC v0.05                1.1
MD5              128     Digest::Perl::MD5 v1.5           1.0
CRC-CCITT         16     Digest::CRC v0.05                0.8
```

These numbers was achieved Apr 2004 with ActivePerl-5.8.3 running under Linux on a P4 2.8 GHz CPU. The last 5 entries differ by being pure perl implementations of the algorithms, which explains why they are so slow.

Modules

- `Digest::MD5` - Compute MD5-128 message digests - fixed 128-bit fingerprints of arbitrary byte strings per RFC 1321.
- `Digest::SHA` - Compute SHA-1 and SHA-2 family message digests: SHA-1, SHA-224, SHA-256, SHA-384, SHA-512, SHA-512/224, and SHA-512/256, with optional HMAC keying.
- `Digest::SHA1` - Compute SHA-1 message digests through the interface of Digest::SHA1, the CPAN module older code uses where newer code uses Digest::SHA.
- `Digest::base` - Digest base class
- `Digest::file` - Calculate digests of files

Digest::MD5

Compute MD5-128 message digests - fixed 128-bit fingerprints of arbitrary byte strings per RFC 1321.

`Digest::MD5` offers two idioms. Pick whichever fits the shape of the data you have at hand.

Functional one-shot

When the whole message is already in memory as a single string (or a few pieces you can list as arguments), the functional form is the shortest path:

```
use Digest::MD5 qw(md5 md5_hex md5_base64);

my $bin = md5($data);           # 16 raw bytes
my $hex = md5_hex($data);       # 32 lowercase hex chars
my $b64 = md5_base64($data);    # 22 base64 chars, no padding
```

All three take any number of arguments and concatenate them before hashing, so `md5("a", "b", "c")` equals `md5("abc")`.

OO incremental

When the message arrives in pieces - streaming bytes, a file read chunk by chunk, or data assembled across multiple code paths - build a context object, feed it, and ask for the digest at the end:

```
use Digest::MD5;

my $ctx = Digest::MD5->new;
$ctx->add($chunk1);
$ctx->add($chunk2, $chunk3);
$ctx->addfile($fh);
my $hex = $ctx->hexdigest;      # also resets the context
```

`add` returns the object, so calls chain: `$ctx->add("a")->add("b")`. Calling any of the `digest` / `hexdigest` / `b64digest` methods is destructive - the context is reset to an empty state afterwards, so the same object is immediately reusable. To peek at the digest without resetting, clone first: `$ctx->clone->hexdigest`.

Output encodings

Every function and method comes in three encodings of the same 128-bit digest:

- **Raw binary** (`md5`, `digest`) - 16 bytes. Suitable for packing into fixed-width fields or feeding into another binary protocol.
- **Hex** (`md5_hex`, `hexdigest`) - 32 lowercase characters from `0-9a-f`. This is the form you usually see in ETag headers and checksum files.
- **Base64** (`md5_base64`, `b64digest`) - 22 characters from the standard alphabet `A-Z a-z 0-9 + /`. The result is *not* padded to a multiple of 4; append `"=="` yourself if an interop partner expects padding.

File-handle ingestion

`addfile` reads an open file handle until EOF and feeds every byte into the context without buffering the whole thing in memory, so it scales to files of arbitrary size. Make sure the handle is in `binmode` first - MD5 is defined over bytes, not decoded text.

Security context

MD5 is **cryptographically broken for collision resistance**: attackers can construct two different messages with the same digest. Do not use it for new digital signatures, certificate fingerprints, password hashing, or any setting where an adversary chooses the input. For those, reach for `Digest::SHA` (SHA-256 or better) or a purpose-built password hash.

MD5 remains perfectly adequate - and widely used - for non-adversarial integrity checks: ETags, cache keys, change detection in build systems, deduplication of trusted data, and checksums over storage where the threat model is accidental corruption rather than forgery.

Bytes only - no wide characters

MD5 hashes bytes. Feeding a string containing code points above `U+00FF` croaks with `Wide character in subroutine entry`. To hash a Unicode string, decide on an encoding first and pass the encoded bytes: `md5_hex(encode_utf8($str))`.

Differences from upstream

This is Digest::MD5 2.59; `Digest/MD5.pm` is upstream's. Two differences, each where perl 5.44 with MD5.xs fails (t/81-xs-native/Digest-MD5/230-or-better.t):

- `Digest::MD5::new("No::Such::Class")` blesses into a new class of that name; perl5 crashes for a class that does not exist yet.
- `$ctx->context($blocks, $state)` with a state shorter than 16 bytes reads the missing bytes as zero; perl5 reads past the end of the string.

Functions

Functional digests

`md5`

One-shot MD5 digest, returned as 16 raw bytes.

`md5_hex`

One-shot MD5 digest, returned as a 32-character lowercase hex string.

`md5_base64`

One-shot MD5 digest, returned as a 22-character base64 string.

OO lifecycle

`new`

Create a fresh MD5 context object, or reset an existing one to empty.

`clone`

Make an independent copy of the current digest state.

`reset`

Clear an existing context so it behaves like a freshly created one.

OO input

`add`

Feed one or more pieces of data into the MD5 context.

`addfile`

Read an open file handle to EOF and feed every byte into the context.

`add_bits`

Add a bit-oriented quantum of data - but only in multiples of 8 bits.

OO output

`digest`

Finalise the context and return the 16-byte raw binary digest.

`hexdigest`

Finalise the context and return the digest as 32 lowercase hex chars.

`b64digest`

Finalise the context and return the digest as a 22-char base64 string.

Utility

context

Save or restore the raw internal MD5 state - for advanced use only.

new

Create a fresh MD5 context object, or reset an existing one to empty.

Synopsis

```
my $ctx = Digest::MD5->new;   # class method - new empty context
$ctx->new;                    # instance method - reset in place
```

What you get back

A blessed `Digest::MD5` reference whose internal state is the MD5 initial vector - i.e. the digest of the empty string is `md5("")`. Called on an existing instance, `new` resets that instance and returns it; no second object is allocated. The common idiom `Digest::MD5->new->add($data)->hexdigest` relies on this chaining.

Examples

Fresh context, then feed and finalise:

```
my $ctx = Digest::MD5->new;
$ctx->add("hello");
print $ctx->hexdigest;   # 5d41402abc4b2a76b9719d911017c592
```

Reset an existing context instead of allocating a new one:

```
$ctx->add("round 1")->hexdigest;   # digest + auto-reset
$ctx->new;                          # explicit reset (idiomatic no-
 ↪op here)
$ctx->add("round 2");
```

Chain straight through in one expression:

```
my $hex = Digest::MD5->new->add("foo", "bar")->hexdigest;
```

Edge cases

- Called on a subclass name, `new` blesses into that subclass, so `MyDigest->new` returns a `MyDigest` object whose internals are a `Digest::MD5` context.
- Called as an instance method, the same object is returned - the caller's variable is unchanged.

Differences from upstream

Fully compatible with upstream `Digest::MD5` 2.59.

See also

- `clone` - copy the current context instead of resetting it
- `reset` - explicit alias for the instance-method form of new
- `add` - feed data into the context you just created
- `hexdigest` - common companion call for one-shot chained use

clone

Make an independent copy of the current digest state.

Synopsis

```
my $copy = $ctx->clone;
```

What you get back

A new `Digest::MD5` object whose internal state is a byte-for-byte copy of the original - same accumulated length, same four state words, same partial-block buffer. The two contexts are independent afterwards: further `add` calls on one do not affect the other. The class of the returned object matches the class of `$ctx`, so cloning a subclass instance yields a subclass instance.

The primary use is peeking at an intermediate digest without destroying the ongoing computation. Because `digest` / `hexdigest` / `b64digest` reset the context, the pattern `$ctx->clone->hexdigest` is how you extract a snapshot and keep hashing.

Examples

Per-line running digest over a stream:

```
my $ctx = Digest::MD5->new;
while (my $line = <$fh>) {
    $ctx->add($line);
    print "after line $.: ", $ctx->clone->hexdigest, "\n";
}
my $final = $ctx->hexdigest;    # digest of the whole stream
```

Fork a digest to feed two suffixes:

```
my $base = Digest::MD5->new;
$base->add("common prefix ");

my $a = $base->clone->add("suffix A")->hexdigest;
my $b = $base->clone->add("suffix B")->hexdigest;
```

Edge cases

- Cloning immediately after `new` yields a context equivalent to a fresh `Digest::MD5->new`.
- Cloning an object whose state was restored via `context` copies that restored state, not a fresh one.

Differences from upstream

Fully compatible with upstream `Digest::MD5` 2.59.

See also

- `new` - create a fresh empty context from scratch
- `digest` - the destructive read that makes `clone` worth having
- `context` - save/restore raw state if you need persistence
- `add` - continue feeding data into the clone or the original

add

Feed one or more pieces of data into the MD5 context.

Synopsis

```
$ctx->add($data);
$ctx->add($a, $b, $c);                # same as add($a.$b.$c)
$ctx->add("a")->add("b")->add("c");   # chained equivalent
```

What you get back

The same context object, so `add` calls chain and compose with `hexdigest` / `digest` / `b64digest`. Every argument is flattened into a byte stream in order; the digest depends only on the concatenation, not on how you split it across calls or arguments.

Examples

One-shot digest of a concatenated message:

```
my $hex = Digest::MD5->new->add("hello world")->hexdigest;
# 5eb63bbbe01eeed093cb22bb8f5acdc3
```

Stream a file line by line:

```
open(my $fh, '<:raw', $path) or die $!;
my $ctx = Digest::MD5->new;
while (my $line = <$fh>) {
    $ctx->add($line);
```

(continues on next page)

(continued from previous page)

```
}
print $ctx->hexdigest, "\n";
```

Multiple arguments are equivalent to concatenation - all four of these produce the same digest:

```
Digest::MD5->new->add("a")->add("b")->add("c")->hexdigest;
Digest::MD5->new->add("a", "b", "c")->hexdigest;
Digest::MD5->new->add("abc")->hexdigest;
md5_hex("abc");
```

Edge cases

- **Wide characters.** Arguments containing code points above `U+00FF` croak with `Wide character in subroutine entry`. Encode first: `$ctx->add(encode_utf8($str))`.
- **Empty strings** are accepted and change nothing.
- **No arguments** (`$ctx->add` with no extra args) is a no-op and returns the context.
- `undef` arguments stringify to the empty string; warnings depend on the caller's `use warnings` state.

Differences from upstream

Fully compatible with upstream `Digest::MD5` 2.59.

See also

- `add_bits` - interface-compatibility wrapper for bit-oriented input
- `addfile` - feed an entire file handle without buffering
- `new` - typical predecessor
- `hexdigest` - typical successor; auto-resets the context
- `clone` - snapshot the intermediate state without stopping `add`

addfile

Read an open file handle to EOF and feed every byte into the context.

Synopsis

```
open(my $fh, '<:raw', $path) or die $!;
$ctx->addfile($fh);
```

What you get back

The same context object, for chaining. `addfile` reads the handle in 4 KiB blocks and feeds them into MD5 without loading the whole file into memory, so it handles files of any size. Once the call returns, the handle is positioned at EOF; the caller is responsible for closing it.

Put the handle in `binmode` (or open with `:raw`) before calling - MD5 hashes bytes, and a text-mode handle on Windows or one with a decoding layer will change what bytes reach the digest.

Examples

Digest a file in one chain:

```
open(my $fh, '<:raw', "/etc/passwd") or die $!;
print Digest::MD5->new->addfile($fh)->hexdigest, "\n";
close $fh;
```

Combine file contents with extra data:

```
my $ctx = Digest::MD5->new;
$ctx->add($salt);
$ctx->addfile($fh);
$ctx->add($pepper);
my $hex = $ctx->hexdigest;
```

Skip the object entirely for the one-file common case:

```
# Same result, shorter:
my $hex = Digest::MD5->new->addfile($fh)->hexdigest;
```

Edge cases

- The handle is resolved as perl resolves any filehandle argument: a glob, a glob or IO reference, or a bareword name such as `"STDIN"`. A name that is no handle croaks `Bad filehandle: NAME`, `undef` croaks `Can't use an undefined value as filehandle reference`, and an unopened handle croaks `No filehandle passed`.
- Croaks with `"Reading from filehandle failed"` if `read` returns an I/O error; the context's state after such a failure is unspecified - discard or `reset` it.
- Reading an empty handle (EOF immediately) is a no-op and returns the context unchanged.
- Handles decoded as UTF-8 still work, but you are hashing the raw *decoded* bytes the PerlIO layer returns, which is rarely what you want. Prefer `binmode`.

Differences from upstream

Fully compatible with upstream `Digest::MD5` 2.59.

See also

- `add` - feed in-memory data instead of a file
- `add_bits` - bit-oriented input for cross-digest compatibility
- `new` - typical predecessor when digesting one file
- `hexdigest` - typical successor for a single-file chain

digest

Finalise the context and return the 16-byte raw binary digest.

Synopsis

```
my $bin = $ctx->digest;        # exactly 16 bytes
```

What you get back

A 16-byte Perl string holding the raw digest. This is the most compact representation - handy for binary protocols or packing into fixed-width records - but it typically contains non-printable bytes, so do not paste it into log lines without encoding.

`digest` is destructive. After it returns, the context is automatically reset to the empty state and is immediately ready to digest a new message. To read the digest without destroying the state, use `$ctx->clone->digest` instead.

Examples

Raw bytes, then convert to hex by hand:

```
my $bin = Digest::MD5->new->add("abc")->digest;
printf "%v02x\n", $bin;   # 90.01.50.98.3c.d2.4f.b0.d6.96.3f.7d.28.
 ↪e1.7f.72
```

Pack into a fixed-width binary record:

```
my $record = pack("A16 a16", $filename, $ctx->digest);
```

Peek at an intermediate digest without resetting:

```
my $snapshot = $ctx->clone->digest;   # $ctx keeps going
$ctx->add($more);
```

Edge cases

- Called on a context with no data added, returns the MD5 of the empty string (`d41d8cd98f00b204e9800998ecf8427e` as hex).
- Resets *before* returning, so calling `digest` twice in a row without adding data between the calls gives the empty-string digest the second time.

Differences from upstream

Fully compatible with upstream `Digest::MD5` 2.59.

See also

- `hexdigest` - same digest, formatted as 32 hex characters
- `b64digest` - same digest, base64-encoded
- `md5` - one-shot functional form
- `clone` - take a snapshot digest without resetting the context

hexdigest

Finalise the context and return the digest as 32 lowercase hex chars.

Synopsis

```
my $hex = $ctx->hexdigest;    # 32 chars, [0-9a-f]
```

What you get back

A 32-character ASCII string containing only `0-9` and `a-f`. This is the form you want for ETags, `md5sum`-style checksum files, log output, and anywhere humans will read the digest. No `0x` prefix, no separators, lowercase.

`hexdigest` is destructive: the context is reset to empty after the digest is produced. Clone first if you need to keep going.

Examples

Common one-liner:

```
my $hex = Digest::MD5->new->add("hello")->hexdigest;
# 5d41402abc4b2a76b9719d911017c592
```

Digest the same context twice by cloning:

```
$ctx->add("stream so far");
my $checkpoint = $ctx->clone->hexdigest;
$ctx->add("more data");
my $final      = $ctx->hexdigest;
```

Build an `md5sum`-compatible line:

```
open(my $fh, '<:raw', $path) or die $!;
printf "%s  %s\n", Digest::MD5->new->addfile($fh)->hexdigest, $path;
```

Edge cases

- Empty context gives `d41d8cd98f00b204e9800998ecf8427e` (the MD5 of the empty string).
- The result is always lowercase; if an external format demands uppercase, call `uc` on it.
- Resets the context, so `$ctx->hexdigest` twice without intervening `add` calls gives the empty-string digest the second time.

Differences from upstream

Fully compatible with upstream `Digest::MD5` 2.59.

See also

- `digest` - same content as 16 raw bytes
- `b64digest` - shorter base64 encoding of the same digest
- `md5_hex` - one-shot functional form
- `clone` - preserve the context before finalising

b64digest

Finalise the context and return the digest as a 22-char base64 string.

Synopsis

```
my $b64 = $ctx->b64digest;    # 22 chars, no padding
```

What you get back

A 22-character string using the standard base64 alphabet `A-Z a-z 0-9 + /`. The result is **not** padded with `=`; the full base64 encoding of 16 bytes would be 24 characters, but the tail is fixed so the padding is redundant. Append `"=="` yourself if an interop partner strictly requires multiples of 4.

Base64 gives you a compact, one-line-friendly identifier that is roughly 30% shorter than hex while still printable. Common in cache keys, URL query parameters, and condensed log formats.

`b64digest` is destructive: the context is reset after use.

Examples

Compact digest for a cache key:

```
my $key = Digest::MD5->new->add($url)->b64digest;
```

Pad to a multiple of 4 for strict base64 consumers:

```
my $padded = Digest::MD5->new->add($data)->b64digest . "==";
```

Peek without consuming:

```
my $snapshot = $ctx->clone->b64digest;
```

Edge cases

- Empty context gives `1B2M2Y8AsgTpgAmY7PhCfg` (the MD5 of the empty string in base64).
- Contains `/` and `+`, so the result is **not** safe to drop into a URL path without further encoding - use URL-safe base64 for that (substitute `-` for `+` and `_` for `/`).
- Resets the context after returning.

Differences from upstream

Fully compatible with upstream `Digest::MD5` 2.59.

See also

- `digest` - raw bytes
- `hexdigest` - hex-encoded digest (longer but URL-safe)
- `md5_base64` - one-shot functional form
- `clone` - preserve the context before finalising

context

Save or restore the raw internal MD5 state - for advanced use only.

Synopsis

```
my @state = $ctx->context;                          # get
$ctx->context($blocks, $state_bytes, $partial);  # restore
```

What you get back

Called with no extra arguments, returns a list that fully captures the current digest state:

1. `$blocks` - number of complete 64-byte blocks processed so far, as an unsigned integer.

2. `$state_bytes` - 16 raw bytes holding the four MD5 state words in little-endian order.
3. `$partial` - present only when some bytes have been added that do not yet fill a full block. Up to 63 bytes of unprocessed data.

Called with those same three values, restores the context to the captured state and returns the object itself. This is the only way to persist a digest across process boundaries - serialise the three values, hand them off, then restore on the other side and continue adding.

For almost every use case, `clone` is a cleaner tool. Reach for `context` only when the state needs to survive something `clone` cannot cross, such as a database round-trip or an out-of-band storage step.

Examples

Round-trip a partial digest through storage:

```
my $ctx = Digest::MD5->new;
$ctx->add($first_half);
my @saved = $ctx->context;            # freeze state

# ... later, possibly in another process ...

my $ctx = Digest::MD5->new;
$ctx->context(@saved);                # thaw state
$ctx->add($second_half);
print $ctx->hexdigest;                # same as hashing whole thing
```

Serialise for storage:

```
use Storable qw(freeze thaw);
my $blob = freeze([$ctx->context]);   # three values in, one blob␣
↪out
# ...
my $ctx = Digest::MD5->new;
$ctx->context(@{ thaw($blob) });
```

Edge cases

- The third (`$partial`) value is only returned when `length($partial) > 0`. Be prepared for a two-element list when the input fits exactly into whole blocks.
- Passing a `$state_bytes` argument shorter than 16 bytes silently leaves the state words untouched. Do not rely on this - pass exactly what `context` gave you.
- `context` is the only method whose interface is genuinely raw. Its output is sensitive to the algorithm, not to a documented wire format; do not pretend values produced by one digest class are interchangeable with another.

Differences from upstream

Fully compatible with upstream `Digest::MD5` 2.59.

See also

- `clone` - the usual way to snapshot state in-process
- `digest` - finalise rather than persist
- `new` - fresh context for use with `context` as a restore target
- `add` - continue hashing after a restore

md5

One-shot MD5 digest, returned as 16 raw bytes.

Synopsis

```
use Digest::MD5 qw(md5);
my $bin = md5($data);               # 16 bytes
my $bin = md5($a, $b, $c);          # md5($a.$b.$c)
```

What you get back

A 16-byte Perl string holding the raw MD5 digest. All arguments are concatenated (in order) and the result is hashed, so `md5("a", "b", "c")` is the same as `md5("abc")`. The function does not allocate an object; it runs through a stack-local context, which makes it the cheapest way to hash something you already hold in memory.

Use `md5_hex` or `md5_base64` when you need a printable form.

Examples

Digest a string to raw bytes:

```
use Digest::MD5 qw(md5);
my $bin = md5("hello world");       # 16 bytes
printf "%v02x\n", $bin;
# 5e.b6.3b.bb.e0.1e.ee.d0.93.cb.22.bb.8f.5a.cd.c3
```

Concatenation is implicit:

```
my $a = md5("foo", "bar");
my $b = md5("foobar");
# $a eq $b
```

Pack into a binary record:

```
my $blob = pack("N a16", length($payload), md5($payload));
```

Edge cases

- `md5()` with no arguments returns the MD5 of the empty string (`d41d8cd98f00b204e9800998ecf8427e` in hex).
- Wide-character arguments (code points above `U+00FF`) croak with `Wide character in subroutine entry`. Encode first: `md5(encode_utf8($str))`.
- Called as a class or instance method (e.g. `Digest::MD5->md5(...)`), it warns about probable misuse but still returns a digest based on all arguments, including the invocant. Prefer the plain function call.

Differences from upstream

Fully compatible with upstream `Digest::MD5` 2.59.

See also

- `md5_hex` - same digest, as 32 lowercase hex characters
- `md5_base64` - same digest, base64-encoded
- `digest` - OO form; reuse one context across many inputs
- `addfile` - for data too large to hold in memory at once

md5_hex

One-shot MD5 digest, returned as a 32-character lowercase hex string.

Synopsis

```
use Digest::MD5 qw(md5_hex);
my $hex = md5_hex($data);              # 32 chars
my $hex = md5_hex($a, $b, $c);         # md5_hex($a.$b.$c)
```

What you get back

A 32-character ASCII string containing only `0-9` and `a-f`. This is the encoding used by `md5sum`, HTTP ETag headers, and virtually every human-readable checksum format. All arguments are concatenated before hashing.

Examples

The canonical one-liner:

```
use Digest::MD5 qw(md5_hex);
print md5_hex("foobarbaz"), "\n";
# 6df23dc03f9b54cc38a0fc1483df6e21
```

Compose a cache key from structured data:

```
my $key = md5_hex($user_id, "|", $query, "|", $locale);
```

Digest bytes from a multi-byte string via UTF-8 encoding:

```
use Encode qw(encode_utf8);
my $hex = md5_hex(encode_utf8("abc\x{300}"));
# 8c2d46911f3f5a326455f0ed7a8ed3b3
```

Edge cases

- `md5_hex()` with no arguments returns `d41d8cd98f00b204e9800998ecf8427e`.
- Wide-character arguments croak; see `md5` for the fix.
- Result is always lowercase. Call `uc` if a tool requires uppercase hex.

Differences from upstream

Fully compatible with upstream `Digest::MD5` 2.59.

See also

- `md5` - same digest as raw bytes
- `md5_base64` - same digest, shorter base64 form
- `hexdigest` - OO form over a reusable context
- `add` - feed data incrementally when you cannot fit it in memory

md5_base64

One-shot MD5 digest, returned as a 22-character base64 string.

Synopsis

```
use Digest::MD5 qw(md5_base64);
my $b64 = md5_base64($data);       # 22 chars, no padding
```

What you get back

A 22-character string from the standard base64 alphabet `A-Z a-z 0-9 + /`. The tail is **not** padded to a multiple of 4 - the redundancy would encode nothing - so if an interop partner demands strict base64, append `"=="` yourself.

Base64 is about 30% shorter than hex and still fits on one line in a log or URL query parameter. The price is that it contains `/` and `+`, which are not safe in URL paths without further escaping.

Examples

Compact digest for a cache key or tag:

```
use Digest::MD5 qw(md5_base64);
my $tag = md5_base64($payload);
# 22-character identifier, e.g. "rL0Y20zC+Fzt72VPzMSk2A"
```

Pad for strict base64 parsers:

```
my $padded = md5_base64($payload) . "==";
```

Store alongside the content in a manifest:

```
printf "%s  %s\n", md5_base64($bytes), $name;
```

Edge cases

- `md5_base64()` with no arguments returns `1B2M2Y8AsgTpgAmY7PhCfg`.
- Wide-character arguments croak; encode first.
- The `+` and `/` characters require percent-encoding if the result appears in a URL path. Consider a URL-safe base64 transform (`tr|+/|-_|`) when serving digests in URLs.

Differences from upstream

Fully compatible with upstream `Digest::MD5` 2.59.

See also

- `md5` - raw-byte form
- `md5_hex` - hex form (longer, URL-safer)
- `b64digest` - OO form over a reusable context
- `add` - feed data incrementally for larger inputs

reset

Clear an existing context so it behaves like a freshly created one.

Synopsis

```
$ctx->reset;                    # discard accumulated data
$ctx->reset->add($data);        # reset and keep going in one line
```

What you get back

The same object, returned so calls chain. After `reset`, the internal state is identical to `Digest::MD5->new`: accumulated length is zero, the four state words hold the MD5 initial vector, and the partial-block buffer is empty. No new allocation happens - the existing `MD5_CTX` is overwritten in place.

`reset` is an alias for the instance-method form of `new`, exposed as a separate method for readability. Use whichever reads better at the call site.

Examples

Reuse a context across independent digests:

```
my $ctx = Digest::MD5->new;
my $h1  = $ctx->add("first")->hexdigest;    # digest + implicit
 ↪reset
my $h2  = $ctx->add("second")->hexdigest;   # starts fresh
```

Explicit reset after a partial computation you want to throw away:

```
$ctx->add("oops, wrong data");
$ctx->reset;
$ctx->add($correct_data);
print $ctx->hexdigest;
```

Edge cases

- Calling `reset` on a fresh context is a harmless no-op.
- Reset does not change the class of the object, so subclasses remain blessed into the subclass after a reset.

Differences from upstream

Fully compatible with upstream `Digest::MD5` 2.59.

See also

- `new` - same effect when called as an instance method
- `digest` - implicitly resets after returning the digest
- `add` - the usual next step after `reset`

add_bits

Add a bit-oriented quantum of data - but only in multiples of 8 bits.

Synopsis

```
$ctx->add_bits($bitstring);         # "01101000..." form
$ctx->add_bits($data, $nbits);      # byte-string + bit count
```

What you get back

The same context object, for chaining. MD5 is a byte-oriented algorithm, so `add_bits` exists purely for interface compatibility with other `Digest::*` modules that *do* hash at bit granularity. It accepts exactly the same two calling forms they do, but requires the bit count to be a whole multiple of 8 and croaks otherwise.

Unless you are writing code that must work across multiple digest backends, use `add` directly - it is clearer and has no restrictions.

Examples

Bit-string form - a string of `'0'` and `'1'` characters:

```
$ctx->add_bits("0110100001101001");   # feeds bytes "hi"
```

Byte-string + bit count - takes the first `$nbits / 8` bytes:

```
$ctx->add_bits("hello world", 40);    # feeds "hello"
```

Chain alongside `add`:

```
my $hex = Digest::MD5->new
                     ->add_bits("0110100001101001")   # "hi"
                     ->add(" there")
                     ->hexdigest;
```

Edge cases

- Croaks with `"Number of bits must be multiple of 8 for this algorithm"` when the bit string's length, or the explicit `$nbits` argument, is not a multiple of 8.
- In the two-argument form, `$nbits` larger than `8 * length($data)` feeds all of `$data`.

Differences from upstream

Fully compatible with upstream `Digest::MD5` 2.59.

See also

- `add` - the direct byte-level input method
- `addfile` - stream bytes from a file handle
- `new` - typical predecessor in a chain

- `hexdigest` - typical successor in a chain

Digest::SHA

Compute SHA-1 and SHA-2 family message digests: SHA-1, SHA-224, SHA-256, SHA-384, SHA-512, SHA-512/224, and SHA-512/256, with optional HMAC keying.

Two call styles are available. The **functional interface** (`sha256_hex`, `hmac_sha512_base64`, and friends) is a one-shot: hand it the data, get the digest back. The **object interface** (`Digest::SHA->new(256)`, `->add`, `->digest`) lets you feed data incrementally - from streams, files, or a mix of sources - and finalize when you are ready.

Every digest can be rendered in three encodings: raw binary (fixed-length bytes), lowercase hex, or unpadded Base64. Choose the encoding by the function suffix (`_hex`, `_base64`, or none for raw). HMAC variants use the same suffixes and live under the `hmac_*` prefix.

File input is supported through `addfile`, which reads a filehandle or filename and feeds its contents straight into the context. A `bits` helper (`add_bits`) lets you hash arbitrary-length bit strings, not just whole bytes. Context state is serialisable with `getstate` / `putstate` (text) and `_getstate` / `_putstate` (packed binary), so a long-running hash can be suspended and resumed across processes.

Pick **SHA-256** by default for new work: it is fast on 32-bit and 64-bit CPUs alike and has the widest interoperability. Prefer **SHA-512** (or its truncated `SHA-512/256` cousin) on 64-bit hardware when you want more performance headroom or a larger internal state; SHA-512 often outperforms SHA-256 there despite the larger output. Avoid **SHA-1** for anything collision-sensitive - it survives only for legacy interoperability.

This is Digest::SHA 6.04; `Digest/SHA.pm` is upstream's.

Synopsis

```
use Digest::SHA qw(sha256_hex sha1_base64 hmac_sha256_hex);

print sha256_hex('abc'), "\n";                  # ba7816bf8f01...
↪f20015ad
print sha1_base64('abc'), "\n";                 #␣
↪qZk+NkcGgWq6PiVxeFDCbJzQ2J0
print hmac_sha256_hex('data', 'key'), "\n";     # 5031fe3d989c...
↪ce221bd0

my $sha = Digest::SHA->new(256);
$sha->add('a', 'b');
$sha->add('c');
print $sha->hexdigest, "\n";                    # the same as␣
↪sha256_hex('abc')

open my $fh, '<', $file or die;
print Digest::SHA->new(512)->addfile($fh)->b64digest, "\n";
```

The functional digests

One function per algorithm and encoding, each taking any number of strings, hashed as their concatenation:

algorithm	raw bytes	hex	base64 (unpadded)
SHA-1	`sha1`	`sha1_hex`	`sha1_base64`
SHA-224	`sha224`	`sha224_hex`	`sha224_base64`
SHA-256	`sha256`	`sha256_hex`	`sha256_base64`
SHA-384	`sha384`	`sha384_hex`	`sha384_base64`
SHA-512	`sha512`	`sha512_hex`	`sha512_base64`
SHA-512/224	`sha512224`	`sha512224_hex`	`sha512224_base64`
SHA-512/256	`sha512256`	`sha512256_hex`	`sha512256_base64`

`hmac_` before each name (`hmac_sha256_hex($data, $key)`) gives the keyed HMAC; the key is the last argument. Strings must be bytes: a character above 0xFF dies "Wide character".

Differences from upstream

Two, each where perl 5.44 with SHA.xs fails (t/81-xs-native/Digest-SHA/495-or-better.t):

- The low-level entry points Digest/SHA.pm builds on (`shainit`, `shawrite`, `sharewind`), given an object that is not a Digest::SHA, refuse it: `shainit` and `shawrite` return 0. perl5 crashes.
- `shawrite($bits, $count, $sha)` with a count past the end of `$bits` writes the bits the string has and returns their number; perl5 reads past the end of the string. (`add_bits`, the documented way in, never passes such a count.)

Functions

Functional digests

sha1

Compute a SHA digest of the concatenated arguments in one call.

Also available as `Digest::SHA::sha1_base64`, `Digest::SHA::sha1_hex`, `Digest::SHA::sha224`, `Digest::SHA::sha224_base64`, `Digest::SHA::sha224_hex`, `Digest::SHA::sha256`, `Digest::SHA::sha256_base64`, `Digest::SHA::sha256_hex`, `Digest::SHA::sha384`, `Digest::SHA::sha384_base64`, `Digest::SHA::sha384_hex`, `Digest::SHA::sha512`, `Digest::SHA::sha512224`, `Digest::SHA::sha512224_base64`, `Digest::SHA::sha512224_hex`, `Digest::SHA::sha512256`, `Digest::SHA::sha512256_base64`, `Digest::SHA::sha512256_hex`, `Digest::SHA::sha512_base64`, `Digest::SHA::sha512_hex`.

OO lifecycle

shainit

(Re)initialise a `Digest::SHA` object for an algorithm; the low-level entry point behind `$sha->new($alg)` on an existing object.

sharewind

Rewind a `Digest::SHA` object to the empty message of its algorithm; the low-level entry point behind `$sha->reset`.

newSHA

Construct a `Digest::SHA` object of class `$classname` for an algorithm number: 1, 224, 256, 384, 512, 512224 or 512256. Any other number returns `undef`.

clone

Copy a `Digest::SHA` object, current state included, into a new object of the same class.

Synopsis

```
my $partial = $sha->clone;
print $partial->hexdigest;   # digest so far; $sha keeps going
```

new

Construct or reinitialise a `Digest::SHA` object.

reset

Rewind a `Digest::SHA` object, optionally switching algorithm.

OO input

shawrite

Feed the first `$bitcnt` bits of `$bitstr` into a `Digest::SHA` object; the low-level entry point behind `add_bits`.

add

Append data to the message being hashed.

add_bits

Feed an arbitrary number of bits into a `Digest::SHA` object.

addfile

Feed a filehandle or a file by name into a `Digest::SHA` object.

OO output

digest

Finish the message and return its digest as raw bytes, then rewind the object to the empty message.

hexdigest

Finish the message and return its digest as lowercase hex, then rewind the object to the empty message.

b64digest

Finish the message and return its digest as unpadded Base64, then rewind the object to the empty message.

algorithm

Return the algorithm code of a `Digest::SHA` object.

hashsize

Return the digest length of a `Digest::SHA` object in bits.

HMAC

hmac_sha1

Compute a keyed HMAC digest of the data arguments in one call.

Also available as `Digest::SHA::hmac_sha1_base64`, `Digest::SHA::hmac_sha1_hex`, `Digest::SHA::hmac_sha224`, `Digest::SHA::hmac_sha224_base64`, `Digest::SHA::hmac_sha224_hex`, `Digest::SHA::hmac_sha256`, `Digest::SHA::hmac_sha256_base64`, `Digest::SHA::hmac_sha256_hex`, `Digest::SHA::hmac_sha384`, `Digest::SHA::hmac_sha384_base64`, `Digest::SHA::hmac_sha384_hex`, `Digest::SHA::hmac_sha512`, `Digest::SHA::hmac_sha512224`, `Digest::SHA::hmac_sha512224_base64`, `Digest::SHA::hmac_sha512224_hex`, `Digest::SHA::hmac_sha512256`, `Digest::SHA::hmac_sha512256_base64`, `Digest::SHA::hmac_sha512256_hex`, `Digest::SHA::hmac_sha512_base64`, `Digest::SHA::hmac_sha512_hex`.

Other Functions

getstate

Export a `Digest::SHA` object's state as a human-readable text string.

putstate

Construct or restore a `Digest::SHA` object from a text state string.

dump

Write the current `Digest::SHA` state to a file or STDOUT in text form.

load

Construct a `Digest::SHA` object from a text state file written by `dump`.

sha1

Compute a SHA digest of the concatenated arguments in one call.

Also available as `Digest::SHA::sha1_base64`, `Digest::SHA::sha1_hex`, `Digest::SHA::sha224`, `Digest::SHA::sha224_base64`, `Digest::SHA::sha224_hex`, `Digest::SHA::sha256`, `Digest::SHA::sha256_base64`, `Digest::SHA::sha256_hex`, `Digest::SHA::sha384`, `Digest::SHA::sha384_base64`, `Digest::SHA::sha384_hex`, `Digest::SHA::sha512`, `Digest::SHA::sha512224`, `Digest::SHA::sha512224_base64`, `Digest::SHA::sha512224_hex`, `Digest::SHA::sha512256`, `Digest::SHA::sha512256_base64`, `Digest::SHA::sha512256_hex`, `Digest::SHA::sha512_base64`, `Digest::SHA::sha512_hex`.

There are 21 functional entry points: 7 algorithms crossed with 3 output encodings. The name you call selects both the algorithm and the encoding: the plain name returns the **raw binary** digest (a fixed-length byte string), `_hex` the **lowercase hex** digest, `_base64` the **unpadded Base64** digest.

Algorithm	Raw binary	Hex	Base64
SHA-1	`sha1`	`sha1_hex`	`sha1_base64`
SHA-224	`sha224`	`sha224_hex`	`sha224_base64`
SHA-256	`sha256`	`sha256_hex`	`sha256_base64`
SHA-384	`sha384`	`sha384_hex`	`sha384_base64`
SHA-512	`sha512`	`sha512_hex`	`sha512_base64`
SHA-512/224	`sha512224`	`sha512224_hex`	`sha512224_base64`
SHA-512/256	`sha512256`	`sha512256_hex`	`sha512256_base64`

All arguments are concatenated byte-wise before hashing, so `sha256_hex("foo", "bar")` is identical to `sha256_hex("foobar")`.

Synopsis

```
use Digest::SHA qw(sha256_hex sha512_base64);
my $hex = sha256_hex($data);
my $b64 = sha512_base64(@chunks);
```

What you get back

A plain scalar. For the raw-binary variants it is a byte string of fixed length (20 bytes for SHA-1, 28 for SHA-224, 32 for SHA-256, 48 for SHA-384, 64 for SHA-512). For _hex variants it is twice that length. For _base64 variants it is the unpadded Base64 encoding (no trailing = characters).

Examples

```
use Digest::SHA qw(sha256_hex);
print sha256_hex("abc");
# e.g.␣
↪ba7816bf8f01cfea414140de5dae2223b00361a396177a9cb410ff61f20015ad
```

```
use Digest::SHA qw(sha1_hex);
my $digest = sha1_hex("The quick brown fox ", "jumps over the lazy␣
↪dog");
# identical to sha1_hex("The quick brown fox jumps over the lazy dog
↪")
```

```
use Digest::SHA qw(sha512_base64);
my $tag = sha512_base64($payload);
# 86-character unpadded Base64 string
```

```
use Digest::SHA qw(sha256);
my $raw = sha256("");     # 32 raw bytes
print length $raw;        # 32
```

Edge cases

- No arguments: hashes the empty string. `sha256_hex()` returns the well-known `e3b0c442...` empty-input digest.
- Wide characters (codepoint above 255) croak with `Wide character in subroutine entry` - encode to UTF-8 first if you want to hash text above Latin-1.

Differences from upstream

Fully compatible with upstream `Digest::SHA` 6.04.

See also

- `hmac_sha256_hex` - keyed variant for message authentication.
- `Digest::SHA->new(256)` - incremental interface for large or streamed input.
- `sha256` - raw-binary counterpart of `sha256_hex`.

hmac_sha1

Compute a keyed HMAC digest of the data arguments in one call.

Also available as `Digest::SHA::hmac_sha1_base64`, `Digest::SHA::hmac_sha1_hex`, `Digest::SHA::hmac_sha224`, `Digest::SHA::hmac_sha224_base64`, `Digest::SHA::hmac_sha224_hex`, `Digest::SHA::hmac_sha256`, `Digest::SHA::hmac_sha256_base64`, `Digest::SHA::hmac_sha256_hex`, `Digest::SHA::hmac_sha384`, `Digest::SHA::hmac_sha384_base64`, `Digest::SHA::hmac_sha384_hex`, `Digest::SHA::hmac_sha512`, `Digest::SHA::hmac_sha512224`, `Digest::SHA::hmac_sha512224_base64`, `Digest::SHA::hmac_sha512224_hex`, `Digest::SHA::hmac_sha512256`, `Digest::SHA::hmac_sha512256_base64`, `Digest::SHA::hmac_sha512256_hex`, `Digest::SHA::hmac_sha512_base64`, `Digest::SHA::hmac_sha512_hex`.

There are 21 `hmac_sha*` entry points: 7 algorithms crossed with 3 output encodings. The name you call selects both the underlying SHA algorithm and the encoding: the plain name returns the **raw binary** MAC, `_hex` the **lowercase hex** MAC, `_base64` the **unpadded Base64** MAC.

Algorithm	Raw binary	Hex	Base64
SHA-1	`hmac_sha1`	`hmac_sha1_hex`	`hmac_sha1_base64`
SHA-224	`hmac_sha224`	`hmac_sha224_hex`	`hmac_sha224_base64`
SHA-256	`hmac_sha256`	`hmac_sha256_hex`	`hmac_sha256_base64`
SHA-384	`hmac_sha384`	`hmac_sha384_hex`	`hmac_sha384_base64`
SHA-512	`hmac_sha512`	`hmac_sha512_hex`	`hmac_sha512_base64`
SHA-512/224	`hmac_sha512224`	`hmac_sha512224_hex`	`hmac_sha512224_base64`
SHA-512/256	`hmac_sha512256`	`hmac_sha512256_hex`	`hmac_sha512256_base64`

The **last** argument is the key, every preceding argument is message data (concatenated byte-wise). With a single argument the key is that argument and the message is empty. With no arguments both key and message are empty.

Synopsis

```
use Digest::SHA qw(hmac_sha256_hex hmac_sha1_base64);
my $tag = hmac_sha256_hex($message, $key);
my $b64 = hmac_sha1_base64(@chunks, $key);
```

What you get back

A plain scalar. The raw-binary form has the fixed length of the chosen algorithm's digest (20 bytes for SHA-1, 32 for SHA-256, 64 for SHA-512, and so on). The `_hex` form is twice that length; the `_base64` form is the unpadded Base64 encoding.

Examples

```
use Digest::SHA qw(hmac_sha256_hex);
my $mac = hmac_sha256_hex("Hi There", "\x0b" x 20);
# b0344c61d8db38535ca8afceaf0bf12b881dc200c9833da726e9376c2e32cff7
```

```
use Digest::SHA qw(hmac_sha1_hex);
# Concatenated message: "Hello, " + "world!"
my $mac = hmac_sha1_hex("Hello, ", "world!", $shared_secret);
```

```
use Digest::SHA qw(hmac_sha512_base64);
my $cookie_tag = hmac_sha512_base64($cookie_body, $server_secret);
```

```
use Digest::SHA qw(hmac_sha256_hex);
my $tag = hmac_sha256_hex($key);   # one arg: key only, empty␣
↪message
```

Edge cases

- Single-argument calls treat the sole argument as the key and hash an empty message. That is rarely what you want - pass message and key explicitly.
- Keys longer than the algorithm's block size are hashed down to digest size before use (standard HMAC key reduction).
- Wide characters in either key or data croak with `Wide character in subroutine entry`.

Differences from upstream

Fully compatible with upstream `Digest::SHA` 6.04.

See also

- `sha256_hex` - unkeyed one-shot digest for integrity-only needs.
- There is no OO HMAC: a `Digest::SHA` object has no `hmac_*` methods. If you need incremental HMAC use `Digest::HMAC_SHA1` or feed a keyed construction manually.
- `hmac_sha1_hex` - SHA-1 variant; prefer SHA-256 or larger for new code.

newSHA

Construct a `Digest::SHA` object of class `$classname` for an algorithm number: 1, 224, 256, 384, 512, 512224 or 512256. Any other number returns `undef`.

`Digest::SHA->new` is the usual way in; it strips a name such as `"SHA-256"` down to its digits and calls `$class->newSHA($alg)`.

Synopsis

```
my $sha = Digest::SHA->newSHA(256);
my $sub = Digest::SHA::newSHA("My::Digest", 1);   # blessed into
 ↪My::Digest
```

add

Append data to the message being hashed.

Every argument is taken as bytes (`SvPVbyte`); a string holding a character above U+00FF croaks `Wide character in subroutine entry`. Returns the object, so calls chain; `undef` when called on anything that is not a `Digest::SHA`.

Synopsis

```
$sha->add($chunk1, $chunk2)->add($chunk3);
print $sha->hexdigest;
```

algorithm

Return the algorithm code of a `Digest::SHA` object.

The code is the same integer you can pass to `new`: 1, 224, 256, 384, 512, 512224, or 512256. Useful when a function receives a `Digest::SHA` object from elsewhere and needs to act differently based on which variant it is.

Synopsis

```
my $code = $sha->algorithm;
```

What you get back

An integer in the set `{1, 224, 256, 384, 512, 512224, 512256}`.

Examples

```
my $sha = Digest::SHA->new("SHA-256");
print $sha->algorithm;   # 256
```

```
my $sha = Digest::SHA->new("SHA-512/224");
print $sha->algorithm;   # 512224
```

```
# Dispatch on algorithm:
my $code = $sha->algorithm;
my $name = $code == 1 ? "SHA-1" : "SHA-$code";
```

Edge cases

- Called on a non-`Digest::SHA` object, returns `undef`.

Differences from upstream

Fully compatible with upstream `Digest::SHA` 6.04.

See also

- `hashsize` - digest length in bits for this algorithm.
- `new` - accepts the values returned here as its algorithm argument.

hashsize

Return the digest length of a `Digest::SHA` object in bits.

For a given algorithm the hashsize is a constant: 160 for SHA-1, 224 for SHA-224, 256 for SHA-256 and SHA-512/256, 384 for SHA-384, 512 for SHA-512. Divide by 8 to get the byte length of the output from `digest`.

Synopsis

```
my $bits = $sha->hashsize;
```

What you get back

An integer, always a multiple of 8.

Examples

```
my $sha = Digest::SHA->new(256);
print $sha->hashsize;         # 256
print $sha->hashsize / 8;     # 32  (bytes per digest)
```

```
my $sha = Digest::SHA->new("SHA-512/224");
print $sha->hashsize;         # 224
```

```
# Preallocate output buffer for $sha->digest:
my $buf = "\0" x ($sha->hashsize / 8);
```

Edge cases

- Called on a non-`Digest::SHA` object, returns `undef`.

Differences from upstream

Fully compatible with upstream `Digest::SHA` 6.04.

See also

- `algorithm` - the integer algorithm code for this object.
- `digest` - output whose length is `hashsize / 8` bytes.

new

Construct or reinitialise a `Digest::SHA` object.

The primary object constructor. Works as both a class method (`Digest::SHA->new(256)`) and an instance method (`$sha->new(512)`), and accepts the algorithm in any of the shapes `Digest::SHA` recognises: an integer like 256, a string like `"SHA-256"`, `"sha256"`, or `"512/224"`. When called without an algorithm argument it defaults to SHA-1.

As an instance method, new reuses the existing object: supplying a new algorithm resets state and switches to that algorithm; omitting it simply rewinds the state (same as `reset`).

Synopsis

```
my $sha = Digest::SHA->new(256);
my $sha = Digest::SHA->new("SHA-512/256");
$sha->new;                      # rewind, keep algorithm
$sha->new(384);                 # rewind, switch to SHA-384
```

What you get back

A blessed `Digest::SHA` object, or `undef` when the algorithm argument cannot be parsed as a supported algorithm.

Examples

```
my $sha = Digest::SHA->new("sha256");
$sha->add("The quick brown fox ", "jumps over the lazy dog");
print $sha->hexdigest;
# d7a8fbb307d7809469ca9abcb0082e4f8d5651e46d3cdb762d02d0bf37c9e592
```

```
my $sha = Digest::SHA->new(512);
$sha->add_bits("01011010");       # hash exactly 8 bits
```

```
my $sha = Digest::SHA->new(256);
$sha->add("first");
$sha->new(512);                  # rewind and switch
$sha->add("second");             # now hashing with SHA-512
```

Edge cases

- No algorithm argument defaults to SHA-1.
- An unparseable algorithm returns undef; check the return value before chaining ->add.
- Called on an existing object, new mutates that object in place and returns it - it does not allocate a second context.

Differences from upstream

Fully compatible with upstream Digest::SHA 6.04.

See also

- reset - explicit rewind, same semantics as the no-argument instance form.
- clone - copy the current state into a fresh object.
- newSHA - lower-level constructor taking an integer algorithm code.

reset

Rewind a Digest::SHA object, optionally switching algorithm.

Clears buffered data and restores the initial hash state so the same object can be reused for a fresh digest. With no argument the algorithm is preserved; with an algorithm argument the object is rewound **and** retargeted at that algorithm. Accepts the same algorithm shapes as new (integer code or string like "SHA-256").

Synopsis

```
$sha->reset;              # rewind, keep algorithm
$sha->reset(512);         # rewind and switch to SHA-512
$sha->reset("SHA-384");   # string form
```

What you get back

The receiver on success (chainable), or undef if an algorithm argument was supplied that could not be parsed.

Examples

```
my $sha = Digest::SHA->new(256);
$sha->add("first");
my $a = $sha->hexdigest;       # finalises and auto-resets already
$sha->reset;                   # defensive rewind before reuse
$sha->add("second");
my $b = $sha->hexdigest;
```

```
my $sha = Digest::SHA->new(256);
$sha->reset(512)->add("hello");
print $sha->algorithm;         # 512
```

```
my $sha = Digest::SHA->new(256);
my $ok = $sha->reset("bogus"); # undef
```

Edge cases

- Called without an algorithm on a reference that is not a `Digest::SHA` object, returns that reference unchanged.
- After the built-in auto-reset inside `digest`, calling `reset` explicitly is harmless.

Differences from upstream

- Called without an algorithm on a reference that is not a `Digest::SHA` object, upstream crashes with a segmentation fault (its XS `sharewind` is handed a null context); pperl leaves the reference alone and returns it.

See also

- `new` - when called on an instance, functionally equivalent to `reset`.
- `digest` - auto-rewinds after finalisation, so explicit `reset` is only needed when you abandon a computation partway.
- `clone` - if you want a copy of the pre-reset state, clone first.

add_bits

Feed an arbitrary number of bits into a `Digest::SHA` object.

Unlike add, this method is not restricted to whole bytes. It accepts two call forms:

- **One-argument form** `add_bits($bitstr)` hashes a string of `'0'` and `'1'` characters - the hash takes one bit per character, so `"01011010"` adds exactly 8 bits of input.
- **Two-argument form** `add_bits($data, $numbits)` hashes the first `$numbits` bits of the packed binary string `$data`. If `$numbits` exceeds `8 * length($data)` it is capped at that value.

Most of the SHA standard is defined on bit-strings rather than byte-strings; this is the entry point for the bit-exact test vectors in FIPS 180-4.

Synopsis

```
$sha->add_bits("11001010");          # 8 bits from ASCII 0/1 string
$sha->add_bits($packed, 13);         # first 13 bits of $packed
```

What you get back

The receiver, for chaining.

Examples

```
my $sha = Digest::SHA->new(256);
$sha->add_bits("01011010" x 8);   # 64 bits
print $sha->hexdigest;
```

```
# FIPS 180-4 1-bit test vector for SHA-1
my $sha = Digest::SHA->new(1);
$sha->add_bits("0");
print $sha->hexdigest;
# bb6b3e18f0115b57925241676f5b1ae88747b08a
```

```
my $sha = Digest::SHA->new(256);
$sha->add_bits("\xab\xcd", 12);  # first 12 bits of 0xabcd
```

Edge cases

- The one-argument form packs the string with `pack("B*", ...)`, so every character counts as one bit: a character other than `'0'` or `'1'` is not skipped but read by its lowest bit. An empty string is a no-op.
- In the two-argument form, a zero bit count leaves the hash state untouched, and a negative one hashes all of `$data`.
- Called on a reference that is not a `Digest::SHA` object, returns that reference unchanged.

Differences from upstream

- A negative bit count in the two-argument form hashes all of `$data`; upstream hands it to XS as a huge unsigned count, reads past the end of the string and crashes.
- Called on a reference that is not a `Digest::SHA` object, upstream crashes with a segmentation fault (its XS `shawrite` is handed a null context); pperl leaves the reference alone and returns it.

See also

- `add` - standard byte-aligned input path; use it unless you truly have sub-byte data.
- `digest` - finalises the running hash once input is complete.
- `addfile` - byte-oriented file ingestion.

addfile

Feed a filehandle or a file by name into a `Digest::SHA` object.

The public file-ingestion entry point. Accepts either an open filehandle or a filename string, plus an optional mode character that controls how bytes are read:

- `"b"` (default): raw binary read. Use this for anything that is not human-readable text, or when you need bit-exact file digests.
- `"U"`: universal newlines. When the file looks like text (`-T`), CR/LF and lone CR line endings are read as LF, so a text file gives the same digest whatever its line endings; any other file is read as in `"b"`.
- `"0"`: BITS mode. Interpret every `'0'` and `'1'` character in the file as a single bit and feed those bits into the hash. Anything else in the file is ignored.

Synopsis

```
$sha->addfile("data.bin");                  # filename, binary
$sha->addfile($fh);                         # handle, binary
$sha->addfile("notes.txt", "U");            # universal newlines
$sha->addfile("bits.txt", "0");             # ASCII bit stream
```

What you get back

The receiver, for chaining.

Examples

```
my $sha = Digest::SHA->new(256);
$sha->addfile("archive.tar.gz");
print $sha->hexdigest;
```

```
# Cross-platform digest of a source file
my $sha = Digest::SHA->new(256);
$sha->addfile("src/main.c", "U");
```

```
# BITS mode: hash the bit pattern "01011010" repeated
my $sha = Digest::SHA->new(1);
$sha->addfile("bitstream.txt", "0");
```

```
my $sha = Digest::SHA->new(256);
open my $fh, "<:raw", "photo.jpg" or die $!;
$sha->addfile($fh);
```

Edge cases

- A missing or unreadable filename croaks with `Open failed: ...`; a read error, such as on a closed filehandle, croaks with `Read failed: ...`.
- The mode applies only to a filename; a filehandle is read as it is, whatever mode is given.
- Unknown mode characters fall back to binary.
- Empty files leave the hash state untouched.
- Called on something that is not a `Digest::SHA` object, dies with `Can't locate object method` or `Can't call method`.

Differences from upstream

Fully compatible with upstream `Digest::SHA` 6.04.

See also

- `add` - use when the data is already in a Perl scalar.
- `add_bits` - for bit-aligned input strings.
- `digest` - finalise and return the digest after the file has been consumed.

getstate

Export a `Digest::SHA` object's state as a human-readable text string.

Produces a multi-line plain-text dump of the current hashing state, including algorithm number, hash registers, pending block, and message length counters. The text form is portable across machines of different endianness and lends itself to inspection, diffing, and manual editing.

Pair with `putstate` to reconstruct the state later.

Synopsis

```
my $text = $sha->getstate;
```

What you get back

A newline-terminated ASCII string.

Examples

```
my $sha = Digest::SHA->new(256);
$sha->add("hello");
print $sha->getstate;
# alg:256
# H:...
# block:...
# blockcnt:40
# lenhh:0
# lenhl:0
# lenlh:0
# lenll:40
```

```
# Resume on another machine:
my $text = $sha->getstate;
...
my $resumed = Digest::SHA->putstate($text);
$resumed->add($more_data);
```

Edge cases

- The text format is stable across `Digest::SHA` versions and endianness.
- Called on something that is not a `Digest::SHA` object, dies with `Can't locate object method` or `Can't call method`.

Differences from upstream

Fully compatible with upstream `Digest::SHA` 6.04.

See also

- `putstate` - inverse: parses text and constructs or updates an object.
- dump - write the text state to a file or STDOUT.
- `_getstate` - binary counterpart for same-machine use.

putstate

Construct or restore a `Digest::SHA` object from a text state string.

Accepts the text produced by `getstate` or dump and either:

- As a **class method** (`Digest::SHA->putstate($text)`), returns a new object with algorithm and state taken from the string.
- As an **instance method** (`$sha->putstate($text)`), rewrites the receiver in place, switching algorithm if the string asks for a different one.

The algorithm is read from the text, so - unlike `_putstate` - you do not need to preconfigure the object with the correct algorithm.

Synopsis

```
my $sha = Digest::SHA->putstate($text);
$sha->putstate($text);
```

What you get back

A `Digest::SHA` object on success, `undef` if the string could not be parsed.

Examples

```
my $text = $other->getstate;
my $sha  = Digest::SHA->putstate($text);
$sha->add($remaining_data);
```

```
# Update an existing object from a state string:
my $sha = Digest::SHA->new(256);
$sha->putstate($text);
```

```
# Invalid input returns undef:
my $sha = Digest::SHA->putstate("garbage");
print defined $sha ? "ok" : "undef"; # undef
```

Edge cases

- Unrecognised or truncated text returns `undef` rather than croaking.
- When used as an instance method, the receiver's algorithm is overwritten by whatever the text specifies.

Differences from upstream

Fully compatible with upstream `Digest::SHA` 6.04.

See also

- `getstate` - produces the strings this method consumes.
- `load` - convenience wrapper that reads the text from a file.
- `_putstate` - binary-state counterpart for same-machine use.

dump

Write the current `Digest::SHA` state to a file or STDOUT in text form.

With a filename argument, writes the text produced by `getstate` to that file, truncating it if it exists. Without an argument, prints the same text to STDOUT. The companion `load` method reads it back.

Synopsis

```
$sha->dump("hash.state");
$sha->dump;                    # to STDOUT
```

What you get back

The receiver on success (truthy), `undef` on I/O failure.

Examples

```
my $sha = Digest::SHA->new(256);
$sha->add("partial");
$sha->dump("checkpoint.state");
# ... later, perhaps in another process ...
my $resumed = Digest::SHA->load("checkpoint.state");
$resumed->add("tail");
print $resumed->hexdigest;
```

```
# Debug-dump to the terminal:
$sha->dump;
```

```
# Check the return value for I/O errors:
defined $sha->dump("/nonexistent/path/file")
    or warn "could not write state";
```

Edge cases

- An unwritable path returns `undef` rather than croaking.
- Called on something that is not a `Digest::SHA` object, dies with `Can't locate object method` or `Can't call method`.

Differences from upstream

Fully compatible with upstream `Digest::SHA` 6.04.

See also

- `load` - counterpart that reads the file `dump` produces.
- `getstate` - underlying text-state producer.
- `putstate` - text-state ingester.

load

Construct a `Digest::SHA` object from a text state file written by `dump`.

Reads the file, parses its contents as a text state string, and returns a new object with the algorithm and internal state recorded in the file. Typically called as a class method, but works as an instance method too (the receiver is overwritten in place and returned, as with `putstate`).

Synopsis

```
my $sha = Digest::SHA->load("hash.state");
```

What you get back

A `Digest::SHA` object on success, `undef` if the file could not be read or the contents could not be parsed.

Examples

```
my $sha = Digest::SHA->new(256);
$sha->add("one");
$sha->dump("hash.state");

my $resumed = Digest::SHA->load("hash.state");
$resumed->add("two");
print $resumed->hexdigest;
# same as Digest::SHA->new(256)->add("one")->add("two")->hexdigest
```

```
# Missing file returns undef rather than croaking:
my $sha = Digest::SHA->load("/does/not/exist");
print defined $sha ? "ok" : "undef"; # undef
```

```
# Works as an instance method too (and overwrites the receiver):
my $dummy = Digest::SHA->new(1);
my $sha = $dummy->load("hash.state");
```

Edge cases

- I/O failure or a parse error returns `undef`.
- The returned object's algorithm comes from the file, not from any receiver.

Differences from upstream

Fully compatible with upstream `Digest::SHA` 6.04.

See also

- dump - writes the file load reads.
- putstate - parses the text state directly from a string.
- _putstate - binary-state counterpart.

Digest::SHA1

Compute SHA-1 message digests through the interface of Digest::SHA1, the CPAN module older code uses where newer code uses Digest::SHA.

The **functional interface** (sha1, sha1_hex, sha1_base64) hashes its arguments in one call. The **object interface** (Digest::SHA1->new, add, addfile, digest) takes the data in pieces. Every digest comes as raw bytes (20), lowercase hex (40) or unpadded Base64 (27). sha1_transform is the bare SHA-1 compression of one block, for the FIPS 186 random-number construction.

The digests are computed by the engine of the built-in Digest::SHA, which uses the processor's SHA instructions where it has them, so the two modules always agree.

This is a native implementation of Digest::SHA1 2.13's SHA1.xs; its Digest/SHA1.pm is used unchanged.

Synopsis

```
use Digest::SHA1 qw(sha1_hex sha1_base64);

print sha1_hex('abc'), "\n";      #␣
↪a9993e364706816aba3e25717850c26c9cd0d89d
print sha1_base64('abc'), "\n";   # qZk+NkcGgWq6PiVxeFDCbJzQ2J0

my $ctx = Digest::SHA1->new;
$ctx->add('a', 'b');
$ctx->add('c');
print $ctx->hexdigest, "\n";      # the same as sha1_hex('abc')
```

Differences from upstream

Two, each where perl 5.44 with SHA1.xs fails (t/81-xs-native/Digest-SHA1/150-or-better.t):

- sha1_transform given more than 64 bytes uses the first 64. perl5 copies the whole string into a 64-byte buffer and aborts with "buffer overflow detected".
- A method called on the class name instead of an object (Digest::SHA1->add($data)) dies "Not a reference to a Digest::SHA1 object". perl5 crashes.

Functions

Functional digests

sha1

Compute the SHA-1 digest of the concatenated arguments in one call.

Also available as `Digest::SHA1::sha1_base64`, `Digest::SHA1::sha1_hex`.

sha1_transform

The SHA-1 compression function over one 64-byte block, from the standard initial state: the 20-byte result, with no padding and no length.

OO lifecycle

new

Create a Digest::SHA1 object, or reset an existing one.

clone

Copy a Digest::SHA1 object, the data added so far included, into a new object of the same class.

Synopsis

```
my $so_far = $ctx->clone->hexdigest;   # $ctx keeps going
```

OO input

add

Append data to the message being hashed.

addfile

Append everything that can be read from a filehandle to the message.

OO output

b64digest

Finish the message and return its digest, then reset the object to the empty message.

Also available as `Digest::SHA1::digest`, `Digest::SHA1::hexdigest`.

new

Create a Digest::SHA1 object, or reset an existing one.

Called on a class it returns a new object of that class, ready for the empty message. Called on an object it forgets what was added and returns the same object.

Synopsis

```
my $ctx = Digest::SHA1->new;
$ctx->add($data);
$ctx->new;                  # back to the empty message
```

add

Append data to the message being hashed.

Every argument is taken as bytes; a string holding a character above U+00FF dies “Wide character in subroutine entry”. Returns the object, so calls chain.

Synopsis

```
$ctx->add($chunk1, $chunk2)->add($chunk3);
```

addfile

Append everything that can be read from a filehandle to the message.

The handle is read to its end as it is, bytes as they come, so a text file should be opened with `binmode` to hash its exact contents. Dies “No filehandle passed” for a handle that is not open for reading and “Reading from filehandle failed” when a read fails. Returns the object.

Synopsis

```
open my $fh, '<:raw', $file or die "$file: $!";
print Digest::SHA1->new->addfile($fh)->hexdigest, "  $file\n";
```

b64digest

Finish the message and return its digest, then reset the object to the empty message.

Also available as `Digest::SHA1::digest`, `Digest::SHA1::hexdigest`.

`digest` returns the 20 raw bytes, `hexdigest` 40 lowercase hex digits, `b64digest` 27 Base64 characters without the = padding.

Synopsis

```
my $ctx = Digest::SHA1->new;
$ctx->add('abc');
print $ctx->hexdigest, "\n";   # a9993e36...
print $ctx->hexdigest, "\n";   # da39a3ee..., the empty message
```

sha1

Compute the SHA-1 digest of the concatenated arguments in one call.

Also available as `Digest::SHA1::sha1_base64`, `Digest::SHA1::sha1_hex`.

`sha1` returns the 20 raw bytes, `sha1_hex` 40 lowercase hex digits, `sha1_base64` 27 Base64 characters without the = padding. No argument hashes the empty string.

Synopsis

```
use Digest::SHA1 qw(sha1 sha1_hex sha1_base64);
my $hex = sha1_hex($data);
my $raw = sha1(@chunks);       # the same as sha1(join '', @chunks)
```

Edge cases

- Under `-w` (`$^W`), a call that looks like a method call warns: `sha1_hex($ctx)` "probably called as method", `Digest::SHA1->sha1_hex($data)` "probably called as class method", and any other single reference "called with reference argument".
- A character above U+00FF dies "Wide character in subroutine entry".

sha1_transform

The SHA-1 compression function over one 64-byte block, from the standard initial state: the 20-byte result, with no padding and no length.

A block shorter than 64 bytes is padded with zero bytes; bytes past the 64th are not used. This is the function G of FIPS 186-2's random-number generator, not a digest of the data.

Synopsis

```
use Digest::SHA1 qw(sha1_transform);
my $g = sha1_transform($xkey);
```

Digest::base

Digest base class

SYNOPSIS

```
package Digest::Foo;
use base 'Digest::base';
```

DESCRIPTION

The `Digest::base` class provide implementations of the methods `addfile` and `add_bits` in terms of add, and of the methods `hexdigest` and `b64digest` in terms of `digest`.

Digest implementations might want to inherit from this class to get this implementations of the alternative *add* and *digest* methods. A minimal subclass needs to implement the following methods by itself:

```
new
clone
add
digest
```

The arguments and expected behaviour of these methods are described in *Digest*.

SEE ALSO

Digest

Digest::file

Calculate digests of files

SYNOPSIS

```
# Poor mans "md5sum" command
use Digest::file qw(digest_file_hex);
for (@ARGV) {
    print digest_file_hex($_, "MD5"), "  $_\n";
}
```

DESCRIPTION

This module provide 3 convenience functions to calculate the digest of files. The following functions are provided:

- digest_file($file, $algorithm, [$arg,...])

  This function will calculate and return the binary digest of the bytes of the given file. The function will croak if it fails to open or read the file.

  The $algorithm is a string like “MD2”, “MD5”, “SHA-1”, “SHA-512”. Additional arguments are passed to the constructor for the implementation of the given algorithm.

- digest_file_hex($file, $algorithm, [$arg,...])

  Same as digest_file(), but return the digest in hex form.

- digest_file_base64($file, $algorithm, [$arg,...])

  Same as digest_file(), but return the digest as a base64 encoded string.

SEE ALSO

Digest

5.2.30 DirHandle

(obsolete) supply object methods for directory handles

SYNOPSIS

```
# recommended approach since Perl 5.6: do not use DirHandle
if (opendir my $d, '.') {
    while (readdir $d) { something($_); }
    rewind $d;
    while (readdir $d) { something_else($_); }
}

# how you would use this module if you were going to
use DirHandle;
if (my $d = DirHandle->new(".")) {
    while (defined($_ = $d->read)) { something($_); }
    $d->rewind;
    while (defined($_ = $d->read)) { something_else($_); }
}
```

DESCRIPTION

There is no reason to use this module nowadays.

The `DirHandle` method provide an alternative interface to the opendir(), closedir(), readdir(), and rewinddir() functions.

Up to Perl 5.5, opendir() could not autovivify a directory handle from `undef`, so using a lexical handle required using a function from *Symbol* to create an anonymous glob, which took a separate step. `DirHandle` encapsulates this, which allowed cleaner code than opendir(). Since Perl 5.6, opendir() alone has been all you need for lexical handles.

5.2.31 Dumpvalue

provides screen dump of Perl data.

SYNOPSIS

```
use Dumpvalue;
my $dumper = Dumpvalue->new;
$dumper->set(globPrint => 1);
$dumper->dumpValue(\*::);
$dumper->dumpvars('main');
my $dump = $dumper->stringify($some_value);
```

DESCRIPTION

Creation

A new dumper is created by a call

```
$d = Dumpvalue->new(option1 => value1, option2 => value2)
```

Recognized options:

- `arrayDepth`, `hashDepth`

  Print only first N elements of arrays and hashes. If false, prints all the elements.

- `compactDump`, `veryCompact`

  Change style of array and hash dump. If true, short array may be printed on one line.

- `globPrint`

  Whether to print contents of globs.

- `dumpDBFiles`

  Dump arrays holding contents of debugged files.

- `dumpPackages`

  Dump symbol tables of packages.

- `dumpReused`

  Dump contents of “reused” addresses.

- `tick`, `quoteHighBit`, `printUndef`

  Change style of string dump. Default value of `tick` is `auto`, one can enable either double-quotish dump, or single-quotish by setting it to `"` or `'`. By default, characters with high bit set are printed *as is*. If `quoteHighBit` is set, they will be quoted.

- `usageOnly`

  rudimentary per-package memory usage dump. If set, `dumpvars` calculates total size of strings in variables in the package.

- unctrl

  Changes the style of printout of strings. Possible values are `unctrl` and `quote`.

- subdump

  Whether to try to find the subroutine name given the reference.

- bareStringify

  Whether to write the non-overloaded form of the stringify-overloaded objects.

- quoteHighBit

  Whether to print chars with high bit set in binary or “as is”.

- stopDbSignal

  Whether to abort printing if debugger signal flag is raised.

Later in the life of the object the methods may be queries with get() method and set() method (which accept multiple arguments).

Methods

- dumpValue

```
$dumper->dumpValue($value);
$dumper->dumpValue([$value1, $value2]);
```

  Prints a dump to the currently selected filehandle.

- dumpValues

```
$dumper->dumpValues($value1, $value2);
```

  Same as `$dumper->dumpValue([$value1, $value2]);`.

- stringify

```
my $dump = $dumper->stringify($value [,$noticks] );
```

  Returns the dump of a single scalar without printing. If the second argument is true, the return value does not contain enclosing ticks. Does not handle data structures.

- dumpvars

```
$dumper->dumpvars('my_package');
$dumper->dumpvars('my_package', 'foo', '~bar$', '!......');
```

  The optional arguments are considered as literal strings unless they start with `~` or `!`, in which case they are interpreted as regular expressions (possibly negated).

  The second example prints entries with names `foo`, and also entries with names which ends on `bar`, or are shorter than 5 chars.

- set_quote

```
$d->set_quote('"');
```

  Sets `tick` and `unctrl` options to suitable values for printout with the given quote char. Possible values are `auto`, `'` and `"`.

- set_unctrl

```
$d->set_unctrl('unctrl');
```

  Sets `unctrl` option with checking for an invalid argument. Possible values are `unctrl` and `quote`.

- compactDump

```
$d->compactDump(1);
```

  Sets `compactDump` option. If the value is 1, sets to a reasonable big number.

- veryCompact

```
$d->veryCompact(1);
```

  Sets `compactDump` and `veryCompact` options simultaneously.

- set

```
$d->set(option1 => value1, option2 => value2);
```

- get

```
@values = $d->get('option1', 'option2');
```

5.2.32 DynaLoader

Dynamically load C libraries into Perl code

> **Note**
>
> Under pperl the `dl_*` functions work as described here, on any shared library: `dl_load_file`, `dl_find_symbol`, `dl_findfile` and the rest. What pperl never does is load a *module's* compiled part from a shared object: see `bootstrap()` below.

SYNOPSIS

```
package YourPackage;
require DynaLoader;
@ISA = qw(... DynaLoader ...);
__PACKAGE__->bootstrap;

# optional method for 'global' loading
sub dl_load_flags { 0x01 }
```

DESCRIPTION

This document defines a standard generic interface to the dynamic linking mechanisms available on many platforms. Its primary purpose is to implement automatic dynamic loading of Perl modules.

This document serves as both a specification for anyone wishing to implement the DynaLoader for a new platform and as a guide for anyone wishing to use the DynaLoader directly in an application.

The DynaLoader is designed to be a very simple high-level interface that is sufficiently general to cover the requirements of SunOS, HP-UX, Linux, VMS and other platforms.

It is also hoped that the interface will cover the needs of OS/2, NT etc and also allow pseudo-dynamic linking (using `ld -A` at runtime).

It must be stressed that the DynaLoader, by itself, is practically useless for accessing non-Perl libraries because it provides almost no Perl-to-C 'glue'. There is, for example, no mechanism for calling a C library function or supplying arguments. A C::DynaLib module is available from CPAN sites which performs that function for some common system types. And since the year 2000, there's also Inline::C, a module that allows you to write Perl subroutines in C. Also available from your local CPAN site.

DynaLoader Interface Summary

```
@dl_library_path
@dl_resolve_using
@dl_require_symbols
$dl_debug
$dl_dlext
@dl_librefs
@dl_modules
@dl_shared_objects
                                                Implemented in:
bootstrap($modulename)                               Perl
@filepaths = dl_findfile(@names)                     Perl
$flags = $modulename->dl_load_flags                  Perl
$symref  = dl_find_symbol_anywhere($symbol)          Perl

$libref  = dl_load_file($filename, $flags)           C
$status  = dl_unload_file($libref)                   C
$symref  = dl_find_symbol($libref, $symbol)          C
@symbols = dl_undef_symbols()                        C
dl_install_xsub($name, $symref [, $filename])        C
$message = dl_error                                  C
```

- @dl_library_path

  The standard/default list of directories in which dl_findfile() will search for libraries etc. Directories are searched in order: $dl_library_path[0], [1], ... etc

  @dl_library_path is initialised to hold the list of 'normal' directories (`/usr/lib`, etc) determined by **Configure** (`$Config{'libpth'}`). This should ensure portability across a wide range of platforms.

  @dl_library_path should also be initialised with any other directories that can

be determined from the environment at runtime (such as LD_LIBRARY_PATH for SunOS).

After initialisation @dl_library_path can be manipulated by an application using push and unshift before calling dl_findfile(). Unshift can be used to add directories to the front of the search order either to save search time or to override libraries with the same name in the 'normal' directories.

The load function that dl_load_file() calls may require an absolute pathname. The dl_findfile() function and @dl_library_path can be used to search for and return the absolute pathname for the library/object that you wish to load.

- @dl_resolve_using

  A list of additional libraries or other shared objects which can be used to resolve any undefined symbols that might be generated by a later call to load_file().

  This is only required on some platforms which do not handle dependent libraries automatically. For example the Socket Perl extension library (`auto/Socket/Socket.so`) contains references to many socket functions which need to be resolved when it's loaded. Most platforms will automatically know where to find the 'dependent' library (e.g., `/usr/lib/libsocket.so`). A few platforms need to be told the location of the dependent library explicitly. Use @dl_resolve_using for this.

  Example usage:

```
@dl_resolve_using = dl_findfile('-lsocket');
```

- @dl_require_symbols

  A list of one or more symbol names that are in the library/object file to be dynamically loaded. This is only required on some platforms.

- @dl_librefs

  An array of the handles returned by successful calls to dl_load_file(), made by bootstrap, in the order in which they were loaded. Can be used with dl_find_symbol() to look for a symbol in any of the loaded files.

- @dl_modules

  An array of module (package) names that have been bootstrap'ed.

- @dl_shared_objects

  An array of file names for the shared objects that were loaded.

- dl_error()

  Syntax:

```
$message = dl_error();
```

  Error message text from the last failed DynaLoader function. Note that, similar to errno in unix, a successful function call does not reset this message.

  Implementations should detect the error as soon as it occurs in any of the other functions and save the corresponding message for later retrieval. This will avoid problems on some platforms (such as SunOS) where the error message is very temporary (e.g., dlerror()).

- $dl_debug

  Internal debugging messages are enabled when $dl_debug is set true. Currently setting $dl_debug only affects the Perl side of the DynaLoader. These messages should help an application developer to resolve any DynaLoader usage problems.

  $dl_debug is set to `$ENV{'PERL_DL_DEBUG'}` if defined.

  For the DynaLoader developer/porter there is a similar debugging variable added to the C code (see dlutils.c) and enabled if Perl was built with the **-DDEBUGGING** flag. This can also be set via the PERL_DL_DEBUG environment variable. Set to 1 for minimal information or higher for more.

- $dl_dlext

  When specified (localised) in a module's `.pm` file, indicates the extension which the module's loadable object will have. For example:

```
local $DynaLoader::dl_dlext = 'unusual_ext';
```

  would indicate that the module's loadable object has an extension of `unusual_ext` instead of the more usual `$Config{dlext}`. NOTE: This also requires that the module's `Makefile.PL` specify (in `WriteMakefile()`):

```
DLEXT => 'unusual_ext',
```

- dl_findfile()

  Syntax:

```
@filepaths = dl_findfile(@names)
```

  Determine the full paths (including file suffix) of one or more loadable files given their generic names and optionally one or more directories. Searches directories in @dl_library_path by default and returns an empty list if no files were found.

  Names can be specified in a variety of platform independent forms. Any names in the form **-lname** are converted into `libname.*`, where `.*` is an appropriate suffix for the platform.

  If a name does not already have a suitable prefix and/or suffix then the corresponding file will be searched for by trying combinations of prefix and suffix appropriate to the platform: "$name.o", "lib$name.*" and "$name".

  If any directories are included in @names they are searched before @dl_library_path. Directories may be specified as **-Ldir**. Any other names are treated as filenames to be searched for.

  Using arguments of the form `-Ldir` and `-lname` is recommended.

  Example:

```
@dl_resolve_using = dl_findfile(qw(-L/usr/5lib -lposix));
```

- dl_expandspec()

  Syntax:

```
$filepath = dl_expandspec($spec)
```

Some unusual systems, such as VMS, require special filename handling in order to deal with symbolic names for files (i.e., VMS's Logical Names).

To support these systems a dl_expandspec() function can be implemented either in the `dl_*.xs` file or code can be added to the dl_expandspec() function in `DynaLoader.pm`. See `DynaLoader_pm.PL` for more information.

- dl_load_file()

  Syntax:

```
$libref = dl_load_file($filename, $flags)
```

  Dynamically load $filename, which must be the path to a shared object or library. An opaque 'library reference' is returned as a handle for the loaded object. Returns undef on error.

  The $flags argument to alters dl_load_file behaviour.
  Assigned bits:

```
0x01  make symbols available for linking later dl_load_file's.
      (only known to work on Solaris 2 using dlopen(RTLD_
↪GLOBAL))
      (ignored under VMS; this is a normal part of image␣
↪linking)
```

  (On systems that provide a handle for the loaded object such as SunOS and HPUX, $libref will be that handle. On other systems $libref will typically be $filename or a pointer to a buffer containing $filename. The application should not examine or alter $libref in any way.)

  This is the function that does the real work. It should use the current values of @dl_require_symbols and @dl_resolve_using if required.

```
SunOS: dlopen($filename)
HP-UX: shl_load($filename)
Linux: dld_create_reference(@dl_require_symbols); dld_link(
↪$filename)
VMS:   lib$find_image_symbol($filename,$dl_require_symbols[0])
```

  (The dlopen() function is also used by Solaris and some versions of Linux, and is a common choice when providing a "wrapper" on other mechanisms as is done in the OS/2 port.)

- dl_unload_file()

  Syntax:

```
$status = dl_unload_file($libref)
```

  Dynamically unload $libref, which must be an opaque 'library reference' as returned from dl_load_file. Returns one on success and zero on failure. This function is optional and may not necessarily be provided on all platforms.

If it is defined and perl is compiled with the C macro DL_UNLOAD_ALL_AT_EXIT defined, then it is called automatically when the interpreter exits for every shared object or library loaded by DynaLoader::bootstrap. All such library references are stored in @dl_librefs by DynaLoader::Bootstrap as it loads the libraries. The files are unloaded in last-in, first-out order.

This unloading is usually necessary when embedding a shared-object perl (e.g. one configured with -Duseshrplib) within a larger application, and the perl interpreter is created and destroyed several times within the lifetime of the application. In this case it is possible that the system dynamic linker will unload and then subsequently reload the shared libperl without relocating any references to it from any files DynaLoaded by the previous incarnation of the interpreter. As a result, any shared objects opened by DynaLoader may point to a now invalid 'ghost' of the libperl shared object, causing apparently random memory corruption and crashes. This behaviour is most commonly seen when using Apache and mod_perl built with the APXS mechanism.

```
SunOS: dlclose($libref)
HP-UX: ???
Linux: ???
VMS:   ???
```

(The dlclose() function is also used by Solaris and some versions of Linux, and is a common choice when providing a "wrapper" on other mechanisms as is done in the OS/2 port.)

- dl_load_flags()

  Syntax:

```
$flags = dl_load_flags $modulename;
```

  Designed to be a method call, and to be overridden by a derived class (i.e. a class which has DynaLoader in its @ISA). The definition in DynaLoader itself returns 0, which produces standard behavior from dl_load_file().

- dl_find_symbol()

  Syntax:

```
$symref = dl_find_symbol($libref, $symbol)
```

  Return the address of the symbol $symbol or undef if not found. If the target system has separate functions to search for symbols of different types then dl_find_symbol() should search for function symbols first and then other types.

  The exact manner in which the address is returned in $symref is not currently defined. The only initial requirement is that $symref can be passed to, and understood by, dl_install_xsub().

```
SunOS: dlsym($libref, $symbol)
HP-UX: shl_findsym($libref, $symbol)
Linux: dld_get_func($symbol) and/or dld_get_symbol($symbol)
VMS:   lib$find_image_symbol($libref,$symbol)
```

- dl_find_symbol_anywhere()

  Syntax:

  ```
  $symref = dl_find_symbol_anywhere($symbol)
  ```

  Applies dl_find_symbol() to the members of @dl_librefs and returns the first match found.

- dl_undef_symbols()

  Example

  ```
  @symbols = dl_undef_symbols()
  ```

  Return a list of symbol names which remain undefined after load_file(). Returns `()` if not known. Don't worry if your platform does not provide a mechanism for this. Most do not need it and hence do not provide it, they just return an empty list.

- dl_install_xsub()

  Syntax:

  ```
  dl_install_xsub($perl_name, $symref [, $filename])
  ```

  Create a new Perl external subroutine named $perl_name using $symref as a pointer to the function which implements the routine. This is simply a direct call to newXS()/newXS_flags(). Returns a reference to the installed function.

  The $filename parameter is used by Perl to identify the source file for the function if required by die(), caller() or the debugger. If $filename is not defined then "DynaLoader" will be used.

- bootstrap()

  Syntax:

  bootstrap($module [...])

  This is the normal entry point for automatic dynamic loading in Perl.

  Under pperl, `bootstrap()` never loads a module's shared object. It starts the module's compiled part when that part is built into pperl, and otherwise dies with `Can't locate loadable object for module $module in @INC`, the message modules with a pure-Perl fallback test for. The steps below are what perl does.

  It performs the following actions:

  - locates an auto/$module directory by searching @INC
  - uses dl_findfile() to determine the filename to load
  - sets @dl_require_symbols to `("boot_$module")`
  - executes an `auto/$module/$module.bs` file if it exists (typically used to add to @dl_resolve_using any files which are required to load the module on the current platform)
  - calls dl_load_flags() to determine how to load the file.

- calls dl_load_file() to load the file
- calls dl_undef_symbols() and warns if any symbols are undefined
- calls dl_find_symbol() for "boot_$module"
- calls dl_install_xsub() to install it as "${module}::bootstrap"
- calls &{"${module}::bootstrap"} to bootstrap the module (actually it uses the function reference returned by dl_install_xsub for speed)

All arguments to bootstrap() are passed to the module's bootstrap function. The default code generated by `xsubpp` expects $module [, $version] If the optional $version argument is not given, it defaults to `$XS_VERSION // $VERSION` in the module's symbol table.

AUTHOR

Tim Bunce, 11 August 1994.

This interface is based on the work and comments of (in no particular order): Larry Wall, Robert Sanders, Dean Roehrich, Jeff Okamoto, Anno Siegel, Thomas Neumann, Paul Marquess, Charles Bailey, myself and others.

Larry Wall designed the elegant inherited bootstrap mechanism and implemented the first Perl 5 dynamic loader using it.

Solaris global loading added by Nick Ing-Simmons with design/coding assistance from Tim Bunce, January 1996.

5.2.33 EV

A fast, full-featured event loop: call your code when a file handle is readable or writable, a timer expires, a signal arrives, a child process changes state or a file changes.

You create watchers - objects recording your interest in an event - and then run the loop, which waits for events and calls each watcher's callback. `EV::io`, `EV::timer`, `EV::periodic`, `EV::signal`, `EV::child`, `EV::stat`, `EV::idle`, `EV::prepare`, `EV::check`, `EV::fork`, `EV::embed` and `EV::async` create watchers on the default loop; `EV::run` runs it. A program needing more than one loop makes more with `EV::Loop->new`, which has the same functions as methods.

Synopsis

```
use EV;

my $once  = EV::timer 2, 0, sub { warn "2 seconds passed\n" };
my $every = EV::timer 0, 3, sub { warn "now, then every 3 seconds\n"␣
 ↪};
my $input = EV::io *STDIN, EV::READ, sub {
    my ($w, $revents) = @_;            # every callback gets these␣
 ↪two
    warn "you typed: ", scalar <STDIN>;
};
```

(continues on next page)

(continued from previous page)

```
my $quit  = EV::signal 'QUIT', sub { EV::break };

EV::run;    # until EV::break, or no active watcher is left
```

Watchers

A watcher stays alive as long as the object its constructor returned does: keep it in a variable, and `undef` it to stop and free the watcher. Every callback is called with the watcher and a bitmask of the events received (`EV::READ`, `EV::TIMER` and the like), so one sub can serve several watchers.

Every constructor starts the watcher; its `_ns` twin (`EV::io_ns`, `EV::timer_ns` ...) creates it stopped, for a later `start`. The methods all watchers share - `start`, `stop`, `is_active`, `data`, `cb`, `priority`, `keepalive` and more - are `EV::Watcher`'s; each watcher class (`EV::IO`, `EV::Timer`, `EV::Periodic`, `EV::Signal`, `EV::Child`, `EV::Stat`, `EV::Embed`, `EV::Async`) adds its own. Changing a running watcher (`set`, `priority`, `fh` ...) stops and restarts it, losing events pending for it. `EV::idle`, `EV::prepare`, `EV::check` and `EV::fork` watchers have only the shared methods.

An exception thrown by a callback does not end the loop: EV calls `$EV::DIED` with the error in `$@`, which by default warns `EV: error in callback (ignoring): ...` and goes on.

Priorities

A watcher's priority, from `EV::MINPRI` (-2) to `EV::MAXPRI` (2), decides which of several pending watchers runs first; new watchers have priority 0. An idle watcher runs only when nothing of its priority or higher is pending.

Constants

Called as functions (`EV::READ`), as EV exports nothing:

- Events: `EV::READ`, `EV::WRITE`, `EV::TIMER`, `EV::PERIODIC`, `EV::SIGNAL`, `EV::CHILD`, `EV::STAT`, `EV::IDLE`, `EV::PREPARE`, `EV::CHECK`, `EV::EMBED`, `EV::FORK`, `EV::CLEANUP`, `EV::ASYNC`, `EV::CUSTOM`, `EV::ERROR`, `EV::IO`, `EV::NONE`, `EV::UNDEF`.
- `EV::run` flags `EV::RUN_NOWAIT`, `EV::RUN_ONCE`; `EV::break` modes `EV::BREAK_ONE`, `EV::BREAK_ALL`, `EV::BREAK_CANCEL`.
- Backends `EV::BACKEND_SELECT`, `EV::BACKEND_POLL`, `EV::BACKEND_EPOLL`, `EV::BACKEND_KQUEUE`, `EV::BACKEND_DEVPOLL`, `EV::BACKEND_PORT`, `EV::BACKEND_ALL`, `EV::BACKEND_MASK`, and loop flags `EV::FLAG_AUTO`, `EV::FLAG_FORKCHECK`, `EV::FLAG_SIGNALFD`, `EV::FLAG_NOSIGMASK`, `EV::FLAG_NOENV`, `EV::FLAG_NOINOTIFY`.
- `EV::MINPRI`, `EV::MAXPRI`; `EV::VERSION_MAJOR`, `EV::VERSION_MINOR` (of libev).
- The names of EV 3 kept for old programs: `EV::TIMEOUT`, `EV::LOOP_NONBLOCK`, `EV::LOOP_ONESHOT`, `EV::UNLOOP_CANCEL`, `EV::UNLOOP_ONE`, `EV::UNLOOP_ALL`, `EV::FLAG_NOSIGFD` (0).

`EV::CHECK` shares its name with Perl's `CHECK` blocks: write it after `use EV`, where it is compiled as the constant.

Backends

The default loop waits with epoll. select, poll, Linux AIO and io_uring are there too, to choose with `EV::Loop->new` flags or the `LIBEV_FLAGS` environment variable (the backend bits added together). `EV::supported_backends` lists them. File status watchers use inotify where it works.

Signals and fork

Perl's own `%SIG` handlers run only when Perl runs, which in an event loop may be late: use `EV::signal` watchers instead, or keep an `EV::check` watcher (`my $c = EV::check sub {}`) so that Perl gets control on every loop iteration.

After `fork`, the child's default loop is reset for it automatically the next time it is used. Loops made with `EV::Loop->new` need `$loop->loop_fork` in the child, or the flag `EV::FLAG_FORKCHECK`.

`$EV::API` holds the C function table EV gives modules such as `Coro::EV` that drive the loop from compiled code.

Differences from upstream

- `EV::signal` (and `EV::Loop->signal`, `$w->signal`) take the second names of signals, `IOT`, `CLD` and `POLL`, as the signals they name; upstream takes them for nonexistent signal numbers 65 to 67 and corrupts its memory. A number that is no signal is refused with `illegal signal number or name`. Covered by `t/81-xs-native/EV/310-signal-alias.t`.
- `EV::Periodic->reschedule_cb` keeps its callback and the watcher alive; upstream frees them early. See `EV::Periodic`.
- A signal watched by EV and by Event reaches both. Under perl5 their handlers compete and the module that installed its handler last takes the signal; the other's watchers never fire. Between EV's own loops a signal still belongs to one, as upstream.

Everything else behaves as with EV 4.37 and the libev 4.33 it bundles. Covered by EV's own test suite, `t/81-xs-native/EV/100-upstream-00_load.t` to `200-upstream-11_signal.t`.

Modules

- `EV::Async` - An async watcher, as `EV::async` makes: anything may trigger it with `send`, and its callback then runs in its loop - the way compiled code or another loop wakes a loop that is waiting.
- `EV::Child` - A child process watcher, as `EV::child` makes: its callback runs when a child ends (or, traced, stops or continues).
- `EV::Embed` - An embed watcher, as `EV::embed` makes: it lets running one loop also serve another loop's I/O.

- EV::IO - An I/O watcher, as EV::io makes: its callback runs when a file handle is readable or writable.
- EV::Loop - An event loop of your own, beside the default one: EV::Loop->new makes one, and EV::default_loop returns the default loop as an EV::Loop too.
- EV::Periodic - A wall-clock timer, as EV::periodic makes: its callback runs at a given time, at every multiple of an interval, or whenever a reschedule sub says - see EV::periodic for the three modes.
- EV::Signal - A signal watcher, as EV::signal makes: its callback runs when the process receives a signal.
- EV::Stat - A file status watcher, as EV::stat makes: its callback runs when a path's status changes - created, deleted, written, its permissions or times changed.
- EV::Timer - A relative timer, as EV::timer makes: its callback runs after a number of seconds, and optionally again at a repeat interval.
- EV::Watcher - The methods every EV watcher has: start and stop it, ask whether it is active or pending, change its callback, data and priority, and decide whether it keeps the loop running.

Functions

Running the loop

default_loop

The default loop, as an EV::Loop object: the one the EV:: functions and watchers use, and the only one that can watch signals and child processes. EV creates it when loaded, so the optional flags (EV::FLAG_*, EV::BACKEND_* bits) matter only to a call after EV::default_destroy, which creates it again. Undef when the loop cannot be created.

default_destroy

Destroy the default loop, with every watcher on it. Nothing may use it until EV::default_loop creates a new one; watcher objects made on the old one must not be used again. Rarely wanted: a program ending need not call it.

iteration

How many times the loop has waited for events - a generation counter. EV::loop_count is its old name.

Also available as EV::loop_count.

depth

How many EV::run calls are in progress: 0 outside the loop, 1 in a callback, more when a callback runs the loop itself. EV::loop_depth is its old name.

Also available as EV::loop_depth.

loop

Run the event loop: wait for events and call the watchers' callbacks.

Also available as `EV::run`.

break

Make `EV::run` return once the current callbacks are done: the innermost call with `EV::break` or `EV::break EV::BREAK_ONE`, all of them with `EV::BREAK_ALL`; `EV::BREAK_CANCEL` withdraws a break not yet acted on. `EV::unloop` is the old name.

Also available as `EV::unloop`.

Watchers

io

Watch a file handle: call the callback whenever it is readable or writable without blocking.

Also available as `EV::io_ns`.

timer

Call the callback after a number of seconds, and optionally again and again after that.

Also available as `EV::timer_ns`.

periodic

Call the callback at wall-clock times: once at a given time, at every multiple of an interval, or whenever a sub of yours says.

Also available as `EV::periodic_ns`.

signal

Call the callback when a signal arrives: `my $w = EV::signal 'HUP', sub { ... }`. The signal is a name or number, as for `kill` and `%SIG`. EV takes the signal from Perl while the watcher is active, and gives it back when stopped; any number of watchers may watch one signal, but only one loop - starting one in a second loop croaks `unable to start signal watcher, signal N already registered in another loop`. A name or number that is no signal croaks `illegal signal number or name`. `EV::signal_ns` creates it stopped. The second names `IOT`, `CLD` and `POLL` work, as `ABRT`, `CHLD` and `IO`, which upstream does not do (covered by `t/81-xs-native/EV/310-signal-alias.t`).

Also available as `EV::signal_ns`.

idle

Call the callback whenever the loop has nothing more urgent to do: `my $w = EV::idle sub { ... }`. It runs when no watcher of its priority or higher is pending, and while it is active the loop does not block - it is called again and again until stopped. At priority `EV::MINPRI` it runs only when nothing else is pending. `EV::idle_ns` creates it stopped.

Also available as `EV::idle_ns`.

prepare

Call the callback just before the loop blocks to wait: `my $w = EV::prepare sub { ... }`. Watchers can still be created and changed in it - a prepare watcher can set up the I/O and timer watchers another event library needs, and an `EV::check` watcher clean them up. `EV::prepare_ns` creates it stopped.

Also available as `EV::prepare_ns`.

check

Call the callback just after the loop wakes up, before any other callback: `my $w = EV::check sub { ... }`. The partner of `EV::prepare`; an empty one also lets Perl's own `%SIG` handlers run on every iteration. `EV::check_ns` creates it stopped. Write the event constant `EV::CHECK` after `use EV`.

Also available as `EV::check_ns`.

fork

Call the callback in a child process after `fork`, before its event loop next blocks: `my $w = EV::fork sub { ... }`. `EV::fork_ns` creates it stopped.

Also available as `EV::fork_ns`.

child

Call the callback when a child process ends: `my $w = EV::child $pid, 0, sub { my ($w) = @_; my $status = $w->rstatus; ... }`. A `$pid` of 0 watches every child; a true `$trace` also reports a child stopping and continuing. EV reaps the child, so its exit status is `$w->rstatus` (as `$?` would be) and its pid `$w->rpid`. The watcher may be made after the child has already exited, as long as the loop has not run since. Only the default loop watches children. `EV::child_ns` creates it stopped.

Also available as `EV::child_ns`.

stat

Call the callback when a file's status changes - its size, times, permissions, or whether it exists: `my $w = EV::stat '/etc/passwd', 0, sub { ... }`. The path need not exist. Changes come from inotify where it works, else from polling every `$interval` seconds (0: about five seconds, recommended). The watcher's `attr` and `prev` give the status after and before the change. Not meant for thousands of files. `EV::stat_ns` creates it stopped.

Also available as `EV::stat_ns`.

embed

Embed another loop in the default loop: running the default loop then also handles the other loop's I/O. `my $w = EV::embed $other_loop`. Without a callback the embedded loop is serviced automatically (the recommended way); with one, the callback is called when the other loop has I/O pending and must call `$w->sweep`. Only I/O watchers of the embedded loop are served reliably, and only a loop using one of `EV::embeddable_backends` can be embedded - another croaks `passed loop is not embeddable via EV::embed`. `EV::embed_ns` creates it stopped.

Also available as `EV::embed_ns`.

async

Create a watcher another thread of control wakes the loop with: `my $w = EV::async sub { ... }`, triggered by `$w->send`. Of little use from Perl itself; compiled code (and `Coro`) uses it to wake a waiting loop. `EV::async_ns` creates it stopped. See `EV::Async`.

Also available as `EV::async_ns`.

once

Wait once for a handle to become ready, a timeout, or the first of the two, without keeping a watcher object.

Time

sleep

Block the whole process for a number of seconds, which may be fractional: `EV::sleep 0.25`. No watcher runs meanwhile.

time

The current time, in fractional seconds since the epoch, asked of the system now. `EV::now` is cheaper where the loop's time will do.

now

The time the current loop iteration began, in fractional seconds since the epoch: the time relative timers count from, and cheaper than `EV::time`.

now_update

Set the loop's idea of the time (`EV::now`) to the time now. The loop does this every iteration; a callback that runs for a long time before starting timers should do it first, or the timers start late.

suspend

Pause the loop's clock, for a program that stops for a while (a game put in the background with ^Z): between `EV::suspend` and `EV::resume`, timers do not run down, and periodic watchers skip what they would have fired. After `EV::suspend` call nothing on the loop but `EV::resume`.

resume

Restart the loop's clock after `EV::suspend`; only after it.

Events

feed_signal

Act as if a signal had arrived, whichever loop watches it: `EV::feed_signal 'USR1'`. The signal is a name or number, as for `kill`. For handing EV signals caught some other way.

feed_fd_event

Act as if a file descriptor had become ready: `EV::feed_fd_event $fd, EV::READ` makes the I/O watchers on `$fd` that wait for those events pending.

feed_signal_event

Act as if a signal had arrived at the default loop: `EV::feed_signal_event 'HUP'` makes its watchers of that signal pending. A name or number, as for `kill`; one that is no signal croaks `illegal signal number or name`.

pending_count

How many watchers have received events whose callbacks have not run yet.

invoke_pending

Call the callbacks of all pending watchers now.

Backends and tuning

supported_backends

The backends this EV can use, as `EV::BACKEND_*` bits: select, poll, epoll, Linux AIO and io_uring.

recommended_backends

The backends recommended on this system, as `EV::BACKEND_*` bits.

embeddable_backends

The backends a loop can use and still be embedded in another with `EV::embed`, as `EV::BACKEND_*` bits.

backend

The backend the default loop waits with, one `EV::BACKEND_*` bit - `EV::BACKEND_EPOLL` unless chosen otherwise.

loop_verify

Check the loop's internal data for consistency, aborting the program if it is corrupt - for debugging. `EV::loop_verify` is its old name.

Also available as `EV::verify`.

set_io_collect_interval

Make the loop wait at least this many seconds between polls for I/O, collecting more events per wakeup - fewer, larger batches for a busy server, at the cost of latency. 0, the default, waits no longer than needed.

set_timeout_collect_interval

Let timers that expire within this many seconds of each other fire in one wakeup, trading timer precision for fewer wakeups. 0, the default, fires each on time.

EV::Async

An async watcher, as `EV::async` makes: anything may trigger it with `send`, and its callback then runs in its loop - the way compiled code or another loop wakes a loop that is waiting. Several sends before the callback runs give one callback. The methods all watchers share are `EV::Watcher`'s.

Synopsis

```
my $wake = EV::async sub { print "woken\n"; EV::break };
my $t    = EV::timer 1, 0, sub { $wake->send };
EV::run;
```

Functions

Waking

send

Trigger the watcher: its callback runs in the loop's next round.

async_pending

True when send was called and the callback has not run yet.

EV::Child

A child process watcher, as `EV::child` makes: its callback runs when a child ends (or, traced, stops or continues). These methods give the child's pid and status; the methods all watchers share are `EV::Watcher`'s. Only the default loop watches children.

EV reaps the children it reports: their status is `rstatus`, not `$?` from a `waitpid` of your own.

Synopsis

```
my $pid = fork // die "fork: $!";
exec 'sleep', 1 unless $pid;
my $w = EV::child $pid, 0, sub {
    my ($w) = @_;
    printf "%d exited with %d\n", $w->rpid, $w->rstatus >> 8;
};
EV::run;
```

Functions

Status

reinit

Re-install EV's own SIGCHLD handler: `EV::Child::reinit`, after code such as `local $SIG{CHLD}` left another one behind and child watchers stopped firing. Experimental upstream; its form may change.

set

Watch another child: `$w->set($pid, $trace)`, as `EV::child` takes them - `$pid` 0 for any child.

pid

The pid the watcher watches (0 for any child). The same method gives, under its other names, what the last status change reported: `$w->rpid`, the pid of the child that changed - useful when watching any child - and `$w->rstatus`, its wait status as `waitpid` sets `$?` (`>> 8` for the exit code).

Also available as `EV::Child::rpid`, `EV::Child::rstatus`.

EV::Embed

An embed watcher, as `EV::embed` makes: it lets running one loop also serve another loop's I/O. These methods name the embedded loop and serve it by hand; the methods all watchers share are `EV::Watcher`'s.

Synopsis

```
my $other = EV::Loop->new(EV::BACKEND_EPOLL);
my $embed = EV::embed $other;    # served automatically
EV::run;                         # runs both
```

Functions

Embedding

set

Embed another loop instead: `$w->set($loop)`.

other

The embedded loop, an `EV::Loop`.

sweep

Run the embedded loop once, without waiting, handling its pending events - what a watcher made with a callback must do in it.

EV::IO

An I/O watcher, as `EV::io` makes: its callback runs when a file handle is readable or writable. These methods change what it watches; the methods all watchers share are `EV::Watcher`'s.

Changing an active watcher stops and restarts it, losing its pending events.

Synopsis

```
my $w = EV::io $sock, EV::READ, \&on_read;
$w->events(EV::READ | EV::WRITE);    # also wait until writable
$w->set($other_sock, EV::READ);      # watch another handle
```

Functions

Configuration

set

Watch another handle, for other events: `$w->set($fh, EV::READ)`. The handle may be a file handle or a descriptor number; one without a descriptor croaks `illegal file descriptor or filehandle`.

fh

The handle the watcher watches, as it was given; with an argument, watch that handle instead and return the old one.

events

The events the watcher waits for, `EV::READ`, `EV::WRITE` or both; with an argument, wait for those instead and return the old mask.

EV::Loop

An event loop of your own, beside the default one: `EV::Loop->new` makes one, and `EV::default_loop` returns the default loop as an `EV::Loop` too.

An `EV::Loop` has, as methods, the `EV::` functions that work on a loop: `$loop->run`, `$loop->now`, `$loop->timer(...)`, `$loop->io(...)` and so on, each doing for this loop what the `EV::` function does for the default loop - see those for the details. A loop lives as long as the object, or a watcher on it, does.

A loop of your own may use another backend than the default loop (`EV::BACKEND_*` flags), or serve part of a program separately. Child process watchers work only on the default loop, and a signal can be watched by one loop at a time. After `fork`, the child must call `$loop->loop_fork` before using such a loop, unless it was made with `EV::FLAG_FORKCHECK`.

Synopsis

```
my $loop = EV::Loop->new;
my $t = $loop->timer(1, 0, sub { print "tick\n"; $loop->break });
$loop->run;
```

Functions

Loops

new

Make a new event loop: `EV::Loop->new`, or `EV::Loop->new($flags)` with `EV::BACKEND_*` bits to choose its backends and `EV::FLAG_*` bits (`EV::FLAG_FORKCHECK` to recover from `fork` by itself, `EV::FLAG_NOENV` to ignore `LIBEV_FLAGS`). Undef when no requested backend works.

loop_fork

Prepare the loop for use in a child process after `fork`: call it in the child before running the loop again. Loops made with `EV::FLAG_FORKCHECK`, and the default loop, do it by themselves.

Running the loop

iteration

How many times this loop has waited for events, as `EV::iteration`; `loop_count` is its old name.

Also available as `EV::Loop::loop_count`.

depth

How many `run` calls of this loop are in progress, as `EV::depth`; `loop_depth` is its old name.

Also available as `EV::Loop::loop_depth`.

loop

Run this loop: `$loop->run`, `$loop->run(EV::RUN_ONCE)`, `$loop->run(EV::RUN_NOWAIT)`, as `EV::run` runs the default loop. True when it returned with work left. `loop` is its old name.

Also available as `EV::Loop::run`.

break

Make this loop's `run` return, as `EV::break`: `$loop->break`, `$loop->break(EV::BREAK_ALL)`. `unloop` is its old name.

Also available as `EV::Loop::unloop`.

Watchers

io

An I/O watcher on this loop: `$loop->io($fh, EV::READ, sub { ... })`, as `EV::io`; `io_ns` makes it stopped.

Also available as `EV::Loop::io_ns`.

timer

A timer on this loop: `$loop->timer($after, $repeat, sub { ... })`, as `EV::timer`; `timer_ns` makes it stopped.

Also available as `EV::Loop::timer_ns`.

periodic

A wall-clock timer on this loop: `$loop->periodic($at, $interval, $reschedule_cb, sub { ... })`, as `EV::periodic`; `periodic_ns` makes it stopped.

Also available as `EV::Loop::periodic_ns`.

signal

A signal watcher on this loop: `$loop->signal('HUP', sub { ... })`, as `EV::signal`; `signal_ns` makes it stopped. A signal can be watched by one loop at a time.

Also available as `EV::Loop::signal_ns`.

idle

An idle watcher on this loop: `$loop->idle(sub { ... })`, as `EV::idle`; `idle_ns` makes it stopped.

Also available as `EV::Loop::idle_ns`.

prepare

A prepare watcher on this loop, as `EV::prepare`; `prepare_ns` makes it stopped.

Also available as `EV::Loop::prepare_ns`.

check

A check watcher on this loop, as `EV::check`; `check_ns` makes it stopped.

Also available as `EV::Loop::check_ns`.

fork

A fork watcher on this loop, as `EV::fork`; `fork_ns` makes it stopped.

Also available as `EV::Loop::fork_ns`.

child

A child process watcher: `$loop->child($pid, $trace, sub { ... })`, as `EV::child`; `child_ns` makes it stopped. Only the default loop can watch children: call it on `EV::default_loop`.

Also available as `EV::Loop::child_ns`.

stat

A file status watcher on this loop: `$loop->stat($path, $interval, sub { ... })`, as `EV::stat`; `stat_ns` makes it stopped.

Also available as `EV::Loop::stat_ns`.

embed

Embed another loop in this one: `$loop->embed($other)`, as `EV::embed`; `embed_ns` makes the watcher stopped.

Also available as `EV::Loop::embed_ns`.

async

An async watcher on this loop, as `EV::async`; `async_ns` makes it stopped.

Also available as `EV::Loop::async_ns`.

once

Wait once on this loop for a handle, a timeout, or the first of the two: `$loop->once($fh, EV::READ, 10, sub { my ($revents) = @_; ... })`, as `EV::once`.

Time

now

The time this loop's current iteration began, as `EV::now`.

now_update

Set this loop's time to the time now, as `EV::now_update`.

suspend

Pause this loop's clock, as `EV::suspend`; only `resume` may follow.

resume

Restart this loop's clock after `suspend`, as `EV::resume`.

Events

feed_fd_event

Act as if a file descriptor had become ready, for this loop's watchers, as `EV::feed_fd_event`.

pending_count

How many of this loop's watchers are pending, as `EV::pending_count`.

invoke_pending

Call the callbacks of this loop's pending watchers now, as `EV::invoke_pending`.

Tuning

set_io_collect_interval

Make this loop wait at least this long between polls for I/O, as `EV::set_io_collect_interval`.

set_timeout_collect_interval

Let this loop's timers that expire close together fire in one wakeup, as `EV::set_timeout_collect_interval`.

backend

The backend this loop waits with, one `EV::BACKEND_*` bit.

loop_verify

Check this loop's internal data, aborting if it is corrupt, as `EV::verify`; `loop_verify` is its old name.

Also available as `EV::Loop::verify`.

EV::Periodic

A wall-clock timer, as `EV::periodic` makes: its callback runs at a given time, at every multiple of an interval, or whenever a reschedule sub says - see `EV::periodic` for the three modes. These methods read and change its schedule; the methods all watchers share are `EV::Watcher`'s.

Changing the offset or interval takes effect at the next firing; `set`, `again` and a new reschedule sub take effect at once.

Synopsis

```
my $w = EV::periodic 0, 3600, 0, sub { print "on the hour\n" };
printf "next at %s\n", scalar localtime $w->at;
$w->interval(1800);    # on the half hour, from the next firing
```

Differences from upstream

- `reschedule_cb` returns the sub without letting it go: upstream frees the watcher's sub when the returned copy goes away, so every later firing fails with `EV: error in callback (ignoring): Not a CODE reference`, and setting one frees the old sub twice (`Attempt to free unreferenced scalar`).

- A reschedule sub set with `reschedule_cb` on a watcher made without one is used; upstream never calls it, and clearing one makes every later firing fail.
- The watcher and the time a reschedule sub is called with are freed after the call; upstream leaks both, and the watcher with them.

Covered by `t/81-xs-native/EV/300-periodic-reschedule-cb.t`.

Functions

Schedule

again

Stop the watcher and start it again, computing its next firing time anew - after the clock or the reschedule sub's idea of time changed.

set

Set the whole schedule anew: `$w->set($at, $interval, $reschedule_cb)`, the interval and sub optional, as `EV::periodic` takes them. A negative interval croaks `interval value must be >= 0`.

at

When the watcher fires next, in seconds since the epoch.

offset

The `$at` the schedule counts from - the offset of the interval's multiples; with an argument, set a new one (from the next firing) and return the old.

interval

The interval, 0 for none; with an argument, set a new one (from the next firing) and return the old. A negative one croaks `interval value must be >= 0`.

reschedule_cb

The reschedule sub, undef for none; with an argument, use that sub (or none, given a false value) from now on and return the old one. The sub is called with the watcher and the current time and returns the next time to fire; it must not stop or change any periodic watcher or call into the loop. Unlike upstream, the sub returned stays the watcher's, and one set later is used (see *Differences from upstream* above; covered by `t/81-xs-native/EV/300-periodic-reschedule-cb.t`).

EV::Signal

A signal watcher, as `EV::signal` makes: its callback runs when the process receives a signal. These methods change which signal; the methods all watchers share are `EV::Watcher`'s.

A signal can be watched by any number of watchers, but in one loop only: `$w->start` in a second loop croaks `unable to start signal watcher, signal N already registered in another loop`. While a watcher of a signal is active, EV holds the signal; Perl's `%SIG` handler for it is not called.

Synopsis

```
my $w = EV::signal 'TERM', sub { EV::break };
print $w->signal;    # 15
$w->set('INT');
```

Functions

Configuration

set

Watch another signal: `$w->set('USR1')`, a name or number as for `kill`. One that is no signal croaks `illegal signal number or name`.

signal

The signal watched, always as a number; with an argument (name or number), watch that one instead and return the old number. The second names `IOT`, `CLD` and `POLL` are the signals `ABRT`, `CHLD` and `IO` (upstream mistakes them for nonexistent signals; covered by `t/81-xs-native/EV/310-signal-alias.t`).

EV::Stat

A file status watcher, as `EV::stat` makes: its callback runs when a path's status changes - created, deleted, written, its permissions or times changed. These methods read the status before and after and change what is watched; the methods all watchers share are `EV::Watcher`'s.

Synopsis

```
my $w = EV::stat '/var/log/app.log', 0, sub {
    my ($w) = @_;
    my $before = ($w->prev)[7];    # size before the change
    my $after  = ($w->attr)[7];    # size after
    print "grew by ", $after - $before, "\n" if $after > $before;
};
```

Functions

Status

attr

The path's status before the change that triggered the callback, as `stat` returns it. The same method has two other names:

Also available as `EV::Stat::prev`, `EV::Stat::stat`.

Configuration

set

Watch another path, with another polling interval: `$w->set($path, $interval)`, as `EV::stat` takes them.

path

The path watched; with an argument, watch that path instead and return the old one.

interval

The polling interval in use, in seconds - the default chosen when 0 was given; with an argument, set a new one and return the old.

attr

The path's status before the change that triggered the callback, as `stat` returns it. The same method has two other names:

Also available as `EV::Stat::prev`, `EV::Stat::stat`.

- `$w->attr` - the status that triggered the change, as EV last saw it; the difference from `prev` is what changed.
- `$w->stat` - stat the path now (with `lstat`), store that as what EV last saw (so it does not report a change you made yourself), and return it.

In list context each returns the 13 values `stat` does (the block size and block count are estimates), or an empty list when the path does not exist; in scalar context, whether it exists. All three also fill Perl's stat cache, for `-X _` tests, and a missing path sets `$!` to `ENOENT`.

EV::Timer

A relative timer, as `EV::timer` makes: its callback runs after a number of seconds, and optionally again at a repeat interval. These methods re-arm it and read or change its times; the methods all watchers share are `EV::Watcher`'s.

A timer counts on a clock that changes to the system time do not move. Starting one with a negative repeat interval croaks `repeat value must be >= 0`.

Synopsis

```
# an inactivity timeout: re-armed on every read
my $timeout = EV::timer 30, 30, sub { warn "idle for 30 s\n" };
my $reader  = EV::io $sock, EV::READ, sub { ...; $timeout->again };
printf "%.1f s left\n", $timeout->remaining;
```

Functions

Timing

again

Re-arm a repeating timer from now - the way to keep a timeout from firing while there is activity.

remaining

The seconds left until the timer fires, fractional; for an inactive timer, the time it was set to wait.

set

Set both times anew: `$w->set($after, $repeat)` (repeat default 0). An active timer restarts, counting `$after` from now.

repeat

The repeat interval; with an argument, set a new one and return the old. The timer is not restarted: an active timer uses the new interval from its next expiry.

again

Re-arm a repeating timer from now - the way to keep a timeout from firing while there is activity.

Synopsis

```
$w->again;          # restart the repeat interval from now
$w->again(10);      # with a new repeat interval
```

What it does

- An active repeating timer: fires the repeat interval after now.
- An inactive repeating timer: starts, firing the repeat interval after now.
- An active timer without repeat: stops.
- Otherwise nothing.

Make the timer with the same first and repeat time (`EV::timer 30, 30, ...`) and call `again` on each sign of activity.

Edge cases

- A negative new repeat croaks `repeat value must be >= 0`.

Differences from upstream

Fully compatible with upstream. Covered by `t/81-xs-native/EV/110-upstream-01_timer.t`.

See also

- `remaining` - how long until it fires
- `repeat` - the repeat interval alone

EV::Watcher

The methods every EV watcher has: start and stop it, ask whether it is active or pending, change its callback, data and priority, and decide whether it keeps the loop running.

Every watcher class - `EV::IO`, `EV::Timer`, `EV::Periodic`, `EV::Signal`, `EV::Child`, `EV::Stat`, `EV::Idle`, `EV::Prepare`, `EV::Check`, `EV::Fork`, `EV::Embed`, `EV::Async` - inherits these. Each class also has these two, with the same meaning everywhere:

- `$w->start` - start the watcher if it is not active; an active one is left as it is. Watchers start active, except those an `_ns` constructor made.
- `$w->stop` - stop the watcher if it is active, and in any case drop the events received for it whose callback has not run yet.

A watcher is stopped and freed when its last reference goes. A callback is called with the watcher and the events it received; the watcher can be stopped, changed or dropped from inside its own callback.

Synopsis

```
my $w = EV::timer 60, 0, sub { my ($w) = @_; warn $w->data };
$w->data('time is up');
$w->priority(1);                # before other pending watchers
$w->keepalive(0);               # EV::run may return while it waits
$w->stop;
$w->start if !$w->is_active;
```

Functions

State

`is_active`

True while the watcher is active - started and not stopped.

is_pending

True while the watcher has received events whose callback has not run yet.

keepalive

Whether the active watcher keeps `EV::run` from returning, and with an argument set it; returns the setting before, 1 or 0.

loop

The `EV::Loop` the watcher belongs to.

priority

The watcher's priority, from `EV::MINPRI` (-2) to `EV::MAXPRI` (2); with an argument, set a new one and return the old. Of the watchers pending at once, those of higher priority are called first. New watchers have priority 0; a value out of range is brought into it when the watcher starts. Setting it on an active watcher stops and restarts it, losing its pending events.

Callback and data

cb

The watcher's callback, as a code reference; with an argument, set a new one and return the old. The watcher is not restarted: the change can be made at any time, even from inside the callback. Something that is no code reference croaks.

data

A scalar of your own stored in the watcher, undef at first; with an argument, store a new one and return the old. The callback finds it as `$_[0]->data`.

Events

invoke

Call the watcher's callback now, with the events given (default `EV::NONE`): `$w->invoke(EV::TIMER)`.

clear_pending

Drop the events the watcher received whose callback has not run, and return them as a bitmask - as if the callback had run; 0 when nothing was pending.

feed_event

Act as if the watcher had received events: `$w->feed_event(EV::READ)` makes it pending, and its callback runs in the loop's next round.

keepalive

Whether the active watcher keeps `EV::run` from returning, and with an argument set it; returns the setting before, 1 or 0.

Synopsis

```
my $was = $w->keepalive;
$w->keepalive(0);
```

Edge cases

- `EV::run` returns when no active watcher with keepalive on is left. Turn it off for a watcher that should serve while there is other work but not keep the program waiting - a module's long-lived socket watcher, for one.
- New watchers have it on; it can change at any time.

Differences from upstream

Fully compatible with upstream. Covered by `t/81-xs-native/EV/130-upstream-03_keepalive.t`.

See also

- `EV::run` - the loop it concerns

loop

Run the event loop: wait for events and call the watchers' callbacks.

Also available as `EV::run`.

Synopsis

```
EV::run;                  # until EV::break, or no active watcher is left
EV::run EV::RUN_ONCE;     # wait for events once, handle them, return
EV::run EV::RUN_NOWAIT;   # handle what is ready now, without waiting
```

What you get back

True when it returned with work left - after `EV::break`, or with `EV::RUN_ONCE` or `EV::RUN_NOWAIT` - and false when no active watcher that keeps the loop alive was left.

Examples

Wait for input, at most five seconds:

```
my $in  = EV::io *STDIN, EV::READ, sub { print "input\n"; EV::break };
my $max = EV::timer 5, 0, sub { print "timeout\n"; EV::break };
EV::run;
```

Edge cases

- A watcher whose `keepalive` is off does not keep `EV::run` from returning.
- A callback may call `EV::run` again; the inner call returns first.
- `EV::loop` is the old name, from EV 3.

Differences from upstream

Fully compatible with upstream. Covered by `t/81-xs-native/EV/130-upstream-03_keepalive.t`.

See also

- `EV::break` - makes `EV::run` return
- `EV::once` - waits for one event without a watcher object

io

Watch a file handle: call the callback whenever it is readable or writable without blocking.

Also available as `EV::io_ns`.

Synopsis

```
my $w = EV::io $fh_or_fileno, EV::READ, sub { my ($w, $revents) = @_; ... };
my $s = EV::io_ns $sock, EV::READ | EV::WRITE, sub { ... };   # not started
```

What you get back

An `EV::IO` watcher, active (except from `EV::io_ns`) as long as the object lives. The callback gets the watcher and the events that occurred, `EV::READ`, `EV::WRITE` or both.

Examples

Read lines as they arrive:

```
my $w = EV::io *STDIN, EV::READ, sub {
    defined(my $line = <STDIN>) or return EV::break;
    print "got: $line";
};
EV::run;
```

Edge cases

- The handle may be a Perl file handle or a file descriptor number. One without a descriptor croaks `illegal file descriptor or filehandle`.
- EV tells when the descriptor is ready, not whether Perl's buffered handle has data: read with `sysread` (or one line per event, as above) so that buffered data is not left waiting.
- Several watchers may watch one descriptor.

Differences from upstream

Fully compatible with upstream. Covered by `t/81-xs-native/EV/190-upstream-09_brandon.t`.

See also

- `EV::IO` - change the handle or the events of a watcher
- `EV::once` - wait for one event without keeping a watcher

timer

Call the callback after a number of seconds, and optionally again and again after that.

Also available as `EV::timer_ns`.

Synopsis

```
my $once  = EV::timer 2.5, 0, sub { ... };    # in 2.5 seconds, once
my $every = EV::timer 0, 60, sub { ... };     # now, then every␣
 ↪minute
my $later = EV::timer_ns 10, 0, sub { ... };  # created stopped
```

What you get back

An `EV::Timer` watcher. The callback gets the watcher and `EV::TIMER`.

Edge cases

- Times count from the loop's time, `EV::now`, on a clock that system clock changes do not move; a timer for "at this wall-clock time" is `EV::periodic`.
- A repeating timer is restarted with the repeat interval after its callback; it fires at most once per loop iteration and may drift.
- A negative repeat croaks `repeat value must be >= 0`.

Differences from upstream

Fully compatible with upstream. Covered by `t/81-xs-native/EV/110-upstream-01_timer.t`.

See also

- `EV::Timer` - `again`, `remaining` and the repeat interval
- `EV::periodic` - timers on wall-clock time

periodic

Call the callback at wall-clock times: once at a given time, at every multiple of an interval, or whenever a sub of yours says.

Also available as `EV::periodic_ns`.

Synopsis

```
my $at     = EV::periodic $epoch_seconds, 0, 0, sub { ... };   #␣
↪once
my $hourly = EV::periodic 0, 3600, 0, sub { ... };             #␣
↪each full hour
my $custom = EV::periodic 0, 0, \&next_time, sub { ... };      # you␣
↪decide
```

What you get back

An `EV::Periodic` watcher. The callback gets the watcher and `EV::PERIODIC`.

The three modes

- `$interval` and `$reschedule_cb` 0: fire once when the system clock reaches `$at`, however the clock is set meanwhile.
- `$interval` above 0: fire at every `$at + N * $interval`, the next such time first (which may be before `$at`) - every full hour UTC above, without drift.

- `$reschedule_cb` a sub: it is called with the watcher and the current time and returns the next time to fire, at or after that time. It must not stop or change any periodic watcher or call into the loop; to stop, return `1e30` and stop the watcher afterwards.

Examples

Every midnight, local time:

```
use Time::Local ();
my $daily = EV::periodic 0, 0, sub {
    my (undef, $now) = @_;
    my (undef, undef, undef, $d, $m, $y) = localtime $now;
    Time::Local::timelocal_nocheck(0, 0, 0, $d + 1, $m, $y);
}, sub { print "midnight\n" };
```

Differences from upstream

`reschedule_cb` keeps its sub and the watcher alive; see `EV::Periodic`. Covered by `t/81-xs-native/EV/300-periodic-reschedule-cb.t`.

See also

- `EV::timer` - relative timeouts
- `EV::Periodic` - read and change a periodic watcher

once

Wait once for a handle to become ready, a timeout, or the first of the two, without keeping a watcher object.

Synopsis

```
EV::once $fh, EV::READ, 10, sub { my ($revents) = @_; ... };
EV::once undef, 0, 2.5, sub { ... };    # a plain timeout
```

What you get back

Nothing. When the handle is ready or the timeout passes, the callback is called once with the events received: a combination of `EV::READ`, `EV::WRITE`, `EV::TIMER` and `EV::ERROR`. Then both watchers are gone.

Edge cases

- `undef` as the handle (with 0 events) waits for the timeout only; an undef or negative timeout waits for the handle only.
- The callback receives only the events, not a watcher.

Differences from upstream

Fully compatible with upstream. Covered by `t/81-xs-native/EV/120-upstream-02_once.t`.

See also

- `EV::io` - a watcher for a handle, kept as long as needed
- `EV::timer` - a watcher for a timeout

5.2.34 Encode

Convert between Perl character strings and byte encodings.

```
use Encode qw(decode encode from_to find_encoding FB_CROAK);

my $chars = decode('UTF-8', "caf\xc3\xa9");          # bytes in,␣
↪characters out
printf "%d characters, U+%04X last\n", length $chars, ord substr
↪$chars, -1;
# 4 characters, U+00E9 last
printf "latin-1: %vX\n", encode('iso-8859-1', $chars);   # latin-1:␣
↪63.61.66.E9
printf "shiftjis: %vX\n", encode('shiftjis', "\x{65e5}\x{672c}");
↪# shiftjis: 93.FA.96.7B

my $data = "\xe9t\xe9";
from_to($data, 'iso-8859-1', 'utf8');                 # converts in␣
↪place
printf "from_to: %vX\n", $data;                       # from_to: C3.
↪A9.74.C3.A9
print eval { decode('UTF-8', "\xff", FB_CROAK); 1 } ? "decoded\n" :
↪"malformed: dies\n";
print find_encoding('latin1')->name, "\n";            # iso-8859-1
```

A string read from a file or socket is bytes; `decode` turns it into characters, and `encode` turns characters back into bytes for output. The third argument of either, CHECK, says what to do with something that cannot be converted: substitute (the default), die (`FB_CROAK`), warn, or stop and leave the rest (`FB_QUIET`). `encode_utf8` and `decode_utf8` are the UTF-8 shortcuts; `find_encoding` returns the encoding object, and `Encode->encodings(':all')` names every encoding available - 124 here, as in perl 5.44.

The encodings are perl 5.44's, from the same tables: `ascii`, `iso-8859-1`, `cp1252` and UTF-8 are built in; the others are in `Encode::Byte`, `CN`, `JP`, `KR`, `TW`, `Symbol`, `EBCDIC` and `Encode::Unicode`, which Encode loads the first time one of their encodings is named.

This is a native implementation of the XS half of Encode 3.24; `Encode.pm` and its Perl modules (`Encode::Alias`, `Encode::Encoding`, the MIME, Guess, JIS7, HZ and UTF-7 encodings) are used unchanged. `use Encode` exports `decode`, `encode`, `decode_utf8`, `encode_utf8`, `str2bytes`, `bytes2str`, `encodings`, `find_encoding`, `find_mime_encoding` and `clone_encoding`; `from_to`, `is_utf8` and the `FB_*` constants are imported

by name, the constants also with `:fallbacks`.

Differences from upstream

None.

Modules

- `Encode::Alias` - alias definitions to encodings
- `Encode::Byte` - the single-byte encodings beyond Latin-1: the ISO
- `Encode::CJKConstants` - Internally used by Encode::??::ISO_2022_*
- `Encode::CN` - the Simplified Chinese encodings: `euc-cn`, `cp936`
- `Encode::Config` - internally used by Encode
- `Encode::EBCDIC` - the EBCDIC encodings: `cp37`, `cp500`, `cp875`,
- `Encode::Encoder` - Object Oriented Encoder
- `Encode::Encoding` - Encode Implementation Base Class
- `Encode::GSM0338` - ETSI GSM 03.38 Encoding
- `Encode::Guess` - Guesses encoding from data
- `Encode::JP` - the Japanese encodings: `euc-jp`, `shiftjis`, `cp932`,
- `Encode::KR` - the Korean encodings: `euc-kr`, `cp949`, `johab`,
- `Encode::MIME`
- `Encode::Symbol` - the symbol-font encodings: `symbol`, `dingbats`,
- `Encode::TW` - the Traditional Chinese encodings: `big5-eten`,
- `Encode::Unicode` - The XS half of `Encode::Unicode`: the UTF-16, UTF-32 and UCS-2 codecs.
- `Encode::XS`
- `Encode::utf8`

Functions

Other Functions

`is_utf8`

`is_utf8($string [, $check])` - whether the string's UTF-8 flag is on; with a true `$check`, also whether its bytes are well-formed.

`_utf8_on`

`_utf8_on($string)` - turn the UTF-8 flag on without changing the bytes; returns the previous state, or undef for a tainted value or a non-string.

_utf8_off

`_utf8_off($string)` - turn the UTF-8 flag off without changing the bytes; returns the previous state, or undef for a tainted value or a non-string.

decode

`decode($encoding, $octets [, CHECK])` (also `bytes2str`) - decode bytes in the named encoding into a character string.

Also available as `Encode::bytes2str`.

encode

`encode($encoding, $string [, CHECK])` (also `str2bytes`) - encode a character string into bytes in the named encoding.

Also available as `Encode::str2bytes`.

decode_utf8

`decode_utf8($octets [, CHECK])` - decode UTF-8 octets (lax `utf8`).

encode_utf8

`encode_utf8($string)` - the string's characters as UTF-8 octets.

from_to

`from_to($octets, $from, $to [, CHECK])` - convert `$octets` in place from one encoding to another; returns the length of the result in bytes, or undef on failure.

onBOOT

`Encode::onBOOT` - register the built-in table encodings (`ascii`, `iso-8859-1`, `cp1252`, `null`, `ascii-ctrl`); Encode.pm calls it once, after `define_encoding` exists.

encodings

Return the list of encoding names the registry knows about.

find_encoding

Look up an encoding by name and return an object you can call methods on.

resolve_alias

Return the canonical encoding name for an alias, or `undef` if unknown.

Encode::Alias

alias definitions to encodings

SYNOPSIS

```
use Encode;
use Encode::Alias;
define_alias( "newName" => ENCODING);
define_alias( qr/.../ => ENCODING);
define_alias( sub { return ENCODING if ...; } );
```

DESCRIPTION

Allows newName to be used as an alias for ENCODING. ENCODING may be either the name of an encoding or an encoding object (as described in *Encode*).

Currently the first argument to define_alias() can be specified in the following ways:

- As a simple string.
- As a qr// compiled regular expression, e.g.:

  ```
  define_alias( qr/^iso8859-(\d+)$/i => '"iso-8859-$1"' );
  ```

  In this case, if *ENCODING* is not a reference, it is `eval`-ed in order to allow `$1` etc. to be substituted. The example is one way to alias names as used in X11 fonts to the MIME names for the iso-8859-* family. Note the double quotes inside the single quotes.

  (or, you don't have to do this yourself because this example is predefined)

  If you are using a regex here, you have to use the quotes as shown or it won't work. Also note that regex handling is tricky even for the experienced. Use this feature with caution.

- As a code reference, e.g.:

  ```
  define_alias( sub {shift =~ /^iso8859-(\d+)$/i ? "iso-8859-$1"␣
  ↪: undef } );
  ```

  The same effect as the example above in a different way. The coderef takes the alias name as an argument and returns a canonical name on success or undef if not. Note the second argument is ignored if provided. Use this with even more caution than the regex version.

Changes in code reference aliasing

As of Encode 1.87, the older form

```
define_alias( sub { return  /^iso8859-(\d+)$/i ? "iso-8859-$1" :␣
↪undef } );
```

no longer works.

Encode up to 1.86 internally used “local $_” to implement this older form. But consider the code below;

```
use Encode;
$_ = "eeeee" ;
while (/(e)/g) {
  my $utf = decode('aliased-encoding-name', $1);
  print "position:",pos,"\n";
}
```

Prior to Encode 1.86 this fails because of “local $_”.

Alias overloading

You can override predefined aliases by simply applying define_alias(). The new alias is always evaluated first, and when necessary, define_alias() flushes the internal cache to make the new definition available.

```
# redirect SHIFT_JIS to MS/IBM Code Page 932, which is a
# superset of SHIFT_JIS

define_alias( qr/shift.*jis$/i  => '"cp932"' );
define_alias( qr/sjis$/i        => '"cp932"' );
```

If you want to zap all predefined aliases, you can use

```
Encode::Alias->undef_aliases;
```

to do so. And

```
Encode::Alias->init_aliases;
```

gets the factory settings back.

Note that define_alias() will not be able to override the canonical name of encodings. Encodings are first looked up by canonical name before potential aliases are tried.

SEE ALSO

Encode, Encode::Supported

Encode::Byte

`Encode::Byte` - the single-byte encodings beyond Latin-1: the ISO 8859 family (`iso-8859-2` to `iso-8859-16`), the Windows code pages (`cp1250` to `cp1258`), the DOS code pages (`cp437`, `cp850`, `cp866`, ...), the KOI8 family (`koi8-r`, `koi8-u`, `koi8-f`), the Mac encodings (`MacRoman`, `MacCyrillic`, `MacGreek`, ...), `viscii`, `nextstep`, `hp-roman8` and `AdobeStandardEncoding` - 65 in all.

Nothing needs to be loaded: `Encode` loads this module the first time one of its encodings is named, as in `encode('koi8-r', $text)`.

This is a native implementation of Encode::Byte 2.04, from the same tables as upstream; `Encode/Byte.pm` is used unchanged.

Differences from upstream

None.

Encode::CJKConstants

Internally used by Encode::??::ISO_2022_*

Encode::CN

`Encode::CN` - the Simplified Chinese encodings: `euc-cn`, `cp936` (GBK), `hz`, `iso-ir-165`, `MacChineseSimp`, and the raw `gb2312-raw` and `gb12345-raw` tables.

Nothing needs to be loaded: `Encode` loads this module the first time one of its encodings is named, as in `decode('euc-cn', $bytes)`.

This is a native implementation of Encode::CN 2.03, from the same tables as upstream; `Encode/CN.pm` is used unchanged.

Differences from upstream

None.

Modules

- `Encode::CN::HZ` - internally used by Encode::CN

Encode::CN::HZ

internally used by Encode::CN

Encode::Config

internally used by Encode

Encode::EBCDIC

`Encode::EBCDIC` - the EBCDIC encodings: `cp37`, `cp500`, `cp875`, `cp1026`, `cp1047` and `posix-bc`.

Nothing needs to be loaded: `Encode` loads this module the first time one of its encodings is named, as in `decode('cp1047', $bytes)`.

This is a native implementation of Encode::EBCDIC 2.02, from the same tables as upstream; `Encode/EBCDIC.pm` is used unchanged.

Differences from upstream

None.

Encode::Encoder

Object Oriented Encoder

SYNOPSIS

```
use Encode::Encoder;
# Encode::encode("ISO-8859-1", $data);
Encode::Encoder->new($data)->iso_8859_1; # OOP way
# shortcut
use Encode::Encoder qw(encoder);
encoder($data)->iso_8859_1;
# you can stack them!
encoder($data)->iso_8859_1->base64;  # provided base64() is defined
# you can use it as a decoder as well
encoder($base64)->bytes('base64')->latin1;
# stringified
print encoder($data)->utf8->latin1;  # prints the string in latin1
# numified
encoder("\x{abcd}\x{ef}g")->utf8 == 6; # true. bytes::length($data)
```

ABSTRACT

Encode::Encoder allows you to use Encode in an object-oriented style. This is not only more intuitive than a functional approach, but also handier when you want to stack encodings. Suppose you want your UTF-8 string converted to Latin1 then Base64: you can simply say

```
my $base64 = encoder($utf8)->latin1->base64;
```

instead of

```
my $latin1 = encode("latin1", $utf8);
my $base64 = encode_base64($utf8);
```

or the lazier and more convoluted

```
my $base64 = encode_base64(encode("latin1", $utf8));
```

Description

Here is how to use this module.

- There are at least two instance variables stored in a hash reference, {data} and {encoding}.

- When there is no method, it takes the method name as the name of the encoding and encodes the instance *data* with *encoding*. If successful, the instance *encoding* is set accordingly.
- You can retrieve the result via ->data but usually you don't have to because the stringify operator ("") is overridden to do exactly that.

Predefined Methods

This module predefines the methods below:

- $e = Encode::Encoder->new([$data, $encoding]);

  returns an encoder object. Its data is initialized with $data if present, and its encoding is set to $encoding if present.

  When $encoding is omitted, it defaults to utf8 if $data is already in utf8 or "" (empty string) otherwise.

- encoder()

  is an alias of Encode::Encoder->new(). This one is exported on demand.

- $e->data([$data])

  When $data is present, sets the instance data to $data and returns the object itself. Otherwise, the current instance data is returned.

- $e->encoding([$encoding])

  When $encoding is present, sets the instance encoding to $encoding and returns the object itself. Otherwise, the current instance encoding is returned.

- $e->bytes([$encoding])

  decodes instance data from $encoding, or the instance encoding if omitted. If the conversion is successful, the instance encoding will be set to "".

  The name *bytes* was deliberately picked to avoid namespace tainting – this module may be used as a base class so method names that appear in Encode::Encoding are avoided.

Example: base64 transcoder

This module is designed to work with *Encode::Encoding*. To make the Base64 transcoder example above really work, you could write a module like this:

```
package Encode::Base64;
use parent 'Encode::Encoding';
__PACKAGE__->Define('base64');
use MIME::Base64;
sub encode{
    my ($obj, $data) = @_;
    return encode_base64($data);
}
sub decode{
    my ($obj, $data) = @_;
```

(continues on next page)

(continued from previous page)

```
    return decode_base64($data);
}
1;
__END__
```

And your caller module would be something like this:

```
use Encode::Encoder;
use Encode::Base64;

# now you can really do the following

encoder($data)->iso_8859_1->base64;
encoder($base64)->bytes('base64')->latin1;
```

Operator Overloading

This module overloads two operators, stringify ("") and numify (0+).

Stringify dumps the data inside the object.

Numify returns the number of bytes in the instance data.

They come in handy when you want to print or find the size of data.

Encode::Encoding

Encode Implementation Base Class

SYNOPSIS

```
package Encode::MyEncoding;
use parent qw(Encode::Encoding);

__PACKAGE__->Define(qw(myCanonical myAlias));
```

DESCRIPTION

As mentioned in *Encode*, encodings are (in the current implementation at least) defined as objects. The mapping of encoding name to object is via the %Encode::Encoding hash. Though you can directly manipulate this hash, it is strongly encouraged to use this base class module and add encode() and decode() methods.

Methods you should implement

You are strongly encouraged to implement methods below, at least either encode() or decode().

- ->encode($string [,$check])

  MUST return the octet sequence representing *$string*.

  - If *$check* is true, it SHOULD modify *$string* in place to remove the converted part (i.e. the whole string unless there is an error). If perlio_ok() is true, SHOULD becomes MUST.
  - If an error occurs, it SHOULD return the octet sequence for the fragment of string that has been converted and modify $string in-place to remove the converted part leaving it starting with the problem fragment. If perlio_ok() is true, SHOULD becomes MUST.
  - If *$check* is false then encode MUST make a "best effort" to convert the string - for example, by using a replacement character.

- ->decode($octets [,$check])

  MUST return the string that *$octets* represents.

  - If *$check* is true, it SHOULD modify *$octets* in place to remove the converted part (i.e. the whole sequence unless there is an error). If perlio_ok() is true, SHOULD becomes MUST.
  - If an error occurs, it SHOULD return the fragment of string that has been converted and modify $octets in-place to remove the converted part leaving it starting with the problem fragment. If perlio_ok() is true, SHOULD becomes MUST.
  - If *$check* is false then decode should make a "best effort" to convert the string - for example by using Unicode's "\x{FFFD}" as a replacement character.

If you want your encoding to work with *encoding* pragma, you should also implement the method below.

- ->cat_decode($destination, $octets, $offset, $terminator [,$check])

  MUST decode *$octets* with *$offset* and concatenate it to *$destination*. Decoding will terminate when $terminator (a string) appears in output. *$offset* will be modified to the last $octets position at end of decode. Returns true if $terminator appears output, else returns false.

Other methods defined in Encode::Encodings

You do not have to override methods shown below unless you have to.

- ->name

  Predefined As:

  ```
  sub name  { return shift->{'Name'} }
  ```

  MUST return the string representing the canonical name of the encoding.

- ->mime_name

  Predefined As:

```
sub mime_name{
  return Encode::MIME::Name::get_mime_name(shift->name);
}
```

  MUST return the string representing the IANA charset name of the encoding.

- ->renew

  Predefined As:

```
sub renew {
  my $self = shift;
  my $clone = bless { %$self } => ref($self);
  $clone->{renewed}++;
  return $clone;
}
```

  This method reconstructs the encoding object if necessary. If you need to store the state during encoding, this is where you clone your object.

  PerlIO ALWAYS calls this method to make sure it has its own private encoding object.

- ->renewed

  Predefined As:

```
sub renewed { $_[0]->{renewed} || 0 }
```

  Tells whether the object is renewed (and how many times). Some modules emit `Use of uninitialized value in null operation` warning unless the value is numeric so return 0 for false.

- ->perlio_ok()

  Predefined As:

```
sub perlio_ok {
  return eval { require PerlIO::encoding } ? 1 : 0;
}
```

  If your encoding does not support PerlIO for some reasons, just;

```
sub perlio_ok { 0 }
```

- ->needs_lines()

  Predefined As:

```
sub needs_lines { 0 };
```

If your encoding can work with PerlIO but needs line buffering, you MUST define this method so it returns true. 7bit ISO-2022 encodings are one example that needs this. When this method is missing, false is assumed.

Example: Encode::ROT13

```
package Encode::ROT13;
use strict;
use parent qw(Encode::Encoding);

__PACKAGE__->Define('rot13');

sub encode($$;$){
    my ($obj, $str, $chk) = @_;
    $str =~ tr/A-Za-z/N-ZA-Mn-za-m/;
    $_[1] = '' if $chk; # this is what in-place edit means
    return $str;
}

# Jr pna or ynml yvxr guvf;
*decode = \&encode;

1;
```

Why the heck Encode API is different?

It should be noted that the *$check* behaviour is different from the outer public API. The logic is that the "unchecked" case is useful when the encoding is part of a stream which may be reporting errors (e.g. STDERR). In such cases, it is desirable to get everything through somehow without causing additional errors which obscure the original one. Also, the encoding is best placed to know what the correct replacement character is, so if that is the desired behaviour then letting low level code do it is the most efficient.

By contrast, if *$check* is true, the scheme above allows the encoding to do as much as it can and tell the layer above how much that was. What is lacking at present is a mechanism to report what went wrong. The most likely interface will be an additional method call to the object, or perhaps (to avoid forcing per-stream objects on otherwise stateless encodings) an additional parameter.

It is also highly desirable that encoding classes inherit from `Encode::Encoding` as a base class. This allows that class to define additional behaviour for all encoding objects.

```
package Encode::MyEncoding;
use parent qw(Encode::Encoding);

__PACKAGE__->Define(qw(myCanonical myAlias));
```

to create an object with `bless {Name => ...}, $class`, and call define_encoding. They inherit their `name` method from `Encode::Encoding`.

Compiled Encodings

Encode provides the enc2xs tool to achieve that. Please see enc2xs for more details.

perlmod, enc2xs

Encode::GSM0338

ETSI GSM 03.38 Encoding

SYNOPSIS

```
use Encode qw/encode decode/;
$gsm0338 = encode("gsm0338", $unicode); # loads Encode::GSM0338␣
↪implicitly
$unicode = decode("gsm0338", $gsm0338); # ditto
```

DESCRIPTION

GSM0338 is for GSM handsets. Though it shares alphanumerals with ASCII, control character ranges and other parts are mapped very differently, mainly to store Greek characters. There are also escape sequences (starting with 0x1B) to cover e.g. the Euro sign.

This was once handled by Encode::Bytes but because of all those unusual specifications, Encode 2.20 has relocated the support to this module.

This module implements only *GSM 7 bit Default Alphabet* and *GSM 7 bit default alphabet extension table* according to standard 3GPP TS 23.038 version 16. Therefore *National Language Single Shift* and *National Language Locking Shift* are not implemented nor supported.

Septets

This modules operates with octets (like any other Encode module) and not with packed septets (unlike other GSM standards). Therefore for processing binary SMS or parts of GSM TPDU payload (3GPP TS 23.040) it is needed to do conversion between octets and packed septets. For this purpose perl's `pack` and `unpack` functions may be useful:

```
$bytes = substr(pack('(b*)*', unpack '(A7)*', unpack 'b*',
↪$septets), 0, $num_of_septets);
$unicode = decode('GSM0338', $bytes);

$bytes = encode('GSM0338', $unicode);
$septets = pack 'b*', join '', map { substr $_, 0, 7 } unpack '(A8)*
↪', unpack 'b*', $bytes;
$num_of_septets = length $bytes;
```

Please note that for correct decoding of packed septets it is required to know number of septets packed in binary buffer as binary buffer is always padded with zero bits and 7

zero bits represents character @. Number of septets is also stored in TPDU payload when dealing with 3GPP TS 23.040.

BUGS

Encode::GSM0338 2.7 and older versions (part of Encode 3.06) incorrectly handled zero bytes (character @). This was fixed in Encode::GSM0338 version 2.8 (part of Encode 3.07).

Encode

Encode::Guess

Guesses encoding from data

SYNOPSIS

```
# if you are sure $data won't contain anything bogus

use Encode;
use Encode::Guess qw/euc-jp shiftjis 7bit-jis/;
my $utf8 = decode("Guess", $data);
my $data = encode("Guess", $utf8);   # this doesn't work!

# more elaborate way
use Encode::Guess;
my $enc = guess_encoding($data, qw/euc-jp shiftjis 7bit-jis/);
ref($enc) or die "Can't guess: $enc"; # trap error this way
$utf8 = $enc->decode($data);
# or
$utf8 = decode($enc->name, $data)
```

ABSTRACT

Encode::Guess enables you to guess in what encoding a given data is encoded, or at least tries to.

DESCRIPTION

By default, it checks only ascii, utf8 and UTF-16/32 with BOM.

```
use Encode::Guess; # ascii/utf8/BOMed UTF
```

To use it more practically, you have to give the names of encodings to check (*suspects* as follows). The name of suspects can either be canonical names or aliases.

CAVEAT: Unlike UTF-(16|32), BOM in utf8 is NOT AUTOMATICALLY STRIPPED.

```
# tries all major Japanese Encodings as well
 use Encode::Guess qw/euc-jp shiftjis 7bit-jis/;
```

If the `$Encode::Guess::NoUTFAutoGuess` variable is set to a true value, no heuristics will be applied to UTF8/16/32, and the result will be limited to the suspects and `ascii`.

- Encode::Guess->set_suspects

  You can also change the internal suspects list via `set_suspects` method.

  ```
  use Encode::Guess;
  Encode::Guess->set_suspects(qw/euc-jp shiftjis 7bit-jis/);
  ```

- Encode::Guess->add_suspects

  Or you can use `add_suspects` method. The difference is that `set_suspects` flushes the current suspects list while `add_suspects` adds.

  ```
  use Encode::Guess;
  Encode::Guess->add_suspects(qw/euc-jp shiftjis 7bit-jis/);
  # now the suspects are euc-jp,shiftjis,7bit-jis, AND
  # euc-kr,euc-cn, and big5-eten
  Encode::Guess->add_suspects(qw/euc-kr euc-cn big5-eten/);
  ```

- Encode::decode("Guess" ...)

  When you are content with suspects list, you can now

  ```
  my $utf8 = Encode::decode("Guess", $data);
  ```

- Encode::Guess->guess($data)

  But it will croak if:

  - Two or more suspects remain
  - No suspects left

  So you should instead try this;

  ```
  my $decoder = Encode::Guess->guess($data);
  ```

  On success, $decoder is an object that is documented in *Encode::Encoding*. So you can now do this;

  ```
  my $utf8 = $decoder->decode($data);
  ```

  On failure, $decoder now contains an error message so the whole thing would be as follows;

  ```
  my $decoder = Encode::Guess->guess($data);
  die $decoder unless ref($decoder);
  my $utf8 = $decoder->decode($data);
  ```

- guess_encoding($data, [, *list of suspects*])

  You can also try `guess_encoding` function which is exported by default. It takes $data to check and it also takes the list of suspects by option. The optional suspect list is *not reflected* to the internal suspects list.

```
my $decoder = guess_encoding($data, qw/euc-jp euc-kr euc-cn/);
die $decoder unless ref($decoder);
my $utf8 = $decoder->decode($data);
# check only ascii, utf8 and UTF-(16|32) with BOM
my $decoder = guess_encoding($data);
```

CAVEATS

- Because of the algorithm used, ISO-8859 series and other single-byte encodings do not work well unless either one of ISO-8859 is the only one suspect (besides ascii and utf8).

```
use Encode::Guess;
# perhaps ok
my $decoder = guess_encoding($data, 'latin1');
# definitely NOT ok
my $decoder = guess_encoding($data, qw/latin1 greek/);
```

  The reason is that Encode::Guess guesses encoding by trial and error. It first splits $data into lines and tries to decode the line for each suspect. It keeps it going until all but one encoding is eliminated out of suspects list. ISO-8859 series is just too successful for most cases (because it fills almost all code points in \x00-\xff).

- Do not mix national standard encodings and the corresponding vendor encodings.

```
# a very bad idea
my $decoder
   = guess_encoding($data, qw/shiftjis MacJapanese cp932/);
```

  The reason is that vendor encoding is usually a superset of national standard so it becomes too ambiguous for most cases.

- On the other hand, mixing various national standard encodings automagically works unless $data is too short to allow for guessing.

```
# This is ok if $data is long enough
my $decoder =
 guess_encoding($data, qw/euc-cn
                          euc-jp shiftjis 7bit-jis
                          euc-kr
                          big5-eten/);
```

- DO NOT PUT TOO MANY SUSPECTS! Don't you try something like this!

```
my $decoder = guess_encoding($data,
                             Encode->encodings(":all"));
```

It is, after all, just a guess. You should alway be explicit when it comes to encodings. But there are some, especially Japanese, environment that guess-coding is a must. Use this module with care.

TO DO

Encode::Guess does not work on EBCDIC platforms.

- `Encode::MIME::Name` - internally used by Encode

Encode::MIME::Header

MIME encoding for an unstructured email header

SYNOPSIS

```
use Encode qw(encode decode);

my $mime_str = encode("MIME-Header", "Sample:Text \N{U+263A}");
# $mime_str is "=?UTF-8?B?U2FtcGxlOlRleHQg4pi6?="

my $mime_q_str = encode("MIME-Q", "Sample:Text \N{U+263A}");
# $mime_q_str is "=?UTF-8?Q?Sample=3AText_=E2=98=BA?="

my $str = decode("MIME-Header",
    "=?ISO-8859-1?B?SWYgeW91IGNhbiByZWFkIHRoaXMgeW8=?=\r\n " .
    "=?ISO-8859-2?B?dSB1bmRlcnN0YW5kIHRoZSBleGFtcGxlLg==?="
);
# $str is "If you can read this you understand the example."

use Encode qw(decode :fallbacks);
use Encode::MIME::Header;
local $Encode::MIME::Header::STRICT_DECODE = 1;
my $strict_string = decode("MIME-Header", $mime_string, FB_CROAK);
# use strict decoding and croak on errors
```

ABSTRACT

This module implements RFC 2047 MIME encoding for an unstructured field body of the email header. It can also be used for RFC 822 'text' token. However, it cannot be used directly for the whole header with the field name or for the structured header fields like From, To, Cc, Message-Id, etc... There are 3 encoding names supported by this module: `MIME-Header`, `MIME-B` and `MIME-Q`.

DESCRIPTION

Decode method takes an unstructured field body of the email header (or RFC 822 'text' token) as its input and decodes each MIME encoded-word from input string to a sequence of bytes according to RFC 2047 and RFC 2231. Subsequently, each sequence of bytes with the corresponding MIME charset is decoded with *the Encode module* and finally, one output string is returned. Text parts of the input string which do not contain MIME encoded-word stay unmodified in the output string. Folded newlines between two consecutive MIME encoded-words are discarded, others are preserved in the output string. `MIME-B` can decode Base64 variant, `MIME-Q` can decode Quoted-Printable variant and `MIME-Header` can decode both of them. If *Encode module* does not support particular MIME charset or chosen variant then an action based on *CHECK flags* is performed (by default, the MIME encoded-word is not decoded).

Encode method takes a scalar string as its input and uses *strict UTF-8* encoder for encoding it to UTF-8 bytes. Then a sequence of UTF-8 bytes is encoded into MIME encoded-words (`MIME-Header` and `MIME-B` use a Base64 variant while `MIME-Q` uses a Quoted-Printable variant) where each MIME encoded-word is limited to 75 characters. MIME encoded-words are separated by `CRLF SPACE` and joined to one output string. Output string is suitable for unstructured field body of the email header.

Both encode and decode methods propagate *CHECK flags* when encoding and decoding the MIME charset.

BUGS

Versions prior to 2.22 (part of Encode 2.83) have a malfunctioning decoder and encoder. The MIME encoder infamously inserted additional spaces or discarded white spaces between consecutive MIME encoded-words, which led to invalid MIME headers produced by this module. The MIME decoder had a tendency to discard white spaces, incorrectly interpret data or attempt to decode Base64 MIME encoded-words as Quoted-Printable. These problems were fixed in version 2.22. It is highly recommended not to use any version prior 2.22!

Versions prior to 2.24 (part of Encode 2.87) ignored *CHECK flags*. The MIME encoder used *not strict utf8* encoder for input Unicode strings which could lead to invalid UTF-8 sequences. MIME decoder used also *not strict utf8* decoder and additionally called the decode method with a `Encode::FB_PERLQQ` flag (thus user-specified *CHECK flags* were ignored). Moreover, it automatically croaked when a MIME encoded-word contained unknown encoding. Since version 2.24, this module uses *strict UTF-8* encoder and decoder. And *CHECK flags* are correctly propagated.

Since version 2.22 (part of Encode 2.83), the MIME encoder should be fully compliant to RFC 2047 and RFC 2231. Due to the aforementioned bugs in previous versions of the MIME encoder, there is a *less strict* compatible mode for the MIME decoder which is

used by default. It should be able to decode MIME encoded-words encoded by pre 2.22 versions of this module. However, note that this is not correct according to RFC 2047.

In default *not strict* mode the MIME decoder attempts to decode every substring which looks like a MIME encoded-word. Therefore, the MIME encoded-words do not need to be separated by white space. To enforce a correct *strict* mode, set variable `$Encode::MIME::Header::STRICT_DECODE` to 1 e.g. by localizing:

```
use Encode::MIME::Header;
local $Encode::MIME::Header::STRICT_DECODE = 1;
```

Encode::Unicode

The XS half of `Encode::Unicode`: the UTF-16, UTF-32 and UCS-2 codecs.

`Encode/Unicode.pm` is upstream's. It creates one blessed hash per encoding - `Name`, `size`, `endian`, `ucs2` - and registers it with `Encode::define_encoding`. The two methods below read those attributes and convert, exactly as `Unicode.xs` does: BOM detection and big-endian fallback for the BOM-less `UTF-16`/`UTF-32`, surrogate pairs, the U+FFFD substitution, and the CHECK handling (croak, warn, leave or consume the source).

```
use Encode;
printf "%vX\n", encode('UTF-16LE', "hi");           # 68.0.69.0
print decode('UTF-16', "\xFE\xFF\0A\0B"), "\n";     # AB (the BOM␣
↪says big-endian)
printf "%vX\n", encode('UTF-16', "\x{1F600}");      # FE.FF.D8.3D.DE.
↪0: BOM, surrogate pair
```

The encodings are `UTF-16`, `UTF-16BE`, `UTF-16LE`, `UTF-32`, `UTF-32BE`, `UTF-32LE`, `UCS-2BE` and `UCS-2LE`; `Encode` loads this module the first time one of them is named. This is a native implementation of the XS half of Encode::Unicode 2.20.

Differences from upstream

None.

Encode::Unicode::UTF7

UTF-7 encoding

SYNOPSIS

```
use Encode qw/encode decode/;
$utf7 = encode("UTF-7", $utf8);
$utf8 = decode("UTF-7", $ucs2);
```

ABSTRACT

This module implements UTF-7 encoding documented in RFC 2152. UTF-7, as its name suggests, is a 7-bit re-encoded version of UTF-16BE. It is designed to be MTA-safe and expected to be a standard way to exchange Unicoded mails via mails. But with the advent of UTF-8 and 8-bit compliant MTAs, UTF-7 is hardly ever used.

UTF-7 was not supported by Encode until version 1.95 because of that. But Unicode::String, a module by Gisle Aas which adds Unicode supports to non-utf8-savvy perl did support UTF-7, the UTF-7 support was added so Encode can supersede Unicode::String 100%.

In Practice

When you want to encode Unicode for mails and web pages, however, do not use UTF-7 unless you are sure your recipients and readers can handle it. Very few MUAs and WWW Browsers support these days (only Mozilla seems to support one). For general cases, use UTF-8 for message body and MIME-Header for header instead.

SEE ALSO

RFC 2781 http://www.ietf.org/rfc/rfc2152.txt

decode

`$obj->decode($octets [, $check])` - UTF-16/32 or UCS-2 octets to a character string.

The byte order comes from the object's `endian`; with none (`UTF-16`, `UTF-32`) a leading BOM decides it and a missing one means big-endian. Surrogate pairs are combined; a lone or malformed surrogate, a surrogate in UCS-2 or UTF-32, and a non-character become U+FFFD - or croak with `FB_CROAK`, or warn with `FB_WARN`. A true CHECK without `LEAVE_SRC` leaves the undecoded tail in `$octets`.

encode

`$obj->encode($string [, $check])` - a character string to UTF-16/32 or UCS-2 octets.

With no fixed byte order (`UTF-16`, `UTF-32`) the output starts with a big-endian BOM. Characters above U+FFFF become surrogate pairs in UTF-16; in UCS-2, and anything above U+10FFFF, they become U+FFFD - or croak with `FB_CROAK`, or warn with `FB_WARN`. A partial UTF-8 character at the end croaks when CHECK has `DIE_ON_ERR` or `LEAVE_SRC`.

Encode::XS

Functions

Other Functions

`renew`

`$enc->renew` - a new reference to the same encoding object (Encode::XS encodings are not cloned).

`renewed`

`$enc->renewed` - always 0 for a table-driven encoding.

`name`

`$enc->name` - the encoding's canonical name.

`cat_decode`

`$enc->cat_decode($dst, $src, $off, $term [, CHECK])` - decode `$src` from byte offset `$off` onto the end of `$dst`, stopping after the terminator `$term`; updates `$off` and returns true if the terminator was found.

`decode`

`$enc->decode($octets [, CHECK])` - decode bytes of this encoding to a character string.

`encode`

`$enc->encode($string [, CHECK])` - encode a character string into bytes of this encoding.

`needs_lines`

`$enc->needs_lines` - false: a table-driven encoding carries no state across lines.

`perlio_ok`

`$enc->perlio_ok` - true if the `:encoding()` layer can use this encoding, which is whether PerlIO::encoding loads.

mime_name

`$enc->mime_name` - the encoding's MIME charset name, from Encode::MIME::Name.

Encode::utf8

Functions

Other Functions

decode

`$utf8->decode($octets [, CHECK])` - decode UTF-8 octets, lax for `utf8` and strict for `UTF-8`, applying CHECK to malformations.

encode

`$utf8->encode($string [, CHECK])` - encode characters as UTF-8. The strict `UTF-8` validates the string first and applies CHECK to what is not interchangeable UTF-8; lax `utf8` copies its octets.

encodings

Return the list of encoding names the registry knows about.

Synopsis

```
my @all = Encode->encodings();      # class method - the documented
↪form
my @all = Encode->encodings(':all');
```

Names are sorted case-insensitively and deduplicated; each canonical name appears exactly once regardless of how many aliases it has, and `Internal`, `Unicode` and `Guess` are excluded as upstream does. Use `resolve_alias` or `find_encoding` to turn any of these into a canonical name or an encoding object.

Only the encodings currently LOADED are reported. An encoding becomes loaded the first time any of its names is resolved, and it arrives with the rest of its module: `find_encoding("cp1251")` takes the list from seven names to seventy-one, because it requires `Encode::Byte`. `:all` merges in everything still dormant; a module name merges in that module's share without loading it.

Differences from upstream

Fully compatible with upstream.

find_encoding

Look up an encoding by name and return an object you can call methods on.

Synopsis

```
my $enc = find_encoding($name);
my $bytes  = $enc->encode($string);
my $string = $enc->decode($bytes);
my $canon  = $enc->name;
```

What you get back

A blessed encoding object: `Encode::utf8` for the UTF-8 family, `Encode::Unicode` for UTF-16 and UTF-32, `Encode::XS` for the table-driven encodings, or the class of whichever module defines the encoding. If the name cannot be resolved, `find_encoding` returns `undef`.

The object provides the `Encode::Encoding` methods, among them `encode`, `decode`, `name` (returns the canonical string), and `perlio_ok` (true when the `:encoding()` layer can use the encoding). `renew` returns the same object for an `Encode::XS` encoding and a copy for the others.

Name resolution is case-insensitive and treats `-` and `_` interchangeably. “utf-8”, “UTF-8”, and “utf_8” all resolve to the same object; “UTF8” without the dash is the lax `utf8` encoding, a different one.

Examples

Cache an encoding object and reuse it in a loop:

```
my $enc = find_encoding('UTF-8');
while (my $line = <$fh>) {
    my $string = $enc->decode($line);
    # ... work with $string ...
}
```

Query by alias:

```
my $enc = find_encoding('latin1');
print $enc->name;   # iso-8859-1
```

Edge cases

- Unknown names return `undef` after falling back to `Encode::Alias::find_alias` for aliases registered with `define_alias`.
- An `Encode::XS` object is a blessed scalar reference with no fields; the others are blessed hashes with a `Name` key. Code that pokes inside is not portable across encodings.

Differences from upstream

Fully compatible with upstream.

See also

- `resolve_alias` - get just the canonical name string.
- `encodings` - list every name the registry knows.
- `encode`, `decode` - the function forms, if you don't want to hold an object.

5.2.35 English

use nice English (or awk) names for ugly punctuation variables

SYNOPSIS

```
use English;
use English qw( -no_match_vars ) ;  # Avoids regex performance
                                    # penalty in perl 5.18 and
                                    # earlier
...
if ($ERRNO =~ /denied/) { ... }
```

DESCRIPTION

This module provides aliases for the built-in variables whose names no one seems to like to read. Variables with side-effects which get triggered just by accessing them (like $0) will still be affected.

For those variables that have an **awk** version, both long and short English alternatives are provided. For example, the `$/` variable can be referred to either $RS or $INPUT_RECORD_SEPARATOR if you are using the English module.

See *perlvar* for a complete list of these.

PERFORMANCE

NOTE: This was fixed in perl 5.20. Mentioning these three variables no longer makes a speed difference. This section still applies if your code is to run on perl 5.18 or earlier.

This module can provoke sizeable inefficiencies for regular expressions, due to unfortunate implementation details. If performance matters in your application and you don't need $PREMATCH, $MATCH, or $POSTMATCH, try doing

```
use English qw( -no_match_vars ) ;
```

. **It is especially important to do this in modules to avoid penalizing all applications which use them.**

5.2.36 Env

perl module that imports environment variables as scalars or arrays

SYNOPSIS

```
use Env;
use Env qw(PATH HOME TERM);
use Env qw($SHELL @LD_LIBRARY_PATH);
```

DESCRIPTION

Perl maintains environment variables in a special hash named `%ENV`. For when this access method is inconvenient, the Perl module `Env` allows environment variables to be treated as scalar or array variables.

The `Env::import()` function ties environment variables with suitable names to global Perl variables with the same names. By default it ties all existing environment variables (`keys %ENV`) to scalars. If the `import` function receives arguments, it takes them to be a list of variables to tie; it's okay if they don't yet exist. The scalar type prefix '$' is inferred for any element of this list not prefixed by '$' or '@'. Arrays are implemented in terms of `split` and `join`, using `$Config::Config{path_sep}` as the delimiter.

After an environment variable is tied, merely use it like a normal variable. You may access its value

```
@path = split(/:/, $PATH);
print join("\n", @LD_LIBRARY_PATH), "\n";
```

or modify it

```
$PATH .= ":/any/path";
push @LD_LIBRARY_PATH, $dir;
```

however you'd like. Bear in mind, however, that each access to a tied array variable requires splitting the environment variable's string anew.

The code:

```
use Env qw(@PATH);
push @PATH, '/any/path';
```

is almost equivalent to:

```
use Env qw(PATH);
$PATH .= ":/any/path";
```

except that if `$ENV{PATH}` started out empty, the second approach leaves it with the (odd) value ":`/any/path`", but the first approach leaves it with "`/any/path`".

To remove a tied environment variable from the environment, assign it the undefined value

```
undef $PATH;
undef @LD_LIBRARY_PATH;
```

LIMITATIONS

On VMS systems, arrays tied to environment variables are read-only. Attempting to change anything will cause a warning.

AUTHOR

Chip Salzenberg <chip@fin.uucp> and Gregor N. Purdy <gregor@focusresearch.com>

5.2.37 Errno

Symbolic names for the `errno(3)` values your system uses - `EINTR`, `EAGAIN`, `ENOENT`, `EACCES`, `EEXIST`, `EIO`, `ENOTDIR`, `EISDIR`, `EBUSY`, `EPIPE`, `ECONNRESET`, `ECONNREFUSED`, `ETIMEDOUT`, and every other errno name the host libc defines.

Most scripts reach for `Errno` to compare `$!` against a specific error after a failed system call, or to probe `%!` for the same purpose without touching `$!` by name.

Synopsis

```
use Errno qw(EINTR EAGAIN);

if ($! == EINTR) { retry() }     # function form
if ($!{EAGAIN})  { backoff() }   # hash form via %!
```

The names and their numbers come from the errno.h of the host pperl was built on, and from the headers it includes, so scripts see exactly the errnos the kernel will actually raise. The `:POSIX` tag groups the POSIX-standard names for bulk import; nothing is exported by default.

Upstream's `Errno.pm` is generated when perl is built, from those headers (ext/Errno/Errno_pm.PL); pperl's build reads them the same way (src/build_errno.rs), so this native implementation of Errno 1.39 has the same names with the same values, the ones the libc crate lacks included.

Differences from upstream

None.

5.2.38 Event

`Event` - an event loop: watchers for timers, file descriptors, signals, variables, idle time, groups and custom event sources, each calling back into Perl when its event happens.

```
use Event qw(loop unloop);

Event->timer(after => 1, interval => 1, cb => sub { print "tick\n" }
↪);
Event->io(fd => \*STDIN, poll => 'r', cb => sub {
    my $line = <STDIN>;
    unloop() unless defined $line;
});
loop();
```

Each `Event->TYPE(%attributes)` creates a watcher and starts it (unless `parked => 1`). When the watched condition occurs, an event is queued at the watcher's priority and `loop` runs its callback with the event as argument; `$event->w` is the watcher, `$event->hits` the number of occurrences it stands for. Watchers are stopped, restarted, suspended or cancelled with the methods of the same names.

The watcher types are `Event::idle`, `Event::timer`, `Event::io`, `Event::var` and `Event::signal`, which `use Event` loads, and `Event::group` and `Event::generic`, which are loaded with their own `use`. Their shared methods are `Event::Watcher`'s; events are `Event::Event` objects; `Event::Watcher::Tied` is the base for watcher types written in Perl.

Timers take fractional seconds when Time::HiRes is available, which `use Event` loads by default; `use Event qw(NO_TIME_HIRES)` prevents that.

Other XS modules can drive the loop from C through `$Event::API` (EventAPI.h, version 22), as Coro::Event does.

This is a native implementation of the CPAN module Event 1.28; its `Event.pm` and every `Event::*` module are used unchanged.

Exports

Nothing by default. On request: `time`, `all_watchers`, `all_running`, `all_idle`, `one_event`, `sweep`, `loop`, `unloop`, `unloop_all`, `sleep`, `queue`, `queue_pending`, `QUEUES`, `PRIO_NORMAL`, `PRIO_HIGH`. (`all_events` and `all_queued` are listed too, but defined nowhere.)

Functions written in Perl

From `Event.pm`:

- `loop()` / `loop($timeout)` - run callbacks until `unloop` or `unloop_all`, and return the value given to it; with `$timeout`, stop after that many seconds, returning `$timeout`. Loops nest. A callback that dies does not end the loop: the error goes to `$Event::DIED` and the loop goes on. With no active watcher left it warns "Event: loop without active watchers" and returns.
- `sweep()` / `sweep($max_prio)` - queue what has happened (queue_pending) and run every queued event of priority better than `$max_prio`, without waiting; by default all events but those of idle watchers. Errors are trapped as in `loop`.
- `Event->add_hooks(name => sub { ... }, ...)` - Perl code run at fixed points of each round: `prepare` (before waiting; returns the longest time to wait),

`check` (after waiting), `asynccheck` (after collecting signals), `callback` (before each callback). Hooks slow the loop down considerably.

- `Event::verbose_exception_handler` - a `$Event::DIED` handler that also lists the attributes of the failing watcher.

Priorities

Events are run in priority order, and in order of arrival within a priority. Priorities go from -1 (highest) to 6 (lowest); `PRIO_HIGH` is 2, `PRIO_NORMAL` 4, and `QUEUES` (7) is the number of queued priorities. An event of priority -1 is not queued: its callback runs at once, as soon as the event occurs. A watcher starts at its type's `$Event::TYPE::DefaultPriority`, or `PRIO_NORMAL` where that is not set; only `Event::signal` sets it, to `PRIO_HIGH`. The constructor attributes `nice => $offset` (added to the default), `async => 1` (priority -1) and `prio => $level` override it, `prio` winning over `async` over `nice`.

Customization

- `$Event::DIED` - called as `$Event::DIED->($event, $error)` when a callback dies inside `loop` or `sweep`; the default warns "Event: trapped error in", the watcher's `desc` and the error. The loop goes on afterwards; a handler that wants to end it can call `Event::unloop_all()`.
- `$Event::DebugLevel` - diagnostics on STDERR: from 1, why a watcher stopped when a change left it unable to generate events; from 2, each wait for events; from 3, each watcher created and the value `loop` returns; from 4, the errors `loop` traps. The finer per-watcher levels exist only when Event is built with debugging (see `Event::Watcher`'s debug).

Differences from upstream

- `Event::queue` checks its argument count. Called past its prototype with none, or with three or more, XS Event reads memory at random; here it dies with its usage (t/81-xs-native/Event/340-queue-arguments.t).
- Destroying an `Event::generic::Source` stops the watchers still watching it; with XS Event it corrupts memory (t/81-xs-native/Event/350-source-destroyed.t; see `Event::generic::Source`).

Modules

- `Event::Event` - An event, as a callback receives it: one occurrence (or several, merged) of what a watcher watches.
- `Event::Watcher` - The base class of every watcher: the methods and attributes all watcher types share.
- `Event::generic` - A generic watcher: an event whenever Perl code says so.
- `Event::group` - A group watcher: an event when none of its member watchers has run its callback for `timeout` seconds - a watchdog over a set of watchers.
- `Event::idle` - An idle watcher: an event when the loop has nothing else to do - no event queued, nothing arriving.

- `Event::io` - An io watcher: an event when a file descriptor is ready to read or to write, or has an exception pending - and, optionally, when it has been quiet for a given time.
- `Event::signal` - A signal watcher: an event when the process receives a signal.
- `Event::timer` - A timer watcher: an event at a given time, and optionally at every interval after it.
- `Event::var` - A var watcher: an event whenever a scalar variable is written to, or read.

Functions

Running the loop

unloop

`unloop($result)`: make the innermost running `loop` return `$result` (undef when omitted), once the current callback returns.

unloop_all

`unloop_all($result)`: make every running `loop`, however deeply nested, return `$result`, as if `unloop` were called for each. It does not `die`.

null_loops_per_second

`null_loops_per_second($seconds)`: a benchmark of the system's polling. For `$seconds` seconds it polls a pipe that has nothing to report, as an idle loop would, and returns how many polls one second allows.

one_event

`one_event($timeout)`: run one callback, waiting for an event if none is queued - at most `$timeout` seconds, 60 by default. Returns true if a callback ran. `loop` is built on it, but unlike `loop` it does not trap exceptions: a callback's `die` propagates out of `one_event`.

Events

queue

`queue($watcher)`, `queue($watcher, $hits)` or `queue($watcher, $event)`: queue an event for the watcher - a new one of one hit, a new one of `$hits` hits, or `$event`, an event of this watcher (one of another dies "queue: event doesn't match watcher"). The watcher need not be active. Returns nothing. Other argument counts (possible only by calling it as `&Event::queue(...)`, past its prototype) die "Usage: Event::queue(watcher, [hits | event])".

queue_pending

Turn what has happened into queued events without running any callback: poll descriptors without waiting, expire due timers, and turn counted signals into events. `sweep` and `one_event` do this themselves; call it directly before `pending` or `start` to take signals that already arrived into account.

queue_time

`queue_time($prio)`: the latest time a callback was started for an event of priority `$prio` or better (0 to 6), or undef if none has been. Other priorities die "queue_time(N) out of domain [0..6]".

Watchers

all_watchers

Every watcher that is not cancelled, stopped ones included, newest first.

all_idle

The idle watchers waiting for the loop to go idle, oldest first. While the queue is busy they stay here; one with `max` set fires anyway when that time has passed (see `Event::idle`).

all_running

The watchers whose callbacks are running, the most recently entered first; in scalar context only that one (undef when none is).

Time

cache_time_api

Switch Event's clock to Time::HiRes's, for fractional seconds; true on success, false when Time::HiRes is not loaded. `use Event` calls it after loading Time::HiRes, unless imported with `NO_TIME_HIRES`.

time

The current time as Event sees it, in seconds since the epoch: fractional with Time::HiRes (see `cache_time_api`), whole seconds without. Timer times are in these units.

sleep

`sleep($seconds)`: block for that long, fractions included, without running the loop. Returns nothing.

Event::Event

An event, as a callback receives it: one occurrence (or several, merged) of what a watcher watches. `loop` calls the watcher's callback with the event as its only argument.

Events of io and var watchers are `Event::Event::Io` objects, which add `got`; events of generic watchers are `Event::Event::Dataful` objects, which add `data`. Both are subclasses of `Event::Event`.

Synopsis

```
use Event;

Event->io(fd => \*STDIN, poll => 'r', cb => sub {
    my $e = shift;
    printf "%s: %s, %d hit(s) at priority %d\n",
        $e->w->desc, $e->got, $e->hits, $e->prio;
    Event::unloop() if eof STDIN;
});
Event::loop();
```

Modules

- `Event::Event::Dataful`
- `Event::Event::Io`

Functions

Attributes

mom

The old name of `w`. Returns the same; the first 16 calls in a program also warn "'mom' renamed to 'w'".

w

The watcher that generated the event. Read-only.

hits

How many occurrences this event stands for. Signals arriving in quick succession are merged into one event; for the other watcher types it is usually 1.

prio

The priority the event was queued at. It can differ from the watcher's current `prio`: the watcher's may have changed since, and `Event::queue` and the C API can queue at any priority.

Event::Event::Dataful

Functions

Attributes

data

The data, on an `Event::Event::Dataful`: the scalar passed to the event source's `event` method (`Event::generic::Source`), or undef. Read-only.

Event::Event::Io

Functions

Attributes

got

What happened, on an `Event::Event::Io`: a string of the letters `r`, `w`, `e` and `t` (read, write, exception, timeout) that is also the number made of the matching bits `R`, `W`, `E` and `T` of `Event::Watcher`. The watcher's `poll` says what it waits for; `got` says which of those occurred.

Event::Watcher

The base class of every watcher: the methods and attributes all watcher types share. A watcher is made by its type's constructor (`Event->timer(...)`, `Event::io->new(...)`, ...; see `Event`), lives on without a reference being kept to it, and is switched between active and inactive with `start` and `stop`. When the condition it watches occurs, an active watcher queues an event at its priority, and the loop passes that event to its callback.

Every attribute is a method: called with no argument it returns the value, called with one it sets the value and returns it. Constructors take the same attributes as `name => value` pairs.

Methods written in Perl

`Event::Watcher` (from `Event/Watcher.pm`) also has:

- `$w->attributes` - the names of the watcher's attributes, its own type's followed by those of its base classes.
- `$w->configure` - with no arguments, a list of `name => value` pairs of all attributes; with pairs, sets them.
- `$w->data` / `$w->data($anything)` - one slot for the user's own data.
- `$w->private` / `$w->private($anything)` - like `data`, but each calling package has its own slot; meant for the implementers of watcher types and subclasses.
- `Event::Watcher->register` - called by a watcher type's module to make `Event->TYPE(...)` construct it.
- `$w->init(\%attributes)` - the common half of every constructor: sets the priority (from the type's `$DefaultPriority` and the `nice`, `async` and `prio` attributes),

every attribute the watcher has a method for, a `desc` naming the caller's file and line if none was given, and starts the watcher unless `parked` is true.

Constants

Exported on request (`use Event::Watcher qw(R W E T)`):

- `R` (1), `W` (2), `E` (4), `T` (8) - the read, write, exception and timeout bits of `poll` and `got`.
- `ACTIVE` (1), `SUSPEND` (4) - bits of `Event::Watcher::Tied`'s `flags`.

Modules

- `Event::Watcher::Tied` - The base class for watcher types written in Perl.

Functions

Activity

again

Like `start`, except for watchers that repeat in a special way: a repeating timer computes its next expiry from `interval`.

start

Activate the watcher; an active watcher does nothing. A watcher that lacks what it needs to generate events refuses with "Event: can't start 'DESC' REASON" - for instance a watcher without a callback ("without callback"), or a repeating timer without `interval`. Constructors call `start` unless given `parked => 1`.

suspend

`$w->suspend(1)` suspends the watcher, `$w->suspend(0)` lifts the suspension. A suspended watcher generates no events and its queued events are cancelled, but it stays active; suspension is a debugging aid. Called without an argument it suspends, warns "Ambiguous use of suspend" and returns true.

resume

Deprecated: the same as `suspend(0)`, with a warning saying so.

stop

Deactivate the watcher. A running callback completes; queued events are cancelled. `start` or `again` activates it again.

cancel

Stop the watcher and destroy it. A running callback completes; queued events are cancelled. A cancelled watcher answers its read-only methods (`prio`, `desc`, ...) but can no longer be started.

now

Generate an event now, even if the watcher is stopped (but not if it is suspended). The event is queued at the watcher's priority like any other, so the callback runs when the loop reaches it. Dies if the watcher has no callback.

State

pending

The watcher's events waiting in the queue. In list context, the events themselves; in scalar context, true if there is any.

is_running

0 when the callback is not running, otherwise how many times it has been entered - more than 1 when a `reentrant` callback runs `loop` or `sweep` itself.

is_active

True if the watcher is started. Suspension does not change it.

is_suspended

True if the watcher is suspended (see `suspend`).

is_cancelled

True if the watcher is cancelled.

Attributes

use_keys

Deprecated; does nothing but warn "use_keys is deprecated".

cb

The callback: a code reference, or `[$class_or_object, $method_name]` to call a method. It is called with the event as its only argument. Anything else dies "Callback must be a code ref or [$object, $method_name]"; a method that does not exist yet only warns. Setting undef removes the callback and stops the watcher.

cbtime

When the callback was last called, in the units of `Event::time`. Read-only: setting it dies.

desc

A name for the watcher, used in diagnostics. Constructors set it to `?? FILE:LINE` of their caller when none is given.

debug

Debugging for this watcher. Stored and returned, but without effect: its per-watcher diagnostics exist only when Event is built with debugging, which a standard build of the module, like this one, is not.

prio

The priority its events are queued at, -1 (highest) to 6 (lowest); see `Event`.

reentrant

Whether the callback may be entered again while it runs, which happens when it calls `loop` or `sweep`. True by default; when false the watcher is suspended during such nested calls. It cannot be turned off while the callback is already entered more than once.

repeat

Whether the watcher stays active after an event; when false it stops after one. The default depends on the type: io, signal, var, group and generic watchers repeat; timers and idle watchers repeat when given `interval`, or `min` or `max`.

max_cb_tm

The most seconds a callback may run, an integer, 1 by default. It takes effect only with the statistics `Event::Stats` installs; otherwise it is recorded and not enforced. A value Perl does not hold as an integer - the string `"5"`, the number 2.5 - sets 0.

Event::Watcher::Tied

The base class for watcher types written in Perl. A subclass makes its watchers with `allocate`, and the loop calls back into it:

- `_start($w, $repeat)` - required; called by `start` (`$repeat` false) and `again` (true). It must arrange for events, by queueing them with `Event::queue` or by setting `at`.
- `_alarm($w)` - called when the time set with `at` has come; required once `at` is used.
- `_stop($w)` - called by `stop`, if the subclass has it.

The shared watcher methods and attributes are `Event::Watcher`'s.

Synopsis

```
package My::Ticker;
use base 'Event::Watcher::Tied';

sub new {
    my ($class, %arg) = @_;
    my $w = $class->allocate({});
    $w->init(\%arg);
    $w;
}
sub _start { my ($w) = @_; $w->at(Event::time() + 1) }
sub _alarm { my ($w) = @_; Event::queue($w); $w->at(Event::time() +
↪1) }
```

Functions

Construction

allocate

Make a new, inactive watcher blessed into `$class`, a subclass; `$template`, a hash or array reference, becomes the object. Dies "Bad template" when it is no reference. The subclass's constructor then usually calls `init` (see `Event::Watcher`).

Attributes

hard

The flag timers use to choose how to reckon their next time (see `Event::timer`). A tied watcher's own `_start` and `_alarm` decide its times, so here it is only stored, for them to read.

at

The time `_alarm` is to be called, in the units of `Event::time`. Setting a time schedules the alarm, replacing a scheduled one; setting undef only cancels it.

flags

The watcher's state bits `ACTIVE` (1) and `SUSPEND` (4) (see `Event::Watcher`). Setting it can change only the bit 0x4000, which is on by default: a repeating watcher with it on stops generating events while its callback runs. Trying to change any other bit warns "Other flags (0xN) cannot be changed".

Event::generic

A generic watcher: an event whenever Perl code says so. Events come from an event source, an `Event::generic::Source` object, whose `event` method gives every active watcher of the source an event; data passed to `event` reaches the callbacks as the event's `data`. The events are `Event::Event::Dataful` objects.

`use Event` does not load this watcher type; `use Event::generic` does, and with it `Event::generic::Source`.

`Event->generic(%attributes)` (or `Event::generic->new(...)`, or the source's `watch` method) takes the shared attributes of `Event::Watcher` and `source`. A generic watcher repeats. It refuses to start without a callback or without a source ("without source").

Synopsis

```
use Event;
use Event::generic;

my $source = Event::generic::Source->new;
my $w = $source->watch(cb => sub { print "got ", $_[0]->data, "\n" }
 ↪);
$source->event("hello");
Event::sweep();
```

Modules

- `Event::generic::Source` - An event source for generic watchers (see `Event::generic`): calling its `event` method gives an event to each of its active watchers.

Functions

Attributes

source

The event source watched: an `Event::generic::Source`, or undef for none. Anything else dies. Changing it moves an active watcher to the new source.

Event::generic::Source

An event source for generic watchers (see `Event::generic`): calling its `event` method gives an event to each of its active watchers.

Written in Perl (`Event/generic.pm`), beside the methods below:

- `Event::generic::Source->new` - a new source.
- `$source->watch(%attributes)` - a new `Event::generic` watcher of this source, as `Event->generic(source => $source, %attributes)`.

A source lives as long as a reference to it does, and each of its watchers holds one, so it normally outlives them.

Differences from upstream

- A source destroyed while watchers still watch it - by calling its DESTROY directly - stops those watchers, as if their `source` were set to undef. Afterwards `event` on it queues nothing, its watchers cannot be started ("without source"), and perl's own later DESTROY of it is harmless. XS Event frees the source but leaves its watchers linked to the freed memory, and frees it a second time; perl aborts with "double free or corruption" (t/81-xs-native/Event/350-source-destroyed.t).

Synopsis

```
use Event;
use Event::generic;

my $jobs = Event::generic::Source->new;
$jobs->watch(cb => sub { run_job($_[0]->data) });
$jobs->event({ id => 1 });
Event::loop();
```

Functions

Sources

`allocate`

The constructor's primitive: a new source blessed into `$class`, with `$template` (a hash or array reference) as the object; `new` calls it with an empty hash. Dies "Bad template" when `$template` is no reference.

`event`

`$source->event` or `$source->event($data)`: queue one event on every active watcher of the source. A copy of `$data` (undef when omitted) becomes each event's `data`. Returns nothing.

Event::group

A group watcher: an event when none of its member watchers has run its callback for `timeout` seconds - a watchdog over a set of watchers.

`use Event` does not load this watcher type; `use Event::group` does (`Event->group` without it still works, with a warning that autoloading is deprecated).

`Event->group(%attributes)` (or `Event::group->new(...)`) takes the shared attributes of `Event::Watcher`, `timeout`, and any number of `add => $watcher` pairs; `del` there is ignored with a warning. A group repeats. It refuses to start without a callback, or without a `timeout` ("repeating group has no timeout").

Synopsis

```
use Event;
use Event::group;

my $in  = Event->io(fd => \*STDIN, cb => \&read_input);
my $tick = Event->timer(interval => 5, cb => \&poll_server);
Event->group(add => $in, add => $tick, timeout => 60,
             cb => sub { warn "nothing happened for a minute\n" });
Event::loop();
```

Functions

Attributes

timeout

Seconds of silence after which the group fires: a number, or a reference to a number. A negative value warns and counts as 0; anything else that is not a number dies.

add

`$group->add($watcher)` makes `$watcher` a member; returns nothing. Adding the group to itself dies "can't add group 'DESC' to itself".

del

`$group->del($watcher)` removes a member; returns nothing. A watcher that is not a member is ignored.

Event::idle

An idle watcher: an event when the loop has nothing else to do - no event queued, nothing arriving. `min` keeps it from firing more often than every so many seconds, and `max` makes it fire after that many seconds even if the loop never goes idle.

`Event->idle(%attributes)` (or `Event::idle->new(...)`) takes the shared attributes of `Event::Watcher` and the ones below. Given `min` or `max`, the watcher repeats; otherwise it fires once. `repeat` overrides either.

`Event::all_idle` lists the idle watchers waiting for the loop to go idle.

Synopsis

```
use Event;

Event->idle(min => 1, max => 10, cb => sub { flush_caches() });
Event::loop();
```

Functions

Attributes

hard

How the waiting time is reckoned when the watcher starts again after its callback: when true from the time the callback was called, when false (the default) from the time it returned.

max

The most seconds to wait for the loop to go idle; after that the watcher fires anyway, as an ordinary event at its priority. A number, a reference to a number, or undef (the default) for no limit.

min

The fewest seconds between two events of this watcher: it starts waiting for idleness only that long after it was started or its callback ran. A number, a reference to a number, or undef for no minimum; 0.01 by default.

Event::io

An io watcher: an event when a file descriptor is ready to read or to write, or has an exception pending - and, optionally, when it has been quiet for a given time. Its events are `Event::Event::Io` objects, whose `got` says what happened.

`Event->io(%attributes)` (or `Event::io->new(...)`) takes the shared attributes of `Event::Watcher` and the ones below. An io watcher repeats, and stays registered while its callback runs. Its default priority is `PRIO_NORMAL`. It refuses to start without a callback ("without io callback"), and with neither a descriptor to poll nor a timeout ("because there is nothing to watch").

One watcher can watch for several conditions, or several watchers can share a descriptor; both work.

The bit constants `R`, `W`, `E` and `T` can be imported from `Event::io` as well as from `Event::Watcher`.

Synopsis

```
use Event;

Event->io(fd => \*STDIN, poll => 'r', timeout => 30,
    cb => sub {
        my $e = shift;
        if ($e->got =~ /t/) { print "30 seconds without input\n";␣
↪return }
        defined(my $line = <STDIN>) or return Event::unloop();
        print "read: $line";
```

(continues on next page)

(continued from previous page)

```
    });
Event::loop();
```

Functions

Attributes

poll

What to wait for: a string of the letters `r` (read), `w` (write) and `e` (exception), or the number made of the bits `R`, `W` and `E`; `"r"` by default. Another letter warns "Ignored 'x' in poll mask" and other bits warn too. The value returned is both the string and the number. It includes `t` exactly when a `timeout` is set, whatever was asked.

fd

The descriptor to watch: a glob or glob reference (`\*STDIN`, an `IO::Handle` object), or a file descriptor number. Its descriptor is taken when the watcher starts; a glob without an open handle dies "isn't a valid IO", anything else "can't find fileno".

timeout

Seconds without a callback after which an event comes anyway, with `t` in its `got`; 0 or undef (the default) for none. Each callback restarts the count. A watcher that does not repeat fires the timeout once and then clears it.

timeout_cb

The callback for timeouts, in the forms `cb` takes; while it is undef (the default), timeouts go to `cb` too. Unlike `cb`, a `[$object, $method_name]` naming a method that does not exist is taken without a warning.

Event::signal

A signal watcher: an event when the process receives a signal.

`Event->signal(%attributes)` (or `Event::signal->new(...)`) takes the shared attributes of `Event::Watcher` and `signal`. A signal watcher repeats; its default priority is `PRIO_HIGH`. It refuses to start without a callback or a signal.

The signal handler only counts arrivals. The counts become events when the loop next looks (`Event::queue_pending`, which `loop`, `sweep` and `one_event` call), so signals can be handled later than, and out of order with, other events; several arrivals of a signal in between make one event whose `hits` is their number. The watchers that receive the event are the ones active when the counts are collected, not when the signal arrived.

A signal is handled either through `%SIG` or by Event, not both: while at least one watcher for it is active, Event's handler is installed directly, without `%SIG`; when the last one stops, the signal is set back to its default action.

Synopsis

```
use Event;

Event->signal(signal => 'HUP', cb => sub { reload_config() });
Event->signal(signal => 'INT', cb => sub { Event::unloop_all() });
Event::loop();
```

Functions

Attributes

signal

The signal, by its name without SIG (`'INT'`, `'HUP'`), as the keys of `%SIG`; it is returned under its main name. An unknown name dies "Unrecognized signal 'NAME'", and a signal that cannot be caught (`KILL`, `STOP`) dies "Signal 'NAME' cannot be caught". Changing it moves an active watcher to the new signal.

Event::timer

A timer watcher: an event at a given time, and optionally at every interval after it. Times are in the units of `Event::time` - seconds, fractional when Time::HiRes is loaded, which `use Event` does.

`Event->timer(%attributes)` (or `Event::timer->new(...)`) takes the shared attributes of `Event::Watcher`, the ones below, and `after`:

- `at => $time` - the first expiry.
- `after => $seconds` - the first expiry, that many seconds from now; also the `interval` when none is given. `at` and `after` together die "'after' and 'at' are mutually exclusive".
- `interval => $seconds` - repeat this often. Given alone, the first expiry is one interval from now.

A timer repeats when it was given `interval` (or `after`, which sets it), unless `repeat => 0` is given; otherwise it fires once. Its default priority is `PRIO_NORMAL`.

Synopsis

```
use Event;

Event->timer(after => 0.5, cb => sub { print "once\n" }, repeat =>␣
↪0);
Event->timer(interval => 1, cb => sub { print "every second\n" });
Event::loop();
```

Functions

Attributes

at

The time of the next expiry. Setting it moves an active timer to the new time.

hard

How a repeating timer reckons its next expiry: when true, one `interval` after the expiry just handled, so the timer keeps to its schedule however long the callback takes; when false (the default), one `interval` after the callback returned.

interval

Seconds between expiries: a number, or a reference to a number, which is then read at every expiry. A negative interval warns and counts as 0; anything else that is not a number dies.

Event::var

A var watcher: an event whenever a scalar variable is written to, or read. Its events are `Event::Event::Io` objects, whose `got` is `w` for a write and `r` for a read.

`Event->var(%attributes)` (or `Event::var->new(...)`) takes the shared attributes of `Event::Watcher` and the ones below. A var watcher repeats; its default priority is `PRIO_NORMAL`. It refuses to start without a callback, without a variable ("watching what?"), with an empty `poll`, or on a read-only variable.

Perl reads variables in more places than are apparent from the source, so watching reads is rarely what is wanted; the default is to watch writes only.

Synopsis

```
use Event;

my $status = 'idle';
Event->var(var => \$status, cb => sub { print "status: $status\n" }
 ↪);
Event->timer(after => 1, cb => sub { $status = 'busy' }, repeat =>␣
 ↪0);
Event::loop(2);
```

Functions

Attributes

var

The variable, as a reference to a plain scalar. A reference to an array, hash or anything else beyond a scalar dies "Var watchers can only watch plain vanilla scalars", and a value

that is no reference dies “Expecting a reference”. The watcher keeps the reference it was given.

poll

What to watch for: `"w"` (writes, the default), `"r"` (reads) or `"rw"`, or the number made of the bits `R` and `W` (see `Event::Watcher`). The value returned is both the string and the number.

one_event

`one_event($timeout)`: run one callback, waiting for an event if none is queued - at most `$timeout` seconds, 60 by default. Returns true if a callback ran. `loop` is built on it, but unlike `loop` it does not trap exceptions: a callback's `die` propagates out of `one_event`.

One round: turn counted signals into events; if an event of priority better than 5 is queued, run it and return; otherwise wait for descriptors and timers (no longer than the next timer and `$timeout`), queue what happened, turn signals into events again, run the best queued event if there is one, and otherwise run an idle watcher.

5.2.39 Exporter

Implements default import method for modules

SYNOPSIS

In module `YourModule.pm`:

```
package YourModule;
use Exporter 'import';
our @EXPORT_OK = qw(munge frobnicate);  # symbols to export on␣
↪request
```

or

```
package YourModule;
require Exporter;
our @ISA = qw(Exporter);  # inherit all of Exporter's methods
our @EXPORT_OK = qw(munge frobnicate);  # symbols to export on␣
↪request
```

or

```
package YourModule;
use parent 'Exporter';  # inherit all of Exporter's methods
our @EXPORT_OK = qw(munge frobnicate);  # symbols to export on␣
↪request
```

In other files which wish to use `YourModule`:

```
use YourModule qw(frobnicate);      # import listed symbols
frobnicate ($left, $right)          # calls YourModule::frobnicate
```

Take a look at “Good Practices” for some variants you will like to use in modern Perl code.

DESCRIPTION

The Exporter module implements an `import` method which allows a module to export functions and variables to its users' namespaces. Many modules use Exporter rather than implementing their own `import` method because Exporter provides a highly flexible interface, with an implementation optimised for the common case.

Perl automatically calls the `import` method when processing a `use` statement for a module. Modules and `use` are documented in *perlfunc* and perlmod. Understanding the concept of modules and how the `use` statement operates is important to understanding the Exporter.

How to Export

The arrays `@EXPORT` and `@EXPORT_OK` in a module hold lists of symbols that are going to be exported into the users name space by default, or which they can request to be exported, respectively. The symbols can represent functions, scalars, arrays, hashes, or typeglobs. The symbols must be given by full name with the exception that the ampersand in front of a function is optional, e.g.

```
our @EXPORT    = qw(afunc $scalar @array);   # afunc is a function
our @EXPORT_OK = qw(&bfunc %hash *typeglob); # explicit prefix on &
 ↪bfunc
```

If you are only exporting function names it is recommended to omit the ampersand, as the implementation is faster this way.

Selecting What to Export

Do **not** export method names!

Do **not** export anything else by default without a good reason!

Exports pollute the namespace of the module user. If you must export try to use `@EXPORT_OK` in preference to `@EXPORT` and avoid short or common symbol names to reduce the risk of name clashes.

Generally anything not exported is still accessible from outside the module using the `YourModule::item_name` (or `$blessed_ref->method`) syntax. By convention you can use a leading underscore on names to informally indicate that they are ‘internal’ and not for public use.

(It is actually possible to get private functions by saying:

```
my $subref = sub { ... };
$subref->(@args);             # Call it as a function
$obj->$subref(@args);         # Use it as a method
```

However if you use them for methods it is up to you to figure out how to make inheritance work.)

As a general rule, if the module is trying to be object oriented then export nothing. If it's just a collection of functions then `@EXPORT_OK` anything but use `@EXPORT` with caution. For function and method names use barewords in preference to names prefixed with ampersands for the export lists.

Other module design guidelines can be found in perlmod.

How to Import

In other files which wish to use your module there are three basic ways for them to load your module and import its symbols:

- `use YourModule;`

  This imports all the symbols from YourModule's `@EXPORT` into the namespace of the `use` statement.

- `use YourModule ();`

  This causes perl to load your module but does not import any symbols.

- `use YourModule qw(...);`

  This imports only the symbols listed by the caller into their namespace. All listed symbols must be in your `@EXPORT` or `@EXPORT_OK`, else an error occurs. The advanced export features of Exporter are accessed like this, but with list entries that are syntactically distinct from symbol names.

Unless you want to use its advanced features, this is probably all you need to know to use Exporter.

Advanced Features

Specialised Import Lists

If any of the entries in an import list begins with !, : or / then the list is treated as a series of specifications which either add to or delete from the list of names to import. They are processed left to right. Specifications are in the form:

```
[!]name         This name only
[!]:DEFAULT     All names in @EXPORT
[!]:tag         All names in $EXPORT_TAGS{tag} anonymous array
[!]/pattern/    All names in @EXPORT and @EXPORT_OK which match
```

A leading ! indicates that matching names should be deleted from the list of names to import. If the first specification is a deletion it is treated as though preceded by :DEFAULT. If you just want to import extra names in addition to the default set you will still need to include :DEFAULT explicitly.

e.g., `Module.pm` defines:

```
our @EXPORT      = qw(A1 A2 A3 A4 A5);
our @EXPORT_OK   = qw(B1 B2 B3 B4 B5);
```

(continues on next page)

(continued from previous page)

```
our %EXPORT_TAGS = (T1 => [qw(A1 A2 B1 B2)], T2 => [qw(A1 A2 B3␣
↪B4)]);
```

Note that you cannot use tags in @EXPORT or @EXPORT_OK.

Names in EXPORT_TAGS must also appear in @EXPORT or @EXPORT_OK.

An application using Module can say something like:

```
use Module qw(:DEFAULT :T2 !B3 A3);
```

Other examples include:

```
use Socket qw(!/^[AP]F_/ !SOMAXCONN !SOL_SOCKET);
use POSIX  qw(:errno_h :termios_h !TCSADRAIN !/^EXIT/);
```

Remember that most patterns (using //) will need to be anchored with a leading ^, e.g., `/^EXIT/` rather than `/EXIT/`.

You can say `BEGIN { $Exporter::Verbose=1 }` to see how the specifications are being processed and what is actually being imported into modules.

Exporting Without Using Exporter's import Method

Exporter has a special method, 'export_to_level' which is used in situations where you can't directly call Exporter's import method. The export_to_level method looks like:

```
MyPackage->export_to_level(
    $where_to_export, $package, @what_to_export
);
```

where `$where_to_export` is an integer telling how far up the calling stack to export your symbols, and `@what_to_export` is an array telling what symbols *to* export (usually this is `@_`). The `$package` argument is currently unused.

For example, suppose that you have a module, A, which already has an import function:

```
package A;

our @ISA = qw(Exporter);
our @EXPORT_OK = qw($b);

sub import
{
    $A::b = 1;     # not a very useful import method
}
```

and you want to Export symbol `$A::b` back to the module that called package A. Since Exporter relies on the import method to work, via inheritance, as it stands Exporter::import() will never get called. Instead, say the following:

```
package A;
our @ISA = qw(Exporter);
our @EXPORT_OK = qw($b);

sub import
{
    $A::b = 1;
    A->export_to_level(1, @_);
}
```

This will export the symbols one level 'above' the current package - ie: to the program or module that used package A.

Note: Be careful not to modify `@_` at all before you call export_to_level - or people using your package will get very unexplained results!

Exporting Without Inheriting from Exporter

By including Exporter in your `@ISA` you inherit an Exporter's import() method but you also inherit several other helper methods which you probably don't want and complicate the inheritance tree. To avoid this you can do:

```
package YourModule;
use Exporter qw(import);
```

which will export Exporter's own import() method into YourModule. Everything will work as before but you won't need to include Exporter in `@YourModule::ISA`.

Note: This feature was introduced in version 5.57 of Exporter, released with perl 5.8.3.

Module Version Checking

The Exporter module will convert an attempt to import a number from a module into a call to `$module_name->VERSION($value)`. This can be used to validate that the version of the module being used is greater than or equal to the required version.

For historical reasons, Exporter supplies a `require_version` method that simply delegates to `VERSION`. Originally, before `UNIVERSAL::VERSION` existed, Exporter would call `require_version`.

Since the `UNIVERSAL::VERSION` method treats the `$VERSION` number as a simple numeric value it will regard version 1.10 as lower than 1.9. For this reason it is strongly recommended that you use numbers with at least two decimal places, e.g., 1.09.

Managing Unknown Symbols

In some situations you may want to prevent certain symbols from being exported. Typically this applies to extensions which have functions or constants that may not exist on some systems.

The names of any symbols that cannot be exported should be listed in the `@EXPORT_FAIL` array.

If a module attempts to import any of these symbols the Exporter will give the module an opportunity to handle the situation before generating an error. The Exporter will call an export_fail method with a list of the failed symbols:

```
@failed_symbols = $module_name->export_fail(@failed_symbols);
```

If the `export_fail` method returns an empty list then no error is recorded and all the requested symbols are exported. If the returned list is not empty then an error is generated for each symbol and the export fails. The Exporter provides a default `export_fail` method which simply returns the list unchanged.

Uses for the `export_fail` method include giving better error messages for some symbols and performing lazy architectural checks (put more symbols into `@EXPORT_FAIL` by default and then take them out if someone actually tries to use them and an expensive check shows that they are usable on that platform).

Tag Handling Utility Functions

Since the symbols listed within `%EXPORT_TAGS` must also appear in either `@EXPORT` or `@EXPORT_OK`, two utility functions are provided which allow you to easily add tagged sets of symbols to `@EXPORT` or `@EXPORT_OK`:

```
our %EXPORT_TAGS = (foo => [qw(aa bb cc)], bar => [qw(aa cc dd)]);

Exporter::export_tags('foo');     # add aa, bb and cc to @EXPORT
Exporter::export_ok_tags('bar');  # add aa, cc and dd to @EXPORT_OK
```

Any names which are not tags are added to `@EXPORT` or `@EXPORT_OK` unchanged but will trigger a warning (with `-w`) to avoid misspelt tags names being silently added to `@EXPORT` or `@EXPORT_OK`. Future versions may make this a fatal error.

Generating Combined Tags

If several symbol categories exist in `%EXPORT_TAGS`, it's usually useful to create the utility ":all" to simplify "use" statements.

The simplest way to do this is:

```
our  %EXPORT_TAGS = (foo => [qw(aa bb cc)], bar => [qw(aa cc dd)]);

 # add all the other ":class" tags to the ":all" class,
 # deleting duplicates
 {
   my %seen;

   push @{$EXPORT_TAGS{all}},
     grep {!$seen{$_}++} @{$EXPORT_TAGS{$_}} foreach keys %EXPORT_
↪TAGS;
 }
```

`CGI.pm` creates an ":all" tag which contains some (but not really all) of its categories. That could be done with one small change:

```
# add some of the other ":class" tags to the ":all" class,
# deleting duplicates
{
  my %seen;

  push @{$EXPORT_TAGS{all}},
    grep {!$seen{$_}++} @{$EXPORT_TAGS{$_}}
      foreach qw/html2 html3 netscape form cgi internal/;
}
```

Note that the tag names in %EXPORT_TAGS don't have the leading ':'.

AUTOLOADed Constants

Many modules make use of AUTOLOADing for constant subroutines to avoid having to compile and waste memory on rarely used values (see *perlsub* for details on constant subroutines). Calls to such constant subroutines are not optimized away at compile time because they can't be checked at compile time for constancy.

Even if a prototype is available at compile time, the body of the subroutine is not (it hasn't been AUTOLOADed yet). perl needs to examine both the () prototype and the body of a subroutine at compile time to detect that it can safely replace calls to that subroutine with the constant value.

A workaround for this is to call the constants once in a BEGIN block:

```
package My ;

use Socket ;

foo( SO_LINGER );  ## SO_LINGER NOT optimized away; called at␣
 ↪runtime
BEGIN { SO_LINGER }
foo( SO_LINGER );  ## SO_LINGER optimized away at compile time.
```

This forces the AUTOLOAD for SO_LINGER to take place before SO_LINGER is encountered later in My package.

If you are writing a package that AUTOLOADs, consider forcing an AUTOLOAD for any constants explicitly imported by other packages or which are usually used when your package is used.

Good Practices

Declaring @EXPORT_OK and Friends

When using Exporter with the standard strict and warnings pragmas, the our keyword is needed to declare the package variables @EXPORT_OK, @EXPORT, @ISA, etc.

```
our @ISA = qw(Exporter);
our @EXPORT_OK = qw(munge frobnicate);
```

If backward compatibility for Perls **under** 5.6 is important, one must write instead a `use vars` statement.

```
use vars qw(@ISA @EXPORT_OK);
@ISA = qw(Exporter);
@EXPORT_OK = qw(munge frobnicate);
```

Playing Safe

There are some caveats with the use of runtime statements like `require Exporter` and the assignment to package variables, which can be very subtle for the unaware programmer. This may happen for instance with mutually recursive modules, which are affected by the time the relevant constructions are executed.

The ideal way to never have to think about that is to use `BEGIN` blocks and the simple import method. So the first part of the "SYNOPSIS" code could be rewritten as:

```
package YourModule;

use strict;
use warnings;

use Exporter 'import';
BEGIN {
  our @EXPORT_OK = qw(munge frobnicate);  # symbols to export on
 ↪request
}
```

Or if you need to inherit from Exporter:

```
package YourModule;

use strict;
use warnings;

BEGIN {
  require Exporter;
  our @ISA = qw(Exporter);  # inherit all of Exporter's methods
  our @EXPORT_OK = qw(munge frobnicate);  # symbols to export on
 ↪request
}
```

The `BEGIN` will assure that the loading of `Exporter.pm` and the assignments to `@ISA` and `@EXPORT_OK` happen immediately like `use`, leaving no room for something to get awry or just plain wrong.

With respect to loading `Exporter` and inheriting, there are alternatives with the use of modules like `base` and `parent`.

```
use base qw(Exporter);
# or
use parent qw(Exporter);
```

Any of these statements are nice replacements for `BEGIN { require Exporter; our @ISA = qw(Exporter); }` with the same compile-time effect. The basic difference is that `base` code interacts with declared `fields` while `parent` is a streamlined version of the older `base` code to just establish the IS-A relationship.

For more details, see the documentation and code of *base* and *parent*.

Another thorough remedy to that runtime vs. compile-time trap is to use Exporter::Easy, which is a wrapper of Exporter that allows all boilerplate code at a single gulp in the use statement.

```
use Exporter::Easy (
    OK => [ qw(munge frobnicate) ],
);
# @ISA setup is automatic
# all assignments happen at compile time
```

What Not to Export

You have been warned already in "Selecting What to Export" to not export:

- method names (because you don't need to and that's likely to not do what you want),
- anything by default (because you don't want to surprise your users... badly)
- anything you don't need to (because less is more)

There's one more item to add to this list. Do **not** export variable names. Just because `Exporter` lets you do that, it does not mean you should.

```
@EXPORT_OK = qw($svar @avar %hvar); # DON'T!
```

Exporting variables is not a good idea. They can change under the hood, provoking horrible effects at-a-distance that are too hard to track and to fix. Trust me: they are not worth it.

To provide the capability to set/get class-wide settings, it is best instead to provide accessors as subroutines or class methods instead.

SEE ALSO

`Exporter` is definitely not the only module with symbol exporter capabilities. At CPAN, you may find a bunch of them. Some are lighter. Some provide improved APIs and features. Pick the one that fits your needs. The following is a sample list of such modules.

```
Exporter::Easy
Exporter::Lite
Exporter::Renaming
Exporter::Tidy
Sub::Exporter / Sub::Installer
Perl6::Export / Perl6::Export::Attrs
```

Modules

- `Exporter::Heavy` - Exporter guts

Exporter::Heavy

Exporter guts

SYNOPSIS

(internal use only)

DESCRIPTION

No user-serviceable parts inside.

5.2.40 ExtUtils

Namespace containing the following modules:

- `ExtUtils::CBuilder` - Compile and link C code for Perl modules
- `ExtUtils::Command` - utilities to replace common UNIX commands in Makefiles etc.
- `ExtUtils::Embed` - Utilities for embedding Perl in C/C++ applications
- `ExtUtils::HasCompiler` - whether a distribution's compiled part will work (pperl)
- `ExtUtils::Install` - install files from here to there
- `ExtUtils::Installed` - Inventory management of installed modules
- `ExtUtils::Liblist` - determine libraries to use and how to use them
- `ExtUtils::MM` - OS adjusted ExtUtils::MakeMaker subclass
- `ExtUtils::MM_Any` - Platform-agnostic MM methods
- `ExtUtils::MM_Unix` - methods used by ExtUtils::MakeMaker
- `ExtUtils::MY` - ExtUtils::MakeMaker subclass for customization
- `ExtUtils::MakeMaker` - Create a module Makefile
- `ExtUtils::Manifest` - Utilities to write and check a MANIFEST file
- `ExtUtils::Miniperl` - write the C code for miniperlmain.c and perlmain.c
- `ExtUtils::PL2Bat` - Batch file creation to run perl scripts on Windows
- `ExtUtils::Packlist` - manage .packlist files
- `ExtUtils::testlib` - add blib/* directories to @INC

ExtUtils::CBuilder

Compile and link C code for Perl modules

SYNOPSIS

```
use ExtUtils::CBuilder;

my $b = ExtUtils::CBuilder->new(%options);
$obj_file = $b->compile(source => 'MyModule.c');
$lib_file = $b->link(objects => $obj_file);
```

DESCRIPTION

This module can build the C portions of Perl modules by invoking the appropriate compilers and linkers in a cross-platform manner. It was motivated by the `Module::Build` project, but may be useful for other purposes as well. However, it is *not* intended as a general cross-platform interface to all your C building needs. That would have been a much more ambitious goal!

METHODS

- new

  Returns a new `ExtUtils::CBuilder` object. A `config` parameter lets you override `Config.pm` settings for all operations performed by the object, as in the following example:

  ```
  # Use a different compiler than Config.pm says
  my $b = ExtUtils::CBuilder->new( config =>
                                   { ld => 'gcc' } );
  ```

  A `quiet` parameter tells `CBuilder` to not print its `system()` commands before executing them:

  ```
  # Be quieter than normal
  my $b = ExtUtils::CBuilder->new( quiet => 1 );
  ```

- have_compiler

  Returns true if the current system has a working C compiler and linker, false otherwise. To determine this, we actually compile and link a sample C library. The sample will be compiled in the system tempdir or, if that fails for some reason, in the current directory.

- have_cplusplus

  Just like have_compiler but for C++ instead of C.

- compile

  Compiles a C source file and produces an object file. The name of the object file is returned. The source file is specified in a `source` parameter, which is required; the other parameters listed below are optional.

- `object_file`

  Specifies the name of the output file to create. Otherwise the `object_file()` method will be consulted, passing it the name of the `source` file.

- `include_dirs`

  Specifies any additional directories in which to search for header files. May be given as a string indicating a single directory, or as a list reference indicating multiple directories.

- `extra_compiler_flags`

  Specifies any additional arguments to pass to the compiler. Should be given as a list reference containing the arguments individually, or if this is not possible, as a string containing all the arguments together.

- `C++`

  Specifies that the source file is a C++ source file and sets appropriate compiler flags

The operation of this method is also affected by the `archlibexp`, `cccdlflags`, `ccflags`, `optimize`, and `cc` entries in `Config.pm`.

- link

Invokes the linker to produce a library file from object files. In scalar context, the name of the library file is returned. In list context, the library file and any temporary files created are returned. A required `objects` parameter contains the name of the object files to process, either in a string (for one object file) or list reference (for one or more files). The following parameters are optional:

- lib_file

  Specifies the name of the output library file to create. Otherwise the `lib_file()` method will be consulted, passing it the name of the first entry in `objects`.

- module_name

  Specifies the name of the Perl module that will be created by linking. On platforms that need to do prelinking (Win32, OS/2, etc.) this is a required parameter.

- extra_linker_flags

  Any additional flags you wish to pass to the linker.

On platforms where `need_prelink()` returns true, `prelink()` will be called automatically.

The operation of this method is also affected by the `lddlflags`, `shrpenv`, and `ld` entries in `Config.pm`.

- link_executable

Invokes the linker to produce an executable file from object files. In scalar context, the name of the executable file is returned. In list context, the executable file and any temporary files created are returned. A required `objects` parameter contains the name of the object files to process, either in a string (for one object file) or list

reference (for one or more files). The optional parameters are the same as `link` with exception for

  - exe_file

    Specifies the name of the output executable file to create. Otherwise the `exe_file()` method will be consulted, passing it the name of the first entry in `objects`.

- object_file

```
my $object_file = $b->object_file($source_file);
```

Converts the name of a C source file to the most natural name of an output object file to create from it. For instance, on Unix the source file `foo.c` would result in the object file `foo.o`.

- lib_file

```
my $lib_file = $b->lib_file($object_file);
```

Converts the name of an object file to the most natural name of a output library file to create from it. For instance, on Mac OS X the object file `foo.o` would result in the library file `foo.bundle`.

- exe_file

```
my $exe_file = $b->exe_file($object_file);
```

Converts the name of an object file to the most natural name of an executable file to create from it. For instance, on Mac OS X the object file `foo.o` would result in the executable file `foo`, and on Windows it would result in `foo.exe`.

- prelink

On certain platforms like Win32, OS/2, VMS, and AIX, it is necessary to perform some actions before invoking the linker. The `ExtUtils::Mksymlists` module does this, writing files used by the linker during the creation of shared libraries for dynamic extensions. The names of any files written will be returned as a list.

Several parameters correspond to `ExtUtils::Mksymlists::Mksymlists()` options, as follows:

```
 Mksymlists()   prelink()          type
-------------|-------------------|-------------------
 NAME        |  dl_name          | string (required)
 DLBASE      |  dl_base          | string
 FILE        |  dl_file          | string
 DL_VARS     |  dl_vars          | array reference
 DL_FUNCS    |  dl_funcs         | hash reference
 FUNCLIST    |  dl_func_list     | array reference
 IMPORTS     |  dl_imports       | hash reference
 VERSION     |  dl_version       | string
```

Please see the documentation for `ExtUtils::Mksymlists` for the details of what these parameters do.

- need_prelink

  Returns true on platforms where `prelink()` should be called during linking, and false otherwise.

- extra_link_args_after_prelink

  Returns list of extra arguments to give to the link command; the arguments are the same as for prelink(), with addition of array reference to the results of prelink(); this reference is indexed by key `prelink_res`.

TO DO

Currently this has only been tested on Unix and doesn't contain any of the Windows-specific code from the `Module::Build` project. I'll do that next.

HISTORY

This module is an outgrowth of the `Module::Build` project, to which there have been many contributors. Notably, Randy W. Sims submitted lots of code to support 3 compilers on Windows and helped with various other platform-specific issues. Ilya Zakharevich has contributed fixes for OS/2; John E. Malmberg and Peter Prymmer have done likewise for VMS.

SUPPORT

ExtUtils::CBuilder is maintained as part of the Perl 5 core. Please submit any bug reports via the `perlbug` tool included with Perl 5. Bug reports will be included in the Perl 5 ticket system at https://rt.perl.org.

The Perl 5 source code is available at https://perl5.git.perl.org/perl.git and ExtUtils-CBuilder may be found in the `dist/ExtUtils-CBuilder` directory of the repository.

ExtUtils::Command

utilities to replace common UNIX commands in Makefiles etc.

SYNOPSIS

```
perl -MExtUtils::Command -e cat files... > destination
perl -MExtUtils::Command -e mv source... destination
perl -MExtUtils::Command -e cp source... destination
perl -MExtUtils::Command -e touch files...
perl -MExtUtils::Command -e rm_f files...
perl -MExtUtils::Command -e rm_rf directories...
perl -MExtUtils::Command -e mkpath directories...
perl -MExtUtils::Command -e eqtime source destination
perl -MExtUtils::Command -e test_f file
perl -MExtUtils::Command -e test_d directory
perl -MExtUtils::Command -e chmod mode files...
...
```

DESCRIPTION

The module is used to replace common UNIX commands. In all cases the functions work from @ARGV rather than taking arguments. This makes them easier to deal with in Makefiles. Call them like this:

```
perl -MExtUtils::Command -e some_command some files to work on
```

and *NOT* like this:

```
perl -MExtUtils::Command -e 'some_command qw(some files to work on)'
```

For that use Shell::Command.

Filenames with * and ? will be glob expanded.

FUNCTIONS

- cat

  ```
  cat file ...
  ```

  Concatenates all files mentioned on command line to STDOUT.

- eqtime

  ```
  eqtime source destination
  ```

  Sets modified time of destination to that of source.

- rm_rf

  ```
  rm_rf files or directories ...
  ```

Removes files and directories - recursively (even if readonly)

- rm_f

```
rm_f file ...
```

Removes files (even if readonly)

- touch

```
touch file ...
```

Makes files exist, with current timestamp

- mv

```
mv source_file destination_file
mv source_file source_file destination_dir
```

Moves source to destination. Multiple sources are allowed if destination is an existing directory.

Returns true if all moves succeeded, false otherwise.

- cp

```
cp source_file destination_file
cp source_file source_file destination_dir
```

Copies sources to the destination. Multiple sources are allowed if destination is an existing directory.

Returns true if all copies succeeded, false otherwise.

- chmod

```
chmod mode files ...
```

Sets UNIX like permissions 'mode' on all the files. e.g. 0666

- mkpath

```
mkpath directory ...
```

Creates directories, including any parent directories.

- test_f

```
test_f file
```

Tests if a file exists. *Exits* with 0 if it does, 1 if it does not (ie. shell's idea of true and false).

- test_d

```
test_d directory
```

Tests if a directory exists. *Exits* with 0 if it does, 1 if it does not (ie. shell's idea of true and false).

- dos2unix

```
dos2unix files or dirs ...
```

Converts DOS and OS/2 linefeeds to Unix style recursively.

SEE ALSO

Shell::Command which is these same functions but take arguments normally.

AUTHOR

Nick Ing-Simmons `ni-s@cpan.org`

Modules

- `ExtUtils::Command::MM` - Commands for the MM's to use in Makefiles

ExtUtils::Command::MM

Commands for the MM's to use in Makefiles

SYNOPSIS

```
perl "-MExtUtils::Command::MM" -e "function" "--" arguments...
```

DESCRIPTION

FOR INTERNAL USE ONLY! The interface is not stable.

ExtUtils::Command::MM encapsulates code which would otherwise have to be done with large "one" liners.

Any $(FOO) used in the examples are make variables, not Perl.

- **test_harness**

```
test_harness($verbose, @test_libs);
```

Runs the tests on @ARGV via Test::Harness passing through the $verbose flag. Any @test_libs will be unshifted onto the test's @INC.

@test_libs are run in alphabetical order.

- **pod2man**

```
pod2man( '--option=value',
         $podfile1 => $manpage1,
         $podfile2 => $manpage2,
         ...
       );

# or args on @ARGV
```

pod2man() is a function performing most of the duties of the pod2man program. Its arguments are exactly the same as pod2man as of 5.8.0 with the addition of:

```
--perm_rw   octal permission to set the resulting manpage to
```

And the removal of:

```
--verbose/-v
--help/-h
```

If no arguments are given to pod2man it will read from @ARGV.

If Pod::Man is unavailable, this function will warn and return undef.

- **warn_if_old_packlist**

```
perl "-MExtUtils::Command::MM" -e warn_if_old_packlist
 ↪<somefile>
```

Displays a warning that an old packlist file was found. Reads the filename from @ARGV.

- **perllocal_install**

```
perl "-MExtUtils::Command::MM" -e perllocal_install
    <type> <module name> <key> <value> ...

# VMS only, key|value pairs come on STDIN
perl "-MExtUtils::Command::MM" -e perllocal_install
    <type> <module name> < <key>|<value> ...
```

Prints a fragment of POD suitable for appending to perllocal.pod. Arguments are read from @ARGV.

'type' is the type of what you're installing. Usually 'Module'.

'module name' is simply the name of your module. (Foo::Bar)

Key/value pairs are extra information about the module. Fields include:

```
installed into      which directory your module was out into
LINKTYPE            dynamic or static linking
VERSION             module version number
EXE_FILES           any executables installed in a space␣
 ↪separated
                    list
```

- **uninstall**

```
perl "-MExtUtils::Command::MM" -e uninstall <packlist>
```

  A wrapper around ExtUtils::Install::uninstall(). Warns that uninstallation is deprecated and doesn't actually perform the uninstallation.

- **test_s**

```
perl "-MExtUtils::Command::MM" -e test_s <file>
```

  Tests if a file exists and is not empty (size > 0). *Exits* with 0 if it does, 1 if it does not.

- **cp_nonempty**

```
perl "-MExtUtils::Command::MM" -e cp_nonempty <srcfile>
↪<dstfile> <perm>
```

  Tests if the source file exists and is not empty (size > 0). If it is not empty it copies it to the given destination with the given permissions.

ExtUtils::Embed

Utilities for embedding Perl in C/C++ applications

SYNOPSIS

```
perl -MExtUtils::Embed -e xsinit
perl -MExtUtils::Embed -e ccopts
perl -MExtUtils::Embed -e ldopts
```

DESCRIPTION

`ExtUtils::Embed` provides utility functions for embedding a Perl interpreter and extensions in your C/C++ applications.
Typically, an application `Makefile` will invoke `ExtUtils::Embed` functions while building your application.

@EXPORT

`ExtUtils::Embed` exports the following functions:

xsinit(), ldopts(), ccopts(), perl_inc(), ccflags(), ccdlflags(), xsi_header(), xsi_protos(), xsi_body()

FUNCTIONS

- xsinit()

  When invoked as `` `perl -MExtUtils::Embed -e xsinit --` `` the following options are recognized:

  -o <output filename> (Defaults to **perlxsi.c**)

-o STDOUT will print to STDOUT.

-std (Write code for extensions that are linked with the current Perl.)

Any additional arguments are expected to be names of modules to generate code for.

When invoked with parameters the following are accepted and optional:

`xsinit($filename,$std,[@modules])`

Where,

$filename is equivalent to the **-o** option.

$std is boolean, equivalent to the **-std** option.

[@modules] is an array ref, same as additional arguments mentioned above.

- Examples

```
perl -MExtUtils::Embed -e xsinit -- -o xsinit.c Socket
```

This will generate code with an `xs_init` function that glues the perl `Socket::bootstrap` function to the C `boot_Socket` function and writes it to a file named `xsinit.c`.

Note that *DynaLoader* is a special case where it must call `boot_DynaLoader` directly.

```
perl -MExtUtils::Embed -e xsinit
```

This will generate code for linking with `DynaLoader` and each static extension found in `$Config{static_ext}`. The code is written to the default file name `perlxsi.c`.

```
perl -MExtUtils::Embed -e xsinit -- -o xsinit.c \
                            -std DBI DBD::Oracle
```

Here, code is written for all the currently linked extensions along with code for `DBI` and `DBD::Oracle`.

If you have a working `DynaLoader` then there is rarely any need to statically link in any other extensions.

- ldopts()

Output arguments for linking the Perl library and extensions to your application.

When invoked as `` `perl -MExtUtils::Embed -e ldopts --` `` the following options are recognized:

-std

Output arguments for linking the Perl library and any extensions linked with the current Perl.

-I <path1:path2>

Search path for ModuleName.a archives.
Default path is `@INC`. Library archives are expected to be found as `/some/path/auto/ModuleName/ModuleName.a` For example, when looking for `Socket.a` relative to a search path, we should find `auto/Socket/Socket.a`

When looking for `DBD::Oracle` relative to a search path, we should find `auto/DBD/Oracle/Oracle.a`

Keep in mind that you can always supply `/my/own/path/ModuleName.a` as an additional linker argument.

– <list of linker args>

Additional linker arguments to be considered.

Any additional arguments found before the – token are expected to be names of modules to generate code for.

When invoked with parameters the following are accepted and optional:

`ldopts($std,[@modules],[@link_args],$path)`

Where:

$std is boolean, equivalent to the **-std** option.

[@modules] is equivalent to additional arguments found before the – token.

[@link_args] is equivalent to arguments found after the – token.

$path is equivalent to the **-I** option.

In addition, when ldopts is called with parameters, it will return the argument string rather than print it to STDOUT.

- Examples

```
perl -MExtUtils::Embed -e ldopts
```

This will print arguments for linking with `libperl` and extensions found in `$Config{static_ext}`. This includes libraries found in `$Config{libs}` and the first ModuleName.a library for each extension that is found by searching `@INC` or the path specified by the **-I** option. In addition, when ModuleName.a is found, additional linker arguments are picked up from the `extralibs.ld` file in the same directory.

```
perl -MExtUtils::Embed -e ldopts -- -std Socket
```

This will do the same as the above example, along with printing additional arguments for linking with the `Socket` extension.

```
perl -MExtUtils::Embed -e ldopts -- -std Msql -- \
                       -L/usr/msql/lib -lmsql
```

Any arguments after the second '–' token are additional linker arguments that will be examined for potential conflict. If there is no conflict, the additional arguments will be part of the output.

- perl_inc()

For including perl header files this function simply prints:

```
-I$Config{archlibexp}/CORE
```

So, rather than having to say:

```
perl -MConfig -e 'print "-I$Config{archlibexp}/CORE"'
```

Just say:

```
perl -MExtUtils::Embed -e perl_inc
```

- ccflags(), ccdlflags()

  These functions simply print $Config{ccflags} and $Config{ccdlflags}

- ccopts()

  This function combines `perl_inc()`, `ccflags()` and `ccdlflags()` into one.

- xsi_header()

  This function simply returns a string defining the same `EXTERN_C` macro as `perlmain.c` along with #including `perl.h` and `EXTERN.h`.

- xsi_protos(@modules)

  This function returns a string of `boot_$ModuleName` prototypes for each @modules.

- xsi_body(@modules)

  This function returns a string of calls to `newXS()` that glue the module *bootstrap* function to *boot_ModuleName* for each @modules.

  `xsinit()` uses the xsi_* functions to generate most of its code.

EXAMPLES

For examples on how to use `ExtUtils::Embed` for building C/C++ applications with embedded perl, see perlembed.

ExtUtils::HasCompiler

whether a distribution's compiled part will work (pperl)

SYNOPSIS

```
use ExtUtils::HasCompiler 0.014 'can_compile_loadable_object';
die 'This distribution requires a working compiler'
    unless can_compile_loadable_object(quiet => 1);
```

DESCRIPTION

The interface of ExtUtils::HasCompiler 0.025. pperl builds no C: the compiled parts it supports are built into it. So each function answers true when every module the distribution in the current directory loads through `XSLoader::load` or `bootstrap` is built into pperl, and false otherwise.

FUNCTIONS

can_compile_loadable_object(%opts)

can_compile_static_library(%opts)

can_compile_extension(%opts)

All three give the same answer. Without `quiet => 1` they print it. Other options are accepted and ignored.

ExtUtils::Install

install files from here to there

SYNOPSIS

```
use ExtUtils::Install;

install({ 'blib/lib' => 'some/install/dir' } );

uninstall($packlist);

pm_to_blib({ 'lib/Foo/Bar.pm' => 'blib/lib/Foo/Bar.pm' });
```

VERSION

2.22

DESCRIPTION

Handles the installing and uninstalling of perl modules, scripts, man pages, etc...

Both install() and uninstall() are specific to the way ExtUtils::MakeMaker handles the installation and deinstallation of perl modules. They are not designed as general purpose tools.

On some operating systems such as Win32 installation may not be possible until after a reboot has occurred. This can have varying consequences: removing an old DLL does not impact programs using the new one, but if a new DLL cannot be installed properly until reboot then anything depending on it must wait. The package variable

```
$ExtUtils::Install::MUST_REBOOT
```

is used to store this status.

If this variable is true then such an operation has occurred and anything depending on this module cannot proceed until a reboot has occurred.

If this value is defined but false then such an operation has occurred, but should not impact later operations.

Functions

install

```
# deprecated forms
install(\%from_to);
install(\%from_to, $verbose, $dry_run, $uninstall_shadows,
            $skip, $always_copy, \%result);

# recommended form as of 1.47
install([
    from_to => \%from_to,
    verbose => 1,
    dry_run => 0,
    uninstall_shadows => 1,
    skip => undef,
    always_copy => 1,
    result => \%install_results,
]);
```

Copies each directory tree of %from_to to its corresponding value preserving timestamps and permissions.

There are two keys with a special meaning in the hash: “read” and “write”. These contain packlist files. After the copying is done, install() will write the list of target files to $from_to{write}. If $from_to{read} is given the contents of this file will be merged into the written file. The read and the written file may be identical, but on AFS it is quite likely that people are installing to a different directory than the one where the files later appear.

If $verbose is true, will print out each file removed. Default is false. This is “make install VERBINST=1”. $verbose values going up to 5 show increasingly more diagnostics output.

If $dry_run is true it will only print what it was going to do without actually doing it. Default is false.

If $uninstall_shadows is true any differing versions throughout @INC will be uninstalled. This is "make install UNINST=1"

As of 1.37_02 install() supports the use of a list of patterns to filter out files that shouldn't be installed. If $skip is omitted or undefined then install will try to read the list from INSTALL.SKIP in the CWD. This file is a list of regular expressions and is just like the MANIFEST.SKIP file used by *ExtUtils::Manifest*.

A default site INSTALL.SKIP may be provided by setting then environment variable EU_INSTALL_SITE_SKIPFILE, this will only be used when there isn't a distribution specific INSTALL.SKIP. If the environment variable EU_INSTALL_IGNORE_SKIP is true then no install file filtering will be performed.

If $skip is undefined then the skip file will be autodetected and used if it is found. If $skip is a reference to an array then it is assumed the array contains the list of patterns, if $skip is a true non reference it is assumed to be the filename holding the list of patterns, any other value of $skip is taken to mean that no install filtering should occur.

Changes As of Version 1.47

As of version 1.47 the following additions were made to the install interface. Note that the new argument style and use of the %result hash is recommended.

The $always_copy parameter which when true causes files to be updated regardless as to whether they have changed, if it is defined but false then copies are made only if the files have changed, if it is undefined then the value of the environment variable EU_INSTALL_ALWAYS_COPY is used as default.

The %result hash will be populated with the various keys/subhashes reflecting the install. Currently these keys and their structure are:

```
install             => { $target    => $source },
install_fail        => { $target    => $source },
install_unchanged   => { $target    => $source },

install_filtered    => { $source    => $pattern },

uninstall           => { $uninstalled => $source },
uninstall_fail      => { $uninstalled => $source },
```

where `$source` is the filespec of the file being installed. `$target` is where it is being installed to, and `$uninstalled` is any shadow file that is in `@INC` or `$ENV{PERL5LIB}` or other standard locations, and `$pattern` is the pattern that caused a source file to be skipped. In future more keys will be added, such as to show created directories, however this requires changes in other modules and must therefore wait.

These keys will be populated before any exceptions are thrown should there be an error.

Note that all updates of the %result are additive, the hash will not be cleared before use, thus allowing status results of many installs to be easily aggregated.

NEW ARGUMENT STYLE

If there is only one argument and it is a reference to an array then the array is assumed to

contain a list of key-value pairs specifying the options. In this case the option "from_to" is mandatory. This style means that you do not have to supply a cryptic list of arguments and can use a self documenting argument list that is easier to understand.

This is now the recommended interface to install().

RETURN

If all actions were successful install will return a hashref of the results as described above for the $result parameter. If any action is a failure then install will die, therefore it is recommended to pass in the $result parameter instead of using the return value. If the result parameter is provided then the returned hashref will be the passed in hashref.

install_default

DISCOURAGED

```
install_default();
install_default($fullext);
```

Calls install() with arguments to copy a module from blib/ to the default site installation location.

$fullext is the name of the module converted to a directory (ie. Foo::Bar would be Foo/Bar). If $fullext is not specified, it will attempt to read it from @ARGV.

This is primarily useful for install scripts.

NOTE This function is not really useful because of the hard-coded install location with no way to control site vs core vs vendor directories and the strange way in which the module name is given. Consider its use discouraged.

uninstall

```
uninstall($packlist_file);
uninstall($packlist_file, $verbose, $dont_execute);
```

Removes the files listed in a $packlist_file.

If $verbose is true, will print out each file removed. Default is false.

If $dont_execute is true it will only print what it was going to do without actually doing it. Default is false.

pm_to_blib

```
pm_to_blib(\%from_to);
pm_to_blib(\%from_to, $autosplit_dir);
pm_to_blib(\%from_to, $autosplit_dir, $filter_cmd);
```

Copies each key of %from_to to its corresponding value efficiently. If an $autosplit_dir is provided, all .pm files will be autosplit into it. Any destination directories are created.

$filter_cmd is an optional shell command to run each .pm file through prior to splitting and copying. Input is the contents of the module, output the new module contents.

You can have an environment variable PERL_INSTALL_ROOT set which will be prepended as a directory to each installed file (and directory).

By default verbose output is generated, setting the PERL_INSTALL_QUIET environment variable will silence this output.

ENVIRONMENT

- **PERL_INSTALL_ROOT**

  Will be prepended to each install path.

- **EU_INSTALL_IGNORE_SKIP**

  Will prevent the automatic use of INSTALL.SKIP as the install skip file.

- **EU_INSTALL_SITE_SKIPFILE**

  If there is no INSTALL.SKIP file in the make directory then this value can be used to provide a default.

- **EU_INSTALL_ALWAYS_COPY**

  If this environment variable is true then normal install processes will always overwrite older identical files during the install process.

  Note that the alias EU_ALWAYS_COPY will be supported if EU_INSTALL_ALWAYS_COPY is not defined until at least the 1.50 release. Please ensure you use the correct EU_INSTALL_ALWAYS_COPY.

AUTHOR

Original author lost in the mists of time. Probably the same as Makemaker.

Production release currently maintained by demerphq `yves at cpan.org`, extensive changes by Michael G. Schwern.

Send bug reports via http://rt.cpan.org/. Please send your generated Makefile along with your report.

ExtUtils::Installed

Inventory management of installed modules

SYNOPSIS

```
use ExtUtils::Installed;
my ($inst) = ExtUtils::Installed->new( skip_cwd => 1 );
my (@modules) = $inst->modules();
my (@missing) = $inst->validate("DBI");
my $all_files = $inst->files("DBI");
my $files_below_usr_local = $inst->files("DBI", "all", "/usr/local
 ↪");
my $all_dirs = $inst->directories("DBI");
my $dirs_below_usr_local = $inst->directory_tree("DBI", "prog");
my $packlist = $inst->packlist("DBI");
```

DESCRIPTION

ExtUtils::Installed provides a standard way to find out what core and module files have been installed. It uses the information stored in .packlist files created during installation to provide this information. In addition it provides facilities to classify the installed files and to extract directory information from the .packlist files.

USAGE

The new() function searches for all the installed .packlists on the system, and stores their contents. The .packlists can be queried with the functions described below. Where it searches by default is determined by the settings found in `%Config::Config`, and what the value is of the PERL5LIB environment variable.

METHODS

Unless specified otherwise all method can be called as class methods, or as object methods. If called as class methods then the "default" object will be used, and if necessary created using the current processes %Config and @INC. See the 'default' option to new() for details.

- new()

  This takes optional named parameters. Without parameters, this searches for all the installed .packlists on the system using information from `%Config::Config` and the default module search paths `@INC`. The packlists are read using the *ExtUtils::Packlist* module.

  If the named parameter `skip_cwd` is true, the current directory `.` will be stripped from `@INC` before searching for .packlists. This keeps ExtUtils::Installed from finding modules installed in other perls that happen to be located below the current directory.

  If the named parameter `config_override` is specified, it should be a reference to a hash which contains all information usually found in `%Config::Config`. For example, you can obtain the configuration information for a separate perl installation and pass that in.

  ```
  my $yoda_cfg  = get_fake_config('yoda');
  my $yoda_inst =
            ExtUtils::Installed->new(config_override=>$yoda_cfg);
  ```

Similarly, the parameter `inc_override` may be a reference to an array which is used in place of the default module search paths from `@INC`.

```
use Config;
my @dirs = split(/\Q$Config{path_sep}\E/, $ENV{PERL5LIB});
my $p5libs = ExtUtils::Installed->new(inc_override=>\@dirs);
```

Note: You probably do not want to use these options alone, almost always you will want to set both together.

The parameter `extra_libs` can be used to specify **additional** paths to search for installed modules. For instance

```
my $installed =
        ExtUtils::Installed->new(extra_libs=>["/my/lib/path"]);
```

This should only be necessary if `/my/lib/path` is not in PERL5LIB.

Finally there is the 'default', and the related 'default_get' and 'default_set' options. These options control the "default" object which is provided by the class interface to the methods. Setting `default_get` to true tells the constructor to return the default object if it is defined. Setting `default_set` to true tells the constructor to make the default object the constructed object. Setting the `default` option is like setting both to true. This is used primarily internally and probably isn't interesting to any real user.

- modules()

  This returns a list of the names of all the installed modules. The perl 'core' is given the special name 'Perl'.

- files()

  This takes one mandatory parameter, the name of a module. It returns a list of all the filenames from the package. To obtain a list of core perl files, use the module name 'Perl'. Additional parameters are allowed. The first is one of the strings "prog", "doc" or "all", to select either just program files, just manual files or all files. The remaining parameters are a list of directories. The filenames returned will be restricted to those under the specified directories.

- directories()

  This takes one mandatory parameter, the name of a module. It returns a list of all the directories from the package. Additional parameters are allowed. The first is one of the strings "prog", "doc" or "all", to select either just program directories, just manual directories or all directories. The remaining parameters are a list of directories. The directories returned will be restricted to those under the specified directories. This method returns only the leaf directories that contain files from the specified module.

- directory_tree()

  This is identical in operation to directories(), except that it includes all the intermediate directories back up to the specified directories.

- validate()

This takes one mandatory parameter, the name of a module. It checks that all the files listed in the modules .packlist actually exist, and returns a list of any missing files. If an optional second argument which evaluates to true is given any missing files will be removed from the .packlist

- packlist()

  This returns the ExtUtils::Packlist object for the specified module.

- version()

  This returns the version number for the specified module.

EXAMPLE

See the example in *ExtUtils::Packlist*.

ExtUtils::Liblist

determine libraries to use and how to use them

SYNOPSIS

```
require ExtUtils::Liblist;

$MM->ext($potential_libs, $verbose, $need_names);

# Usually you can get away with:
ExtUtils::Liblist->ext($potential_libs, $verbose, $need_names)
```

DESCRIPTION

This utility takes a list of libraries in the form `-llib1 -llib2 \-llib3` and returns lines suitable for inclusion in an extension Makefile. Extra library paths may be included with the form `-L/another/path` this will affect the searches for all subsequent libraries.

It returns an array of four or five scalar values: EXTRALIBS, BSLOADLIBS, LDLOADLIBS, LD_RUN_PATH, and, optionally, a reference to the array of the filenames of actual libraries. Some of these don't mean anything unless on Unix. See the details about those platform specifics below. The list of the filenames is returned only if $need_names argument is true.

Dependent libraries can be linked in one of three ways:

- For static extensions

  by the ld command when the perl binary is linked with the extension library. See EXTRALIBS below.

- For dynamic extensions at build/link time

  by the ld command when the shared object is built/linked. See LDLOADLIBS below.

- For dynamic extensions at load time

  by the DynaLoader when the shared object is loaded. See BSLOADLIBS below.

EXTRALIBS

List of libraries that need to be linked with when linking a perl binary which includes this extension. Only those libraries that actually exist are included. These are written to a file and used when linking perl.

LDLOADLIBS and LD_RUN_PATH

List of those libraries which can or must be linked into the shared library when created using ld. These may be static or dynamic libraries. LD_RUN_PATH is a colon separated list of the directories in LDLOADLIBS. It is passed as an environment variable to the process that links the shared library.

BSLOADLIBS

List of those libraries that are needed but can be linked in dynamically at run time on this platform. SunOS/Solaris does not need this because ld records the information (from LDLOADLIBS) into the object file. This list is used to create a .bs (bootstrap) file.

PORTABILITY

This module deals with a lot of system dependencies and has quite a few architecture specific `if`s in the code.

VMS implementation

The version of ext() which is executed under VMS differs from the Unix-OS/2 version in several respects:

- Input library and path specifications are accepted with or without the `-l` and `-L` prefixes used by Unix linkers. If neither prefix is present, a token is considered a directory to search if it is in fact a directory, and a library to search for otherwise. Authors who wish their extensions to be portable to Unix or OS/2 should use the Unix prefixes, since the Unix-OS/2 version of ext() requires them.
- Wherever possible, shareable images are preferred to object libraries, and object libraries to plain object files. In accordance with VMS naming conventions, ext() looks for files named _lib_shr and _lib_rtl; it also looks for *lib_lib and lib_lib* to accommodate Unix conventions used in some ported software.
- For each library that is found, an appropriate directive for a linker options file is generated. The return values are space-separated strings of these directives, rather than elements used on the linker command line.
- LDLOADLIBS contains both the libraries found based on `$potential_libs` and the CRTLs, if any, specified in Config.pm. EXTRALIBS contains just those libraries

found based on `$potential_libs`. BSLOADLIBS and LD_RUN_PATH are always empty.

In addition, an attempt is made to recognize several common Unix library names, and filter them out or convert them to their VMS equivalents, as appropriate.

In general, the VMS version of ext() should properly handle input from extensions originally designed for a Unix or VMS environment. If you encounter problems, or discover cases where the search could be improved, please let us know.

Win32 implementation

The version of ext() which is executed under Win32 differs from the Unix-OS/2 version in several respects:

- If `$potential_libs` is empty, the return value will be empty. Otherwise, the libraries specified by `$Config{perllibs}` (see Config.pm) will be appended to the list of `$potential_libs`. The libraries will be searched for in the directories specified in `$potential_libs`, `$Config{libpth}`, and in `$Config{installarchlib}/CORE`. For each library that is found, a space-separated list of fully qualified library pathnames is generated.
- Input library and path specifications are accepted with or without the `-l` and `-L` prefixes used by Unix linkers.

  An entry of the form `-La:\foo` specifies the `a:\foo` directory to look for the libraries that follow.

  An entry of the form `-lfoo` specifies the library `foo`, which may be spelled differently depending on what kind of compiler you are using. If you are using GCC, it gets translated to `libfoo.a`, but for other win32 compilers, it becomes `foo.lib`. If no files are found by those translated names, one more attempt is made to find them using either `foo.a` or `libfoo.lib`, depending on whether GCC or some other win32 compiler is being used, respectively.

  If neither the `-L` or `-l` prefix is present in an entry, the entry is considered a directory to search if it is in fact a directory, and a library to search for otherwise. The `$Config{lib_ext}` suffix will be appended to any entries that are not directories and don't already have the suffix.

  Note that the `-L` and `-l` prefixes are **not required**, but authors who wish their extensions to be portable to Unix or OS/2 should use the prefixes, since the Unix-OS/2 version of ext() requires them.
- Entries cannot be plain object files, as many Win32 compilers will not handle object files in the place of libraries.
- Entries in `$potential_libs` beginning with a colon and followed by alphanumeric characters are treated as flags. Unknown flags will be ignored.

  An entry that matches `/:nodefault/i` disables the appending of default libraries found in `$Config{perllibs}` (this should be only needed very rarely).

  An entry that matches `/:nosearch/i` disables all searching for the libraries specified after it. Translation of `-Lfoo` and `-lfoo` still happens as appropriate (depending on compiler being used, as reflected by `$Config{cc}`), but the entries are not verified to be valid files or directories.

An entry that matches `/:search/i` reenables searching for the libraries specified after it. You can put it at the end to enable searching for default libraries specified by `$Config{perllibs}`.

- The libraries specified may be a mixture of static libraries and import libraries (to link with DLLs). Since both kinds are used pretty transparently on the Win32 platform, we do not attempt to distinguish between them.
- LDLOADLIBS and EXTRALIBS are always identical under Win32, and BSLOADLIBS and LD_RUN_PATH are always empty (this may change in future).
- You must make sure that any paths and path components are properly surrounded with double-quotes if they contain spaces. For example, `$potential_libs` could be (literally):

```
"-Lc:\Program Files\vc\lib" msvcrt.lib "la test\foo bar.lib"
```

Note how the first and last entries are protected by quotes in order to protect the spaces.

- Since this module is most often used only indirectly from extension `Makefile.PL` files, here is an example `Makefile.PL` entry to add a library to the build process for an extension:

```
LIBS => ['-lgl']
```

When using GCC, that entry specifies that MakeMaker should first look for `libgl.a` (followed by `gl.a`) in all the locations specified by `$Config{libpth}`.

When using a compiler other than GCC, the above entry will search for `gl.lib` (followed by `libgl.lib`).

If the library happens to be in a location not in `$Config{libpth}`, you need:

```
LIBS => ['-Lc:\gllibs -lgl']
```

Here is a less often used example:

```
LIBS => ['-lgl', ':nosearch -Ld:\mesalibs -lmesa -luser32']
```

This specifies a search for library `gl` as before. If that search fails to find the library, it looks at the next item in the list. The `:nosearch` flag will prevent searching for the libraries that follow, so it simply returns the value as `-Ld:\mesalibs -lmesa -luser32`, since GCC can use that value as is with its linker.

When using the Visual C compiler, the second item is returned as `-libpath:d:\mesalibs mesa.lib user32.lib`.

When using the Borland compiler, the second item is returned as `-Ld:\mesalibs mesa.lib user32.lib`, and MakeMaker takes care of moving the `-Ld:\mesalibs` to the correct place in the linker command line.

SEE ALSO

ExtUtils::MakeMaker

ExtUtils::MM

OS adjusted ExtUtils::MakeMaker subclass

SYNOPSIS

```
require ExtUtils::MM;
my $mm = MM->new(...);
```

DESCRIPTION

FOR INTERNAL USE ONLY

ExtUtils::MM is a subclass of *ExtUtils::MakeMaker* which automatically chooses the appropriate OS specific subclass for you (ie. *ExtUtils::MM_Unix*, etc...).

It also provides a convenient alias via the MM class (I didn't want MakeMaker modules outside of ExtUtils/).

This class might turn out to be a temporary solution, but MM won't go away.

ExtUtils::MM_Any

Platform-agnostic MM methods

SYNOPSIS

```
FOR INTERNAL USE ONLY!

package ExtUtils::MM_SomeOS;

# Temporarily, you have to subclass both.  Put MM_Any first.
require ExtUtils::MM_Any;
require ExtUtils::MM_Unix;
@ISA = qw(ExtUtils::MM_Any ExtUtils::Unix);
```

DESCRIPTION

FOR INTERNAL USE ONLY!

ExtUtils::MM_Any is a superclass for the ExtUtils::MM_* set of modules. It contains methods which are either inherently cross-platform or are written in a cross-platform manner.

Subclass off of ExtUtils::MM_Any *and* *ExtUtils::MM_Unix*. This is a temporary solution.

THIS MAY BE TEMPORARY!

METHODS

Any methods marked *Abstract* must be implemented by subclasses.

Cross-platform helper methods

These are methods which help writing cross-platform code.

os_flavor *Abstract*

```
my @os_flavor = $mm->os_flavor;
```

@os_flavor is the style of operating system this is, usually corresponding to the MM_*.pm file we're using.

The first element of @os_flavor is the major family (ie. Unix, Windows, VMS, OS/2, etc...) and the rest are sub families.

Some examples:

```
Cygwin98       ('Unix',  'Cygwin', 'Cygwin9x')
Windows        ('Win32')
Win98          ('Win32', 'Win9x')
Linux          ('Unix',  'Linux')
MacOS X        ('Unix',  'Darwin', 'MacOS', 'MacOS X')
OS/2           ('OS/2')
```

This is used to write code for styles of operating system. See os_flavor_is() for use.

os_flavor_is

```
my $is_this_flavor = $mm->os_flavor_is($this_flavor);
my $is_this_flavor = $mm->os_flavor_is(@one_of_these_flavors);
```

Checks to see if the current operating system is one of the given flavors.

This is useful for code like:

```
if( $mm->os_flavor_is('Unix') ) {
    $out = `foo 2>&1`;
}
else {
    $out = `foo`;
}
```

can_load_xs

```
my $can_load_xs = $self->can_load_xs;
```

can_run

```
use ExtUtils::MM;
my $runnable = MM->can_run($Config{make});
```

If called in a scalar context it will return the full path to the binary you asked for if it was found, or `undef` if it was not.

If called in a list context, it will return a list of the full paths to instances of the binary where found in `PATH`, or an empty list if it was not found.

Copied from *IPC::Cmd*, but modified into a method (and removed `$INSTANCES` capability).

can_redirect_error

```
$useredirect = MM->can_redirect_error;
```

True if on an OS where qx operator (or backticks) can redirect `STDERR` onto `STDOUT`.

is_make_type

```
my $is_dmake = $self->is_make_type('dmake');
```

Returns true if `$self->make` is the given type; possibilities are:

```
gmake    GNU make
dmake
nmake
bsdmake  BSD pmake-derived
```

can_dep_space

```
my $can_dep_space = $self->can_dep_space;
```

Returns true if `make` can handle (probably by quoting) dependencies that contain a space. Currently known true for GNU make, false for BSD pmake derivative.

quote_dep

```
$text = $mm->quote_dep($text);
```

Method that protects Makefile single-value constants (mainly filenames), so that make will still treat them as single values even if they inconveniently have spaces in. If the make program being used cannot achieve such protection and the given text would need it, throws an exception.

split_command

```
my @cmds = $MM->split_command($cmd, @args);
```

Most OS have a maximum command length they can execute at once. Large modules can easily generate commands well past that limit. Its necessary to split long commands up into a series of shorter commands.

`split_command` will return a series of @cmds each processing part of the args. Collectively they will process all the arguments. Each individual line in @cmds will not be longer than the $self->max_exec_len being careful to take into account macro expansion.

$cmd should include any switches and repeated initial arguments. If it has newlines, they should be already escaped.

If no @args are given, no @cmds will be returned.

Pairs of arguments will always be preserved in a single command, this is a heuristic for things like pm_to_blib and pod2man which work on pairs of arguments. This makes things like this safe:

```
$self->split_command($cmd, %pod2man);
```

make_type

Returns a suitable string describing the type of makefile being written.

stashmeta

```
my @recipelines = $MM->stashmeta($text, $file);
```

Generates a set of `@recipelines` which will result in the literal `$text` ending up in literal `$file` when the recipe is executed. Call it once, with all the text you want in `$file`. Make macros will not be expanded, so the locations will be fixed at configure-time, not at build-time.

echo

```
my @commands = $MM->echo($text);
my @commands = $MM->echo($text, $file);
my @commands = $MM->echo($text, $file, \%opts);
```

Generates a set of @commands which print the $text to a $file.

If $file is not given, output goes to STDOUT.

If $opts{append} is true the $file will be appended to rather than overwritten. Default is to overwrite.

If $opts{allow_variables} is true, make variables of the form `$(...)` will not be escaped. Other $ will. Default is to escape all $.

Example of use:

```
my $make = join '', map "\t$_\n", $MM->echo($text, $file);
```

wraplist

```
my $args = $mm->wraplist(@list);
```

Takes an array of items and turns them into a well-formatted list of arguments. In most cases this is simply something like:

```
FOO \
BAR \
BAZ
```

maketext_filter

```
my $filter_make_text = $mm->maketext_filter($make_text);
```

The text of the Makefile is run through this method before writing to disk. It allows systems a chance to make portability fixes to the Makefile.

By default it does nothing.

This method is protected and not intended to be called outside of MakeMaker.

cd *Abstract*

```
my $subdir_cmd = $MM->cd($subdir, @cmds);
```

This will generate a make fragment which runs the @cmds in the given $dir. The rough equivalent to this, except cross platform.

```
cd $subdir && $cmd
```

Currently $dir can only go down one level. “foo” is fine. “foo/bar” is not. “../foo” is right out.

The resulting $subdir_cmd has no leading tab nor trailing newline. This makes it easier to embed in a make string. For example.

```
    my $make = sprintf <<'CODE', $subdir_cmd;
foo :
    $(ECHO) what
    %s
    $(ECHO) mouche
CODE
```

oneliner *Abstract*

```
my $oneliner = $MM->oneliner($perl_code);
my $oneliner = $MM->oneliner($perl_code, \@switches);
```

This will generate a perl one-liner safe for the particular platform you're on based on the given $perl_code and @switches (a -e is assumed) suitable for using in a make target. It will use the proper shell quoting and escapes.

$(PERLRUN) will be used as perl.

Any newlines in $perl_code will be escaped. Leading and trailing newlines will be stripped. Makes this idiom much easier:

```
    my $code = $MM->oneliner(<<'CODE', [...switches...]);
some code here
another line here
CODE
```

Usage might be something like:

```
# an echo emulation
$oneliner = $MM->oneliner('print "Foo\n"');
$make = '$oneliner > somefile';
```

Dollar signs in the $perl_code will be protected from make using the `quote_literal` method, unless they are recognised as being a make variable, `$(varname)`, in which case they will be left for make to expand. Remember to quote make macros else it might be used as a bareword. For example:

```
# Assign the value of the $(VERSION_FROM) make macro to $vf.
$oneliner = $MM->oneliner('$vf = "$(VERSION_FROM)"');
```

It's currently very simple, and may be expanded sometime in the future to include more flexible code and switches.

quote_literal *Abstract*

```
my $safe_text = $MM->quote_literal($text);
my $safe_text = $MM->quote_literal($text, \%options);
```

This will quote $text so it is interpreted literally in the shell.

For example, on Unix this would escape any single-quotes in $text and put single-quotes around the whole thing.

If $options{allow_variables} is true it will leave `'$(FOO)'` make variables untouched. If false they will be escaped like any other `$`. Defaults to true.

escape_dollarsigns

```
my $escaped_text = $MM->escape_dollarsigns($text);
```

Escapes stray $ so they are not interpreted as make variables.

It lets by $(...).

escape_all_dollarsigns

```
my $escaped_text = $MM->escape_all_dollarsigns($text);
```

Escapes all $ so they are not interpreted as make variables.

escape_newlines *Abstract*

```
my $escaped_text = $MM->escape_newlines($text);
```

Shell escapes newlines in $text.

max_exec_len *Abstract*

```
my $max_exec_len = $MM->max_exec_len;
```

Calculates the maximum command size the OS can exec. Effectively, this is the max size of a shell command line.

make

```
my $make = $MM->make;
```

Returns the make variant we're generating the Makefile for. This attempts to do some normalization on the information from %Config or the user.

Targets

These are methods which produce make targets.

all_target

Generate the default target 'all'.

blibdirs_target

```
my $make_frag = $mm->blibdirs_target;
```

Creates the blibdirs target which creates all the directories we use in blib/.

The blibdirs.ts target is deprecated. Depend on blibdirs instead.

clean (o)

Defines the clean target.

clean_subdirs_target

```
my $make_frag = $MM->clean_subdirs_target;
```

Returns the clean_subdirs target. This is used by the clean target to call clean on any subdirectories which contain Makefiles.

dir_target

```
my $make_frag = $mm->dir_target(@directories);
```

Generates targets to create the specified directories and set its permission to PERM_DIR.

Because depending on a directory to just ensure it exists doesn't work too well (the modified time changes too often) dir_target() creates a .exists file in the created directory. It is this you should depend on. For portability purposes you should use the $(DIRFILESEP) macro rather than a '/' to separate the directory from the file.

```
yourdirectory$(DIRFILESEP).exists
```

distdir

Defines the scratch directory target that will hold the distribution before tar-ing (or shar-ing).

dist_test

Defines a target that produces the distribution in the scratch directory, and runs 'perl Makefile.PL; make ;make test' in that subdirectory.

xs_dlsyms_arg

Returns command-line arg(s) to linker for file listing dlsyms to export. Defaults to returning empty string, can be overridden by e.g. AIX.

xs_dlsyms_ext

Returns file-extension for `xs_make_dlsyms` method's output file, including any "." character.

xs_dlsyms_extra

Returns any extra text to be prepended to the `$extra` argument of `xs_make_dlsyms`.

xs_dlsyms_iterator

Iterates over necessary shared objects, calling `xs_make_dlsyms` method for each with appropriate arguments.

xs_make_dlsyms

```
$self->xs_make_dlsyms(
    \%attribs, # hashref from %attribs in caller
    "$self->{BASEEXT}.def", # output file for Makefile target
    'Makefile.PL', # dependency
    $self->{NAME}, # shared object's "name"
    $self->{DLBASE}, # last ::-separated part of name
    $attribs{DL_FUNCS} || $self->{DL_FUNCS} || {}, # various params
    $attribs{FUNCLIST} || $self->{FUNCLIST} || [],
    $attribs{IMPORTS} || $self->{IMPORTS} || {},
    $attribs{DL_VARS} || $self->{DL_VARS} || [],
    # optional extra param that will be added as param to Mksymlists
);
```

Utility method that returns Makefile snippet to call `Mksymlists`.

dynamic (o)

Defines the dynamic target.

makemakerdflt_target

```
my $make_frag = $mm->makemakerdflt_target
```

Returns a make fragment with the makemakerdeflt_target specified. This target is the first target in the Makefile, is the default target and simply points off to 'all' just in case any make variant gets confused or something gets snuck in before the real 'all' target.

manifypods_target

```
my $manifypods_target = $self->manifypods_target;
```

Generates the manifypods target. This target generates man pages from all POD files in MAN1PODS and MAN3PODS.

metafile_target

```
my $target = $mm->metafile_target;
```

Generate the metafile target.

Writes the file META.yml (YAML encoded meta-data) and META.json (JSON encoded meta-data) about the module in the distdir. The format follows Module::Build's as closely as possible.

metafile_data

```
my $metadata_hashref = $mm->metafile_data(\%meta_add, \%meta_merge);
```

Returns the data which MakeMaker turns into the META.yml file and the META.json file. It is always in version 2.0 of the format.

Values of %meta_add will overwrite any existing metadata in those keys. %meta_merge will be merged with them.

metafile_file

```
my $meta_yml = $mm->metafile_file(@metadata_pairs);
```

Turns the @metadata_pairs into YAML.

This method does not implement a complete YAML dumper, being limited to dump a hash with values which are strings, undef's or nested hashes and arrays of strings. No quoting/escaping is done.

distmeta_target

```
my $make_frag = $mm->distmeta_target;
```

Generates the distmeta target to add META.yml and META.json to the MANIFEST in the distdir.

mymeta

```
my $mymeta = $mm->mymeta;
```

Generate MYMETA information as a hash either from an existing CPAN Meta file (META.json or META.yml) or from internal data.

write_mymeta

```
$self->write_mymeta( $mymeta );
```

Write MYMETA information to MYMETA.json and MYMETA.yml.

realclean (o)

Defines the realclean target.

realclean_subdirs_target

```
my $make_frag = $MM->realclean_subdirs_target;
```

Returns the realclean_subdirs target. This is used by the realclean target to call realclean on any subdirectories which contain Makefiles.

signature_target

```
my $target = $mm->signature_target;
```

Generate the signature target.

Writes the file SIGNATURE with “cpansign -s”.

distsignature_target

```
my $make_frag = $mm->distsignature_target;
```

Generates the distsignature target to add SIGNATURE to the MANIFEST in the distdir.

special_targets

```
my $make_frag = $mm->special_targets
```

Returns a make fragment containing any targets which have special meaning to make. For example, .SUFFIXES and .PHONY.

Init methods

Methods which help initialize the MakeMaker object and macros.

init_ABSTRACT

```
$mm->init_ABSTRACT
```

init_INST

```
$mm->init_INST;
```

Called by init_main. Those are handled in init_xs.

init_INSTALL

```
$mm->init_INSTALL;
```

Called by init_main. Sets up all INSTALL_* variables (except INSTALLDIRS) and *PREFIX.

init_INSTALL_from_PREFIX

```
$mm->init_INSTALL_from_PREFIX;
```

init_from_INSTALL_BASE

```
$mm->init_from_INSTALL_BASE
```

init_VERSION *Abstract*

```
$mm->init_VERSION
```

Initialize macros representing versions of MakeMaker and other tools

MAKEMAKER: path to the MakeMaker module.

MM_VERSION: ExtUtils::MakeMaker Version

MM_REVISION: ExtUtils::MakeMaker version control revision (for backwards compat)

VERSION: version of your module

VERSION_MACRO: which macro represents the version (usually 'VERSION')

VERSION_SYM: like version but safe for use as an RCS revision number

DEFINE_VERSION: -D line to set the module version when compiling

Defaults to $(VERSION)

Called by init_main.

init_tools

```
$MM->init_tools();
```

Initializes the simple macro definitions used by tools_other() and places them in the $MM object. These use conservative cross platform versions and should be overridden with platform specific versions for performance.

Defines at least these macros.

```
Macro             Description

NOOP              Do nothing
NOECHO            Tell make not to display the command itself

SHELL             Program used to run shell commands

ECHO              Print text adding a newline on the end
RM_F              Remove a file
RM_RF             Remove a directory
TOUCH             Update a file's timestamp
TEST_F            Test for a file's existence
TEST_S            Test the size of a file
CP                Copy a file
CP_NONEMPTY       Copy a file if it is not empty
MV                Move a file
```

(continues on next page)

(continued from previous page)

```
CHMOD             Change permissions on a file
FALSE             Exit with non-zero
TRUE              Exit with zero

UMASK_NULL        Nullify umask
DEV_NULL          Suppress all command output
```

init_others

```
$MM->init_others();
```

Initializes the macro definitions having to do with compiling and linking used by tools_other() and places them in the $MM object.

If there is no description, its the same as the parameter to WriteMakefile() documented in *ExtUtils::MakeMaker*.

tools_other

```
my $make_frag = $MM->tools_other;
```

Returns a make fragment containing definitions for the macros init_others() initializes.

init_DIRFILESEP *Abstract*

```
$MM->init_DIRFILESEP;
my $dirfilesep = $MM->{DIRFILESEP};
```

Initializes the DIRFILESEP macro which is the separator between the directory and filename in a filepath. ie. / on Unix, \ on Win32 and nothing on VMS.

For example:

```
# instead of $(INST_ARCHAUTODIR)/extralibs.ld
$(INST_ARCHAUTODIR)$(DIRFILESEP)extralibs.ld
```

Something of a hack but it prevents a lot of code duplication between MM_* variants.

Do not use this as a separator between directories. Some operating systems use different separators between subdirectories as between directories and filenames (for example: VOLUME:[dir1.dir2]file on VMS).

init_linker *Abstract*

```
$mm->init_linker;
```

Initialize macros which have to do with linking.

PERL_ARCHIVE: path to libperl.a equivalent to be linked to dynamic extensions.

PERL_ARCHIVE_AFTER: path to a library which should be put on the linker command line *after* the external libraries to be linked to dynamic extensions. This may be needed if the linker is one-pass, and Perl includes some overrides for C RTL functions, such as malloc().

EXPORT_LIST: name of a file that is passed to linker to define symbols to be exported.

Some OSes do not need these in which case leave it blank.

init_platform

```
$mm->init_platform
```

Initialize any macros which are for platform specific use only.

A typical one is the version number of your OS specific module. (ie. MM_Unix_VERSION or MM_VMS_VERSION).

init_MAKE

```
$mm->init_MAKE
```

Initialize MAKE from either a MAKE environment variable or $Config{make}.

Tools

A grab bag of methods to generate specific macros and commands.

manifypods

Defines targets and routines to translate the pods into manpages and put them into the INST_* directories.

POD2MAN_macro

```
my $pod2man_macro = $self->POD2MAN_macro
```

Returns a definition for the POD2MAN macro. This is a program which emulates the pod2man utility. You can add more switches to the command by simply appending them on the macro.

Typical usage:

```
$(POD2MAN) --section=3 --perm_rw=$(PERM_RW) podfile1 man_page1 ...
```

test_via_harness

```
my $command = $mm->test_via_harness($perl, $tests);
```

Returns a $command line which runs the given set of $tests with Test::Harness and the given $perl.

Used on the t/*.t files.

test_via_script

```
my $command = $mm->test_via_script($perl, $script);
```

Returns a $command line which just runs a single test without Test::Harness. No checks are done on the results, they're just printed.

Used for test.pl, since they don't always follow Test::Harness formatting.

tool_autosplit

Defines a simple perl call that runs autosplit. May be deprecated by pm_to_blib soon.

arch_check

```
my $arch_ok = $mm->arch_check(
    $INC{"Config.pm"},
    File::Spec->catfile($Config{archlibexp}, "Config.pm")
);
```

A sanity check that what Perl thinks the architecture is and what Config thinks the architecture is are the same. If they're not it will return false and show a diagnostic message.

When building Perl it will always return true, as nothing is installed yet.

The interface is a bit odd because this is the result of a quick refactoring. Don't rely on it.

File::Spec wrappers

ExtUtils::MM_Any is a subclass of *File::Spec*. The methods noted here override File::Spec.

catfile

File::Spec <= 0.83 has a bug where the file part of catfile is not canonicalized. This override fixes that bug.

Misc

Methods I can't really figure out where they should go yet.

find_tests

```
my $test = $mm->find_tests;
```

Returns a string suitable for feeding to the shell to return all tests in t/*.t.

find_tests_recursive

```
my $tests = $mm->find_tests_recursive;
```

Returns a string suitable for feeding to the shell to return all tests in t/ but recursively. Equivalent to

```
my $tests = $mm->find_tests_recursive_in('t');
```

find_tests_recursive_in

```
my $tests = $mm->find_tests_recursive_in($dir);
```

Returns a string suitable for feeding to the shell to return all tests in $dir recursively.

extra_clean_files

```
my @files_to_clean = $MM->extra_clean_files;
```

Returns a list of OS specific files to be removed in the clean target in addition to the usual set.

installvars

```
my @installvars = $mm->installvars;
```

A list of all the INSTALL* variables without the INSTALL prefix. Useful for iteration or building related variable sets.

libscan

```
my $wanted = $self->libscan($path);
```

Takes a path to a file or dir and returns an empty string if we don't want to include this file in the library. Otherwise it returns the the $path unchanged.

Mainly used to exclude version control administrative directories and base-level `README.pod` from installation.

platform_constants

```
my $make_frag = $mm->platform_constants
```

Returns a make fragment defining all the macros initialized in init_platform() rather than put them in constants().

post_constants (o)

Returns an empty string per default. Dedicated to overrides from within Makefile.PL after all constants have been defined.

post_initialize (o)

Returns an empty string per default. Used in Makefile.PLs to add some chunk of text to the Makefile after the object is initialized.

postamble (o)

Returns an empty string. Can be used in Makefile.PLs to write some text to the Makefile at the end.

AUTHOR

Michael G Schwern schwern@pobox.com and the denizens of makemaker@perl.org with code from ExtUtils::MM_Unix and ExtUtils::MM_Win32.

ExtUtils::MM_Unix

methods used by ExtUtils::MakeMaker

SYNOPSIS

```
require ExtUtils::MM_Unix;
```

DESCRIPTION

The methods provided by this package are designed to be used in conjunction with *ExtUtils::MakeMaker*. When MakeMaker writes a Makefile, it creates one or more objects that inherit their methods from a package *MM*. MM itself doesn't provide any methods, but it ISA ExtUtils::MM_Unix class. The inheritance tree of MM lets operating specific packages take the responsibility for all the methods provided by MM_Unix. We are trying to reduce the number of the necessary overrides by defining rather primitive operations within ExtUtils::MM_Unix.

If you are going to write a platform specific MM package, please try to limit the necessary overrides to primitive methods, and if it is not possible to do so, let's work out how to achieve that gain.

If you are overriding any of these methods in your Makefile.PL (in the MY class), please report that to the makemaker mailing list. We are trying to minimize the necessary method overrides and switch to data driven Makefile.PLs wherever possible. In the long run less methods will be overridable via the MY class.

METHODS

The following description of methods is still under development. Please refer to the code for not suitably documented sections and complain loudly to the makemaker@perl.org mailing list. Better yet, provide a patch.

Not all of the methods below are overridable in a Makefile.PL. Overridable methods are marked as (o). All methods are overridable by a platform specific MM_*.pm file.

Cross-platform methods are being moved into *MM_Any*. If you can't find something that used to be in here, look in MM_Any.

Methods

- os_flavor

  Simply says that we're Unix.

- c_o (o)

  Defines the suffix rules to compile different flavors of C files to object files.

- xs_obj_opt

  Takes the object file as an argument, and returns the portion of compile command-line that will output to the specified object file.

- dbgoutflag

  Returns a CC flag that tells the CC to emit a separate debugging symbol file when compiling an object file.

- cflags (o)

  Does very much the same as the cflags script in the perl distribution. It doesn't return the whole compiler command line, but initializes all of its parts. The const_cccmd method then actually returns the definition of the CCCMD macro which uses these parts.

- const_cccmd (o)

  Returns the full compiler call for C programs and stores the definition in CONST_CCCMD.

- const_config (o)

  Sets SHELL if needed, then defines a couple of constants in the Makefile that are imported from %Config.

- const_loadlibs (o)

  Defines EXTRALIBS, LDLOADLIBS, BSLOADLIBS, LD_RUN_PATH. See *ExtUtils::Liblist* for details.

- constants (o)

  ```
  my $make_frag = $mm->constants;
  ```

  Prints out macros for lots of constants.

- dep_constants (o)

```
my $make_frag = $mm->dep_constants;
```

Prints out macros for dependency constants.

- depend (o)

  Same as macro for the depend attribute.

- init_DEST

```
$mm->init_DEST
```

Defines the DESTDIR and DEST* variables paralleling the INSTALL*.

- init_dist

```
$mm->init_dist;
```

Defines a lot of macros for distribution support.

```
macro         description                     default

TAR           tar command to use              tar
TARFLAGS      flags to pass to TAR            cvf

ZIP           zip command to use              zip
ZIPFLAGS      flags to pass to ZIP            -r

COMPRESS      compression command to          gzip --best
              use for tarfiles
SUFFIX        suffix to put on                .gz
              compressed files

SHAR          shar command to use             shar

PREOP         extra commands to run before
              making the archive
POSTOP        extra commands to run after
              making the archive

TO_UNIX       a command to convert linefeeds
              to Unix style in your archive

CI            command to checkin your         ci -u
              sources to version control
RCS_LABEL     command to label your sources   rcs -Nv$(VERSION_
 ↪SYM): -q
              just after CI is run

DIST_CP       $how argument to manicopy()     best
              when the distdir is created

DIST_DEFAULT  default target to use to        tardist
```

(continues on next page)

(continued from previous page)

```
                create a distribution

DISTVNAME       name of the resulting archive   $(DISTNAME)-
 ↪$(VERSION)
                (minus suffixes)
```

- dist (o)

```
my $dist_macros = $mm->dist(%overrides);
```

Generates a make fragment defining all the macros initialized in init_dist.

- dist_basics (o)

Defines the targets distclean, distcheck, skipcheck, manifest, veryclean.

- dist_ci (o)

Defines a check in target for RCS.

- dist_core (o)

```
my $dist_make_fragment = $MM->dist_core;
```

Puts the targets necessary for 'make dist' together into one make fragment.

- **dist_target**

```
my $make_frag = $MM->dist_target;
```

Returns the 'dist' target to make an archive for distribution. This target simply checks to make sure the Makefile is up-to-date and depends on $(DIST_DEFAULT).

- **tardist_target**

```
my $make_frag = $MM->tardist_target;
```

Returns the 'tardist' target which is simply so 'make tardist' works. The real work is done by the dynamically named tardistfile_target() method, tardist should have that as a dependency.

- **zipdist_target**

```
my $make_frag = $MM->zipdist_target;
```

Returns the 'zipdist' target which is simply so 'make zipdist' works. The real work is done by the dynamically named zipdistfile_target() method, zipdist should have that as a dependency.

- **tarfile_target**

```
my $make_frag = $MM->tarfile_target;
```

The name of this target is the name of the tarball generated by tardist. This target does the actual work of turning the distdir into a tarball.

- zipfile_target

```
my $make_frag = $MM->zipfile_target;
```

The name of this target is the name of the zip file generated by zipdist. This target does the actual work of turning the distdir into a zip file.

- uutardist_target

```
my $make_frag = $MM->uutardist_target;
```

Converts the tarfile into a uuencoded file

- shdist_target

```
my $make_frag = $MM->shdist_target;
```

Converts the distdir into a shell archive.

- dlsyms (o)

Used by some OS' to define DL_FUNCS and DL_VARS and write the *.exp files.

Normally just returns an empty string.

- dynamic_bs (o)

Defines targets for bootstrap files.

- dynamic_lib (o)

Defines how to produce the *.so (or equivalent) files.

- xs_dynamic_lib_macros

Defines the macros for the `dynamic_lib` section.

- xs_make_dynamic_lib

Defines the recipes for the `dynamic_lib` section.

- exescan

Deprecated method. Use libscan instead.

- extliblist

Called by init_others, and calls ext ExtUtils::Liblist. See *ExtUtils::Liblist* for details.

- find_perl

Finds the executables PERL and FULLPERL

- fixin

```
$mm->fixin(@files);
```

Inserts the sharpbang or equivalent magic number to a set of @files.

- force (o)

Writes an empty FORCE: target.

- guess_name

  Guess the name of this package by examining the working directory's name. MakeMaker calls this only if the developer has not supplied a NAME attribute.

- has_link_code

  Does not descend into subdirectories as needs_linking() does.

  Under pperl this is always false. These two, needs_linking() and the strict.pm check in init_main() are the differences between this file and ExtUtils::MakeMaker's own.

- init_dirscan

  Called by init_main.

- init_MANPODS

  Determines if man pages should be generated and initializes MAN1PODS and MAN3PODS as appropriate.

- init_MAN1PODS

  Initializes MAN1PODS from the list of EXE_FILES.

- init_MAN3PODS

  Initializes MAN3PODS from the list of PM files.

- init_PM

  Initializes PMLIBDIRS and PM from PMLIBDIRS.

- init_DIRFILESEP

  Using / for Unix. Called by init_main.

- init_main

- init_tools

  Initializes tools to use their common (and faster) Unix commands.

- init_linker

  Unix has no need of special linker flags.

- init_PERL

```
$mm->init_PERL;
```

  Called by init_main. Sets up ABSPERL, PERL, FULLPERL and all the *PERLRUN* permutations.

```
PERL is allowed to be miniperl
FULLPERL must be a complete perl

ABSPERL is PERL converted to an absolute path

*PERLRUN contains everything necessary to run perl, find it's
     libraries, etc...
```

(continues on next page)

(continued from previous page)

```
*PERLRUNINST is *PERLRUN + everything necessary to find the
     modules being built.
```

- init_platform
- platform_constants

  Add MM_Unix_VERSION.
- init_PERM

```
$mm->init_PERM
```

  Called by init_main. Initializes PERL_*
- init_xs

```
$mm->init_xs
```

  Currently just INST_STATIC, INST_DYNAMIC and INST_BOOT.
- install (o)

  Defines the install target.
- installbin (o)

  Defines targets to make and to install EXE_FILES.
- linkext (o)

  Defines the linkext target which in turn defines the LINKTYPE.
- lsdir

  Takes as arguments a directory name and a regular expression. Returns all entries in the directory that match the regular expression.
- macro (o)

  Simple subroutine to insert the macros defined by the macro attribute into the Makefile.
- makeaperl (o)

  Called by staticmake. Defines how to write the Makefile to produce a static new perl.

  By default the Makefile produced includes all the static extensions in the perl library. (Purified versions of library files, e.g., DynaLoader_pure_p1_c0_032.a are automatically ignored to avoid link errors.)
- xs_static_lib_is_xs (o)

  Called by a utility method of makeaperl.
- makefile (o)

  Defines how to rewrite the Makefile.

- maybe_command

  Returns true, if the argument is likely to be a command.

- needs_linking (o)

  Does this module need linking? Looks into subdirectory objects (see also has_link_code())

  Under pperl nothing is linked, for the reason has_link_code() gives: neither this object nor a subdirectory's has link code, and there is no perl to relink (MAKEAPERL).

- parse_abstract

  parse a file and return what you think is the ABSTRACT

- parse_version

```
my $version = MM->parse_version($file);
```

  Parse a $file and return what $VERSION is set to by the first assignment. It will return the string "undef" if it can't figure out what $VERSION is. $VERSION should be for all to see, so `our $VERSION` or plain $VERSION are okay, but `my $VERSION` is not.

  `package Foo VERSION` is also checked for. The first version declaration found is used, but this may change as it differs from how Perl does it.

  parse_version() will try to `use version` before checking for `$VERSION` so the following will work.

```
$VERSION = qv(1.2.3);
```

- pasthru (o)

  Defines the string that is passed to recursive make calls in subdirectories. The variables like `PASTHRU_DEFINE` are used in each level, and passed downwards on the command-line with e.g. the value of that level's DEFINE. Example:

```
# Level 0 has DEFINE = -Dfunky
# This code will define level 0's PASTHRU=PASTHRU_DEFINE="
 ↪$(DEFINE)
#     $(PASTHRU_DEFINE)"
# Level 0's $(CCCMD) will include macros $(DEFINE) and
 ↪$(PASTHRU_DEFINE)
# So will level 1's, so when level 1 compiles, it will get␣
 ↪right values
# And so ad infinitum
```

- perl_script

  Takes one argument, a file name, and returns the file name, if the argument is likely to be a perl script. On MM_Unix this is true for any ordinary, readable file.

- perldepend (o)

  Defines the dependency from all *.h files that come with the perl distribution.

- pm_to_blib

  Defines target that copies all files in the hash PM to their destination and autosplits them. See *"DESCRIPTION" in ExtUtils::Install*

- ppd

  Defines target that creates a PPD (Perl Package Description) file for a binary distribution.

- prefixify

```
$MM->prefixify($var, $prefix, $new_prefix, $default);
```

  Using either $MM->{uc $var} || $Config{lc $var}, it will attempt to replace it's $prefix with a $new_prefix.

  Should the $prefix fail to match *AND* a PREFIX was given as an argument to WriteMakefile() it will set it to the $new_prefix + $default. This is for systems whose file layouts don't neatly fit into our ideas of prefixes.

  This is for heuristics which attempt to create directory structures that mirror those of the installed perl.

  For example:

```
$MM->prefixify('installman1dir', '/usr', '/home/foo', 'man/man1
 ↪');
```

  this will attempt to remove '/usr' from the front of the $MM->{INSTALLMAN1DIR} path (initializing it to $Config{installman1dir} if necessary) and replace it with '/home/foo'. If this fails it will simply use '/home/foo/man/man1'.

- processPL (o)

  Defines targets to run *.PL files.

- specify_shell

  Specify SHELL if needed - not done on Unix.

- quote_paren

  Backslashes parentheses `()` in command line arguments. Doesn't handle recursive Makefile `$(...)` constructs, but handles simple ones.

- replace_manpage_separator

```
my $man_name = $MM->replace_manpage_separator($file_path);
```

  Takes the name of a package, which may be a nested package, in the form 'Foo/Bar.pm' and replaces the slash with `::` or something else safe for a man page file name. Returns the replacement.

- cd

  On BSD make, will add a countervailing `cd ..` on each command since parallel builds run all the commands in a recipe in the same shell.

- oneliner

- quote_literal

  Quotes macro literal value suitable for being used on a command line so that when expanded by make, will be received by command as given to this method:

```
my $quoted = $mm->quote_literal(q{it isn't});
# returns:
#   'it isn'\''t'
print MAKEFILE "target:\n\techo $quoted\n";
# when run "make target", will output:
#   it isn't
```

- escape_newlines
- max_exec_len

  Using *POSIX*::ARG_MAX. Otherwise falling back to 4096.

- static (o)

  Defines the static target.

- xs_make_static_lib

  Defines the recipes for the `static_lib` section.

- static_lib_closures

  Records `$(EXTRALIBS)` in `extralibs.ld` and `$(PERL_SRC)/ext.libs`.

- static_lib_fixtures

  Handles copying `$(MYEXTLIB)` as starter for final static library that then gets added to.

- static_lib_pure_cmd

  Defines how to run the archive utility.

- staticmake (o)

  Calls makeaperl.

- subdir_x (o)

  Helper subroutine for subdirs

- subdirs (o)

  Defines targets to process subdirectories.

- test (o)

  Defines the test targets.

- test_via_harness (override)

  For some reason which I forget, Unix machines like to have PERL_DL_NONLAZY set for tests.

- test_via_script (override)

  Again, the PERL_DL_NONLAZY thing.

- tool_xsubpp (o)

  Determines typemaps, xsubpp version, prototype behaviour.

- all_target

  Build man pages, too

- top_targets (o)

  Defines the targets all, subdirs, config, and O_FILES

- writedoc

  Obsolete, deprecated method. Not used since Version 5.21.

- xs_c (o)
- xs_cpp (o)
- xs_o (o)

SEE ALSO

ExtUtils::MakeMaker

ExtUtils::MY

ExtUtils::MakeMaker subclass for customization

SYNOPSIS

```
# in your Makefile.PL
sub MY::whatever {
    ...
}
```

DESCRIPTION

FOR INTERNAL USE ONLY

ExtUtils::MY is a subclass of *ExtUtils::MM*. It is provided in your Makefile.PL for you to add and override MakeMaker functionality.

It also provides a convenient alias via the MY class.

ExtUtils::MY might turn out to be a temporary solution, but MY won't go away.

ExtUtils::MakeMaker

Create a module Makefile

SYNOPSIS

```
use ExtUtils::MakeMaker;

WriteMakefile(
    NAME              => "Foo::Bar",
    VERSION_FROM      => "lib/Foo/Bar.pm",
);
```

DESCRIPTION

This utility is designed to write a Makefile for an extension module from a Makefile.PL. It is based on the Makefile.SH model provided by Andy Dougherty and the perl5-porters.

It splits the task of generating the Makefile into several subroutines that can be individually overridden. Each subroutine returns the text it wishes to have written to the Makefile.

As there are various Make programs with incompatible syntax, which use operating system shells, again with incompatible syntax, it is important for users of this module to know which flavour of Make a Makefile has been written for so they'll use the correct one and won't have to face the possibly bewildering errors resulting from using the wrong one.

On POSIX systems, that program will likely be GNU Make; on Microsoft Windows, it will be either Microsoft NMake, DMake or GNU Make. See the section on the "MAKE" parameter for details.

ExtUtils::MakeMaker (EUMM) is object oriented. Each directory below the current directory that contains a Makefile.PL is treated as a separate object. This makes it possible to write an unlimited number of Makefiles with a single invocation of WriteMakefile().

All inputs to WriteMakefile are Unicode characters, not just octets. EUMM seeks to handle all of these correctly. It is currently still not possible to portably use Unicode characters in module names, because this requires Perl to handle Unicode filenames, which is not yet the case on Windows.

See ExtUtils::MakeMaker::FAQ for details of the design and usage.

How To Write A Makefile.PL

See ExtUtils::MakeMaker::Tutorial.

The long answer is the rest of the manpage :-)

Default Makefile Behaviour

The generated Makefile enables the user of the extension to invoke

```
perl Makefile.PL # optionally "perl Makefile.PL verbose"
make
make test        # optionally set TEST_VERBOSE=1
make install     # See below
```

The Makefile to be produced may be altered by adding arguments of the form KEY=VALUE. E.g.

```
perl Makefile.PL INSTALL_BASE=~
```

Other interesting targets in the generated Makefile are

```
make config     # to check if the Makefile is up-to-date
make clean      # delete local temp files (Makefile gets renamed)
make realclean  # delete derived files (including ./blib)
make ci         # check in all the files in the MANIFEST file
make dist       # see below the Distribution Support section
```

make test

MakeMaker checks for the existence of a file named `test.pl` in the current directory, and if it exists it executes the script with the proper set of perl `-I` options.

MakeMaker also checks for any files matching glob("t/*.t"). It will execute all matching files in alphabetical order via the *Test::Harness* module with the `-I` switches set correctly.

You can also organize your tests within subdirectories in the `t/` directory. To do so, use the `test` directive in your *Makefile.PL*. For example, if you had tests in:

```
t/foo
t/foo/bar
```

You could tell make to run tests in both of those directories with the following directives:

```
test => {TESTS => 't/*/*.t t/*/*/*.t'}
test => {TESTS => 't/foo/*.t t/foo/bar/*.t'}
```

The first will run all test files in all first-level subdirectories and all subdirectories they contain. The second will run tests in only the `t/foo` and `t/foo/bar`.

If you'd like to see the raw output of your tests, set the `TEST_VERBOSE` variable to true.

```
make test TEST_VERBOSE=1
```

If you want to run particular test files, set the `TEST_FILES` variable. It is possible to use globbing with this mechanism.

```
make test TEST_FILES='t/foobar.t t/dagobah*.t'
```

Windows users who are using `nmake` should note that due to a bug in `nmake`, when specifying `TEST_FILES` you must use back-slashes instead of forward-slashes.

```
nmake test TEST_FILES='t\foobar.t t\dagobah*.t'
```

make testdb

A useful variation of the above is the target `testdb`. It runs the test under the Perl debugger (see perldebug). If the file `test.pl` exists in the current directory, it is used for the test.

If you want to debug some other testfile, set the `TEST_FILE` variable thusly:

```
make testdb TEST_FILE=t/mytest.t
```

By default the debugger is called using `-d` option to perl. If you want to specify some other option, set the `TESTDB_SW` variable:

```
make testdb TESTDB_SW=-Dx
```

make install

make alone puts all relevant files into directories that are named by the macros INST_LIB, INST_ARCHLIB, INST_SCRIPT, INST_MAN1DIR and INST_MAN3DIR. All these default to something below ./blib if you are *not* building below the perl source directory. If you *are* building below the perl source, INST_LIB and INST_ARCHLIB default to ../../lib, and INST_SCRIPT is not defined.

The *install* target of the generated Makefile copies the files found below each of the INST_* directories to their INSTALL* counterparts. Which counterparts are chosen depends on the setting of INSTALLDIRS according to the following table:

```
                             INSTALLDIRS set to
                        perl         site          vendor

               PERLPREFIX      SITEPREFIX          VENDORPREFIX
INST_ARCHLIB   INSTALLARCHLIB  INSTALLSITEARCH     INSTALLVENDORARCH
INST_LIB       INSTALLPRIVLIB  INSTALLSITELIB      INSTALLVENDORLIB
INST_BIN       INSTALLBIN      INSTALLSITEBIN      INSTALLVENDORBIN
INST_SCRIPT    INSTALLSCRIPT   INSTALLSITESCRIPT   ␣
 ↪INSTALLVENDORSCRIPT
INST_MAN1DIR   INSTALLMAN1DIR  INSTALLSITEMAN1DIR ␣
 ↪INSTALLVENDORMAN1DIR
INST_MAN3DIR   INSTALLMAN3DIR  INSTALLSITEMAN3DIR ␣
 ↪INSTALLVENDORMAN3DIR
```

The INSTALL... macros in turn default to their %Config ($Config{installprivlib}, $Config{installarchlib}, etc.) counterparts.

You can check the values of these variables on your system with

```
perl '-V:install.*'
```

And to check the sequence in which the library directories are searched by perl, run

```
perl -le 'print join $/, @INC'
```

Sometimes older versions of the module you're installing live in other directories in @INC. Because Perl loads the first version of a module it finds, not the newest, you might

accidentally get one of these older versions even after installing a brand new version. To delete *all other versions of the module you're installing* (not simply older ones) set the `UNINST` variable.

```
make install UNINST=1
```

INSTALL_BASE

INSTALL_BASE can be passed into Makefile.PL to change where your module will be installed. INSTALL_BASE is more like what everyone else calls "prefix" than PREFIX is.

To have everything installed in your home directory, do the following.

```
# Unix users, INSTALL_BASE=~ works fine
perl Makefile.PL INSTALL_BASE=/path/to/your/home/dir
```

Like PREFIX, it sets several INSTALL* attributes at once. Unlike PREFIX it is easy to predict where the module will end up. The installation pattern looks like this:

```
INSTALLARCHLIB     INSTALL_BASE/lib/perl5/$Config{archname}
INSTALLPRIVLIB     INSTALL_BASE/lib/perl5
INSTALLBIN         INSTALL_BASE/bin
INSTALLSCRIPT      INSTALL_BASE/bin
INSTALLMAN1DIR     INSTALL_BASE/man/man1
INSTALLMAN3DIR     INSTALL_BASE/man/man3
```

INSTALL_BASE in MakeMaker and `--install_base` in Module::Build (as of 0.28) install to the same location. If you want MakeMaker and Module::Build to install to the same location simply set INSTALL_BASE and `--install_base` to the same location.

INSTALL_BASE was added in 6.31.

PREFIX and LIB attribute

PREFIX and LIB can be used to set several INSTALL* attributes in one go. Here's an example for installing into your home directory.

```
# Unix users, PREFIX=~ works fine
perl Makefile.PL PREFIX=/path/to/your/home/dir
```

This will install all files in the module under your home directory, with man pages and libraries going into an appropriate place (usually ~/man and ~/lib). How the exact location is determined is complicated and depends on how your Perl was configured. INSTALL_BASE works more like what other build systems call "prefix" than PREFIX and we recommend you use that instead.

Another way to specify many INSTALL directories with a single parameter is LIB.

```
perl Makefile.PL LIB=~/lib
```

This will install the module's architecture-independent files into ~/lib, the architecture-dependent files into ~/lib/$archname.

Note, that in both cases the tilde expansion is done by MakeMaker, not by perl by default, nor by make.

Conflicts between parameters LIB, PREFIX and the various INSTALL* arguments are resolved so that:

- setting LIB overrides any setting of INSTALLPRIVLIB, INSTALLARCHLIB, INSTALLSITELIB, INSTALLSITEARCH (and they are not affected by PREFIX);
- without LIB, setting PREFIX replaces the initial `$Config{prefix}` part of those INSTALL* arguments, even if the latter are explicitly set (but are set to still start with `$Config{prefix}`).

If the user has superuser privileges, and is not working on AFS or relatives, then the defaults for INSTALLPRIVLIB, INSTALLARCHLIB, INSTALLSCRIPT, etc. will be appropriate, and this incantation will be the best:

```
perl Makefile.PL;
make;
make test
make install
```

make install by default writes some documentation of what has been done into the file `$(INSTALLARCHLIB)/perllocal.pod`. This feature can be bypassed by calling make pure_install.

AFS users

will have to specify the installation directories as these most probably have changed since perl itself has been installed. They will have to do this by calling

```
perl Makefile.PL INSTALLSITELIB=/afs/here/today \
    INSTALLSCRIPT=/afs/there/now INSTALLMAN3DIR=/afs/for/manpages
make
```

Be careful to repeat this procedure every time you recompile an extension, unless you are sure the AFS installation directories are still valid.

Static Linking of a new Perl Binary

An extension that is built with the above steps is ready to use on systems supporting dynamic loading. On systems that do not support dynamic loading, any newly created extension has to be linked together with the available resources. MakeMaker supports the linking process by creating appropriate targets in the Makefile whenever an extension is built. You can invoke the corresponding section of the makefile with

```
make perl
```

That produces a new perl binary in the current directory with all extensions linked in that can be found in INST_ARCHLIB, SITELIBEXP, and PERL_ARCHLIB. To do that, MakeMaker writes a new Makefile, on UNIX, this is called `Makefile.aperl` (may be system dependent). If you want to force the creation of a new perl, it is recommended that you delete this `Makefile.aperl`, so the directories are searched through for linkable libraries again.

The binary can be installed into the directory where perl normally resides on your machine with

```
make inst_perl
```

To produce a perl binary with a different name than `perl`, either say

```
perl Makefile.PL MAP_TARGET=myperl
make myperl
make inst_perl
```

or say

```
perl Makefile.PL
make myperl MAP_TARGET=myperl
make inst_perl MAP_TARGET=myperl
```

In any case you will be prompted with the correct invocation of the `inst_perl` target that installs the new binary into INSTALLBIN.

make inst_perl by default writes some documentation of what has been done into the file `$(INSTALLARCHLIB)/perllocal.pod`. This can be bypassed by calling make pure_inst_perl.

Warning: the inst_perl: target will most probably overwrite your existing perl binary. Use with care!

Sometimes you might want to build a statically linked perl although your system supports dynamic loading. In this case you may explicitly set the linktype with the invocation of the Makefile.PL or make:

```
perl Makefile.PL LINKTYPE=static    # recommended
```

or

```
make LINKTYPE=static                # works on most systems
```

Determination of Perl Library and Installation Locations

MakeMaker needs to know, or to guess, where certain things are located. Especially INST_LIB and INST_ARCHLIB (where to put the files during the make(1) run), PERL_LIB and PERL_ARCHLIB (where to read existing modules from), and PERL_INC (header files and `libperl*.*`).

Extensions may be built either using the contents of the perl source directory tree or from the installed perl library. The recommended way is to build extensions after you have run 'make install' on perl itself. You can do that in any directory on your hard disk that is not below the perl source tree. The support for extensions below the ext directory of the perl distribution is only good for the standard extensions that come with perl.

If an extension is being built below the `ext/` directory of the perl source then MakeMaker will set PERL_SRC automatically (e.g., `../..`). If PERL_SRC is defined and the extension is recognized as a standard extension, then other variables default to the following:

```
PERL_INC     = PERL_SRC
PERL_LIB     = PERL_SRC/lib
PERL_ARCHLIB = PERL_SRC/lib
INST_LIB     = PERL_LIB
INST_ARCHLIB = PERL_ARCHLIB
```

If an extension is being built away from the perl source then MakeMaker will leave PERL_SRC undefined and default to using the installed copy of the perl library. The other variables default to the following:

```
PERL_INC     = $archlibexp/CORE
PERL_LIB     = $privlibexp
PERL_ARCHLIB = $archlibexp
INST_LIB     = ./blib/lib
INST_ARCHLIB = ./blib/arch
```

If perl has not yet been installed then PERL_SRC can be defined on the command line as shown in the previous section.

Which architecture dependent directory?

If you don't want to keep the defaults for the INSTALL* macros, MakeMaker helps you to minimize the typing needed: the usual relationship between INSTALLPRIVLIB and INSTALLARCHLIB is determined by Configure at perl compilation time. MakeMaker supports the user who sets INSTALLPRIVLIB. If INSTALLPRIVLIB is set, but INSTALLARCHLIB not, then MakeMaker defaults the latter to be the same subdirectory of INSTALLPRIVLIB as Configure decided for the counterparts in %Config, otherwise it defaults to INSTALLPRIVLIB. The same relationship holds for INSTALLSITELIB and INSTALLSITEARCH.

MakeMaker gives you much more freedom than needed to configure internal variables and get different results. It is worth mentioning that make(1) also lets you configure most of the variables that are used in the Makefile. But in the majority of situations this will not be necessary, and should only be done if the author of a package recommends it (or you know what you're doing).

Using Attributes and Parameters

The following attributes may be specified as arguments to WriteMakefile() or as NAME=VALUE pairs on the command line. Attributes that became available with later versions of MakeMaker are indicated.

A computer-readable list of recognized attributes is available as `%ExtUtils::MakeMakers::Recognized_Att_Keys`, supported since 7.72. You can check whether a particular parameter is supported by the current version of ExtUtils::MakeMaker by checking whether it exists in the hash.

In order to maintain portability of attributes with older versions of MakeMaker you may want to use App::EUMM::Upgrade with your `Makefile.PL`.

- ABSTRACT

  One line description of the module. Will be included in PPD file.

- ABSTRACT_FROM

  Name of the file that contains the package description. MakeMaker looks for a line in the POD matching /^($package\s-\s)(.*)/. This is typically the first line in the "=head1 NAME" section. $2 becomes the abstract.

- AUTHOR

  Array of strings containing name (and email address) of package author(s). Is used in CPAN Meta files (META.yml or META.json) and PPD (Perl Package Description) files for PPM (Perl Package Manager).

- BINARY_LOCATION

  Used when creating PPD files for binary packages. It can be set to a full or relative path or URL to the binary archive for a particular architecture. For example:

  ```
  perl Makefile.PL BINARY_LOCATION=x86/Agent.tar.gz
  ```

  builds a PPD package that references a binary of the `Agent` package, located in the `x86` directory relative to the PPD itself.

- BUILD_REQUIRES

  Available in version 6.55_03 and above.

  A hash of modules that are needed to build your module but not run it.

  This will go into the `build_requires` field of your `META.yml` and the `build` of the `prereqs` field of your `META.json`.

  Defaults to `{ "ExtUtils::MakeMaker" => 0 }` if this attribute is not specified.

  The format is the same as PREREQ_PM.

- C

  Ref to array of *.c file names. This is not currently used by MakeMaker but may be handy in Makefile.PLs.

- CCFLAGS

  String that will be included in the compiler call command line between the arguments INC and OPTIMIZE. Note that setting this will overwrite its default value (`$Config::Config{ccflags}`); to preserve that, include the default value directly, e.g.:

  ```
  CCFLAGS => "$Config::Config{ccflags} ..."
  ```

- CONFIG

  Arrayref. E.g. [qw(archname manext)] defines ARCHNAME & MANEXT from config.sh. MakeMaker will add to CONFIG the following values anyway: ar cc cccdlflags ccdlflags cpprun dlext dlsrc ld lddlflags ldflags libc lib_ext obj_ext ranlib sitelibexp sitearchexp so

- CONFIGURE

  CODE reference. The subroutine should return a hash reference. The hash may contain further attributes, e.g. {LIBS => ...}, that have to be determined by some evaluation method.

- CONFIGURE_REQUIRES

  Available in version 6.52 and above.

  A hash of modules that are required to run Makefile.PL itself, but not to run your distribution.

  This will go into the `configure_requires` field of your `META.yml` and the `configure` of the `prereqs` field of your `META.json`.

  Defaults to `{ "ExtUtils::MakeMaker" => 0 }` if this attribute is not specified.

  The format is the same as PREREQ_PM.

- DEFINE

  Something like `"-DHAVE_UNISTD_H"`

- DESTDIR

  This is the root directory into which the code will be installed. It *prepends itself to the normal prefix*. For example, if your code would normally go into `/usr/local/lib/perl` you could set DESTDIR=~/tmp/ and installation would go into `~/tmp/usr/local/lib/perl`.

  This is primarily of use for people who repackage Perl modules.

  NOTE: Due to the nature of make, it is important that you put the trailing slash on your DESTDIR. `~/tmp/` not `~/tmp`.

- DIR

  Ref to array of subdirectories containing Makefile.PLs e.g. ['sdbm'] in ext/SDBM_File

- DISTNAME

  A safe filename for the package.

  Defaults to NAME below but with :: replaced with -.

  For example, Foo::Bar becomes Foo-Bar.

- DISTVNAME

  Your name for distributing the package with the version number included. This is used by 'make dist' to name the resulting archive file.

  Defaults to DISTNAME-VERSION.

  For example, version 1.04 of Foo::Bar becomes Foo-Bar-1.04.

  On some OS's where . has special meaning VERSION_SYM may be used in place of VERSION.

- DLEXT

  Specifies the extension of the module's loadable object. For example:

  ```
  DLEXT => 'unusual_ext', # Default value is $Config{so}
  ```

  NOTE: When using this option to alter the extension of a module's loadable object, it is also necessary that the module's pm file specifies the same change:

```
local $DynaLoader::dl_dlext = 'unusual_ext';
```

- DL_FUNCS

  Hashref of symbol names for routines to be made available as universal symbols. Each key/value pair consists of the package name and an array of routine names in that package. Used only under AIX, OS/2, VMS and Win32 at present. Defaults to

```
{"$(NAME)" => ["boot_$(NAME)" ] }
```

  e.g.

```
{"RPC" => [qw( boot_rpcb rpcb_gettime getnetconfigent )],
 "NetconfigPtr" => [ 'DESTROY'] }
```

  Please see the ExtUtils::Mksymlists documentation for more information about the DL_FUNCS, DL_VARS and FUNCLIST attributes.

- DL_VARS

  Array of symbol names for variables to be made available as universal symbols. Used only under AIX, OS/2, VMS and Win32 at present. Defaults to []. (e.g. [qw(Foo_version Foo_numstreams Foo_tree)])

- EXCLUDE_EXT

  Array of extension names to exclude when doing a static build. This is ignored if INCLUDE_EXT is present. Consult INCLUDE_EXT for more details. (e.g. [qw(Socket POSIX)])

  This attribute may be most useful when specified as a string on the command line: perl Makefile.PL EXCLUDE_EXT='Socket Safe'

- EXE_FILES

  Ref to array of executable files. The files will be copied to the INST_SCRIPT directory. Make realclean will delete them from there again.

  If your executables start with something like #!perl or #!/usr/bin/perl MakeMaker will change this to the path of the perl 'Makefile.PL' was invoked with so the programs will be sure to run properly even if perl is not in /usr/bin/perl.

- FIRST_MAKEFILE

  The name of the Makefile to be produced. This is used for the second Makefile that will be produced for the MAP_TARGET.

  Defaults to 'Makefile' or 'Descrip.MMS' on VMS.

  (Note: we couldn't use MAKEFILE because dmake uses this for something else).

- FULLPERL

- FULLPERLRUN

  Like PERLRUN, except it uses FULLPERL.

- FULLPERLRUNINST

  Like PERLRUNINST, except it uses FULLPERL.

- FUNCLIST

  This provides an alternate means to specify function names to be exported from the extension. Its value is a reference to an array of function names to be exported by the extension. These names are passed through unaltered to the linker options file.

- H

  Ref to array of *.h file names. Similar to C.

- IMPORTS

  This attribute is used to specify names to be imported into the extension. Takes a hash ref.

  It is only used on OS/2 and Win32.

- INC

  Include file dirs eg: `"-I/usr/5include -I/path/to/inc"`

- INCLUDE_EXT

  Array of extension names to be included when doing a static build. MakeMaker will normally build with all of the installed extensions when doing a static build, and that is usually the desired behavior. If INCLUDE_EXT is present then MakeMaker will build only with those extensions which are explicitly mentioned. (e.g. [qw(Socket POSIX)])

  It is not necessary to mention DynaLoader or the current extension when filling in INCLUDE_EXT. If the INCLUDE_EXT is mentioned but is empty then only DynaLoader and the current extension will be included in the build.

  This attribute may be most useful when specified as a string on the command line: perl Makefile.PL INCLUDE_EXT='POSIX Socket Devel::Peek'

- INSTALLARCHLIB

  Used by 'make install', which copies files from INST_ARCHLIB to this directory if INSTALLDIRS is set to perl.

- INSTALLBIN

  Directory to install binary files (e.g. tkperl) into if INSTALLDIRS=perl.

- INSTALLDIRS

  Determines which of the sets of installation directories to choose: perl, site or vendor. Defaults to site.

- INSTALLMAN1DIR

- INSTALLMAN3DIR

  These directories get the man pages at 'make install' time if INSTALLDIRS=perl. Defaults to $Config{installman*dir}.

  If set to 'none', no man pages will be installed.

- INSTALLPRIVLIB

Used by 'make install', which copies files from INST_LIB to this directory if INSTALLDIRS is set to perl.

Defaults to $Config{installprivlib}.

- INSTALLSCRIPT

  Available in version 6.30_02 and above.

  Used by 'make install' which copies files from INST_SCRIPT to this directory if INSTALLDIRS=perl.

- INSTALLSITEARCH

  Used by 'make install', which copies files from INST_ARCHLIB to this directory if INSTALLDIRS is set to site (default).

- INSTALLSITEBIN

  Used by 'make install', which copies files from INST_BIN to this directory if INSTALLDIRS is set to site (default).

- INSTALLSITELIB

  Used by 'make install', which copies files from INST_LIB to this directory if INSTALLDIRS is set to site (default).

- INSTALLSITEMAN1DIR
- INSTALLSITEMAN3DIR

  These directories get the man pages at 'make install' time if INSTALLDIRS=site (default). Defaults to $(SITEPREFIX)/man/man$(MAN*EXT).

  If set to 'none', no man pages will be installed.

- INSTALLSITESCRIPT

  Used by 'make install' which copies files from INST_SCRIPT to this directory if INSTALLDIRS is set to site (default).

- INSTALLVENDORARCH

  Used by 'make install', which copies files from INST_ARCHLIB to this directory if INSTALLDIRS is set to vendor. Note that if you do not set this, the value of INSTALLVENDORLIB will be used, which is probably not what you want.

- INSTALLVENDORBIN

  Used by 'make install', which copies files from INST_BIN to this directory if INSTALLDIRS is set to vendor.

- INSTALLVENDORLIB

  Used by 'make install', which copies files from INST_LIB to this directory if INSTALLDIRS is set to vendor.

- INSTALLVENDORMAN1DIR
- INSTALLVENDORMAN3DIR

  These directories get the man pages at 'make install' time if INSTALLDIRS=vendor. Defaults to $(VENDORPREFIX)/man/man$(MAN*EXT).

If set to 'none', no man pages will be installed.

- INSTALLVENDORSCRIPT

  Available in version 6.30_02 and above.

  Used by 'make install' which copies files from INST_SCRIPT to this directory if INSTALLDIRS is set to vendor.

- INST_ARCHLIB

  Same as INST_LIB for architecture dependent files.

- INST_BIN

  Directory to put real binary files during 'make'. These will be copied to INSTALLBIN during 'make install'

- INST_LIB

  Directory where we put library files of this extension while building it.

- INST_MAN1DIR

  Directory to hold the man pages at 'make' time

- INST_MAN3DIR

  Directory to hold the man pages at 'make' time

- INST_SCRIPT

  Directory where executable files should be installed during 'make'. Defaults to "./blib/script", just to have a dummy location during testing. make install will copy the files in INST_SCRIPT to INSTALLSCRIPT.

- LD

  Program to be used to link libraries for dynamic loading.

  Defaults to $Config{ld}.

- LDDLFLAGS

  Any special flags that might need to be passed to ld to create a shared library suitable for dynamic loading. It is up to the makefile to use it. (See *"lddlflags" in Config*)

  Defaults to $Config{lddlflags}.

- LDFROM

  Defaults to "$(OBJECT)" and is used in the ld command to specify what files to link/load from (also see dynamic_lib below for how to specify ld flags)

- LIB

  LIB should only be set at `perl Makefile.PL` time but is allowed as a MakeMaker argument. It has the effect of setting both INSTALLPRIVLIB and INSTALLSITELIB to that value regardless any explicit setting of those arguments (or of PREFIX). INSTALLARCHLIB and INSTALLSITEARCH are set to the corresponding architecture subdirectory.

- LIBPERL_A

The filename of the perllibrary that will be used together with this extension. Defaults to libperl.a.

- LIBS

  An anonymous array of alternative library specifications to be searched for (in order) until at least one library is found. E.g.

```
'LIBS' => ["-lgdbm", "-ldbm -lfoo", "-L/path -ldbm.nfs"]
```

  Mind, that any element of the array contains a complete set of arguments for the ld command. So do not specify

```
'LIBS' => ["-ltcl", "-ltk", "-lX11"]
```

  See ODBM_File/Makefile.PL for an example, where an array is needed. If you specify a scalar as in

```
'LIBS' => "-ltcl -ltk -lX11"
```

  MakeMaker will turn it into an array with one element.

- LICENSE

  Available in version 6.31 and above.

  The licensing terms of your distribution. Generally it's "perl_5" for the same license as Perl itself.

  See *CPAN::Meta::Spec* for the list of options.

  Defaults to "unknown".

- LINKTYPE

  'static' or 'dynamic' (default unless usedl=undef in config.sh). Should only be used to force static linking (also see linkext below).

- MAGICXS

  Available in version 6.8305 and above.

  When this is set to 1, `OBJECT` will be automagically derived from `O_FILES`.

- MAKE

  Available in version 6.30_01 and above.

  Variant of make you intend to run the generated Makefile with. This parameter lets Makefile.PL know what make quirks to account for when generating the Makefile.

  MakeMaker also honors the MAKE environment variable. This parameter takes precedence.

  Currently the only significant values are 'dmake' and 'nmake' for Windows users, instructing MakeMaker to generate a Makefile in the flavour of DMake ("Dennis Vadura's Make") or Microsoft NMake respectively.

  Defaults to $Config{make}, which may go looking for a Make program in your environment.

How are you supposed to know what flavour of Make a Makefile has been generated for if you didn't specify a value explicitly? Search the generated Makefile for the definition of the MAKE variable, which is used to recursively invoke the Make utility. That will tell you what Make you're supposed to invoke the Makefile with.

- MAKEAPERL

  Boolean which tells MakeMaker that it should include the rules to make a perl. This is handled automatically as a switch by MakeMaker. The user normally does not need it.

- MAKEFILE_OLD

  When 'make clean' or similar is run, the $(FIRST_MAKEFILE) will be backed up at this location.

  Defaults to $(FIRST_MAKEFILE).old or $(FIRST_MAKEFILE)_old on VMS.

- MAN1PODS

  Hashref of pod-containing files. MakeMaker will default this to all EXE_FILES files that include POD directives. The files listed here will be converted to man pages and installed as was requested at Configure time.

  This hash should map POD files (or scripts containing POD) to the man file names under the `blib/man1/` directory, as in the following example:

```
MAN1PODS            => {
  'doc/command.pod'    => 'blib/man1/command.1',
  'scripts/script.pl'  => 'blib/man1/script.1',
}
```

- MAN3PODS

  Hashref that assigns to *.pm and *.pod files the files into which the manpages are to be written. MakeMaker parses all *.pod and *.pm files for POD directives. Files that contain POD will be the default keys of the MAN3PODS hashref. These will then be converted to man pages during `make` and will be installed during `make install`.

  Example similar to MAN1PODS.

- MAP_TARGET

  If it is intended that a new perl binary be produced, this variable may hold a name for that binary. Defaults to perl

- META_ADD

- META_MERGE

  Available in version 6.46 and above.

  A hashref of items to add to the CPAN Meta file (`META.yml` or `META.json`).

  They differ in how they behave if they have the same key as the default metadata. META_ADD will override the default value with its own. META_MERGE will merge its value with the default.

  Unless you want to override the defaults, prefer META_MERGE so as to get the advantage of any future defaults.

Where prereqs are concerned, if META_MERGE is used, prerequisites are merged with their counterpart `WriteMakefile()` argument (PREREQ_PM is merged into {prereqs}{runtime}{requires}, BUILD_REQUIRES into `{prereqs}{build}{requires}`, CONFIGURE_REQUIRES into `{prereqs}{configure}{requires}`, and TEST_REQUIRES into `{prereqs}{test}{requires}`). When prereqs are specified with META_ADD, the only prerequisites added to the file come from the metadata, not `WriteMakefile()` arguments.

Note that these configuration options are only used for generating `META.yml` and `META.json` – they are NOT used for `MYMETA.yml` and `MYMETA.json`. Therefore data in these fields should NOT be used for dynamic (user-side) configuration.

By default CPAN Meta specification `1.4` is used. In order to use CPAN Meta specification `2.0`, indicate with `meta-spec` the version you want to use.

```
META_MERGE         => {

  "meta-spec" => { version => 2 },

  resources => {

    repository => {
        type => 'git',

```

- MIN_PERL_VERSION

  Available in version 6.48 and above.

  The minimum required version of Perl for this distribution.

  Either the 5.006001 or the 5.6.1 format is acceptable.

- MYEXTLIB

  If the extension links to a library that it builds, set this to the name of the library (see SDBM_File)

- NAME

  The package representing the distribution. For example, `Test::More` or `ExtUtils::MakeMaker`.

  `NAME` *must* be a valid Perl package name and it *must* have an associated `.pm` file. For example, `Foo::Bar` is a valid `NAME` and there must exist `Foo/Bar.pm`.

  Your distribution **must** have a `NAME`.

- NEEDS_LINKING

MakeMaker will figure out if an extension contains linkable code anywhere down the directory tree, and will set this variable accordingly, but you can speed it up a very little bit if you define this boolean variable yourself.

- NOECHO

  Command so make does not print the literal commands it's running.

  By setting it to an empty string you can generate a Makefile that prints all commands. Mainly used in debugging MakeMaker itself.

  Defaults to @.

- NORECURS

  Boolean. Attribute to inhibit descending into subdirectories.

- NO_META

  When true, suppresses the generation and addition to the MANIFEST of the META.yml and META.json module meta-data files during 'make distdir'.

  Defaults to false.

- NO_MYMETA

  Available in version 6.57_02 and above.

  When true, suppresses the generation of MYMETA.yml and MYMETA.json module meta-data files during 'perl Makefile.PL'.

  Defaults to false.

- NO_PACKLIST

  Available in version 6.7501 and above.

  When true, suppresses the writing of `packlist` files for installs.

  Defaults to false.

- NO_PERLLOCAL

  Available in version 6.7501 and above.

  When true, suppresses the appending of installations to `perllocal`.

  Defaults to false.

- NO_VC

  In general, any generated Makefile checks for the current version of MakeMaker and the version the Makefile was built under. If NO_VC is set, the version check is neglected. Do not write this into your Makefile.PL, use it interactively instead.

- OBJECT

  List of object files, defaults to '$(BASEEXT)$(OBJ_EXT)', but can be a long string or an array containing all object files, e.g. "tkpBind.o tkpButton.o tkpCanvas.o" or ["tkpBind.o", "tkpButton.o", "tkpCanvas.o"]

  (Where BASEEXT is the last component of NAME, and OBJ_EXT is $Config{obj_ext}.)

- OPTIMIZE

  Defaults to -O. Set it to -g to turn debugging on. The flag is passed to subdirectory makes.

- PERL

  Perl binary for tasks that can be done by miniperl. If it contains spaces or other shell metacharacters, it needs to be quoted in a way that protects them, since this value is intended to be inserted in a shell command line in the Makefile. E.g.:

```
# Perl executable lives in "C:/Program Files/Perl/bin"
# Normally you don't need to set this yourself!
$ perl Makefile.PL PERL='"C:/Program Files/Perl/bin/perl.exe" -w
 ↪'
```

- PERL_CORE

  Set only when MakeMaker is building the extensions of the Perl core distribution.

- PERLMAINCC

  The call to the program that is able to compile perlmain.c. Defaults to $(CC).

- PERL_ARCHLIB

  Same as for PERL_LIB, but for architecture dependent files.

  Used only when MakeMaker is building the extensions of the Perl core distribution (because normally $(PERL_ARCHLIB) is automatically in @INC, and adding it would get in the way of PERL5LIB).

- PERL_LIB

  Directory containing the Perl library to use.

  Used only when MakeMaker is building the extensions of the Perl core distribution (because normally $(PERL_LIB) is automatically in @INC, and adding it would get in the way of PERL5LIB).

- PERL_MALLOC_OK

  defaults to 0. Should be set to TRUE if the extension can work with the memory allocation routines substituted by the Perl malloc() subsystem. This should be applicable to most extensions with exceptions of those

  – with bugs in memory allocations which are caught by Perl's malloc();

  – which interact with the memory allocator in other ways than via malloc(), realloc(), free(), calloc(), sbrk() and brk();

  – which rely on special alignment which is not provided by Perl's malloc().

  NOTE. Neglecting to set this flag in *any one* of the loaded extension nullifies many advantages of Perl's malloc(), such as better usage of system resources, error detection, memory usage reporting, catchable failure of memory allocations, etc.

- PERLPREFIX

  Directory under which core modules are to be installed.

Defaults to $Config{installprefixexp}, falling back to $Config{installprefix}, $Config{prefixexp} or $Config{prefix} should $Config{installprefixexp} not exist.

Overridden by PREFIX.

- PERLRUN

  Use this instead of $(PERL) when you wish to run perl. It will set up extra necessary flags for you.

- PERLRUNINST

  Use this instead of $(PERL) when you wish to run perl to work with modules. It will add things like -I$(INST_ARCH) and other necessary flags so perl can see the modules you're about to install.

- PERL_SRC

  Directory containing the Perl source code (use of this should be avoided, it may be undefined)

- PERM_DIR

  Available in version 6.51_01 and above.

  Desired permission for directories. Defaults to 755.

- PERM_RW

  Desired permission for read/writable files. Defaults to 644.

- PERM_RWX

  Desired permission for executable files. Defaults to 755.

- PL_FILES

  MakeMaker can run programs to generate files for you at build time. By default any file named *.PL (except Makefile.PL and Build.PL) in the top level directory will be assumed to be a Perl program and run passing its own basename in as an argument. This basename is actually a build target, and there is an intention, but not a requirement, that the *.PL file make the file passed to to as an argument. For example...

```
perl foo.PL foo
```

  This behavior can be overridden by supplying your own set of files to search. PL_FILES accepts a hash ref, the key being the file to run and the value is passed in as the first argument when the PL file is run.

```
PL_FILES => {'bin/foobar.PL' => 'bin/foobar'}

PL_FILES => {'foo.PL' => 'foo.c'}
```

  Would run bin/foobar.PL like this:

```
perl bin/foobar.PL bin/foobar
```

  If multiple files from one program are desired an array ref can be used.

```
PL_FILES => {'bin/foobar.PL' => [qw(bin/foobar1 bin/foobar2)]}
```

In this case the program will be run multiple times using each target file.

```
perl bin/foobar.PL bin/foobar1
perl bin/foobar.PL bin/foobar2
```

If an output file depends on extra input files beside the script itself, a hash ref can be used in version 7.36 and above:

```
PL_FILES => { 'foo.PL' => {
    'foo.out' => 'foo.in',
    'bar.out' => [qw(bar1.in bar2.in)],
}
```

In this case the extra input files will be passed to the program after the target file:

```
perl foo.PL foo.out foo.in
perl foo.PL bar.out bar1.in bar2.in
```

PL files are normally run **after** pm_to_blib and include INST_LIB and INST_ARCH in their `@INC`, so the just built modules can be accessed... unless the PL file is making a module (or anything else in PM) in which case it is run **before** pm_to_blib and does not include INST_LIB and INST_ARCH in its `@INC`. This apparently odd behavior is there for backwards compatibility (and it's somewhat DWIM). The argument passed to the .PL is set up as a target to build in the Makefile. In other sections such as `postamble` you can specify a dependency on the filename/argument that the .PL is supposed (or will have, now that that is is a dependency) to generate. Note the file to be generated will still be generated and the .PL will still run even without an explicit dependency created by you, since the `all` target still depends on running all eligible to run.PL files.

- PM

  Hashref of .pm files and *.pl files to be installed. e.g.

  ```
  {'name_of_file.pm' => '$(INST_LIB)/install_as.pm'}
  ```

  By default this will include *.pm and *.pl and the files found in the PMLIBDIRS directories. Defining PM in the Makefile.PL will override PMLIBDIRS.

- PMLIBDIRS

  Ref to array of subdirectories containing library files. Defaults to ['lib', $(BASEEXT)]. The directories will be scanned and *any* files they contain will be installed in the corresponding location in the library. A libscan() method can be used to alter the behaviour. Defining PM in the Makefile.PL will override PMLIBDIRS.

  (Where BASEEXT is the last component of NAME.)

- PM_FILTER

  A filter program, in the traditional Unix sense (input from stdin, output to stdout) that is passed on each .pm file during the build (in the pm_to_blib() phase). It is empty by default, meaning no filtering is done. You could use:

```
PM_FILTER => 'perl -ne "print unless /^#/"',
```

to remove all the leading comments on the fly during the build. In order to be as portable as possible, please consider using a Perl one-liner rather than Unix (or other) utilities, as above. MakeMaker will escape the # for the Makefile, since what goes in the Makefile will depend on which `make` implementation is being targeted.

You will almost certainly be better off using the `PL_FILES` system, instead. See above, or the ExtUtils::MakeMaker::FAQ entry.

- POLLUTE

  Prior to 5.6 various interpreter variables were available without a `PL_` prefix, eg. `PL_undef` was available as `undef`. As of release 5.6, these are only defined if the POLLUTE flag is enabled:

  ```
  perl Makefile.PL POLLUTE=1
  ```

  Please inform the module author if this is necessary to successfully install a module under 5.6 or later.

- PPM_INSTALL_EXEC

  Name of the executable used to run `PPM_INSTALL_SCRIPT` below. (e.g. perl)

- PPM_INSTALL_SCRIPT

  Name of the script that gets executed by the Perl Package Manager after the installation of a package.

- PPM_UNINSTALL_EXEC

  Available in version 6.8502 and above.

  Name of the executable used to run `PPM_UNINSTALL_SCRIPT` below. (e.g. perl)

- PPM_UNINSTALL_SCRIPT

  Available in version 6.8502 and above.

  Name of the script that gets executed by the Perl Package Manager before the removal of a package.

- PREFIX

  This overrides all the default install locations. Man pages, libraries, scripts, etc... MakeMaker will try to make an educated guess about where to place things under the new PREFIX based on your Config defaults. Failing that, it will fall back to a structure which should be sensible for your platform.

  If you specify LIB or any INSTALL* variables they will not be affected by the PREFIX.

- PREREQ_FATAL

  Bool. If this parameter is true, failing to have the required modules (or the right versions thereof) will be fatal. `perl Makefile.PL` will `die` instead of simply informing the user of the missing dependencies.

  It is *extremely* rare to have to use `PREREQ_FATAL`. Its use by module authors is *strongly discouraged* and should never be used lightly.

For dependencies that are required in order to run `Makefile.PL`, see `CONFIGURE_REQUIRES`.

Module installation tools have ways of resolving unmet dependencies but to do that they need a `Makefile`. Using `PREREQ_FATAL` breaks this. That's bad.

Assuming you have good test coverage, your tests should fail with missing dependencies informing the user more strongly that something is wrong. You can write a `t/00compile.t` test which will simply check that your code compiles and stop "make test" prematurely if it doesn't. See *"BAIL_OUT" in Test::More* for more details.

- PREREQ_PM

  A hash of modules that are needed to run your module. The keys are the module names ie. Test::More, and the minimum version is the value. If the required version number is 0 any version will do. The versions given may be a Perl v-string (see *version*) or a range (see *CPAN::Meta::Requirements*).

  This will go into the `requires` field of your `META.yml` and the `runtime` of the `prereqs` field of your `META.json`.

```
PREREQ_PM => {
    # Require Test::More at least 0.47
    "Test::More" => "0.47",

    # Require any version of Acme::Buffy
    "Acme::Buffy" => 0,
}
```

- PREREQ_PRINT

  Bool. If this parameter is true, the prerequisites will be printed to stdout and MakeMaker will exit. The output format is an evalable hash ref.

```
$PREREQ_PM = {
               'A::B' => Vers1,
               'C::D' => Vers2,
               ...
             };
```

  If a distribution defines a minimal required perl version, this is added to the output as an additional line of the form:

```
$MIN_PERL_VERSION = '5.008001';
```

  If BUILD_REQUIRES is not empty, it will be dumped as $BUILD_REQUIRES hashref.

- PRINT_PREREQ

  RedHatism for `PREREQ_PRINT`. The output format is different, though:

```
perl(A::B)>=Vers1 perl(C::D)>=Vers2 ...
```

  A minimal required perl version, if present, will look like this:

```
perl(perl)>=5.008001
```

- SITEPREFIX

  Like PERLPREFIX, but only for the site install locations.

  Defaults to $Config{siteprefixexp}. Perls prior to 5.6.0 didn't have an explicit siteprefix in the Config. In those cases $Config{installprefix} will be used.

  Overridable by PREFIX

- SIGN

  Available in version 6.18 and above.

  When true, perform the generation and addition to the MANIFEST of the SIGNATURE file in the distdir during 'make distdir', via 'cpansign -s'.

  Note that you need to install the Module::Signature module to perform this operation.

  Defaults to false.

- SKIP

  Arrayref. E.g. [qw(name1 name2)] skip (do not write) sections of the Makefile. Caution! Do not use the SKIP attribute for the negligible speedup. It may seriously damage the resulting Makefile. Only use it if you really need it.

- TEST_REQUIRES

  Available in version 6.64 and above.

  A hash of modules that are needed to test your module but not run or build it.

  This will go into the `build_requires` field of your `META.yml` and the `test` of the `prereqs` field of your `META.json`.

  The format is the same as PREREQ_PM.

- TYPEMAPS

  Ref to array of typemap file names. Use this when the typemaps are in some directory other than the current directory or when they are not named **typemap**. The last typemap in the list takes precedence. A typemap in the current directory has highest precedence, even if it isn't listed in TYPEMAPS. The default system typemap has lowest precedence.

- VENDORPREFIX

  Like PERLPREFIX, but only for the vendor install locations.

  Defaults to $Config{vendorprefixexp}.

  Overridable by PREFIX

- VERBINST

  If true, make install will be verbose

- VERSION

  Your version number for distributing the package. This defaults to 0.1.

- VERSION_FROM

  Instead of specifying the VERSION in the Makefile.PL you can let MakeMaker parse a file to determine the version number. The parsing routine requires that the file named by VERSION_FROM contains one single line to compute the version number. The first line in the file that contains something like a $VERSION assignment or `package Name VERSION` will be used. The following lines will be parsed o.k.:

```
# Good
package Foo::Bar 1.23;                          # 1.23
$VERSION   = '1.00';                            # 1.00
*VERSION   = \'1.01';                           # 1.01
($VERSION) = q$Revision$ =~ /(\d+)/g;           # The digits in
 ↪$Revision$
$FOO::VERSION = '1.10';                         # 1.10
*FOO::VERSION = \'1.11';                        # 1.11
```

  but these will fail:

```
# Bad
my $VERSION         = '1.01';
local $VERSION      = '1.02';
local $FOO::VERSION = '1.30';
```

  (Putting `my` or `local` on the preceding line will work o.k.)

  "Version strings" are incompatible and should not be used.

```
# Bad
$VERSION = 1.2.3;
$VERSION = v1.2.3;
```

  version objects are fine. As of MakeMaker 6.35 version.pm will be automatically loaded, but you must declare the dependency on version.pm. For compatibility with older MakeMaker you should load on the same line as $VERSION is declared.

```
# All on one line
use version; our $VERSION = qv(1.2.3);
```

  The file named in VERSION_FROM is not added as a dependency to Makefile. This is not really correct, but it would be a major pain during development to have to rewrite the Makefile for any smallish change in that file. If you want to make sure that the Makefile contains the correct VERSION macro after any change of the file, you would have to do something like

```
depend => { Makefile => '$(VERSION_FROM)' }
```

  See attribute depend below.

- VERSION_SYM

  A sanitized VERSION with . replaced by _. For places where . has special meaning (some filesystems, RCS labels, etc...)

- XSBUILD

Available in version 7.12 and above.

Hashref with options controlling the operation of `XSMULTI`:

```
{
  xs => {
      all => {
          # options applying to all .xs files for this␣
↪distribution
      },
      'lib/Class/Name/File' => { # specifically for this file
          DEFINE => '-Dfunktastic', # defines for only this file
          INC => "-I$funkyliblocation", # include flags for␣
↪only this file
          # OBJECT => 'lib/Class/Name/File$(OBJ_EXT)', # default
          LDFROM => "lib/Class/Name/File\$(OBJ_EXT) $otherfile\
↪$(OBJ_EXT)", # what's linked
      },
  },
}
```

Note `xs` is the file-extension. More possibilities may arise in the future.

`LDFROM` defaults to the same as `OBJECT`.

The distinction between `OBJECT` and `LDFROM`: `OBJECT` is the make target, so make will try to build it.

- XSMULTI

  Available in version 7.12 and above.

  This feature should be considered experimental, and details of it may change.

  This feature was inspired by, and small portions of code copied from, ExtUtils::MakeMaker::BigHelper. Hopefully this feature will render that module mainly obsolete.

- XSOPT

  String of options to pass to xsubpp. This might include `-C++` or `-extern`. Do not include typemaps here; the TYPEMAP parameter exists for that purpose.

- XSPROTOARG

  May be set to `-prototypes`, `-noprototypes` or the empty string. The empty string is equivalent to the xsubpp default, or `-noprototypes`. See the xsubpp documentation for details. MakeMaker defaults to the empty string.

Additional lowercase attributes

can be used to pass parameters to the methods which implement that part of the Makefile. Parameters are specified as a hash ref but are passed to the method as a hash.

- clean

```
{FILES => "*.xyz foo"}
```

- depend

```
{ANY_TARGET => ANY_DEPENDENCY, ...}
```

(ANY_TARGET must not be given a double-colon rule by MakeMaker.)

- dist

```
{TARFLAGS => 'cvfF', COMPRESS => 'gzip', SUFFIX => '.gz',
SHAR => 'shar -m', DIST_CP => 'ln', ZIP => '/bin/zip',
ZIPFLAGS => '-rl', DIST_DEFAULT => 'private tardist' }
```

If you specify COMPRESS, then SUFFIX should also be altered, as it is needed to tell make the target file of the compression. Setting DIST_CP to ln can be useful, if you need to preserve the timestamps on your files. DIST_CP can take the values 'cp', which copies the file, 'ln', which links the file, and 'best' which copies symbolic links and links the rest. Default is 'best'.

- dynamic_lib

```
{ARMAYBE => 'ar', OTHERLDFLAGS => '...', INST_DYNAMIC_DEP => '..
↪.'}
```

- linkext

```
{LINKTYPE => 'static', 'dynamic' or ''}
```

NB: Extensions that have nothing but *.pm files had to say

```
{LINKTYPE => ''}
```

with Pre-5.0 MakeMakers. Since version 5.00 of MakeMaker such a line can be deleted safely. MakeMaker recognizes when there's nothing to be linked.

- macro

```
{ANY_MACRO => ANY_VALUE, ...}
```

- postamble

Anything put here will be passed to *MY::postamble()* if you have one.

- realclean

```
{FILES => '$(INST_ARCHAUTODIR)/*.xyz'}
```

- test

Specify the targets for testing.

```
{TESTS => 't/*.t'}
```

RECURSIVE_TEST_FILES can be used to include all directories recursively under t that contain .t files. It will be ignored if you provide your own TESTS attribute, defaults to false.

```
{RECURSIVE_TEST_FILES=>1}
```

This is supported since 6.76

- tool_autosplit

```
{MAXLEN => 8}
```

Overriding MakeMaker Methods

If you cannot achieve the desired Makefile behaviour by specifying attributes you may define private subroutines in the Makefile.PL. Each subroutine returns the text it wishes to have written to the Makefile. To override a section of the Makefile you can either say:

```
sub MY::c_o { "new literal text" }
```

or you can edit the default by saying something like:

```
package MY; # so that "SUPER" works right
sub c_o {
    my $inherited = shift->SUPER::c_o(@_);
    $inherited =~ s/old text/new text/;
    $inherited;
}
```

If you are running experiments with embedding perl as a library into other applications, you might find MakeMaker is not sufficient. You'd better have a look at *ExtUtils::Embed* which is a collection of utilities for embedding.

If you still need a different solution, try to develop another subroutine that fits your needs and submit the diffs to makemaker@perl.org

For a complete description of all MakeMaker methods see *ExtUtils::MM_Unix*.

Here is a simple example of how to add a new target to the generated Makefile:

```
sub MY::postamble {
    return <<'MAKE_FRAG';
$(MYEXTLIB): sdbm/Makefile
        cd sdbm && $(MAKE) all

MAKE_FRAG
}
```

The End Of Cargo Cult Programming

WriteMakefile() now does some basic sanity checks on its parameters to protect against typos and malformatted values. This means some things which happened to work in the past will now throw warnings and possibly produce internal errors.

Some of the most common mistakes:

- `MAN3PODS => ' '`

  This is commonly used to suppress the creation of man pages. MAN3PODS takes a hash ref not a string, but the above worked by accident in old versions of MakeMaker.

  The correct code is `MAN3PODS => { }`.

Hintsfile support

MakeMaker.pm uses the architecture-specific information from Config.pm. In addition it evaluates architecture specific hints files in a `hints/` directory. The hints files are expected to be named like their counterparts in `PERL_SRC/hints`, but with an `.pl` file name extension (eg. `next_3_2.pl`). They are simply `eval`ed by MakeMaker within the WriteMakefile() subroutine, and can be used to execute commands as well as to include special variables. The rules which hintsfile is chosen are the same as in Configure.

The hintsfile is eval()ed immediately after the arguments given to WriteMakefile are stuffed into a hash reference $self but before this reference becomes blessed. So if you want to do the equivalent to override or create an attribute you would say something like

```
$self->{LIBS} = ['-ldbm -lucb -lc'];
```

Distribution Support

For authors of extensions MakeMaker provides several Makefile targets. Most of the support comes from the *ExtUtils::Manifest* module, where additional documentation can be found.

- make distcheck

  reports which files are below the build directory but not in the MANIFEST file and vice versa. (See *"fullcheck" in ExtUtils::Manifest* for details)

- make skipcheck

  reports which files are skipped due to the entries in the `MANIFEST.SKIP` file (See *"skipcheck" in ExtUtils::Manifest* for details)

- make distclean

  does a realclean first and then the distcheck. Note that this is not needed to build a new distribution as long as you are sure that the MANIFEST file is ok.

- make veryclean

  does a realclean first and then removes backup files such as `*~`, `*.bak`, `*.old` and `*.orig`

- make manifest

  rewrites the MANIFEST file, adding all remaining files found (See *"mkmanifest" in ExtUtils::Manifest* for details)

- make distdir

  Copies all the files that are in the MANIFEST file to a newly created directory with the name `$(DISTNAME)-$(VERSION)`. If that directory exists, it will be removed first.

  Additionally, it will create META.yml and META.json module meta-data file in the distdir and add this to the distdir's MANIFEST. You can shut this behavior off with the NO_META flag.

- make disttest

  Makes a distdir first, and runs a `perl Makefile.PL`, a make, and a make test in that directory.

- make tardist

  First does a distdir. Then a command $(PREOP) which defaults to a null command, followed by $(TO_UNIX), which defaults to a null command under UNIX, and will convert files in distribution directory to UNIX format otherwise. Next it runs `tar` on that directory into a tarfile and deletes the directory. Finishes with a command $(POSTOP) which defaults to a null command.

- make dist

  Defaults to $(DIST_DEFAULT) which in turn defaults to tardist.

- make uutardist

  Runs a tardist first and uuencodes the tarfile.

- make shdist

  First does a distdir. Then a command $(PREOP) which defaults to a null command. Next it runs `shar` on that directory into a sharfile and deletes the intermediate directory again. Finishes with a command $(POSTOP) which defaults to a null command. Note: For shdist to work properly a `shar` program that can handle directories is mandatory.

- make zipdist

  First does a distdir. Then a command $(PREOP) which defaults to a null command. Runs `$(ZIP) $(ZIPFLAGS)` on that directory into a zipfile. Then deletes that directory. Finishes with a command $(POSTOP) which defaults to a null command.

- make ci

  Does a $(CI) and a $(RCS_LABEL) on all files in the MANIFEST file.

Customization of the dist targets can be done by specifying a hash reference to the dist attribute of the WriteMakefile call. The following parameters are recognized:

```
CI           ('ci -u')
COMPRESS     ('gzip --best')
POSTOP       ('@ :')
PREOP        ('@ :')
TO_UNIX      (depends on the system)
RCS_LABEL    ('rcs -q -Nv$(VERSION_SYM):')
SHAR         ('shar')
```

(continues on next page)

(continued from previous page)

```
SUFFIX       ('.gz')
TAR          ('tar')
TARFLAGS     ('cvf')
ZIP          ('zip')
ZIPFLAGS     ('-r')
```

An example:

```
WriteMakefile(
    ...other options...
    dist => {
        COMPRESS => "bzip2",
        SUFFIX   => ".bz2"
    }
);
```

Module Meta-Data (META and MYMETA)

Long plaguing users of MakeMaker based modules has been the problem of getting basic information about the module out of the sources *without* running the `Makefile.PL` and doing a bunch of messy heuristics on the resulting `Makefile`. Over the years, it has become standard to keep this information in one or more CPAN Meta files distributed with each distribution.

The original format of CPAN Meta files was *YAML* and the corresponding file was called `META.yml`. In 2010, version 2 of the *CPAN::Meta::Spec* was released, which mandates JSON format for the metadata in order to overcome certain compatibility issues between YAML serializers and to avoid breaking older clients unable to handle a new version of the spec. The *CPAN::Meta* library is now standard for accessing old and new-style Meta files.

If *CPAN::Meta* is installed, MakeMaker will automatically generate `META.json` and `META.yml` files for you and add them to your `MANIFEST` as part of the 'distdir' target (and thus the 'dist' target). This is intended to seamlessly and rapidly populate CPAN with module meta-data. If you wish to shut this feature off, set the `NO_META WriteMakefile()` flag to true.

At the 2008 QA Hackathon in Oslo, Perl module toolchain maintainers agreed to use the CPAN Meta format to communicate post-configuration requirements between toolchain components. These files, `MYMETA.json` and `MYMETA.yml`, are generated when `Makefile.PL` generates a `Makefile` (if *CPAN::Meta* is installed). Clients like *CPAN* or CPANPLUS will read these files to see what prerequisites must be fulfilled before building or testing the distribution. If you wish to shut this feature off, set the `NO_MYMETA WriteMakefile()` flag to true.

Disabling an extension

If some events detected in `Makefile.PL` imply that there is no way to create the Module, but this is a normal state of things, then you can create a `Makefile` which does nothing, but succeeds on all the "usual" build targets. To do so, use

```
use ExtUtils::MakeMaker qw(WriteEmptyMakefile);
WriteEmptyMakefile();
```

instead of WriteMakefile().

This may be useful if other modules expect this module to be *built* OK, as opposed to *work* OK (say, this system-dependent module builds in a subdirectory of some other distribution, or is listed as a dependency in a CPAN::Bundle, but the functionality is supported by different means on the current architecture).

Other Handy Functions

- prompt

  ```
  my $value = prompt($message);
  my $value = prompt($message, $default);
  ```

  The `prompt()` function provides an easy way to request user input used to write a makefile. It displays the $message as a prompt for input. If a $default is provided it will be used as a default. The function returns the $value selected by the user.

  If `prompt()` detects that it is not running interactively and there is nothing on STDIN or if the PERL_MM_USE_DEFAULT environment variable is set to true, the $default will be used without prompting. This prevents automated processes from blocking on user input.

  If no $default is provided an empty string will be used instead.

- os_unsupported

  ```
  os_unsupported();
  os_unsupported if $^O eq 'MSWin32';
  ```

  The `os_unsupported()` function provides a way to correctly exit your `Makefile.PL` before calling `WriteMakefile`. It is essentially a `die` with the message "OS unsupported".

  This is supported since 7.26

Supported versions of Perl

Please note that while this module works on Perl 5.6, it is no longer being routinely tested on 5.6 - the earliest Perl version being routinely tested, and expressly supported, is 5.8.1. However, patches to repair any breakage on 5.6 are still being accepted.

ENVIRONMENT

- PERL_MM_OPT

  Command line options used by `MakeMaker->new()`, and thus by `WriteMakefile()`. The string is split as the shell would, and the result is processed before any actual command line arguments are processed.

```
PERL_MM_OPT='CCFLAGS="-Wl,-rpath -Wl,/foo/bar/lib" LIBS="-
↪lwibble -lwobble"'
```

- PERL_MM_USE_DEFAULT

  If set to a true value then MakeMaker's prompt function will always return the default without waiting for user input.

- PERL_CORE

  Same as the PERL_CORE parameter. The parameter overrides this.

SEE ALSO

Module::Build is a pure-Perl alternative to MakeMaker which does not rely on make or any other external utility. It may be easier to extend to suit your needs.

Module::Build::Tiny is a minimal pure-Perl alternative to MakeMaker that follows the Build.PL protocol of Module::Build but without its complexity and cruft, implementing only the installation of the module and leaving authoring to mbtiny or other authoring tools.

Module::Install is a (now discouraged) wrapper around MakeMaker which adds features not normally available.

ExtUtils::ModuleMaker and Module::Starter are both modules to help you setup your distribution.

CPAN::Meta and *CPAN::Meta::Spec* explain CPAN Meta files in detail.

File::ShareDir::Install makes it easy to install static, sometimes also referred to as 'shared' files. *File::ShareDir* helps accessing the shared files after installation. Test::File::ShareDir helps when writing tests to use the shared files both before and after installation.

Dist::Zilla is an authoring tool which allows great customization and extensibility of the author experience, relying on the existing install tools like ExtUtils::MakeMaker only for installation.

Dist::Milla is a Dist::Zilla bundle that greatly simplifies common usage.

Minilla is a minimal authoring tool that does the same things as Dist::Milla without the overhead of Dist::Zilla.

Modules

- `ExtUtils::MakeMaker::Config` - Wrapper around Config.pm
- `ExtUtils::MakeMaker::Locale` - bundled Encode::Locale

ExtUtils::MakeMaker::Config

Wrapper around Config.pm

SYNOPSIS

```
use ExtUtils::MakeMaker::Config;
print $Config{installbin};  # or whatever
```

DESCRIPTION

FOR INTERNAL USE ONLY

A very thin wrapper around Config.pm so MakeMaker is easier to test.

ExtUtils::MakeMaker::Locale

bundled Encode::Locale

SYNOPSIS

```
use Encode::Locale;
use Encode;

$string = decode(locale => $bytes);
$bytes = encode(locale => $string);

if (-t) {
    binmode(STDIN, ":encoding(console_in)");
    binmode(STDOUT, ":encoding(console_out)");
    binmode(STDERR, ":encoding(console_out)");
}

# Processing file names passed in as arguments
my $uni_filename = decode(locale => $ARGV[0]);
```

(continues on next page)

(continued from previous page)

```
open(my $fh, "<", encode(locale_fs => $uni_filename))
   || die "Can't open '$uni_filename': $!";
binmode($fh, ":encoding(locale)");
...
```

DESCRIPTION

In many applications it's wise to let Perl use Unicode for the strings it processes. Most of the interfaces Perl has to the outside world are still byte based. Programs therefore need to decode byte strings that enter the program from the outside and encode them again on the way out.

The POSIX locale system is used to specify both the language conventions requested by the user and the preferred character set to consume and output. The `Encode::Locale` module looks up the charset and encoding (called a CODESET in the locale jargon) and arranges for the *Encode* module to know this encoding under the name "locale". It means bytes obtained from the environment can be converted to Unicode strings by calling `Encode::encode(locale => $bytes)` and converted back again with `Encode::decode(locale => $string)`.

Where file systems interfaces pass file names in and out of the program we also need care. The trend is for operating systems to use a fixed file encoding that don't actually depend on the locale; and this module determines the most appropriate encoding for file names. The *Encode* module will know this encoding under the name "locale_fs". For traditional Unix systems this will be an alias to the same encoding as "locale".

For programs running in a terminal window (called a "Console" on some systems) the "locale" encoding is usually a good choice for what to expect as input and output. Some systems allows us to query the encoding set for the terminal and `Encode::Locale` will do that if available and make these encodings known under the `Encode` aliases "console_in" and "console_out". For systems where we can't determine the terminal encoding these will be aliased as the same encoding as "locale". The advice is to use "console_in" for input known to come from the terminal and "console_out" for output to the terminal.

In addition to arranging for various Encode aliases the following functions and variables are provided:

- decode_argv( )
- decode_argv(Encode::FB_CROAK)

  This will decode the command line arguments to perl (the `@ARGV` array) in-place.

  The function will by default replace characters that can't be decoded by "\x{FFFD}", the Unicode replacement character.

  Any argument provided is passed as CHECK to underlying Encode::decode() call. Pass the value `Encode::FB_CROAK` to have the decoding croak if not all the command line arguments can be decoded. See *"Handling Malformed Data" in Encode* for details on other options for CHECK.
- env($uni_key)
- env($uni_key => $uni_value)

Interface to get/set environment variables. Returns the current value as a Unicode string. The $uni_key and $uni_value arguments are expected to be Unicode strings as well. Passing undef as $uni_value deletes the environment variable named $uni_key.

The returned value will have the characters that can't be decoded replaced by "\x{FFFD}", the Unicode replacement character.

There is no interface to request alternative CHECK behavior as for decode_argv(). If you need that you need to call encode/decode yourself. For example:

```
my $key = Encode::encode(locale => $uni_key, Encode::FB_CROAK);
my $uni_value = Encode::decode(locale => $ENV{$key}, Encode::FB_
↪CROAK);
```

- reinit( )
- reinit($encoding)

  Reinitialize the encodings from the locale. You want to call this function if you changed anything in the environment that might influence the locale.

  This function will croak if the determined encoding isn't recognized by the Encode module.

  With argument force $ENCODING_... variables to set to the given value.

- $ENCODING_LOCALE

  The encoding name determined to be suitable for the current locale. *Encode* know this encoding as "locale".

- $ENCODING_LOCALE_FS

  The encoding name determined to be suitable for file system interfaces involving file names. *Encode* know this encoding as "locale_fs".

- $ENCODING_CONSOLE_IN
- $ENCODING_CONSOLE_OUT

  The encodings to be used for reading and writing output to the a console. *Encode* know these encodings as "console_in" and "console_out".

NOTES

This table summarizes the mapping of the encodings set up by the Encode::Locale module:

```
Encode      |         |              |
Alias       | Windows | Mac OS X     | POSIX
------------+---------+--------------+------------
locale      | ANSI    | nl_langinfo  | nl_langinfo
locale_fs   | ANSI    | UTF-8        | nl_langinfo
console_in  | OEM     | nl_langinfo  | nl_langinfo
console_out | OEM     | nl_langinfo  | nl_langinfo
```

Windows

Windows has basically 2 sets of APIs. A wide API (based on passing UTF-16 strings) and a byte based API based a character set called ANSI. The regular Perl interfaces to the OS currently only uses the ANSI APIs. Unfortunately ANSI is not a single character set.

The encoding that corresponds to ANSI varies between different editions of Windows. For many western editions of Windows ANSI corresponds to CP-1252 which is a character set similar to ISO-8859-1. Conceptually the ANSI character set is a similar concept to the POSIX locale CODESET so this module figures out what the ANSI code page is and make this available as $ENCODING_LOCALE and the "locale" Encoding alias.

Windows systems also operate with another byte based character set. It's called the OEM code page. This is the encoding that the Console takes as input and output. It's common for the OEM code page to differ from the ANSI code page.

Mac OS X

On Mac OS X the file system encoding is always UTF-8 while the locale can otherwise be set up as normal for POSIX systems.

File names on Mac OS X will at the OS-level be converted to NFD-form. A file created by passing a NFC-filename will come in NFD-form from readdir(). See *Unicode::Normalize* for details of NFD/NFC.

Actually, Apple does not follow the Unicode NFD standard since not all character ranges are decomposed. The claim is that this avoids problems with round trip conversions from old Mac text encodings. See Encode::UTF8Mac for details.

POSIX (Linux and other Unixes)

File systems might vary in what encoding is to be used for filenames. Since this module has no way to actually figure out what the is correct it goes with the best guess which is to assume filenames are encoding according to the current locale. Users are advised to always specify UTF-8 as the locale charset.

ExtUtils::Manifest

Utilities to write and check a MANIFEST file

VERSION

version 1.75

SYNOPSIS

```
use ExtUtils::Manifest qw(...funcs to import...);

mkmanifest();

my @missing_files     = manicheck;
my @skipped           = skipcheck;
my @extra_files       = filecheck;
my($missing, $extra) = fullcheck;

my $found    = manifind();

my $manifest = maniread();

manicopy($read,$target);

maniadd({$file => $comment, ...});
```

DESCRIPTION

...

FUNCTIONS

ExtUtils::Manifest exports no functions by default. The following are exported on request:

mkmanifest

```
mkmanifest();
```

Writes all files in and below the current directory to your `MANIFEST`. It works similar to the result of the Unix command

```
find . > MANIFEST
```

All files that match any regular expression in a file `MANIFEST.SKIP` (if it exists) are ignored.

Any existing `MANIFEST` file will be saved as `MANIFEST.bak`.

manifind

```
my $found = manifind();
```

returns a hash reference. The keys of the hash are the files found below the current directory.

manicheck

```
my @missing_files = manicheck();
```

checks if all the files within a MANIFEST in the current directory really do exist. If MANIFEST and the tree below the current directory are in sync it silently returns an empty list. Otherwise it returns a list of files which are listed in the MANIFEST but missing from the directory, and by default also outputs these names to STDERR.

filecheck

```
my @extra_files = filecheck();
```

finds files below the current directory that are not mentioned in the MANIFEST file. An optional file MANIFEST.SKIP will be consulted. Any file matching a regular expression in such a file will not be reported as missing in the MANIFEST file. The list of any extraneous files found is returned, and by default also reported to STDERR.

fullcheck

```
my($missing, $extra) = fullcheck();
```

does both a manicheck() and a filecheck(), returning then as two array refs.

skipcheck

```
my @skipped = skipcheck();
```

lists all the files that are skipped due to your MANIFEST.SKIP file.

maniread

```
my $manifest = maniread();
my $manifest = maniread($manifest_file);
```

reads a named MANIFEST file (defaults to MANIFEST in the current directory) and returns a HASH reference with files being the keys and comments being the values of the HASH. Blank lines and lines which start with # in the MANIFEST file are discarded.

maniskip

```
my $skipchk = maniskip();
my $skipchk = maniskip($manifest_skip_file);

if ($skipchk->($file)) { .. }
```

reads a named `MANIFEST.SKIP` file (defaults to `MANIFEST.SKIP` in the current directory) and returns a CODE reference that tests whether a given filename should be skipped.

manicopy

```
manicopy(\%src, $dest_dir);
manicopy(\%src, $dest_dir, $how);
```

Copies the files that are the keys in %src to the $dest_dir. %src is typically returned by the maniread() function.

```
manicopy( maniread(), $dest_dir );
```

This function is useful for producing a directory tree identical to the intended distribution tree.

$how can be used to specify a different methods of "copying". Valid values are `cp`, which actually copies the files, `ln` which creates hard links, and `best` which mostly links the files but copies any symbolic link to make a tree without any symbolic link. `cp` is the default.

maniadd

```
maniadd({ $file => $comment, ...});
```

Adds an entry to an existing `MANIFEST` unless its already there.

$file will be normalized (ie. Unixified). **UNIMPLEMENTED**

MANIFEST

A list of files in the distribution, one file per line. The MANIFEST always uses Unix filepath conventions even if you're not on Unix. This means `foo/bar` style not `foo\bar`.

Anything between white space and an end of line within a `MANIFEST` file is considered to be a comment. Any line beginning with # is also a comment. Beginning with ExtUtils::Manifest 1.52, a filename may contain whitespace characters if it is enclosed in single quotes; single quotes or backslashes in that filename must be backslash-escaped.

```
# this a comment
some/file
some/other/file           comment about some/file
'some/third file'         comment
```

MANIFEST.SKIP

The file MANIFEST.SKIP may contain regular expressions of files that should be ignored by mkmanifest() and filecheck(). The regular expressions should appear one on each line. Blank lines and lines which start with # are skipped. Use \# if you need a regular expression to start with a #.

For example:

```
# Version control files and dirs.
\bRCS\b
\bCVS\b
,v$
\B\.svn\b

# Makemaker generated files and dirs.
^MANIFEST\.
^Makefile$
^blib/
^MakeMaker-\d

# Temp, old and emacs backup files.
~$
\.old$
^#.*#$
^\.#
```

If no MANIFEST.SKIP file is found, a default set of skips will be used, similar to the example above. If you want nothing skipped, simply make an empty MANIFEST.SKIP file.

In one's own MANIFEST.SKIP file, certain directives can be used to include the contents of other MANIFEST.SKIP files. At present two such directives are recognized.

- #!include_default

  This tells ExtUtils::Manifest to read the default `MANIFEST.SKIP` file and skip files accordingly, but *not* to include it in the local `MANIFEST.SKIP`. This is intended to skip files according to a system default, which can change over time without requiring further changes to the distribution's `MANIFEST.SKIP`.

- #!include /Path/to/another/manifest.skip

  This inserts the contents of the specified external file in the local `MANIFEST.SKIP`. This is intended for authors to have a central `MANIFEST.SKIP` file, and to include it with their various distributions.

The included contents will be inserted into the MANIFEST.SKIP file in between *#!start included /path/to/manifest.skip* and *#!end included /path/to/manifest.skip* markers. The original MANIFEST.SKIP is saved as MANIFEST.SKIP.bak.

EXPORT_OK

`&mkmanifest`, `&manicheck`, `&filecheck`, `&fullcheck`, `&maniread`, and `&manicopy` are exportable.

GLOBAL VARIABLES

`$ExtUtils::Manifest::MANIFEST` defaults to `MANIFEST`. Changing it results in both a different `MANIFEST` and a different `MANIFEST.SKIP` file. This is useful if you want to maintain different distributions for different audiences (say a user version and a developer version including RCS).

`$ExtUtils::Manifest::Quiet` defaults to 0. If set to a true value, all functions act silently.

`$ExtUtils::Manifest::Debug` defaults to 0. If set to a true value, or if PERL_MM_MANIFEST_DEBUG is true, debugging output will be produced.

DIAGNOSTICS

All diagnostic output is sent to `STDERR`.

- `Not in MANIFEST:` *file*

  is reported if a file is found which is not in `MANIFEST`.

- `Skipping` *file*

  is reported if a file is skipped due to an entry in `MANIFEST.SKIP`.

- `No such file:` *file*

  is reported if a file mentioned in a `MANIFEST` file does not exist.

- `MANIFEST:` *$!*

  is reported if `MANIFEST` could not be opened.

- `Added to MANIFEST:` *file*

  is reported by mkmanifest() if $Verbose is set and a file is added to MANIFEST. $Verbose is set to 1 by default.

ENVIRONMENT

- **PERL_MM_MANIFEST_DEBUG**

  Turns on debugging

ExtUtils::Miniperl

write the C code for miniperlmain.c and perlmain.c

SYNOPSIS

```
use ExtUtils::Miniperl;
writemain(@directories);
# or
writemain($fh, @directories);
# or
writemain(\$filename, @directories);
```

DESCRIPTION

`writemain()` takes an argument list of zero or more directories containing archive libraries that relate to perl modules and should be linked into a new perl binary. It writes a corresponding `miniperlmain.c` or `perlmain.c` file that is a plain C file containing all the bootstrap code to make the modules associated with the libraries available from within perl. If the first argument to `writemain()` is a reference to a scalar it is used as the filename to open for output. Any other reference is used as the filehandle to write to. Otherwise output defaults to `STDOUT`.

The typical usage is from within perl's own Makefile (to build `perlmain.c`) or from `regen/miniperlmain.pl` (to build miniperlmain.c). So under normal circumstances you won't have to deal with this module directly.

ExtUtils::MakeMaker

ExtUtils::PL2Bat

Batch file creation to run perl scripts on Windows

VERSION

version 0.005

OVERVIEW

This module converts a perl script into a batch file that can be executed on Windows/DOS-like operating systems. This is intended to allow you to use a Perl script like regular programs and batch files where you just enter the name of the script [probably minus the extension] plus any command-line arguments and the script is found in your **PATH** and run.

FUNCTIONS

pl2bat(%opts)

This function takes a perl script and write a batch file that contains the script. This is sometimes necessary

- `in`

  The name of the script that is to be batchified. This argument is mandatory.

- `out`

  The name of the output batch file. If not given, it will be generated using `in` and `stripsuffix`.

- `ntargs`

  Arguments to invoke perl with in generated batch file when run from Windows NT. Defaults to '-x -S %0 %*'.

- `otherargs`

  Arguments to invoke perl with in generated batch file except when run from Windows NT (ie. when run from DOS, Windows 3.1, or Windows 95). Defaults to '-x -S "%0" %1 %2 %3 %4 %5 %6 %7 %8 %9'.

- `stripsuffix`

  Strip a suffix string from file name before appending a ".bat" suffix. The suffix is not case-sensitive. It can be a regex or a string and a trailing $ is always assumed). Defaults to `qr/\.plx?/`.

- `usewarnings`

  With the `usewarnings` option, `" -w"` is added after the value of `$Config{startperl}`. If a line matching `/^#!.*perl/` already exists in the script, then it is not changed and the **-w** option is ignored.

- `update`

  If the script appears to have already been processed by **pl2bat**, then the script is skipped and not processed unless `update` was specified. If `update` is specified, the existing preamble is replaced.

ACKNOWLEDGEMENTS

This code was taken from Module::Build and then modified; which had taken it from perl's pl2bat script. This module is an attempt at unifying all three implementations.

ExtUtils::Packlist

manage .packlist files

SYNOPSIS

```
use ExtUtils::Packlist;
my ($pl) = ExtUtils::Packlist->new('.packlist');
$pl->read('/an/old/.packlist');
my @missing_files = $pl->validate();
$pl->write('/a/new/.packlist');

$pl->{'/some/file/name'}++;
   or
$pl->{'/some/other/file/name'} = { type => 'file',
                                   from => '/some/file' };
```

DESCRIPTION

ExtUtils::Packlist provides a standard way to manage .packlist files. Functions are provided to read and write .packlist files. The original .packlist format is a simple list of absolute pathnames, one per line. In addition, this package supports an extended format, where as well as a filename each line may contain a list of attributes in the form of a space separated list of key=value pairs. This is used by the installperl script to differentiate between files and links, for example.

USAGE

The hash reference returned by the new() function can be used to examine and modify the contents of the .packlist. Items may be added/deleted from the .packlist by modifying the hash. If the value associated with a hash key is a scalar, the entry written to the .packlist by any subsequent write() will be a simple filename. If the value is a hash, the entry written will be the filename followed by the key=value pairs from the hash. Reading back the .packlist will recreate the original entries.

FUNCTIONS

- new()

  This takes an optional parameter, the name of a .packlist. If the file exists, it will be opened and the contents of the file will be read. The new() method returns a reference to a hash. This hash holds an entry for each line in the .packlist. In the case of old-style .packlists, the value associated with each key is undef. In the case of new-style .packlists, the value associated with each key is a hash containing the key=value pairs following the filename in the .packlist.

- read()

  This takes an optional parameter, the name of the .packlist to be read. If no file is specified, the .packlist specified to new() will be read. If the .packlist does not exist, Carp::croak will be called.

- write()

  This takes an optional parameter, the name of the .packlist to be written. If no file is specified, the .packlist specified to new() will be overwritten.

- validate()

  This checks that every file listed in the .packlist actually exists. If an argument which evaluates to true is given, any missing files will be removed from the internal hash. The return value is a list of the missing files, which will be empty if they all exist.

- packlist_file()

  This returns the name of the associated .packlist file

EXAMPLE

Here's `modrm`, a little utility to cleanly remove an installed module.

```
#!/usr/local/bin/perl -w

use strict;
use IO::Dir;
use ExtUtils::Packlist;
use ExtUtils::Installed;

sub emptydir($) {
    my ($dir) = @_;
    my $dh = IO::Dir->new($dir) || return(0);
    my @count = $dh->read();
    $dh->close();
    return(@count == 2 ? 1 : 0);
}

# Find all the installed packages
print("Finding all installed modules...\n");
my $installed = ExtUtils::Installed->new();
```

(continues on next page)

(continued from previous page)

```
foreach my $module (grep(!/^Perl$/, $installed->modules())) {
   my $version = $installed->version($module) || "???";
   print("Found module $module Version $version\n");
   print("Do you want to delete $module? [n] ");
   my $r = <STDIN>; chomp($r);
   if ($r && $r =~ /^y/i) {
      # Remove all the files
      foreach my $file (sort($installed->files($module))) {
         print("rm $file\n");
         unlink($file);
      }
      my $pf = $installed->packlist($module)->packlist_file();
      print("rm $pf\n");
      unlink($pf);
      foreach my $dir (sort($installed->directory_tree($module))) {
         if (emptydir($dir)) {
            print("rmdir $dir\n");
            rmdir($dir);
         }
      }
   }
}
```

Alan Burlison Alan.Burlison@uk.sun.com

ExtUtils::testlib

add blib/* directories to @INC

SYNOPSIS

```
use ExtUtils::testlib;
```

DESCRIPTION

After an extension has been built and before it is installed it may be desirable to test it bypassing `make test`. By adding

```
use ExtUtils::testlib;
```

to a test program the intermediate directories used by `make` are added to @INC.

5.2.41 FFI

Namespace containing the following modules:

- `FFI::Build` - Build shared libraries for use with FFI
- `FFI::CheckLib` - Check that a library is available for FFI
- `FFI::Platypus` - Call C functions in shared libraries from Perl, with no compiler.
- `FFI::Probe` - System detection and probing for FFI extensions.
- `FFI::Temp` - Temp Dir support for FFI::Platypus

FFI::Build

Build shared libraries for use with FFI

VERSION

version 2.12

SYNOPSIS

```
use FFI::Platypus 2.00;
use FFI::Build;

my $build = FFI::Build->new(
  'frooble',
  source => 'ffi/*.c',
);

# $lib is an instance of FFI::Build::File::Library
my $lib = $build->build;

my $ffi = FFI::Platypus->new( api => 2 );
# The filename will be platform dependant, but something like␣
↪libfrooble.so or frooble.dll
$ffi->lib($lib->path);

... # use $ffi to attach functions in ffi/*.c
```

DESCRIPTION

Sometimes, however, you need to bundle a little C code with your FFI module, but this has never been that easy to use. Module::Build::FFI was an early attempt to address this use case, but it uses the now out of fashion Module::Build.

This module itself doesn't directly integrate with CPAN installers like *ExtUtils::MakeMaker* or Module::Build, but there is a light weight layer *FFI::Build::MM* that will allow you to easily use this module with *ExtUtils::MakeMaker*. If you are using Dist::Zilla as your dist builder, then there is also Dist::Zilla::Plugin::FFI::Build, which will help with the connections.

There is some functional overlap with *ExtUtils::CBuilder*, which was in fact used by Module::Build::FFI.

Supported languages out of the box are C, C++ and Fortran. Rust is supported via a language plugin, see FFI::Platypus::Lang::Rust.

CONSTRUCTOR

new

```
my $build = FFI::Build->new($name, %options);
```

Create an instance of this class. The `$name` argument is used when computing the file name for the library. The actual name will be something like `lib$name.so` or `$name.dll`. The following options are supported:

- alien

  List of Aliens to compile/link against. *FFI::Build* will work with any Alien::Base based alien, or modules that provide a compatible API.

- buildname

  Directory name that will be used for building intermediate files, such as object files. This is `_build` by default.

- cflags

  Extra compiler flags to use. Things like `-I/foo/include` or `-DFOO=1`.

- dir

  The directory where the library will be written. This is `.` by default.

- export

  Functions that should be exported (Windows + Visual C++ only)

- file

  An instance of *FFI::Build::File::Library* to which the library will be written. Normally not needed.

- libs

  Extra library flags to use. Things like `-L/foo/lib -lfoo`.

- platform

  An instance of *FFI::Build::Platform*. Usually you want to omit this and use the default instance.

- source

  List of source files. You can use wildcards supported by `bsd_glob` from *File::Glob*.

- verbose

  By default this class does not print out the actual compiler and linker commands used in building the library unless there is a failure. You can alter this behavior with this option. Set to one of these values:

- zero (0)

  Default, quiet unless there is a failure.

- one (1)

  Output the operation (compile, link, etc) and the file, but nothing else

- two (2)

  Output the complete commands run verbatim.

If the environment variable `V` is set to a true value then the verbosity will be set to 2 regardless of what is passed in.

METHODS

dir

```
my $dir = $build->dir;
```

Returns the directory where the library will be written.

buildname

```
my $builddir = $build->builddir;
```

Returns the build name. This is used in computing a directory to save intermediate files like objects. For example, if you specify a file like `ffi/foo.c`, then the object file will be stored in `ffi/_build/foo.o` by default. `_build` in this example (the default) is the build name.

export

```
my $exports = $build->export;
```

Returns a array reference of the exported functions (Windows + Visual C++ only)

file

```
my $file = $build->file;
```

Returns an instance of *FFI::Build::File::Library* corresponding to the library being built. This is also returned by the `build` method below.

platform

```
my $platform = $build->platform;
```

An instance of *FFI::Build::Platform*, which contains information about the platform on which you are building. The default is usually reasonable.

verbose

```
my $verbose = $build->verbose;
```

Returns the verbose flag.

cflags

```
my @cflags = @{ $build->cflags };
```

Returns the compiler flags.

cflags_I

```
my @cflags_I = @{ $build->cflags_I };
```

Returns the `-I` cflags.

libs

```
my @libs = @{ $build->libs };
```

Returns the library flags.

libs_L

```
my @libs = @{ $build->libs };
```

Returns the `-L` library flags.

alien

```
my @aliens = @{ $build->alien };
```

Returns a the list of aliens being used.

source

```
$build->source(@files);
```

Add the `@files` to the list of source files that will be used in building the library. The format is the same as with the `source` attribute above.

build

```
my $lib = $build->build;
```

This compiles the source files and links the library. Files that have already been compiled or linked may be reused without recompiling/linking if the timestamps are newer than the source files. An instance of *FFI::Build::File::Library* is returned which can be used to get the path to the library, which can be feed into *FFI::Platypus* or similar.

clean

```
$build->clean;
```

Removes the library and intermediate files.

Modules

- `FFI::Build::File`
- `FFI::Build::MM` - FFI::Build installer code for ExtUtils::MakeMaker
- `FFI::Build::Platform` - Platform specific configuration.
- `FFI::Build::Plugin` - Platform and local customizations of FFI::Build
- `FFI::Build::PluginData` - Platform and local customizations of FFI::Build

FFI::Build::File

Namespace containing the following modules:

- `FFI::Build::File::Base` - Base class for File::Build files
- `FFI::Build::File::C` - Class to track C source file in FFI::Build
- `FFI::Build::File::CXX` - Class to track C source file in FFI::Build
- `FFI::Build::File::Library` - Class to track object file in FFI::Build
- `FFI::Build::File::Object` - Class to track object file in FFI::Build

FFI::Build::File::Base

Base class for File::Build files

VERSION

version 2.12

SYNOPSIS

Create your own file class

```
package FFI::Build::File::Foo;
use parent qw( FFI::Build::File::Base );
use constant default_suffix => '.foo';
use constant default_encoding => ':utf8';
```

Use it:

```
# use an existing file in the filesystem
my $file = FFI::Build::File::Foo->new('src/myfile.foo');
```

(continues on next page)

(continued from previous page)

```
# generate a temp file with provided content
# file will be deletd when $file falls out of scope.
my $file = FFI::Build::File::Foo->new(\'content for a temp foo');
```

DESCRIPTION

This class is the base class for other `FFI::Build::File::*` classes.

CONSTRUCTOR

new

```
my $file = FFI::Build::File::Base->new(\$content, %options);
my $file = FFI::Build::File::Base->new($filename, %options);
```

Create a new instance of the file class. You may provide either the content of the file as a scalar reference, or the path to an existing filename. Options:

- base

  The base name for any temporary file `ffi_build_` by default.

- build

  The *FFI::Build* instance to use.

- dir

  The directory to store any temporary file.

- platform

  The *FFI::Build::Platform* instance to use.

METHODS

default_suffix

```
my $suffix = $file->default_suffix;
```

MUST be overridden in the subclass. This is the standard extension for the file type. `.c` for a C file, `.o` or `.obj` for an object file depending on platform. etc.

default_encoding

```
my $encoding = $file->default_encoding;
```

MUST be overridden in the subclass. This is the passed to `binmode` when the file is opened for reading or writing.

accept_suffix

```
my @suffix_list = $file->accept_suffix;
```

Returns a list of regexes that recognize the file type.

path

```
my $path = $file->path;
```

The full or relative path to the file.

basename

```
my $basename = $file->basename;
```

The base filename part of the path.

dirname

```
my $dir = $file->dirname;
```

The directory part of the path.

is_temp

```
my $bool = $file->is_temp;
```

Returns true if the file is temporary, that is, it will be deleted when the file object falls out of scope. You can call keep, to keep the file.

platform

```
my $platform = $file->platform;
```

The *FFI::Build::Platform* instance used for this file object.

build

```
my $build = $file->build;
```

The *FFI::Build* instance used for this file object, if any.

native

```
my $path = $file->native;
```

Returns the operating system native version of the filename path. On Windows, this means that forward slash `\` is used instead of backslash `/`.

slurp

```
my $content = $file->slurp;
```

Returns the content of the file.

keep

```
$file->keep;
```

Turns off the temporary flag on the file object, meaning it will not automatically be deleted when the file object is deallocated or falls out of scope.

build_item

```
$file->build_item;
```

Builds the file into its natural output type, usually an object file. It returns a new file instance, or if the file is an object file then it returns empty list.

build_all

```
$file->build_all;
```

If implemented the file in question can directly create a shared or dynamic library without needing a link step. This is useful for languages that have their own build systems.

needs_rebuild

```
my $bool = $file->needs_rebuild
```

FFI::Build::File::Library

Class to track object file in FFI::Build

VERSION

version 2.12

SYNOPSIS

```
use FFI::Build;

my $build = FFI::Build->new(source => 'src/*.c');
# $lib is an instance of FFI::Build::File::Library
my $lib = $build->build;
```

DESCRIPTION

This is a class to track a library generated by *FFI::Build*. This is returned by *FFI::Build*'s build method. This class is a subclass of *FFI::Build::File::Base*. The most important method is probably `path`, which returns the path to the library which can be passed into *FFI::Platypus* for immediate use.

METHODS

path

```
my $path = $lib->path;
```

Returns the path of the library.

FFI::Build::File::Object

Class to track object file in FFI::Build

VERSION

version 2.12

SYNOPSIS

```
use FFI::Build::File::Object;
my $o = FFI::Build::File::Object->new('src/_build/foo.o');
```

DESCRIPTION

This class represents an object file. You normally do not need to use it directly.

FFI::Build::MM

FFI::Build installer code for ExtUtils::MakeMaker

VERSION

version 2.12

SYNOPSIS

In your Makefile.PL:

```
use ExtUtils::MakeMaker;
use FFI::Build::MM;

my $fbmm = FFI::Build::MM->new;

```

(continues on next page)

(continued from previous page)

```
WriteMakefile($fbmm->mm_args(
  ABSTRACT     => 'My FFI extension',
  DISTNAME     => 'Foo-Bar-Baz-FFI',
  NAME         => 'Foo::Bar::Baz::FFI',
  VERSION_FROM => 'lib/Foo/Bar/Baz/FFI.pm',
  ...
));

sub MY::postamble {
  $fbmm->mm_postamble;
}
```

Then put the C, C++ or Fortran files in `./ffi` for your runtime library and `./t/ffi` for your test time library.

DESCRIPTION

This module provides a thin layer between *FFI::Build* and *ExtUtils::MakeMaker*. Its interface is influenced by the design of Alien::Build::MM. The idea is that for your distribution you throw some C, C++ or Fortran source files into a directory called `ffi` and these files will be compiled and linked into a library that can be used by your module. There is a control file `ffi/*.fbx` which can be used to control the compiler and linker options. (options passed directly into *FFI::Build*). The interface for this file is still under development.

CONSTRUCTOR

new

```
my $fbmm = FFI::Build::MM->new;
```

Create a new instance of *FFI::Build::MM*.

METHODS

mm_args

```
my %new_args = $fbmm->mm_args(%old_args);
```

This method does two things:

- reads the arguments to determine sensible defaults (library name, install location, etc).
- adjusts the arguments as necessary and returns an updated set of arguments.

mm_postamble

```
my $postamble = $fbmm->mm_postamble;
```

This returns the Makefile postamble used by *ExtUtils::MakeMaker*. The synopsis above for how to invoke it properly. It adds the following Make targets:

- fbx_build / ffi

  build the main runtime library in `./ffi`.

- fbx_test / ffi-test

  Build the test library in `./t/ffi`.

- fbx_clean / ffi-clean

  Clean any runtime or test libraries already built.

Normally you do not need to build these targets manually, they will be built automatically at the appropriate stage.

FFI::Build::Platform

Platform specific configuration.

VERSION

version 2.12

SYNOPSIS

```
use FFI::Build::Platform;
```

DESCRIPTION

This class is used to abstract out the platform specific parts of the *FFI::Build* system. You shouldn't need to use it directly in most cases, unless you are working on *FFI::Build* itself.

CONSTRUCTOR

new

```
my $platform = FFI::Build::Platform->new;
```

Create a new instance of *FFI::Build::Platform*.

default

```
my $platform = FFI::Build::Platform->default;
```

Returns the default instance of *FFI::Build::Platform*.

METHODS

All of these methods may be called either as instance or classes methods. If called as a class method, the default instance will be used.

osname

```
my $osname = $platform->osname;
```

The "os name" as understood by Perl. This is the same as `$^O`.

object_suffix

```
my $suffix = $platform->object_suffix;
```

The object suffix for the platform. On UNIX this is usually `.o`. On Windows this is usually `.obj`.

library_suffix

```
my(@suffix) = $platform->library_suffix;
my $suffix  = $platform->library_suffix;
```

The library suffix for the platform. On Linux and some other UNIX this is often `.so`. On OS X, this is `.dylib` and `.bundle`. On Windows this is `.dll`.

library_prefix

```
my $prefix = $platform->library_prefix;
```

The library prefix for the platform. On Unix this is usually `lib`, as in `libfoo`.

cc

```
my @cc = @{ $platform->cc };
```

The C compiler

cpp

```
my @cpp = @{ $platform->cpp };
```

The C pre-processor

cxx

```
my @cxx = @{ $platform->cxx };
```

The C++ compiler that naturally goes with the C compiler.

cxxld

```
my @cxxld = @{ $platform->cxxld };
```

The C++ linker that naturally goes with the C compiler.

for

```
my @for = @{ $platform->for };
```

The Fortran compiler that naturally goes with the C compiler.

ld

```
my $ld = $platform->ld;
```

The C linker

shellwords

```
my @words = $platform->shellwords(@strings);
```

This is a wrapper around *Text::ParseWords*'s `shellwords` with some platform workarounds applied.

ccflags

```
my @ccflags = @{ $platform->cflags};
```

The compiler flags, including those needed to compile object files that can be linked into a dynamic library. On Linux, for example, this is usually includes `-fPIC`.

ldflags

```
my @ldflags = @{ $platform->ldflags };
```

The linker flags needed to link object files into a dynamic library. This is NOT the `libs` style library flags that specify the location and name of a library to link against, this is instead the flags that tell the linker to generate a dynamic library. On Linux, for example, this is usually `-shared`.

cc_mm_works

```
my $bool = $platform->cc_mm_works;
```

Returns the flags that can be passed into the C compiler to compute dependencies.

flag_object_output

```
my @flags = $platform->flag_object_output($object_filename);
```

Returns the flags that the compiler recognizes as being used to write out to a specific object filename.

flag_library_output

```
my @flags = $platform->flag_library_output($library_filename);
```

Returns the flags that the compiler recognizes as being used to write out to a specific library filename.

flag_exe_output

```
my @flags = $platform->flag_exe_output($library_filename);
```

Returns the flags that the compiler recognizes as being used to write out to a specific exe filename.

flag_export

```
my @flags = $platform->flag_export(@symbols);
```

Returns the flags that the linker recognizes for exporting functions.

which

```
my $path = $platform->which($command);
```

Returns the full path of the given command, if it is available, otherwise undef is returned.

run

```
$platform->run(@command);
```

diag

Diagnostic for the platform as a string. This is for human consumption only, and the format may and will change over time so do not attempt to use is programmatically.

FFI::CheckLib

Check that a library is available for FFI

VERSION

version 0.31

SYNOPSIS

```
use FFI::CheckLib;

check_lib_or_exit( lib => 'jpeg', symbol => 'jinit_memory_mgr' );
check_lib_or_exit( lib => [ 'iconv', 'jpeg' ] );

# or prompt for path to library and then:
print "where to find jpeg library: ";
my $path = <STDIN>;
check_lib_or_exit( lib => 'jpeg', libpath => $path );
```

DESCRIPTION

This module checks whether a particular dynamic library is available for FFI to use. It is modeled heavily on Devel::CheckLib, but will find dynamic libraries even when development packages are not installed. It also provides a *find_lib* function that will return the full path to the found dynamic library, which can be feed directly into *FFI::Platypus* or another FFI system.

Although intended mainly for FFI modules via *FFI::Platypus* and similar, this module does not actually use any FFI to do its detection and probing. This module does not have any non-core runtime dependencies. The test suite does depend on *Test2::Suite*.

FUNCTIONS

All of these take the same named parameters and are exported by default.

find_lib

```
my(@libs) = find_lib(%args);
```

This will return a list of dynamic libraries, or empty list if none were found.

[version 0.05]

If called in scalar context it will return the first library found.

Arguments are key value pairs with these keys:

- lib

  Must be either a string with the name of a single library or a reference to an array of strings of library names. Depending on your platform, `CheckLib` will prepend `lib` or append `.dll` or `.so` when searching.

  [version 0.11]

  As a special case, if * is specified then any libs found will match.

- libpath

  A string or array of additional paths to search for libraries.

- systempath

  [version 0.11]

  A string or array of system paths to search for instead of letting *FFI::CheckLib* determine the system path. You can set this to `[]` in order to not search *any* system paths.

- symbol

  A string or a list of symbol names that must be found.

- verify

  A code reference used to verify a library really is the one that you want. It should take two arguments, which is the name of the library and the full path to the library pathname. It should return true if it is acceptable, and false otherwise. You can use this in conjunction with *FFI::Platypus* to determine if it is going to meet your needs. Example:

```
use FFI::CheckLib;
use FFI::Platypus;

my($lib) = find_lib(
  lib => 'foo',
  verify => sub {
    my($name, $libpath) = @_;

    my $ffi = FFI::Platypus->new;
    $ffi->lib($libpath);

    my $f = $ffi->function('foo_version', [] => 'int');
```

(continues on next page)

(continued from previous page)

```
    return $f->call() >= 500; # we accept version 500 or better
  },
);
```

- recursive

  [version 0.11]

  Recursively search for libraries in any non-system paths (those provided via `lib-path` above).

- try_linker_script

  [version 0.24]

  Some vendors provide `.so` files that are linker scripts that point to the real binary shared library. These linker scripts can be used by gcc or clang, but are not directly usable by *FFI::Platypus* and friends. On select platforms, this options will use the linker command (`ld`) to attempt to resolve the real `.so` for non-binary files. Since there is extra overhead this is off by default.

  An example is libyaml on Red Hat based Linux distributions. On Debian these are handled with symlinks and no trickery is required.

- alien

  [version 0.25]

  If no libraries can be found, try the given aliens instead. The Alien classes specified must provide the Alien::Base interface for dynamic libraries, which is to say they should provide a method called `dynamic_libs` that returns a list of dynamic libraries.

  [version 0.28]

  In 0.28 and later, if the Alien is not installed then it will be ignored and this module will search in system or specified directories only. This module *will* still throw an exception, if the Alien doesn't look like a module name or if it does not provide a `dynamic_libs` method (which is implemented by all Alien::Base subclasses).

  [version 0.30] [breaking change]

  Starting with version 0.30, libraries provided by Aliens is preferred over the system libraries. The original thinking was that you want to prefer the system libraries because they are more likely to get patched with regular system updates. Unfortunately, the reason a module needs to install an Alien is likely because the system library is not new enough, so we now prefer the Aliens instead.

assert_lib

```
assert_lib(%args);
```

This behaves exactly the same as *find_lib*, except that instead of returning empty list of failure it throws an exception.

check_lib_or_exit

```
check_lib_or_exit(%args);
```

This behaves exactly the same as *assert_lib*, except that instead of dying, it warns (with exactly the same error message) and exists. This is intended for use in `Makefile.PL` or `Build.PL`

find_lib_or_exit

[version 0.05]

```
my(@libs) = find_lib_or_exit(%args);
```

This behaves exactly the same as *find_lib*, except that if the library is not found, it will call exit with an appropriate diagnostic.

find_lib_or_die

[version 0.06]

```
my(@libs) = find_lib_or_die(%args);
```

This behaves exactly the same as *find_lib*, except that if the library is not found, it will die with an appropriate diagnostic.

check_lib

```
my $bool = check_lib(%args);
```

This behaves exactly the same as *find_lib*, except that it returns true (1) on finding the appropriate libraries or false (0) otherwise.

which

[version 0.17]

```
my $path = which($name);
```

Return the path to the first library that matches the given name.

Not exported by default.

where

[version 0.17]

```
my @paths = where($name);
```

Return the paths to all the libraries that match the given name.

Not exported by default.

has_symbols

[version 0.17]

```
my $bool = has_symbols($path, @symbol_names);
```

Returns true if *all* of the symbols can be found in the dynamic library located at the given path. Can be useful in conjunction with `verify` with `find_lib` above.

Not exported by default.

system_path

[version 0.20]

```
my $path = FFI::CheckLib::system_path;
```

Returns the system path as a list reference. On some systems, this is `PATH` on others it might be `LD_LIBRARY_PATH` on still others it could be something completely different. So although you *may* add items to this list, you should probably do some careful consideration before you do so.

This function is not exportable, even on request.

ENVIRONMENT

FFI::CheckLib responds to these environment variables:

- FFI_CHECKLIB_PACKAGE

  On macOS platforms with Homebrew and/or MacPorts installed, their corresponding lib paths will be automatically appended to `$system_path`. In case of having both managers installed, Homebrew will appear before.

  This behaviour can be overridden using the environment variable `FFI_CHECKLIB_PACKAGE`.

  Allowed values are:

  - none: Won't use either Homebrew's path nor MacPorts - homebrew: Will append `$(brew --prefix)/lib` to the system paths - `macports`: Will append `port`'s default lib path

  A comma separated list is also valid:

  ```
  export FFI_CHECKLIB_PACKAGE=macports,homebrew
  ```

  Order matters. So in this example, MacPorts' lib path appears before Homebrew's path.

- FFI_CHECKLIB_PATH

  List of directories that will be considered by *FFI::CheckLib* as additional "system directories". They will be searched before other system directories but after `libpath`. The variable is colon separated on Unix and semicolon separated on Windows. If you use this variable, `FFI_CHECKLIB_PACKAGE` will be ignored.

- PATH

  On Windows the PATH environment variable will be used as a search path for libraries.

On some operating systems LD_LIBRARY_PATH, DYLD_LIBRARY_PATH, DYLD_FALLBACK_LIBRARY_PATH or others *may* be used as part of the search for dynamic libraries and *may* be used (indirectly) by *FFI::CheckLib* as well.

FAQ

- Why not just use dlopen?

  Calling dlopen on a library name and then dlclose immediately can tell you if you have the exact name of a library available on a system. It does have a number of drawbacks as well.

  – No absolute or relative path

    It only tells you that the library is *somewhere* on the system, not having the absolute or relative path makes it harder to generate useful diagnostics.

  – POSIX only

    This doesn't work on non-POSIX systems like Microsoft Windows. If you are using a POSIX emulation layer on Windows that provides dlopen, like Cygwin, there are a number of gotchas there as well. Having a layer written in Perl handles this means that developers on Unix can develop FFI that will more likely work on these platforms without special casing them.

  – inconsistent implementations

    Even on POSIX systems you have inconsistent implementations. OpenBSD for example don't usually include symlinks for .so files meaning you need to know the exact .so version.

  – non-system directories

    By default dlopen only works for libraries in the system paths. Most platforms have a way of configuring the search for different non-system paths, but none of them are portable, and are usually discouraged anyway. Alien and friends need to do searches for dynamic libraries in non-system directories for share installs.

- My 64-bit Perl is misconfigured and has 32-bit libraries in its search path. Is that a bug in *FFI::CheckLib*?

  Nope.

- The way *FFI::CheckLib* is implemented it won't work on AIX, HP-UX, OpenVMS or Plan 9.

  I know for a fact that it doesn't work on AIX *as currently implemented* because I used to develop on AIX in the early 2000s, and I am aware of some of the technical challenges. There are probably other systems that it won't work on. I would love to add support for these platforms. Realistically these platforms have a tiny market share, and absent patches from users or the companies that own these operating systems (patches welcome), or hardware / CPU time donations, these platforms are unsupportable anyway.

SEE ALSO

- *FFI::Platypus*

  Call library functions dynamically without a compiler.

- Dist::Zilla::Plugin::FFI::CheckLib

  Dist::Zilla plugin for this module.

FFI::Platypus

Call C functions in shared libraries from Perl, with no compiler.

`FFI::Platypus->new(api => 2, lib => ...)` finds a library; `$ffi->attach(name => [argument types] => return type)` makes a C function a Perl sub, `$ffi->function(...)` an object to call. Types cover the C integers and floats, `long double` and the complex types, strings, pointers and fixed arrays of them, records (C structs) by pointer and by value, closures (Perl subs C can call back), objects and custom types written in Perl.

This is a native implementation of FFI::Platypus 2.12's compiled part, `Platypus.xs` with its `xs/*.xs` and helpers; its Perl modules are used unchanged. Its calls, types, records and closures are those of pperl's own *Peta::FFI*, which can express everything FFI::Platypus can.

Synopsis

```
use FFI::Platypus 2.00;

my $ffi = FFI::Platypus->new( api => 2, lib => undef );
$ffi->attach( puts   => ['string'] => 'int' );
$ffi->attach( strlen => ['string'] => 'size_t' );

puts("hello");
my $n = strlen("hello");                # 5

my $qsort = $ffi->function( qsort =>
    ['int*', 'size_t', 'size_t', '(opaque,opaque)->int'] => 'void'␣
↪);
```

Differences from upstream

- Reading an array member of a record does not leak the array; perl leaks it and the reference on every read.
- An index past an opaque `[N]` member warns "illegal index" and returns nothing, as for the other array members; perl reads beyond the member.
- A reference to a hash or code for a pointer argument under api 2 warns and passes NULL; perl crashes.
- An argument with get-magic - a regex capture, a tied scalar - passes its value; perl passes 0 for a number and NULL for a string, which crashes `strlen($1)`.
- A closure that a library calls from a thread of its own stops the program with a message saying so; perl runs Perl on that thread and crashes ("longjmp causes uninitialized stack frame").

Modules

- `FFI::Platypus::API` - Platypus arguments and return value API for custom types
- `FFI::Platypus::Buffer` - Convert scalars to C buffers
- `FFI::Platypus::Bundle` - Bundle foreign code with your Perl module
- `FFI::Platypus::Closure` - Platypus closure object
- `FFI::Platypus::Constant` - Define constants in C space for Perl
- `FFI::Platypus::DL` - Slightly non-portable interface to libdl
- `FFI::Platypus::Function` - An FFI function object
- `FFI::Platypus::Internal` - For internal use only
- `FFI::Platypus::Lang` - Language specific customizations
- `FFI::Platypus::Legacy` - Legacy Platypus interfaces
- `FFI::Platypus::Memory` - Memory functions for FFI
- `FFI::Platypus::Record` - FFI support for structured records data

- `FFI::Platypus::ShareConfig` - FFI::Platypus::ShareConfig
- `FFI::Platypus::Type` - Defining types for FFI::Platypus
- `FFI::Platypus::TypeParser` - FFI Type Parser

FFI::Platypus::API

Platypus arguments and return value API for custom types

VERSION

version 2.12

SYNOPSIS

```
package FFI::Platypus::Type::MyCustomType;

use FFI::Platypus::API;

sub ffi_custom_type_api_1
{
  {
    native_type => 'uint32',
    perl_to_native => sub {
      my($value, $i) = @_;
      # Translates ($value) passed in from Perl
      # into ($value+1, $value+2)
      arguments_set_uint32($i, $value+1);
      arguments_set_uint32($i+1, $value+2);
    },
    argument_count => 2,
  }
}
```

DESCRIPTION

NOTE: I added this interface early on to *FFI::Platypus*, but haven't used it much, generally finding function wrappers to be a more powerful (although possibly not as fast) interface. It has thus not been tested as much as the rest of Platypus. If you feel the need to use this interface please coordinate with the Platypus developers.

The custom types API for *FFI::Platypus* allows you to set multiple C arguments from a single Perl argument as a common type. This is sometimes useful for pointer / size pairs which are a common pattern in C, but are usually represented by a single value (a string scalar) in Perl.

The custom type API is somewhat experimental, and you should expect some changes as needs arise (I won't break compatibility lightly, however).

FUNCTIONS

These functions are only valid within a custom type callback.

arguments_count

```
my $count = argument_count;
```

Returns the total number of native arguments.

arguments_get_sint8

```
my $sint8 = arguments_get_sint8 $i;
```

Get the 8 bit signed integer argument from position *$i*.

arguments_set_sint8

```
arguments_set_sint8 $i, $sint8;
```

Set the 8 bit signed integer argument at position *$i* to *$sint8*.

arguments_get_uint8

```
my $uint8 = arguments_get_uint8 $i;
```

Get the 8 bit unsigned integer argument from position *$i*.

arguments_set_uint8

```
arguments_set_uint8 $i, $uint8;
```

Set the 8 bit unsigned integer argument at position *$i* to *$uint8*.

arguments_get_sint16

```
my $sint16 = arguments_get_sint16 $i;
```

Get the 16 bit signed integer argument from position *$i*.

arguments_set_sint16

```
arguments_set_sint16 $i, $sint16;
```

Set the 16 bit signed integer argument at position *$i* to *$sint16*.

arguments_get_uint16

```
my $uint16 = arguments_get_uint16 $i;
```

Get the 16 bit unsigned integer argument from position *$i*.

arguments_set_uint16

```
arguments_set_uint16 $i, $uint16;
```

Set the 16 bit unsigned integer argument at position *$i* to *$uint16*.

arguments_get_sint32

```
my $sint32 = arguments_get_sint32 $i;
```

Get the 32 bit signed integer argument from position *$i*.

arguments_set_sint32

```
arguments_set_sint32 $i, $sint32;
```

Set the 32 bit signed integer argument at position *$i* to *$sint32*.

arguments_get_uint32

```
my $uint32 = arguments_get_uint32 $i;
```

Get the 32 bit unsigned integer argument from position *$i*.

arguments_set_uint32

```
arguments_set_uint32 $i, $uint32;
```

Set the 32 bit unsigned integer argument at position *$i* to *$uint32*.

arguments_get_sint64

```
my $sint64 = arguments_get_sint64 $i;
```

Get the 64 bit signed integer argument from position *$i*.

arguments_set_sint64

```
arguments_set_sint64 $i, $sint64;
```

Set the 64 bit signed integer argument at position *$i* to *$sint64*.

arguments_get_uint64

```
my $uint64 = arguments_get_uint64 $i;
```

Get the 64 bit unsigned integer argument from position *$i*.

arguments_set_uint64

```
arguments_set_uint64 $i, $uint64;
```

Set the 64 bit unsigned integer argument at position *$i* to *$uint64*.

arguments_get_float

```
my $float = arguments_get_float $i;
```

Get the floating point argument from position *$i*.

arguments_set_float

```
arguments_set_float $i, $float;
```

Set the floating point argument at position *$i* to *$float*

arguments_get_double

```
my $double = arguments_get_double $i;
```

Get the double precision floating point argument from position *$i*.

arguments_set_double

```
arguments_set_double $i, $double;
```

Set the double precision floating point argument at position *$i* to *$double*

arguments_get_pointer

```
my $pointer = arguments_get_pointer $i;
```

Get the pointer argument from position *$i*.

arguments_set_pointer

```
arguments_set_pointer $i, $pointer;
```

Set the pointer argument at position *$i* to *$pointer*.

arguments_get_string

```
my $string = arguments_get_string $i;
```

Get the string argument from position *$i*.

arguments_set_string

```
arguments_set_string $i, $string;
```

Set the string argument at position *$i* to *$string*.

FFI::Platypus::Buffer

Convert scalars to C buffers

VERSION

version 2.12

SYNOPSIS

```
use FFI::Platypus::Buffer;
my($pointer, $size) = scalar_to_buffer $scalar;
my $scalar2 = buffer_to_scalar $pointer, $size;
```

DESCRIPTION

A common pattern in C is to pass a "buffer" or region of memory into a function with a pair of arguments, an opaque pointer and the size of the memory region. In Perl the equivalent structure is a scalar containing a string of bytes. This module provides portable functions for converting a Perl string or scalar into a buffer and back.

These functions are implemented using pack and unpack and so they should be relatively fast.

Both functions are exported by default, but you can explicitly export one or neither if you so choose.

A better way to do this might be with custom types see *FFI::Platypus::API* and *FFI::Platypus::Type*. These functions were taken from the now obsolete FFI::Util module, as they may be useful in some cases.

Caution: This module provides great power in the way that you interact with C code, but with that power comes great responsibility. Since you are dealing with blocks of memory you need to take care to understand the underlying ownership model of these pointers.

FUNCTIONS

scalar_to_buffer

```
my($pointer, $size) = scalar_to_buffer $scalar;
```

Convert a string scalar into a buffer. Returned in order are a pointer to the start of the string scalar's memory region and the size of the region.

You should NEVER try to free `$pointer`.

When you pass this pointer and size into a C function, it has direct access to the data stored in your scalar, so it is important that you not resize or free the scalar while it is in use by the C code. Typically if you are passing a buffer into a C function which reads or writes to the buffer, but does not keep the pointer for later use you are okay. If the buffer is in use long term by the C code, then you should consider copying the buffer instead. For example:

```
use FFI::Platypus::Buffer qw( scalar_to_buffer );
use FFI::Platypus::Memory qw( malloc memcpy free )

my($ptr, $size) = scalar_to_buffer $string;
c_function_that_does_not_keep_ptr( $ptr, $size); # okay

my($ptr, $size) = scalar_to_buffer $string;
my $ptr_copy = malloc($size);
memcpy($ptr_copy, $ptr, $size);
c_function_that_DOES_keep_ptr( $ptr_copy, $size); # also okay

...

# later when you know that the c code is no longer using the pointer
# Since you allocated the copy, you are responsible for free'ing it.
free($ptr_copy);
```

scalar_to_pointer

```
my $pointer = scalar_to_pointer $scalar;
```

Get the pointer to the scalar. (Similar to `scalar_to_buffer` above, but the size of the scalar is not computed or returned).

Not exported by default, but may be exported on request.

buffer_to_scalar

```
my $scalar = buffer_to_scalar $pointer, $size;
```

Convert the buffer region defined by the pointer and size into a string scalar.

Because of the way memory management works in Perl, the buffer is copied from the buffer into the scalar. If this pointer was returned from C land, then you should only free it if you allocated it.

grow

```
grow $scalar, $size, \%options;
```

Ensure that the scalar can contain at least `$size` bytes. The following are recognized:

- clear => *boolean*

  If true, `$scalar` is cleared prior to being enlarged. This avoids copying the existing contents to the reallocated memory if they are not needed.

  ```
  For example, after

   $scalar = "my string";
   grow $scalar, 100, { clear => 0 };
  ```

  `$scalar == "my string"`, while after

  ```
  $scalar = "my string";
  grow $scalar, 100;
  ```

  `length($scalar) == 0`

  It defaults to `true`.

- set_length => *boolean*

  If true, the length of the *string* in the `$scalar` is set to `$size`. (See the discussion in "set_used_length".) This is useful if a foreign function writes exactly `$size` bytes to `$scalar`, as it avoids a subsequent call to `set_used_length`. Contrast this

  ```
  grow my $scalar, 100;
  read_exactly_100_bytes_into_scalar( scalar_to_pointer($scalar)␣
   ↪);
  @chars = unpack( 'c*', $scalar );
  ```

  with this:

  ```
  grow my $scalar, 100, { set_length => 0 };
  read_exactly_100_bytes_into_scalar( scalar_to_pointer($scalar)␣
   ↪);
  set_used_length( $scalar, 100 );
  @chars = unpack( 'c*', $scalar );
  ```

  It defaults to `true`.

Any pointers obtained with `scalar_to_pointer` or `scalar_to_buffer` are no longer valid after growing the scalar.

Not exported by default, but may be exported on request.

set_used_length

```
set_used_length $scalar, $length;
```

Update Perl's notion of the length of the string in the scalar. A string scalar keeps track of two lengths: the number of available bytes and the number of used bytes. When a string scalar is used as a buffer by a foreign function, it is necessary to indicate to Perl how many bytes were actually written to it so that Perl's string functions (such as `substr` or `unpack`) will work correctly.

If `$length` is larger than what the scalar can hold, it is set to the maximum possible size.

In the following example, the foreign routine `read_doubles` may fill the buffer with up to a set number of doubles, returning the number actually written.

```
my $sizeof_double = $ffi->sizeof( 'double' );
my $max_doubles = 100;
my $max_length = $max_doubles * $sizeof_double;

my $buffer;                    # length($buffer) == 0
grow $buffer, $max_length;     # length($buffer) is still  0
my $pointer = scalar_to_pointer($buffer);

my $num_read = read_doubles( $pointer, $max_doubles );
                               # length($buffer) is still == 0

set_used_length $buffer, $num_read * $sizeof_double;
                               # length($buffer) is finally != 0

# unpack the native doubles into a Perl array
my @doubles = unpack( 'd*', $buffer );  # @doubles == $num_read
```

Not exported by default, but may be exported on request.

window

```
window $scalar, $pointer;
window $scalar, $pointer, $size;
window $scalar, $pointer, $size, $utf8;
```

This makes the scalar a read-only window into the arbitrary region of memory defined by `$pointer`, pointing to the start of the region and `$size`, the size of the region. If `$size` is omitted then it will assume a C style string and use the C `strlen` function to determine the size (the terminating `'\0'` will not be included).

This can be useful if you have a C function that returns a buffer pair (pointer, size), and want to access it from Perl without having to copy the data. This can also be useful when interfacing with programming languages that store strings as a address/length pair instead of a pointer to null-terminated sequence of bytes.

You can specify `$utf8` to set the UTF-8 flag on the scalar. Note that the behavior of setting the UTF-8 flag on a buffer that does not contain UTF-8 as understood by the version of Perl that you are running is undefined.

Hint: If you have a buffer that needs to be free'd by C once the scalar falls out of scope you can use Variable::Magic to apply magic to the scalar and free the pointer once it falls out of scope.

```
use FFI::Platypus::Buffer qw( scalar_to_pointer );
use FFI::Platypus::Memory qw( strdup free );
use Variable::Magic qw( wizard cast );

my $free_when_out_of_scope = wizard(
  free => sub {
    my $ptr = scalar_to_pointer ${$_[0]};
    free $ptr;
  }
);

my $ptr = strdup "Hello Perl";
my $scalar;
window $scalar, $ptr, 10;
cast $scalar, $free_when_out_of_scope;
undef $ptr;  # don't need to track the pointer anymore.

# we can now use scalar as a regular read-only Perl variable
print $scalar, "\n";  # prints "Hello Perl" without the \0

# this will free the C pointer
undef $scalar;
```

Hint: Returning a scalar string from a Perl function actually copies the value. If you want to return a string without copying then you need to return a reference.

```
sub c_string
{
  my $ptr = strdup "Hello Perl";
  my $scalar;
  window $scalar, $ptr, 10;
  cast $scalar, $free_when_out_of_scope;
  \$scalar;
}

my $ref = c_string();
print $$ref, "\n";  # prints "Hello Perl" without the \0
```

Not exported by default, but may be exported on request.

raw_scalar

```
my $buffer = raw_scalar $size;
```

Returns a new scalar of exactly `$size` bytes, suitable for use as a buffer. The contents of the returned scalar are **not** initialized, so it will contain whatever happened to be in the memory that was allocated for it. This makes it cheaper than the equivalent

```
my $buffer = "\0" x $size;
```

when you are about to have a foreign function overwrite the whole thing anyway. If you need the buffer zeroed out, use the `"\0" x $size` form instead.

Not exported by default, but may be exported on request.

FFI::Platypus::Bundle

Bundle foreign code with your Perl module

VERSION

version 2.12

SYNOPSIS

`ffi/foo.c`:

```
#include <ffi_platypus_bundle.h>
#include <string.h>

typedef struct {
  char *name;
  int value;
} foo_t;

foo_t*
foo__new(const char *class_name, const char *name, int value) {
  (void)class_name;
  foo_t *self = malloc( sizeof( foo_t ) );
  self->name = strdup(name);
  self->value = value;
  return self;
}

const char *
foo__name(foo_t *self) {
  return self->name;
}

int
foo__value(foo_t *self) {
  return self->value;
}

void
foo__DESTROY(foo_t *self) {
  free(self->name);
  free(self);
}
```

lib/Foo.pm:

```
package Foo;

use strict;
use warnings;
use FFI::Platypus 2.00;

my $ffi = FFI::Platypus->new( api => 2 );

$ffi->type('object(Foo)' => 'foo_t');
$ffi->mangler(sub {
  my $name = shift;
  $name =~ s/^/foo__/;
  $name;
});

$ffi->bundle;

$ffi->attach( new =>     [ 'string', 'string', 'int' ] => 'foo_t' ␣
↪);
$ffi->attach( name =>    [ 'foo_t' ]                   => 'string'␣
↪);
$ffi->attach( value =>   [ 'foo_t' ]                   => 'int'   ␣
↪);
$ffi->attach( DESTROY => [ 'foo_t' ]                   => 'void'  ␣
↪);

1;
```

t/foo.t

```
use Test2::V0;
use Foo;

my $foo = Foo->new("platypus", 10);
isa_ok $foo, 'Foo';
is $foo->name, "platypus";
is $foo->value, 10;

done_testing;
```

Makefile.PL:

```
use ExtUtils::MakeMaker;
use FFI::Build::MM;
my $fbmm = FFI::Build::MM->new;
WriteMakefile(
  $fbmm->mm_args(
    NAME     => 'Foo',
    DISTNAME => 'Foo',
```

(continues on next page)

(continued from previous page)

```
    VERSION  => '1.00',
    # ...
  )
);

sub MY::postamble
{
  $fbmm->mm_postamble;
}
```

or `dist.ini`:

```
name    = Foo
version = 0.01
...

[FFI::Build]
version = 1.04
```

DESCRIPTION

This document serves as a tutorial for using the new bundling interface provided by *FFI::Platypus* as of api version 1. It requires *FFI::Platypus* of at least 1.00.

Sometimes when writing FFI bindings you need to include a little C code (or your favorite compiled language) to finish things off. Alternatively, you might just want to write some C code (or your favorite compiled language) to include with your Perl module to make a tight loop faster. The bundling interface has you covered.

Basic example

To illustrate we will go through the files in the synopsis and explain how and why they work. To start with we have some C code which emulates object oriented code using `foo__` as a prefix. We use a C struct that we call `foo_t` to store our object data. On the C level the struct acts as a class, when combined with its functions that act as methods. The constructor just allocates the memory it needs for the `foo_t` instance, fills in the appropriate fields and returns the pointer:

```
foo_t*
foo__new(const char *class_name, const char *name, int value)
{
  (void) class_name;
  foo_t *self = malloc( sizeof( foo_t ) );
  self->name = strdup(name);
  self->value = value;
  return self;
}
```

We include a class name as the first argument, because Perl will include that when calling the constructor, but we do not use it here. An exercise for the reader would be to

add hierarchical inheritance.

There are also some methods which return member values. This class has only read only members, but you could have read/write or other methods depending on your needs.

```
const char *
foo__name(foo_t *self)
{
  return self->name;
}
```

We also include a destructor so that the memory owned by the object can be freed when it is no longer needed.

```
void
foo__DESTROY(foo_t *self)
{
  free(self->name);
  free(self);
}
```

This might start to look a little like a Perl module, and when we look at the Perl code that binds to this code, you will see why. First lets prepare the *FFI::Platypus* instance and specify the correct api version:

```
my $ffi = FFI::Platypus->new( api => 2 );
```

The bundle interface is only supported with api version 1, so if you try to use version 0 it will not work. Next we define an object type for `foo_t` which will associate it with the Perl class `Foo`.

```
$ffi->type('object(Foo)' => 'foo_t');
```

As object type is a blessed reference to an opaque (default) or integer type which can be used as a Perl object. Platypus does the translating of Perl object to and from the foo_t pointers that the C code understands. For more details on Platypus types see *FFI::Platypus::Type*.

Next we set the mangler on the Platypus instance so that we can refer to function names without the `foo__` prefix. You could just not use the prefix in your C code and skip this step, or you could refer to the function names in their full in your Perl code, however, this saves extra typing and allows you to bundle more than one class with your Perl code without having to worry about name conflicts.

```
$ffi->mangler(sub {
  my $name = shift;
  $name =~ s/^/foo__/;
  $name;
});
```

Finally we let Platypus know that we will be bundling code.

```
$ffi->bundle;
```

By default, this searches for the appropriate place for your dynamic libraries using the current package. In some cases you may need to override this, for example if your dist is named `Foo-Bar` but your specific class is named `Foo::Bar::Baz`, you'd want something like this:

```
package Foo::Bar::Baz;
use FFI::Platypus 2.00;
my $ffi = FFI::Platypus->new( api => 2 );
$ffi->bundle('Foo::Bar');
...
```

Now, finally we can attach the methods for our class:

```
$ffi->attach( new =>      [ 'string', 'int' ] => 'foo_t'  );
$ffi->attach( name =>     [ 'foo_t' ]         => 'string' );
$ffi->attach( value =>    [ 'foo_t' ]         => 'int'    );
$ffi->attach( DESTROY => [ 'foo_t' ]          => 'void'   );
```

Note that we do not have to include the `foo__` prefix because of the way we set up the mangler. If we hadn't done that then we could instead attach with the full names:

```
$ffi->attach( [ 'foo__new'  => 'new' ]  => [ 'string', 'int' ] =>
 ↪'foo_t'  );
$ffi->attach( [ 'foo__name' => 'name' ] => [ 'foo_t' ]         =>
 ↪'string' );
...
```

You're done! You can now use this class. Lets write a test to make sure it works,

```
use Test2::V0;
use Foo;

my $foo = Foo->new("platypus", 10);
isa_ok $foo, 'Foo';
is $foo->name, "platypus";
is $foo->value, 10;

done_testing;
```

and use `prove` to check that it works:

```
% prove -lvm
t/foo.t ..
ok 1 - An object of class 'Foo' isa 'Foo'
ok 2
ok 3
1..3
ok
All tests successful.
Files=1, Tests=3,  0 wallclock secs ( 0.02 usr  0.00 sys +  0.14␣
 ↪cusr  0.03 csys =  0.19 CPU)
Result: PASS
```

Platypus automatically compiles and links the dynamic library for you:

```
% ls ffi/_build
foo.c.o  libFoo.so
```

The C code will be rebuilt next time if the source code is newer than the object or dynamic libraries files. If the source files are not changed, then it won't be rebuilt to save time. If you are using the code without MakeMaker, or another build system you are responsible for cleaning up these files. This is intended as a convenience to allow you to test your code without having to invoke MakeMaker, or `dzil` or whatever build system you are using.

When you distribute your module though, you will want the dynamic library built just once at build-time and installed correctly so that it can be found at run-time. You don't need to make any changes to your C or Perl code, but you do need to tell MakeMaker to build and install the appropriate files using *FFI::Build::MM*:

```
use ExtUtils::MakeMaker;
use FFI::Build::MM;
my $fbmm = FFI::Build::MM->new;
WriteMakefile(
  $fbmm->mm_args(
    NAME     => 'Foo',
    DISTNAME => 'Foo',
    VERSION  => '1.00',
    # ...
  )
);

sub MY::postamble
{
  $fbmm->mm_postamble;
}
```

And we can invoke all the normal MakeMaker style stuff and our C code will be compiled, linked and installed at the appropriate steps.

```
% perl Makefile.PL
Generating a Unix-style Makefile
Writing Makefile for Foo
Writing MYMETA.yml and MYMETA.json
% make
cp lib/Foo.pm blib/lib/Foo.pm
"/Users/ollisg/perl5/perlbrew/perls/perl-5.30.0/bin/perl" -
 ↪MFFI::Build::MM=cmd -e fbx_build
CC ffi/foo.c
LD blib/lib/auto/share/dist/Foo/lib/libFoo.dylib
% make test
"/Users/ollisg/perl5/perlbrew/perls/perl-5.30.0/bin/perl" -
 ↪MFFI::Build::MM=cmd -e fbx_build
"/Users/ollisg/perl5/perlbrew/perls/perl-5.30.0/bin/perl" -
 ↪MFFI::Build::MM=cmd -e fbx_test
```

(continues on next page)

(continued from previous page)

```
PERL_DL_NONLAZY=1 "/Users/ollisg/perl5/perlbrew/perls/perl-5.30.0/
 ↪bin/perl" "-MExtUtils::Command::MM" "-MTest::Harness" "-e" "undef␣
 ↪*Test::Harness::Switches; test_harness(0, 'blib/lib', 'blib/arch')
 ↪" t/*.t
t/foo.t .. ok
All tests successful.
Files=1, Tests=3,  0 wallclock secs ( 0.01 usr  0.00 sys +  0.06␣
 ↪cusr  0.01 csys =  0.08 CPU)
Result: PASS
```

If the `Makefile.PL` file above looks overly complicated, you can use the Dist::Zilla::Plugin::FFI::Build plugin to simplify your life if you are using Dist::Zilla:

```
[FFI::Build]
version = 1.04
```

Specifying version 1.04 will ensure that any `.o` or `.so` files are pruned from your build tree and not distributed by mistake.

Initialization example

The bundle interface also gives you entry points which will be called automatically when your code is loaded and unloaded if they are found.

- `ffi_pl_bundle_init`

  ```
  void ffi_pl_bundle_init(const char *package, int argc, void␣
   ↪*argv[]);
  ```

  Called when the dynamic library is loaded. `package` is the Perl package that called `bundle` from Perl space. `argc` and `argv` represents an array of opaque pointers that can be passed as an array to bundle as the last argument. (the count `argc` is a little redundant because `argv` is also NULL terminated).

- `ffi_pl_bundle_constant`

  ```
  void ffi_pl_bundle_constant(const char *package, ffi_platypus_
   ↪constant_t *c);
  ```

  Called immediately after `ffi_pl_bundle_init`, and is intended to allow you to set Perl constants from C space. For details on how this works and what methods you can call on the `ffi_platypus_constant_t` instance, see *FFI::Platypus::Constant*.

- `ffi_pl_bundle_fini`

  ```
  void ffi_pl_bundle_fini(const char *package);
  ```

  Called when the dynamic library is unloaded. `package` is the Perl package that called `bundle` from Perl space when the library was loaded. **CAVEAT**: if you attach any functions then this will never be called, because attaching functions locks the Platypus instance into memory along with the libraries which it is using.

Here is an example that passes the version and a callback back into Perl space that emulates the Perl 5.10 say feature.

ffi/init.c:

```
#include <ffi_platypus_bundle.h>

char buffer[512];
const char *version;
void (*say)(const char *);

void
ffi_pl_bundle_init(const char *package, int argc, void *argv[])
{
  version = argv[0];
  say     = argv[1];

  say("in init!");

  snprintf(buffer, 512, "package = %s, version = %s", package,
↪version);
  say(buffer);

  snprintf(buffer, 512, "args = %d", argc);
  say(buffer);
}

void
ffi_pl_bundle_fini(const char *package)
{
  say("in fini!");
}
```

lib/Init.pm:

```
package Init;

use strict;
use warnings;
use FFI::Platypus 2.00;

our $VERSION = '1.00';

{
  my $ffi = FFI::Platypus->new( api => 2 );

  my $say = $ffi->closure(sub {
    my $string = shift;
    print "$string\n";
  });
```

(continues on next page)

(continued from previous page)

```
  $ffi->bundle([
    $ffi->cast( 'string' => 'opaque', $VERSION ),
    $ffi->cast( '(string)->void' => 'opaque', $say ),
  ]);

  undef $ffi;
  undef $say;
}

1;
```

The deinitialization order for the `$say` callback and the `$ffi` instance is essential here, so we do it manually with `undef`:

```
undef $ffi;
undef $say;
```

First we deallocate `$ffi` which calls `ffi_pl_bundle_fini`, which calls `$say`, so we want to make sure the latter is still allocated. Once `ffi_pl_bundle_fini` is done, we can safely deallocate `$say`.

If `ffi_pl_bundle_fini` didn't call back into Perl space like this then we don't have to be as careful about deallocating things in Perl space.

Compiler or linker flags example

There are times when you will want to specify your own compiler and linker flags for the C code that you are bundling. The `TL;DR` is that you can put a `.fbx` file in your `ffi` directory. This is a Perl script that returns a hash reference that is passed into the *FFI::Build* constructor. This allows you to set a number of options, including compiler and linker flags. A more detailed example follows:

You may want or need to set compiler and linker flags for your bundled C code. For example, say we have a header file, but instead of putting it in the `ffi` directory we want to put it in a separate directory called `include`.

`include/answer.h`:

```
#ifndef ANSWER_H
#define ANSWER_H

int answer(void);

#endif
```

`ffi/answer.c`:

```
int
answer(void)
{
  /* the answer to life the universe and everything */
```

(continues on next page)

(continued from previous page)

```
  return 42;
}
```

lib/Answer.pm:

```
package Answer;

use strict;
use warnings;
use FFI::Platypus 2.00;
use Exporter qw( import );

our @EXPORT = qw( answer );

my $ffi = FFI::Platypus->new( api => 2 );
$ffi->bundle;
$ffi->attach( answer => [] => 'int' );

1;
```

If you try to use this module just as-is you will get an error, about not being able to find the header file. Probably something like this:

```
ffi/answer.c:1:10: fatal error: 'answer.h' file not found
```

So we put a `answer.fbx` file in the `ffi` directory. (In case you are wondering FBX stands for "Ffi Build and file eXtensions should whenever possible be three characters long"). The name of the file can be anything so long as it ends in `.fbx`, we just choose `answer` here because that is the name of the project.

ffi/answer.fbx:

```
our $DIR;

return {
  cflags => "-I/include",
  source => "$DIR/*.c",
}
```

The `$DIR` variable is provided by the builder code. It is the root of the distribution, and is helpful if you need a fully qualified path. In this case you could have also used `ffi/*.c`.

The script returns a hash reference which is passed into the *FFI::Build* constructor, so you can use any of the options supported by that class. Now we should be able to use our bundled module:

```
% perl -Ilib -MAnswer=answer -E 'say answer'
42
```

Using bundled code with Alien.

A useful technique is to use Platypus with Alien technology. The Alien namespace is reserved for providing external non-Perl dependencies for CPAN modules. The nominal Alien module when installed looks for the library locally, and if it can't be found it fetches it from the internet, builds it, and installs it in a private directory so that it can be used by other CPAN modules. For Aliens that provide shared libraries, and that have simple interfaces that do not require additional C code you can easily just pass the shared libraries to Platypus directly. For modules that require some bundled C code and an Alien you have to link the Alien library with your bundled code. If the Alien uses the Alien::Base interface then all you have to do is give the name of the Alien to *FFI::Build*.

For example, the `bzip2` library provides an interface that requires the caller to allocate a C `struct` and then pass it to its various functions. The `struct` is actually pretty simple and you could use FFI::C or *FFI::Platypus::Record*, but here is an example of how you would connect bundled C code with an Alien.

`ffi/compress.c`:

```
#include <bzlib.h>
#include <stdlib.h>

int
bzip2__new(bz_stream **stream, int blockSize100k, int verbosity, int␣
↪workFactor )
{
  *stream = calloc(1, sizeof(bz_stream));

  return BZ2_bzCompressInit(*stream, blockSize100k, verbosity,␣
↪workFactor );
}
```

`lib/Bzip2.pm`:

```
package Bzip2;

use strict;
use warnings;
use FFI::Platypus 2.00;
use FFI::Platypus::Memory qw( free );

my $ffi = FFI::Platypus->new( api => 2 );
$ffi->bundle;

$ffi->mangler(sub {
  my $name = shift;
  $name =~ s/^/bzip2__/ unless $name =~ /^BZ2_/;
  $name;
});

=head2 new
```

(continues on next page)

(continued from previous page)

```
 my $bzip2 = Bzip2->new($block_size_100k, $verbosity, $work_flow);

=cut

$ffi->attach( new => ['opaque*', 'int', 'int', 'int'] => 'int' =>␣
 ↪sub {
  my $xsub = shift;
  my $class = shift;
  my $ptr;
  my $ret = $xsub->(\$ptr, @_);
  return bless \$ptr, $class;
});

$ffi->attach( [ BZ2_bzCompressEnd => 'DESTROY' ] => ['opaque'] =>
 ↪'int' => sub {
  my $xsub = shift;
  my $self = shift;
  my $ret = $xsub->($$self);
  free $$self;
});

1;
```

The `.fbx` file that goes with this to make it work with Alien::Libbz2 is now pretty trivial:

`ffi/bz2.fbx`:

```
{
  alien => ['Alien::Libbz2'],
  source => ['ffi/*.c'],
};
```

FFI::Platypus::Closure

Platypus closure object

VERSION

version 2.12

SYNOPSIS

create closure with OO interface

```
use FFI::Platypus::Closure;
my $closure = FFI::Platypus::Closure->new(sub { print "hello world\n
 ↪" });
```

create closure from Platypus object

```
use FFI::Platypus 2.00;
my $ffi = FFI::Platypus->new( api => 2 );
my $closure = $ffi->closure(sub { print "hello world\n" });
```

use closure

```
$ffi->function(foo => ['()->void'] => 'void')->call($closure);
```

DESCRIPTION

This class represents a Perl code reference that can be called from compiled code. When you create a closure object, you can pass it into any function that expects a function pointer. Care needs to be taken with closures because compiled languages typically have a different way of handling lifetimes of objects. You have to make sure that if the compiled code is going to call a closure that the closure object is still in scope somewhere, or has been made sticky, otherwise you may get a segment violation or other mysterious crash.

CONSTRUCTOR

new

```
my $closure = FFI::Platypus::Closure->new($coderef);
```

Create a new closure object; `$coderef` must be a subroutine code reference.

METHODS

call

```
$closure->call(@arguments);
$closure->(@arguments);
```

Call the closure from Perl space. May also be invoked by treating the closure object as a code reference.

sticky

```
$closure->sticky;
```

Mark the closure sticky, meaning that it won't be free'd even if all the reference of the object fall out of scope.

[version 2.12]

Returns `$self`, so this method may be chained.

unstick

```
$closure->unstick;
```

Unmark the closure as sticky.

[version 2.12]

Returns `$self`, so this method may be chained.

FFI::Platypus::Constant

Define constants in C space for Perl

VERSION

version 2.12

SYNOPSIS

`ffi/foo.c`:

```
#include <ffi_platypus_bundle.h>

void
ffi_pl_bundle_constant(const char *package, ffi_platypus_constant_t
 ↪*c)
{
  c->set_str("FOO", "BAR");       /* sets $package::FOO to "BAR" */
  c->set_str("ABC::DEF", "GHI");  /* sets ABC::DEF to GHI        */
}
```

`lib/Foo.pm`:

```
package Foo;

use strict;
use warnings;
use FFI::Platypus 2.00;
use Exporter qw( import );

my $ffi = FFI::Platypus->new( api => 2 );
# sets constants Foo::FOO and ABC::DEF from C
$ffi->bundle;

1;
```

DESCRIPTION

The Platypus bundle interface (see *FFI::Platypus::Bundle*) has an entry point `ffi_pl_bundle_constant` that lets you define constants in Perl space from C.

```
void ffi_pl_bundle_constant(const char *package, ffi_platypus_
 ↪constant_t *c);
```

The first argument `package` is the name of the Perl package. The second argument `c` is a struct with function pointers that lets you define constants of different types. The first argument for each function is the name of the constant and the second is the value. If `::` is included in the constant name then it will be defined in that package space. If it isn't then the constant will be defined in whichever package called `bundle`.

- set_str

  ```
  c->set_str(name, value);
  ```

  Sets a string constant.

- set_sint

```
c->set_sint(name, value);
```

  Sets a 64-bit signed integer constant.

- set_uint

```
c->set_uint(name, value);
```

  Sets a 64-bit unsigned integer constant.

- set_double

```
c->set_double(name, value);
```

  Sets a double precision floating point constant.

Example

Suppose you have a header file `myheader.h`:

```
#ifndef MYHEADER_H
#define MYHEADER_H

#define MYVERSION_STRING "1.2.3"
#define MYVERSION_MAJOR 1
#define MYVERSION_MINOR 2
#define MYVERSION_PATCH 3

enum {
  MYBAD = -1,
  MYOK  = 1
};

#define MYPI 3.14

#endif
```

You can define these constants from C:

```
#include <ffi_platypus_bundle.h>
#include "myheader.h"

void ffi_pl_bundle_constant(const char *package, ffi_platypus_
 ↪constant_t *c)
{
  c->set_str("MYVERSION_STRING", MYVERSION_STRING);
  c->set_uint("MYVERSION_MAJOR", MYVERSION_MAJOR);
  c->set_uint("MYVERSION_MINOR", MYVERSION_MINOR);
  c->set_uint("MYVERSION_PATCH", MYVERSION_PATCH);
  c->set_sint("MYBAD", MYBAD);
```

(continues on next page)

(continued from previous page)

```
  c->set_sint("MYOK", MYOK);
  c->set_double("MYPI", MYPI);
}
```

Your Perl code doesn't have to do anything when calling bundle:

```
package Const;

use strict;
use warnings;
use FFI::Platypus 2.00;

{
  my $ffi = FFI::Platypus->new( api => 2 );
  $ffi->bundle;
}

1;
```

FFI::Platypus::DL

Slightly non-portable interface to libdl

VERSION

version 2.12

SYNOPSIS

```
use FFI::Platypus 2.00;
use FFI::Platypus::DL;

my $handle = dlopen("./libfoo.so", RTLD_PLATYPUS_DEFAULT);
my $address = dlsym($handle, "my_function_named_foo");
my $ffi = FFI::Platypus->new( api => 2 );
$ffi->function($address => [] => 'void')->call;
dlclose($handle);
```

DESCRIPTION

This module provides an interface to libdl, the dynamic loader on UNIX. The underlying interface has always been used by *FFI::Platypus*, but it wasn't a public interface until version 0.52. The name was changed with that version when it became a public interface, so be sure to specify that version if you are going to use it.

It is somewhat non-portable for these reasons:

- GNU extensions

  It provides some GNU extensions to platforms such as Linux that support them.

- Windows

  It provides an emulation layer on Windows. The emulation layer only supports `RTLD_PLATYPUS_DEFAULT` as a flag. The emulation layer emulates the convention described below of passing `undef` as the dynamic library name to mean, use the currently running executable. I've used it without any problems for years, but Windows is not my main development platform.

FUNCTIONS

dlopen

```
my $handle = dlopen($filename, $flags);
```

This opens a dynamic library in the context of the dynamic loader. `$filename` is the full or relative path to a dynamic library (usually a `.so` on Linux and some other UNIXen, a `.dll` on Windows and a `.dylib` on OS X). `$flags` are flags that can be used to alter the behavior of the library and the symbols it contains. The return value is an opaque pointer or `$handle` which can be used to look up symbols with `dlsym`. The handle should be closed with `dlclose` when you are done with it.

By convention if you pass in `undef` for the filename, the currently loaded executable will be used instead of a separate dynamic library. This is the easiest and most portable way to find the address of symbols in the standard C library. This convention is baked into most UNIXen, but this capability is emulated in Windows which doesn't come with the capability out of the box.

If there is an error in opening the library then `undef` will be returned and the diagnostic for the failure can be retrieved with `dlerror` as described below.

Not all flags are supported on all platforms. You can test if a flag is available using can:

```
if(FFI::Platypus::DL->can('RTLD_LAZY'))
{
  ...
}
```

Typically where flags are not mutually exclusive, they can be or'd together:

```
my $handle = dlopen("libfoo.so", RTLD_LAZY | RTLD_GLOBAL);
```

Check your operating system documentation for detailed descriptions of these flags.

- RTLD_PLATYPUS_DEFAULT

  This is the *FFI::Platypus* default for `dlopen` (NOTE: NOT the libdl default). This is the only flag supported on Windows. For historical reasons, this is usually `RTLD_LAZY` on Unix and `0` on Windows.

- RTLD_LAZY

  Perform lazy binding.

- RTLD_NOW

  Resolve all symbols before returning from `dlopen`. Error if all symbols cannot resolve.

- RTLD_GLOBAL

  Symbols are shared.

- RTLD_LOCAL

  Symbols are NOT shared.

- RTLD_NODELETE

  glibc 2.2 extension.

- RTLD_NOLOAD

  glibc 2.2 extension.

- RTLD_DEEPBIND

  glibc 2.3.4 extension.

dlsym

```
my $opaque = dlsym($handle, $symbol);
```

This looks up the given `$symbol` in the library pointed to by `$handle`. If the symbol is found, the address for that symbol is returned as an opaque pointer. This pointer can be passed into the *FFI::Platypus* `function` and `attach` methods instead of a function name.

If the symbol cannot be found then `undef` will be returned and the diagnostic for the failure can be retrieved with `dlerror` as described below.

dlclose

```
my $status = dlclose($handle);
```

On success, `dlclose` returns 0; on error, it returns a nonzero value, and the diagnostic for the failure can be retrieved with `dlerror` as described below.

dlerror

```
my $error_string = dlerror;
```

Returns the human readable diagnostic for the reason for the failure for the most recent `dl` prefixed function call.

CAVEATS

Some flags for `dlopen` are not portable. This module may not be supported platforms added to *FFI::Platypus* in the future. It does work as far as I know on all of the currently supported platforms.

FFI::Platypus::Function

An FFI function object

VERSION

version 2.12

SYNOPSIS

```
use FFI::Platypus 2.00;

# call directly
my $ffi = FFI::Platypus->new( api => 2 );
my $f = $ffi->function(puts => ['string'] => 'int');
$f->call("hello there");

# attach as xsub and call (faster for repeated calls)
$f->attach('puts');
puts('hello there');
```

DESCRIPTION

This class represents an unattached platypus function. For more context and better examples see *FFI::Platypus*.

METHODS

attach

```
$f->attach($name);
$f->attach($name, $prototype);
```

Attaches the function as an xsub (similar to calling attach directly from an *FFI::Platypus* instance). You may optionally include a prototype.

call

```
my $ret = $f->call(@arguments);
my $ret = $f->(@arguments);
```

Calls the function and returns the result. You can also use the function object **like** a code reference.

sub_ref

```
my $code = $f->sub_ref;
```

Returns an anonymous code reference. This will usually be faster than using the `call` method above.

FFI::Platypus::Lang

Language specific customizations

VERSION

version 2.12

SYNOPSIS

```
perldoc FFI::Platypus::Lang;
```

DESCRIPTION

This namespace is reserved for language specific customizations of *FFI::Platypus*. This usually involves providing native type maps. It can also involve computing mangled names. The default language is C, and is defined in *FFI::Platypus::Lang::C*.

This package itself doesn't do anything, it serves only as documentation.

SEE ALSO

- *FFI::Platypus*

  Platypus itself.

- *FFI::Platypus::Lang::ASM*

  This language plugin provides no type aliases, and is intended for use with assembly language or for when no other language plugin is appropriate.

- *FFI::Platypus::Lang::C*

  Language plugin for the C programming language.

- FFI::Platypus::Lang::Fortran

  Non-core language plugin for the Fortran programming language.

- FFI::Platypus::Lang::CPP

  Non-core language plugin for the C++ programming language.

- FFI::Platypus::Lang::Go

  Non-core language plugin for the Go programming language.

- FFI::Platypus::Lang::Pascal

  Non-core language plugin for the Pascal programming language.

- FFI::Platypus::Lang::Rust

  Non-core language plugin for the Rust programming language.

- *FFI::Platypus::Lang::Win32*

  Language plugin for use with the Win32 API.

- FFI::Platypus::Lang::Zig

  Non-core language plugin for the Zig programming language.

FFI::Platypus::Lang::ASM

Documentation and tools for using Platypus with the Assembly

VERSION

version 2.12

SYNOPSIS

```
use FFI::Platypus 2.00;
my $ffi = FFI::Platypus->new( api => 2 );
$ffi->lang('ASM');
```

DESCRIPTION

Setting your lang to `ASM` includes no native type aliases, so types like `int` or `unsigned long` will not work. You need to specify instead `sint32` or `sint64`. Although intended for use with Assembly it could also be used for other languages if you did not want to use the normal C aliases for native types.

This document will one day include information on bundling Assembly with your Perl / FFI / Platypus distribution. Pull requests welcome!

METHODS

native_type_map

```
my $hashref = FFI::Platypus::Lang::ASM->native_type_map;
```

This returns an empty hash reference. For other languages it returns a hash reference that defines the aliases for the types normally used for that language.

SEE ALSO

FFI::Platypus::Lang::C

Documentation and tools for using Platypus with the C programming language

VERSION

version 2.12

SYNOPSIS

```
use FFI::Platypus 2.00;
my $ffi = FFI::Platypus->new( api => 2 );
$ffi->lang('C'); # the default
```

DESCRIPTION

This module provides some hooks for Platypus to interact with the C programming language. It is generally used by default if you do not specify another foreign programming language with the *FFI::Platypus#lang* attribute.

METHODS

native_type_map

```
my $hashref = FFI::Platypus::Lang::C->native_type_map;
```

This returns a hash reference containing the native aliases for the C programming languages. That is the keys are native C types and the values are libffi native types.

SEE ALSO

- *FFI::Platypus*

  The Core Platypus documentation.

- *FFI::Platypus::Lang*

  Includes a list of other language plugins for Platypus.

FFI::Platypus::Lang::Win32

Documentation and tools for using Platypus with the Windows API

VERSION

version 2.12

SYNOPSIS

```
use utf8;
use FFI::Platypus 2.00;

my $ffi = FFI::Platypus->new(
  api  => 2,
  lib  => [undef],
);

# load this plugin
$ffi->lang('Win32');

# Pass two double word integer values to the Windows API Beep␣
 ↪function.
$ffi->attach( Beep => ['DWORD','DWORD'] => 'BOOL');
```

(continues on next page)

(continued from previous page)

```
Beep(262, 300);

# Send a Unicode string to the Windows API MessageBoxW function.
use constant MB_OK                   => 0x00000000;
use constant MB_DEFAULT_DESKTOP_ONLY => 0x00020000;
$ffi->attach( [MessageBoxW => 'MessageBox'] => [ 'HWND', 'LPCWSTR',
 ↪'LPCWSTR', 'UINT'] => 'int' );
MessageBox(undef, "I ❤ Platypus", "Confession", MB_OK|MB_DEFAULT_
 ↪DESKTOP_ONLY);

# Get a Unicode string from the Windows API GetCurrentDirectoryW␣
 ↪function.
$ffi->attach( [GetCurrentDirectoryW => 'GetCurrentDirectory'] => [
 ↪'DWORD', 'LPWSTR'] => 'DWORD');
my $buf_size = GetCurrentDirectory(0,undef);
my $dir = "\0\0" x $buf_size;
GetCurrentDirectory($buf_size, \$dir) or die $^E;
print "$dir\n";
```

DESCRIPTION

This module provides the Windows datatypes used by the Windows API. This means that you can use things like `DWORD` as an alias for `uint32`. The full list of type aliases is not documented here as it may change over time or be dynamic. You can get the list for your current environment with this one-liner:

```
perl -MFFI::Platypus::Lang::Win32 -E "say for sort keys %{␣
 ↪FFI::Platypus::Lang::Win32->native_type_map }"
```

This plugin will also set the correct ABI for use with Win32 API functions. (On 32 bit systems a different ABI is used for Win32 API than what is used by the C library, on 32 bit systems the same ABI is used). Most of the time this exactly what you want, but if you need to use functions that are using the standard C calling convention, but need the Win32 types, you can do that by setting the ABI back immediately after loading the language plugin:

```
$ffi->lang('Win32');
$ffi->abi('default_abi');
```

Most of the types should be pretty self-explanatory or at least provided in the Microsoft documentation on the internet, but the use of Unicode strings probably requires some more detail:

[version 1.35]

This plugin also provides `LPCWSTR` and `LPWSTR` "wide" string types which are implemented using *FFI::Platypus::Type::WideString*. For full details, please see the documentation for that module, and note that `LPCWSTR` is a wide string in the read-only string mode and `LPWSTR` is a wide string in the read-write buffer mode.

The `LPCWSTR` is handled fairly transparently by the plugin, but for when using read-write

buffers (LPWSTR) with the Win32 API you typically need to allocate a buffer string of the right size. These examples will use GetCurrentDirectoryW attached as GetCurrentDirectory as in the synopsis above. These are illustrative only, you would normally want to use the *Cwd* module to get the current working directory.

- default buffer size 2048

  The simplest way is to fallback on the rather arbitrary default buffer size of 2048.

```
my $dir;
GetCurrentDirectory(1024, \$dir);
print "I am in the directory: $dir\n";
```

  Discussion: This only works if you know the API that you are using will not ever use more than 2048 bytes. The author believes this to be the case for GetCurrentDirectoryW since directory paths in windows have a maximum of 260 characters. If every character was outside the Basic Multilingual Plane (BMP) they would take up exactly 4 characters each. (This is probably not ever the case since the disk volume at least will be a Latin letter). Taking account of the NULL termination you would need 260 * 4 + 2 bytes or 1048 bytes.

  We pass in a reference to our scalar so that the Win32 API can write into it.

  We are passing in half the number of bytes as the first argument because the API expects the number of WCHAR (or wchar_t), not the number of bytes or the technically the number of characters since characters can take up either 2 or 4 bytes in UTF-16.

- allocate your buffer to your own size.

  If possible it is of course always best to allocate exactly the size of buffer that you need.

```
my $size = GetCurrentDirectory(0, undef);
my $dir = "\0\0" x $size;
GetCurrentDirectory($size, \$dir);
print "I am in the directory: $dir\n";
```

  Discussion: In this case the API provides a way of getting the exact size of buffer that you need. We allocate this in Perl by creating a string of NULLs of the right length. The Perl string "\0" is exactly on byte, so we double that before using the x operator to multiple that by the size returned by the API.

  Now, somewhat unexpectedly what is returned is not the same buffer, but a new string in new UTF-8 encoded Perl string. This is what you want most of the time.

- initialize your read-write buffer

  Some APIs might be modifying an existing string rather than just writing an entirely new one. In that case you still want to allocate a buffer, but you want to initialize it with a value. You can do this by passing an array reference instead of a scalar reference. The firs element of the array is the buffer, and the second is the initialization.

```
my $dir;
GetCurrentDirectory($size, [ \$dir, "I ❤ Perl + Platypus" ]);
```

Discussion: Note that this particular API ignores the string passed in and writes over it, but this demonstrates how you would initialize a buffer string. Once again, if `$dir` is not initialized (is `undef`), then a buffer of the default size of 2048 bytes will be created internally. You can also allocate a specific number of bytes as in the previous example.

- allocate memory using `malloc` etc.

  You can also allocate memory using `malloc` (see *FFI::Platypus::Memory*) and encode your string using *Encode* and copy it using `wcscpy`. This may be appropriate in some cases, but it is beyond the scope of this document.

METHODS

abi

```
my $abi = FFI::Platypus::Lang::Win32->abi;
```

This is called internally when the type plugin is loaded by Platypus. It selects the appropriate ABI to make Win32 API function calls.

native_type_map

```
my $hashref = FFI::Platypus::Lang::Win32->native_type_map;
```

This is called internally when the type plugin is loaded by Platypus. It provides types aliases useful on the Windows platform, so it may also be useful for introspection.

This returns a hash reference containing the native aliases for the Windows API. That is the keys are native Windows API C types and the values are libffi native types.

This will includes types like `DWORD` and `HWND`, and others. The full list may be adjusted over time and may be computed dynamically. To get the full list for your install you can use this one-liner:

```
perl -MFFI::Platypus::Lang::Win32 -E "say for sort keys %{␣
↪FFI::Platypus::Lang::Win32->native_type_map }"
```

load_custom_types

```
FFI::Platypus::Lang::Win32->load_custom_types($ffi);
```

This is called internally when the type plugin is loaded by Platypus. It provides custom types useful on the Windows platform. For now that means the `LPWSTR` and `LPCWSTR` types.

CAVEATS

The Win32 API isn't a different computer language in the same sense that the other language plugins (those for Fortran or Rust for example). But implementing these types as a language plugin is the most convenient way to do it.

Prior to version 1.35, this plugin didn't provide an implementation for `LPWSTR` or `LPCWSTR`, so in the likely event that you need those types make sure you also require at least that version of Platypus.

SEE ALSO

FFI::Platypus::Memory

Memory functions for FFI

VERSION

version 2.12

SYNOPSIS

```
use FFI::Platypus::Memory;

# allocate 64 bytes of memory using the
# libc malloc function.
my $pointer = malloc 64;

# use that memory wisely
...

# free the memory when you are done.
free $pointer;
```

DESCRIPTION

This module provides an interface to common memory functions provided by the standard C library. They may be useful when constructing interfaces to C libraries with FFI. It works mostly with the opaque type and it is worth reviewing the section on opaque pointers in *FFI::Platypus::Type*.

Allocating memory and forgetting to free it is a common source of memory leaks in C and when using this module. Very recent Perls have a `defer` keyword that lets you automatically call functions like `free` when a block ends. This can be especially handy when you have multiple code paths or possible exceptions to keep track of.

```
use feature 'defer';
use FFI::Platypus::Memory qw( malloc free );
```

(continues on next page)

(continued from previous page)

```
sub run {
  my $ptr = malloc 66;
  defer { free $ptr };

  my $data = do_something($ptr);

  # do not need to remember to place free $ptr here, as it will
  # run through defer.

  return $data;
}
```

If you are not lucky enough to have the `defer` feature in your version of Perl you may be able to use Feature::Compat::Defer, which will use the feature if available, and provides its own mostly compatible version if not.

FUNCTIONS

calloc

```
my $pointer = calloc $count, $size;
```

The `calloc` function contiguously allocates enough space for *$count* objects that are *$size* bytes of memory each.

free

```
free $pointer;
```

The `free` function frees the memory allocated by `malloc`, `calloc`, `realloc` or `strdup`. It is important to only free memory that you yourself have allocated. A good way to crash your program is to try and free a pointer that some C library has returned to you.

malloc

```
my $pointer = malloc $size;
```

The `malloc` function allocates *$size* bytes of memory.

memcpy

```
memcpy $dst_pointer, $src_pointer, $size;
```

The `memcpy` function copies *$size* bytes from *$src_pointer* to *$dst_pointer*. It also returns *$dst_pointer*.

memset

```
memset $buffer, $value, $length;
```

The `memset` function writes *$length* bytes of *$value* to the address specified by *$buffer*.

realloc

```
my $new_pointer = realloc $old_pointer, $size;
```

The `realloc` function reallocates enough memory to fit *$size* bytes. It copies the existing data and frees *$old_pointer*.

If you pass `undef` in as *$old_pointer*, then it behaves exactly like `malloc`:

```
my $pointer = realloc undef, 64; # same as malloc 64
```

strcpy

```
strcpy $opaque, $string;
```

Copies the string to the memory location pointed to by `$opaque`.

strdup

```
my $pointer = strdup $string;
```

The `strdup` function allocates enough memory to contain *$string* and then copies it to that newly allocated memory. This version of `strdup` returns an opaque pointer type, not a string type. This may seem a little strange, but returning a string type would not be very useful in Perl.

strndup

```
my $pointer = strndup $string, $max;
```

The same as `strdup` above, except at most `$max` characters will be copied in the new string.

FFI::Platypus::Record

FFI support for structured records data

VERSION

version 2.12

SYNOPSIS

C:

```
struct my_person {
  int         age;
  const char  title[3];
  const char *name
};

void process_person(struct my_person *person)
{
  /* ... */
}
```

Perl:

```
package MyPerson;

use FFI::Platypus::Record;

record_layout_1(
  'int'       => 'age',
  'string(3)' => 'title',
  'string rw' => 'name',
);

package main;

use FFI::Platypus 2.00;

my $ffi = FFI::Platypus->new( api => 2 );
$ffi->lib("myperson.so");
$ffi->type("record(MyPerson)" => 'MyPerson');

my $person = MyPerson->new(
  age   => 40,
  title => "Mr.",
  name  => "John Smith",
);

$ffi->attach( process_person => [ 'MyPerson*' ] => 'void' );

process_person($person);

$person->age($person->age + 1); # another year older

process_person($person);
```

DESCRIPTION

[version 0.21]

This module provides a mechanism for building classes that can be used to mange structured data records (known as C as “structs” and in some languages as “records”). A

structured record is a series of bytes that have structure understood by the C or other foreign language library that you are interfacing with. It is designed for use with FFI and *FFI::Platypus*, though it may have other applications.

Before you get to deep into using this class you should also consider the FFI::C, which provides some overlapping functionality. Briefly, it comes down to this:

(The tl;dr is: use this class when you need to pass by value (since FFI::C does not support pass by value) and use FFI::C in all other circumstances).

- *FFI::Platypus::Record*

  Supports:

  - C pointers to `struct` types
  - Passing C `structs` by-value.

  Does not support:

  - C `union` types.
  - C arrays of `struct` and `union` types.

- FFI::C

  Supports:

  - C `struct` and`union` types
  - C arrays of `struct` and `union` types.

  Does not support:

  - Passing C `structs` by-value.

  String members are as of this writing a TODO for FFI::C, but should be coming soon!

FUNCTIONS

record_layout_1

```
record_layout_1($ffi, $type => $name, ... );
record_layout_1(\@ffi_args, $type => $name, ... );
record_layout_1($type => $name, ... );
```

Define the layout of the record. You may optionally provide an instance of *FFI::Platypus* as the first argument in order to use its type aliases. Alternatively you may provide constructor arguments that will be passed to the internal platypus instance. Thus this is the same:

```
my $ffi = FFI::Platypus->new( lang => 'Rust', api => 2 );
record_layout_1( $ffi, ... );
# same as:
record_layout_1( [ lang => 'Rust' ], ... );
```

and this is the same:

```
my $ffi = FFI::Platypus->new( api => 2 );
record_layout_1( $ffi, ... );
# same as:
record_layout_1( ... );
```

Then you provide members as type/name pairs.

For each member you declare, `record_layout_1` will create an accessor which can be used to read and write its value. For example imagine a class `Foo`:

```
package Foo;

use FFI::Platypus::Record;

record_layout_1(
  int          => 'bar',  #  int bar;
  'string(10)' => 'baz',  #  char baz[10];
);
```

You can get and set its fields with like named `bar` and `baz` accessors:

```
my $foo = Foo->new;

$foo->bar(22);
my $value = $foo->bar;

$foo->baz("grimlock\0\0"); # should be 10 characters long
my $string_value = $foo->baz; # includes the trailing \0\0
```

You can also pass initial values in to the constructor, either passing as a list of key value pairs or by passing a hash reference:

```
$foo = Foo->new(
  bar => 22,
  baz => "grimlock\0\0",
);

# same as:

$foo = Foo->new( {
  bar => 22,
  baz => "grimlock\0\0",
} );
```

If there are members of a record that you need to account for in terms of size and alignment, but do not want to have an accessor for, you can use `:` as a place holder for its name:

```
record_layout_1(
  'int'        => ':',
  'string(10)' => 'baz',
);
```

strings

So far I've shown fixed length strings. These are declared with the word `string` followed by the length of the string in parentheticals. Fixed length strings are included inside the record itself and do not need to be allocated or deallocated separately from the record. Variable length strings must be allocated on the heap, and thus require a sense of "ownership", that is whomever allocates variable length strings should be responsible for also free'ing them. To handle this, you can add a `ro` or `rw` trait to a string field. The default is `ro`, means that you can get, but not set its value:

```
package Foo;

record_layout_1(
  'string ro' => 'bar',  # same type as 'string' and 'string_ro'
);

package main;

my $foo = Foo->new;

my $string = $foo->bar;  # GOOD
$foo->bar("starscream"); # BAD
```

If you specify a field is `rw`, then you can set its value:

```
package Foo;

record_layout_1(
  'string rw' => 'bar',  # same type as 'string_rw'
);

package main;

my $foo = Foo->new;

my $string = $foo->bar;  # GOOD
$foo->bar("starscream"); # GOOD
```

Any string value that is pointed to by the record will be free'd when it falls out of scope, so you must be very careful that any `string rw` fields are not set or modified by C code. You should also take care not to copy any record that has a `rw` string in it because its values will be free'd twice!

```
use Clone qw( clone );

my $foo2 = clone $foo;  # BAD  bar will be free'd twice
```

arrays

Arrays of integer, floating points and opaque pointers are supported.

```
package Foo;

record_layout_1(
  'int[10]' => 'bar',
);

my $foo = Foo->new;

$foo->bar([1,2,3,4,5,6,7,8,9,10]); # sets the values for the array
my $list = $foo->bar;  # returns a list reference

$foo->bar(5, -6); # sets the 5th element in the array to -6
my $item = $foo->bar(5); gets the 5th element in the array
```

record_layout

```
record_layout($ffi, $type => $name, ... );
record_layout(\@ffi_args, $type => $name, ... );
record_layout($type => $name, ... );
```

This function works like `record_layout` except that `api => 0` is used instead of `api => 1`. All new code should use `record_layout_1` instead.

CAVEATS

These useful features (and probably more) are missing, and unlikely to be added.

- Unions
- Nested records

If you need these features, consider using FFI::C instead.

SEE ALSO

- *FFI::Platypus*

  The main platypus documentation.

- FFI::C

  Another interface for constructing structured data. It includes support for `union` and array types (which this module does not), but lacks support for passing records by-value.

- *FFI::Platypus::Record::TieArray*

  Tied array interface for record array members.

- Convert::Binary::C

  Another method for constructing and dissecting structured data records.

- pack and unpack

  Built-in Perl functions for constructing and dissecting structured data records.

FFI::Platypus::Record::TieArray

Tied array interface for record array members

VERSION

version 2.12

SYNOPSIS

```
package Foo;

use FFI::Platypus::Record;
use FFI::Platypus::Record::TieArray;

record_layout(qw(
  int[20]  _bar
));

sub bar
{
  my($self, $arg) = @_;
  $self->_bar($arg) if ref($arg) eq ' ARRAY';
  tie my @list, 'FFI::Platypus::Record::TieArray',
    $self, '_bar', 20;
}

package main;

my $foo = Foo->new;

my $bar5 = $foo->bar->[5];  # get the 5th element of the bar array
$foo->bar->[5] = 10;        # set the 5th element of the bar array
@{ $foo->bar } = ();        # set all elements in bar to 0
@{ $foo->bar } = (1..5);    # set the first five elements of the bar
 ↪array
```

DESCRIPTION

WARNING: This module is considered EXPERIMENTAL. It may go away or be changed in incompatible ways, possibly without notice, but not without a good reason.

This class provides a tie interface for record array members.

In the future a short cut for using this with *FFI::Platypus::Record* directly may be provided.

FFI::Platypus::Type

Defining types for FFI::Platypus

VERSION

version 2.12

SYNOPSIS

OO Interface:

```
use FFI::Platypus 2.00;
my $ffi = FFI::Platypus->new( api => 2 );
$ffi->type('int' => 'my_int');
```

DESCRIPTION

Note: This document assumes that you are using `api => 2`, which you should be using for all new code.

This document describes how to define types using *FFI::Platypus*. Types may be "defined" ahead of time, or simply used when defining or attaching functions.

```
# Example of defining types
use FFI::Platypus 2.00;
my $ffi = FFI::Platypus->new( api => 2 );
$ffi->type('int');
$ffi->type('string');

# Example of simply using types in function declaration or␣
 ↪attachment
my $f = $ffi->function(puts => ['string'] => 'int');
$ffi->attach(puts => ['string'] => 'int');
```

Unless you are using aliases the *FFI::Platypus#type* method is not necessary, but they will throw an exception if the type is incorrectly specified or not supported, which may be helpful for determining if the types are available or not.

Note: This document sometimes uses the term "C Function" as short hand for function implemented in a compiled language. Unless the term is referring literally to a C function example code, you can assume that it should also work with another compiled language.

meta information about types

You can get the size of a type using the *FFI::Platypus#sizeof* method.

```
my $intsize = $ffi->sizeof('int');           # usually 4
my $intarraysize = $ffi->sizeof('int[64]');  # usually 256
```

converting types

Sometimes it is necessary to convert types. In particular various pointer types often need to be converted for consumption in Perl. For this purpose the *FFI::Platypus#cast* method is provided. It needs to be used with care though, because not all type combinations are supported. Here are some useful ones:

```
my $address = $ffi->cast('string' => 'opaque', $string);
```

This converts a Perl string to a pointer address that can be used by functions that take an opaque type. Be carefully though that the Perl string is not resized or free'd while in use from C code.

```
my $string  = $ffi->cast('opaque' => 'string', $pointer);
```

This does the opposite, converting a null terminated string (the type of strings used by C) into a Perl string. In this case the string is copied, so the other language is free to deallocate or otherwise manipulate the string after the conversion without adversely affecting the Perl.

aliases

Some times using alternate names is useful for documenting the purpose of an argument or return type. For this "aliases" can be helpful. The second argument to the *FFI::Platypus#type* method can be used to define a type alias that can later be used by function declaration and attachment.

```
use FFI::Platypus 2.00;
my $ffi = FFI::Platypus->new( api => 2 );
$ffi->type('int'    => 'myint');
$ffi->type('string' => 'mystring');
my $f = $ffi->function( puts => ['mystring'] => 'myint' );
$ffi->attach( puts => ['mystring'] => 'myint' );
```

Aliases are contained without the *FFI::Platypus* object, so feel free to define your own crazy types without stepping on the toes of other CPAN developers using Platypus.

One useful application of an alias is when you know types are different on two different platforms:

```
if($^O eq 'MSWin32')
{
  $type->type('sint16' => 'foo_t');
} elsif($^O eq 'linux')
```

(continues on next page)

(continued from previous page)

```
{
  $type->type('sint32' => 'foo_t');
}

# function foo takes 16 bit signed integer on Windows
# and a 32 bit signed integer on Linux.
$ffi->attach( foo => [ 'foo_t' ] => 'void' );
```

TYPE CATEGORIES

Native types

So called native types are the types that the CPU understands that can be passed on the argument stack or returned by a function. It does not include more complicated types like arrays or structs, which can be passed via pointers (see the opaque type below). Generally native types include void, integers, floats and pointers.

the void type

This can be used as a return value to indicate a function does not return a value (or if you want the return value to be ignored).

```
$ffi->type( foo => [] => 'void' );
```

Newer versions of Platypus also allow you to omit the return type and `void` is assumed.

```
$ffi->type( foo => [] );
```

It doesn't really make sense to use `void` in any other context. However, because of historical reasons involving older versions of Perl.

It doesn't really make sense for `void` to be passed in as an argument. However, because C functions that take no arguments frequently are specified as taking `void` as this was required by older C compilers, as a special case you can specify a function's arguments as taking a single `void` to mean it takes no arguments.

```
# C: void foo(void);
$ffi->type( foo => ['void'] );
# same (but probably better)
$ffi->type( foo => [] );
```

integer types

The following native integer types are always available (parentheticals indicates the usual corresponding C type):

- sint8

  Signed 8 bit byte (`signed char`, `int8_t`).

- uint8

Unsigned 8 bit byte (`unsigned char`, `uint8_t`).

- sint16

  Signed 16 bit integer (`short`, `int16_t`)

- uint16

  Unsigned 16 bit integer (`unsigned short`, `uint16_t`)

- sint32

  Signed 32 bit integer (`int`, `int32_t`)

- uint32

  Unsigned 32 bit integer (`unsigned int`, `uint32_t`)

- sint64

  Signed 64 bit integer (`long long`, `int64_t`)

- uint64

  Unsigned 64 bit integer (`unsigned long long`, `uint64_t`)

You may also use `uchar`, `ushort`, `uint` and `ulong` as short names for `unsigned char`, `unsigned short`, `unsigned int` and `unsigned long`.

These integer types are also available, but there actual size and sign may depend on the platform.

- char

  Somewhat confusingly, `char` is an integer type! This is really an alias for either `sint8_t` or `uint8_t` depending on your platform. If you want to pass a character (not integer) in to a C function that takes a character you want to use the perl *ord* function. Here is an example that uses the standard libc `isalpha`, `isdigit` type functions:

```
use FFI::Platypus 2.00;

my $ffi = FFI::Platypus->new( api => 2 );
$ffi->lib(undef);
$ffi->type('int' => 'character');

my @list = qw(
  alnum alpha ascii blank cntrl digit lower print punct
  space upper xdigit
);

$ffi->attach("is$_" => ['character'] => 'int') for @list;

my $char = shift(@ARGV) || 'a';

no strict 'refs';
printf "'%s' is %s %s\n", $char, $_, &{'is'.$_}(ord $char) for␣
↪@list;
```

- size_t

  This is usually an `unsigned long`, but it is up to the compiler to decide. The `malloc` function is defined in terms of `size_t`:

  ```
  $ffi->attach( malloc => ['size_t'] => 'opaque';
  ```

  (Note that you can get `malloc` from *FFI::Platypus::Memory*).

- long, unsigned long

  On 64 bit systems, this is usually a 64 bit integer. On 32 bit systems this is frequently a 32 bit integer (and `long long` or `unsigned long long` are for 64 bit).

There are a number of other types that may or may not be available if they are detected when *FFI::Platypus* is installed. This includes things like `wchar_t`, `off_t`, `wint_t`. You can use this script to list all the integer types that *FFI::Platypus* knows about, plus how they are implemented.

```
use FFI::Platypus 2.00;

my $ffi = FFI::Platypus->new( api => 2 );

foreach my $type_name (sort $ffi->types)
{
  my $meta = $ffi->type_meta($type_name);
  next unless defined $meta->{element_type} && $meta->{element_type}
 ↪eq 'int';
  printf "%20s %s\n", $type_name, $meta->{ffi_type};
}
```

If you need a common system type that is not provided, please open a ticket in the Platypus project's GitHub issue tracker. Be sure to include the usual header file the type can be found in.

Enum types

C provides enumerated types, which are typically implemented as integer types.

```
enum {
  BAR = 1,
  BAZ = 2
} foo_t;

void f(enum foo_t foo);
```

Platypus provides `enum` and `senum` types for the integer types used to represent enum and signed enum types respectively.

```
use constant BAR => 1;
use constant BAZ => 2;
$ffi->attach( f => [ 'enum' ] => 'void' );
f(BAR);
f(BAZ);
```

When do you use `senum`? Anytime the enum has negative values:

```
enum {
  BAR = -1;
  BAZ = 2;
} foo_t;

void f(enum foo_t foo);
```

Perl:

```
use constant BAR => -1;
use constant BAZ => 2;
$ffi->attach( f => [ 'senum' ] => 'void' );
f(BAR);
f(BAZ);
```

Dealing with enumerated values with FFI can be tricky because these are usually defined in C header files and cannot be found in dynamic libraries. For trivial usage you can do as illustrated above, simply define your own Perl constants. For more complicated usage, or where the values might vary from platform to platform you may want to consider the new Platypus bundle interface to define Perl constants (essentially the same as an enumerated value) from C space. This is more reliable, but does require a compiler at install time. See *FFI::Platypus::Constant* for details.

The main FAQ (*"FAQ" in FFI::Platypus*) also has a discussion on dealing with constants and enumerated types.

There is also a type plugin (FFI::Platypus::Type::Enum) that can be helpful in writing interfaces that use enums.

Boolean types

At install time Platypus attempts to detect the correct type for `bool` for your platform, and you can use that. `bool` is really an integer type, but the type used varies from platform to platform.

C header:

```
#include <stdbool.h>
bool foo();
```

Platypus

```
$ffi->attach( foo => [] => 'bool' );
```

If you get an exception when trying to use this type it means you either have a very old version of Platypus, or for some reason it was unable to detect the correct type at install time. Please open a ticket if that is the case.

floating point types

The following native floating point types are always available (parentheticals indicates the usual corresponding C type):

- float

  Single precision floating point (*float*)

- double

  Double precision floating point (*double*)

- longdouble

  Floating point that may be larger than `double` (*longdouble*). This type is only available if supported by the C compiler used to build *FFI::Platypus*. There may be a performance penalty for using this type, even if your Perl uses long doubles internally for its number value (NV) type, because of the way *FFI::Platypus* interacts with `libffi`.

  As an argument type either regular number values (NV) or instances of Math::LongDouble are accepted. When used as a return type, Math::LongDouble will be used, if you have that module installed. Otherwise the return type will be downgraded to whatever your Perl's number value (NV) is.

- complex_float

  Complex single precision floating point (*float complex*)

- complex_double

  Complex double precision floating point (*double complex*)

  `complex_float` and `complex_double` are only available if supported by your C compiler and by libffi. Complex numbers are only supported in very recent versions of libffi, and as of this writing the latest production version doesn't work on x86_64. It does seem to work with the latest production version of libffi on 32 bit Intel (x86), and with the latest libffi version in git on x86_64.

opaque pointers

Opaque pointers are simply a pointer to a region of memory that you do not manage, and do not know or care about its structure. It is like a `void *` in C. These types are represented in Perl space as integers and get converted to and from pointers by *FFI::Platypus*. You may use `pointer` as an alias for `opaque`, although this is discouraged. (The Platypus documentation uses the convention of using "pointer" to refer to pointers to known types (see below) and "opaque" as short hand for opaque pointer).

As an example, libarchive defines `struct archive` type in its header files, but does not define its content. Internally it is defined as a `struct` type, but the caller does not see this. It is therefore opaque to its caller. There are `archive_read_new` and `archive_write_new` functions to create a new instance of this opaque object and `archive_read_free` and `archive_write_free` to destroy this objects when you are done.

C header:

```
struct archive;
struct archive *archive_read_new(void);
struct archive *archive_write_new(void);
int archive_free(struct archive *);
int archive_write_free(struct archive *);
```

Perl code:

```
$lib->find_lib( lib => 'archive' );
$ffi->attach(archive_read_new   => []         => 'opaque');
$ffi->attach(archive_write_new  => []         => 'opaque');
$ffi->attach(archive_read_free  => ['opaque'] => 'int');
$ffi->attach(archive_write_free => ['opaque'] => 'int');
```

It is often useful to alias an opaque type like this so that you know what the object represents:

```
$lib->find_lib( lib => 'archive' );
$ffi->type('opaque' => 'archive');
$ffi->attach(archive_read_new   => [] => 'archive');
$ffi->attach(archive_read_free  => ['archive'] => 'int');
...
```

As a special case, when you pass `undef` into a function that takes an opaque type it will be translated into `NULL` for C. When a C function returns a NULL pointer, it will be translated back to `undef`.

For functions that take a pointer to a void pointer (that is a `void **`), you can use a pointer to an opaque type. Consider the C code:

```
struct archive_entry;
int archive_read_next_header(struct archive *, struvct archive_entry
↪**);
```

Once again the internals of `archive_entry` are not provided. Perl code:

```
$ffi->type('opaque' => 'archive_entry');
$ffi->attach(archive_read_next_header => [ 'archive', 'archive_
↪entry*' ] => 'int');
```

Now we can call this function

```
my $archive = archive_read_new();
...  # additional prep for $active is required
while(1) {
  my $entry;
  archive_read_next_header($archive, \$entry);
  last unless defined $entry;
  # can now use $entry for other archive_entry_ methods.
}
```

The way `archive_read_next_header` works, it will return a pointer to the next

`archive_entry` object until it gets to the end, when it will return a pointer to `NULL` which will be represented in Perl by a `undef`.

There are a number of useful utility functions for dealing with opaque types in the *FFI::Platypus::Memory* module.

Objects

Object types are thin wrappers around two native types: integer and opaque types. They are just blessed references around either of those two types so that methods can be defined on them, but when they get passed to a Platypus xsub they are converted into the native integer or opaque types. This type is most useful when a API provides an OO style interface with an integer or opaque value acting as an instance of a class. There are two detailed examples in the main Platypus documentation using libarchive and unix open:

- *"libarchive" in FFI::Platypus*
- *"unix open" in FFI::Platypus*

Strings

```
# used when you need a char * or const char *
$ffi->attach( puts => [ 'string' ] => 'int' );
```

The `string` type is a series of bytes that usually represent a series of characters. They will be NULL terminated for C and passed in as a pointer. This will typically work for APIs that take ASCII or UTF-8 strings which are common in Unix environments.

(Note if you need to handle the native "wide" string for example if you need to talk UTF-16 on Windows see *FFI::Platypus::Type::WideString*).

(Note if you need to pass in a fixed length string by value (not as a pointer) then you can do so using *FFI::Platypus::Record*).

(Note that languages like Go and Rust do not use NULL terminated strings and need their own string types; see the appropriate language plugins for details)

```
# can also be used when you need a void * or const void *
$ffi->attach( write => ['int', 'string', 'size_t' ] => 'ssizet' );
```

The `string` type can also be used to pass in the start of a buffer of arbitrary bytes stored in a Perl scalar. Because a `string` is passed just as a pointer you will typically need to also pass the length of the buffer as a separate argument. This is necessary because buffers could potentially have a NULL in them.

The pointer passed into C (or other language) is to the content of the actual scalar, which means it can modify the content of a scalar.

NOTE: When used as a return type, the string is *copied* into a new scalar rather than using the original address. This is due to the ownership model of scalars in Perl, but it is also most of the time what you want.

This can be problematic when a function returns a string that the callee is expected to free. Consider the functions:

```
char *
get_string()
{
  char *buffer;
  buffer = malloc(20);
  strcpy(buffer, "Perl");
}

void
free_string(char *buffer)
{
  free(buffer);
}
```

This API returns a string that you are expected to free when you are done with it. (At least they have provided an API for freeing the string instead of expecting you to call libc free)! A simple binding to get the string would be:

```
$ffi->attach( get_string => [] => 'string' );  # memory leak
my $str = get_string();
```

Which will work to a point, but the memory allocated by get_string will leak. Instead you need to get the opaque pointer, cast it to a string and then free it.

```
$ffi->attach( get_string => [] => 'opaque' );
$ffi->attach( free_string => ['opaque'] => 'void' );
my $ptr = get_string();
my $str = $ffi->cast( 'opaque' => 'string', $ptr );  # copies the␣
↪string
free_string($ptr);
```

If you are doing this sort of thing a lot, it can be worth adding a custom type:

```
$ffi->attach( free_string => ['opaque'] => 'void' );
$ffi->custom_type( 'my_string' => {
  native_type => 'opaque',
  native_to_perl => sub {
    my($ptr) = @_;
    my $str = $ffi->cast( 'opaque' => 'string', $ptr ); # copies the␣
↪string
    free_string($ptr);
    $str;
  }
});

$ffi->attach( get_string => [] => 'my_string' );
my $str = get_string();
```

Since version 0.62, pointers and arrays to strings are supported as a first class type. Prior to that *FFI::Platypus::Type::StringArray* and *FFI::Platypus::Type::StringPointer* could be used, though their use in new code is discouraged.

```
$ffi->attach( foo => ['string[]'] => 'void' );
foo( [ 'array', 'of', 'strings' ] );

$ffi->attach( bar => ['string*'] => 'void' );
my $string = 'baz';
bar( \$string );  # $string may be modified.
```

Strings are not allowed as return types from closure. This, again is due to the ownership model of scalars in Perl. (There is no way for Perl to know when calling language is done with the memory allocated to the string). Consider the API:

```
typedef const char *(*get_message_t)(void);

void
print_message(get_message_t get_message)
{
  const char *str;
  str = get_message();
  printf("message = %s\n", str);
}
```

It feels like this should be able to work:

```
$ffi->type('()->string' => 'get_message_t'); # not ok
$ffi->attach( print_message => ['get_message_t'] => 'void' );
my $get_message = $ffi->closure(sub {
  return "my message";
});
print_message($get_message);
```

If the type declaration for `get_message_t` were legal, then this script would likely segfault or in the very least corrupt memory. The problem is that once `"my message"` is returned from the closure Perl doesn't have a reference to it anymore and will free it. To do this safely, you have to keep a reference to the scalar around and return an opaque pointer to the string using a cast.

```
$ffi->type('()->opaque' => 'get_message_t');
$ffi->attach( print_message => ['get_message_t'] => 'void' );
my $get_message => $ffi->closure(sub {
  our $message = "my message";  # needs to be our so that it doesn't
                                # get free'd
  my $ptr = $ffi->cast('string' => 'opaque', $message);
  return $ptr;
});
print_message($get_message);
```

Another type of string that you may run into with some APIs is the so called "wide" string. In your C code if you see `wchar_t*` or `const wchar_t*` or if in Win32 API code you see `LPWSTR` or `LPCWSTR`. Most commonly you will see these types when working with the Win32 API, but you may see them in Unix as well. These types are intended for dealing with Unicode, but they do not use the same UTF-8 format used by Perl internally, so they need to be converted. You can do this manually by allocating the memory and using

the *Encode* module, but the easier way is to use either *FFI::Platypus::Type::WideString* or *FFI::Platypus::Lang::Win32*, which handle the memory allocation and conversion for you.

String types can be defined to have a fixed length using a trailing parenthetical like so `string(10)`. For arguments this has little practical effect since the strings are passed as pointers anyway, but does impact return values. If a function that returns a `string(10)` type returns a string that is not NULL terminated, only the first ten bytes will be returned in the result.

Internally fixed length strings are implemented the same as classless record types (that is to say `string(10)` is identically internally to `record(10)*`).

For the 1.00 Platypus API, the `string(10)` type was specified as a pointer (that is `string(10)*`). This was a mistake, but you can still use the latter as an alias for the correct form in the 2.00 API.

Pointers and Arrays of Strings

As of the 1.00 Platypus API, you can specify pointers to strings (`string*`) and arrays of strings (`string[10]`). Since strings themselves are passed as pointers, this means these types are passed in as pointers to pointers. If the pointer to the string is changed then when the function returns the scalar or array will be updated as well.

Pointer / References

In C you can pass a pointer to a variable to a function in order accomplish the task of pass by reference. In Perl the same task is accomplished by passing a reference (although you can also modify the argument stack thus Perl supports proper pass by reference as well).

With *FFI::Platypus* you can define a pointer to any native, string or record type. You cannot (at least not yet) define a pointer to a pointer or a pointer to an array or any other type not otherwise supported. When passing in a pointer to something you must make sure to pass in a reference to a scalar, or `undef` (`undef` will be translated int `NULL`).

If the C code makes a change to the value pointed to by the pointer, the scalar will be updated before returning to Perl space. Example, with C code.

```
/* foo.c */
void increment_int(int *value)
{
  if(value != NULL)
    (*value)++;
  else
    fprintf(stderr, "NULL pointer!\n");
}

# foo.pl
use FFI::Platypus 2.00;
my $ffi = FFI::Platypus->new( api => 2 );
$ffi->lib('libfoo.so'); # change to reflect the dynamic lib
                        # that contains foo.c
$ffi->type('int*' => 'int_p');
```

(continues on next page)

(continued from previous page)

```
$ffi->attach(increment_int => ['int_p'] => 'void');
my $i = 0;
increment_int(\$i);   # $i == 1
increment_int(\$i);   # $i == 2
increment_int(\$i);   # $i == 3
increment_int(undef); # prints "NULL pointer!\n"
```

Older versions of Platypus did not support pointers to strings or records.

Records

Records are structured data of a fixed length. In C they are called `structs`.

For most C structured data, as long as you do not need to a record by value, FFI::C is the better choice. Briefly, FFI::C supports `struct`, `union`, and arrays of `struct` and `unions`. FFI::C does not support passing by value. The reminder of this section will discuss only the `record` type.

To declare a record type, use `record`:

```
$ffi->type( 'record (42)' => 'my_record_of_size_42_bytes' );
```

The easiest way to mange records with Platypus is by using *FFI::Platypus::Record* to define a record layout for a record class. Here is a brief example:

```
package Unix::TimeStruct;

use FFI::Platypus 2.00;
use FFI::Platypus::Record;

record_layout_1(qw(
    int    tm_sec
    int    tm_min
    int    tm_hour
    int    tm_mday
    int    tm_mon
    int    tm_year
    int    tm_wday
    int    tm_yday
    int    tm_isdst
    long   tm_gmtoff
    string tm_zone
));

my $ffi = FFI::Platypus->new( api => 2 );
$ffi->lib(undef);
# define a record class Unix::TimeStruct and alias it to "tm"
$ffi->type("record(Unix::TimeStruct)*" => 'tm');

# attach the C localtime function as a constructor
```

(continues on next page)

(continued from previous page)

```
$ffi->attach( localtime => ['time_t*'] => 'tm', sub {
  my($inner, $class, $time) = @_;
  $time = time unless defined $time;
  $inner->(\$time);
});

package main;

# now we can actually use our Unix::TimeStruct class
my $time = Unix::TimeStruct->localtime;
printf "time is %d:%d:%d %s\n",
  $time->tm_hour,
  $time->tm_min,
  $time->tm_sec,
  $time->tm_zone;
```

For more detailed usage, see *FFI::Platypus::Record*.

Platypus does not manage the structure of a record (that is up to you), it just keeps track of their size and makes sure that they are copied correctly when used as a return type. A record in Perl is just a string of bytes stored as a scalar. In addition to defining a record layout for a record class, there are a number of tools you can use manipulate records in Perl, two notable examples are pack and unpack and Convert::Binary::C.

Here is an example with commentary that uses Convert::Binary::C to extract the component time values from the C `localtime` function, and then smushes them back together to get the original `time_t` (an integer).

```
use Convert::Binary::C;
use FFI::Platypus 2.00;
use Data::Dumper qw( Dumper );

my $c = Convert::Binary::C->new;

# Alignment of zero (0) means use
# the alignment of your CPU
$c->configure( Alignment => 0 );

# parse the tm record structure so
# that Convert::Binary::C knows
# what to spit out and suck in
$c->parse(<<ENDC);
struct tm {
  int tm_sec;
  int tm_min;
  int tm_hour;
  int tm_mday;
  int tm_mon;
  int tm_year;
  int tm_wday;
```

(continues on next page)

(continued from previous page)

```
  int tm_yday;
  int tm_isdst;
  long int tm_gmtoff;
  const char *tm_zone;
};
ENDC

# get the size of tm so that we can give it
# to Platypus
my $tm_size = $c->sizeof("tm");

# create the Platypus instance and create the appropriate
# types and functions
my $ffi = FFI::Platypus->new( api => 2 );
$ffi->lib(undef);
$ffi->type("record($tm_size)*" => 'tm');
$ffi->attach( [ localtime => 'my_localtime' ] => ['time_t*'] => 'tm'
 ↪    );
$ffi->attach( [ time      => 'my_time'      ] => ['tm']      =>
 ↪'time_t' );

# ================================================
# get the tm struct from the C localtime function
# note that we pass in a reference to the value that time
# returns because localtime takes a pointer to time_t
# for some reason.
my $time_hashref = $c->unpack( tm => my_localtime(\time) );

# tm_zone comes back from Convert::Binary::C as an opaque,
# cast it into a string.  We localize it to just this do
# block so that it will be a pointer when we pass it back
# to C land below.
do {
  local $time_hashref->{tm_zone} = $ffi->cast(opaque => string =>
 ↪$time_hashref->{tm_zone});
  print Dumper($time_hashref);
};

# ================================================
# convert the tm struct back into an epoch value
my $time = my_time( $c->pack( tm => $time_hashref ) );

print "time      = $time\n";
print "perl time = ", time, "\n";
```

You can also link a record type to a class. It will then be accepted when blessed into that class as an argument passed into a C function, and when it is returned from a C function it will be blessed into that class. Basically:

```
$ffi->type( 'record(My::Class)*' => 'my_class' );
$ffi->attach( my_function1 => [ 'my_class' ] => 'void' );
$ffi->attach( my_function2 => [ ] => 'my_class' );
```

The only thing that your class MUST provide is either a `ffi_record_size` or `_ffi_record_size` class method that returns the size of the record in bytes.

Contrast a record type which is stored as a scalar string of bytes in Perl to an opaque pointer which is stored as an integer in Perl. Both are treated as pointers in C functions. The situations when you usually want to use a record are when you know ahead of time what the size of the object that you are working with and probably something about its structure. Because a function that returns a structure copies the structure into a Perl data structure, you want to make sure that it is okay to copy the record objects that you are dealing with if any of your functions will be returning one of them.

Opaque pointers should be used when you do not know the size of the object that you are using, or if the objects are created and free'd through an API interface other than `malloc` and `free`.

The examples in this section actually use pointers to records (note the trailing star * in the declarations). Most programming languages allow you to pass or return a record as either pass-by-value or as a pointer (pass-by-reference).

C code:

```
struct { int a; } foo_t;
void pass_by_value_example( struct foo_t foo );
void pass_by_reference_example( struct foo_t *foo );
```

Perl code:

```
{
  package Foo;
  use FFI::Platypus::Record;
  record_layout_1( int => 'a' );
}
$ffi->type( 'Record(Foo)' => 'foo_t' );
$ffi->attach( pass_by_value_example => [ 'foo_t' ] => 'void' );
$ffi->attach( pass_by_reference_example => [ 'foo_t*' ] => 'void' );
```

As with strings, functions that return a pointer to a record are actually copied.

C code:

```
struct foo_t *return_struct_pointer_example();
```

Perl code:

```
$ffi->attach( return_struct_pointer_example => [] => 'foo_t*' );
my $foo = return_struct_pointer_example();
# $foo is a copy of the record returned by the function.
```

As with strings, if the API expects you to free the record it returns (it is misbehaving a little, but lets set that aside), then you can work around this by returning an opaque

type, casting to the record, and finally freeing the original pointer.

```
use FFI::Platypus::Memory qw( free );
$ffi->attach( return_struct_pointer_example => [] => 'opaque' );
my $foo_ptr = return_struct_pointer_example();
my $foo = $ffi->cast( 'opaque' => 'foo_t*', $foo_ptr );
free $foo_ptr;
```

You can pass records into a closure, but care needs to be taken. Records passed into a closure are read-only inside the closure, including `string rw` members. Although you can pass a "pointer" to a record into a closure, because of limitations of the implementation you actually have a copy, so all records passed into closures are passed by-value.

Note that a record that does not have a class (classless) and is defined instead using a length is internally identical to fixed strings. That is to say `string(10)` and `record(10)*` are identical.

Fixed length arrays

Fixed length arrays of native types and strings are supported by *FFI::Platypus*. Like pointers, if the values contained in the array are updated by the C function these changes will be reflected when it returns to Perl space. An example of using this is the Unix `pipe` command which returns a list of two file descriptors as an array.

```
use FFI::Platypus 2.00;

my $ffi = FFI::Platypus->new( api => 2 );
$ffi->lib(undef);
$ffi->attach([pipe=>'mypipe'] => ['int[2]'] => 'int');

my @fd = (0,0);
mypipe(\@fd);
my($fd1,$fd2) = @fd;

print "$fd1 $fd2\n";
```

Because of the way records are implemented, an array of records does not make sense and is not currently supported.

Variable length arrays

[version 0.22]

Variable length arrays are supported for argument types can also be specified by using the `[]` notation but by leaving the size empty:

```
$ffi->type('int[]' => 'var_int_array');
```

When used as an argument type it will probe the array reference that you pass in to determine the correct size. Usually you will need to communicate the size of the array to the C code. One way to do this is to pass the length of the array in as an additional argument. For example the C code:

```
int
sum(int *array, int size)
{
  int total, i;
  for (i = 0, total = 0; i < size; i++)
  {
    total += array[i];
  }
  return total;
}
```

Can be called from Perl like this:

```
use FFI::Platypus 2.00;

my $ffi = FFI::Platypus->new( api => 2 );
$ffi->lib('./var_array.so');

$ffi->attach( sum => [ 'int[]', 'int' ] => 'int' );

my @list = (1..100);

print sum(\@list, scalar @list), "\n";
```

Another method might be to have a special value, such as 0 or NULL indicate the termination of the array.

Because of the way records are implemented, an array of records does not make sense and is not currently supported.

Closures

A closure (sometimes called a "callback", we use the `libffi` terminology) is a Perl subroutine that can be called from C. In order to be called from C it needs to be passed to a C function. To define the closure type you need to provide a list of argument types and a return type. Currently only native types (integers, floating point values, opaque), strings and records (by-value; you can pass a pointer to a record, but due to limitations of the record implementation this is actually a copy) are supported as closure argument types, and only native types and records (by-value; pointer records and records with string pointers cannot be returned from a closure) are supported as closure return types. Inside the closure any records passed in are read-only.

We plan to add other types, though they can be converted using the Platypus `cast` or `attach_cast` methods.

Here is an example, with C code:

```
/*
 * closure.c - on Linux compile with: gcc closure.c -shared -o␣
↪closure.so -fPIC
 */
```

(continues on next page)

(continued from previous page)

```
#include <stdio.h>

typedef int (*closure_t)(int);
closure_t my_closure = NULL;

void set_closure(closure_t value)
{
  my_closure = value;
}

int call_closure(int value)
{
  if(my_closure != NULL)
    return my_closure(value);
  else
    fprintf(stderr, "closure is NULL\n");
}
```

And the Perl code:

```
use FFI::Platypus 2.00;

my $ffi = FFI::Platypus->new( api => 2 );
$ffi->lib('./closure.so');
$ffi->type('(int)->int' => 'closure_t');

$ffi->attach(set_closure => ['closure_t'] => 'void');
$ffi->attach(call_closure => ['int'] => 'int');

my $closure1 = $ffi->closure(sub { $_[0] * 2 });
set_closure($closure1);
print  call_closure(2), "\n"; # prints "4"

my $closure2 = $ffi->closure(sub { $_[0] * 4 });
set_closure($closure2);
print call_closure(2), "\n"; # prints "8"
```

If you have a pointer to a function in the form of an opaque type, you can pass this in place of a closure type:

```
use FFI::Platypus 2.00;

my $ffi = FFI::Platypus->new( api => 2 );
$ffi->lib('./closure.so');
$ffi->type('(int)->int' => 'closure_t');

$ffi->attach(set_closure => ['closure_t'] => 'void');
$ffi->attach(call_closure => ['int'] => 'int');

my $closure = $ffi->closure(sub { $_[0] * 6 });
```

(continues on next page)

(continued from previous page)

```
my $opaque = $ffi->cast(closure_t => 'opaque', $closure);
set_closure($opaque);
print call_closure(2), "\n"; # prints "12"
```

The syntax for specifying a closure type is a list of comma separated types in parentheticals followed by a narrow arrow `->`, followed by the return type for the closure. For example a closure that takes a pointer, an integer and a string and returns an integer would look like this:

```
$ffi->type('(opaque, int, string) -> int' => 'my_closure_type');
```

Care needs to be taken with scoping and closures, because of the way Perl and C handle responsibility for allocating memory differently. Perl keeps reference counts and frees objects when nothing is referencing them. In C the code that allocates the memory is considered responsible for explicitly free'ing the memory for objects it has created when they are no longer needed. When you pass a closure into a C function, the C code has a pointer or reference to that object, but it has no way up letting Perl know when it is no longer using it. As a result, if you do not keep a reference to your closure around it will be free'd by Perl and if the C code ever tries to call the closure it will probably SIGSEGV. Thus supposing you have a C function `set_closure` that takes a Perl closure, this is almost always wrong:

```
set_closure($ffi->closure({ $_[0] * 2 }));  # BAD
```

In some cases, you may want to create a closure shouldn't ever be free'd. For example you are passing a closure into a C function that will retain it for the lifetime of your application. You can use the sticky method to keep the closure, without the need to keep a reference of the closure:

```
{
  my $closure = $ffi->closure(sub { $_[0] * 2 });
  $closure->sticky;
  set_closure($closure); # OKAY
}
# closure still exists and is accesible from C, but
# not from Perl land.
```

Custom Types

Custom Types in Perl

They offer a method for converting Perl types into native types that the `libffi` can understand and pass on to the C code.

Example 1: Integer constants

Say you have a C header file like this:

```
/* possible foo types: */
#define FOO_STATIC  1
```

(continues on next page)

(continued from previous page)

```
#define FOO_DYNAMIC 2
#define FOO_OTHER   3

typedef int foo_t;

void foo(foo_t foo);
foo_t get_foo();
```

The challenge is here that once the source is processed by the C pre-processor the name/value mappings for these FOO_ constants are lost. There is no way to fetch them from the library once it is compiled and linked.

One common way of implementing this would be to create and export constants in your Perl module, like this:

```
package Foo;

use FFI::Platypus 2.00;
use Exporter qw( import );

our @EXPORT_OK = qw( FOO_STATIC FOO_DYNAMIC FOO_OTHER foo get_foo );

use constant FOO_STATIC  => 1;
use constant FOO_DYNAMIC => 2;
use constant FOO_OTHER   => 3;

my $ffi = FFI::Platypus->new( api => 2 );
$ffi->attach(foo     => ['int'] => 'void');
$ffi->attach(get_foo => []      => 'int');
```

Then you could use the module thus:

```
use Foo qw( foo FOO_STATIC );
foo(FOO_STATIC);
```

If you didn't want to rely on integer constants or exports, you could also define a custom type, and allow strings to be passed into your function, like this:

```
package Foo;

use FFI::Platypus 2.00;

our @EXPORT_OK = qw( foo get_foo );

my %foo_types = (
  static  => 1,
  dynamic => 2,
  other   => 3,
);
my %foo_types_reverse = reverse %foo_types;
```

(continues on next page)

(continued from previous page)

```
my $ffi = FFI::Platypus->new( api => 2 );
$ffi->custom_type(foo_t => {
  native_type    => 'int',
  native_to_perl => sub {
    $foo_types{$_[0]};
  },
  perl_to_native => sub {
    $foo_types_reverse{$_[0]};
  },
});

$ffi->attach(foo     => ['foo_t'] => 'void');
$ffi->attach(get_foo => []        => 'foo_t');
```

Now when an argument of type `foo_t` is called for it will be converted from an appropriate string representation, and any function that returns a `foo_t` type will return a string instead of the integer representation:

```
use Foo;
foo('static');
```

If the library that you are using has a lot of these constants you can try using Convert::Binary::C or another C header parser to obtain the appropriate name/value pairings for the constants that you need.

Example 2: Blessed references

Supposing you have a C library that uses an opaque pointer with a pseudo OO interface, like this:

```
typedef struct foo_t;

foo_t *foo_new();
void foo_method(foo_t *, int argument);
void foo_free(foo_t *);
```

One approach to adapting this to Perl would be to create a OO Perl interface like this:

```
package Foo;

use FFI::Platypus 2.00;
use FFI::Platypus::API qw( arguments_get_string );

my $ffi = FFI::Platypus->new( api => 2 );
$ffi->custom_type(foo_t => {
  native_type    => 'opaque',
  native_to_perl => sub {
    my $class = arguments_get_string(0);
    bless \$_[0], $class;
```

(continues on next page)

(continued from previous page)

```
  }
  perl_to_native => sub { ${$_[0]} },
});

$ffi->attach([ foo_new => 'new' ] => [ 'string' ] => 'foo_t' );
$ffi->attach([ foo_method => 'method' ] => [ 'foo_t', 'int' ] =>
↪'void');
$ffi->attach([ foo_free => 'DESTROY' ] => [ 'foo_t' ] => 'void');

my $foo = Foo->new;
```

Here we are blessing a reference to the opaque pointer when we return the custom type for `foo_t`, and dereferencing that reference before we pass it back in. The function `arguments_get_string` queries the C arguments to get the class name to make sure the object is blessed into the correct class (for more details on the custom type API see *FFI::Platypus::API*), so you can inherit and extend this class like a normal Perl class. This works because the C "constructor" ignores the class name that we pass in as the first argument. If you have a C "constructor" like this that takes arguments you'd have to write a wrapper for new.

A good example of a C library that uses this pattern, including inheritance is `libarchive`. Platypus comes with a more extensive example in `examples/archive.pl` that demonstrates this.

Example 3: Pointers with pack / unpack

TODO

See example *FFI::Platypus::Type::StringPointer*.

Example 4: Custom Type modules and the Custom Type API

TODO

See example *FFI::Platypus::Type::PointerSizeBuffer*.

Example 5: Custom Type on CPAN

You can distribute your own Platypus custom types on CPAN, if you think they may be applicable to others. The default namespace is prefix with `FFI::Platypus::Type::`, though you can stick it anywhere (under your own namespace may make more sense if the custom type is specific to your application).

A good example and pattern to follow is *FFI::Platypus::Type::StringArray*.

FFI::Platypus::Type::PointerSizeBuffer

Convert string scalar to a buffer as a pointer / size_t combination

VERSION

version 2.12

SYNOPSIS

In your C code:

```
void
function_with_buffer(void *pointer, size_t size)
{
  ...
}
```

In your Platypus::FFI code:

```
use FFI::Platypus 2.00;

my $ffi = FFI::Platypus->new( api => 2 );
$ffi->load_custom_type('::PointerSizeBuffer' => 'buffer');

$ffi->attach(function_with_buffer => ['buffer'] => 'void');
my $string = "content of buffer";
function_with_buffer($string);
```

DESCRIPTION

A common pattern in C code is to pass in a region of memory as a buffer, consisting of a pointer and a size of the memory region. In Perl, string scalars also point to a contiguous series of bytes that has a size, so when interfacing with C libraries it is handy to be able to pass in a string scalar as a pointer / size buffer pair.

FFI::Platypus::Type::StringArray

Platypus custom type for arrays of strings

VERSION

version 2.12

SYNOPSIS

In your C code:

```
void
takes_string_array(const char **array)
{
  ...
}

void
takes_fixed_string_array(const char *array[5])
{
  ...
}
```

In your *FFI::Platypus* code:

```
use FFI::Platypus 2.00;

my $ffi = FFI::Platypus->new( api => 2 );
$ffi->load_custom_type('::StringArray' => 'string_array');
$ffi->load_custom_type('::StringArray' => 'string_5' => 5);

$ffi->attach(takes_string_array => ['string_array'] => 'void');
$ffi->attach(takes_fixed_string_array => ['string_5'] => 'void');

my @list = qw( foo bar baz );

takes_string_array(\@list);
takes_fixed_string_array([qw( s1 s2 s3 s4 s5 )]);
```

DESCRIPTION

NOTE: The primary motivation for this custom type was originally to fill the void left by the fact that *FFI::Platypus* did not support arrays of strings by itself. Since 0.62 this support has been added, and that is probably what you want to use, but the semantics and feature set are slightly different, so there are cases where you might want to use this custom type.

This module provides a *FFI::Platypus* custom type for arrays of strings. The array is always NULL terminated. Return types are supported!

This custom type takes two optional arguments. The first is the size of arrays and the second is a default value to fill in any values that aren't provided when the function is called. If not default is provided then `NULL` will be passed in for those values.

SUPPORT

If something does not work the way you think it should, or if you have a feature request, please open an issue on this project's GitHub Issue tracker:

https://github.com/plicease/FFI-Platypus-Type-StringArray/issues

CONTRIBUTING

If you have implemented a new feature or fixed a bug then you may make a pull request on this project's GitHub repository:

https://github.com/plicease/FFI-Platypus-Type-StringArray/pulls

This project's GitHub issue tracker listed above is not Write-Only. If you want to contribute then feel free to browse through the existing issues and see if there is something you feel you might be good at and take a whack at the problem. I frequently open issues myself that I hope will be accomplished by someone in the future but do not have time to immediately implement myself.

Another good area to help out in is documentation. I try to make sure that there is good document coverage, that is there should be documentation describing all the public features and warnings about common pitfalls, but an outsider's or alternate view point on such things would be welcome; if you see something confusing or lacks sufficient detail I encourage documentation only pull requests to improve things.

FFI::Platypus::Type::StringPointer

Convert a pointer to a string and back

VERSION

version 2.12

SYNOPSIS

In your C code:

```
void
string_pointer_argument(const char **string)
{
  ...
}
const char **
string_pointer_return(void)
{
  ...
}
```

In your Platypus::FFI code:

```
use FFI::Platypus 2.00;

my $ffi = FFI::Platypus->new( api => 2 );
$ffi->load_custom_type('::StringPointer' => 'string_pointer');

$ffi->attach(string_pointer_argument => ['string_pointer'] => 'void
 ↪');
$ffi->attach(string_pointer_return   => [] => 'string_pointer');

my $string = "foo";

string_pointer_argument(\$string); # $string may be modified

$ref = string_pointer_return();

print $$ref;  # print the string pointed to by $ref
```

DESCRIPTION

NOTE: As of version 0.61, this custom type is now deprecated since pointers to strings are supported in the *FFI::Platypus* directly without custom types.

This module provides a *FFI::Platypus* custom type for pointers to strings.

FFI::Platypus::Type::WideString

Platypus custom type for Unicode “wide” strings

VERSION

version 2.12

SYNOPSIS

```
use FFI::Platypus 2.00;

my $ffi = FFI::Platypus->new( api => 2, lib => [undef] );
$ffi->load_custom_type('::WideString' => 'wstring', access => 'read'␣
↪);
$ffi->load_custom_type('::WideString' => 'wstring_w', access =>
↪'write' );

# call function that takes a constant wide string
$ffi->attach( wcscmp => ['wstring', 'wstring'] => 'int' );
my $diff = wcscmp("I ❤ perl + Platypus", "I ❤ perl + Platypus"); #␣
↪returns 0

# call a function that takes a wide string for writing
$ffi->attach( wcscpy => ['wstring_w', 'wstring'] );
my $buf;
```

(continues on next page)

(continued from previous page)

```
wcscpy(\$buf, "I ❤ perl + Platypus");
print $buf, "\n";  # prints "I ❤ perl + Platypus"

# call a function that takes a wide string for modification
$ffi->attach( wcscat => ['wstring_w', 'wstring'] );
my $buf;
wcscat( [ \$buf, "I ❤ perl" ], " + Platypus");
print $buf, "\n";  # prints "I ❤ perl + Platypus"
```

On Windows use with LPCWSTR:

```
use FFI::Platypus 2.00;

my $ffi = FFI::Platypus->new( api => 2, lib => [undef] );

# define some custom Win32 Types
# to get these automatically see FFI::Platypus::Lang::Win32
$ffi->load_custom_type('::WideString' => 'LPCWSTR', access => 'read'
 ↪);
$ffi->type('opaque' => 'HWND');
$ffi->type('uint'   => 'UINT');

use constant MB_OK                    => 0x00000000;
use constant MB_DEFAULT_DESKTOP_ONLY => 0x00020000;

$ffi->attach( [MessageBoxW => 'MessageBox'] => [ 'HWND', 'LPCWSTR',
 ↪'LPCWSTR', 'UINT'] => 'int' );

MessageBox(undef, "I ❤ Platypus", "Confession", MB_OK|MB_DEFAULT_
 ↪DESKTOP_ONLY);
```

DESCRIPTION

This custom type plugin for *FFI::Platypus* provides support for the native “wide” string type on your platform, if it is available.

Wide strings are made of up wide characters (wchar_t, also known as WCHAR on Windows) and have enough bits to represent character sets that require larger than the traditional one byte char.

These strings are most commonly used on Windows where they are referred to as LPWSTR and LPCWSTR (The former for read/write buffers and the latter for const read-only strings), where they are encoded as UTF-16LE.

They are also supported by libc on many modern Unix systems where they are usually UTF-32 of the native byte-order of the system. APIs on Unix systems more commonly use UTF-8 which provides some compatibility with ASCII, but you may occasionally find APIs that talk in wide strings. (libarchive, for example, can work in both).

This plugin will detect the native wide string format for you and transparently convert Perl strings, which are typically encoded internally as UTF-8. If for some reason it cannot detect the correct encoding, or if your platform is currently supported, an exception will

be thrown (please open a ticket if this is the case). It can be used either for read/write buffers, for const read-only strings, and for return values. It supports these options:

Options:

- access

  Either `read` or `write` depending on if you are using a read/write buffer or a const read-only string.

- size

  For read/write buffer, the size of the buffer to create, if not provided by the caller.

read-only

Read-only strings are the easiest of all, are converted to the native wide string format in a buffer and are freed after that function call completes.

```
$ffi->load_custom_type('::WideString' => 'wstring' );
$ffi->function( wprintf => [ 'wstring' ] => [ 'wstring' ] => 'int' )
     ->call("I %s perl + Platypus", "❤");
```

This is the mode that you want to use when you are calling a function that takes a `const wchar_t*` or a `LPCWSTR`.

return value

For return values the `access` and `size` options are ignored. The string is simply copied into a Perl native string.

```
$ffi->load_custom_type('::WideString' => 'wstring' );
# see note below in CAVEATS about wcsdup
my $str = $ffi->function( wcsdup => [ 'wstring' ] => 'wstring' )
               ->call("I ❤ perl + Platypus");
```

This is the mode that you want to use when you are calling a function that returns a `const wchar_t*`, `wchar_t`, `LPWSTR` or `LPCWSTR`.

read/write

Read/write strings can be passed in one of two ways. Which you choose depends on if you want to initialize the read/write buffer or not.

- default buffer size

  The simplest way is to fallback on the default buffer size, which can be specified using the `size` option when creating the custom type.

  ```
  my $ffi = FFI::Platypus->new( api => 2, lib => [undef] );
  $ffi->load_custom_type('::WideString' => 'wstring',   access =>
   ↪'read' );
  $ffi->load_custom_type('::WideString' => 'wstring_w', access =>
   ↪'write', size => 512 );
  ```

(continues on next page)

(continued from previous page)

```
$ffi->attach( wcscpy => ['wstring_w', 'wstring'] );
my $buf;
wcscpy(\$buf, "I ❤ perl + Platypus");
print $buf, "\n";  # prints "I ❤ perl + Platypus"
```

Discussion: This is the most sensical approach when the exact size of the buffer is known for all usages of the string type. It can also be sensical if the buffer size is larger than any possible output, though care should be taken since this may be hard to determine reliably.

The default size if none is specified when creating the custom type is 2048, which is probably large enough for many uses, but also probably wastes memory for many of them.

- allocate your buffer of a specific size

  The safest and most memory efficient method is of course to allocate exactly the amount of memory that you need.

```
my $ffi = FFI::Platypus->new( api => 2, lib => [undef] );
$ffi->load_custom_type('::WideString' => 'wstring',   access =>
 ↪'read'  );
$ffi->load_custom_type('::WideString' => 'wstring_w', access =>
 ↪'write' );

$ffi->attach( wcscpy => ['wstring_w', 'wstring'] );
my $width = $ffi->sizeof('wchar_t');
my $buf = "\0" x ( (length ("I ❤ perl + Platypus") + 1)*$width);
wcscpy(\$buf, "I ❤ perl + Platypus");
print $buf, "\n";  # prints "I ❤ perl + Platypus"
```

Discussion: By assigning `$buf` to a string of null characters the length of the source string, plus one (for the null at the end) and then multiplying that by the size of `wchar_t`, you get the exact number of bytes needed for the destination buffer.

Note that although we pass in a reference to a buffer, what comes back is converted to a Perl string, which will be internally UTF-8, not stored at the original buffer location. This is slightly awkward, but what you need most of the time.

- initialize the read/write buffer

  Some functions don't expect empty null padded buffers though, in this case you will want to initialize the buffer.

```
my $ffi = FFI::Platypus->new( api => 2, lib => [undef] );
$ffi->load_custom_type('::WideString' => 'wstring',   access =>
 ↪'read'  );
$ffi->load_custom_type('::WideString' => 'wstring_w', access =>
 ↪'write' );

$ffi->attach( wcscat => ['wstring_w', 'wstring'] );
my $buf;
```

(continues on next page)

(continued from previous page)

```
wcscat( [ \$buf, "I ❤ perl" ], " + Platypus");
print $buf, "\n";  # prints "I ❤ perl + Platypus"
```

Discussion: To initialize we pass in an array reference instead of a scalar reference. The first element is a scalar reference to the buffer (which can be pre-allocated or not; if it is not allocated then it will be allocated to the default size for the type). The second argument is what the buffer should be initialized to before the underlying C function is called. The Perl string is encoded into wide string format before being used to initialize the buffer.

As before a reference to the translated string is returned, and the buffer that was used to pass in is freed.

- allocate memory using `malloc` or `wcsdup` etc.

  You can also allocate memory using `malloc` or `wcsdup` to return an opaque type and manipulate it using the libc `wcs*` functions. It will still probably be useful to use this plugin to cast the opaque back to a Perl string. The CAVEATS section below includes several examples.

This is the mode that you want to use when you are calling a function that takes a <wchar_t*> or a `LPWSTR`.

CAVEATS

As with the Platypus built in `string` type, return values are copied into a Perl scalar. This is usually what you want anyway, but some APIs expect the caller to take responsibility for freeing the pointer to the wide string that it returns. For example, `wcsdup` works in this way. The workaround is to return an opaque pointer, cast it from a wide string and free the pointer.

```
use FFI::Platypus::Memory qw( free );
$ffi->load_custom_type('::WideString' => 'wstring' );
my $ptr = $ffi->function( wcsdup => [ 'wstring' ] => 'opaque' )
               ->call("I ❤ perl + Platypus");
my $str = $ffi->cast('opaque', 'wstring', $ptr);
free $ptr;
```

Because of the order in which objects are freed you cannot return a wide string if it is also a wide string argument to a function. For example `wcscpy` may crash if you specify the return value as a wide string:

```
# wchar_t *wcscpy(wchar_t *dest, const wchar_t *src);
$ffi->attach( wcscpy => [ 'wstring_w', 'wstring' ] => 'wstring' ); #␣
↪no
my $str;
wcscpy( \$str, "I ❤ perl + Platypus");  # may crash on memory error
```

This is because the order in which things are done here are 1. `$str` is allocated 2. `$str` is re-encoded as utf and the old buffer is freed 3. the return value is computed based on the `$str` buffer that was freed.

If you look at `wcscpy` though you don't actually need the return value. To make this code work, you can just ignore the return value:

```
$ffi->attach( wcscpy => [ 'wstring_w', 'wstring' ] => 'void' ); #␣
↪yes
my $str;
wcscpy( \$str, "I ❤ perl + Platypus"); # good!
```

On the other hand you do care about the return value from `wcschr`, which returns a pointer to the first occurrence of a character in an argument string:

```
# wchar_t *wcschr(const wchar_t *wcs, wchar_t wc);
$ffi->attach( wcschr => [ 'wstring', 'wchar_t' ] => 'wstring' ); #␣
↪no
# this may crash on memory error or return the wrong value
my $str = wcschr("I ❤ perl + Platypus", ord("❤"));
```

Instead you need to work with pointers and casts to use this function:

```
use FFI::Platypus 2.00;
use FFI::Platypus::Memory qw( free );

my $ffi = FFI::Platypus->new( api => 2, lib => [undef] );

$ffi->attach( wcsdup => ['wstring'] => 'opaque' );
$ffi->attach( strchr => [ opaque', 'wchar_t' ] => 'wstring' );

# create a wcs string in memory using wcsdup
my $haystack = wcsdup("I ❤ perl + Platypus");
# find the heart and return as a wide string
my $needle = strchr($haystack, ord("❤"));
# safe to free the pointer to the larger string now
free $haystack;
```

FFI::Platypus::TypeParser::Version0

FFI Type Parser Version Zero

VERSION

version 2.12

SYNOPSIS

```
use FFI::Platypus;
my $ffi = FFI::Platypus->new( api => 0 );
$ffi->type('record(Foo::Bar)' => 'foo_bar_t');
$ffi->type('opaque' => 'baz_t');
$ffi->type('opaque*' => 'baz_ptr');
```

DESCRIPTION

This documents the original *FFI::Platypus* type parser. It was the default and only type parser used by *FFI::Platypus* starting with version `0.02`. Starting with version `1.00` *FFI::Platypus* comes with a new type parser with design fixes that are not backward compatibility.

Interface differences

- Pass-by-value records are not allowed

  Originally *FFI::Platypus* only supported passing records as a pointer. The type `record(Foo::Bar)` actually passes a pointer to the record. In the version 1.00 parser allows `record(Foo::Bar)` which is pass-by-value (the contents of the record is copied onto the stack) and `record(Foo::Bar)*` which is pass-by-reference or pointer (a pointer to the record is passed to the callee so that it can make modifications to the record).

  TL;DR `record(Foo::Bar)` in version 0 is equivalent to `record(Foo::Bar)*` in the version 1 API. There is no equivalent to `record(Foo::Bar)*` in the version 0 API.

- decorate aliases of basic types

  This is not allowed in the version 0 API:

  ```
  $ffi->type('opaque' => 'foo_t');    # ok!
  $ffi->type('foo_t*' => 'foo_ptr');  # not ok! in version 0, ok!
   ↪in version 1
  ```

Instead you need to use the basic type in the second type definition:

```
$ffi->type('opaque' => 'foo_t');    # ok!
$ffi->type('opaque*' => 'foo_ptr'); # ok!
```

- object types are not allowed

```
$ffi->type('object(Foo::Bar)');   # not ok! in version 0, ok!
 ↪in version 1
```

FFI::Platypus::TypeParser::Version1

FFI Type Parser Version One

VERSION

version 2.12

SYNOPSIS

```
use FFI::Platypus 1.00;
my $ffi = FFI::Platypus->new( api => 1 );
$ffi->type('record(Foo::Bar)' => 'foo_bar_t');
$ffi->type('record(Foo::Bar)*' => 'foo_bar_ptr');
$ffi->type('opaque' => 'baz_t');
$ffi->type('bar_t*' => 'baz_ptr');
```

DESCRIPTION

This documents the second (version 1) type parser for *FFI::Platypus*. This type parser was included with *FFI::Platypus* starting with version `0.91` in an experimental capability, and `1.00` as a stable interface. Starting with version `1.00` the main *FFI::Platypus* documentation describes the version 1 API and you can refer to *FFI::Platypus::TypeParser::Version0* for details on the version0 API.

SEE ALSO

FFI::Platypus::TypeParser::Version2

FFI Type Parser Version Two

VERSION

version 2.12

SYNOPSIS

```
use FFI::Platypus 2.00;
my $ffi = FFI::Platypus->new( api => 2 );
$ffi->type('string(10)');
```

DESCRIPTION

This documents the third (version 2) type parser for *FFI::Platypus*. This type parser was included with *FFI::Platypus* starting with version `1.58` in an experimental capability, and `2.00` as a stable interface. Starting with version `1.00` the main *FFI::Platypus* documentation describes the version 2 API and you can refer to *FFI::Platypus::TypeParser::Version1* for details on the version1 API.

FFI::Probe

System detection and probing for FFI extensions.

VERSION

version 2.12

SYNOPSIS

```
use FFI::Probe;

my $probe = FFI::Probe->new;
$probe->check_header('foo.h');
...
```

DESCRIPTION

This class provides an interface for probing for system capabilities. It is used internally as part of the *FFI::Platypus* build process, but it may also be useful for extensions that use Platypus as well.

CONSTRUCTOR

new

```
my $probe = FFI::Probe->new(%args);
```

Creates a new instance.

- log

  Path to a log or file handle to write to.

- data_filename

  Path to a file which will be used to store/cache results.

METHODS

check_header

```
my $bool = $probe->check_header($header);
```

Checks that the given C header file is available. Stores the result, and returns a true/false value.

check_cpp

check_eval

```
my $bool = $probe>check_eval(%args);
```

- headers

  Any additional headers.

- decl

  Any C declarations that need to be made before the `dlmain` function.

- stmt

  Any C statements that should be made before the evaluation.

- eval

  Any evaluations that should be returned.

check

check_type_int

```
my $type = $probe->check_type_int($type);
```

check_type_enum

```
my $type = $probe->check_type_enum;
```

check_type_enum

```
my $type = $probe->check_type_enum;
```

check_type_float

```
my $type = $probe->check_type_float($type);
```

check_type_pointer

```
my $type = $probe->check_type_pointer;
```

set

```
$probe->set(@key, $value);
```

Used internally to store a value.

save

```
$probe->save;
```

Saves the values already detected.

data

```
my $data = $probe->data;
```

Returns a hashref of the data already detected.

log

```
$probe->log($string);
```

Sends the given string to the log.

log_code

```
$prbe->log_code($string);
```

Sends the given multi-line code block to the log.

template

```
my $template = $probe->template;
```

Returns the C code template used for `check_eval` and other `check_` methods.

Modules

- `FFI::Probe::Runner` - Probe runner for FFI

FFI::Probe::Runner

Probe runner for FFI

VERSION

version 2.12

SYNOPSIS

```
use FFI::Probe::Runner;

my $runner = FFI::Probe::Runner->new;
$runner->run('foo.so');
```

DESCRIPTION

This class executes code in a dynamic library for probing and detecting platform properties.

CONSTRUCTOR

new

```
my $runner = FFI::Probe::Runner->new(%args);
```

Creates a new instance.

- exe

  The path to the dlrun wrapper. The default is usually correct.

- flags

  The flags to pass into `dlopen`. The default is `RTLD_LAZY` on Unix and `0` on windows..

METHODS

exe

```
my $exe = $runner->exe;
```

The path to the dlrun wrapper.

flags

```
my $flags = $runner->flags;
```

The flags to pass into `dlopen`.

verify

```
$runner->verify;
```

Verifies the dlrun wrapper is working. Throws an exception in the event of failure.

run

```
$runner->run($dll, @args);
```

Runs the `dlmain` function in the given dynamic library, passing in the given arguments. Returns a *FFI::Probe::Runner::Result* object which contains the results.

Modules

- `FFI::Probe::Runner::Builder` - Probe runner builder for FFI
- `FFI::Probe::Runner::Result` - The results from a probe run.

FFI::Probe::Runner::Builder

Probe runner builder for FFI

VERSION

version 2.12

SYNOPSIS

```
use FFI::Probe::Runner::Builder;
my $builder = FFI::Probe::Runner::Builder->new
  dir => "/foo/bar",
);
my $exe = $builder->build;
```

DESCRIPTION

This is a builder class for the FFI probe runner. It is mostly only of interest if you are hacking on *FFI::Platypus* itself.

The interface may and will change over time without notice. Use in external dependencies at your own peril.

CONSTRUCTORS

new

```
my $builder = FFI::Probe::Runner::Builder->new(%args);
```

Create a new instance.

- dir

  The root directory for where to place the probe runner files. Will be created if it doesn't already exist. The default makes sense for when *FFI::Platypus* is being built.

METHODS

dir

```
my $dir = $builder->dir(@subdirs);
```

Returns a subdirectory from the builder root. Directory will be created if it doesn't already exist.

cc

```
my @cc = @{ $builder->cc };
```

The C compiler to use. Returned as an array reference so that it may be modified.

ccflags

```
my @ccflags = @{ $builder->ccflags };
```

The C compiler flags to use. Returned as an array reference so that it may be modified.

optimize

The C optimize flags to use. Returned as an array reference so that it may be modified.

ld

```
my @ld = @{ $builder->ld };
```

The linker to use. Returned as an array reference so that it may be modified.

ldflags

```
my @ldflags = @{ $builder->ldflags };
```

The linker flags to use. Returned as an array reference so that it may be modified.

libs

```
my @libs = @{ $builder->libs };
```

The library flags to use. Returned as an array reference so that it may be modified.

file

```
my $file = $builder->file(@subdirs, $filename);
```

Returns a file in a subdirectory from the builder root. Directory will be created if it doesn't already exist. File will not be created.

exe

```
my $exe = $builder->exe;
```

The name of the executable, once it is built.

source

```
my $source = $builder->source;
```

The C source for the probe runner.

extract

```
$builder->extract;
```

Extract the source for the probe runner.

run

```
$builder->run($type, @command);
```

Runs the given command. Dies if the command fails.

run_list

```
$builder->run($type, \@command, \@command, ...);
```

Runs the given commands in order until one succeeds. Dies if they all fail.

build

```
my $exe = $builder->build;
```

Builds the probe runner. Returns the path to the executable.

5.2.42 Fatal

Replace functions with equivalents which succeed or die

SYNOPSIS

```
use Fatal qw(open close);

open(my $fh, "<", $filename);  # No need to check errors!

use File::Copy qw(move);
use Fatal qw(move);

move($file1, $file2); # No need to check errors!

sub juggle { . . . }
Fatal->import('juggle');
```

BEST PRACTICE

Fatal has been obsoleted by the new *autodie* pragma. Please use *autodie* in preference to `Fatal`. *autodie* supports lexical scoping, throws real exception objects, and provides much nicer error messages.

The use of `:void` with Fatal is discouraged.

DESCRIPTION

`Fatal` provides a way to conveniently replace functions which normally return a false value when they fail with equivalents which raise exceptions if they are not successful. This lets you use these functions without having to test their return values explicitly on each call. Exceptions can be caught using `eval{}`. See *perlfunc* and *perlvar* for details.

The do-or-die equivalents are set up simply by calling Fatal's `import` routine, passing it the names of the functions to be replaced. You may wrap both user-defined functions and overridable CORE operators (except `exec`, `system`, `print`, or any other built-in that cannot be expressed via prototypes) in this way.

If the symbol `:void` appears in the import list, then functions named later in that import list raise an exception only when these are called in void context–that is, when their return values are ignored. For example

```
use Fatal qw/:void open close/;

# properly checked, so no exception raised on error
if (not open(my $fh, '<', '/bogotic') {
    warn "Can't open /bogotic: $!";
}

# not checked, so error raises an exception
close FH;
```

The use of `:void` is discouraged, as it can result in exceptions not being thrown if you *accidentally* call a method without void context. Use *autodie* instead if you need to be able to disable autodying/Fatal behaviour for a small block of code.

DIAGNOSTICS

- Bad subroutine name for Fatal: %s

  You've called `Fatal` with an argument that doesn't look like a subroutine name, nor a switch that this version of Fatal understands.

- You've asked `Fatal` to try and replace a subroutine which does not exist, or has not yet been defined.

- You've asked `Fatal` to replace a subroutine, but it's not a Perl built-in, and `Fatal` couldn't find it as a regular subroutine. It either doesn't exist or has not yet been defined.

- Cannot make the non-overridable %s fatal

  You've tried to use `Fatal` on a Perl built-in that can't be overridden, such as `print` or `system`, which means that `Fatal` can't help you, although some other modules might. See the "SEE ALSO" section of this documentation.

- Internal error: %s

  You've found a bug in `Fatal`. Please report it using the `perlbug` command.

BUGS

`Fatal` clobbers the context in which a function is called and always makes it a scalar context, except when the `:void` tag is used. This problem does not exist in *autodie*.

"Used only once" warnings can be generated when `autodie` or `Fatal` is used with package filehandles (eg, `FILE`). It's strongly recommended you use scalar filehandles instead.

SEE ALSO

autodie for a nicer way to use lexical Fatal.

IPC::System::Simple for a similar idea for calls to `system()` and backticks.

5.2.43 Fcntl

Symbolic constants for `fcntl(2)`, `flock(2)`, `lseek(2)`, and file-mode bits - everything you need to call `sysopen`, `fcntl`, `flock`, `seek`, and to interpret the mode word returned by `stat`.

Import individual names, or a named group via one of the export tags: `:DEFAULT` (open and file-descriptor flags), `:flock` (advisory locks), `:seek` (whence positions), `:mode` (mode bits and `S_IS*` predicates), `:Fcompat` (BSD-style `flock` aliases).

Open flags (sysopen)

- `O_RDONLY`, `O_WRONLY`, `O_RDWR` - access mode.
- `O_CREAT` - create the file if it does not exist.
- `O_EXCL` - with `O_CREAT`, fail if the file already exists.
- `O_TRUNC` - truncate to zero length on open.
- `O_APPEND` - every write seeks to end of file first.
- `O_NONBLOCK` - open without blocking; I/O returns `EAGAIN` instead.
- `O_NOCTTY`, `O_NOFOLLOW`, `O_BINARY` - additional platform flags (`O_BINARY` is a no-op on Linux).

File-descriptor control (fcntl)

- `F_DUPFD` - duplicate a descriptor.
- `F_GETFD`, `F_SETFD` - read / set the close-on-exec flag `FD_CLOEXEC`.
- `F_GETFL`, `F_SETFL` - read / set the open-file status flags.

Lock types (flock)

- `LOCK_SH` - shared lock.
- `LOCK_EX` - exclusive lock.
- `LOCK_UN` - release lock.
- `LOCK_NB` - OR with the above to request a non-blocking attempt.

Seek whence

- SEEK_SET - from start of file.
- SEEK_CUR - from current position.
- SEEK_END - from end of file.

File mode bits (stat)

- Type mask and values: S_IFMT, S_IFREG, S_IFDIR, S_IFCHR, S_IFBLK, S_IFIFO, S_IFLNK, S_IFSOCK.
- Permission triplets: S_IRWXU, S_IRWXG, S_IRWXO and the per-bit S_IRUSR / S_IWUSR / S_IXUSR (and the GRP, OTH variants).
- Setuid / setgid / sticky bits: S_ISUID, S_ISGID, S_ISVTX.

Mode test helpers

Function-form predicates over a stat-mode value: S_ISREG, S_ISDIR, S_ISCHR, S_ISBLK, S_ISFIFO, S_ISLNK, S_ISSOCK, plus S_IFMT (extract file-type bits) and S_IMODE (extract permission bits).

Performance

Every constant in this module is resolved at compile time - using O_CREAT in an expression costs exactly what writing the integer literal would cost. No per-call lookup.

A constant this system does not have dies when called: a name Fcntl knows but the platform lacks (O_EXLOCK, S_IFWHT) with "Your vendor has not defined Fcntl macro O_EXLOCK, used at FILE line N", any other name with "FOO is not a valid Fcntl macro at FILE line N".

```
use Fcntl qw(:DEFAULT :flock :seek :mode);

sysopen(my $fh, $file, O_WRONLY | O_CREAT | O_EXCL, 0644) or die
 ↪"sysopen: $!";
flock($fh, LOCK_EX | LOCK_NB) or die "flock: $!";
syswrite $fh, "data\n";
sysseek $fh, 0, SEEK_SET;
my $mode = (stat $fh)[2];
printf "%s, permissions %04o\n", S_ISREG($mode) ? "regular file" :
 ↪"other", S_IMODE($mode);
# regular file, permissions 0644
```

This is a native implementation of Fcntl 1.20; its Fcntl.pm is used unchanged, and use Fcntl alone exports the :DEFAULT set.

Differences from upstream

None.

Functions

Mode test helpers

S_IMODE

Extract the permission bits from a stat-mode value.

S_IFMT

Extract the file-type bits from a stat-mode value.

S_ISREG

True if a stat-mode value names a file of the predicate's type: `S_ISREG` a regular file, `S_ISDIR` a directory, `S_ISLNK` a symbolic link, `S_ISSOCK` a socket, `S_ISBLK` a block device, `S_ISCHR` a character device, `S_ISFIFO` a named pipe.

Also available as `Fcntl::S_ISDIR`, `Fcntl::S_ISLNK`, `Fcntl::S_ISSOCK`, `Fcntl::S_ISBLK`, `Fcntl::S_ISCHR`, `Fcntl::S_ISFIFO`.

S_IMODE

Extract the permission bits from a stat-mode value.

Synopsis

```
my $perm = S_IMODE($mode);
```

Returns `$mode & 07777` - the nine permission bits plus the setuid, setgid, and sticky bits. Strips the file-type bits that `S_IFMT` would keep. With no argument, warns "Use of uninitialized value" and returns `0`.

Examples

```
use Fcntl qw(:mode);
my $mode = (stat $path)[2];
printf "perms = %04o\n", S_IMODE($mode);    # perms = 0644
```

S_IFMT

Extract the file-type bits from a stat-mode value.

Synopsis

```
my $type = S_IFMT($mode);
my $mask = S_IFMT();           # the mask constant itself
```

Called with an argument, returns `$mode & S_IFMT` - the bits that classify the file (regular, directory, symlink, ...). Called with no argument, returns the mask constant, which is how Perl code commonly compares against `S_IFREG`, `S_IFDIR`, and friends.

Examples

```
use Fcntl qw(:mode);
my $mode = (stat $path)[2];
print "is a directory\n" if S_IFMT($mode) == S_IFDIR;
```

S_ISREG

True if a stat-mode value names a file of the predicate's type: `S_ISREG` a regular file, `S_ISDIR` a directory, `S_ISLNK` a symbolic link, `S_ISSOCK` a socket, `S_ISBLK` a block device, `S_ISCHR` a character device, `S_ISFIFO` a named pipe.

Also available as `Fcntl::S_ISDIR`, `Fcntl::S_ISLNK`, `Fcntl::S_ISSOCK`, `Fcntl::S_ISBLK`, `Fcntl::S_ISCHR`, `Fcntl::S_ISFIFO`.

Synopsis

```
my $mode = (lstat $path)[2];
print "plain file\n" if S_ISREG($mode);
print "symlink\n"    if S_ISLNK($mode);
```

Returns true (1) when (`$mode & S_IFMT`) is the predicate's `S_IF*` value, false (`""`) otherwise. With no argument, warns "Use of uninitialized value" and returns false. Use `lstat` rather than `stat` for `S_ISLNK`: plain `stat` follows symlinks and reports the target's mode. `S_ISWHT` exists only where the system has whiteouts, which Linux does not.

5.2.44 File

Namespace containing the following modules:

- `File::Basename` - Parse file paths into directory, filename and suffix.
- `File::Compare` - Compare files or filehandles
- `File::Copy` - Copy files or filehandles
- `File::DosGlob` - A DOS-style `glob`, whose iterators live per call site.
- `File::Fetch` - A generic file fetching mechanism
- `File::Find` - Traverse a directory tree.
- `File::Glob` - POSIX pathname globbing - expand shell-style wildcard patterns into lists of filenames.

- `File::GlobMapper` - Extend File Glob to Allow Input and Output Files
- `File::Map` - Memory-mapped scalars: make a file look like an ordinary string.
- `File::Path` - Create or remove directory trees
- `File::ShareDir` - Locate per-dist and per-module shared files
- `File::Spec` - portably perform operations on file names
- `File::Temp` - return name and handle of a temporary file safely
- `File::Which` - Perl implementation of the which utility as an API
- `File::stat` - by-name interface to Perl's built-in stat() functions

File::Basename

Parse file paths into directory, filename and suffix.

SYNOPSIS

```
use File::Basename;

my ($name, $path, $suffix) = fileparse($fullname, @suffixlist);
my $name = fileparse($fullname, @suffixlist);

my $basename = basename($fullname, @suffixlist);
my $dirname  = dirname($fullname);
```

DESCRIPTION

These routines allow you to parse file paths into their directory, filename and suffix.

NOTE: `dirname()` and `basename()` emulate the behaviours, and quirks, of the shell and C functions of the same name. See each function's documentation for details. If your concern is just parsing paths it is safer to use *File::Spec*'s `splitpath()` and `splitdir()` methods.

It is guaranteed that

```
# Where $path_separator is / for Unix, \ for Windows, etc...
dirname($path) . $path_separator . basename($path);
```

is equivalent to the original path for all systems but VMS.

- `fileparse`

  ```
  my($filename, $dirs, $suffix) = fileparse($path);
  my($filename, $dirs, $suffix) = fileparse($path, @suffixes);
  my $filename                  = fileparse($path, @suffixes);
  ```

  The `fileparse()` routine divides a file path into its $dirs, $filename and (optionally) the filename $suffix.

$dirs contains everything up to and including the last directory separator in the $path including the volume (if applicable). The remainder of the $path is the $filename.

```
# On Unix returns ("baz", "/foo/bar/", "")
fileparse("/foo/bar/baz");

# On Windows returns ("baz", 'C:\foo\bar\', "")
fileparse('C:\foo\bar\baz');

# On Unix returns ("", "/foo/bar/baz/", "")
fileparse("/foo/bar/baz/");
```

If @suffixes are given each element is a pattern (either a string or a `qr//`) matched against the end of the $filename. The matching portion is removed and becomes the $suffix.

```
# On Unix returns ("baz", "/foo/bar/", ".txt")
fileparse("/foo/bar/baz.txt", qr/\.[^.]*/);
```

If type is non-Unix (see "fileparse_set_fstype") then the pattern matching for suffix removal is performed case-insensitively, since those systems are not case-sensitive when opening existing files.

You are guaranteed that `$dirs . $filename . $suffix` will denote the same location as the original $path.

- `basename`

```
my $filename = basename($path);
my $filename = basename($path, @suffixes);
```

This function is provided for compatibility with the Unix shell command `basename(1)`. It does **NOT** always return the file name portion of a path as you might expect. To be safe, if you want the file name portion of a path use `fileparse()`.

`basename()` returns the last level of a filepath even if the last level is clearly directory. In effect, it is acting like `pop()` for paths. This differs from `fileparse()`'s behaviour.

```
# Both return "bar"
basename("/foo/bar");
basename("/foo/bar/");
```

@suffixes work as in `fileparse()` except all regex metacharacters are quoted.

```
# These two function calls are equivalent.
my $filename = basename("/foo/bar/baz.txt",  ".txt");
my $filename = fileparse("/foo/bar/baz.txt", qr/\Q.txt\E/);
```

Also note that in order to be compatible with the shell command, `basename()` does not strip off a suffix if it is identical to the remaining characters in the filename.

- `dirname`

This function is provided for compatibility with the Unix shell command `dirname(1)` and has inherited some of its quirks. In spite of its name it does **NOT** always return the directory name as you might expect. To be safe, if you want the directory name of a path use `fileparse()`.

Only on VMS (where there is no ambiguity between the file and directory portions of a path) and AmigaOS (possibly due to an implementation quirk in this module) does `dirname()` work like `fileparse($path)`, returning just the $dirs.

```
# On VMS and AmigaOS
my $dirs = dirname($path);
```

When using Unix or MSDOS syntax this emulates the `dirname(1)` shell function which is subtly different from how `fileparse()` works. It returns all but the last level of a file path even if the last level is clearly a directory. In effect, it is not returning the directory portion but simply the path one level up acting like `chop()` for file paths.

Also unlike `fileparse()`, `dirname()` does not include a trailing slash on its returned path.

```
# returns /foo/bar.  fileparse() would return /foo/bar/
dirname("/foo/bar/baz");

# also returns /foo/bar despite the fact that baz is clearly a
# directory.  fileparse() would return /foo/bar/baz/
dirname("/foo/bar/baz/");

# returns '.'.  fileparse() would return 'foo/'
dirname("foo/");
```

Under VMS, if there is no directory information in the $path, then the current default device and directory is used.

- `fileparse_set_fstype`

```
my $type = fileparse_set_fstype();
my $previous_type = fileparse_set_fstype($type);
```

Normally File::Basename will assume a file path type native to your current operating system (ie. /foo/bar style on Unix, \foo\bar on Windows, etc...). With this function you can override that assumption.

Valid $types are “MacOS”, “VMS”, “AmigaOS”, “OS2”, “RISCOS”, “MSWin32”, “DOS” (also “MSDOS” for backwards bug compatibility), “Epoc” and “Unix” (all case-insensitive). If an unrecognized $type is given “Unix” will be assumed.

If you’ve selected VMS syntax, and the file specification you pass to one of these routines contains a “/”, they assume you are using Unix emulation and apply the Unix syntax rules instead, for that function call only.

File::Compare

Compare files or filehandles

SYNOPSIS

```
use File::Compare;

if (compare("file1", "file2") == 0) {
    print "They're equal\n";
}
```

DESCRIPTION

The `File::Compare::compare` function compares the contents of two sources, each of which can be a file or a file handle. It is exported from `File::Compare` by default.

`File::Compare::cmp` is a synonym for `File::Compare::compare`. It is exported from `File::Compare` only by request.

`File::Compare::compare_text` does a line by line comparison of the two files. It stops as soon as a difference is detected. `compare_text()` accepts an optional third argument: This must be a CODE reference to a line comparison function, which returns `0` when both lines are considered equal. For example:

```
compare_text($file1, $file2)
```

is basically equivalent to

```
compare_text($file1, $file2, sub {$_[0] ne $_[1]} )
```

RETURN

`File::Compare::compare` and its sibling functions return `0` if the files are equal, `1` if the files are unequal, or `-1` if an error was encountered.

AUTHOR

`File::Compare` was written by Nick Ing-Simmons. Its original documentation was written by Chip Salzenberg.

File::Copy

Copy files or filehandles

SYNOPSIS

```
use File::Copy;

copy("sourcefile", "destinationfile") or die "Copy failed: $!";
copy("Copy.pm", \*STDOUT);
move("/dev1/sourcefile", "/dev2/destinationfile");

use File::Copy "cp";

my $n = FileHandle->new("/a/file", "r");
cp($n, "x");
```

DESCRIPTION

The File::Copy module provides two basic functions, `copy` and `move`, which are useful for getting the contents of a file from one place to another.

- copy

  The `copy` function takes two parameters: a file to copy from and a file to copy to. Either argument may be a string, a FileHandle reference or a FileHandle glob. Obviously, if the first argument is a filehandle of some sort, it will be read from, and if it is a file *name* it will be opened for reading. Likewise, the second argument will be written to. If the second argument does not exist but the parent directory does exist, then it will be created. Trying to copy a file into a non-existent directory is an error. Trying to copy a file on top of itself is also an error. `copy` will not overwrite read-only files.

  If the destination (second argument) already exists and is a directory, and the source (first argument) is not a filehandle, then the source file will be copied into the directory specified by the destination, using the same base name as the source file. It's a failure to have a filehandle as the source when the destination is a directory.

  Note that passing in files as handles instead of names may lead to loss of information on some operating systems; it is recommended that you use file names whenever possible. Files are opened in binary mode where applicable. To get a consistent behaviour when copying from a filehandle to a file, use `binmode` on the filehandle.

  An optional third parameter can be used to specify the buffer size used for copying. This is the number of bytes from the first file, that will be held in memory at any given time, before being written to the second file. The default buffer size depends upon the file, but will generally be the whole file (up to 2MB), or 1k for filehandles that do not reference files (eg. sockets).

  You may use the syntax `use File::Copy "cp"` to get at the `cp` alias for this function. The syntax is *exactly* the same. The behavior is nearly the same as well: as of version 2.15, `cp` will preserve the source file's permission bits like the shell utility `cp(1)` would do with default options, while `copy` uses the default permissions for the target file (which may depend on the process' `umask`, file ownership, inherited ACLs, etc.). That is, if the destination file already exists, `cp` will leave its permissions unchanged; otherwise the permissions are taken from the source file and modified

by the `umask`. If an error occurs in setting permissions, `cp` will return 0, regardless of whether the file was successfully copied.

- move

  The `move` function also takes two parameters: the current name and the intended name of the file to be moved. If the destination already exists and is a directory, and the source is not a directory, then the source file will be renamed into the directory specified by the destination.

  If possible, move() will simply rename the file. Otherwise, it copies the file to the new location and deletes the original. If an error occurs during this copy-and-delete process, you may be left with a (possibly partial) copy of the file under the destination name.

  You may use the `mv` alias for this function in the same way that you may use the `cp` alias for `copy`.

- syscopy

  File::Copy also provides the `syscopy` routine, which copies the file specified in the first parameter to the file specified in the second parameter, preserving OS-specific attributes and file structure. For Unix systems, this is equivalent to the simple `copy` routine, which doesn't preserve OS-specific attributes. For VMS systems, this calls the `rmscopy` routine (see below). For Win32 systems, this calls `Win32::CopyFile`.

  Special behaviour if `syscopy` is defined (OS/2, VMS and Win32):

  If both arguments to `copy` are not file handles, then `copy` will perform a "system copy" of the input file to a new output file, in order to preserve file attributes, indexed file structure, *etc.* The buffer size parameter is ignored. If either argument to `copy` is a handle to an opened file, then data is copied using Perl operators, and no effort is made to preserve file attributes or record structure.

  The system copy routine may also be called directly under VMS and OS/2 as `File::Copy::syscopy` (or under VMS as `File::Copy::rmscopy`, which is the routine that does the actual work for syscopy).

- rmscopy($from,$to[,$date_flag])

  The first and second arguments may be strings, typeglobs, typeglob references, or objects inheriting from IO::Handle; they are used in all cases to obtain the *filespec* of the input and output files, respectively. The name and type of the input file are used as defaults for the output file, if necessary.

  A new version of the output file is always created, which inherits the structure and RMS attributes of the input file, except for owner and protections (and possibly timestamps; see below). All data from the input file is copied to the output file; if either of the first two parameters to `rmscopy` is a file handle, its position is unchanged. (Note that this means a file handle pointing to the output file will be associated with an old version of that file after `rmscopy` returns, not the newly created version.)

  The third parameter is an integer flag, which tells `rmscopy` how to handle timestamps. If it is < 0, none of the input file's timestamps are propagated to the output file. If it is > 0, then it is interpreted as a bitmask: if bit 0 (the LSB) is set, then timestamps other than the revision date are propagated; if bit 1 is set, the revision date is propagated. If the third parameter to `rmscopy` is 0, then it behaves much like

the DCL COPY command: if the name or type of the output file was explicitly specified, then no timestamps are propagated, but if they were taken implicitly from the input filespec, then all timestamps other than the revision date are propagated. If this parameter is not supplied, it defaults to 0.

`rmscopy` is VMS specific and cannot be exported; it must be referenced by its full name, e.g.:

```
File::Copy::rmscopy($from, $to) or die $!;
```

Like `copy`, `rmscopy` returns 1 on success. If an error occurs, it sets `$!`, deletes the output file, and returns 0.

RETURN

All functions return 1 on success, 0 on failure. `$!` will be set if an error was encountered.

NOTES

Before calling copy() or move() on a filehandle, the caller should close or flush() the file to avoid writes being lost. Note that this is the case even for move(), because it may actually copy the file, depending on the OS-specific implementation, and the underlying filesystem(s).

AUTHOR

File::Copy was written by Aaron Sherman *ajs@ajs.com* in 1995, and updated by Charles Bailey *bailey@newman.upenn.edu* in 1996.

File::DosGlob

A DOS-style `glob`, whose iterators live per call site.

```
use File::DosGlob 'glob';                 # overrides glob() in this␣
↪package

print join(" ", map { s{.*/}{}r } glob("$d/*.txt")), "\n";   # b.txt␣
↪a.txt
while (my $f = glob("$d/*.log")) { print "log: $f\n" }       # one␣
↪iterator per call site
```

It understands DOS-style paths as well as Unix ones - drive letters, `\` as a separator, spaces in names - and, unlike the built-in `glob`, returns names in directory order, unsorted. Importing `glob` replaces it in the importing package; `use File::DosGlob 'GLOBAL_glob'` replaces it everywhere.

This is a native implementation of the XS half of File::DosGlob 1.12: `File/DosGlob.pm` is used unchanged and does the globbing, keeping each call site's iterator in `%File::DosGlob::entries`, keyed by the op that called `glob`. The XS half supplies that key, `_callsite()`, and an op-free hook that deletes an op's entry when the op is freed, so a new op at the same address does not inherit it.

Differences from upstream

None.

File::Fetch

A generic file fetching mechanism

SYNOPSIS

```
use File::Fetch;

### build a File::Fetch object ###
my $ff = File::Fetch->new(uri => 'http://some.where.com/dir/a.txt');

### fetch the uri to cwd() ###
my $where = $ff->fetch() or die $ff->error;

### fetch the uri to /tmp ###
my $where = $ff->fetch( to => '/tmp' );

### parsed bits from the uri ###
$ff->uri;
$ff->scheme;
$ff->host;
$ff->path;
$ff->file;
```

DESCRIPTION

File::Fetch is a generic file fetching mechanism.

It allows you to fetch any file pointed to by a `ftp`, `http`, `file`, `git` or `rsync` uri by a number of different means.

See the `HOW IT WORKS` section further down for details.

ACCESSORS

A `File::Fetch` object has the following accessors

- $ff->uri

  The uri you passed to the constructor

- $ff->scheme

  The scheme from the uri (like 'file', 'http', etc)

- $ff->host

  The hostname in the uri. Will be empty if host was originally 'localhost' for a 'file://' url.

- $ff->vol

  On operating systems with the concept of a volume the second element of a file:// is considered to the be volume specification for the file. Thus on Win32 this routine returns the volume, on other operating systems this returns nothing.

  On Windows this value may be empty if the uri is to a network share, in which case the 'share' property will be defined. Additionally, volume specifications that use '|' as ':' will be converted on read to use ':'.

  On VMS, which has a volume concept, this field will be empty because VMS file specifications are converted to absolute UNIX format and the volume information is transparently included.

- $ff->share

  On systems with the concept of a network share (currently only Windows) returns the sharename from a file:/// url. On other operating systems returns empty.

- $ff->path

  The path from the uri, will be at least a single '/'.

- $ff->file

  The name of the remote file. For the local file name, the result of $ff->output_file will be used.

- $ff->file_default

  The name of the default local file, that $ff->output_file falls back to if it would otherwise return no filename. For example when fetching a URI like http://www.abc.net.au/ the contents retrieved may be from a remote file called 'index.html'. The default value of this attribute is literally 'file_default'.

- $ff->output_file

  The name of the output file. This is the same as $ff->file, but any query parameters are stripped off. For example:

  ```
  http://example.com/index.html?x=y
  ```

  would make the output file be `index.html` rather than `index.html?x=y`.

METHODS

$ff = File::Fetch->new(uri => 'http://some.where.com/dir/file.txt');

Parses the uri and creates a corresponding File::Fetch::Item object, that is ready to be `fetch`ed and returns it.

Returns false on failure.

$where = $ff->fetch([to => /my/output/dir/ | \$scalar])

Fetches the file you requested and returns the full path to the file.

By default it writes to `cwd()`, but you can override that by specifying the `to` argument:

```
### file fetch to /tmp, full path to the file in $where
$where = $ff->fetch( to => '/tmp' );

### file slurped into $scalar, full path to the file in $where
### file is downloaded to a temp directory and cleaned up at exit␣
 ↪time
$where = $ff->fetch( to => \$scalar );
```

Returns the full path to the downloaded file on success, and false on failure.

$ff->error([BOOL])

Returns the last encountered error as string. Pass it a true value to get the `Carp::longmess()` output instead.

HOW IT WORKS

File::Fetch is able to fetch a variety of uris, by using several external programs and modules.

Below is a mapping of what utilities will be used in what order for what schemes, if available:

```
file    => LWP, lftp, file
http    => LWP, HTTP::Tiny, wget, curl, lftp, fetch, HTTP::Lite,␣
 ↪lynx, iosock
ftp     => LWP, Net::FTP, wget, curl, lftp, fetch, ncftp, ftp
rsync   => rsync
git     => git
```

If you'd like to disable the use of one or more of these utilities and/or modules, see the `$BLACKLIST` variable further down.

If a utility or module isn't available, it will be marked in a cache (see the `$METHOD_FAIL` variable further down), so it will not be tried again. The `fetch` method will only fail when all options are exhausted, and it was not able to retrieve the file.

The `fetch` utility is available on FreeBSD. NetBSD and Dragonfly BSD may also have it from `pkgsrc`. We only check for `fetch` on those three platforms.

`iosock` is a very limited *IO::Socket::INET* based mechanism for retrieving `http` schemed urls. It doesn't follow redirects for instance.

`git` only supports `git://` style urls.

A special note about fetching files from an ftp uri:

By default, all ftp connections are done in passive mode. To change that, see the `$FTP_PASSIVE` variable further down.

Furthermore, ftp uris only support anonymous connections, so no named user/password pair can be passed along.

`/bin/ftp` is blacklisted by default; see the `$BLACKLIST` variable further down.

GLOBAL VARIABLES

The behaviour of File::Fetch can be altered by changing the following global variables:

$File::Fetch::FROM_EMAIL

This is the email address that will be sent as your anonymous ftp password.

Default is `File-Fetch@example.com`.

$File::Fetch::USER_AGENT

This is the useragent as `LWP` will report it.

Default is `File::Fetch/$VERSION`.

$File::Fetch::FTP_PASSIVE

This variable controls whether the environment variable `FTP_PASSIVE` and any passive switches to commandline tools will be set to true.

Default value is 1.

Note: When $FTP_PASSIVE is true, `ncftp` will not be used to fetch files, since passive mode can only be set interactively for this binary

$File::Fetch::TIMEOUT

When set, controls the network timeout (counted in seconds).

Default value is 0.

$File::Fetch::WARN

This variable controls whether errors encountered internally by `File::Fetch` should be `carp`'d or not.

Set to false to silence warnings. Inspect the output of the `error()` method manually to see what went wrong.

Defaults to `true`.

$File::Fetch::DEBUG

This enables debugging output when calling commandline utilities to fetch files. This also enables `Carp::longmess` errors, instead of the regular `carp` errors.

Good for tracking down why things don't work with your particular setup.

Default is 0.

$File::Fetch::BLACKLIST

This is an array ref holding blacklisted modules/utilities for fetching files with.

To disallow the use of, for example, `LWP` and `Net::FTP`, you could set $File::Fetch::BLACKLIST to:

```
$File::Fetch::BLACKLIST = [qw|lwp netftp|]
```

The default blacklist is [qw|ftp|], as `/bin/ftp` is rather unreliable.

See the note on `MAPPING` below.

$File::Fetch::METHOD_FAIL

This is a hashref registering what modules/utilities were known to fail for fetching files (mostly because they weren't installed).

You can reset this cache by assigning an empty hashref to it, or individually remove keys.

See the note on `MAPPING` below.

MAPPING

Here's a quick mapping for the utilities/modules, and their names for the $BLACKLIST, $METHOD_FAIL and other internal functions.

```
LWP          => lwp
HTTP::Lite   => httplite
HTTP::Tiny   => httptiny
Net::FTP     => netftp
wget         => wget
lynx         => lynx
ncftp        => ncftp
ftp          => ftp
curl         => curl
rsync        => rsync
lftp         => lftp
fetch        => fetch
IO::Socket   => iosock
```

FREQUENTLY ASKED QUESTIONS

So how do I use a proxy with File::Fetch?

`File::Fetch` currently only supports proxies with LWP::UserAgent. You will need to set your environment variables accordingly. For example, to use an ftp proxy:

```
$ENV{ftp_proxy} = 'foo.com';
```

Refer to the LWP::UserAgent manpage for more details.

I used 'lynx' to fetch a file, but its contents is all wrong!

`lynx` can only fetch remote files by dumping its contents to `STDOUT`, which we in turn capture. If that content is a 'custom' error file (like, say, a `404 handler`), you will get that contents instead.

Sadly, `lynx` doesn't support any options to return a different exit code on non-`200 OK` status, giving us no way to tell the difference between a 'successful' fetch and a custom error page.

Therefor, we recommend to only use `lynx` as a last resort. This is why it is at the back of our list of methods to try as well.

Files I'm trying to fetch have reserved characters or non-ASCII characters in them. What do I do?

`File::Fetch` is relatively smart about things. When trying to write a file to disk, it removes the `query parameters` (see the `output_file` method for details) from the file name before creating it. In most cases this suffices.

If you have any other characters you need to escape, please install the `URI::Escape` module from CPAN, and pre-encode your URI before passing it to `File::Fetch`. You can read about the details of URIs and URI encoding here:

https://datatracker.ietf.org/doc/html/rfc2396

TODO

- Implement $PREFER_BIN

  To indicate to rather use commandline tools than modules

File::Find

Traverse a directory tree.

SYNOPSIS

```
use File::Find;
find(\&wanted, @directories_to_search);
sub wanted { ... }

use File::Find;
finddepth(\&wanted, @directories_to_search);
sub wanted { ... }

use File::Find;
find({ wanted => \&process, follow => 1 }, '.');
```

DESCRIPTION

These are functions for searching through directory trees doing work on each file found similar to the Unix find(1) command. `File::Find` exports two functions, `find` and `finddepth`. They work similarly but have subtle differences.

- **find**

  ```
  find(\&wanted,  @directories);
  find(\%options, @directories);
  ```

  `find()` does a depth-first search over the given `@directories` in the order they are given. For each file or directory found, it calls the `&wanted` subroutine. (See below for details on how to use the `&wanted` function). Additionally, for each directory found, it will `chdir()` into that directory and continue the search, invoking the `&wanted` function on each file or subdirectory in the directory.

- **finddepth**

  ```
  finddepth(\&wanted,  @directories);
  finddepth(\%options, @directories);
  ```

  `finddepth()` works just like `find()` except that it invokes the `&wanted` function for a directory *after* invoking it for the directory's contents. It does a postorder traversal instead of a preorder traversal, working from the bottom of the directory tree up where `find()` works from the top of the tree down.

Despite the name of the `finddepth()` function, both `find()` and `finddepth()` perform a depth-first search of the directory hierarchy.

%options

The first argument to `find()` is either a code reference to your `&wanted` function, or a hash reference describing the operations to be performed for each file. The code reference is described in "The wanted function" below.

Here are the possible **keys** for the hash:

- `wanted`

The value should be a code reference. This code reference is described in "The wanted function" below. The &wanted subroutine is mandatory.

- bydepth

  Reports the name of a directory only AFTER all its entries have been reported. Entry point finddepth() is a shortcut for specifying { bydepth => 1 } in the first argument of find().

- preprocess

  The value should be a code reference. This code reference is used to preprocess the current directory. The name of the currently processed directory is in $File::Find::dir. Your preprocessing function is called after readdir(), but before the loop that calls the wanted() function. It is called with a list of strings (actually file/directory names) and is expected to return a list of strings. The code can be used to sort the file/directory names alphabetically, numerically, or to filter out directory entries based on their name alone. When follow or follow_fast are in effect, preprocess is a no-op.

- postprocess

  The value should be a code reference. It is invoked just before leaving the currently processed directory. It is called in void context with no arguments. The name of the current directory is in $File::Find::dir. This hook is handy for summarizing a directory, such as calculating its disk usage. When follow or follow_fast are in effect, postprocess is a no-op.

- follow

  Causes symbolic links to be followed. Since directory trees with symbolic links (followed) may contain files more than once and may even have cycles, a hash has to be built up with an entry for each file. This might be expensive both in space and time for a large directory tree. See "follow_fast" and "follow_skip" below. If either follow or follow_fast is in effect:

  – It is guaranteed that an lstat has been called before the user's wanted() function is called. This enables fast file checks involving _. Note that this guarantee no longer holds if follow or follow_fast are not set.

  – There is a variable $File::Find::fullname which holds the absolute pathname of the file with all symbolic links resolved. If the link is a dangling symbolic link, then fullname will be set to undef.

- follow_fast

  This is similar to follow except that it may report some files more than once. It does detect cycles, however. Since only symbolic links have to be hashed, this is much cheaper both in space and time. If processing a file more than once (by the user's wanted() function) is worse than just taking time, the option follow should be used.

- follow_skip

  follow_skip==1, which is the default, causes all files which are neither directories nor symbolic links to be ignored if they are about to be processed a second time. If a directory or a symbolic link are about to be processed a second time, File::Find dies.

`follow_skip==0` causes `File::Find` to die if any file is about to be processed a second time.

`follow_skip==2` causes `File::Find` to ignore any duplicate files and directories but to proceed normally otherwise.

- `dangling_symlinks`

  Specifies what to do with symbolic links whose target doesn't exist. If true and a code reference, will be called with the symbolic link name and the directory it lives in as arguments. Otherwise, if true and warnings are on, a warning of the form `"symbolic_link_name is a dangling symbolic link\n"` will be issued. If false, the dangling symbolic link will be silently ignored.

- `no_chdir`

  Does not `chdir()` to each directory as it recurses. The `wanted()` function will need to be aware of this, of course. In this case, `$_` will be the same as `$File::Find::name`.

- `untaint`

  If find is used in *taint-mode* (`-T` command line switch or `if EUID != UID` or `if EGID != GID`), then internally directory names have to be untainted before they can be `chdir`'d to. Therefore they are checked against a regular expression `untaint_pattern`. Note that all names passed to the user's `wanted()` function are still tainted. If this option is used while not in taint-mode, `untaint` is a no-op.

- `untaint_pattern`

  See above. This should be set using the `qr` quoting operator. The default is set to `qr|^([-+@\w./]+)$|`. Note that the parentheses are vital.

- `untaint_skip`

  If set, a directory which fails the `untaint_pattern` is skipped, including all its sub-directories. The default is to `die` in such a case.

The wanted function

The `wanted()` function does whatever verifications you want on each file and directory. Note that despite its name, the `wanted()` function is a generic callback function, and does **not** tell `File::Find` if a file is "wanted" or not. In fact, its return value is ignored.

The `wanted` function takes no arguments but rather does its work through a collection of variables.

- `$File::Find::dir` is the current directory name,
- `$_` is the current filename within that directory
- `$File::Find::name` is the complete pathname to the file.

The above variables have all been localized and may be changed without affecting data outside of the wanted function.

For example, when examining the file `/some/path/foo.ext` you will have:

```
$File::Find::dir  = /some/path/
$_                = foo.ext
$File::Find::name = /some/path/foo.ext
```

You are `chdir()`'d to `$File::Find::dir` when the function is called, unless `no_chdir` was specified. Note that when changing to directories is in effect, the root directory (`/`) is a somewhat special case inasmuch as the concatenation of `$File::Find::dir`, `'/'` and `$_` is not literally equal to `$File::Find::name`. The table below summarizes all variants:

```
             $File::Find::name  $File::Find::dir  $_
default      /                  /                 .
no_chdir=>0  /etc               /                 etc
             /etc/x             /etc              x

no_chdir=>1  /                  /                 /
             /etc               /                 /etc
             /etc/x             /etc              /etc/x
```

When `follow` or `follow_fast` are in effect, there is also a `$File::Find::fullname`. The function may set `$File::Find::prune` to prune the tree unless `bydepth` was specified. Unless `follow` or `follow_fast` is specified, for compatibility reasons (`find.pl`, find2perl) there are in addition the following globals available: `$File::Find::topdir`, `$File::Find::topdev`, `$File::Find::topino`, `$File::Find::topmode` and `$File::Find::topnlink`.

This library is useful for the `find2perl` tool (distributed with the App::find2perl CPAN module), which when fed:

```
find2perl / -name .nfs\* -mtime +7 \
  -exec rm -f {} \; -o -fstype nfs -prune
```

produces something like:

```
sub wanted {
   /^\.nfs.*\z/s &&
   (($dev, $ino, $mode, $nlink, $uid, $gid) = lstat($_)) &&
   int(-M _) > 7 &&
   unlink($_)
   ||
   ($nlink || (($dev, $ino, $mode, $nlink, $uid, $gid) = lstat($_))
↪&&
   $dev < 0 &&
   ($File::Find::prune = 1);
}
```

Notice the `_` in the above `int(-M _)`: the `_` is a magical filehandle that caches the information from the preceding `stat()`, `lstat()`, or filetest.

Here's another interesting wanted function. It will find all symbolic links that don't resolve:

```
sub wanted {
     -l && !-e && print "bogus link: $File::Find::name\n";
}
```

Note that you may mix directories and (non-directory) files in the list of directories to be searched by the `wanted()` function.

```
find(\&wanted, "./foo", "./bar", "./baz/epsilon");
```

In the example above, no file in `./baz/` other than `./baz/epsilon` will be evaluated by `wanted()`.

See also the script `pfind` on CPAN for a nice application of this module.

WARNINGS

If you run your program with the `-w` switch, or if you use the `warnings` pragma, File::Find will report warnings for several weird situations. You can disable these warnings by putting the statement

```
no warnings 'File::Find';
```

in the appropriate scope. See *warnings* for more info about lexical warnings.

BUGS AND CAVEATS

- `$dont_use_nlink`

  You can set the variable `$File::Find::dont_use_nlink` to `0` if you are sure the filesystem you are scanning reflects the number of subdirectories in the parent directory's `nlink` count.

  If you do set `$File::Find::dont_use_nlink` to 0, you may notice an improvement in speed at the risk of not recursing into subdirectories if a filesystem doesn't populate `nlink` as expected.

  `$File::Find::dont_use_nlink` now defaults to 1 on all platforms.

- Symlinks

  Be aware that the option to follow symbolic links can be dangerous. Depending on the structure of the directory tree (including symbolic links to directories) you might traverse a given (physical) directory more than once (only if `follow_fast` is in effect). Furthermore, deleting or changing files in a symbolically linked directory might cause very unpleasant surprises, since you delete or change files in an unknown directory.

HISTORY

`File::Find` used to produce incorrect results if called recursively. During the development of perl 5.8 this bug was fixed. The first fixed version of `File::Find` was 1.01.

File::Glob

POSIX pathname globbing - expand shell-style wildcard patterns into lists of filenames.

`File::Glob` is what backs Perl's built-in `glob` operator and its angle-bracket form `<*.pl>`. Give it a pattern with shell metacharacters (`*`, `?`, `[...]`, `{a,b,c}`, `~user`) and you get back the list of paths on disk that match. The same machinery is exposed directly as `bsd_glob` when you want explicit control over flags.

The mental model is simple: a pattern goes in, a list of real filenames comes out. Behaviour is tuned by a bitmask of `GLOB_*` flags - tilde expansion, brace expansion, case folding, sort order, and what happens when nothing matches are all flag-controlled. Every flag has a named constant (`GLOB_TILDE`, `GLOB_BRACE`, `GLOB_NOCASE`, `GLOB_NOMAGIC`, `GLOB_CSH`, etc.) and they OR together.

Three call styles, one engine: the built-in `glob`, the angle-bracket form `<*.pl>` and `bsd_glob` all run the same matcher, so they agree on flag handling, on sort order and on what `$File::Glob::DEFAULT_FLAGS` means. None of them forks a shell.

```
use File::Glob ':bsd_glob';
my @pl  = <*.pl>;                          # angle-bracket form
my @c   = bsd_glob('*.[ch]');              # function form,␣
 ↪default flags
my @hd  = bsd_glob('~gnat', GLOB_TILDE | GLOB_ERR);
```

The default flag set is `GLOB_CSH` - brace expansion, tilde expansion, backslash quoting, alphabetical sort, and the `GLOB_NOMAGIC` fallback that returns the literal pattern when it has no metacharacters and doesn't match. Two import tags nudge the default: `:nocase` turns `GLOB_NOCASE` on globally, `:case` turns it off.

This is a native implementation of the XS half of File::Glob 1.44, the BSD glob engine included; `File/Glob.pm` is used unchanged. `use File::Glob ':glob'` exports `bsd_glob`, `GLOB_ERROR` and the constants; `':bsd_glob'` exports the same and also replaces the caller's `glob` with one that takes its pattern whole instead of splitting it on whitespace; `':globally'` makes `csh_glob` the `glob` of every package.

Differences from upstream

None.

Functions

Globbing

bsd_glob_override

The `glob` that `use File::Glob ':bsd_glob'` installs in the calling package, replacing the built-in.

bsd_glob

Expand a shell-style pattern and return the list of matching paths.

csh_glob

Expand a pattern using the default flag set - the engine behind Perl's built-in `glob`.

GLOB_ERROR

Report the error status of the most recent `bsd_glob` call.

bsd_glob

Expand a shell-style pattern and return the list of matching paths.

Synopsis

```
my @list    = bsd_glob('*.[ch]');
my @homes   = bsd_glob('~gnat', GLOB_TILDE | GLOB_ERR);
my @latest  = bsd_glob('src/*.pl', GLOB_NOSORT);
```

What you get back

A list of filenames, possibly empty. In scalar context you get the count of matches. Filenames are returned as plain strings in the order determined by the flags (alphabetical under the default `GLOB_CSH`, unsorted under `GLOB_NOSORT`).

When the pattern matches nothing and neither `GLOB_NOCHECK` nor `GLOB_NOMAGIC` is in effect, the list is empty. With `GLOB_NOCHECK` the original pattern is returned as the sole element; with `GLOB_NOMAGIC` the pattern is returned only when it contains no metacharacters.

Examples

```
use File::Glob ':bsd_glob';
my @perl = bsd_glob('*.pl');          # ('a.pl', 'b.pl', ...)
```

```
# Brace expansion - default flags include GLOB_BRACE
my @src = bsd_glob('{lib,t}/*.pm');   # files under lib/ and t/
```

```
# Tilde expansion to another user's home
my ($home) = bsd_glob('~gnat', GLOB_TILDE);
```

```
# Case-insensitive match
my @readmes = bsd_glob('readme*', GLOB_NOCASE);
```

Edge cases

- No second argument: flags come from `$File::Glob::DEFAULT_FLAGS` (initialised to `GLOB_CSH`).
- `GLOB_APPEND`, `GLOB_DOOFFS`, `GLOB_ALTDIRFUNC` and `GLOB_MAGCHAR` are cleared from the caller's flags, as upstream clears them: they only make sense to a C caller.
- A pattern containing an embedded NUL byte returns the empty list, sets `$!` to ENOENT and warns "Invalid \0 character in pattern for bsd_glob" (a `syscalls` warning).
- Called with no pattern at all, croaks "Usage: File::Glob::bsd_glob(pattern_sv, ...)".
- Under taint mode (`-T`) every returned name is tainted, as with every other glob form: filenames come from outside the program.
- Brace alternatives are globbed one after the other, each sorted on its own: `bsd_glob('{b,a}.*')` lists the `b` names before the `a` names. A lone `{}` is kept as it is.
- In a set, `!` negates (`[!a]*`); `^` is an ordinary member.

See also

- `csh_glob` - the form Perl's built-in `glob` uses internally.
- `GLOB_ERROR` - non-zero after a traversal error.
- `GLOB_CSH` - the default flag bundle.
- `GLOB_NOCHECK` - return the pattern itself when nothing matches.

csh_glob

Expand a pattern using the default flag set - the engine behind Perl's built-in `glob`.

Synopsis

```
use File::Glob qw(csh_glob);
my @files = csh_glob('*.pl');
```

What you get back

A list of matching filenames. Flags always come from `$File::Glob::DEFAULT_FLAGS` (initially `GLOB_CSH`); `csh_glob` takes no flag argument. Sort order, brace expansion, tilde expansion, and the rest follow whatever `DEFAULT_FLAGS` currently holds.

You almost certainly want `bsd_glob` or the angle-bracket operator `<...>` instead. `csh_glob` exists because Perl's built-in `glob` dispatches through it; calling it directly is documented as "don't unless you know what you're doing."

Examples

```
use File::Glob qw(csh_glob);
my @matches = csh_glob('*.txt');        # uses DEFAULT_FLAGS
```

```
# Flip case sensitivity globally, then call
use File::Glob qw(csh_glob :nocase);
my @any = csh_glob('ReadMe*');          # matches README, readme,␣
↪ReadMe, ...
```

Edge cases

- Called with no argument: the pattern comes from `$_`, as it does for the built-in `glob`.
- The pattern is split on whitespace into several sub-patterns, so `csh_glob('*.c *.h')` globs both. Quote a token, or use `bsd_glob`, when the pattern itself contains a space.
- A pattern containing an embedded NUL byte warns and returns the empty list.

Differences from upstream

Fully compatible with upstream: patterns are tokenised on whitespace (honouring quotes and backslash escapes), and the per-op cache gives scalar context one name per call.

See also

- `bsd_glob` - the public, flag-accepting equivalent; prefer it.
- `GLOB_CSH` - the flag set `DEFAULT_FLAGS` is seeded with.
- `:nocase` / `:case` - import tags that toggle `GLOB_NOCASE` in `DEFAULT_FLAGS`.

GLOB_ERROR

Report the error status of the most recent `bsd_glob` call.

Synopsis

```
my @files = bsd_glob('~nobody', GLOB_TILDE | GLOB_ERR);
if (GLOB_ERROR) {
    warn "glob failed: $!";
}
```

What you get back

An integer. Zero means the last `bsd_glob` call completed without error. A non-zero value signals that an error interrupted traversal: `GLOB_NOSPACE` for allocation failure, `GLOB_ABEND` for a stopped traversal. When non-zero, `$!` carries the underlying errno.

Examples

```
use File::Glob ':bsd_glob';
my @out = bsd_glob('/root/*', GLOB_ERR);   # root-only dir
print "error\n" if GLOB_ERROR;              # usually prints under
 ↪non-root
```

Edge cases

- Reading `GLOB_ERROR` without a preceding glob returns `0`.
- It is `0` after a glob that completed, with or without matches.
- An unreadable directory stops a glob made with `GLOB_ERR` (`GLOB_ABEND`, -2); without `GLOB_ERR` one that cannot be read for want of permission, or that does not exist, is skipped.
- The built-in `glob` and `<*.c>` set it too.

See also

- `bsd_glob` - the call whose outcome this function reports.
- `GLOB_ERR` - the flag that makes `bsd_glob` stop (rather than skip) on unreadable directories.
- `GLOB_NOSPACE`, `GLOB_ABEND` - the two non-zero values it returns.

File::GlobMapper

Extend File Glob to Allow Input and Output Files

SYNOPSIS

```
use File::GlobMapper qw( globmap );

my $aref = globmap $input => $output
    or die $File::GlobMapper::Error ;

my $gm = File::GlobMapper->new( $input => $output )
    or die $File::GlobMapper::Error ;
```

DESCRIPTION

This module needs Perl5.005 or better.

This module takes the existing `File::Glob` module as a starting point and extends it to allow new filenames to be derived from the files matched by `File::Glob`.

This can be useful when carrying out batch operations on multiple files that have both an input filename and output filename and the output file can be derived from the input filename. Examples of operations where this can be useful include, file renaming, file copying and file compression.

Behind The Scenes

To help explain what `File::GlobMapper` does, consider what code you would write if you wanted to rename all files in the current directory that ended in `.tar.gz` to `.tgz`. So say these files are in the current directory

```
alpha.tar.gz
beta.tar.gz
gamma.tar.gz
```

and they need renamed to this

```
alpha.tgz
beta.tgz
gamma.tgz
```

Below is a possible implementation of a script to carry out the rename (error cases have been omitted)

```
foreach my $old ( glob "*.tar.gz" )
{
    my $new = $old;
    $new =~ s#(.*)\.tar\.gz$#$1.tgz# ;

    rename $old => $new
        or die "Cannot rename '$old' to '$new': $!\n;
}
```

Notice that a file glob pattern `*.tar.gz` was used to match the `.tar.gz` files, then a fairly similar regular expression was used in the substitute to allow the new filename to be created.

Given that the file glob is just a cut-down regular expression and that it has already done a lot of the hard work in pattern matching the filenames, wouldn't it be handy to be able to use the patterns in the fileglob to drive the new filename?

Well, that's *exactly* what `File::GlobMapper` does.

Here is same snippet of code rewritten using `globmap`

```
for my $pair (globmap '<*.tar.gz>' => '<#1.tgz>' )
{
```

(continues on next page)

(continued from previous page)

```
    my ($from, $to) = @$pair;
    rename $from => $to
        or die "Cannot rename '$old' to '$new': $!\n;
}
```

So how does it work?

Behind the scenes the `globmap` function does a combination of a file glob to match existing filenames followed by a substitute to create the new filenames.

Notice how both parameters to `globmap` are strings that are delimited by <>. This is done to make them look more like file globs - it is just syntactic sugar, but it can be handy when you want the strings to be visually distinctive. The enclosing <> are optional, so you don't have to use them - in fact the first thing globmap will do is remove these delimiters if they are present.

The first parameter to `globmap`, `*.tar.gz`, is an *Input File Glob*. Once the enclosing "< ... >" is removed, this is passed (more or less) unchanged to `File::Glob` to carry out a file match.

Next the fileglob `*.tar.gz` is transformed behind the scenes into a full Perl regular expression, with the additional step of wrapping each transformed wildcard metacharacter sequence in parenthesis.

In this case the input fileglob `*.tar.gz` will be transformed into this Perl regular expression

```
([^/]*)\.tar\.gz
```

Wrapping with parenthesis allows the wildcard parts of the Input File Glob to be referenced by the second parameter to `globmap`, `#1.tgz`, the *Output File Glob*. This parameter operates just like the replacement part of a substitute command. The difference is that the `#1` syntax is used to reference sub-patterns matched in the input fileglob, rather than the `$1` syntax that is used with perl regular expressions. In this case `#1` is used to refer to the text matched by the `*` in the Input File Glob. This makes it easier to use this module where the parameters to `globmap` are typed at the command line.

The final step involves passing each filename matched by the `*.tar.gz` file glob through the derived Perl regular expression in turn and expanding the output fileglob using it.

The end result of all this is a list of pairs of filenames. By default that is what is returned by `globmap`. In this example the data structure returned will look like this

```
( ['alpha.tar.gz' => 'alpha.tgz'],
  ['beta.tar.gz'  => 'beta.tgz' ],
  ['gamma.tar.gz' => 'gamma.tgz']
)
```

Each pair is an array reference with two elements - namely the *from* filename, that `File::Glob` has matched, and a *to* filename that is derived from the *from* filename.

Limitations

`File::GlobMapper` has been kept simple deliberately, so it isn't intended to solve all filename mapping operations. Under the hood `File::Glob` (or for older versions of Perl, `File::BSDGlob`) is used to match the files, so you will never have the flexibility of full Perl regular expression.

Input File Glob

The syntax for an Input FileGlob is identical to `File::Glob`, except for the following

1. No nested {}
2. Whitespace does not delimit fileglobs.
3. The use of parenthesis can be used to capture parts of the input filename.
4. If an Input glob matches the same file more than once, only the first will be used.

The syntax

- **~**
- **~user**
- **.**

  Matches a literal '.'. Equivalent to the Perl regular expression

  ```
  \.
  ```

- ***

  Matches zero or more characters, except '/'. Equivalent to the Perl regular expression

  ```
  [^/]*
  ```

- **?**

  Matches zero or one character, except '/'. Equivalent to the Perl regular expression

  ```
  [^/]?
  ```

- \

  Backslash is used, as usual, to escape the next character.

- **[]**

  Character class.

- **{,}**

  Alternation

- **()**

  Capturing parenthesis that work just like perl

Any other character it taken literally.

Output File Glob

The Output File Glob is a normal string, with 2 glob-like features.

The first is the '*' metacharacter. This will be replaced by the complete filename matched by the input file glob. So

```
*.c *.Z
```

The second is

Output FileGlobs take the

- "*"

  The "*" character will be replaced with the complete input filename.

- #1

  Patterns of the form /#\d/ will be replaced with the

Returned Data

EXAMPLES

A Rename script

Below is a simple "rename" script that uses `globmap` to determine the source and destination filenames.

```
use File::GlobMapper qw(globmap) ;
use File::Copy;

die "rename: Usage rename 'from' 'to'\n"
    unless @ARGV == 2 ;

my $fromGlob = shift @ARGV;
my $toGlob   = shift @ARGV;

my $pairs = globmap($fromGlob, $toGlob)
    or die $File::GlobMapper::Error;

for my $pair (@$pairs)
{
    my ($from, $to) = @$pair;
    move $from => $to ;
}
```

Here is an example that renames all c files to cpp.

```
$ rename '*.c' '#1.cpp'
```

A few example globmaps

Below are a few examples of globmaps

To copy all your .c file to a backup directory

```
'</my/home/*.c>'    '</my/backup/#1.c>'
```

If you want to compress all

```
'</my/home/*.[ch]>'    '<*.gz>'
```

To uncompress

```
'</my/home/*.[ch].gz>'    '</my/home/#1.#2>'
```

File::Map

Memory-mapped scalars: make a file look like an ordinary string.

`File::Map` attaches a file - or a fresh anonymous region of memory - to a Perl scalar. Reads and writes to the scalar go straight to the kernel's mapping: the file appears in your variable as a string, and changes propagate back without you ever calling `read` or `write`. A multi-gigabyte file costs almost nothing to open this way, because pages are faulted in lazily as you touch them.

Once a scalar is mapped it behaves like a regular string for the operations that matter: `substr`, regex match and substitution, `index`, `length`, and slicing. Direct assignment (`$map = "..."`) is caught and fixed up so you never corrupt the mapping, though `substr` is the recommended way to write. The mapping is released automatically when the scalar goes out of scope; `unmap` is available for explicit control.

Synopsis

```
use File::Map qw(map_file map_anonymous unmap);

map_file my $map, 'data.bin', '+<';   # read/write
$map =~ s/foo/bar/g;                  # edits go to disk
```

(continues on next page)

(continued from previous page)

```
substr $map, 0, 4, "HEAD";            # in-place write

map_anonymous my $buf, 4096, 'shared'; # scratch region
unmap $map;                             # optional
```

Choosing a mapping function

- `map_file` - give a filename and a mode, get a mapped scalar. The common case.
- `map_handle` - same idea, but you already have an open filehandle.
- `map_anonymous` - no file; a scratch region shared with forked children or private to the process.
- `sys_map` - low-level wrapper around raw `mmap(2)` flags for when the convenience functions don't fit.

Managing a live mapping

- `sync` - flush pending writes back to disk.
- `advise` - hint the kernel about access patterns (`"sequential"`, `"random"`, `"willneed"`, and so on).
- `protect` - change read/write protection at runtime.
- `remap` - resize an existing mapping (Linux only).
- `unmap` - drop the mapping explicitly.
- `pin` / `unpin` - keep the mapping in physical memory.

This is a native implementation of the XS half of `File::Map` 0.71; its `File/Map.pm` is used unchanged. Nothing is exported by default. Name the functions, or take them by tag: `:map` (`map_handle`, `map_file`, `map_anonymous`, `sys_map`, `unmap`), `:extra` (`remap`, `sync`, `pin`, `unpin`, `advise`, `protect`), `:lock` (`lock_map`), `:constants` (`PROT_*`, `MAP_*`), or `:all`.

Differences from upstream

None. It is `File::Map` as a perl without threads builds it, so the thread functions `wait_until`, `notify` and `broadcast` are absent and `lock_map` locks nothing.

Functions

Mapping

`map_file`

Open a file by name and attach it to a scalar as a memory map.

map_handle

Attach an already-open filehandle to a scalar as a memory map.

map_anonymous

Allocate a fresh memory region backed by no file and attach it to a scalar.

sys_map

Low-level mapping with raw `mmap(2)` protection and flag constants.

remap

Resize an existing mapping in place.

Unmapping

unmap

Release a mapping explicitly before the scalar goes out of scope.

Synchronisation

sync

Flush pending writes from a mapped scalar back to disk.

Locking

pin

`pin $map`: lock the mapping in physical memory, so it is never paged out (`mlock(2)`). The system limits how much a process may pin (`ulimit -l`); beyond it `pin` dies with the error.

unpin

`unpin $map`: undo `pin`; the mapping may be paged out again.

lock_map

`lock_map $map`: take the mapping's lock until the end of the enclosing scope - the lock that serialises threads using the same mapping. Perl here has no threads, so it only checks that `$map` is a mapped scalar; the thread-only condition functions `wait_until`, `notify` and `broadcast` do not exist, as in any unthreaded perl.

Advice

advise

Tell the kernel how the mapped region will be accessed.

protect

Change the read/write/execute protection of a mapped region.

map_file

Open a file by name and attach it to a scalar as a memory map.

Synopsis

```
map_file my $map, $filename;           # read-only
map_file my $map, $filename, '+<';     # read/write
map_file my $map, $filename, '<', $offset, $length;
```

Arguments

- `$lvalue` - scalar to receive the mapping. Any previous value is discarded. The variable must not already be mapped.
- `$filename` - path to the file. The file is opened with a `:raw` layer added automatically, so encoding and newline translation never interfere with the mapping.
- `$mode` - defaults to `'<'`. Accepted values are `'<'`, `'+<'`, `'>'`, and `'+>'`, with the same meaning as open.
- `$offset` - byte position at which the mapping starts. Defaults to `0`.
- `$length` - length of the mapping in bytes. Defaults to `-s($filename) - $offset`, i.e. the rest of the file.

Examples

Read an entire file into a scalar without loading it eagerly:

```
map_file my $text, 'big.log';
print "lines: ", scalar(() = $text =~ /\n/g), "\n";
```

Patch bytes inside a binary file:

```
map_file my $map, 'image.bin', '+<';
substr $map, 0, 4, "MZ\0\0";
```

Map a window into a large file:

```
map_file my $chunk, 'archive.tar', '<', 1024 * 1024, 4096;
```

Edge cases

- Opening a zero-length file succeeds but produces a mapping that cannot be written to; writes are silently truncated to the empty string.
- `$offset` does not need to be page-aligned; the module adjusts internally.
- A filehandle with a non-binary PerlIO layer is rejected.
- Going out of scope unmaps the variable; an explicit `unmap` is rarely needed.

Differences from upstream

Fully compatible with upstream `File::Map` 0.71.

See also

- `map_handle` - same operation starting from an open filehandle.
- `map_anonymous` - allocate a scratch region with no backing file.
- `sys_map` - drop down to raw `mmap(2)` flags.
- `unmap` - release a mapping explicitly before scope exit.
- `sync` - flush writes to disk without waiting for scope exit.

map_handle

Attach an already-open filehandle to a scalar as a memory map.

Synopsis

```
open my $fh, '<:raw', $filename;
map_handle my $map, $fh;
map_handle my $map, $fh, '+<', $offset, $length;
```

Arguments

- `$lvalue` - scalar to receive the mapping.
- `$filehandle` - a real filehandle. Scalar-string handles and tied handles are rejected.
- `$mode` - defaults to `'<'`. Same accepted values as `map_file`.
- `$offset`, `$length` - same meaning and defaults as `map_file`.

Examples

Map the tail of a log file:

```
open my $fh, '<:raw', '/var/log/syslog' or die $!;
my $size = -s $fh;
map_handle my $tail, $fh, '<', $size - 4096, 4096;
```

Edge cases

- The filehandle must be binary. Encoding layers like `:utf8` or `:crlf` cause `map_handle` to reject the handle.
- The handle must refer to a regular file, block device, or character device. Pipes and sockets cannot be mapped.
- The handle stays valid after the call; closing it does not invalidate the mapping.

Differences from upstream

Fully compatible with upstream `File::Map` 0.71.

See also

- `map_file` - take a filename instead of a filehandle.
- `sys_map` - pass raw `mmap(2)` flags directly.
- `unmap` - release the mapping before scope exit.

map_anonymous

Allocate a fresh memory region backed by no file and attach it to a scalar.

Synopsis

```
map_anonymous my $buf, 4096;                # shared (default)
map_anonymous my $buf, 4096, 'shared';      # visible to forked
↪children
map_anonymous my $buf, 1 << 20, 'private'; # process-local
```

Arguments

- `$lvalue` - scalar to receive the mapping.
- `$length` - size of the region in bytes. Must be greater than zero.
- `$type` - `'shared'` or `'private'`. A shared region is inherited by child processes created with `fork`; a private region is not. Defaults to `'shared'`.

Examples

Share a buffer with a forked child:

```
map_anonymous my $counter, 16, 'shared';
substr $counter, 0, 16, pack('Q', 0) . pack('Q', 0);
if (fork() == 0) {
    substr $counter, 0, 8, pack('Q', 42);
    exit;
}
```

Allocate a private scratch region:

```
map_anonymous my $scratch, 1_000_000, 'private';
substr $scratch, 0, 5, "hello";
```

Edge cases

- Zero-length anonymous maps are rejected.
- Any `$type` other than `'shared'` or `'private'` raises an exception.

Differences from upstream

Fully compatible with upstream `File::Map` 0.71.

See also

- `map_file` - map a file instead of raw memory.
- `sys_map` - take raw `mmap(2)` flags.
- `remap` - grow or shrink a private anonymous mapping on Linux.

sys_map

Low-level mapping with raw `mmap(2)` protection and flag constants.

Synopsis

```
use File::Map qw(sys_map :constants);

sys_map my $map, $length, PROT_READ | PROT_WRITE,
        MAP_SHARED, $fh, 0;

sys_map my $buf, 4096, PROT_READ | PROT_WRITE,
        MAP_PRIVATE | MAP_ANONYMOUS;
```

Arguments

- `$lvalue` - scalar to receive the mapping.
- `$length` - size in bytes.
- `$protection` - bitwise-or of `PROT_NONE`, `PROT_READ`, `PROT_WRITE`, `PROT_EXEC`.
- `$flags` - bitwise-or of `MAP_SHARED`, `MAP_PRIVATE`, `MAP_ANONYMOUS`, `MAP_ANON`, `MAP_FILE`.
- `$filehandle` - omitted or `undef` when `MAP_ANONYMOUS` is set.
- `$offset` - byte offset into the file. Defaults to `0`.

When to reach for it

Use `sys_map` only when `map_file`, `map_handle`, or `map_anonymous` cannot express what you need - for example, to request `PROT_EXEC` on an executable page, or to combine flags that the convenience functions do not expose. If the `mmap(2)` man page does not feel familiar, `map_file` or `map_anonymous` is almost certainly the better choice.

Differences from upstream

Fully compatible with upstream `File::Map` 0.71.

See also

- `map_file`, `map_handle`, `map_anonymous` - the high-level alternatives.
- `protect` - change protection after the mapping exists.

sync

Flush pending writes from a mapped scalar back to disk.

Synopsis

```
sync $map;          # synchronous - wait for the kernel to finish
sync $map, 0;       # asynchronous - queue the flush and return
```

Arguments

- `$lvalue` - a currently mapped scalar.
- `$synchronous` - defaults to true. When true, `sync` does not return until the kernel reports the data on stable storage. When false, the flush is only queued.

The mapping is always flushed automatically when the scalar goes out of scope, so explicit calls to `sync` are only needed when you want other processes, or a crash-safe on-disk snapshot, to see the changes before then.

Edge cases

- Calling `sync` on an unmapped scalar raises an exception.
- Calling `sync` on an empty mapping is a no-op.

Differences from upstream

Fully compatible with upstream `File::Map` 0.71.

See also

- `unmap` - release the mapping (also triggers a flush).
- `advise` - influence the kernel's write-back strategy.

remap

Resize an existing mapping in place.

Synopsis

```
remap $map, $new_size;
```

Arguments

- `$lvalue` - a currently mapped scalar.
- `$new_size` - new length in bytes. Must be greater than zero.

When it applies

`remap` is Linux-specific. It wraps `mremap(2)` with `MREMAP_MAYMOVE`, so the scalar may end up pointing to a different virtual address after the call.

- For a file-backed mapping, the underlying file must be large enough to cover `$new_size`, or accessing the extra pages will produce a bus fault.
- Anonymous shared mappings cannot be remapped.

Use with caution on production data.

Differences from upstream

Fully compatible with upstream `File::Map` 0.71.

See also

- `map_file` - pick the right size up front if you can.
- `unmap` - drop the mapping entirely instead of resizing.

unmap

Release a mapping explicitly before the scalar goes out of scope.

Synopsis

```
unmap $map;
```

When to call it

Most programs never need to. A mapped scalar is unmapped automatically when it is freed - at scope exit for `my` variables, at the end of the program for globals - and the kernel flushes any pending writes as part of that. Call `unmap` explicitly when you want to release the memory (and close the mapping of the file) before the natural lifetime of the scalar ends.

After `unmap`, the scalar becomes an ordinary empty string and can be reused for any purpose, including being mapped again.

Edge cases

- Calling `unmap` on a scalar that is not mapped raises an exception.

Differences from upstream

Fully compatible with upstream `File::Map` 0.71.

See also

- `sync` - flush writes without releasing the mapping.

advise

Tell the kernel how the mapped region will be accessed.

Synopsis

```
advise $map, 'sequential';
advise $map, 'willneed';
```

Arguments

- `$lvalue` - a currently mapped scalar.
- `$advice` - a string naming an access pattern.

The portable values are:

- `'normal'` - no particular pattern (the default).
- `'random'` - access order is unpredictable.
- `'sequential'` - read start to end once.
- `'willneed'` - prefault pages that will be needed soon.
- `'dontneed'` - release pages that will not be needed soon.

On Linux additional values are accepted: `'remove'`, `'dontfork'`, `'dofork'`, `'mergeable'`, `'unmergeable'`, `'free'`. Unknown values are silently ignored.

Examples

Hint that a large log file will be scanned top to bottom:

```
map_file my $log, 'huge.log';
advise $log, 'sequential';
while ($log =~ /^(ERROR:.*)/mg) { ... }
```

Edge cases

- Advising an unmapped scalar raises an exception.
- Advising an empty mapping is a no-op.
- `advise` is a hint to the kernel; it may do nothing on some systems.

Differences from upstream

Fully compatible with upstream `File::Map` 0.71.

See also

- `protect` - change read/write permissions rather than access hints.
- `sync` - control flush timing explicitly.

protect

Change the read/write/execute protection of a mapped region.

Synopsis

```
protect $map, '<';              # read-only
protect $map, '+<';             # read/write
protect $map, PROT_READ;        # constants also work
```

Arguments

- `$lvalue` - a currently mapped scalar.
- `$mode` - either a string in the same format as open (`'<'`, `'+<'`, `'>'`, `'+>'`), or a bitmask built from the `PROT_*` constants.

If the new protection includes write permission the scalar becomes writable; otherwise it is marked read-only and direct assignment raises an exception.

Examples

Load a file read/write, patch it, then lock it down:

```
map_file my $map, 'data.bin', '+<';
substr $map, 0, 4, "HEAD";
sync $map;
protect $map, '<';             # prevent further writes
```

Edge cases

- Protecting an unmapped scalar raises an exception.
- Protecting an empty mapping updates the scalar's read-only flag but performs no kernel call.

Differences from upstream

Fully compatible with upstream `File::Map` 0.71.

See also

- `sys_map` - set protection when creating the mapping.
- `advise` - hint access patterns rather than enforce permissions.

File::Path

Create or remove directory trees

VERSION

2.18 - released November 4 2020.

SYNOPSIS

```
use File::Path qw(make_path remove_tree);

@created = make_path('foo/bar/baz', '/zug/zwang');
@created = make_path('foo/bar/baz', '/zug/zwang', {
    verbose => 1,
    mode => 0711,
});
make_path('foo/bar/baz', '/zug/zwang', {
    chmod => 0777,
});

$removed_count = remove_tree('foo/bar/baz', '/zug/zwang', {
    verbose => 1,
    error  => \my $err_list,
    safe => 1,
});
```

(continues on next page)

(continued from previous page)

```
# legacy (interface promoted before v2.00)
@created = mkpath('/foo/bar/baz');
@created = mkpath('/foo/bar/baz', 1, 0711);
@created = mkpath(['/foo/bar/baz', 'blurfl/quux'], 1, 0711);
$removed_count = rmtree('foo/bar/baz', 1, 1);
$removed_count = rmtree(['foo/bar/baz', 'blurfl/quux'], 1, 1);

# legacy (interface promoted before v2.06)
@created = mkpath('foo/bar/baz', '/zug/zwang', { verbose => 1, mode␣
↪=> 0711 });
$removed_count = rmtree('foo/bar/baz', '/zug/zwang', { verbose => 1,␣
↪mode => 0711 });
```

DESCRIPTION

This module provides a convenient way to create directories of arbitrary depth and to delete an entire directory subtree from the filesystem.

The following functions are provided:

- make_path($dir1, $dir2, ...)
- make_path($dir1, $dir2, ..., \%opts)

  The `make_path` function creates the given directories if they don't exist before, much like the Unix command `mkdir -p`.

  The function accepts a list of directories to be created. Its behaviour may be tuned by an optional hashref appearing as the last parameter on the call.

  The function returns the list of directories actually created during the call; in scalar context the number of directories created.

  The following keys are recognised in the option hash:

  – mode => $num

    The numeric permissions mode to apply to each created directory (defaults to `0777`), to be modified by the current `umask`. If the directory already exists (and thus does not need to be created), the permissions will not be modified.

    `mask` is recognised as an alias for this parameter.

  – chmod => $num

    Takes a numeric mode to apply to each created directory (not modified by the current `umask`). If the directory already exists (and thus does not need to be created), the permissions will not be modified.

  – verbose => $bool

    If present, will cause `make_path` to print the name of each directory as it is created. By default nothing is printed.

  – error => \$err

If present, it should be a reference to a scalar. This scalar will be made to reference an array, which will be used to store any errors that are encountered. See the "ERROR HANDLING" section for more information.

If this parameter is not used, certain error conditions may raise a fatal error that will cause the program to halt, unless trapped in an `eval` block.

- owner => $owner
- user => $owner
- uid => $owner

If present, will cause any created directory to be owned by `$owner`. If the value is numeric, it will be interpreted as a uid; otherwise a username is assumed. An error will be issued if the username cannot be mapped to a uid, the uid does not exist or the process lacks the privileges to change ownership.

Ownership of directories that already exist will not be changed.

`user` and `uid` are aliases of `owner`.

- group => $group

If present, will cause any created directory to be owned by the group `$group`. If the value is numeric, it will be interpreted as a gid; otherwise a group name is assumed. An error will be issued if the group name cannot be mapped to a gid, the gid does not exist or the process lacks the privileges to change group ownership.

Group ownership of directories that already exist will not be changed.

```
make_path '/var/tmp/webcache', {owner=>'nobody', group=>
↪'nogroup'};
```

- mkpath($dir)
- mkpath($dir, $verbose, $mode)
- mkpath([$dir1, $dir2,...], $verbose, $mode)
- mkpath($dir1, $dir2,..., \%opt)

The `mkpath()` function provide the legacy interface of `make_path()` with a different interpretation of the arguments passed. The behaviour and return value of the function is otherwise identical to `make_path()`.

- remove_tree($dir1, $dir2, ...)
- remove_tree($dir1, $dir2, ..., \%opts)

The `remove_tree` function deletes the given directories and any files and subdirectories they might contain, much like the Unix command `rm -rf` or the Windows commands `rmdir /s` and `rd /s`.

The function accepts a list of directories to be removed. (In point of fact, it will also accept filesystem entries which are not directories, such as regular files and symlinks. But, as its name suggests, its intent is to remove trees rather than individual files.)

`remove_tree()`'s behaviour may be tuned by an optional hashref appearing as the last parameter on the call. If an empty string is passed to `remove_tree`, an error will occur.

NOTE: For security reasons, we strongly advise use of the hashref-as-final-argument syntax – specifically, with a setting of the `safe` element to a true value.

```
remove_tree( $dir1, $dir2, ....,
    {
        safe => 1,
        ...          # other key-value pairs
    },
);
```

The function returns the number of files successfully deleted.

The following keys are recognised in the option hash:

– verbose => $bool

  If present, will cause `remove_tree` to print the name of each file as it is unlinked. By default nothing is printed.

– safe => $bool

  When set to a true value, will cause `remove_tree` to skip the files for which the process lacks the required privileges needed to delete files, such as delete privileges on VMS. In other words, the code will make no attempt to alter file permissions. Thus, if the process is interrupted, no filesystem object will be left in a more permissive mode.

– keep_root => $bool

  When set to a true value, will cause all files and subdirectories to be removed, except the initially specified directories. This comes in handy when cleaning out an application's scratch directory.

  ```
  remove_tree( '/tmp', {keep_root => 1} );
  ```

– result => \$res

  If present, it should be a reference to a scalar. This scalar will be made to reference an array, which will be used to store all files and directories unlinked during the call. If nothing is unlinked, the array will be empty.

  ```
  remove_tree( '/tmp', {result => \my $list} );
  print "unlinked $_\n" for @$list;
  ```

  This is a useful alternative to the `verbose` key.

– error => \$err

  If present, it should be a reference to a scalar. This scalar will be made to reference an array, which will be used to store any errors that are encountered. See the "ERROR HANDLING" section for more information.

Removing things is a much more dangerous proposition than creating things. As such, there are certain conditions that `remove_tree` may encounter that are so dangerous that the only sane action left is to kill the program.

Use `error` to trap all that is reasonable (problems with permissions and the like), and let it die if things get out of hand. This is the safest course of action.

- rmtree($dir)
- rmtree($dir, $verbose, $safe)
- rmtree([$dir1, $dir2,...], $verbose, $safe)
- rmtree($dir1, $dir2,..., \%opt)

The `rmtree()` function provide the legacy interface of `remove_tree()` with a different interpretation of the arguments passed. The behaviour and return value of the function is otherwise identical to `remove_tree()`.

NOTE: For security reasons, we strongly advise use of the hashref-as-final-argument syntax, specifically with a setting of the `safe` element to a true value.

```
rmtree( $dir1, $dir2, ....,
    {
        safe => 1,
        ...          # other key-value pairs
    },
);
```

ERROR HANDLING

- **NOTE:**

  The following error handling mechanism is consistent throughout all code paths EXCEPT in cases where the ROOT node is nonexistent. In version 2.11 the maintainers attempted to rectify this inconsistency but too many downstream modules encountered problems. In such case, if you require root node evaluation or error checking prior to calling `make_path` or `remove_tree`, you should take additional precautions.

If `make_path` or `remove_tree` encounters an error, a diagnostic message will be printed to `STDERR` via `carp` (for non-fatal errors) or via `croak` (for fatal errors).

If this behaviour is not desirable, the `error` attribute may be used to hold a reference to a variable, which will be used to store the diagnostics. The variable is made a reference to an array of hash references. Each hash contain a single key/value pair where the key is the name of the file, and the value is the error message (including the contents of `$!` when appropriate). If a general error is encountered the diagnostic key will be empty.

An example usage looks like:

```
remove_tree( 'foo/bar', 'bar/rat', {error => \my $err} );
if ($err && @$err) {
    for my $diag (@$err) {
        my ($file, $message) = %$diag;
```

(continues on next page)

(continued from previous page)

```
        if ($file eq '') {
            print "general error: $message\n";
        }
        else {
            print "problem unlinking $file: $message\n";
        }
    }
}
else {
    print "No error encountered\n";
}
```

Note that if no errors are encountered, `$err` will reference an empty array. This means that `$err` will always end up TRUE; so you need to test `@$err` to determine if errors occurred.

NOTES

`File::Path` blindly exports `mkpath` and `rmtree` into the current namespace. These days, this is considered bad style, but to change it now would break too much code. Nonetheless, you are invited to specify what it is you are expecting to use:

```
use File::Path 'rmtree';
```

The routines `make_path` and `remove_tree` are **not** exported by default. You must specify which ones you want to use.

```
use File::Path 'remove_tree';
```

Note that a side-effect of the above is that `mkpath` and `rmtree` are no longer exported at all. This is due to the way the `Exporter` module works. If you are migrating a codebase to use the new interface, you will have to list everything explicitly. But that's just good practice anyway.

```
use File::Path qw(remove_tree rmtree);
```

API CHANGES

The API was changed in the 2.0 branch. For a time, `mkpath` and `rmtree` tried, unsuccessfully, to deal with the two different calling mechanisms. This approach was considered a failure.

The new semantics are now only available with `make_path` and `remove_tree`. The old semantics are only available through `mkpath` and `rmtree`. Users are strongly encouraged to upgrade to at least 2.08 in order to avoid surprises.

SECURITY CONSIDERATIONS

There were race conditions in the 1.x implementations of File::Path's `rmtree` function (although sometimes patched depending on the OS distribution or platform). The 2.0 version contains code to avoid the problem mentioned in CVE-2002-0435.

See the following pages for more information:

```
http://bugs.debian.org/cgi-bin/bugreport.cgi?bug=286905
http://www.nntp.perl.org/group/perl.perl5.porters/2005/01/msg97623.
↪html
http://www.debian.org/security/2005/dsa-696
```

Additionally, unless the `safe` parameter is set (or the third parameter in the traditional interface is TRUE), should a `remove_tree` be interrupted, files that were originally in read-only mode may now have their permissions set to a read-write (or "delete OK") mode.

The following CVE reports were previously filed against File-Path and are believed to have been addressed:

- http://cve.circl.lu/cve/CVE-2004-0452
- http://cve.circl.lu/cve/CVE-2005-0448

In February 2017 the cPanel Security Team reported an additional vulnerability in File-Path. The `chmod()` logic to make directories traversable can be abused to set the mode on an attacker-chosen file to an attacker-chosen value. This is due to the time-of-check-to-time-of-use (TOCTTOU) race condition (https://en.wikipedia.org/wiki/Time_of_check_to_time_of_use) between the `stat()` that decides the inode is a directory and the `chmod()` that tries to make it user-rwx. CPAN versions 2.13 and later incorporate a patch provided by John Lightsey to address this problem. This vulnerability has been reported as CVE-2017-6512.

DIAGNOSTICS

FATAL errors will cause the program to halt (`croak`), since the problem is so severe that it would be dangerous to continue. (This can always be trapped with `eval`, but it's not a good idea. Under the circumstances, dying is the best thing to do).

SEVERE errors may be trapped using the modern interface. If the they are not trapped, or if the old interface is used, such an error will cause the program will halt.

All other errors may be trapped using the modern interface, otherwise they will be `carp`ed about. Program execution will not be halted.

- mkdir [path]: [errmsg] (SEVERE)

  `make_path` was unable to create the path. Probably some sort of permissions error at the point of departure or insufficient resources (such as free inodes on Unix).

- No root path(s) specified

  `make_path` was not given any paths to create. This message is only emitted if the routine is called with the traditional interface. The modern interface will remain silent if given nothing to do.

- No such file or directory

  On Windows, if `make_path` gives you this warning, it may mean that you have exceeded your filesystem's maximum path length.

- cannot fetch initial working directory: [errmsg]

  `remove_tree` attempted to determine the initial directory by calling `Cwd::getcwd`, but the call failed for some reason. No attempt will be made to delete anything.

- cannot stat initial working directory: [errmsg]

  `remove_tree` attempted to stat the initial directory (after having successfully obtained its name via `getcwd`), however, the call failed for some reason. No attempt will be made to delete anything.

- cannot chdir to [dir]: [errmsg]

  `remove_tree` attempted to set the working directory in order to begin deleting the objects therein, but was unsuccessful. This is usually a permissions issue. The routine will continue to delete other things, but this directory will be left intact.

- directory [dir] changed before chdir, expected dev=[n] ino=[n], actual dev=[n] ino=[n], aborting. (FATAL)

  `remove_tree` recorded the device and inode of a directory, and then moved into it. It then performed a `stat` on the current directory and detected that the device and inode were no longer the same. As this is at the heart of the race condition problem, the program will die at this point.

- cannot make directory [dir] read+writeable: [errmsg]

  `remove_tree` attempted to change the permissions on the current directory to ensure that subsequent unlinkings would not run into problems, but was unable to do so. The permissions remain as they were, and the program will carry on, doing the best it can.

- cannot read [dir]: [errmsg]

  `remove_tree` tried to read the contents of the directory in order to acquire the names of the directory entries to be unlinked, but was unsuccessful. This is usually a permissions issue. The program will continue, but the files in this directory will remain after the call.

- cannot reset chmod [dir]: [errmsg]

  `remove_tree`, after having deleted everything in a directory, attempted to restore its permissions to the original state but failed. The directory may wind up being left behind.

- cannot remove [dir] when cwd is [dir]

  The current working directory of the program is `/some/path/to/here` and you are attempting to remove an ancestor, such as `/some/path`. The directory tree is left untouched.

  The solution is to `chdir` out of the child directory to a place outside the directory tree to be removed.

- cannot chdir to [parent-dir] from [child-dir]: [errmsg], aborting. (FATAL)

`remove_tree`, after having deleted everything and restored the permissions of a directory, was unable to chdir back to the parent. The program halts to avoid a race condition from occurring.

- cannot stat prior working directory [dir]: [errmsg], aborting. (FATAL)

  `remove_tree` was unable to stat the parent directory after having returned from the child. Since there is no way of knowing if we returned to where we think we should be (by comparing device and inode) the only way out is to `croak`.

- previous directory [parent-dir] changed before entering [child-dir], expected dev=[n] ino=[n], actual dev=[n] ino=[n], aborting. (FATAL)

  When `remove_tree` returned from deleting files in a child directory, a check revealed that the parent directory it returned to wasn't the one it started out from. This is considered a sign of malicious activity.

- cannot make directory [dir] writeable: [errmsg]

  Just before removing a directory (after having successfully removed everything it contained), `remove_tree` attempted to set the permissions on the directory to ensure it could be removed and failed. Program execution continues, but the directory may possibly not be deleted.

- cannot remove directory [dir]: [errmsg]

  `remove_tree` attempted to remove a directory, but failed. This may be because some objects that were unable to be removed remain in the directory, or it could be a permissions issue. The directory will be left behind.

- cannot restore permissions of [dir] to [0nnn]: [errmsg]

  After having failed to remove a directory, `remove_tree` was unable to restore its permissions from a permissive state back to a possibly more restrictive setting. (Permissions given in octal).

- cannot make file [file] writeable: [errmsg]

  `remove_tree` attempted to force the permissions of a file to ensure it could be deleted, but failed to do so. It will, however, still attempt to unlink the file.

- cannot unlink file [file]: [errmsg]

  `remove_tree` failed to remove a file. Probably a permissions issue.

- cannot restore permissions of [file] to [0nnn]: [errmsg]

  After having failed to remove a file, `remove_tree` was also unable to restore the permissions on the file to a possibly less permissive setting. (Permissions given in octal).

- unable to map [owner] to a uid, ownership not changed");

  `make_path` was instructed to give the ownership of created directories to the symbolic name [owner], but `getpwnam` did not return the corresponding numeric uid. The directory will be created, but ownership will not be changed.

- unable to map [group] to a gid, group ownership not changed

make_path was instructed to give the group ownership of created directories to the symbolic name [group], but getgrnam did not return the corresponding numeric gid. The directory will be created, but group ownership will not be changed.

SEE ALSO

- File::Remove

  Allows files and directories to be moved to the Trashcan/Recycle Bin (where they may later be restored if necessary) if the operating system supports such functionality. This feature may one day be made available directly in File::Path.

- File::Find::Rule

  When removing directory trees, if you want to examine each file to decide whether to delete it (and possibly leaving large swathes alone), File::Find::Rule offers a convenient and flexible approach to examining directory trees.

BUGS AND LIMITATIONS

The following describes File::Path limitations and how to report bugs.

MULTITHREADED APPLICATIONS

File::Path rmtree and remove_tree will not work with multithreaded applications due to its use of chdir. At this time, no warning or error is generated in this situation. You will certainly encounter unexpected results.

The implementation that surfaces this limitation will not be changed. See the File::Path::Tiny module for functionality similar to File::Path but which does not chdir.

NFS Mount Points

File::Path is not responsible for triggering the automounts, mirror mounts, and the contents of network mounted filesystems. If your NFS implementation requires an action to be performed on the filesystem in order for File::Path to perform operations, it is strongly suggested you assure filesystem availability by reading the root of the mounted filesystem.

REPORTING BUGS

Please report all bugs on the RT queue, either via the web interface:

http://rt.cpan.org/NoAuth/Bugs.html?Dist=File-Path

or by email:

```
bug-File-Path@rt.cpan.org
```

In either case, please **attach** patches to the bug report rather than including them inline in the web post or the body of the email.

You can also send pull requests to the Github repository:

https://github.com/rpcme/File-Path

ACKNOWLEDGEMENTS

Paul Szabo identified the race condition originally, and Brendan O'Dea wrote an implementation for Debian that addressed the problem. That code was used as a basis for the current code. Their efforts are greatly appreciated.

Gisle Aas made a number of improvements to the documentation for 2.07 and his advice and assistance is also greatly appreciated.

File::ShareDir

Locate per-dist and per-module shared files

SYNOPSIS

```
use File::ShareDir ':ALL';

# Where are distribution-level shared data files kept
$dir = dist_dir('File-ShareDir');

# Where are module-level shared data files kept
$dir = module_dir('File::ShareDir');

# Find a specific file in our dist/module shared dir
$file = dist_file(  'File-ShareDir',  'file/name.txt');
$file = module_file('File::ShareDir', 'file/name.txt');

# Like module_file, but search up the inheritance tree
$file = class_file( 'Foo::Bar', 'file/name.txt' );
```

DESCRIPTION

The intent of *File::ShareDir* is to provide a companion to *Class::Inspector* and File::HomeDir, modules that take a process that is well-known by advanced Perl developers but gets a little tricky, and make it more available to the larger Perl community.

Quite often you want or need your Perl module (CPAN or otherwise) to have access to a large amount of read-only data that is stored on the file-system at run-time.

On a linux-like system, this would be in a place such as /usr/share, however Perl runs on a wide variety of different systems, and so the use of any one location is unreliable.

Perl provides a little-known method for doing this, but almost nobody is aware that it exists. As a result, module authors often go through some very strange ways to make the data available to their code.

The most common of these is to dump the data out to an enormous Perl data structure and save it into the module itself. The result are enormous multi-megabyte .pm files that chew up a lot of memory needlessly.

Another method is to put the data "file" after the __DATA__ compiler tag and limit yourself to access as a filehandle.

The problem to solve is really quite simple.

```
1. Write the data files to the system at install time.

2. Know where you put them at run-time.
```

Perl's install system creates an "auto" directory for both every distribution and for every module file.

These are used by a couple of different auto-loading systems to store code fragments generated at install time, and various other modules written by the Perl "ancient masters".

But the same mechanism is available to any dist or module to store any sort of data.

Using Data in your Module

`File::ShareDir` forms one half of a two part solution.

Once the files have been installed to the correct directory, you can use `File::ShareDir` to find your files again after the installation.

For the installation half of the solution, see File::ShareDir::Install and its `install_share` directive.

Using File::ShareDir::Install together with *File::ShareDir* allows one to rely on the files in appropriate `dist_dir()` or `module_dir()` in development phase, too.

FUNCTIONS

`File::ShareDir` provides four functions for locating files and directories.

For greater maintainability, none of these are exported by default and you are expected to name the ones you want at use-time, or provide the `':ALL'` tag. All of the following are equivalent.

```
# Load but don't import, and then call directly
use File::ShareDir;
$dir = File::ShareDir::dist_dir('My-Dist');

# Import a single function
use File::ShareDir 'dist_dir';
dist_dir('My-Dist');

# Import all the functions
use File::ShareDir ':ALL';
dist_dir('My-Dist');
```

All of the functions will check for you that the dir/file actually exists, and that you have read permissions, or they will throw an exception.

dist_dir

```
# Get a distribution's shared files directory
my $dir = dist_dir('My-Distribution');
```

The `dist_dir` function takes a single parameter of the name of an installed (CPAN or otherwise) distribution, and locates the shared data directory created at install time for it.

Returns the directory path as a string, or dies if it cannot be located or is not readable.

module_dir

```
# Get a module's shared files directory
my $dir = module_dir('My::Module');
```

The `module_dir` function takes a single parameter of the name of an installed (CPAN or otherwise) module, and locates the shared data directory created at install time for it.

In order to find the directory, the module **must** be loaded when calling this function.

Returns the directory path as a string, or dies if it cannot be located or is not readable.

dist_file

```
# Find a file in our distribution shared dir
my $dir = dist_file('My-Distribution', 'file/name.txt');
```

The `dist_file` function takes two parameters of the distribution name and file name, locates the dist directory, and then finds the file within it, verifying that the file actually exists, and that it is readable.

The filename should be a relative path in the format of your local filesystem. It will simply added to the directory using *File::Spec*'s `catfile` method.

Returns the file path as a string, or dies if the file or the dist's directory cannot be located, or the file is not readable.

module_file

```
# Find a file in our module shared dir
my $dir = module_file('My::Module', 'file/name.txt');
```

The `module_file` function takes two parameters of the module name and file name. It locates the module directory, and then finds the file within it, verifying that the file actually exists, and that it is readable.

In order to find the directory, the module **must** be loaded when calling this function.

The filename should be a relative path in the format of your local filesystem. It will simply added to the directory using *File::Spec*'s `catfile` method.

Returns the file path as a string, or dies if the file or the dist's directory cannot be located, or the file is not readable.

class_file

```
# Find a file in our module shared dir, or in our parent class
my $dir = class_file('My::Module', 'file/name.txt');
```

The `module_file` function takes two parameters of the module name and file name. It locates the module directory, and then finds the file within it, verifying that the file actually exists, and that it is readable.

In order to find the directory, the module **must** be loaded when calling this function.

The filename should be a relative path in the format of your local filesystem. It will simply added to the directory using *File::Spec*'s `catfile` method.

If the file is NOT found for that module, `class_file` will scan up the module's @ISA tree, looking for the file in all of the parent classes.

This allows you to, in effect, "subclass" shared files.

Returns the file path as a string, or dies if the file or the dist's directory cannot be located, or the file is not readable.

EXTENDING

Overriding Directory Resolution

`File::ShareDir` has two convenience hashes for people who have advanced usage requirements of `File::ShareDir` such as using uninstalled `share` directories during development.

```
#
# Dist-Name => /absolute/path/for/DistName/share/dir
#
%File::ShareDir::DIST_SHARE

#
# Module::Name => /absolute/path/for/Module/Name/share/dir
#
%File::ShareDir::MODULE_SHARE
```

Setting these values any time before the corresponding calls

```
dist_dir('Dist-Name')
dist_file('Dist-Name','some/file');

module_dir('Module::Name');
module_file('Module::Name','some/file');
```

Will override the base directory for resolving those calls.

An example of where this would be useful is in a test for a module that depends on files installed into a share directory, to enable the tests to use the development copy without needing to install them first.

```
use File::ShareDir;
use Cwd qw( getcwd );
use File::Spec::Functions qw( rel2abs catdir );

$File::ShareDir::MODULE_SHARE{'Foo::Module'} =␣
↪rel2abs(catfile(getcwd,'share'));

use Foo::Module;

# internal calls in Foo::Module to module_file('Foo::Module','bar')␣
```

(continues on next page)

(continued from previous page)

```
 ↪now resolves to
# the source trees share/ directory instead of something in @INC
```

SUPPORT

Bugs should always be submitted via the CPAN request tracker, see below.

You can find documentation for this module with the perldoc command.

```
perldoc File::ShareDir
```

You can also look for information at:

- RT: CPAN's request tracker

  http://rt.cpan.org/NoAuth/Bugs.html?Dist=File-ShareDir

- AnnoCPAN: Annotated CPAN documentation

  http://annocpan.org/dist/File-ShareDir

- CPAN Ratings

  http://cpanratings.perl.org/s/File-ShareDir

- CPAN Search

  http://search.cpan.org/dist/File-ShareDir/

Where can I go for other help?

If you have a bug report, a patch or a suggestion, please open a new report ticket at CPAN (but please check previous reports first in case your issue has already been addressed).

Report tickets should contain a detailed description of the bug or enhancement request and at least an easily verifiable way of reproducing the issue or fix. Patches are always welcome, too.

Where can I go for help with a concrete version?

Bugs and feature requests are accepted against the latest version only. To get patches for earlier versions, you need to get an agreement with a developer of your choice - who may or not report the issue and a suggested fix upstream (depends on the license you have chosen).

Business support and maintenance

For business support you can contact the maintainer via his CPAN email address. Please keep in mind that business support is neither available for free nor are you eligible to receive any support based on the license distributed with this package.

File::Spec

portably perform operations on file names

SYNOPSIS

```
use File::Spec;

my $x = File::Spec->catfile('a', 'b', 'c');
```

which returns 'a/b/c' under Unix. Or:

```
use File::Spec::Functions;

my $x = catfile('a', 'b', 'c');
```

DESCRIPTION

This module is designed to support operations commonly performed on file specifications (usually called "file names", but not to be confused with the contents of a file, or Perl's file handles), such as concatenating several directory and file names into a single path, or determining whether a path is rooted. It is based on code directly taken from MakeMaker 5.17, code written by Andreas König, Andy Dougherty, Charles Bailey, Ilya Zakharevich, Paul Schinder, and others.

Since these functions are different for most operating systems, each set of OS specific routines is available in a separate module, including:

```
File::Spec::Unix
File::Spec::Mac
File::Spec::OS2
File::Spec::Win32
File::Spec::VMS
```

The module appropriate for the current OS is automatically loaded by File::Spec. Since some modules (like VMS) make use of facilities available only under that OS, it may not be possible to load all modules under all operating systems.

Since File::Spec is object oriented, subroutines should not be called directly, as in:

```
File::Spec::catfile('a','b');
```

but rather as class methods:

```
File::Spec->catfile('a','b');
```

For simple uses, *File::Spec::Functions* provides convenient functional forms of these methods.

METHODS

- canonpath

  No physical check on the filesystem, but a logical cleanup of a path.

  ```
  $cpath = File::Spec->canonpath( $path ) ;
  ```

  Note that this does *not* collapse `x/../y` sections into `y`. This is by design. If `/foo` on your system is a symlink to `/bar/baz`, then `/foo/../quux` is actually `/bar/quux`, not `/quux` as a naive `../`-removal would give you. If you want to do this kind of processing, you probably want `Cwd`'s `realpath()` function to actually traverse the filesystem cleaning up paths like this.

- catdir

  Concatenate two or more directory names to form a complete path ending with a directory. But remove the trailing slash from the resulting string, because it doesn't look good, isn't necessary and confuses OS/2. Of course, if this is the root directory, don't cut off the trailing slash :-)

  ```
  $path = File::Spec->catdir( @directories );
  ```

- catfile

  Concatenate one or more directory names and a filename to form a complete path ending with a filename

  ```
  $path = File::Spec->catfile( @directories, $filename );
  ```

- curdir

  Returns a string representation of the current directory.

```
$curdir = File::Spec->curdir();
```

- devnull

  Returns a string representation of the null device.

```
$devnull = File::Spec->devnull();
```

- rootdir

  Returns a string representation of the root directory.

```
$rootdir = File::Spec->rootdir();
```

- tmpdir

  Returns a string representation of the first writable directory from a list of possible temporary directories. Returns the current directory if no writable temporary directories are found. The list of directories checked depends on the platform; e.g. File::Spec::Unix checks `$ENV{TMPDIR}` (unless taint is on) and `/tmp`.

```
$tmpdir = File::Spec->tmpdir();
```

- updir

  Returns a string representation of the parent directory.

```
$updir = File::Spec->updir();
```

- no_upwards

  Given a list of files in a directory (such as from `readdir()`), strip out `'.'` and `'..'`.

  SECURITY NOTE: This does NOT filter paths containing `'..'`, like `'../../../../etc/passwd'`, only literal matches to `'.'` and `'..'`.

```
@paths = File::Spec->no_upwards( readdir $dirhandle );
```

- case_tolerant

  Returns a true or false value indicating, respectively, that alphabetic case is not or is significant when comparing file specifications. Cygwin and Win32 accept an optional drive argument.

```
$is_case_tolerant = File::Spec->case_tolerant();
```

- file_name_is_absolute

  Takes as its argument a path, and returns true if it is an absolute path.

```
$is_absolute = File::Spec->file_name_is_absolute( $path );
```

  This does not consult the local filesystem on Unix, Win32, OS/2, or Mac OS (Classic). It does consult the working environment for VMS (see *"file_name_is_absolute" in File::Spec::VMS*).

- path

  Takes no argument. Returns the environment variable PATH (or the local platform's equivalent) as a list.

```
@PATH = File::Spec->path();
```

- join

  join is the same as catfile.

- splitpath

  Splits a path in to volume, directory, and filename portions. On systems with no concept of volume, returns '' for volume.

```
($volume,$directories,$file) =
                    File::Spec->splitpath( $path );
($volume,$directories,$file) =
                    File::Spec->splitpath( $path, $no_file );
```

  For systems with no syntax differentiating filenames from directories, assumes that the last file is a path unless `$no_file` is true or a trailing separator or `/.` or `/..` is present. On Unix, this means that `$no_file` true makes this return ('', $path, '').

  The directory portion may or may not be returned with a trailing '/'.

  The results can be passed to "catpath()" to get back a path equivalent to (usually identical to) the original path.

- splitdir

  The opposite of "catdir".

```
@dirs = File::Spec->splitdir( $directories );
```

  `$directories` must be only the directory portion of the path on systems that have the concept of a volume or that have path syntax that differentiates files from directories.

  Unlike just splitting the directories on the separator, empty directory names (`''`) can be returned, because these are significant on some OSes.

- catpath()

  Takes volume, directory and file portions and returns an entire path. Under Unix, `$volume` is ignored, and directory and file are concatenated. A '/' is inserted if need be. On other OSes, `$volume` is significant.

```
$full_path = File::Spec->catpath( $volume, $directory, $file );
```

- abs2rel

  Takes a destination path and an optional base path returns a relative path from the base path to the destination path:

```
$rel_path = File::Spec->abs2rel( $path ) ;
$rel_path = File::Spec->abs2rel( $path, $base ) ;
```

If $base is not present or '', then *Cwd::cwd()* is used. If $base is relative, then it is converted to absolute form using "rel2abs()". This means that it is taken to be relative to *Cwd::cwd()*.

On systems with the concept of volume, if $path and $base appear to be on two different volumes, we will not attempt to resolve the two paths, and we will instead simply return $path. Note that previous versions of this module ignored the volume of $base, which resulted in garbage results part of the time.

On systems that have a grammar that indicates filenames, this ignores the $base filename as well. Otherwise all path components are assumed to be directories.

If $path is relative, it is converted to absolute form using "rel2abs()". This means that it is taken to be relative to *Cwd::cwd()*.

No checks against the filesystem are made. On VMS, there is interaction with the working environment, as logicals and macros are expanded.

Based on code written by Shigio Yamaguchi.

- rel2abs()

  Converts a relative path to an absolute path.

```
$abs_path = File::Spec->rel2abs( $path ) ;
$abs_path = File::Spec->rel2abs( $path, $base ) ;
```

If $base is not present or '', then *Cwd::cwd()* is used. If $base is relative, then it is converted to absolute form using "rel2abs()". This means that it is taken to be relative to *Cwd::cwd()*.

On systems with the concept of volume, if $path and $base appear to be on two different volumes, we will not attempt to resolve the two paths, and we will instead simply return $path. Note that previous versions of this module ignored the volume of $base, which resulted in garbage results part of the time.

On systems that have a grammar that indicates filenames, this ignores the $base filename as well. Otherwise all path components are assumed to be directories.

If $path is absolute, it is cleaned up and returned using "canonpath".

No checks against the filesystem are made. On VMS, there is interaction with the working environment, as logicals and macros are expanded.

Based on code written by Shigio Yamaguchi.

Modules

- `File::Spec::AmigaOS` - File::Spec for AmigaOS
- `File::Spec::Cygwin` - methods for Cygwin file specs
- `File::Spec::Epoc` - methods for Epoc file specs
- `File::Spec::Functions` - portably perform operations on file names
- `File::Spec::Mac` - File::Spec for Mac OS (Classic)
- `File::Spec::OS2` - methods for OS/2 file specs
- `File::Spec::Unix` - File::Spec for Unix, base for other File::Spec modules
- `File::Spec::VMS` - methods for VMS file specs
- `File::Spec::Win32` - methods for Win32 file specs

File::Spec::AmigaOS

File::Spec for AmigaOS

SYNOPSIS

```
require File::Spec::AmigaOS; # Done automatically by File::Spec
                             # if needed
```

DESCRIPTION

Methods for manipulating file specifications.

METHODS

- tmpdir

  Returns $ENV{TMPDIR} or if that is unset, “/t”.

- file_name_is_absolute

  Returns true if there’s a colon in the file name, or if it begins with a slash.

All the other methods are from *File::Spec::Unix*.

File::Spec::Cygwin

methods for Cygwin file specs

SYNOPSIS

```
require File::Spec::Cygwin; # Done internally by File::Spec if␣
↪needed
```

DESCRIPTION

See *File::Spec* and *File::Spec::Unix*. This package overrides the implementation of these methods, not the semantics.

This module is still in beta. Cygwin-knowledgeable folks are invited to offer patches and suggestions.

- canonpath

  Any \ (backslashes) are converted to / (forward slashes), and then File::Spec::Unix canonpath() is called on the result.

- file_name_is_absolute

  True is returned if the file name begins with `drive_letter:`, and if not, File::Spec::Unix file_name_is_absolute() is called.

- tmpdir (override)

  Returns a string representation of the first existing directory from the following list:

  ```
  $ENV{TMPDIR}
  /tmp
  $ENV{'TMP'}
  $ENV{'TEMP'}
  C:/temp
  ```

  If running under taint mode, and if the environment variables are tainted, they are not used.

- case_tolerant

  Override Unix. Cygwin case-tolerance depends on managed mount settings and as with MsWin32 on GetVolumeInformation() $ouFsFlags == FS_CASE_SENSITIVE, indicating the case significance when comparing file specifications. Default: 1

File::Spec::Epoc

methods for Epoc file specs

SYNOPSIS

```
require File::Spec::Epoc; # Done internally by File::Spec if needed
```

DESCRIPTION

See File::Spec::Unix for a documentation of the methods provided there. This package overrides the implementation of these methods, not the semantics.

This package is still a work in progress. ;-)

- canonpath()

  No physical check on the filesystem, but a logical cleanup of a path. On UNIX eliminated successive slashes and successive "/.".

File::Spec::Functions

portably perform operations on file names

SYNOPSIS

```
use File::Spec::Functions;
my $x = catfile('a', 'b');
```

DESCRIPTION

This module exports convenience functions for all of the class methods provided by File::Spec.

For a reference of available functions, please consult *File::Spec::Unix*, which contains the entire set, and which is inherited by the modules for other platforms. For further information, please see *File::Spec::Mac*, *File::Spec::OS2*, *File::Spec::Win32*, or *File::Spec::VMS*.

Exports

The following functions are exported by default.

```
canonpath
catdir
catfile
curdir
rootdir
updir
no_upwards
file_name_is_absolute
path
```

The following functions are exported only by request.

```
devnull
tmpdir
splitpath
splitdir
catpath
abs2rel
rel2abs
case_tolerant
```

All the functions may be imported using the `:ALL` tag.

File::Spec::Mac

File::Spec for Mac OS (Classic)

SYNOPSIS

```
require File::Spec::Mac; # Done internally by File::Spec if needed
```

DESCRIPTION

Methods for manipulating file specifications.

METHODS

- canonpath

  On Mac OS, there's nothing to be done. Returns what it's given.

- catdir()

  Concatenate two or more directory names to form a path separated by colons (":") ending with a directory. Resulting paths are **relative** by default, but can be forced to be absolute (but avoid this, see below). Automatically puts a trailing ":" on the end of the complete path, because that's what's done in MacPerl's environment and helps to distinguish a file path from a directory path.

  IMPORTANT NOTE: Beginning with version 1.3 of this module, the resulting path is relative by default and *not* absolute. This decision was made due to portability reasons. Since `File::Spec->catdir()` returns relative paths on all other operating systems, it will now also follow this convention on Mac OS. Note that this may break some existing scripts.

  The intended purpose of this routine is to concatenate *directory names*. But because of the nature of Macintosh paths, some additional possibilities are allowed to make using this routine give reasonable results for some common situations. In other words, you are also allowed to concatenate *paths* instead of directory names (strictly speaking, a string like ":a" is a path, but not a name, since it contains a punctuation character ":").

  So, beside calls like

  ```
  catdir("a") = ":a:"
  catdir("a","b") = ":a:b:"
  catdir() = ""                    (special case)
  ```

  calls like the following

```
catdir(":a:") = ":a:"
catdir(":a","b") = ":a:b:"
catdir(":a:","b") = ":a:b:"
catdir(":a:",":b:") = ":a:b:"
catdir(":") = ":"
```

are allowed.

Here are the rules that are used in `catdir()`; note that we try to be as compatible as possible to Unix:

1. The resulting path is relative by default, i.e. the resulting path will have a leading colon.
2. A trailing colon is added automatically to the resulting path, to denote a directory.
3. Generally, each argument has one leading ":" and one trailing ":" removed (if any). They are then joined together by a ":". Special treatment applies for arguments denoting updir paths like "::lib:", see (4), or arguments consisting solely of colons ("colon paths"), see (5).
4. When an updir path like ":::lib::" is passed as argument, the number of directories to climb up is handled correctly, not removing leading or trailing colons when necessary. E.g.

   ```
   catdir(":::a","::b","c")    = ":::a::b:c:"
   catdir(":::a::","::b","c")  = ":::a:::b:c:"
   ```

5. Adding a colon ":" or empty string "" to a path at *any* position doesn't alter the path, i.e. these arguments are ignored. (When a "" is passed as the first argument, it has a special meaning, see (6)). This way, a colon ":" is handled like a "." (curdir) on Unix, while an empty string "" is generally ignored (see *"canonpath()" in File::Spec::Unix*). Likewise, a "::" is handled like a ".." (updir), and a ":::" is handled like a "../.." etc. E.g.

   ```
   catdir("a",":",":","b")   = ":a:b:"
   catdir("a",":","::",":b") = ":a::b:"
   ```

6. If the first argument is an empty string "" or is a volume name, i.e. matches the pattern /^[^:]+:/, the resulting path is **absolute**.
7. Passing an empty string "" as the first argument to `catdir()` is like passing`File::Spec->rootdir()` as the first argument, i.e.

   ```
   catdir("","a","b")          is the same as

   catdir(rootdir(),"a","b").
   ```

   This is true on Unix, where `catdir("","a","b")` yields "/a/b" and `rootdir()` is "/". Note that `rootdir()` on Mac OS is the startup volume, which is the closest in concept to Unix' "/". This should help to run existing scripts originally written for Unix.

8. For absolute paths, some cleanup is done, to ensure that the volume name isn't immediately followed by updirs. This is invalid, because this would go beyond "root". Generally, these cases are handled like their Unix counterparts:

```
Unix:
   Unix->catdir("","")                    =  "/"
   Unix->catdir("",".")                   =  "/"
   Unix->catdir("","..")                  =  "/"         # can't␣
↪go
                                                         #␣
↪beyond root
   Unix->catdir("",".","..","..","a")     =  "/a"
Mac:
   Mac->catdir("","")                     =  rootdir()   # (e.g.
↪"HD:")
   Mac->catdir("",":")                    =  rootdir()
   Mac->catdir("","::")                   =  rootdir()   # can't␣
↪go
                                                         #␣
↪beyond root
   Mac->catdir("",":","::","::","a")      =  rootdir() . "a:"
                                                      # (e.g.
↪"HD:a:")
```

However, this approach is limited to the first arguments following "root" (again, see *"canonpath()" in File::Spec::Unix*. If there are more arguments that move up the directory tree, an invalid path going beyond root can be created.

As you've seen, you can force `catdir()` to create an absolute path by passing either an empty string or a path that begins with a volume name as the first argument. However, you are strongly encouraged not to do so, since this is done only for backward compatibility. Newer versions of File::Spec come with a method called `catpath()` (see below), that is designed to offer a portable solution for the creation of absolute paths. It takes volume, directory and file portions and returns an entire path. While `catdir()` is still suitable for the concatenation of *directory names*, you are encouraged to use `catpath()` to concatenate *volume names* and *directory paths*. E.g.

```
$dir      = File::Spec->catdir("tmp","sources");
$abs_path = File::Spec->catpath("MacintoshHD:", $dir,"");
```

yields

```
"MacintoshHD:tmp:sources:" .
```

- catfile

  Concatenate one or more directory names and a filename to form a complete path ending with a filename. Resulting paths are **relative** by default, but can be forced to be absolute (but avoid this).

  IMPORTANT NOTE: Beginning with version 1.3 of this module, the resulting path is relative by default and *not* absolute. This decision was made due to portability

reasons. Since `File::Spec->catfile()` returns relative paths on all other operating systems, it will now also follow this convention on Mac OS. Note that this may break some existing scripts.

The last argument is always considered to be the file portion. Since `catfile()` uses `catdir()` (see above) for the concatenation of the directory portions (if any), the following with regard to relative and absolute paths is true:

```
catfile("")     = ""
catfile("file") = "file"
```

but

```
catfile("","")        = rootdir()         # (e.g. "HD:")
catfile("","file")    = rootdir() . file  # (e.g. "HD:file")
catfile("HD:","file") = "HD:file"
```

This means that `catdir()` is called only when there are two or more arguments, as one might expect.

Note that the leading ":" is removed from the filename, so that

```
catfile("a","b","file")  = ":a:b:file"    and

catfile("a","b",":file") = ":a:b:file"
```

give the same answer.

To concatenate *volume names*, *directory paths* and *filenames*, you are encouraged to use `catpath()` (see below).

- curdir

  Returns a string representing the current directory. On Mac OS, this is ":".

- devnull

  Returns a string representing the null device. On Mac OS, this is "Dev:Null".

- rootdir

  Returns the empty string. Mac OS has no real root directory.

- tmpdir

  Returns the contents of $ENV{TMPDIR}, if that directory exits or the current working directory otherwise. Under MacPerl, $ENV{TMPDIR} will contain a path like "MacintoshHD:Temporary Items:", which is a hidden directory on your startup volume.

- updir

  Returns a string representing the parent directory. On Mac OS, this is "::".

- file_name_is_absolute

  Takes as argument a path and returns true, if it is an absolute path. If the path has a leading ":", it's a relative path. Otherwise, it's an absolute path, unless the path doesn't contain any colons, i.e. it's a name like "a". In this particular case,

the path is considered to be relative (i.e. it is considered to be a filename). Use ":" in the appropriate place in the path if you want to distinguish unambiguously. As a special case, the filename '' is always considered to be absolute. Note that with version 1.2 of File::Spec::Mac, this does no longer consult the local filesystem.

E.g.

```
File::Spec->file_name_is_absolute("a");         # false␣
↪(relative)
File::Spec->file_name_is_absolute(":a:b:");     # false␣
↪(relative)
File::Spec->file_name_is_absolute("MacintoshHD:");
                                                # true␣
↪(absolute)
File::Spec->file_name_is_absolute("");          # true␣
↪(absolute)
```

- path

  Returns the null list for the MacPerl application, since the concept is usually meaningless under Mac OS. But if you're using the MacPerl tool under MPW, it gives back $ENV{Commands} suitably split, as is done in

  lib
  ExtUtils:MM_Mac.pm.

- splitpath

```
($volume,$directories,$file) = File::Spec->splitpath( $path );
($volume,$directories,$file) = File::Spec->splitpath( $path,
                                                      $no_file␣
↪);
```

  Splits a path into volume, directory, and filename portions.

  On Mac OS, assumes that the last part of the path is a filename unless $no_file is true or a trailing separator ":" is present.

  The volume portion is always returned with a trailing ":". The directory portion is always returned with a leading (to denote a relative path) and a trailing ":" (to denote a directory). The file portion is always returned *without* a leading ":". Empty portions are returned as empty string ''.

  The results can be passed to `catpath()` to get back a path equivalent to (usually identical to) the original path.

- splitdir

  The opposite of `catdir()`.

```
@dirs = File::Spec->splitdir( $directories );
```

  $directories should be only the directory portion of the path on systems that have the concept of a volume or that have path syntax that differentiates files from directories. Consider using `splitpath()` otherwise.

Unlike just splitting the directories on the separator, empty directory names ("") can be returned. Since `catdir()` on Mac OS always appends a trailing colon to distinguish a directory path from a file path, a single trailing colon will be ignored, i.e. there's no empty directory name after it.

Hence, on Mac OS, both

```
File::Spec->splitdir( ":a:b::c:" );    and
File::Spec->splitdir( ":a:b::c" );
```

yield:

```
( "a", "b", "::", "c")
```

while

```
File::Spec->splitdir( ":a:b::c::" );
```

yields:

```
( "a", "b", "::", "c", "::")
```

- catpath

```
$path = File::Spec->catpath($volume,$directory,$file);
```

Takes volume, directory and file portions and returns an entire path. On Mac OS, $volume, $directory and $file are concatenated. A ':' is inserted if need be. You may pass an empty string for each portion. If all portions are empty, the empty string is returned. If $volume is empty, the result will be a relative path, beginning with a ':'. If $volume and $directory are empty, a leading ":" (if any) is removed form $file and the remainder is returned. If $file is empty, the resulting path will have a trailing ':'.

- abs2rel

Takes a destination path and an optional base path and returns a relative path from the base path to the destination path:

```
$rel_path = File::Spec->abs2rel( $path ) ;
$rel_path = File::Spec->abs2rel( $path, $base ) ;
```

Note that both paths are assumed to have a notation that distinguishes a directory path (with trailing ':') from a file path (without trailing ':').

If $base is not present or '', then the current working directory is used. If $base is relative, then it is converted to absolute form using `rel2abs()`. This means that it is taken to be relative to the current working directory.

If $path and $base appear to be on two different volumes, we will not attempt to resolve the two paths, and we will instead simply return $path. Note that previous versions of this module ignored the volume of $base, which resulted in garbage results part of the time.

If $base doesn't have a trailing colon, the last element of $base is assumed to be a filename. This filename is ignored. Otherwise all path components are assumed to

be directories.

If $path is relative, it is converted to absolute form using `rel2abs()`. This means that it is taken to be relative to the current working directory.

Based on code written by Shigio Yamaguchi.

- rel2abs

  Converts a relative path to an absolute path:

```
$abs_path = File::Spec->rel2abs( $path ) ;
$abs_path = File::Spec->rel2abs( $path, $base ) ;
```

  Note that both paths are assumed to have a notation that distinguishes a directory path (with trailing ':') from a file path (without trailing ':').

  If $base is not present or '', then $base is set to the current working directory. If $base is relative, then it is converted to absolute form using `rel2abs()`. This means that it is taken to be relative to the current working directory.

  If $base doesn't have a trailing colon, the last element of $base is assumed to be a filename. This filename is ignored. Otherwise all path components are assumed to be directories.

  If $path is already absolute, it is returned and $base is ignored.

  Based on code written by Shigio Yamaguchi.

File::Spec::OS2

methods for OS/2 file specs

SYNOPSIS

```
require File::Spec::OS2; # Done internally by File::Spec if needed
```

DESCRIPTION

See *File::Spec* and *File::Spec::Unix*. This package overrides the implementation of these methods, not the semantics.

Amongst the changes made for OS/2 are...

- tmpdir

  Modifies the list of places temp directory information is looked for.

  ```
  $ENV{TMPDIR}
  $ENV{TEMP}
  $ENV{TMP}
  /tmp
  /
  ```

- splitpath

  Volumes can be drive letters or UNC sharenames (\server\share).

File::Spec::Unix

File::Spec for Unix, base for other File::Spec modules

SYNOPSIS

```
require File::Spec::Unix; # Done automatically by File::Spec
```

DESCRIPTION

Methods for manipulating file specifications. Other File::Spec modules, such as File::Spec::Mac, inherit from File::Spec::Unix and override specific methods.

METHODS

- canonpath()

  No physical check on the filesystem, but a logical cleanup of a path. On UNIX eliminates successive slashes and successive “/.”.

```
$cpath = File::Spec->canonpath( $path ) ;
```

Note that this does *not* collapse `x/../y` sections into `y`. This is by design. If `/foo` on your system is a symlink to `/bar/baz`, then `/foo/../quux` is actually `/bar/quux`, not `/quux` as a naive `../`-removal would give you. If you want to do this kind of processing, you probably want `Cwd`'s `realpath()` function to actually traverse the filesystem cleaning up paths like this.

- catdir()

  Concatenate two or more directory names to form a complete path ending with a directory. But remove the trailing slash from the resulting string, because it doesn't look good, isn't necessary and confuses OS2. Of course, if this is the root directory, don't cut off the trailing slash :-)

- catfile

  Concatenate one or more directory names and a filename to form a complete path ending with a filename

- curdir

  Returns a string representation of the current directory. "." on UNIX.

- devnull

  Returns a string representation of the null device. "/dev/null" on UNIX.

- rootdir

  Returns a string representation of the root directory. "/" on UNIX.

- tmpdir

  Returns a string representation of the first writable directory from the following list or the current directory if none from the list are writable:

```
$ENV{TMPDIR}
/tmp
```

  If running under taint mode, and if $ENV{TMPDIR} is tainted, it is not used.

- updir

  Returns a string representation of the parent directory. ".." on UNIX.

- no_upwards

  Given a list of file names, strip out those that refer to a parent directory. (Does not strip symlinks, only '.', '..', and equivalents.)

- case_tolerant

  Returns a true or false value indicating, respectively, that alphabetic is not or is significant when comparing file specifications.

- file_name_is_absolute

  Takes as argument a path and returns true if it is an absolute path.

This does not consult the local filesystem on Unix, Win32, OS/2 or Mac OS (Classic). It does consult the working environment for VMS (see *"file_name_is_absolute" in File::Spec::VMS*).

- path

  Takes no argument, returns the environment variable PATH as an array.

- join

  join is the same as catfile.

- splitpath

```
($volume,$directories,$file) = File::Spec->splitpath( $path );
($volume,$directories,$file) = File::Spec->splitpath( $path,
                                                      $no_file␣
↪);
```

  Splits a path into volume, directory, and filename portions. On systems with no concept of volume, returns '' for volume.

  For systems with no syntax differentiating filenames from directories, assumes that the last file is a path unless $no_file is true or a trailing separator or /. or /.. is present. On Unix this means that $no_file true makes this return ('', $path, '').

  The directory portion may or may not be returned with a trailing '/'.

  The results can be passed to "catpath()" to get back a path equivalent to (usually identical to) the original path.

- splitdir

  The opposite of "catdir()".

```
@dirs = File::Spec->splitdir( $directories );
```

  $directories must be only the directory portion of the path on systems that have the concept of a volume or that have path syntax that differentiates files from directories.

  Unlike just splitting the directories on the separator, empty directory names ('') can be returned, because these are significant on some OSs.

  On Unix,

```
File::Spec->splitdir( "/a/b//c/" );
```

  Yields:

```
( '', 'a', 'b', '', 'c', '' )
```

- catpath()

  Takes volume, directory and file portions and returns an entire path. Under Unix, $volume is ignored, and directory and file are concatenated. A '/' is inserted if needed (though if the directory portion doesn't start with '/' it is not added). On other OSs, $volume is significant.

- abs2rel

  Takes a destination path and an optional base path returns a relative path from the base path to the destination path:

```
$rel_path = File::Spec->abs2rel( $path ) ;
$rel_path = File::Spec->abs2rel( $path, $base ) ;
```

  If $base is not present or '', then *cwd()* is used. If $base is relative, then it is converted to absolute form using "rel2abs()". This means that it is taken to be relative to *cwd()*.

  On systems that have a grammar that indicates filenames, this ignores the $base filename. Otherwise all path components are assumed to be directories.

  If $path is relative, it is converted to absolute form using "rel2abs()". This means that it is taken to be relative to *cwd()*.

  No checks against the filesystem are made, so the result may not be correct if `$base` contains symbolic links. (Apply *Cwd::abs_path()* beforehand if that is a concern.) On VMS, there is interaction with the working environment, as logicals and macros are expanded.

  Based on code written by Shigio Yamaguchi.

- rel2abs()

  Converts a relative path to an absolute path.

```
$abs_path = File::Spec->rel2abs( $path ) ;
$abs_path = File::Spec->rel2abs( $path, $base ) ;
```

  If $base is not present or '', then *cwd()* is used. If $base is relative, then it is converted to absolute form using "rel2abs()". This means that it is taken to be relative to *cwd()*.

  On systems that have a grammar that indicates filenames, this ignores the $base filename. Otherwise all path components are assumed to be directories.

  If $path is absolute, it is cleaned up and returned using "canonpath()".

  No checks against the filesystem are made. On VMS, there is interaction with the working environment, as logicals and macros are expanded.

  Based on code written by Shigio Yamaguchi.

SEE ALSO

File::Spec

Functions

File::Spec

canonpath

`File::Spec->canonpath($path)` - logical cleanup of a path.

catdir

`File::Spec->catdir(@dirs)` - join directory names into a path.

catfile

`File::Spec->catfile(@dirs, $file)` - join directories and a filename.

File::Spec::VMS

methods for VMS file specs

SYNOPSIS

```
require File::Spec::VMS; # Done internally by File::Spec if needed
```

DESCRIPTION

See File::Spec::Unix for a documentation of the methods provided there. This package overrides the implementation of these methods, not the semantics.

The default behavior is to allow either VMS or Unix syntax on input and to return VMS syntax on output unless Unix syntax has been explicitly requested via the `DECC$FILE_NAME_UNIX_REPORT` CRTL feature.

- canonpath (override)

  Removes redundant portions of file specifications and returns results in native syntax unless Unix filename reporting has been enabled.

- catdir (override)

  Concatenates a list of file specifications, and returns the result as a native directory specification unless the Unix filename reporting feature has been enabled. No check is made for "impossible" cases (e.g. elements other than the first being absolute filespecs).

- catfile (override)

  Concatenates a list of directory specifications with a filename specification to build a path.

- curdir (override)

  Returns a string representation of the current directory: '[]' or '.'

- devnull (override)

  Returns a string representation of the null device: '_NLA0:' or '/dev/null'

- rootdir (override)

  Returns a string representation of the root directory: 'SYS$DISK:[000000]' or '/'

- tmpdir (override)

  Returns a string representation of the first writable directory from the following list or '' if none are writable:

```
/tmp if C<DECC$FILENAME_UNIX_REPORT> is enabled.
sys$scratch:
$ENV{TMPDIR}
```

  If running under taint mode, and if $ENV{TMPDIR} is tainted, it is not used.

- updir (override)

  Returns a string representation of the parent directory: '[-]' or '..'

- case_tolerant (override)

  VMS file specification syntax is case-tolerant.

- path (override)

  Translate logical name DCL$PATH as a searchlist, rather than trying to `split` string value of `$ENV{'PATH'}`.

- file_name_is_absolute (override)

  Checks for VMS directory spec as well as Unix separators.

- splitpath (override)

```
($volume,$directories,$file) = File::Spec->splitpath( $path );
($volume,$directories,$file) = File::Spec->splitpath( $path,
                                                      $no_file␣
↪);
```

  Passing a true value for `$no_file` indicates that the path being split only contains directory components, even on systems where you can usually (when not supporting a foreign syntax) tell the difference between directories and files at a glance.

- splitdir (override)

  Split a directory specification into the components.

- catpath (override)

  Construct a complete filespec.

- abs2rel (override)

  Attempt to convert an absolute file specification to a relative specification.

- rel2abs (override)

  Return an absolute file specification from a relative one.

File::Spec::Win32

methods for Win32 file specs

SYNOPSIS

```
require File::Spec::Win32; # Done internally by File::Spec if needed
```

DESCRIPTION

See File::Spec::Unix for a documentation of the methods provided there. This package overrides the implementation of these methods, not the semantics.

- devnull

  Returns a string representation of the null device.

- tmpdir

  Returns a string representation of the first existing directory from the following list:

  ```
  $ENV{TMPDIR}
  $ENV{TEMP}
  $ENV{TMP}
  SYS:/temp
  C:\system\temp
  C:/temp
  /tmp
  /
  ```

  The SYS:/temp is preferred in Novell NetWare and the C:\system\temp for Symbian (the File::Spec::Win32 is used also for those platforms).

If running under taint mode, and if the environment variables are tainted, they are not used.

- case_tolerant

  MSWin32 case-tolerance depends on GetVolumeInformation() $ouFsFlags == FS_CASE_SENSITIVE, indicating the case significance when comparing file specifications. Since XP FS_CASE_SENSITIVE is effectively disabled for the NT subsubsystem. See http://cygwin.com/ml/cygwin/2007-07/msg00891.html Default: 1

- file_name_is_absolute

  As of right now, this returns 2 if the path is absolute with a volume, 1 if it's absolute with no volume, 0 otherwise.

- catfile

  Concatenate one or more directory names and a filename to form a complete path ending with a filename

- canonpath

  No physical check on the filesystem, but a logical cleanup of a path. On UNIX eliminated successive slashes and successive "/.". On Win32 makes

```
dir1\dir2\dir3\..\..\dir4 -> \dir\dir4 and even
dir1\dir2\dir3\...\dir4   -> \dir\dir4
```

- splitpath

```
($volume,$directories,$file) = File::Spec->splitpath( $path );
($volume,$directories,$file) = File::Spec->splitpath( $path,
                                                      $no_file␣
↪);
```

  Splits a path into volume, directory, and filename portions. Assumes that the last file is a path unless the path ends in '\', '\.', '\..' or $no_file is true. On Win32 this means that $no_file true makes this return ($volume, $path, '').

  Separators accepted are \ and /.

  Volumes can be drive letters or UNC sharenames (\server\share).

  The results can be passed to "catpath" to get back a path equivalent to (usually identical to) the original path.

- splitdir

  The opposite of *catdir()*.

```
@dirs = File::Spec->splitdir( $directories );
```

  $directories must be only the directory portion of the path on systems that have the concept of a volume or that have path syntax that differentiates files from directories.

  Unlike just splitting the directories on the separator, leading empty and trailing directory entries can be returned, because these are significant on some OSs. So,

```
File::Spec->splitdir( "/a/b//c/" );
```

Yields:

```
( '', 'a', 'b', '', 'c', '' )
```

- catpath

  Takes volume, directory and file portions and returns an entire path. Under Unix, $volume is ignored, and this is just like catfile(). On other OSs, the $volume become significant.

Note For File::Spec::Win32 Maintainers

Novell NetWare inherits its File::Spec behaviour from File::Spec::Win32.

File::Temp

return name and handle of a temporary file safely

VERSION

version 0.2312

SYNOPSIS

```
use File::Temp qw/ tempfile tempdir /;

$fh = tempfile();
($fh, $filename) = tempfile();

($fh, $filename) = tempfile( $template, DIR => $dir);
($fh, $filename) = tempfile( $template, SUFFIX => '.dat');
($fh, $filename) = tempfile( $template, TMPDIR => 1 );

binmode( $fh, ":utf8" );

$dir = tempdir( CLEANUP => 1 );
($fh, $filename) = tempfile( DIR => $dir );
```

Object interface:

```
require File::Temp;
use File::Temp ();
use File::Temp qw/ :seekable /;

$fh = File::Temp->new();
$fname = $fh->filename;

$fh = File::Temp->new(TEMPLATE => $template);
$fname = $fh->filename;

$tmp = File::Temp->new( UNLINK => 0, SUFFIX => '.dat' );
print $tmp "Some data\n";
print "Filename is $tmp\n";
$tmp->seek( 0, SEEK_END );

$dir = File::Temp->newdir(); # CLEANUP => 1 by default
```

The following interfaces are provided for compatibility with existing APIs. They should not be used in new code.

MkTemp family:

```
use File::Temp qw/ :mktemp  /;

($fh, $file) = mkstemp( "tmpfileXXXXX" );
($fh, $file) = mkstemps( "tmpfileXXXXXX", $suffix);

$tmpdir = mkdtemp( $template );

$unopened_file = mktemp( $template );
```

POSIX functions:

```
use File::Temp qw/ :POSIX /;

$file = tmpnam();
$fh = tmpfile();

($fh, $file) = tmpnam();
```

Compatibility functions:

```
$unopened_file = File::Temp::tempnam( $dir, $pfx );
```

DESCRIPTION

`File::Temp` can be used to create and open temporary files in a safe way. There is both a function interface and an object-oriented interface. The File::Temp constructor or the tempfile() function can be used to return the name and the open filehandle of a temporary file. The tempdir() function can be used to create a temporary directory.

The security aspect of temporary file creation is emphasized such that a filehandle and filename are returned together. This helps guarantee that a race condition can not occur where the temporary file is created by another process between checking for the existence of the file and its opening. Additional security levels are provided to check, for example, that the sticky bit is set on world writable directories. See “safe_level” for more information.

For compatibility with popular C library functions, Perl implementations of the mkstemp() family of functions are provided. These are, mkstemp(), mkstemps(), mkdtemp() and mktemp().

Additionally, implementations of the standard *POSIX* tmpnam() and tmpfile() functions are provided if required.

Implementations of mktemp(), tmpnam(), and tempnam() are provided, but should be used with caution since they return only a filename that was valid when function was called, so cannot guarantee that the file will not exist by the time the caller opens the filename.

Filehandles returned by these functions support the seekable methods.

OBJECT-ORIENTED INTERFACE

This is the primary interface for interacting with `File::Temp`. Using the OO interface a temporary file can be created when the object is constructed and the file can be removed when the object is no longer required.

Note that there is no method to obtain the filehandle from the `File::Temp` object. The object itself acts as a filehandle. The object isa `IO::Handle` and isa `IO::Seekable` so all those methods are available.

Also, the object is configured such that it stringifies to the name of the temporary file and so can be compared to a filename directly. It numifies to the `refaddr` the same as other handles and so can be compared to other handles with ==.

```
$fh eq $filename        # as a string
$fh != \*STDOUT         # as a number
```

Available since 0.14.

- **new**

  Create a temporary file object.

  ```
  my $tmp = File::Temp->new();
  ```

  by default the object is constructed as if `tempfile` was called without options, but with the additional behaviour that the temporary file is removed by the object destructor if UNLINK is set to true (the default).

  Supported arguments are the same as for `tempfile`: UNLINK (defaulting to true), DIR, EXLOCK, PERMS and SUFFIX. Additionally, the filename template is specified using the TEMPLATE option. The OPEN option is not supported (the file is always opened).

```
$tmp = File::Temp->new( TEMPLATE => 'tempXXXXX',
                        DIR => 'mydir',
                        SUFFIX => '.dat');
```

Arguments are case insensitive.

Can call croak() if an error occurs.

Available since 0.14.

TEMPLATE available since 0.23

- **newdir**

  Create a temporary directory using an object oriented interface.

```
$dir = File::Temp->newdir();
```

  By default the directory is deleted when the object goes out of scope.

  Supports the same options as the `tempdir` function. Note that directories created with this method default to CLEANUP => 1.

```
$dir = File::Temp->newdir( $template, %options );
```

  A template may be specified either with a leading template or with a TEMPLATE argument.

  Available since 0.19.

  TEMPLATE available since 0.23.

- **filename**

  Return the name of the temporary file associated with this object (if the object was created using the "new" constructor).

```
$filename = $tmp->filename;
```

  This method is called automatically when the object is used as a string.

  Current API available since 0.14

- **dirname**

  Return the name of the temporary directory associated with this object (if the object was created using the "newdir" constructor).

```
$dirname = $tmpdir->dirname;
```

  This method is called automatically when the object is used in string context.

- **unlink_on_destroy**

  Control whether the file is unlinked when the object goes out of scope. The file is removed if this value is true and $KEEP_ALL is not.

```
$fh->unlink_on_destroy( 1 );
```

Default is for the file to be removed.

Current API available since 0.15

- **DESTROY**

  When the object goes out of scope, the destructor is called. This destructor will attempt to unlink the file (using unlink1) if the constructor was called with UNLINK set to 1 (the default state if UNLINK is not specified).

  No error is given if the unlink fails.

  If the object has been passed to a child process during a fork, the file will be deleted when the object goes out of scope in the parent.

  For a temporary directory object the directory will be removed unless the CLEANUP argument was used in the constructor (and set to false) or `unlink_on_destroy` was modified after creation. Note that if a temp directory is your current directory, it cannot be removed - a warning will be given in this case. `chdir()` out of the directory before letting the object go out of scope.

  If the global variable $KEEP_ALL is true, the file or directory will not be removed.

FUNCTIONS

This section describes the recommended interface for generating temporary files and directories.

- **tempfile**

  This is the basic function to generate temporary files. The behaviour of the file can be changed using various options:

```
$fh = tempfile();
($fh, $filename) = tempfile();
```

  Create a temporary file in the directory specified for temporary files, as specified by the tmpdir() function in *File::Spec*.

```
($fh, $filename) = tempfile($template);
```

  Create a temporary file in the current directory using the supplied template. Trailing `X' characters are replaced with random letters to generate the filename. At least four `X' characters must be present at the end of the template.

```
($fh, $filename) = tempfile($template, SUFFIX => $suffix)
```

  Same as previously, except that a suffix is added to the template after the `X' translation. Useful for ensuring that a temporary filename has a particular extension when needed by other applications. But see the WARNING at the end.

```
($fh, $filename) = tempfile($template, DIR => $dir);
```

  Translates the template as before except that a directory name is specified.

```
($fh, $filename) = tempfile($template, TMPDIR => 1);
```

Equivalent to specifying a DIR of "File::Spec->tmpdir", writing the file into the same temporary directory as would be used if no template was specified at all.

```
($fh, $filename) = tempfile($template, UNLINK => 1);
```

Return the filename and filehandle as before except that the file is automatically removed when the program exits (dependent on $KEEP_ALL). Default is for the file to be removed if a file handle is requested and to be kept if the filename is requested. In a scalar context (where no filename is returned) the file is always deleted either (depending on the operating system) on exit or when it is closed (unless $KEEP_ALL is true when the temp file is created).

Use the object-oriented interface if fine-grained control of when a file is removed is required.

If the template is not specified, a template is always automatically generated. This temporary file is placed in tmpdir() (*File::Spec*) unless a directory is specified explicitly with the DIR option.

```
$fh = tempfile( DIR => $dir );
```

If called in scalar context, only the filehandle is returned and the file will automatically be deleted when closed on operating systems that support this (see the description of tmpfile() elsewhere in this document). This is the preferred mode of operation, as if you only have a filehandle, you can never create a race condition by fumbling with the filename. On systems that can not unlink an open file or can not mark a file as temporary when it is opened (for example, Windows NT uses the `O_TEMPORARY` flag) the file is marked for deletion when the program ends (equivalent to setting UNLINK to 1). The `UNLINK` flag is ignored if present.

```
(undef, $filename) = tempfile($template, OPEN => 0);
```

This will return the filename based on the template but will not open this file. Cannot be used in conjunction with UNLINK set to true. Default is to always open the file to protect from possible race conditions. A warning is issued if warnings are turned on. Consider using the tmpnam() and mktemp() functions described elsewhere in this document if opening the file is not required.

To open the temporary filehandle with O_EXLOCK (open with exclusive file lock) use `EXLOCK=>1`. This is supported only by some operating systems (most notably BSD derived systems). By default EXLOCK will be false. Former `File::Temp` versions set EXLOCK to true, so to be sure to get an unlocked filehandle also with older versions, explicitly set `EXLOCK=>0`.

```
($fh, $filename) = tempfile($template, EXLOCK => 1);
```

By default, the temp file is created with 0600 file permissions. Use `PERMS` to change this:

```
($fh, $filename) = tempfile($template, PERMS => 0666);
```

Options can be combined as required.

Will croak() if there is an error.

Available since 0.05.

UNLINK flag available since 0.10.

TMPDIR flag available since 0.19.

EXLOCK flag available since 0.19.

PERMS flag available since 0.2310.

- **tempdir**

  This is the recommended interface for creation of temporary directories. By default the directory will not be removed on exit (that is, it won't be temporary; this behaviour can not be changed because of issues with backwards compatibility). To enable removal either use the CLEANUP option which will trigger removal on program exit, or consider using the "newdir" method in the object interface which will allow the directory to be cleaned up when the object goes out of scope.

  The behaviour of the function depends on the arguments:

```
$tempdir = tempdir();
```

  Create a directory in tmpdir() (see *File::Spec*).

```
$tempdir = tempdir( $template );
```

  Create a directory from the supplied template. This template is similar to that described for tempfile(). `X' characters at the end of the template are replaced with random letters to construct the directory name. At least four `X' characters must be in the template.

```
$tempdir = tempdir ( DIR => $dir );
```

  Specifies the directory to use for the temporary directory. The temporary directory name is derived from an internal template.

```
$tempdir = tempdir ( $template, DIR => $dir );
```

  Prepend the supplied directory name to the template. The template should not include parent directory specifications itself. Any parent directory specifications are removed from the template before prepending the supplied directory.

```
$tempdir = tempdir ( $template, TMPDIR => 1 );
```

  Using the supplied template, create the temporary directory in a standard location for temporary files. Equivalent to doing

```
$tempdir = tempdir ( $template, DIR => File::Spec->tmpdir);
```

  but shorter. Parent directory specifications are stripped from the template itself. The `TMPDIR` option is ignored if `DIR` is set explicitly. Additionally, `TMPDIR` is implied if neither a template nor a directory are supplied.

```
$tempdir = tempdir( $template, CLEANUP => 1);
```

Create a temporary directory using the supplied template, but attempt to remove it (and all files inside it) when the program exits. Note that an attempt will be made to remove all files from the directory even if they were not created by this module (otherwise why ask to clean it up?). The directory removal is made with the rmtree() function from the *File::Path* module. Of course, if the template is not specified, the temporary directory will be created in tmpdir() and will also be removed at program exit.

Will croak() if there is an error.

Current API available since 0.05.

MKTEMP FUNCTIONS

The following functions are Perl implementations of the mktemp() family of temp file generation system calls.

- **mkstemp**

  Given a template, returns a filehandle to the temporary file and the name of the file.

```
($fh, $name) = mkstemp( $template );
```

  In scalar context, just the filehandle is returned.

  The template may be any filename with some number of X's appended to it, for example `/tmp/temp.XXXX`. The trailing X's are replaced with unique alphanumeric combinations.

  Will croak() if there is an error.

  Current API available since 0.05.

- **mkstemps**

  Similar to mkstemp(), except that an extra argument can be supplied with a suffix to be appended to the template.

```
($fh, $name) = mkstemps( $template, $suffix );
```

  For example a template of `testXXXXXX` and suffix of `.dat` would generate a file similar to `testhGji_w.dat`.

  Returns just the filehandle alone when called in scalar context.

  Will croak() if there is an error.

  Current API available since 0.05.

- **mkdtemp**

  Create a directory from a template. The template must end in X's that are replaced by the routine.

```
$tmpdir_name = mkdtemp($template);
```

  Returns the name of the temporary directory created.

Directory must be removed by the caller.

Will croak() if there is an error.

Current API available since 0.05.

- **mktemp**

  Returns a valid temporary filename but does not guarantee that the file will not be opened by someone else.

```
$unopened_file = mktemp($template);
```

  Template is the same as that required by mkstemp().

  Will croak() if there is an error.

  Current API available since 0.05.

POSIX FUNCTIONS

This section describes the re-implementation of the tmpnam() and tmpfile() functions described in *POSIX* using the mkstemp() from this module.

Unlike the *POSIX* implementations, the directory used for the temporary file is not specified in a system include file (`P_tmpdir`) but simply depends on the choice of tmpdir() returned by *File::Spec*. On some implementations this location can be set using the `TMPDIR` environment variable, which may not be secure. If this is a problem, simply use mkstemp() and specify a template.

- **tmpnam**

  When called in scalar context, returns the full name (including path) of a temporary file (uses mktemp()). The only check is that the file does not already exist, but there is no guarantee that that condition will continue to apply.

```
$file = tmpnam();
```

  When called in list context, a filehandle to the open file and a filename are returned. This is achieved by calling mkstemp() after constructing a suitable template.

```
($fh, $file) = tmpnam();
```

  If possible, this form should be used to prevent possible race conditions.

  See *"tmpdir" in File::Spec* for information on the choice of temporary directory for a particular operating system.

  Will croak() if there is an error.

  Current API available since 0.05.

- **tmpfile**

  Returns the filehandle of a temporary file.

```
$fh = tmpfile();
```

The file is removed when the filehandle is closed or when the program exits. No access to the filename is provided.

If the temporary file can not be created undef is returned. Currently this command will probably not work when the temporary directory is on an NFS file system.

Will croak() if there is an error.

Available since 0.05.

Returning undef if unable to create file added in 0.12.

ADDITIONAL FUNCTIONS

These functions are provided for backwards compatibility with common tempfile generation C library functions.

They are not exported and must be addressed using the full package name.

- **tempnam**

  Return the name of a temporary file in the specified directory using a prefix. The file is guaranteed not to exist at the time the function was called, but such guarantees are good for one clock tick only. Always use the proper form of `sysopen` with `O_CREAT | O_EXCL` if you must open such a filename.

```
$filename = File::Temp::tempnam( $dir, $prefix );
```

  Equivalent to running mktemp() with $dir/$prefixXXXXXXXX (using unix file convention as an example)

  Because this function uses mktemp(), it can suffer from race conditions.

  Will croak() if there is an error.

  Current API available since 0.05.

UTILITY FUNCTIONS

Useful functions for dealing with the filehandle and filename.

- **unlink0**

  Given an open filehandle and the associated filename, make a safe unlink. This is achieved by first checking that the filename and filehandle initially point to the same file and that the number of links to the file is 1 (all fields returned by stat() are compared). Then the filename is unlinked and the filehandle checked once again to verify that the number of links on that file is now 0. This is the closest you can come to making sure that the filename unlinked was the same as the file whose descriptor you hold.

```
unlink0($fh, $path)
   or die "Error unlinking file $path safely";
```

  Returns false on error but croaks() if there is a security anomaly. The filehandle is not closed since on some occasions this is not required.

On some platforms, for example Windows NT, it is not possible to unlink an open file (the file must be closed first). On those platforms, the actual unlinking is deferred until the program ends and good status is returned. A check is still performed to make sure that the filehandle and filename are pointing to the same thing (but not at the time the end block is executed since the deferred removal may not have access to the filehandle).

Additionally, on Windows NT not all the fields returned by stat() can be compared. For example, the `dev` and `rdev` fields seem to be different. Also, it seems that the size of the file returned by stat() does not always agree, with `stat(FH)` being more accurate than `stat(filename)`, presumably because of caching issues even when using autoflush (this is usually overcome by waiting a while after writing to the tempfile before attempting to `unlink0` it).

Finally, on NFS file systems the link count of the file handle does not always go to zero immediately after unlinking. Currently, this command is expected to fail on NFS disks.

This function is disabled if the global variable $KEEP_ALL is true and an unlink on open file is supported. If the unlink is to be deferred to the END block, the file is still registered for removal.

This function should not be called if you are using the object oriented interface since the it will interfere with the object destructor deleting the file.

Available Since 0.05.

If can not unlink open file, defer removal until later available since 0.06.

- **cmpstat**

  Compare `stat` of filehandle with `stat` of provided filename. This can be used to check that the filename and filehandle initially point to the same file and that the number of links to the file is 1 (all fields returned by stat() are compared).

```
cmpstat($fh, $path)
   or die "Error comparing handle with file";
```

  Returns false if the stat information differs or if the link count is greater than 1. Calls croak if there is a security anomaly.

  On certain platforms, for example Windows, not all the fields returned by stat() can be compared. For example, the `dev` and `rdev` fields seem to be different in Windows. Also, it seems that the size of the file returned by stat() does not always agree, with `stat(FH)` being more accurate than `stat(filename)`, presumably because of caching issues even when using autoflush (this is usually overcome by waiting a while after writing to the tempfile before attempting to `unlink0` it).

  Not exported by default.

  Current API available since 0.14.

- **unlink1**

  Similar to `unlink0` except after file comparison using cmpstat, the filehandle is closed prior to attempting to unlink the file. This allows the file to be removed without using an END block, but does mean that the post-unlink comparison of the filehandle state provided by `unlink0` is not available.

```
unlink1($fh, $path)
   or die "Error closing and unlinking file";
```

Usually called from the object destructor when using the OO interface.

Not exported by default.

This function is disabled if the global variable $KEEP_ALL is true.

Can call croak() if there is a security anomaly during the stat() comparison.

Current API available since 0.14.

- **cleanup**

  Calling this function will cause any temp files or temp directories that are registered for removal to be removed. This happens automatically when the process exits but can be triggered manually if the caller is sure that none of the temp files are required. This method can be registered as an Apache callback.

  Note that if a temp directory is your current directory, it cannot be removed. `chdir()` out of the directory first before calling `cleanup()`. (For the cleanup at program exit when the CLEANUP flag is set, this happens automatically.)

  On OSes where temp files are automatically removed when the temp file is closed, calling this function will have no effect other than to remove temporary directories (which may include temporary files).

```
File::Temp::cleanup();
```

  Not exported by default.

  Current API available since 0.15.

PACKAGE VARIABLES

These functions control the global state of the package.

- **safe_level**

  Controls the lengths to which the module will go to check the safety of the temporary file or directory before proceeding. Options are:

  – STANDARD

    Do the basic security measures to ensure the directory exists and is writable, that temporary files are opened only if they do not already exist, and that possible race conditions are avoided. Finally the unlink0 function is used to remove files safely.

  – MEDIUM

    In addition to the STANDARD security, the output directory is checked to make sure that it is owned either by root or the user running the program. If the directory is writable by group or by other, it is then checked to make sure that the sticky bit is set.

    Will not work on platforms that do not support the `-k` test for sticky bit.

– HIGH

In addition to the MEDIUM security checks, also check for the possibility of ``chown() giveaway'' using the *POSIX* sysconf() function. If this is a possibility, each directory in the path is checked in turn for safeness, recursively walking back to the root directory.

For platforms that do not support the *POSIX* `_PC_CHOWN_RESTRICTED` symbol (for example, Windows NT) it is assumed that ``chown() giveaway'' is possible and the recursive test is performed.

The level can be changed as follows:

```
File::Temp->safe_level( File::Temp::HIGH );
```

The level constants are not exported by the module.

Currently, you must be running at least perl v5.6.0 in order to run with MEDIUM or HIGH security. This is simply because the safety tests use functions from *Fcntl* that are not available in older versions of perl. The problem is that the version number for Fcntl is the same in perl 5.6.0 and in 5.005_03 even though they are different versions.

On systems that do not support the HIGH or MEDIUM safety levels (for example Win NT or OS/2) any attempt to change the level will be ignored. The decision to ignore rather than raise an exception allows portable programs to be written with high security in mind for the systems that can support this without those programs failing on systems where the extra tests are irrelevant.

If you really need to see whether the change has been accepted simply examine the return value of `safe_level`.

```
$newlevel = File::Temp->safe_level( File::Temp::HIGH );
die "Could not change to high security"
    if $newlevel != File::Temp::HIGH;
```

Available since 0.05.

- TopSystemUID

This is the highest UID on the current system that refers to a root UID. This is used to make sure that the temporary directory is owned by a system UID (`root`, `bin`, `sys` etc) rather than simply by root.

This is required since on many unix systems `/tmp` is not owned by root.

Default is to assume that any UID less than or equal to 10 is a root UID.

```
File::Temp->top_system_uid(10);
my $topid = File::Temp->top_system_uid;
```

This value can be adjusted to reduce security checking if required. The value is only relevant when `safe_level` is set to MEDIUM or higher.

Available since 0.05.

- **$KEEP_ALL**

Controls whether temporary files and directories should be retained regardless of any instructions in the program to remove them automatically. This is useful for debugging but should not be used in production code.

```
$File::Temp::KEEP_ALL = 1;
```

Default is for files to be removed as requested by the caller.

In some cases, files will only be retained if this variable is true when the file is created. This means that you can not create a temporary file, set this variable and expect the temp file to still be around when the program exits.

- **$DEBUG**

  Controls whether debugging messages should be enabled.

```
$File::Temp::DEBUG = 1;
```

  Default is for debugging mode to be disabled.

  Available since 0.15.

WARNING

For maximum security, endeavour always to avoid ever looking at, touching, or even imputing the existence of the filename. You do not know that that filename is connected to the same file as the handle you have, and attempts to check this can only trigger more race conditions. It's far more secure to use the filehandle alone and dispense with the filename altogether.

If you need to pass the handle to something that expects a filename then on a unix system you can use `"/dev/fd/" . fileno($fh)` for arbitrary programs. Perl code that uses the 2-argument version of open can be passed `"+<=&" . fileno($fh)`. Otherwise you will need to pass the filename. You will have to clear the close-on-exec bit on that file descriptor before passing it to another process.

```
use Fcntl qw/F_SETFD F_GETFD/;
fcntl($tmpfh, F_SETFD, 0)
    or die "Can't clear close-on-exec flag on temp fh: $!\n";
```

Temporary files and NFS

Some problems are associated with using temporary files that reside on NFS file systems and it is recommended that a local filesystem is used whenever possible. Some of the security tests will most probably fail when the temp file is not local. Additionally, be aware that the performance of I/O operations over NFS will not be as good as for a local disk.

Forking

In some cases files created by File::Temp are removed from within an END block. Since END blocks are triggered when a child process exits (unless `POSIX::_exit()` is used by the child) File::Temp takes care to only remove those temp files created by a particular

process ID. This means that a child will not attempt to remove temp files created by the parent process.

If you are forking many processes in parallel that are all creating temporary files, you may need to reset the random number seed using srand(EXPR) in each child else all the children will attempt to walk through the same set of random file names and may well cause themselves to give up if they exceed the number of retry attempts.

Directory removal

Note that if you have chdir'ed into the temporary directory and it is subsequently cleaned up (either in the END block or as part of object destruction), then you will get a warning from File::Path::rmtree().

Taint mode

If you need to run code under taint mode, updating to the latest *File::Spec* is highly recommended. On Windows, if the directory given by File::Spec::tmpdir isn't writable, File::Temp will attempt to fallback to the user's local application data directory or croak with an error.

BINMODE

The file returned by File::Temp will have been opened in binary mode if such a mode is available. If that is not correct, use the `binmode()` function to change the mode of the filehandle.

Note that you can modify the encoding of a file opened by File::Temp also by using `binmode()`.

HISTORY

In March 2000, the OpenBSD mkstemp() code was translated to Perl for total control of the code's security checking, to ensure the presence of the function regardless of operating system and to help with portability. The module was shipped as a standard part of perl from v5.6.1.

Thanks to Tom Christiansen for suggesting that this module should be written and providing ideas for code improvements and security enhancements.

File::Which

Perl implementation of the which utility as an API

VERSION

version 1.27

SYNOPSIS

```
use File::Which;                    # exports which()
use File::Which qw(which where);  # exports which() and where()

my $exe_path = which 'perldoc';

my @paths = where 'perl';
# Or
my @paths = which 'perl'; # an array forces search for all of them
```

DESCRIPTION

File::Which finds the full or relative paths to executable programs on the system. This is normally the function of `which` utility. `which` is typically implemented as either a program or a built in shell command. On some platforms, such as Microsoft Windows it is not provided as part of the core operating system. This module provides a consistent API to this functionality regardless of the underlying platform.

The focus of this module is correctness and portability. As a consequence platforms where the current directory is implicitly part of the search path such as Microsoft Windows will find executables in the current directory, whereas on platforms such as UNIX where this is not the case executables in the current directory will only be found if the current directory is explicitly added to the path.

If you need a portable `which` on the command line in an environment that does not provide it, install App::pwhich which provides a command line interface to this API.

Implementations

File::Which searches the directories of the user's `PATH` (the current implementation uses *File::Spec#path* to determine the correct `PATH`), looking for executable files having the name specified as a parameter to "which". Under Win32 systems, which do not have a notion of directly executable files, but uses special extensions such as `.exe` and `.bat` to identify them, `File::Which` takes extra steps to assure that you will find the correct file (so for example, you might be searching for `perl`, it'll try `perl.exe`, `perl.bat`, etc.)

Linux, *BSD and other UNIXes

There should not be any surprises here. The current directory will not be searched unless it is explicitly added to the path.

Modern Windows (including NT, XP, Vista, 7, 8, 10 etc)

Windows NT has a special environment variable called `PATHEXT`, which is used by the shell to look for executable files. Usually, it will contain a list in the form `.EXE;.BAT;.COM;.JS;.VBS` etc. If `File::Which` finds such an environment variable, it parses the list and uses it as the different extensions.

Cygwin

Cygwin provides a Unix-like environment for Microsoft Windows users. In most ways it works like other Unix and Unix-like environments, but in a few key aspects it works like Windows. As with other Unix environments, the current directory is not included in the search unless it is explicitly included in the search path. Like on Windows, files with `.EXE` or <.BAT> extensions will be discovered even if they are not part of the query. `.COM` or extensions specified using the `PATHEXT` environment variable will NOT be discovered without the fully qualified name, however.

Windows ME, 98, 95, MS-DOS, OS/2

This set of operating systems don't have the `PATHEXT` variable, and usually you will find executable files there with the extensions `.exe`, `.bat` and (less likely) `.com`. `File::Which` uses this hardcoded list if it's running under Win32 but does not find a `PATHEXT` variable.

As of 2015 none of these platforms are tested frequently (or perhaps ever), but the current maintainer is determined not to intentionally remove support for older operating systems.

VMS

Same case as Windows 9x: uses `.exe` and `.com` (in that order).

As of 2015 the current maintainer does not test on VMS, and is in fact not certain it has ever been tested on VMS. If this platform is important to you and you can help me verify and or support it on that platform please contact me.

FUNCTIONS

which

```
my $path = which $short_exe_name;
my @paths = which $short_exe_name;
```

Exported by default.

`$short_exe_name` is the name used in the shell to call the program (for example, `perl`).

If it finds an executable with the name you specified, `which()` will return the absolute path leading to this executable (for example, `/usr/bin/perl` or `C:\Perl\Bin\perl.exe`).

If it does *not* find the executable, it returns `undef`.

If `which()` is called in list context, it will return *all* the matches.

where

```
my @paths = where $short_exe_name;
```

Not exported by default.

Same as "which" in array context. Similar to the `where` csh built-in command or `which -a` command for platforms that support the `-a` option. Will return an array containing all the path names matching `$short_exe_name`.

GLOBALS

$IMPLICIT_CURRENT_DIR

True if the current directory is included in the search implicitly on whatever platform you are using. Normally the default is reasonable, but on Windows the current directory is included implicitly for older shells like `cmd.exe` and `command.com`, but not for newer shells like PowerShell. If you overrule this default, you should ALWAYS localize the variable to the tightest scope possible, since setting this variable from a module can affect other modules. Thus on Windows you can get the correct result if the user is running either `cmd.exe` or PowerShell on Windows you can do this:

```
use File::Which qw( which );
use Shell::Guess;

my $path = do {
  my $is_power = Shell::Guess->running_shell->is_power;
  local $File::Which::IMPLICIT_CURRENT_DIR = !$is_power;
  which 'foo';
};
```

For a variety of reasons it is difficult to accurately compute the shell that a user is using, but Shell::Guess makes a reasonable effort.

CAVEATS

This module has no non-core requirements for Perl 5.6.2 and better.

This module is fully supported back to Perl 5.8.1. It may work on 5.8.0. It should work on Perl 5.6.x and I may even test on 5.6.2. I will accept patches to maintain compatibility for such older Perls, but you may need to fix it on 5.6.x / 5.8.0 and send me a patch.

Not tested on VMS although there is platform specific code for those. Anyone who haves a second would be very kind to send me a report of how it went.

SUPPORT

Bugs should be reported via the GitHub issue tracker

https://github.com/uperl/File-Which/issues

For other issues, contact the maintainer.

SEE ALSO

- pwhich, App::pwhich

  Command line interface to this module.

- *IPC::Cmd*

  Requires Perl 5.8.3. Included as part of the Perl core as of 5.9.5.

  This module provides (among other things) a `can_run` function, which is similar to `which`. It is a much heavier module since it does a lot more, and if you use `can_run` it pulls in *ExtUtils::MakeMaker*. This combination may be overkill for applications which do not need *IPC::Cmd*'s complicated interface for running programs, or do not need the memory overhead required for installing Perl modules.

  At least some older versions will find executables in the current directory, even if the current directory is not in the search path (which is the default on modern Unix).

  `can_run` converts directory path name to the 8.3 version on Windows using `Win32::GetShortPathName` in some cases. This is frequently useful for tools that just need to run something using `system` in scalar mode, but may be inconvenient for tools like App::pwhich where user readability is a premium. Relying on `Win32::GetShortPathName` to produce filenames without spaces is problematic, as 8.3 filenames can be turned off with tweaks to the registry (see https://technet.microsoft.com/en-us/library/cc959352.aspx).

- Devel::CheckBin

  Requires Perl 5.8.1.

  This module purports to "check that a command is available", but does not provide any documentation on how you might use it.

  This module also relies on *ExtUtils::MakeMaker* so has the same overhead burdens as *IPC::Cmd*.

File::stat

by-name interface to Perl's built-in stat() functions

SYNOPSIS

```
use File::stat;
my $st = stat($file) or die "No $file: $!";
if ( ($st->mode & 0111) && ($st->nlink > 1) ) {
    print "$file is executable with lotsa links\n";
}

if ( -x $st ) {
    print "$file is executable\n";
}

use Fcntl "S_IRUSR";
if ( $st->cando(S_IRUSR, 1) ) {
    print "My effective uid can read $file\n";
}

use File::stat qw(:FIELDS);
stat($file) or die "No $file: $!";
if ( ($st_mode & 0111) && ($st_nlink > 1) ) {
    print "$file is executable with lotsa links\n";
}
```

DESCRIPTION

This module's default exports override the core stat() and lstat() functions, replacing them with versions that return "File::stat" objects. This object has methods that return the similarly named structure field name from the stat(2) function; namely, dev, ino, mode, nlink, uid, gid, rdev, size, atime, mtime, ctime, blksize, and blocks.

As of version 1.02 (provided with perl 5.12) the object provides `"-X"` overloading, so you can call filetest operators (`-f`, `-x`, and so on) on it. It also provides a `->cando` method, called like

```
$st->cando( ACCESS, EFFECTIVE )
```

where *ACCESS* is one of `S_IRUSR`, `S_IWUSR` or `S_IXUSR` from the *Fcntl* module, and *EFFECTIVE* indicates whether to use effective (true) or real (false) ids. The method interprets the `mode`, `uid` and `gid` fields, and returns whether or not the current process would be allowed the specified access.

If you don't want to use the objects, you may import the `->cando` method into your namespace as a regular function called `stat_cando`. This takes an arrayref containing the return values of `stat` or `lstat` as its first argument, and interprets it for you.

You may also import all the structure fields directly into your namespace as regular variables using the :FIELDS import tag. (Note that this still overrides your stat() and lstat() functions.) Access these fields as variables named with a preceding `st_` in front their method names. Thus, `$stat_obj->dev()` corresponds to $st_dev if you import the fields.

To access this functionality without the core overrides, pass the `use` an empty import list, and then access functions with their full qualified names:

```
use File::stat ();
my $st = File::stat::stat($file);
```

On the other hand, the built-ins are still available via the `CORE::` pseudo-package even if you let File::stat override them:

```
use File::stat;
my ($dev, $ino, $mode) = CORE::stat($file);
```

As of version 1.15 (provided with perl 5.44) `stat` and `lstat` can be called without arguments, in which case $_ is used (just like the built-in `stat`/`lstat` functions):

```
my $st_1 = stat;   # stat($_)
my $st_2 = lstat;  # lstat($_)
```

BUGS

The built-in `stat` and `lstat` functions recognize the special filehandle _ (underscore) to indicate that no actual `stat` be done; instead the results of the last `stat` or `lstat` or filetest operation should be returned. This syntax does not work with File::stat, but the same result can be achieved by passing `stat` a reference to the *_ typeglob:

```
use File::stat;
my $stat_obj = stat \*_;  # reuse results of last stat operation
```

Alternatively, another workaround is to explicitly populate the object using the unexported and undocumented populate() function with CORE::stat():

```
my $stat_obj = File::stat::populate(CORE::stat(_));
```

ERRORS

- -%s is not implemented on a File::stat object

  The filetest operators `-t`, `-T` and `-B` are not implemented, as they require more information than just a stat buffer.

WARNINGS

These can all be disabled with

```
no warnings "File::stat";
```

- File::stat ignores use filetest 'access'

  You have tried to use one of the `-rwxRWX` filetests with `use filetest 'access'` in effect. `File::stat` will ignore the pragma, and just use the information in the `mode` member as usual.

- File::stat ignores VMS ACLs

  VMS systems have a permissions structure that cannot be completely represented in a stat buffer, and unlike on other systems the builtin filetest operators respect this. The `File::stat` overloads, however, do not, since the information required is not available.

NOTE

While this class is currently implemented using the *Class::Struct* module to build a struct-like class, you shouldn't rely upon this.

AUTHOR

Tom Christiansen

5.2.45 FileCache

keep more files open than the system permits

SYNOPSIS

```
no strict 'refs';

use FileCache;
# or
use FileCache maxopen => 16;

cacheout $mode, $path;
# or
cacheout $path;
print $path @data;

$fh = cacheout $mode, $path;
# or
$fh = cacheout $path;
print $fh @data;
```

DESCRIPTION

The `cacheout` function will make sure that there's a filehandle open for reading or writing available as the pathname you give it. It automatically closes and re-opens files if you exceed your system's maximum number of file descriptors, or the suggested maximum *maxopen*.

- cacheout EXPR

  The 1-argument form of cacheout will open a file for writing (`'>'`) on it's first use, and appending (`'>>'`) thereafter.

  Returns EXPR on success for convenience. You may neglect the return value and manipulate EXPR as the filehandle directly if you prefer.

- cacheout MODE, EXPR

  The 2-argument form of cacheout will use the supplied mode for the initial and subsequent openings. Most valid modes for 3-argument open are supported namely; `'>'`, `'+>'`, `'<'`, `'<+'`, `'>>'`, `'|-'` and `'-|'`

  To pass supplemental arguments to a program opened with `'|-'` or `'-|'` append them to the command string as you would system EXPR.

  Returns EXPR on success for convenience. You may neglect the return value and manipulate EXPR as the filehandle directly if you prefer.

CAVEATS

While it is permissible to `close` a FileCache managed file, do not do so if you are calling `FileCache::cacheout` from a package other than which it was imported, or with another module which overrides `close`. If you must, use `FileCache::cacheout_close`.

Although FileCache can be used with piped opens ('-|' or '|-') doing so is strongly discouraged. If FileCache finds it necessary to close and then reopen a pipe, the command at the far end of the pipe will be reexecuted - the results of performing IO on FileCache'd pipes is unlikely to be what you expect. The ability to use FileCache on pipes may be removed in a future release.

FileCache does not store the current file offset if it finds it necessary to close a file. When the file is reopened, the offset will be as specified by the original open file mode. This could be construed to be a bug.

The module functionality relies on symbolic references, so things will break under 'use strict' unless 'no strict "refs"' is also specified.

BUGS

`sys/param.h` lies with its `NOFILE` define on some systems, so you may have to set *maxopen* yourself.

5.2.46 FileHandle

supply object methods for filehandles

SYNOPSIS

```
use FileHandle;

my $fh = FileHandle->new;
if ($fh->open("< file")) {
    print <$fh>;
    $fh->close;
}

my $fh = FileHandle->new("> FOO");
if (defined $fh) {
    print $fh "bar\n";
    $fh->close;
}

my $fh = FileHandle->new("file", "r");
if (defined $fh) {
    print <$fh>;
    undef $fh;       # automatically closes the file
}

my $fh = FileHandle->new("file", O_WRONLY|O_APPEND);
if (defined $fh) {
    print $fh "corge\n";
    undef $fh;       # automatically closes the file
}

my $pos = $fh->getpos;
$fh->setpos($pos);

$fh->setvbuf(my $buffer_var, _IOLBF, 1024);

my ($readfh, $writefh) = FileHandle::pipe;

autoflush STDOUT 1;
```

DESCRIPTION

NOTE: This class is now a front-end to the IO::* classes.

`FileHandle::new` creates a `FileHandle`, which is a reference to a newly created symbol (see the *Symbol* package). If it receives any parameters, they are passed to `FileHandle::open`; if the open fails, the `FileHandle` object is destroyed. Otherwise, it is returned to the caller.

`FileHandle::new_from_fd` creates a `FileHandle` like `new` does. It requires two parameters, which are passed to `FileHandle::fdopen`; if the fdopen fails, the `FileHandle` object is destroyed. Otherwise, it is returned to the caller.

`FileHandle::open` accepts one parameter or two. With one parameter, it is just a front end for the built-in open function. With two parameters, the first parameter is a file-

name that may include whitespace or other special characters, and the second parameter is the open mode, optionally followed by a file permission value.

If `FileHandle::open` receives a Perl mode string (">", "+<", etc.) or a POSIX fopen() mode string ("w", "r+", etc.), it uses the basic Perl open operator.

If `FileHandle::open` is given a numeric mode, it passes that mode and the optional permissions value to the Perl `sysopen` operator. For convenience, `FileHandle::import` tries to import the O_XXX constants from the Fcntl module. If dynamic loading is not available, this may fail, but the rest of FileHandle will still work.

`FileHandle::fdopen` is like open except that its first parameter is not a filename but rather a file handle name, a FileHandle object, or a file descriptor number.

If the C functions fgetpos() and fsetpos() are available, then `FileHandle::getpos` returns an opaque value that represents the current position of the FileHandle, and `FileHandle::setpos` uses that value to return to a previously visited position.

If the C function setvbuf() is available, then `FileHandle::setvbuf` sets the buffering policy for the FileHandle. The calling sequence for the Perl function is the same as its C counterpart, including the macros `_IOFBF`, `_IOLBF`, and `_IONBF`, except that the buffer parameter specifies a scalar variable to use as a buffer. WARNING: A variable used as a buffer by `FileHandle::setvbuf` must not be modified in any way until the FileHandle is closed or until `FileHandle::setvbuf` is called again, or memory corruption may result!

See *perlfunc* for complete descriptions of each of the following supported `FileHandle` methods, which are just front ends for the corresponding built-in functions:

```
close
fileno
getc
gets
eof
clearerr
seek
tell
```

See *perlvar* for complete descriptions of each of the following supported `FileHandle` methods:

```
autoflush
output_field_separator
output_record_separator
input_record_separator
input_line_number
format_page_number
format_lines_per_page
format_lines_left
format_name
format_top_name
format_line_break_characters
format_formfeed
```

Furthermore, for doing normal I/O you might need these:

- $fh->print

  See *"print" in perlfunc*.

- $fh->printf

  See *"printf" in perlfunc*.

- $fh->getline

  This works like <$fh> described in *"I/O Operators" in perlop* except that it's more readable and can be safely called in a list context but still returns just one line.

- $fh->getlines

  This works like <$fh> when called in a list context to read all the remaining lines in a file, except that it's more readable. It will also croak() if accidentally called in a scalar context.

There are many other functions available since FileHandle is descended from IO::File, IO::Seekable, and IO::Handle. Please see those respective pages for documentation on more functions.

SEE ALSO

The **IO** extension, *perlfunc*, *"I/O Operators" in perlop*.

5.2.47 Filter

Namespace containing the following modules:

- `Filter::Simple` - Simplified source filtering
- `Filter::Util`
- `Filter::cpp` - cpp source filter
- `Filter::decrypt` - A sample decrypting source filter: the source after `use Filter::decrypt` is XOR-ed with "Perl" as the compiler reads it.
- `Filter::exec` - exec source filter
- `Filter::m4` - M4 source filter
- `Filter::sh` - sh source filter
- `Filter::tee` - Copies the source that follows `use Filter::tee` to a file, as the compiler reads it.

Filter::Simple

Simplified source filtering

SYNOPSIS

```
# in MyFilter.pm:

    package MyFilter;
```

(continues on next page)

(continued from previous page)

```
    use Filter::Simple;

    FILTER { ... };

    # or just:
    #
    # use Filter::Simple sub { ... };

# in user's code:

    use MyFilter;

    # this code is filtered

    no MyFilter;

    # this code is not
```

DESCRIPTION

The Problem

Source filtering is an immensely powerful feature of recent versions of Perl. It allows one to extend the language itself (e.g. the Switch module), to simplify the language (e.g. Language::Pythonesque), or to completely recast the language (e.g. Lingua::Romana::Perligata). Effectively, it allows one to use the full power of Perl as its own, recursively applied, macro language.

The excellent Filter::Util::Call module (by Paul Marquess) provides a usable Perl interface to source filtering, but it is often too powerful and not nearly as simple as it could be.

To use the module it is necessary to do the following:

1. Download, build, and install the Filter::Util::Call module. (If you have Perl 5.7.1 or later, this is already done for you.)
2. Set up a module that does a `use Filter::Util::Call`.
3. Within that module, create an `import` subroutine.
4. Within the `import` subroutine do a call to `filter_add`, passing it either a subroutine reference.
5. Within the subroutine reference, call `filter_read` or `filter_read_exact` to "prime" $_ with source code data from the source file that will `use` your module. Check the status value returned to see if any source code was actually read in.
6. Process the contents of $_ to change the source code in the desired manner.
7. Return the status value.
8. If the act of unimporting your module (via a no) should cause source code filtering to cease, create an `unimport` subroutine, and have it call `filter_del`. Make sure

that the call to `filter_read` or `filter_read_exact` in step 5 will not accidentally read past the no. Effectively this limits source code filters to line-by-line operation, unless the `import` subroutine does some fancy pre-pre-parsing of the source code it's filtering.

For example, here is a minimal source code filter in a module named BANG.pm. It simply converts every occurrence of the sequence `BANG\s+BANG` to the sequence `die 'BANG' if $BANG` in any piece of code following a `use BANG;` statement (until the next `no BANG;` statement, if any):

```
package BANG;

use Filter::Util::Call ;

sub import {
    filter_add( sub {
    my $caller = caller;
    my ($status, $no_seen, $data);
    while ($status = filter_read()) {
        if (/^\s*no\s+$caller\s*;\s*?$/) {
            $no_seen=1;
            last;
        }
        $data .= $_;
        $_ = "";
    }
    $_ = $data;
    s/BANG\s+BANG/die 'BANG' if \$BANG/g
        unless $status < 0;
    $_ .= "no $class;\n" if $no_seen;
    return 1;
    })
}

sub unimport {
    filter_del();
}

1 ;
```

This level of sophistication puts filtering out of the reach of many programmers.

A Solution

The Filter::Simple module provides a simplified interface to Filter::Util::Call; one that is sufficient for most common cases.

Instead of the above process, with Filter::Simple the task of setting up a source code filter is reduced to:

1. Download and install the Filter::Simple module. (If you have Perl 5.7.1 or later, this is already done for you.)

2. Set up a module that does a `use Filter::Simple` and then calls `FILTER { ... }`.
3. Within the anonymous subroutine or block that is passed to `FILTER`, process the contents of `$_` to change the source code in the desired manner.

In other words, the previous example, would become:

```
package BANG;
use Filter::Simple;

FILTER {
    s/BANG\s+BANG/die 'BANG' if \$BANG/g;
};

1 ;
```

Note that the source code is passed as a single string, so any regex that uses `^` or `$` to detect line boundaries will need the `/m` flag.

Disabling or changing <no> behaviour

By default, the installed filter only filters up to a line consisting of one of the three standard source "terminators":

```
no ModuleName;  # optional comment
```

or:

```
__END__
```

or:

```
__DATA__
```

but this can be altered by passing a second argument to `use Filter::Simple` or `FILTER` (just remember: there's *no* comma after the initial block when you use `FILTER`).

That second argument may be either a `qr`'d regular expression (which is then used to match the terminator line), or a defined false value (which indicates that no terminator line should be looked for), or a reference to a hash (in which case the terminator is the value associated with the key `'terminator'`.

For example, to cause the previous filter to filter only up to a line of the form:

```
GNAB esu;
```

you would write:

```
package BANG;
use Filter::Simple;

FILTER {
    s/BANG\s+BANG/die 'BANG' if \$BANG/g;
```

(continues on next page)

(continued from previous page)

```
}
qr/^\s*GNAB\s+esu\s*;\s*?$/;
```

or:

```
FILTER {
    s/BANG\s+BANG/die 'BANG' if \$BANG/g;
}
{ terminator => qr/^\s*GNAB\s+esu\s*;\s*?$/ };
```

and to prevent the filter's being turned off in any way:

```
package BANG;
use Filter::Simple;

FILTER {
    s/BANG\s+BANG/die 'BANG' if \$BANG/g;
}
"";    # or: 0
```

or:

```
FILTER {
    s/BANG\s+BANG/die 'BANG' if \$BANG/g;
}
{ terminator => "" };
```

Note that, no matter what you set the terminator pattern to, the actual terminator itself *must* be contained on a single source line.

All-in-one interface

Separating the loading of Filter::Simple:

```
use Filter::Simple;
```

from the setting up of the filtering:

```
FILTER { ... };
```

is useful because it allows other code (typically parser support code or caching variables) to be defined before the filter is invoked. However, there is often no need for such a separation.

In those cases, it is easier to just append the filtering subroutine and any terminator specification directly to the `use` statement that loads Filter::Simple, like so:

```
use Filter::Simple sub {
    s/BANG\s+BANG/die 'BANG' if \$BANG/g;
};
```

This is exactly the same as:

```
use Filter::Simple;
BEGIN {
    Filter::Simple::FILTER {
        s/BANG\s+BANG/die 'BANG' if \$BANG/g;
    };
}
```

except that the FILTER subroutine is not exported by Filter::Simple.

Filtering only specific components of source code

One of the problems with a filter like:

```
use Filter::Simple;

FILTER { s/BANG\s+BANG/die 'BANG' if \$BANG/g };
```

is that it indiscriminately applies the specified transformation to the entire text of your source program. So something like:

```
warn 'BANG BANG, YOU'RE DEAD';
BANG BANG;
```

will become:

```
warn 'die 'BANG' if $BANG, YOU'RE DEAD';
die 'BANG' if $BANG;
```

It is very common when filtering source to only want to apply the filter to the non-character-string parts of the code, or alternatively to *only* the character strings.

Filter::Simple supports this type of filtering by automatically exporting the FILTER_ONLY subroutine.

FILTER_ONLY takes a sequence of specifiers that install separate (and possibly multiple) filters that act on only parts of the source code. For example:

```
use Filter::Simple;

FILTER_ONLY
    code      => sub { s/BANG\s+BANG/die 'BANG' if \$BANG/g },
    quotelike => sub { s/BANG\s+BANG/CHITTY CHITTY/g };
```

The "code" subroutine will only be used to filter parts of the source code that are not quotelikes, POD, or __DATA__. The quotelike subroutine only filters Perl quotelikes (including here documents).

The full list of alternatives is:

- "code"

  Filters only those sections of the source code that are not quotelikes, POD, or __DATA__.

- `"code_no_comments"`

  Filters only those sections of the source code that are not quotelikes, POD, comments, or `__DATA__`.

- `"executable"`

  Filters only those sections of the source code that are not POD or `__DATA__`.

- `"executable_no_comments"`

  Filters only those sections of the source code that are not POD, comments, or `__DATA__`.

- `"quotelike"`

  Filters only Perl quotelikes (as interpreted by `&Text::Balanced::extract_quotelike`).

- `"string"`

  Filters only the string literal parts of a Perl quotelike (i.e. the contents of a string literal, either half of a `tr///`, the second half of an `s///`).

- `"regex"`

  Filters only the pattern literal parts of a Perl quotelike (i.e. the contents of a `qr//` or an `m//`, the first half of an `s///`).

- `"all"`

  Filters everything. Identical in effect to `FILTER`.

Except for `FILTER_ONLY code => sub {...}`, each of the component filters is called repeatedly, once for each component found in the source code.

Note that you can also apply two or more of the same type of filter in a single `FILTER_ONLY`. For example, here's a simple macro-preprocessor that is only applied within regexes, with a final debugging pass that prints the resulting source code:

```
use Regexp::Common;
FILTER_ONLY
    regex => sub { s/!\[/[^/g },
    regex => sub { s/%d/$RE{num}{int}/g },
    regex => sub { s/%f/$RE{num}{real}/g },
    all   => sub { print if $::DEBUG };
```

Filtering only the code parts of source code

Most source code ceases to be grammatically correct when it is broken up into the pieces between string literals and regexes. So the `'code'` and `'code_no_comments'` component filter behave slightly differently from the other partial filters described in the previous section.

Rather than calling the specified processor on each individual piece of code (i.e. on the bits between quotelikes), the `'code...'` partial filters operate on the entire source code, but with the quotelike bits (and, in the case of `'code_no_comments'`, the comments) "blanked out".

That is, a `'code...'` filter *replaces* each quoted string, quotelike, regex, POD, and __DATA__ section with a placeholder. The delimiters of this placeholder are the contents of the `$;` variable at the time the filter is applied (normally `"\034"`). The remaining four bytes are a unique identifier for the component being replaced.

This approach makes it comparatively easy to write code preprocessors without worrying about the form or contents of strings, regexes, etc.

For convenience, during a `'code...'` filtering operation, Filter::Simple provides a package variable (`$Filter::Simple::placeholder`) that contains a pre-compiled regex that matches any placeholder...and captures the identifier within the placeholder. Placeholders can be moved and re-ordered within the source code as needed.

In addition, a second package variable (`@Filter::Simple::components`) contains a list of the various pieces of `$_`, as they were originally split up to allow placeholders to be inserted.

Once the filtering has been applied, the original strings, regexes, POD, etc. are re-inserted into the code, by replacing each placeholder with the corresponding original component (from `@components`). Note that this means that the `@components` variable must be treated with extreme care within the filter. The `@components` array stores the "back- translations" of each placeholder inserted into `$_`, as well as the interstitial source code between placeholders. If the placeholder backtranslations are altered in `@components`, they will be similarly changed when the placeholders are removed from `$_` after the filter is complete.

For example, the following filter detects concatenated pairs of strings/quotelikes and reverses the order in which they are concatenated:

```
package DemoRevCat;
use Filter::Simple;

FILTER_ONLY code => sub {
    my $ph = $Filter::Simple::placeholder;
    s{ ($ph) \s* [.] \s* ($ph) }{ $2.$1 }gx
};
```

Thus, the following code:

```
use DemoRevCat;

my $str = "abc" . q(def);

print "$str\n";
```

would become:

```
my $str = q(def)."abc";

print "$str\n";
```

and hence print:

```
defabc
```

Using Filter::Simple with an explicit `import` subroutine

Filter::Simple generates a special `import` subroutine for your module (see "How it works") which would normally replace any `import` subroutine you might have explicitly declared.

However, Filter::Simple is smart enough to notice your existing `import` and Do The Right Thing with it. That is, if you explicitly define an `import` subroutine in a package that's using Filter::Simple, that `import` subroutine will still be invoked immediately after any filter you install.

The only thing you have to remember is that the `import` subroutine *must* be declared *before* the filter is installed. If you use `FILTER` to install the filter:

```
package Filter::TurnItUpTo11;

use Filter::Simple;

FILTER { s/(\w+)/\U$1/ };
```

that will almost never be a problem, but if you install a filtering subroutine by passing it directly to the `use Filter::Simple` statement:

```
package Filter::TurnItUpTo11;

use Filter::Simple sub{ s/(\w+)/\U$1/ };
```

then you must make sure that your `import` subroutine appears before that `use` statement.

Using Filter::Simple and Exporter together

Likewise, Filter::Simple is also smart enough to Do The Right Thing if you use Exporter:

```
package Switch;
use base Exporter;
use Filter::Simple;

@EXPORT    = qw(switch case);
@EXPORT_OK = qw(given  when);

FILTER { $_ = magic_Perl_filter($_) }
```

Immediately after the filter has been applied to the source, Filter::Simple will pass control to Exporter, so it can do its magic too.

Of course, here too, Filter::Simple has to know you're using Exporter before it applies the filter. That's almost never a problem, but if you're nervous about it, you can guarantee that things will work correctly by ensuring that your `use base Exporter` always precedes your `use Filter::Simple`.

How it works

The Filter::Simple module exports into the package that calls `FILTER` (or `use`s it directly) – such as package "BANG" in the above example – two automagically constructed subroutines – `import` and `unimport` – which take care of all the nasty details.

In addition, the generated `import` subroutine passes its own argument list to the filtering subroutine, so the BANG.pm filter could easily be made parametric:

```
package BANG;

use Filter::Simple;

FILTER {
    my ($die_msg, $var_name) = @_;
    s/BANG\s+BANG/die '$die_msg' if \${$var_name}/g;
};

# and in some user code:

use BANG "BOOM", "BAM";  # "BANG BANG" becomes: die 'BOOM' if $BAM
```

The specified filtering subroutine is called every time a `use BANG` is encountered, and passed all the source code following that call, up to either the next `no BANG;` (or whatever terminator you've set) or the end of the source file, whichever occurs first. By default, any `no BANG;` call must appear by itself on a separate line, or it is ignored.

and/or modified under the same terms as Perl itself.
```

Filter::Util

Namespace containing the following modules:

- `Filter::Util::Call` - Framework for writing Perl *source filters* - modules that rewrite program text on the fly as the tokenizer reads it.
- `Filter::Util::Exec` - Source filters that run the source through a command: the text after the `use` line goes to the command's standard input, and the compiler reads what the command writes.

Filter::Util::Call

Framework for writing Perl *source filters* - modules that rewrite program text on the fly as the tokenizer reads it.

A source filter is a normal Perl module that registers a callback with the compiler. Each time the tokenizer needs more source, it calls back into the filter, which pulls raw text from the next filter in the chain (or the file), mangles it, and hands the result back. The compiler never sees the original bytes - it sees whatever the filter produces. This is the mechanism behind `Switch`, `Filter::Simple`, `PDL::NiceSlice`, `Smart::Comments`, and similar compile-time rewriters.

The filter lifecycle

A filter goes through three phases. Each phase corresponds to one of the primary functions exported by this module:

- **Install** - the filter's `import` is called when Perl processes `use MyFilter`. `import` calls `filter_add` to register itself with the compiler. From this point on the compiler will route every read through the filter.
- **Read** - each time the compiler wants more source, it invokes the filter's `filter` method (or anonymous sub). The filter calls `filter_read` (line mode) or `filter_read_exact` (block mode) to pull raw text from the chain below, transforms it in `$_`, and returns a status: positive for "more data", `0` for EOF, negative for error.
- **Remove** - when the filter decides it is done (for example on seeing an end-marker in the source), it calls `filter_del`. The compiler then reads directly from whatever filter - or file - sat below it in the chain.

The two filter shapes

A filter is either a **method filter** (a blessed object whose class provides a `filter` method) or a **closure filter** (an anonymous sub passed directly to `filter_add`). The two shapes carry context differently - method filters stash state on the object, closure filters close over lexicals - but the read/return contract is identical in both cases.

Shared conventions

- `$_` is the filter's scratch buffer. It is cleared before the filter's `filter` is called; `filter_read` appends to it; the transformed contents of `$_` on return are what the compiler sees.

- The status code is three-valued: `> 0` success, `= 0` EOF, `< 0` error. Check it after every read.
- Filters only run at compile time. Calling `filter_add` while nothing is being compiled (at run time, outside a `BEGIN` or a string `eval`) installs nothing, because there is no parser to register with.

Skeleton

```
package MyFilter;
use Filter::Util::Call;

sub import {
    filter_add(bless []);         # method filter
}

sub filter {
    my ($self) = @_;
    my $status = filter_read();
    s/old/new/g if $status > 0;   # rewrite $_
    $status;
}
1;
```

filter_add and filter_read_exact

These two are Call.pm's own Perl, unchanged:

- `filter_add($obj)` installs a filter for the calling package. A `CODE` reference is a closure filter. Anything else is a method filter: a plain scalar, or a reference whose `ref` is exactly `ARRAY` or `HASH`, is wrapped as a scalar reference blessed into the caller's package; a blessed reference - an object built on an array or a hash included - is used as it is.
- `filter_read_exact($size)` calls `filter_read` until `$_` holds `$size` bytes or the chain reports EOF or an error. It returns 1 for EOF with data still in `$_`, and croaks `filter_read_exact: size parameter must be > 0` for a size that is not positive.

This is a native implementation of the XS half of Filter::Util::Call 1.65; its `Filter/Util/Call.pm` is used unchanged.

Differences from upstream

One, where perl 5.44 with Call.xs crashes (t/81-xs-native/Filter-Util-Call/150-or-better.t):

- `filter_add` while nothing is being compiled installs nothing and leaves memory alone. Call.xs stores the filter's state in the slots of a handle the tokenizer never made, which are past the end of the string it allocated: it overwrites neighbouring variables, and perl5 can segfault.

Functions

Filter lifecycle

`filter_del`

Remove the calling filter from the active chain. Subsequent reads bypass it and hit the next filter down (or the source file).

`filter_add`

Install a source filter for the current package. Called from the filter module's `import`.

Input handling

`filter_read`

Pull the next line of source - or up to a given number of bytes - from the filter chain into `$_`.

`filter_read_exact`

Pull exactly `$size` bytes from the filter chain into `$_`, looping over short reads until the request is satisfied or the stream ends.

Internal dispatch

`real_import`

Low-level installer that wires a pre-blessed object or code ref into the tokenizer. Called by `filter_add` after it has determined the filter shape; not intended for direct user calls.

filter_read

Pull the next line of source - or up to a given number of bytes - from the filter chain into `$_`.

Synopsis

```
my $status = filter_read();         # line mode
my $status = filter_read($size);    # block mode, up to $size bytes
```

What you get back

An integer status, three-valued:

- `> 0` - more source was appended to `$_`.
- `= 0` - EOF: no more source is available from anything below this filter in the chain.
- `< 0` - a read error occurred.

The data is appended to `$_`, not returned. The caller's filter body then transforms `$_` and hands it back to the compiler by returning the same status.

In block mode, `filter_read($size)` may return fewer than `$size` bytes - short reads are normal. Use `filter_read_exact` when the filter needs a guaranteed block size.

Examples

A minimal filter that rewrites `Joe` to `Jim` line by line:

```
sub filter {
    my $status = filter_read();
    s/Joe/Jim/g if $status > 0;
    $status;
}
```

Block mode, processing a chunk at a time:

```
sub filter {
    my $status = filter_read(4096);
    s/secret/*****/g if $status > 0;
    $status;
}
```

Edge cases

- Calling `filter_read` from outside a filter's body (for example at module top level) has no useful effect - no parser is active to read from.
- On EOF, `$_` may still contain buffered data from an earlier partial read; the caller decides whether to flush it.

See also

- `filter_read_exact` - same, but insists on a full block.
- `filter_add` - installs the filter that `filter_read` reads under.
- `filter_del` - stops the current filter so subsequent reads go straight to the chain below.

real_import

Low-level installer that wires a pre-blessed object or code ref into the tokenizer. Called by `filter_add` after it has determined the filter shape; not intended for direct user calls.

Synopsis

```
Filter::Util::Call::real_import($object_or_coderef, $package, $is_
↪coderef);
```

What you get back

Nothing. `real_import` installs the filter as a side effect: the tokenizer now routes every read through it until `filter_del` is called or compilation of the enclosing file finishes.

The three arguments carry the state that the tokenizer will hand back to every `filter` invocation:

- `$object_or_coderef` - the blessed filter object (method filter) or the anonymous sub (closure filter).
- `$package` - the module name, used in diagnostic messages such as `"Filter::Util::Call - MyFilter::filter returned N values, 1 was expected"`.
- `$is_coderef` - true if the first argument is a code ref (the closure-filter shape), false if it is an object (the method-filter shape).

Edge cases

- If `real_import` runs while nothing is being compiled (for example at run time), it installs nothing: there is no parser to drive the filter.
- The module-name argument is copied into a C-string buffer that lives for the lifetime of the process; filter registrations are intentionally not reclaimed.

See also

- `filter_add` - the high-level entry point that prepares arguments and calls `real_import`.
- `unimport` - the inverse operation, exposed for `no MyFilter` idioms.

filter_del

Remove the calling filter from the active chain. Subsequent reads bypass it and hit the next filter down (or the source file).

Synopsis

```
filter_del();
```

What you get back

Nothing useful - `filter_del` is a statement, not an expression.

It does not stop the current `filter` invocation: the caller finishes its current call and returns a status to the compiler normally. Starting with the *next* read, the compiler skips this filter and reads from whatever sat below it in the chain.

Examples

Disable the filter as soon as a sentinel line is seen, so the compiler processes the rest of the file untouched:

```
sub filter {
    my $status = filter_read();
    if ($status > 0 && /^__END_FILTER__$/) {
        filter_del();
        $_ = '';     # drop the sentinel line itself
    }
    $status;
}
```

Edge cases

- Calling `filter_del` when no filter is active is a no-op.
- `filter_del` marks the filter inactive but does not free its per-filter state; the tokenizer releases that state when it tears down the parser at end of compilation.
- It takes no arguments.

See also

- `filter_add` - installs the filter that `filter_del` later removes.
- `filter_read` - normally called right before `filter_del` in the sentinel branch.

filter_read_exact

Pull exactly `$size` bytes from the filter chain into `$_`, looping over short reads until the request is satisfied or the stream ends.

Synopsis

```
my $status = filter_read_exact($size);
```

What you get back

An integer status using the same convention as `filter_read`:

- `> 0` - a full `$size`-byte block was read into `$_`.
- `= 0` - EOF reached with no pending data, or EOF reached with a partial block (the partial block is still in `$_`, and the status returned to the caller is 1 in that specific case to signal "there is data to process"). See the note below.
- `< 0` - a read error occurred.

`filter_read_exact` keeps calling `filter_read` internally until it has accumulated `$size` bytes or the chain reports EOF / error. It is the right choice for filters that operate on fixed-size frames (for example, a binary decoder).

Examples

Read 16-byte records until end of file:

```
sub filter {
    my $status = filter_read_exact(16);
    decode_record($_) if $status > 0;
    $status;
}
```

Edge cases

- `$size` must be strictly positive. Calling `filter_read_exact(0)` or with a negative argument croaks with "`filter_read_exact: size parameter must be > 0`".
- On EOF with a partially-filled `$_`, the returned status is 1, not `0` - this lets the filter process the tail of the stream before the next call reports true EOF.

Differences from upstream

Fully compatible with upstream `Filter::Util::Call` 1.65.

See also

- `filter_read` - the short-read variant; cheaper when the filter can tolerate partial reads.
- `filter_add` - every filter that calls `filter_read_exact` must first register itself with `filter_add`.

filter_add

Install a source filter for the current package. Called from the filter module's `import`.

Synopsis

```
filter_add($object);     # method filter: $object is blessed state
filter_add(sub { ... }); # closure filter: anonymous sub
```

What you get back

Nothing. `filter_add` registers the filter as a side effect; the compiler now routes every subsequent read through it until the filter calls `filter_del` or compilation of the enclosing file finishes.

The shape of the argument picks the filter style:

- A `CODE` reference - closure filter. The sub is called for every compiler read; state lives in lexicals captured by the closure.

- Anything else - method filter. If the argument is a plain scalar or an unblessed ARRAY / HASH reference, `filter_add` blesses a reference to it into the caller's package, so the caller's `filter` method receives it as `$self`. An already-blessed reference is used as-is.

Examples

A closure filter installed from `import`:

```
sub import {
    filter_add(sub {
        my $status = filter_read();
        tr/a-z/A-Z/ if $status > 0;
        $status;
    });
}
```

A method filter that carries a substitution count as its state:

```
sub import {
    my $count = 0;
    filter_add(bless \$count); # becomes $self in filter()
}
sub filter {
    my ($self) = @_;
    my $status = filter_read();
    $$self++ if s/Joe/Jim/g && $status > 0;
    $status;
}
```

Edge cases

- `filter_add` looks up the caller's package through `caller`, so it must be called from code in the filter module's package, normally its `import`. Invoking it from a helper in another package will bless the state object into that package.
- Source filters only act during compilation. Calling `filter_add` at runtime (outside any `use`/`BEGIN` chain) has no effect.
- Passing a plain scalar or an unblessed ARRAY / HASH reference is legal: `filter_add` wraps and blesses the value for you. Any other unblessed reference, such as a SCALAR reference, is installed unblessed, and the first read dies with `Can't call method "filter" on unblessed reference`.

Differences from upstream

Fully compatible with upstream `Filter::Util::Call` 1.65.

See also

- `filter_read` - the read primitive every filter body calls.
- `filter_del` - stop the filter from inside its own body.
- `Filter::Simple` - a higher-level wrapper around this module, preferred for new filters that do not need the fine-grained read control.

Filter::Util::Exec

Source filters that run the source through a command: the text after the `use` line goes to the command's standard input, and the compiler reads what the command writes.

Synopsis

```
use Filter::exec qw(tr a-z A-Z);     # the command and its arguments
use Filter::sh 'tr a-z A-Z';         # a command line for sh -c
use Filter::cpp;                     # the C preprocessor
use Filter::m4;                      # m4
```

How it works

`Filter::Util::Exec::filter_add($module, $command, @args)`, which those four modules call from their `import`, forks and runs the command with a pipe on each side and installs a source filter. Each time the compiler wants more source, the filter writes the next lines of the file into the command's input and reads what it has written back; when the file ends it closes the command's input, and when the command's output ends the filter removes itself. A command that cannot be run dies "execvp failed for command 'NAME': REASON".

This is a native implementation of `Exec.xs` of Filter 1.65 (its Unix branch); its `Filter/Util/Exec.pm` is used unchanged, and so are the `Filter::exec`, `Filter::sh`, `Filter::cpp` and `Filter::m4` built on it.

Differences from upstream

Two, each where perl 5.44 with Exec.xs crashes or loses the program (t/81-xs-native/Filter/150-or-better.t):

- `filter_add` while nothing is being compiled installs nothing and runs no command; perl5 segfaults.
- A command that stops reading before the end of the source (`head -n 1` on a file longer than the pipe holds) is read to the end of its output. perl5 dies of SIGPIPE without a word; with SIGPIPE ignored, it mostly drops what the command wrote and compiles an empty program.

Functions

Source filters

`filter_add`

Run a command as a coprocess and filter the rest of the source through it.

filter_add

Run a command as a coprocess and filter the rest of the source through it.

Synopsis

```
sub import {
    my ($self, @args) = @_;
    Filter::Util::Exec::filter_add($self, 'sh', '-c', "@args");
}
```

What you get back

Nothing. The first argument is the calling module (unused); the command is looked up in PATH and gets the rest as its arguments. The filter reads the source from the line after the `use` that called the `import`.

Filter::cpp

cpp source filter

SYNOPSIS

```
use Filter::cpp ;
```

DESCRIPTION

This source filter pipes the current source file through the C pre-processor (cpp) if it is available.

As with all source filters its scope is limited to the current source file only. Every file you want to be processed by the filter must have a

```
use Filter::cpp ;
```

near the top.

Here is an example script which uses the filter:

```
use Filter::cpp ;

#define FRED 1
```

(continues on next page)

(continued from previous page)

```
$a = 2 + FRED ;
print "a = $a\n" ;
#ifdef FRED
print "Hello FRED\n" ;
#else
print "Where is FRED\n" ;
#endif
```

And here is what it will output:

```
a = 3
Hello FRED
```

This example below, provided by Michael G Schwern, shows a clever way to get Perl to use a C pre-processor macro when the Filter::cpp module is available, or to use a Perl sub when it is not.

```
# use Filter::cpp if we can.
BEGIN { eval 'use Filter::cpp' }

sub PRINT {
    my($string) = shift;

#define PRINT($string) \
    (print $string."\n")
}

PRINT("Mu");
```

Look at Michael's Tie::VecArray module for a practical use.

AUTHOR

Paul Marquess

DATE

11th December 1995.

Filter::decrypt

A sample decrypting source filter: the source after `use Filter::decrypt` is XOR-ed with "Perl" as the compiler reads it.

Synopsis

```
use Filter::decrypt;
```

The rest of the file is the output of the dist's `decrypt/encrypt` script: the two bytes 0xff 0x00, then the source, each block of four bytes XOR-ed with "Perl".

How it works

`import` installs a source filter. On its first read it checks the two-byte header ("truncated file", "bad encryption format") and that no filter was added on the `use` line after it ("too many filters"); then it reads four bytes at a time and serves the decrypted text by the line or the block, as the compiler asks. `import` dies "debugger disabled" under `perl -d`, and loading the module dies "Aborting, Compiler detected" once the compiler backend (`B`) is loaded.

The module is a template for a real decryption filter, not a protection: the decrypted source passes through memory, and `B::Deparse` can print what it compiled to.

This is a native implementation of `decrypt.xs` of Filter 1.65 as the dist builds it (`-DBYPASS`: no refusal of a dynamically linked module or of a perl built with -DDEBUGGING); its `Filter/decrypt.pm` is used unchanged.

Differences from upstream

One, where perl 5.44 with decrypt.xs crashes (t/81-xs-native/Filter/150-or-better.t):

- `Filter::decrypt->import` while nothing is being compiled installs nothing and leaves memory alone. decrypt.xs stores the filter's state in the slots of a handle the tokenizer never made, past the end of the string it allocated: it overwrites neighbouring variables, and perl5 can segfault.

Filter::exec

exec source filter

SYNOPSIS

```
use Filter::exec qw(command parameters) ;
```

DESCRIPTION

This filter pipes the current source file through the program which corresponds to the `command` parameter.

As with all source filters its scope is limited to the current source file only. Every file you want to be processed by the filter must have a

```
use Filter::exec qw(command ) ;
```

near the top.

Here is an example script which uses the filter:

```
use Filter::exec qw(tr XYZ PQR) ;
$a = 1 ;
print "XYZ a = $a\n" ;
```

And here is what it will output:

```
PQR = 1
```

WARNING

You should be *very* careful when using this filter. Because of the way the filter is implemented it is possible to end up with deadlock.

Be especially careful when stacking multiple instances of the filter in a single source file.

Filter::m4

M4 source filter

SYNOPSIS

```
use Filter::m4;
use Filter::m4 'prefix';
```

DESCRIPTION

This source filter pipes the current source file through the M4 macro processor (`m4`) if it is available.

As with all source filters its scope is limited to the current source file only. Every file you want to be processed by the filter must have the following line near the top.

```
use Filter::m4;
```

EXAMPLE

Here is a small example that shows how to define and use an M4 macro:

```
use Filter::m4;

define(`foo', `$1 =~ s/bar/baz/r')

$a = "foobar";
print "a = " . foo(`$a') . "\n";
```

The output of the above example:

```
a = foobaz
```

NOTES

By default, M4 uses ` and ‘ as quotes; however, this is configurable using M4's `changequote` builtin.

M4 uses `$1`, `$2`, etc., to indicate arguments in macros. To avoid clashes with Perl regex syntax it is recommended to use Perl's alternative forms `${1}`, `${1}`, etc.

The following keywords in M4 and Perl are identical:

```
eval
format
index
mkstemp
shift
substr
```

If you need such keywords in your Perl code you have to use one of the following three solutions.

- Protect the keyword with M4 quotes, for example `` `shift' ``.
- Redefine the problematic M4 builtin using `defn`, as outlined in section *Renaming macros* of the M4 info manual.
- Use the `prefix` option. This adds the prefix `m4_` to all M4 builtins (but not to user-defined macros). For example, you will have to use `m4_shift` instead of `shift`.

Filter::sh

sh source filter

SYNOPSIS

```
use Filter::sh 'command' ;
```

DESCRIPTION

This filter pipes the current source file through the program which corresponds to the `command` parameter using the Bourne shell.

As with all source filters its scope is limited to the current source file only. Every file you want to be processed by the filter must have a

```
use Filter::sh 'command' ;
```

near the top.

Here is an example script which uses the filter:

```
use Filter::sh 'tr XYZ PQR' ;
$a = 1 ;
print "XYZ a = $a\n" ;
```

And here is what it will output:

```
PQR = 1
```

WARNING

You should be *very* careful when using this filter. Because of the way the filter is implemented it is possible to end up with deadlock.

Be especially careful when stacking multiple instances of the filter in a single source file.

Filter::tee

Copies the source that follows `use Filter::tee` to a file, as the compiler reads it.

Synopsis

```
use Filter::tee 'filename';     # empty the file first, then write
use Filter::tee '>filename';    # the same
use Filter::tee '>>filename';   # append
```

How it works

`import` opens the file and installs a source filter. Each time the compiler reads more of the file being compiled, the filter passes the text on unchanged and writes a copy of it to the file; at the end of the source it closes the file and removes itself. Used after another filter (`use Filter::decrypt; use Filter::tee ...`), it copies what that filter produced, which is what makes it a debugging aid for filters.

This is a native implementation of `tee.xs` of Filter 1.65; its `Filter/tee.pm` is used unchanged.

Differences from upstream

None.

5.2.48 FindBin

Locate directory of original Perl script

SYNOPSIS

```
use FindBin;
use lib "$FindBin::Bin/../lib";

use FindBin qw($Bin);
use lib "$Bin/../lib";
```

DESCRIPTION

Locates the full path to the script bin directory to allow the use of paths relative to the bin directory.

This allows a user to setup a directory tree for some software with directories `<root>/bin` and `<root>/lib`, and then the above example will allow the use of modules in the lib directory without knowing where the software tree is installed.

If `perl` is invoked using the `-e` option or the Perl script is read from `STDIN`, then `FindBin` sets both `$Bin` and `$RealBin` to the current directory.

EXPORTABLE VARIABLES

- `$Bin` or `$Dir`

  Path to the bin **directory** from where script was invoked

- `$Script`

  Basename of the script from which `perl` was invoked

- `$RealBin` or `$RealDir`

  `$Bin` with all links resolved

- `$RealScript`

  `$Script` with all links resolved

You can also use the ALL tag to export all of the above variables together:

```
use FindBin ':ALL';
```

KNOWN ISSUES

If there are two modules using FindBin from different directories under the same interpreter, this won't work. Since FindBin uses a BEGIN block, it'll be executed only once, and only the first caller will get it right. This is a problem under mod_perl and other persistent Perl environments, where you shouldn't use this module. Which also means that you should avoid using FindBin in modules that you plan to put on CPAN. Call the again function to make sure that FindBin will work:

```
use FindBin;
FindBin::again(); # or FindBin->again;
```

In former versions of FindBin there was no again function. The workaround was to force the BEGIN block to be executed again:

```
delete $INC{'FindBin.pm'};
require FindBin;
```

AUTHORS

FindBin is supported as part of the core perl distribution. Please submit bug reports at https://github.com/Perl/perl5/issues.

5.2.49 GD

Perl bindings for libgd, the GD graphics library.

This is the GD module, version 2.91 of the CPAN API: the same packages, methods, arguments and return values that Perl code written against GD already expects. Drawing goes to the libgd.so.3 installed on the machine, which is located when the module is loaded; if that library is absent, use GD dies with a message naming the distribution package to install, as it does under a perl whose GD was never built.

```
use GD;

my $im    = GD::Image->new(200, 200, 1);   # 1 = truecolor
my $white = $im->colorAllocate(255, 255, 255);
my $blue  = $im->colorAllocate(0, 0, 255);
```

(continues on next page)

(continued from previous page)

```
$im->filledRectangle(0, 0, 199, 199, $white);
$im->line(0, 0, 199, 199, $blue);

open my $fh, '>', 'out.png' or die $!;
binmode $fh;
print $fh $im->png;
```

The colour index

GD's defining quirk is that you do not draw with a colour, you draw with the integer `colorAllocate` gives back. On a palette image that integer really is an index into a 256-entry table, and running out of entries makes `colorAllocate` return -1. On a true-color image - what you get by passing a true third argument to `new` - the integer is the packed colour itself and there is no limit, but the API keeps the same shape.

GD::Image

An image is either **palette** or **truecolor**, chosen when you make it, and the difference runs through the whole API:

```
my $palette   = GD::Image->new(200, 200);      # 256 colours, indexed
my $truecolor = GD::Image->new(200, 200, 1);   # 24-bit + alpha
```

Drawing

Note the shapes of the argument lists, which are not uniform and are the usual source of surprise. Rectangles take two corners; arcs and ellipses take a centre plus **width and height** (not a radius); `filledArc` adds start and end angles in degrees.

```
$im->line(0, 0, 199, 199, $blue);
$im->rectangle(10, 10, 60, 60, $blue);          # outline
$im->filledRectangle(70, 10, 120, 60, $red);    # solid
$im->arc(100, 100, 80, 80, 0, 360, $blue);      # centre, w, h, start, end
$im->filledArc(100, 100, 120, 60, 0, 180, $red);
$im->setPixel(5, 5, $blue);
$im->fill(30, 30, $red);                        # flood fill
```

Polygons are drawn from a `GD::Polygon`, and the special colour values `gdBrushed`, `gdStyled`, `gdTiled` and `gdAntiAliased` select the brush, style or tile you set beforehand instead of a plain colour.

Reading and writing

Output methods return the encoded bytes rather than writing a file, so you print them yourself:

```
open my $fh, '>', 'out.png' or die $!;
binmode $fh;
print $fh $im->png;             # or ->jpeg($quality), ->gif, ->webp
```

Reading goes through `newFrom<Format>` for a filehandle or `newFrom<Format>Data` for bytes you already have. Which formats work depends on how the installed libgd was built. `GD::Image->supported` lists them, `GD::supportsFileType('photo.webp')` answers for one file name, and the methods of a format this libgd lacks do not exist, so `GD::Image->can('newFromTiff')` is a test too. A GD built from source settles that when it is compiled; here it is settled when the module is loaded, by the libgd found then.

A reader dies when libgd cannot decode what it was given. The PNG, JPEG and TIFF readers, and `newFromBmpData` and `newFromWBMPData`, return palette images unless you pass a true final argument - `GD::Image->newFromPngData($bytes, 1)` - or have made truecolor the default with `GD::Image->trueColor(1)`.

GD::Font - the built-in bitmap fonts

libgd ships five fixed-size bitmap fonts, reached as class methods:

```
my $font = GD::Font->Small;
$image->string($font, 10, 10, 'hello', $black);
```

The five are `Tiny`, `Small`, `MediumBold`, `Large` and `Giant`, and `GD` also exports them as the functions `gdTinyFont`, `gdSmallFont`, `gdMediumBoldFont`, `gdLargeFont` and `gdGiantFont`, which is the spelling most existing code uses.

A font knows its own metrics: `$font->width` and `$font->height` are the size of one character cell, which is what you need to work out where a string will land, and `$font->nchars` and `$font->offset` describe which characters it covers.

These fonts are fixed-width bitmaps and cannot be scaled or rotated. For scalable text, use `$image->stringFT`, which draws with FreeType from a TrueType file at any size and angle.

What is native and what is Perl

GD is a large module whose pure-Perl half does real work: `GD::Polygon`, `GD::Polyline` and `GD::Simple` are Perl, and so is the filehandle plumbing behind `newFromPng` and friends. That half runs here exactly as it does on perl5, from the module's own source; only the parts that were C are native. So `GD::Simple->new(...)->moveTo(...)` behaves as its own documentation says, because it IS its own code.

Differences from upstream

Each where XS GD crashes, reads memory it does not own, or refuses what libgd can do (t/64-auto-ffi/332-gd-or-better.t):

- `cloneImage` after `filledPolygon` copies the image, where libgd's `gdImageClone` crashes on such an image.
- A `newFrom*` reader or an `affine*` constructor called with an argument short (through &, past the prototype) croaks its usage; GD.xs reads the missing argument from beyond the stack.

- `scatterColor` treats a colour that is not an integer as 0, and an empty colour list as no colours; GD.xs passes uninitialised memory for the one and a negative count for the other.
- The formats are the ones libgd reads, not the ones the module's build guessed from pkg-config: an XS GD may lack `newFromXpm` on a libgd that reads XPM.
- A method on an image whose `DESTROY` has run, or on the empty copy `Storable::dclone` makes of an image, croaks "not a live GD::Image"; GD.xs passes the NULL pointer to libgd.
- `GD::Font->load` refuses a font file whose header gives no characters or a negative size, as it refuses a file it cannot read; GD.xs trusts the header.

Modules

- `GD::Group` - Simple object for recursive grouping
- `GD::Image` - Image class for the GD image library
- `GD::Polygon` - Polygon class for the GD image library
- `GD::Polyline` - Polyline object and Polygon utilities (including splines) for use with GD
- `GD::Simple` - Simplified interface to GD library

Functions

Library information

`VERSION_STRING`

The version of the libgd actually loaded, as a string such as `"2.3.3"` (gd.h's `GD_VERSION_STRING`). This is a run-time answer: it describes the library on this machine, not the one anything was built against. The version of the Perl module is `$GD::VERSION`.

`LIBGD_VERSION`

The version of the libgd actually loaded, as one number: major, then minor and release as two decimal places each, so that versions compare numerically. libgd 2.3.3 is `2.0303`.

`supportsFileType`

True when the loaded libgd can read, or with a true second argument write, the image file named by its first argument.

GD::Group

Simple object for recursive grouping

DESCRIPTION

Does absolutely nothing with GD, but works nicely with GD::SVG.

GD::Image

Image class for the GD image library

SYNOPSIS

See *GD*

DESCRIPTION

Supported Image formats, also returned by `supported()`, as lowercase strings.

- Png
- Gif
- Gd
- Gd2
- Jpeg
- Tiff
- Xpm
- Xbm
- WBMP
- BMP
- GifAnim
- Webp
- Heif
- Avif
- Jxl

GD::Polyline

Polyline object and Polygon utilities (including splines) for use with GD

SYNOPSIS

```
use GD;
use GD::Polyline;

# create an image
$image = GD::Image->new (500,300);
$white  = $image->colorAllocate(255,255,255);
$black  = $image->colorAllocate(  0,  0,  0);
$red    = $image->colorAllocate(255,  0,  0);

# create a new polyline
$polyline = GD::Polyline->new;

# add some points
```

(continues on next page)

(continued from previous page)

```
$polyline->addPt(  0,  0);
$polyline->addPt(  0,100);
$polyline->addPt( 50,125);
$polyline->addPt(100,  0);

# polylines can use polygon methods (and vice versa)
$polyline->offset(200,100);

# rotate 60 degrees, about the centroid
$polyline->rotate(3.14159/3, $polyline->centroid());

# scale about the centroid
$polyline->scale(1.5, 2, $polyline->centroid());

# draw the polyline
$image->polydraw($polyline,$black);

# create a spline, which is also a polyine
$spline = $polyline->addControlPoints->toSpline;
$image->polydraw($spline,$red);

# output the png
binmode STDOUT;
print $image->png;
```

DESCRIPTION

Polyline.pm extends the GD module by allowing you to create polylines. Think of a polyline as "an open polygon", that is, the last vertex is not connected to the first vertex (unless you expressly add the same value as both points).

For the remainder of this doc, "polyline" will refer to a GD::Polyline, "polygon" will refer to a GD::Polygon that is not a polyline, and "polything" and "$poly" may be either.

The big feature added to GD by this module is the means to create splines, which are approximations to curves.

The Polyline Object

GD::Polyline defines the following class:

- `GD::Polyline`

  A polyline object, used for storing lists of vertices prior to rendering a polyline into an image.

- `new`

  `GD::Polyline->new` *class method*

  Create an empty polyline with no vertices.

```
$polyline = GD::Polyline->new;

$polyline->addPt(  0,  0);
$polyline->addPt(  0,100);
$polyline->addPt( 50,100);
$polyline->addPt(100,  0);

$image->polydraw($polyline,$black);
```

In fact GD::Polyline is a subclass of GD::Polygon, so all polygon methods (such as **offset** and **transform**) may be used on polylines. Some new methods have thus been added to GD::Polygon (such as **rotate**) and a few updated/modified/enhanced (such as **scale**) *in this module*. See section "New or Updated GD::Polygon Methods" for more info.

Note that this module is very "young" and should be considered subject to change in future releases, and/or possibly folded in to the existing polygon object and/or GD module.

Updated Polygon Methods

The following methods (defined in GD.pm) are OVERRIDDEN if you use this module.

All effort has been made to provide 100% backward compatibility, but if you can confirm that has not been achieved, please consider that a bug and let the the author of Polyline.pm know.

- `scale`

  `$poly->scale($sx, $sy, $cx, $cy)` *object method – UPDATE to GD::Polygon::scale*

  Scale a polything in along x-axis by $sx and along the y-axis by $sy, about centery point ($cx, $cy).

  Center point ($cx, $cy) is optional – if these are omitted, the function will scale about the origin.

  To flip a polything, use a scale factor of -1. For example, to flip the polything top to bottom about line y = 100, use:

```
$poly->scale(1, -1, 0, 100);
```

New Polygon Methods

The following methods are added to GD::Polygon, and thus can be used by polygons and polylines.

Don't forget: a polyline is a GD::Polygon, so GD::Polygon methods like offset() can be used, and they can be used in GD::Image methods like filledPolygon().

- `rotate`

  `$poly->rotate($angle, $cx, $cy)` *object method*

  Rotate a polything through $angle (clockwise, in radians) about center point ($cx, $cy).

Center point ($cx, $cy) is optional – if these are omitted, the function will rotate about the origin

In this function and other angle-oriented functions in GD::Polyline, positive $angle corresponds to clockwise rotation. This is opposite of the usual Cartesian sense, but that is because the raster is opposite of the usual Cartesian sense in that the y-axis goes "down".

- `centroid`

  `($cx, $cy) = $poly->centroid($scale)` *object method*

  Calculate and return ($cx, $cy), the centroid of the vertices of the polything. For example, to rotate something 180 degrees about it's centroid:

```
$poly->rotate(3.14159, $poly->centroid());
```

  $scale is optional; if supplied, $cx and $cy are multiplied by $scale before returning. The main use of this is to shift an polything to the origin like this:

```
$poly->offset($poly->centroid(-1));
```

- `segLength`

  `@segLengths = $poly->segLength()` *object method*

  In array context, returns an array the lengths of the segments in the polything. Segment n is the segment from vertex n to vertex n+1. Polygons have as many segments as vertices; polylines have one fewer.

  In a scalar context, returns the sum of the array that would have been returned in the array context.

- `segAngle`

  `@segAngles = $poly->segAngle()` *object method*

  Returns an array the angles of each segment from the x-axis. Segment n is the segment from vertex n to vertex n+1. Polygons have as many segments as vertices; polylines have one fewer.

  Returned angles will be on the interval 0 <= $angle < 2 * pi and angles increase in a clockwise direction.

- `vertexAngle`

  `@vertexAngles = $poly->vertexAngle()` *object method*

  Returns an array of the angles between the segment into and out of each vertex. For polylines, the vertex angle at vertex 0 and the last vertex are not defined; however $vertexAngle[0] will be undef so that $vertexAngle[1] will correspond to vertex 1.

  Returned angles will be on the interval 0 <= $angle < 2 * pi and angles increase in a clockwise direction.

  Note that this calculation does not attempt to figure out the "interior" angle with respect to "inside" or "outside" the polygon, but rather, just the angle between the adjacent segments in a clockwise sense. Thus a polygon with all right angles will have vertex angles of either pi/2 or 3*pi/2, depending on the way the polygon was "wound".

- `toSpline`

  `$poly->toSpline()` *object method & factory method*

  Create a new polything which is a reasonably smooth curve using cubic spline algorithms, often referred to as Bezier curves. The "source" polything is called the "control polything". If it is a polyline, the control polyline must have 4, 7, 10, or some number of vertices of equal to 3n+1. If it is a polygon, the control polygon must have 3, 6, 9, or some number of vertices of equal to 3n.

```
$spline = $poly->toSpline();
$image->polydraw($spline,$red);
```

  In brief, groups of four points from the control polyline are considered "control points" for a given portion of the spline: the first and fourth are "anchor points", and the spline passes through them; the second and third are "director points". The spline does not pass through director points, however the spline is tangent to the line segment from anchor point to adjacent director point.

  The next portion of the spline reuses the previous portion's last anchor point. The spline will have a cusp (non-continuous slope) at an anchor point, unless the anchor points and its adjacent director point are colinear.

  In the current implementation, toSpline() return a fixed number of segments in the returned polyline per set-of-four control points. In the future, this and other parameters of the algorithm may be configurable.

- `addControlPoints`

  `$polyline->addControlPoints()` *object method & factory method*

  So you say: "OK. Splines sound cool. But how can I get my anchor points and its adjacent director point to be colinear so that I have a nice smooth curves from my polyline?" Relax! For The Lazy: addControlPoints() to the rescue.

  addControlPoints() returns a polyline that can serve as the control polyline for toSpline(), which returns another polyline which is the spline. Is your head spinning yet? Think of it this way:

  - *

    If you have a polyline, and you have already put your control points where you want them, call toSpline() directly. Remember, only every third vertex will be "on" the spline.

    You get something that looks like the spline "inscribed" inside the control polyline.

  - *

    If you have a polyline, and you want all of its vertices on the resulting spline, call addControlPoints() and then toSpline():

```
$control = $polyline->addControlPoints();
$spline  = $control->toSpline();
$image->polyline($spline,$red);
```

You get something that looks like the control polyline "inscribed" inside the spline.

Adding "good" control points is subjective; this particular algorithm reveals its author's tastes. In the future, you may be able to alter the taste slightly via parameters to the algorithm. For The Hubristic: please build a better one!

And for The Impatient: note that addControlPoints() returns a polyline, so you can pile up the call like this, if you'd like:

```
$image->polyline($polyline->addControlPoints()->toSpline(),
 ↪$mauve);
```

New GD::Image Methods

- `polyline`

  `$image->polyline(polyline,color)` *object method*

  ```
  $image->polyline($polyline,$black)
  ```

  This draws a polyline with the specified color. Both real color indexes and the special colors gdBrushed, gdStyled and gdStyledBrushed can be specified.

  Neither the polyline() method or the polygon() method are very picky: you can call either method with either a GD::Polygon or a GD::Polyline. The *method* determines if the shape is "closed" or "open" as drawn, *not* the object type.

- `polydraw`

  `$image->polydraw(polything,color)` *object method*

  ```
  $image->polydraw($poly,$black)
  ```

  This method draws the polything as expected (polygons are closed, polylines are open) by simply checking the object type and calling either $image->polygon() or $image->polyline().

Examples

Please see file "polyline-examples.pl" that is included with the distribution.

See Also

For more info on Bezier splines, see http://www.webreference.com/dlab/9902/bezier.html.

Future Features

On the drawing board are additional features such as:

```
- polygon winding algorithms (to determine if a point is "inside" or␣
↪"outside" the polygon)

- new polygon from bounding box

- find bounding polygon (tightest fitting simple convex polygon for␣
↪a given set of vertices)

- addPts() method to add many points at once

- clone() method for polygon

- functions to interwork GD with SVG
```

Please provide input on other possible features you'd like to see.

Author

This module has been written by Daniel J. Harasty. Please send questions, comments, complaints, and kudos to him at harasty@cpan.org.

Thanks to Lincoln Stein for input and patience with me and this, my first CPAN contribution.

The Polyline.pm module is copyright 2002, Daniel J. Harasty. It is distributed under the same terms as Perl itself. See the "Artistic License" in the Perl source code distribution for licensing terms.

The latest version of Polyline.pm is available at your favorite CPAN repository and/or along with GD.pm by Lincoln D. Stein at http://stein.cshl.org/WWW/software/GD.

GD::Simple

Simplified interface to GD library

SYNOPSIS

For a nice tutorial on using this module, see Gabor Szabo's article at http://perl-maven.com/drawing-images-using-gd-simple.

```
use GD::Simple;

# create a new image
$img = GD::Simple->new(400,250);

# draw a red rectangle with blue borders
$img->bgcolor('red');
$img->fgcolor('blue');
```

(continues on next page)

(continued from previous page)

```
$img->rectangle(10,10,50,50);

# draw an empty rectangle with green borders
$img->bgcolor(undef);
$img->fgcolor('green');
$img->rectangle(30,30,100,100);

# move to (80,80) and draw a green line to (100,190)
$img->moveTo(80,80);
$img->lineTo(100,190);

# draw a solid orange ellipse
$img->moveTo(110,100);
$img->bgcolor('orange');
$img->fgcolor('orange');
$img->ellipse(40,40);

# draw a black filled arc
$img->moveTo(150,150);
$img->fgcolor('black');
$img->arc(50,50,0,100,gdNoFill|gdEdged);

# draw a string at (10,180) using the default
# built-in font
$img->moveTo(10,180);
$img->string('This is very simple');

# draw a string at (280,210) using 20 point
# times italic, angled upward 90 degrees
$img->moveTo(280,210);
$img->font('Times:italic');
$img->fontsize(20);
$img->angle(-90);
$img->string('This is very fancy');

# some turtle graphics
$img->moveTo(300,100);
$img->penSize(3,3);
$img->angle(0);
$img->line(20);   # 20 pixels going to the right
$img->turn(30);   # set turning angle to 30 degrees
$img->line(20);   # 20 pixel line
$img->line(20);
$img->line(20);
$img->turn(-90); # set turning angle to -90 degrees
$img->line(50);  # 50 pixel line

# draw a cyan polygon edged in blue
my $poly = GD::Polygon->new;
```

(continues on next page)

(continued from previous page)

```
 $poly->addPt(150,100);
 $poly->addPt(199,199);
 $poly->addPt(100,199);
 $img->bgcolor('cyan');
 $img->fgcolor('blue');
 $img->penSize(1,1);
 $img->polygon($poly);

# convert into png data
print $img->png;
```

DESCRIPTION

GD::Simple is a subclass of the GD library that shortens many of the long GD method calls by storing information about the pen color, size and position in the GD object itself. It also adds a small number of "turtle graphics" style calls for those who prefer to work in polar coordinates. In addition, the library allows you to use symbolic names for colors, such as "chartreuse", and will manage the colors for you.

The Pen

GD::Simple maintains a "pen" whose settings are used for line- and shape-drawing operations. The pen has the following properties:

- fgcolor

  The pen foreground color is the color of lines and the borders of filled and unfilled shapes.

- bgcolor

  The pen background color is the color of the contents of filled shapes.

- pensize

  The pen size is the width of the pen. Larger sizes draw thicker lines.

- position

  The pen position is its current position on the canvas in (X,Y) coordinates.

- angle

  When drawing in turtle mode, the pen angle determines the current direction of lines of relative length.

- turn

  When drawing in turtle mode, the turn determines the clockwise or counterclockwise angle that the pen will turn before drawing the next line.

- font

  The font to use when drawing text. Both built-in bitmapped fonts and TrueType fonts are supported.

- fontsize

  The size of the font to use when drawing with TrueType fonts.

One sets the position and properties of the pen and then draws. As the drawing progresses, the position of the pen is updated.

Methods

GD::Simple introduces a number of new methods, a few of which have the same name as GD::Image methods, and hence change their behavior. In addition to these new methods, GD::Simple objects support all of the GD::Image methods. If you make a method call that isn't directly supported by GD::Simple, it refers the request to the underlying GD::Image object. Hence one can load a JPEG image into GD::Simple and declare it to be TrueColor by using this call, which is effectively inherited from GD::Image:

```
my $img = GD::Simple->newFromJpeg('./myimage.jpg',1);
```

The rest of this section describes GD::Simple-specific methods.

- $img = GD::Simple->new($x,$y [,$truecolor])
- $img = GD::Simple->new($gd)

  Create a new GD::Simple object. There are two forms of new(). In the first form, pass the width and height of the desired canvas, and optionally a boolean flag to request a truecolor image. In the second form, pass a previously-created GD::Image object.

- GD::Simple->class('GD');
- GD::Simple->class('GD::SVG');

  Select whether new() should use GD or GD::SVG internally. Call GD::Simple->class('GD::SVG') before calling new() if you wish to generate SVG images.

  If future GD subclasses are created, this method will subport them.

- $img->moveTo($x,$y)

  This call changes the position of the pen without drawing. It moves the pen to position ($x,$y) on the drawing canvas.

- $img->move($dx,$dy)
- $img->move($dr)

  This call changes the position of the pen without drawing. When called with two arguments it moves the pen $dx pixels to the right and $dy pixels downward. When called with one argument it moves the pen $dr pixels along the vector described by the current pen angle.

- $img->lineTo($x,$y)

  The lineTo() call simultaneously draws and moves the pen. It draws a line from the current pen position to the position defined by ($x,$y) using the current pen size and color. After drawing, the position of the pen is updated to the new position.

- $img->line($x1,$y1,$x2,$y2 [,$color])

- $img->line($dx,$dy)
- $img->line($dr)

  The line() call simultaneously draws and moves the pen. When called with two arguments it draws a line from the current position of the pen to the position $dx pixels to the right and $dy pixels down. When called with one argument, it draws a line $dr pixels long along the angle defined by the current pen angle.

  When called with four or five arguments, line() behaves like GD::Image->line().

- $img->clear

  This method clears the canvas by painting over it with the current background color.

- $img->rectangle($x1,$y1,$x2,$y2)

  This method draws the rectangle defined by corners ($x1,$y1), ($x2,$y2). The rectangle's edges are drawn in the foreground color and its contents are filled with the background color. To draw a solid rectangle set bgcolor equal to fgcolor. To draw an unfilled rectangle (transparent inside), set bgcolor to undef.

- $img->ellipse($width,$height)

  This method draws the ellipse centered at the current location with width $width and height $height. The ellipse's border is drawn in the foreground color and its contents are filled with the background color. To draw a solid ellipse set bgcolor equal to fgcolor. To draw an unfilled ellipse (transparent inside), set bgcolor to undef.

- $img->arc([$cx,$cy,] $width,$height,$start,$end [,$style])

  This method draws filled and unfilled arcs, at the current position, with the current fore- and background colors. See *GD* for a description of the arguments. To draw a solid arc (such as a pie wedge) set bgcolor equal to fgcolor. To draw an unfilled arc, set bgcolor to undef.

- $img->polygon($poly)

  This method draws filled and unfilled polygon using the current settings of fgcolor for the polygon border and bgcolor for the polygon fill color. See *GD* for a description of creating polygons. To draw a solid polygon set bgcolor equal to fgcolor. To draw an unfilled polygon, set bgcolor to undef.

- $img->polyline($poly)

  This method draws polygons without closing the first and last vertices (similar to GD::Image->unclosedPolygon()). It uses the fgcolor to draw the line.

- $img->string($string)

  This method draws the indicated string starting at the current position of the pen. The pen is moved to the end of the drawn string. Depending on the font selected with the font() method, this will use either a bitmapped GD font or a TrueType font. The angle of the pen will be consulted when drawing the text. For TrueType fonts, any angle is accepted. For GD bitmapped fonts, the angle can be either 0 (draw horizontal) or -90 (draw upwards).

For consistency between the TrueType and GD font behavior, the string is always drawn so that the current position of the pen corresponds to the bottom left of the first character of the text. This is different from the GD behavior, in which the first character of bitmapped fonts hangs down from the pen point.

This method returns a polygon indicating the bounding box of the rendered text. If an error occurred (such as invalid font specification) it returns undef and an error message in $@.

- $metrics = $img->fontMetrics
- ($metrics,$width,$height) = GD::Simple->fontMetrics($font,$fontsize,$string)

  This method returns information about the current font, most commonly a TrueType font. It can be invoked as an instance method (on a previously-created GD::Simple object) or as a class method (on the 'GD::Simple' class).

  When called as an instance method, fontMetrics() takes no arguments and returns a single hash reference containing the metrics that describe the currently selected font and size. The hash reference contains the following information:

```
xheight      the base height of the font from the bottom to the
↪top of
             a lowercase 'm'

ascent       the length of the upper stem of the lowercase 'd'

descent      the length of the lower step of the lowercase 'j'

lineheight   the distance from the bottom of the 'j' to the top
↪of
             the 'd'

leading      the distance between two adjacent lines
```

  This description and code was changed with 2.75.

- ($delta_x,$delta_y)= $img->stringBounds($string)

  This method indicates the X and Y offsets (which may be negative) that will occur when the given string is drawn using the current font, fontsize and angle. When the string is drawn horizontally, it gives the width and height of the string's bounding box.

- $delta_x = $img->stringWidth($string)

  This method indicates the width of the string given the current font, fontsize and angle. It is the same as ($img->stringBounds($string))[0]

- ($x,$y) = $img->curPos

  Return the current position of the pen. Set the current position using moveTo().

- $font = $img->font([$newfont] [,$newsize])

  Get or set the current font. Fonts can be GD::Font objects, TrueType font file paths, or fontconfig font patterns like "Times:italic" (see fontconfig). The latter feature

requires that you have the fontconfig library installed and are using libgd version 2.0.33 or higher.

As a shortcut, you may pass two arguments to set the font and the fontsize simultaneously. The fontsize is only valid when drawing with TrueType fonts.

- $size = $img->fontsize([$newfontsize])

  Get or set the current font size. This is only valid for TrueType fonts.

- $size = $img->penSize([$newpensize])

  Get or set the current pen width for use during line drawing operations.

- $angle = $img->angle([$newangle])

  Set the current angle for use when calling line() or move() with a single argument.

  Here is an example of using turn() and angle() together to draw an octagon. The first line drawn is the downward-slanting top right edge. The last line drawn is the horizontal top of the octagon.

```
$img->moveTo(200,50);
$img->angle(0);
$img->turn(360/8);
for (1..8) { $img->line(50) }
```

- $angle = $img->turn([$newangle])

  Get or set the current angle to turn prior to drawing lines. This value is only used when calling line() or move() with a single argument. The turning angle will be applied to each call to line() or move() just before the actual drawing occurs.

  Angles are in degrees. Positive values turn the angle clockwise.

- $color = $img->fgcolor([$newcolor])

  Get or set the pen's foreground color. The current pen color can be set by (1) using an (r,g,b) triple; (2) using a previously-allocated color from the GD palette; or (3) by using a symbolic color name such as "chartreuse." The list of color names can be obtained using color_names(). The special color name 'transparent' will create a completely transparent color.

- $color = $img->bgcolor([$newcolor])

  Get or set the pen's background color. The current pen color can be set by (1) using an (r,g,b) triple; (2) using a previously-allocated color from the GD palette; or (3) by using a symbolic color name such as "chartreuse." The list of color names can be obtained using color_names(). The special color name 'transparent' will create a completely transparent color.

- $index = $img->translate_color(@args)

  Translates a color into a GD palette or TrueColor index. You may pass either an (r,g,b) triple or a symbolic color name. If you pass a previously-allocated index, the method will return it unchanged.

- $index = $img->alphaColor(@args,$alpha)

Creates an alpha color. You may pass either an (r,g,b) triple or a symbolic color name, followed by an integer indicating its opacity. The opacity value ranges from 0 (fully opaque) to 127 (fully transparent).

- @names = GD::Simple->color_names
- $translate_table = GD::Simple->color_names

  Called in a list context, color_names() returns the list of symbolic color names recognized by this module. Called in a scalar context, the method returns a hash reference in which the keys are the color names and the values are array references containing [r,g,b] triples.

- $gd = $img->gd

  Return the internal GD::Image object. Usually you will not need to call this since all GD methods are automatically referred to this object.

- ($red,$green,$blue) = GD::Simple->HSVtoRGB($hue,$saturation,$value)

  Convert a Hue/Saturation/Value (HSV) color into an RGB triple. The hue, saturation and value are integers from 0 to 255.

- ($hue,$saturation,$value) = GD::Simple->RGBtoHSV($red,$green,$blue)

  Convert a Red/Green/Blue (RGB) value into a Hue/Saturation/Value (HSV) triple. The hue, saturation and value are integers from 0 to 255.

COLORS

This script will create an image showing all the symbolic colors.

```
#!/usr/bin/perl

use strict;
use GD::Simple;

my @color_names = GD::Simple->color_names;
my $cols = int(sqrt(@color_names));
my $rows = int(@color_names/$cols)+1;

my $cell_width    = 100;
my $cell_height   = 50;
my $legend_height = 16;
my $width       = $cols * $cell_width;
my $height      = $rows * $cell_height;

my $img = GD::Simple->new($width,$height);
$img->font(gdSmallFont);

for (my $c=0; $c<$cols; $c++) {
  for (my $r=0; $r<$rows; $r++) {
    my $color = $color_names[$c*$rows + $r] or next;
    my @topleft  = ($c*$cell_width,$r*$cell_height);
    my @botright = ($topleft[0]+$cell_width,$topleft[1]+$cell_
```

(continues on next page)

(continued from previous page)

```
↪height-$legend_height);
    $img->bgcolor($color);
    $img->fgcolor($color);
    $img->rectangle(@topleft,@botright);
    $img->moveTo($topleft[0]+2,$botright[1]+$legend_height-2);
    $img->fgcolor('black');
    $img->string($color);
  }
}

print $img->png;
```

GD, *GD::Polyline*, GD::SVG, Image::Magick

supportsFileType

True when the loaded libgd can read, or with a true second argument write, the image file named by its first argument.

```
print "can do webp\n" if GD::supportsFileType('photo.webp');
print "can write tga\n" if GD::supportsFileType('out.tga', 1);
```

libgd judges by the file name's extension, case-insensitively, so pass a file name: a bare `'webp'` has no extension and is always false. libgd is routinely packaged without WebP, AVIF or JXL, and some formats (TGA, XPM) can be read but not written, so asking is worth doing before offering a format to a user.

5.2.50 GDBM_File

Tie a Perl hash to a database file with GNU dbm's interface: its open modes, error codes, options, dumps and recovery calls.

`GDBM_File` binds a hash to a file with `tie`; from then on `$h{key}`, `delete`, `exists`, `keys` and `each` read and write the file. The object `tie` returns has gdbm's own methods besides: `count` the keys, `sync`, `reorganize`, `dump` and `load` the data in gdbm's dump formats, read the last error, and read or set options.

Synopsis

```
use GDBM_File;

my $db = tie my %h, 'GDBM_File', 'data.gdbm', GDBM_WRCREAT, 0640
    or die "$GDBM_File::gdbm_errno";
$h{greeting} = 'hello';
print $db->count, "\n";          # 1
$db->dump('data.dump');
undef $db;
untie %h;
```

Opening a database

```
my $db = tie %h, 'GDBM_File', $filename, $flags, $mode;
```

`$flags` is one access mode, OR'd with modifiers:

- `GDBM_READER` - open an existing file to read.
- `GDBM_WRITER` - open an existing file to read and write.
- `GDBM_WRCREAT` - the same, creating the file if it does not exist.
- `GDBM_NEWDB` - create the file, emptying it if it exists.
- `GDBM_SYNC` - commit every write to disk as it happens (see `sync`).
- `GDBM_FAST`, `GDBM_NOLOCK`, `GDBM_NOMMAP`, `GDBM_CLOEXEC`, `GDBM_BSEXACT`, `GDBM_XVERIFY`, `GDBM_PREREAD`, `GDBM_NUMSYNC` - accepted and without effect.

`$mode` is the permission of a file it creates. `tie` returns the database object, or undef when the file cannot be opened: `$GDBM_File::gdbm_errno` then says why. Keep the object to call methods on it, and `undef` it (or call `close`) before `untie`: the file stays open as long as the object lives.

Errors

`$GDBM_File::gdbm_errno` holds the code of the last failure: compare it with the `GDBM_*_ERROR` constants as a number, or print it for gdbm's message (with `$!` appended when the system's error says more). A failed method croaks with that message; `errno`, `syserrno` and `strerror` give the last error of one database, and `clear_error` clears it.

Options

These methods read an option and, given a value, set it:

- `$db->sync_mode`, `$db->sync_mode($bool)` - whether every write is committed to disk as it happens. Off unless the database was tied with `GDBM_SYNC`.
- `$db->cache_size`, `$db->cache_size($n)` - the cache size. It reads only once set: before, it croaks `GDBM_File::cache_size not implemented`.
- `$db->centfree`, `$db->centfree($bool)` and `$db->coalesce`, `$db->coalesce($bool)` - gdbm's free-space settings, both off until set. As with gdbm 1.26, `centfree` reads back inverted: 1 while off, 0 once set on.

- `$db->mmapsize`, `$db->mmapsize($n)` - the largest memory map.
- `$db->mmap` - true: the file is always memory-mapped.
- `$db->block_size` - the file's page size, typically 4096.
- `$db->dbname` - the file name the database was tied with.
- `$db->flags` - the `$flags` it was tied with, `GDBM_SYNC` included while the sync mode is on.

Only `sync_mode` changes how the database works. The cache size, free space settings and memory map size keep the value they are given and change nothing: they tune gdbm's own file layout, which pperl's files do not have. `setopt` reaches the same options by their `GDBM_SET*` codes.

DBM filters

`$db->filter_store_key(sub {...})`, `filter_store_value`, `filter_fetch_key` and `filter_fetch_value` install a sub that rewrites every key or value on its way into, or out of, the database. The sub changes `$_` in place; a store filter works on a copy, so your own variable keeps its value. Each method returns the filter it replaces (or undef), and `undef` as the argument removes the filter. The `DBM_Filter` module offers ready-made ones (`utf8`, `null`, `int32` and others). A filter that uses the same database croaks `recursion detected in filter_store_key` (or the filter's own name).

Files

pperl keeps a GDBM_File database in an LMDB file: the file named, with LMDB's lock file, `NAME-lock`, beside it. The gdbm library is not used, and its files cannot be read: tying a real gdbm file (or a Berkeley DB file) croaks, naming what the file is, and the file is left as it was, even with `GDBM_NEWDB`. To bring a gdbm database over, dump it with gdbm's own tools (`gdbm_dump`, or `dump` under perl 5) and `load` the dump. A key may be at most 511 bytes, 510 if it starts with a NUL byte; a longer one croaks.

Writes reach the file at `sync` and when the database is untied: until then the tie holds the file's one writer slot, and another process that writes the file waits for it (readers never wait), as with gdbm's own writer lock. `GDBM_SYNC`, `sync_mode(1)` or `$Peta::FFI::LMDB::DBM_WRITE = 'through'` commit every write as it happens; see `Peta::FFI::LMDB`.

Constants

GDBM_File exports gdbm's constants: the open modes and modifiers above, `GDBM_INSERT` and `GDBM_REPLACE` (the flag of `STORE`), the `GDBM_*_ERROR` and other error codes `$GDBM_File::gdbm_errno` holds, the `GDBM_SET*` option codes of `setopt`, and the `GDBM_SNAPSHOT_*` codes of `latest_snapshot`.

Differences from upstream

- The files are LMDB files, not gdbm files: real gdbm files are refused, and pperl's files cannot be read by gdbm. Data moves between them through `dump` and `load`, in either direction. Covered by `t/82-native/Peta-FFI-LMDB/090-gdbm.t` and `t/81-xs-native/GDBM_File/010-phenotype.t`.

- Keys are limited to 511 bytes; gdbm has no limit. Covered by `t/82-native/Peta-FFI-LMDB/090-gdbm.t`.
- Writes reach the file at `sync` and `untie` unless the sync mode is on, as with gdbm, and a writer holds the file until then. Covered by `t/82-native/Peta-FFI-LMDB/090-gdbm.t`.
- `load` reads dumps with empty keys or values, which gdbm itself writes but cannot load. Covered by `t/82-native/Peta-FFI-LMDB/090-gdbm.t`.
- Deleting the key `each` just returned is safe: the walk goes on with the next key, where gdbm loses its place and ends the walk early. Covered by `t/82-native/Peta-FFI-LMDB/090-gdbm.t`.
- Crash tolerance (`failure_atomic`, `latest_snapshot`) is reported unsupported, as by a gdbm built without it: pperl's files survive a crash by themselves. Covered by `t/81-xs-native/GDBM_File/150-upstream-snapshot.t`.
- The cache size, free-space and memory-map options have no effect. `cache_size` reads back a size once set, where perl 5 with gdbm 1.26 croaks `not implemented` on every read. Covered by `t/82-native/Peta-FFI-LMDB/090-gdbm.t`.

Everything else - error codes and messages, options, dump formats - behaves as with gdbm. Covered by `t/81-xs-native/GDBM_File/010-phenotype.t` and GDBM_File's own test suite, `t/81-xs-native/GDBM_File/100-upstream-count.t` to `150-upstream-snapshot.t`.

Functions

Errors

gdbm_check_syserr

True when an error code is one that `$!` explains further - a failed open, read or write - as in `gdbm_check_syserr($GDBM_File::gdbm_errno)`.

errno

The last error of this database: as a number one of the `GDBM_*` error codes (`GDBM_NO_ERROR`, 0, when none), as a string gdbm's message for it, such as `Item not found`.

syserrno

The system error number (the `$!` value) behind this database's last error, when that error is one the system's error explains; 0 otherwise.

strerror

gdbm's message for this database's last error, with the system's message appended when that says more.

clear_error

Forget this database's last error: `errno` reads `GDBM_NO_ERROR` again.

Maintenance

close

Close the database now, writing what is pending, even while copies of the database object exist. Needed when the object was kept from `tie`: `untie` alone leaves the file open as long as the object lives. Returns 0. Methods called afterwards croak `database was closed`.

needs_recovery

Whether the database needs `recover`: always 0, as an interrupted write leaves pperl's file as it was before the write.

reorganize

Shrink the file after many deletes: the data is copied, without the free space, into a new file that takes the old one's place and mode.

recover

Recover a damaged database. pperl's files are never left damaged, so recovery finds every key intact; it still makes the backup copy and fills in the statistics asked for.

sync

Write everything stored so far to the file and to disk, so that other processes - and the file after a crash - have it. Returns 0; a failure croaks. Without it, writes reach the file at `untie`, or as they happen in sync mode (`GDBM_SYNC`, `sync_mode(1)`).

count

The number of keys in the database, without walking them.

dump

Write the database's keys and values to a dump file in gdbm's format, which `load` - here or in perl 5 with gdbm - reads back.

load

Read a dump file - ASCII or binary, from `dump` here or from gdbm's own tools - into the database.

Options

block_size

The `$flags` the database was tied with, `GDBM_SYNC` included while the sync mode is on. The same method, under the option's name, reads and sets the options listed under *Options* above (`sync_mode`, `cache_size`, `block_size` and the others); with a value too many it croaks `NAME: too many arguments`.

Also available as `GDBM_File::cache_size`, `GDBM_File::centfree`, `GDBM_File::coalesce`, `GDBM_File::dbname`, `GDBM_File::flags`, `GDBM_File::mmap`, `GDBM_File::mmapsize`, `GDBM_File::sync_mode`.

setopt

`$db->setopt($code, $value, $length)`: gdbm's raw option call. `$code` is a `GDBM_SET*` (or `GDBM_GET*`) constant, `$value` an integer and `$length` its size in bytes, 4. Returns 0; an unknown option or a bad value croaks. The named methods under *Options* are easier to use.

Crash tolerance

convert

`$db->convert($format)`: change gdbm's file format, `GDBM_NUMSYNC` for its extended format or 0 for its standard one. pperl's files have one format, so it does nothing and returns 0.

failure_atomic

`$db->failure_atomic($even, $odd)`: gdbm's crash tolerance, which keeps two snapshot files of the database. Not supported: it croaks `gdbm_failure_atomic: Function usage error: Function not implemented`. pperl's files survive a crash without snapshots, keeping the writes made up to the last `sync`.

latest_snapshot

`GDBM_File->latest_snapshot($even, $odd)`: which of crash tolerance's two snapshot files to recover from. Not supported: it returns undef, in list context `(undef, GDBM_SNAPSHOT_ERR, ENOSYS)`.

crash_tolerance_status

`GDBM_File->crash_tolerance_status`: whether `failure_atomic` is supported - 0.

Library version

GDBM_version

The version of gdbm whose interface the module follows: in scalar context a string such as `1.26`, in list context its numbers, such as `(1, 26, 0)`. Call it on the class: `GDBM_File->GDBM_version`.

reorganize

Shrink the file after many deletes: the data is copied, without the free space, into a new file that takes the old one's place and mode.

Synopsis

```
delete @h{@old_keys};
$db->reorganize;
```

What you get back

0, or -1 with `errno` set: `GDBM_READER_CANT_REORGANIZE` for a database tied `GDBM_READER`, `GDBM_REORGANIZE_FAILED` when it cannot be done.

Edge cases

- It fails while another tie in the same process has the file open, and should not be run while other processes use the file.
- Writes pending are written first.

Differences from upstream

The work is a copy of the file without its free pages; gdbm rebuilds its own file instead. The result is the same: a smaller file with the same data. Covered by `t/82-native/Peta-FFI-LMDB/090-gdbm.t`.

See also

- `count` - how many keys there are
- `sync` - writes what is pending without shrinking

recover

Recover a damaged database. pperl's files are never left damaged, so recovery finds every key intact; it still makes the backup copy and fills in the statistics asked for.

Synopsis

```
my ($backup, %stat);
$db->recover(backup => \$backup, stat => \%stat);
```

Options

- `backup => \$name` - copy the file first, to `NAME.~N~` with the first free number `N`, and put that name in `$name`.

- `stat => \%stat` - fill in `recovered_keys` (every key), `recovered_buckets`, `failed_keys` and `failed_buckets` (both 0).
- `err => sub {...}`, `max_failed_keys`, `max_failed_buckets`, `max_failures` - accepted; with nothing failing they never matter.

What you get back

Nothing; a failure (the backup copy cannot be made) croaks. An unknown option croaks `NAME: unrecognized argument`, and an odd number of arguments with a usage message.

Differences from upstream

gdbm rebuilds a damaged file and reports what it lost; pperl's file has nothing to rebuild. Covered by `t/81-xs-native/GDBM_File/010-phenotype.t`.

See also

- `needs_recovery` - always 0

dump

Write the database's keys and values to a dump file in gdbm's format, which `load` - here or in perl 5 with gdbm - reads back.

Synopsis

```
$db->dump('data.dump');
$db->dump('data.bin', binary => 1, mode => 0600, overwrite => 1);
```

Options

- `binary => 1` - gdbm's old binary format instead of its ASCII one. The ASCII dump also records the file's name, owner and mode.
- `mode => $mode` - the dump file's permissions (default `0666`, less the umask).
- `overwrite => 1` - replace an existing dump file; without it, an existing file croaks.

What you get back

Nothing; a failure croaks with gdbm's message. An unknown option croaks `unrecognized keyword: NAME`.

Examples

Move a real gdbm database to pperl: dump it under perl 5 with gdbm, then load it here.

```
# perl 5:  (tied %old)->dump('move.dump');
my $db = tie my %h, 'GDBM_File', 'new.gdbm', GDBM_NEWDB, 0640 or␣
↪die;
$db->load('move.dump');
```

Differences from upstream

Fully compatible with upstream: gdbm loads pperl's dumps and pperl gdbm's. Covered by `t/81-xs-native/GDBM_File/010-phenotype.t`.

See also

- `load` - reads a dump back

load

Read a dump file - ASCII or binary, from dump here or from gdbm's own tools - into the database.

Synopsis

```
my $db = tie my %h, 'GDBM_File', 'a.gdbm', GDBM_NEWDB, 0640 or die;
$db->load('a.dump');
$db->load('more.dump', replace => 1);
```

Options

- `replace => 1` - a key already in the database takes the dump's value; without it such a key croaks.
- `restore_mode => 0`, `restore_owner => 0` - do not give the database file the mode, or the owner, an ASCII dump records. By default both are restored, and failing to restore them is not an error.
- `strict_errors => 1` - croak when the mode or owner cannot be restored.

What you get back

Nothing; a failure croaks `FILE:LINE: database load error: MESSAGE` (or without the line). An unknown option croaks `unrecognized keyword: NAME`.

Differences from upstream

A dump holding an empty key or an empty value loads; gdbm 1.26 writes such dumps but cannot load them. Covered by `t/82-native/Peta-FFI-LMDB/090-gdbm.t`.

- dump - writes a dump

5.2.51 Getopt

Namespace containing the following modules:

- `Getopt::Long` - Extended processing of command line options
- `Getopt::Std` - Process single-character switches with switch clustering

Getopt::Long

Extended processing of command line options

SYNOPSIS

```
use Getopt::Long;
my $data   = "file.dat";
my $length = 24;
my $verbose;
GetOptions ("length=i" => \$length,    # numeric
            "file=s"   => \$data,      # string
            "verbose"  => \$verbose)   # flag
or die("Error in command line arguments\n");
```

DESCRIPTION

The Getopt::Long module implements an extended getopt function called GetOptions(). It parses the command line from `@ARGV`, recognizing and removing specified options and their possible values.

This function adheres to the POSIX syntax for command line options, with GNU extensions. In general, this means that options have long names instead of single letters, and are introduced with a double dash "–". Support for bundling of command line options, as was the case with the more traditional single-letter approach, is provided but not enabled by default.

Command Line Options, an Introduction

Command line operated programs traditionally take their arguments from the command line, for example filenames or other information that the program needs to know. Besides arguments, these programs often take command line *options* as well. Options are not necessary for the program to work, hence the name 'option', but are used to modify its default behaviour. For example, a program could do its job quietly, but with a suitable option it could provide verbose information about what it did.

Command line options come in several flavours. Historically, they are preceded by a single dash -, and consist of a single letter.

```
-l -a -c
```

Usually, these single-character options can be bundled:

```
-lac
```

Options can have values, the value is placed after the option character. Sometimes with whitespace in between, sometimes not:

```
-s 24 -s24
```

Due to the very cryptic nature of these options, another style was developed that used long names. So instead of a cryptic `-l` one could use the more descriptive `--long`. To distinguish between a bundle of single-character options and a long one, two dashes are used to precede the option name. Early implementations of long options used a plus + instead. Also, option values could be specified either like

```
--size=24
```

or

```
--size 24
```

The + form is now obsolete and strongly deprecated.

Getting Started with Getopt::Long

Getopt::Long is the Perl5 successor of `newgetopt.pl`. This was the first Perl module that provided support for handling the new style of command line options, in particular long option names, hence the Perl5 name Getopt::Long. This module also supports single-character options and bundling.

To use Getopt::Long from a Perl program, you must include the following line in your Perl program:

```
use Getopt::Long;
```

This will load the core of the Getopt::Long module and prepare your program for using it. Most of the actual Getopt::Long code is not loaded until you really call one of its functions.

In the default configuration, options names may be abbreviated to uniqueness, case does not matter, and a single dash is sufficient, even for long option names. Also, options may be placed between non-option arguments. See “Configuring Getopt::Long” for more details on how to configure Getopt::Long.

Simple options

The most simple options are the ones that take no values. Their mere presence on the command line enables the option. Popular examples are:

```
--all --verbose --quiet --debug
```

Handling simple options is straightforward:

```
my $verbose = '';   # option variable with default value (false)
my $all = '';       # option variable with default value (false)
GetOptions ('verbose' => \$verbose, 'all' => \$all);
```

The call to GetOptions() parses the command line arguments that are present in `@ARGV` and sets the option variable to the value 1 if the option did occur on the command line. Otherwise, the option variable is not touched. Setting the option value to true is often called *enabling* the option.

The option name as specified to the GetOptions() function is called the option *specification*. Later we'll see that this specification can contain more than just the option name. The reference to the variable is called the option *destination*.

GetOptions() will return a true value if the command line could be processed successfully. Otherwise, it will write error messages using die() and warn(), and return a false result.

A little bit less simple options

Getopt::Long supports two useful variants of simple options: *negatable* options and *incremental* options.

A negatable option is specified with an exclamation mark `!` after the option name:

```
my $verbose = '';   # option variable with default value (false)
GetOptions ('verbose!' => \$verbose);
```

Now, using `--verbose` on the command line will enable `$verbose`, as expected. But it is also allowed to use `--noverbose`, which will disable `$verbose` by setting its value to `0`. Using a suitable default value, the program can find out whether `$verbose` is false by default, or disabled by using `--noverbose`.

(If both `--verbose` and `--noverbose` are given, whichever is given last takes precedence.)

An incremental option is specified with a plus `+` after the option name:

```
my $verbose = '';   # option variable with default value (false)
GetOptions ('verbose+' => \$verbose);
```

Using `--verbose` on the command line will increment the value of `$verbose`. This way the program can keep track of how many times the option occurred on the command line. For example, each occurrence of `--verbose` could increase the verbosity level of the program.

Mixing command line option with other arguments

Usually programs take command line options as well as other arguments, for example, file names. It is good practice to always specify the options first, and the other arguments last. Getopt::Long will, however, allow the options and arguments to be mixed and 'filter out' all the options before passing the rest of the arguments to the program.

To stop Getopt::Long from processing further arguments, insert a double dash `--` on the command line:

```
--size 24 -- --all
```

In this example, `--all` will *not* be treated as an option, but passed to the program unharmed, in `@ARGV`.

Options with values

For options that take values it must be specified whether the option value is required or not, and what kind of value the option expects.

Three kinds of values are supported: integer numbers, floating point numbers, and strings.

If the option value is required, Getopt::Long will take the command line argument that follows the option and assign this to the option variable. If, however, the option value is specified as optional, this will only be done if that value does not look like a valid command line option itself.

```
my $tag = '';       # option variable with default value
GetOptions ('tag=s' => \$tag);
```

In the option specification, the option name is followed by an equals sign `=` and the letter `s`. The equals sign indicates that this option requires a value. The letter `s` indicates that this value is an arbitrary string. Other possible value types are `i` for integer values, and `f` for floating point values. Using a colon `:` instead of the equals sign indicates that the option value is optional. In this case, if no suitable value is supplied, string valued options get an empty string `''` assigned, while numeric options are set to `0`.

(If the same option appears more than once on the command line, the last given value is used. If you want to take all the values, see below.)

Options with multiple values

Options sometimes take several values. For example, a program could use multiple directories to search for library files:

```
--library lib/stdlib --library lib/extlib
```

To accomplish this behaviour, simply specify an array reference as the destination for the option:

```
GetOptions ("library=s" => \@libfiles);
```

Alternatively, you can specify that the option can have multiple values by adding a “@”, and pass a reference to a scalar as the destination:

```
GetOptions ("library=s@" => \$libfiles);
```

Used with the example above, `@libfiles` c.q. `@$libfiles` would contain two strings upon completion: `"lib/stdlib"` and `"lib/extlib"`, in that order. It is also possible to specify that only integer or floating point numbers are acceptable values.

Often it is useful to allow comma-separated lists of values as well as multiple occurrences of the options. This is easy using Perl's split() and join() operators:

```
GetOptions ("library=s" => \@libfiles);
@libfiles = split(/,/,join(',',@libfiles));
```

Of course, it is important to choose the right separator string for each purpose.

Warning: What follows is an experimental feature.

Options can take multiple values at once, for example

```
--coordinates 52.2 16.4 --rgbcolor 255 255 149
```

This can be accomplished by adding a repeat specifier to the option specification. Repeat specifiers are very similar to the `{...}` repeat specifiers that can be used with regular expression patterns. For example, the above command line would be handled as follows:

```
GetOptions('coordinates=f{2}' => \@coor, 'rgbcolor=i{3}' => \
 ↪@color);
```

The destination for the option must be an array or array reference.

It is also possible to specify the minimal and maximal number of arguments an option takes. `foo=s{2,4}` indicates an option that takes at least two and at most 4 arguments. `foo=s{1,}` indicates one or more values; `foo:s{,}` indicates zero or more option values.

Options with hash values

If the option destination is a reference to a hash, the option will take, as value, strings of the form *key=value*. The value will be stored with the specified key in the hash.

```
GetOptions ("define=s" => \%defines);
```

Alternatively you can use:

```
GetOptions ("define=s%" => \$defines);
```

When used with command line options:

```
--define os=linux --define vendor=redhat
```

the hash `%defines` (or `%$defines`) will contain two keys, `"os"` with value `"linux"` and `"vendor"` with value `"redhat"`. It is also possible to specify that only integer or floating point numbers are acceptable values. The keys are always taken to be strings.

User-defined subroutines to handle options

Ultimate control over what should be done when (actually: each time) an option is encountered on the command line can be achieved by designating a reference to a subroutine (or an anonymous subroutine) as the option destination. When GetOptions() encounters the option, it will call the subroutine with two or three arguments. The first

argument is the name of the option. (Actually, it is an object that stringifies to the name of the option.) For a scalar or array destination, the second argument is the value to be stored. For a hash destination, the second argument is the key to the hash, and the third argument the value to be stored. It is up to the subroutine to store the value, or do whatever it thinks is appropriate.

A trivial application of this mechanism is to implement options that are related to each other. For example:

```
my $verbose = '';   # option variable with default value (false)
GetOptions ('verbose' => \$verbose,
            'quiet'   => sub { $verbose = 0 });
```

Here `--verbose` and `--quiet` control the same variable `$verbose`, but with opposite values.

If the subroutine needs to signal an error, it should call die() with the desired error message as its argument. GetOptions() will catch the die(), issue the error message, and record that an error result must be returned upon completion.

If the text of the error message starts with an exclamation mark `!` it is interpreted specially by GetOptions(). There is currently one special command implemented: `die("!FINISH")` will cause GetOptions() to stop processing options, as if it encountered a double dash `--`.

Here is an example of how to access the option name and value from within a subroutine:

```
GetOptions ('opt=i' => \&handler);
sub handler {
    my ($opt_name, $opt_value) = @_;
    print("Option name is $opt_name and value is $opt_value\n");
}
```

Options with multiple names

Often it is user friendly to supply alternate mnemonic names for options. For example `--height` could be an alternate name for `--length`. Alternate names can be included in the option specification, separated by vertical bar `|` characters. To implement the above example:

```
GetOptions ('length|height=f' => \$length);
```

The first name is called the *primary* name, the other names are called *aliases*. When using a hash to store options, the key will always be the primary name.

Multiple alternate names are possible.

Case and abbreviations

Without additional configuration, GetOptions() will ignore the case of option names, and allow the options to be abbreviated to uniqueness.

```
GetOptions ('length|height=f' => \$length, "head" => \$head);
```

This call will allow `--l` and `--L` for the length option, but requires a least `--hea` and `--hei` for the head and height options.

Summary of Option Specifications

Each option specifier consists of two parts: the name specification and the argument specification.

The name specification contains the name of the option, optionally followed by a list of alternative names separated by vertical bar characters. The name is made up of alphanumeric characters, hyphens, underscores. If `pass_through` is disabled, a period is also allowed in option names.

```
length            option name is "length"
length|size|l     name is "length", aliases are "size" and "l"
```

The argument specification is optional. If omitted, the option is considered boolean, a value of 1 will be assigned when the option is used on the command line.

The argument specification can be

- !

  The option does not take an argument and may be negated by prefixing it with "no" or "no-". E.g. `"foo!"` will allow `--foo` (a value of 1 will be assigned) as well as `--nofoo` and `--no-foo` (a value of 0 will be assigned). If the option has aliases, this applies to the aliases as well.

  Using negation on a single letter option when bundling is in effect is pointless and will result in a warning.

- +

  The option does not take an argument and will be incremented by 1 every time it appears on the command line. E.g. `"more+"`, when used with `--more --more --more`, will increment the value three times, resulting in a value of 3 (provided it was 0 or undefined at first).

  The + specifier is ignored if the option destination is not a scalar.

- = *type* [*desttype*] [*repeat*]

  The option requires an argument of the given type. Supported types are:

  - s

    String. An arbitrary sequence of characters. It is valid for the argument to start with - or --.

  - i

    Integer. An optional leading plus or minus sign, followed by a sequence of digits.

  - o

Extended integer, Perl style. This can be either an optional leading plus or minus sign, followed by a sequence of digits, or an octal string (a zero, optionally followed by '0', '1', .. '7'), or a hexadecimal string (`0x` followed by '0' .. '9', 'a' .. 'f', case insensitive), or a binary string (`0b` followed by a series of '0' and '1').

– f

Real number. For example `3.14`, `-6.23E24` and so on.

The *desttype* can be `@` or `%` to specify that the option is list or a hash valued. This is only needed when the destination for the option value is not otherwise specified. It should be omitted when not needed.

The *repeat* specifies the number of values this option takes per occurrence on the command line. It has the format `{` [*min*] [`,` [*max*]] `}`.

min denotes the minimal number of arguments. It defaults to 1 for options with `=` and to 0 for options with `:`, see below. Note that *min* overrules the `=` / `:` semantics.

max denotes the maximum number of arguments. It must be at least *min*. If *max* is omitted, *but the comma is not*, there is no upper bound to the number of argument values taken.

- : *type* [*desttype*]

  Like `=`, but designates the argument as optional. If omitted, an empty string will be assigned to string values options, and the value zero to numeric options.

  Note that if a string argument starts with `-` or `--`, it will be considered an option on itself.

- : *number* [*desttype*]

  Like `:i`, but if the value is omitted, the *number* will be assigned.

  If the *number* is octal, hexadecimal or binary, behaves like `:o`.

- : `+` [*desttype*]

  Like `:i`, but if the value is omitted, the current value for the option will be incremented.

Advanced Possibilities

Object oriented interface

See *Getopt::Long::Parser*.

Callback object

In version 2.37 the first argument to the callback function was changed from string to object. This was done to make room for extensions and more detailed control. The object stringifies to the option name so this change should not introduce compatibility problems.

The callback object has the following methods:

- name

The name of the option, unabbreviated. For an option with multiple names it return the first (canonical) name.

- given

  The name of the option as actually used, unabbreveated.

Thread Safety

Getopt::Long is thread safe when using ithreads as of Perl 5.8. It is *not* thread safe when using the older (experimental and now obsolete) threads implementation that was added to Perl 5.005.

Documentation and help texts

Getopt::Long encourages the use of Pod::Usage to produce help messages. For example:

```
use Getopt::Long;
use Pod::Usage;

my $man = 0;
my $help = 0;

GetOptions('help|?' => \$help, man => \$man) or pod2usage(2);
pod2usage(1) if $help;
pod2usage(-exitval => 0, -verbose => 2) if $man;

__END__

B<This program> will read the given input file(s) and do something
useful with the contents thereof.

=cut
```

See *Pod::Usage* for details.

Parsing options from an arbitrary array

By default, GetOptions parses the options that are present in the global array `@ARGV`. A special entry `GetOptionsFromArray` can be used to parse options from an arbitrary array.

```
use Getopt::Long qw(GetOptionsFromArray);
$ret = GetOptionsFromArray(\@myopts, ...);
```

When used like this, options and their possible values are removed from `@myopts`, the global `@ARGV` is not touched at all.

The following two calls behave identically:

```
$ret = GetOptions( ... );
$ret = GetOptionsFromArray(\@ARGV, ... );
```

This also means that a first argument hash reference now becomes the second argument:

```
$ret = GetOptions(\%opts, ... );
$ret = GetOptionsFromArray(\@ARGV, \%opts, ... );
```

Parsing options from an arbitrary string

A special entry `GetOptionsFromString` can be used to parse options from an arbitrary string.

```
use Getopt::Long qw(GetOptionsFromString);
$ret = GetOptionsFromString($string, ...);
```

The contents of the string are split into arguments using a call to `Text::ParseWords::shellwords`. As with `GetOptionsFromArray`, the global `@ARGV` is not touched.

It is possible that, upon completion, not all arguments in the string have been processed. `GetOptionsFromString` will, when called in list context, return both the return status and an array reference to any remaining arguments:

```
($ret, $args) = GetOptionsFromString($string, ... );
```

If any arguments remain, and `GetOptionsFromString` was not called in list context, a message will be given and `GetOptionsFromString` will return failure.

As with GetOptionsFromArray, a first argument hash reference now becomes the second argument. See the next section.

Storing options values in a hash

Sometimes, for example when there are a lot of options, having a separate variable for each of them can be cumbersome. GetOptions() supports, as an alternative mechanism, storing options values in a hash.

To obtain this, a reference to a hash must be passed *as the first argument* to GetOptions(). For each option that is specified on the command line, the option value will be stored in the hash with the option name as key. Options that are not actually used on the command line will not be put in the hash, on other words, `exists($h{option})` (or defined()) can be used to test if an option was used. The drawback is that warnings will be issued if the program runs under `use strict` and uses `$h{option}` without testing with exists() or defined() first.

```
my %h = ();
GetOptions (\%h, 'length=i');       # will store in $h{length}
```

For options that take list or hash values, it is necessary to indicate this by appending an @ or % sign after the type:

```
GetOptions (\%h, 'colours=s@');     # will push to @{$h{colours}}
```

To make things more complicated, the hash may contain references to the actual destinations, for example:

```
my $len = 0;
my %h = ('length' => \$len);
GetOptions (\%h, 'length=i');       # will store in $len
```

This example is fully equivalent with:

```
my $len = 0;
GetOptions ('length=i' => \$len);   # will store in $len
```

Any mixture is possible. For example, the most frequently used options could be stored in variables while all other options get stored in the hash:

```
my $verbose = 0;                    # frequently referred
my $debug = 0;                      # frequently referred
my %h = ('verbose' => \$verbose, 'debug' => \$debug);
GetOptions (\%h, 'verbose', 'debug', 'filter', 'size=i');
if ( $verbose ) { ... }
if ( exists $h{filter} ) { ... option 'filter' was specified ... }
```

Bundling

With bundling it is possible to set several single-character options at once. For example if a, v and x are all valid options,

```
-vax
```

will set all three.

Getopt::Long supports three styles of bundling. To enable bundling, a call to Getopt::Long::Configure is required.

The simplest style of bundling can be enabled with:

```
Getopt::Long::Configure ("bundling");
```

Configured this way, single-character options can be bundled but long options (and any of their auto-abbreviated shortened forms) **must** always start with a double dash `--` to avoid ambiguity. For example, when `vax`, `a`, `v` and `x` are all valid options,

```
-vax
```

will set `a`, `v` and `x`, but

```
--vax
```

will set `vax`.

The second style of bundling lifts this restriction. It can be enabled with:

```
Getopt::Long::Configure ("bundling_override");
```

Now, `-vax` will set the option `vax`.

In all of the above cases, option values may be inserted in the bundle. For example:

```
-h24w80
```

is equivalent to

```
-h 24 -w 80
```

A third style of bundling allows only values to be bundled with options. It can be enabled with:

```
Getopt::Long::Configure ("bundling_values");
```

Now, `-h24` will set the option `h` to `24`, but option bundles like `-vxa` and `-h24w80` are flagged as errors.

Enabling `bundling_values` will disable the other two styles of bundling.

When configured for bundling, single-character options are matched case sensitive while long options are matched case insensitive. To have the single-character options matched case insensitive as well, use:

```
Getopt::Long::Configure ("bundling", "ignorecase_always");
```

It goes without saying that bundling can be quite confusing.

The lonesome dash

Normally, a lone dash - on the command line will not be considered an option. Option processing will terminate (unless "permute" is configured) and the dash will be left in @ARGV.

It is possible to get special treatment for a lone dash. This can be achieved by adding an option specification with an empty name, for example:

```
GetOptions ('' => \$stdio);
```

A lone dash on the command line will now be a legal option, and using it will set variable $stdio.

Argument callback

A special option 'name' <> can be used to designate a subroutine to handle non-option arguments. When GetOptions() encounters an argument that does not look like an option, it will immediately call this subroutine and passes it one parameter: the argument name.

For example:

```
my $width = 80;
sub process { ... }
GetOptions ('width=i' => \$width, '<>' => \&process);
```

When applied to the following command line:

```
arg1 --width=72 arg2 --width=60 arg3
```

This will call process("arg1") while $width is 80, process("arg2") while $width is 72, and process("arg3") while $width is 60.

This feature requires configuration option **permute**, see section "Configuring Getopt::Long".

Configuring Getopt::Long

Getopt::Long can be configured by calling subroutine Getopt::Long::Configure(). This subroutine takes a list of quoted strings, each specifying a configuration option to be enabled, e.g. ignore_case. To disable, prefix with no or no_, e.g. no_ignore_case. Case does not matter. Multiple calls to Configure() are possible.

Alternatively, as of version 2.24, the configuration options may be passed together with the use statement:

```
use Getopt::Long qw(:config no_ignore_case bundling);
```

The following options are available:

- default

  This option causes all configuration options to be reset to their default values.

- posix_default

  This option causes all configuration options to be reset to their default values as if the environment variable POSIXLY_CORRECT had been set.

- auto_abbrev

  Allow option names to be abbreviated to uniqueness. Default is enabled unless environment variable POSIXLY_CORRECT has been set, in which case `auto_abbrev` is disabled.

- getopt_compat

  Allow `+` to start options. Default is enabled unless environment variable POSIXLY_CORRECT has been set, in which case `getopt_compat` is disabled.

- gnu_compat

  `gnu_compat` controls whether `--opt=` is allowed, and what it should do. Without `gnu_compat`, `--opt=` gives an error. With `gnu_compat`, `--opt=` will give option `opt` an empty value. This is the way GNU getopt_long() does it.

  Note that for options with optional arguments, `--opt value` is still accepted, even though GNU getopt_long() requires writing `--opt=value` in this case.

- gnu_getopt

  This is a short way of setting `gnu_compat` `bundling` `permute` `no_getopt_compat`. With `gnu_getopt`, command line handling should be reasonably compatible with GNU getopt_long().

- require_order

  Whether command line arguments are allowed to be mixed with options. Default is disabled unless environment variable POSIXLY_CORRECT has been set, in which case `require_order` is enabled.

  See also `permute`, which is the opposite of `require_order`.

- permute

  Whether command line arguments are allowed to be mixed with options. Default is enabled unless environment variable POSIXLY_CORRECT has been set, in which case `permute` is disabled. Note that `permute` is the opposite of `require_order`.

  If `permute` is enabled, this means that

  ```
  --foo arg1 --bar arg2 arg3
  ```

  is equivalent to

  ```
  --foo --bar arg1 arg2 arg3
  ```

If an argument callback routine is specified, @ARGV will always be empty upon successful return of GetOptions() since all options have been processed. The only exception is when `--` is used:

```
--foo arg1 --bar arg2 -- arg3
```

This will call the callback routine for arg1 and arg2, and then terminate GetOptions() leaving `"arg3"` in @ARGV.

If `require_order` is enabled, options processing terminates when the first non-option is encountered.

```
--foo arg1 --bar arg2 arg3
```

is equivalent to

```
--foo -- arg1 --bar arg2 arg3
```

If `pass_through` is also enabled, options processing will terminate at the first unrecognized option, or non-option, whichever comes first.

- bundling (default: disabled)

  Enabling this option will allow single-character options to be bundled. To distinguish bundles from long option names, long options (and any of their auto-abbreviated shortened forms) *must* be introduced with `--` and bundles with `-`.

  Note that, if you have options `a`, `l` and `all`, and auto_abbrev enabled, possible arguments and option settings are:

```
using argument               sets option(s)
------------------------------------------
-a, --a                      a
-l, --l                      l
-al, -la, -ala, -all,...     a, l
--al, --all                  all
```

  The surprising part is that `--a` sets option `a` (due to auto completion), not `all`.

  Note: disabling `bundling` also disables `bundling_override`.

- bundling_override (default: disabled)

  If `bundling_override` is enabled, bundling is enabled as with `bundling` but now long option names override option bundles.

  Note: disabling `bundling_override` also disables `bundling`.

  Note: Using option bundling can easily lead to unexpected results, especially when mixing long options and bundles. Caveat emptor.

- ignore_case (default: enabled)

  If enabled, case is ignored when matching option names. If, however, bundling is enabled as well, single character options will be treated case-sensitive.

With `ignore_case`, option specifications for options that only differ in case, e.g., `"foo"` and `"Foo"`, will be flagged as duplicates.

Note: disabling `ignore_case` also disables `ignore_case_always`.

- ignore_case_always (default: disabled)

  When bundling is in effect, case is ignored on single-character options also.

  Note: disabling `ignore_case_always` also disables `ignore_case`.

- auto_version (default:disabled)

  Automatically provide support for the –**version** option if the application did not specify a handler for this option itself.

  Getopt::Long will provide a standard version message that includes the program name, its version (if $main::VERSION is defined), and the versions of Getopt::Long and Perl. The message will be written to standard output and processing will terminate.

  `auto_version` will be enabled if the calling program explicitly specified a version number higher than 2.32 in the `use` or `require` statement.

- auto_help (default:disabled)

  Automatically provide support for the –**help** and **-?** options if the application did not specify a handler for this option itself.

  Getopt::Long will provide a help message using module *Pod::Usage*. The message, derived from the SYNOPSIS POD section, will be written to standard output and processing will terminate.

  `auto_help` will be enabled if the calling program explicitly specified a version number higher than 2.32 in the `use` or `require` statement.

- pass_through (default: disabled)

  With `pass_through` anything that is unknown, ambiguous or supplied with an invalid option will not be flagged as an error. Instead the unknown option(s) will be passed to the catchall `<>` if present, otherwise through to `@ARGV`. This makes it possible to write wrapper scripts that process only part of the user supplied command line arguments, and pass the remaining options to some other program.

  If `require_order` is enabled, options processing will terminate at the first unrecognized option, or non-option, whichever comes first and all remaining arguments are passed to `@ARGV` instead of the catchall `<>` if present. However, if `permute` is enabled instead, results can become confusing.

  Note that the options terminator (default `--`), if present, will also be passed through in `@ARGV`.

- prefix

  The string that starts options. If a constant string is not sufficient, see `prefix_pattern`.

- prefix_pattern

A Perl pattern that identifies the strings that introduce options. Default is `--|-|\+` unless environment variable POSIXLY_CORRECT has been set, in which case it is `--|-`.

- long_prefix_pattern

  A Perl pattern that allows the disambiguation of long and short prefixes. Default is `--`.

  Typically you only need to set this if you are using nonstandard prefixes and want some or all of them to have the same semantics as '–' does under normal circumstances.

  For example, setting prefix_pattern to `--|-|\+|\/` and long_prefix_pattern to `--|\/` would add Win32 style argument handling.

- debug (default: disabled)

  Enable debugging output.

Exportable Methods

- VersionMessage

  This subroutine provides a standard version message. Its argument can be:

  – A string containing the text of a message to print *before* printing the standard message.

  – A numeric value corresponding to the desired exit status.

  – A reference to a hash.

  If more than one argument is given then the entire argument list is assumed to be a hash. If a hash is supplied (either as a reference or as a list) it should contain one or more elements with the following keys:

  – `-message`

  – `-msg`

    The text of a message to print immediately prior to printing the program's usage message.

  – `-exitval`

    The desired exit status to pass to the **exit()** function. This should be an integer, or else the string "NOEXIT" to indicate that control should simply be returned without terminating the invoking process.

  – `-output`

    A reference to a filehandle, or the pathname of a file to which the usage message should be written. The default is `\*STDERR` unless the exit value is less than 2 (in which case the default is `\*STDOUT`).

  You cannot tie this routine directly to an option, e.g.:

```
GetOptions("version" => \&VersionMessage);
```

  Use this instead:

```
GetOptions("version" => sub { VersionMessage() });
```

- HelpMessage

  This subroutine produces a standard help message, derived from the program's POD section SYNOPSIS using *Pod::Usage*. It takes the same arguments as VersionMessage(). In particular, you cannot tie it directly to an option, e.g.:

```
GetOptions("help" => \&HelpMessage);
```

  Use this instead:

```
GetOptions("help" => sub { HelpMessage() });
```

Return values and Errors

Configuration errors and errors in the option definitions are signalled using die() and will terminate the calling program unless the call to Getopt::Long::GetOptions() was embedded in `eval { ... }`, or die() was trapped using `$SIG{__DIE__}`.

GetOptions returns true to indicate success. It returns false when the function detected one or more errors during option parsing. These errors are signalled using warn() and can be trapped with `$SIG{__WARN__}`.

Legacy

The earliest development of `newgetopt.pl` started in 1990, with Perl version 4. As a result, its development, and the development of Getopt::Long, has gone through several stages. Since backward compatibility has always been extremely important, the current version of Getopt::Long still supports a lot of constructs that nowadays are no longer necessary or otherwise unwanted. This section describes briefly some of these 'features'.

Default destinations

When no destination is specified for an option, GetOptions will store the resultant value in a global variable named `opt_`*XXX*, where *XXX* is the primary name of this option. When a program executes under `use strict` (recommended), these variables must be pre-declared with our().

```
our $opt_length = 0;
GetOptions ('length=i');    # will store in $opt_length
```

To yield a usable Perl variable, characters that are not part of the syntax for variables are translated to underscores. For example, `--fpp-struct-return` will set the variable `$opt_fpp_struct_return`. Note that this variable resides in the namespace of the calling program, not necessarily `main`. For example:

```
GetOptions ("size=i", "sizes=i@");
```

with command line "-size 10 -sizes 24 -sizes 48" will perform the equivalent of the assignments

```
$opt_size = 10;
@opt_sizes = (24, 48);
```

Alternative option starters

A string of alternative option starter characters may be passed as the first argument (or the first argument after a leading hash reference argument).

```
my $len = 0;
GetOptions ('/', 'length=i' => $len);
```

Now the command line may look like:

```
/length 24 -- arg
```

Note that to terminate options processing still requires a double dash `--`.

GetOptions() will not interpret a leading `"<>"` as option starters if the next argument is a reference. To force `"<"` and `">"` as option starters, use `"><"`. Confusing? Well, **using a starter argument is strongly deprecated** anyway.

Configuration variables

Previous versions of Getopt::Long used variables for the purpose of configuring. Although manipulating these variables still work, it is strongly encouraged to use the `Configure` routine that was introduced in version 2.17. Besides, it is much easier.

Tips and Techniques

Pushing multiple values in a hash option

Sometimes you want to combine the best of hashes and arrays. For example, the command line:

```
--list add=first --list add=second --list add=third
```

where each successive 'list add' option will push the value of add into array ref $list->{'add'}. The result would be like

```
$list->{add} = [qw(first second third)];
```

This can be accomplished with a destination routine:

```
GetOptions('list=s%' =>
            sub { push(@{$list{$_[1]}}, $_[2]) });
```

Troubleshooting

GetOptions does not return a false result when an option is not supplied

That's why they're called 'options'.

GetOptions does not split the command line correctly

The command line is not split by GetOptions, but by the command line interpreter (CLI). On Unix, this is the shell. On Windows, it is COMMAND.COM or CMD.EXE. Other operating systems have other CLIs.

It is important to know that these CLIs may behave different when the command line contains special characters, in particular quotes or backslashes. For example, with Unix shells you can use single quotes (') and double quotes (") to group words together. The following alternatives are equivalent on Unix:

```
"two words"
'two words'
two\ words
```

In case of doubt, insert the following statement in front of your Perl program:

```
print STDERR (join("|",@ARGV),"\n");
```

to verify how your CLI passes the arguments to the program.

Undefined subroutine &main::GetOptions called

Are you running Windows, and did you write

```
use GetOpt::Long;
```

(note the capital 'O')?

How do I put a "-?" option into a Getopt::Long?

You can only obtain this using an alias, and Getopt::Long of at least version 2.13.

```
use Getopt::Long;
GetOptions ("help|?");    # -help and -? will both set $opt_help
```

Other characters that can't appear in Perl identifiers are also supported in aliases with Getopt::Long of at version 2.39. Note that the characters `!`, `|`, `+`, `=`, and `:` can only appear as the first (or only) character of an alias.

As of version 2.32 Getopt::Long provides auto-help, a quick and easy way to add the options –help and -? to your program, and handle them.

See `auto_help` in section "Configuring Getopt::Long".

Modules

- `Getopt::Long::Parser` - Getopt::Long object-oriented interface

Getopt::Long::Parser

Getopt::Long object-oriented interface

SYNOPSIS

```
use Getopt::Long::Parser;
my $p = Getopt::Long::Parser->new;
$p->configure( %options );
if ( $p->getoptions( @options ) ) { ... }
if ( $p->getoptionsfromarray( \@array, @options ) ) { ... }
```

Configuration options can be passed to the constructor:

```
my $p = Getopt::Long::Parser->new( config => [ %options ] );
```

DESCRIPTION

`Getopt::Long::Parser` is an object-oriented interface to *Getopt::Long*. See its documentation for configuration and use.

Note that `Getopt::Long` and `Getopt::Long::Parser` are not object-oriented. `Getopt::Long::Parser` emulates an object-oriented interface, which should be okay for most purposes.

CONSTRUCTOR

```
my $p = Getopt::Long::Parser->new( %options );
```

The constructor takes an optional hash with parameters.

- config

  An array reference with configuration settings. See *"Configuring Getopt::Long" in Getopt::Long* for all possible settings.

METHODS

In the examples, $p is assumed to be the result of a call to the constructor.

configure

```
$p->configure( %settings );
```

Update the current config settings. See *"Configuring Getopt::Long" in Getopt::Long* for all possible settings.

getoptionsfromarray

```
my $res = $p->getoptionsfromarray( $aref, @opts );
```

getoptions

```
my $res = $p->getoptions( @opts );
```

The same as `getoptionsfromarray( \@ARGV, @opts )`.

Getopt::Std

Process single-character switches with switch clustering

SYNOPSIS

```
use Getopt::Std;

getopts('oif:');  # -o & -i are boolean flags, -f takes an argument
                  # Sets $opt_* global variables as a side effect
getopts('oif:', \my %opts);  # Options as above, values in %opts
getopt('oDI');    # -o, -D & -I take arguments
                  # Sets $opt_* global variables as a side effect
getopt('oDI', \my %opts);    # -o, -D & -I take arg, values in %opts
```

DESCRIPTION

The `getopts()` function processes single-character switches with switch clustering. Pass one argument which is a string containing all switches to be recognized. For each switch found, if an argument is expected and provided, `getopts()` sets `$opt_x` (where `x` is the switch name) to the value of the argument. If an argument is expected but none is provided, `$opt_x` is set to an undefined value. If a switch does not take an argument, `$opt_x` is set to 1.

Switches which take an argument don't care whether there is a space between the switch and the argument. If unspecified switches are found on the command-line, the user will be warned that an unknown option was given.

The `getopts()` function returns true unless an invalid option was found.

The `getopt()` function is similar, but its argument is a string containing all switches that take an argument. If no argument is provided for a switch, say, `y`, the corresponding `$opt_y` will be set to an undefined value. Unspecified switches are silently accepted. Use of `getopt()` is **not recommended**.

Note that, if your code is running under the recommended `use strict vars` pragma, you will need to declare these package variables with `our`:

```
our($opt_x, $opt_y);
```

For those of you who don't like additional global variables being created, `getopt()` and `getopts()` will also accept a hash reference as an optional second argument. Hash keys will be `x` (where `x` is the switch name) with key values the value of the argument or 1 if no argument is specified.

To allow programs to process arguments that look like switches, but aren't, both functions will stop processing switches when they see the argument `--`. The `--` will be removed from `@ARGV`.

`--help` and `--version`

If `-` is not a recognized switch letter, `getopts()` supports arguments `--help` and `--version`. If `main::HELP_MESSAGE()` and/or `main::VERSION_MESSAGE()` are defined, they are called; the arguments are the output file handle, the name of option-processing package, its version, and the switches string. If the subroutines are not defined, an attempt is made to generate intelligent messages; for best results, define `$main::VERSION`.

If embedded documentation (in pod format, see perlpod) is detected in the script, `--help` will also show how to access the documentation.

Note that due to excessive paranoia, if `$Getopt::Std::STANDARD_HELP_VERSION` isn't true (the default is false), then the messages are printed on `STDERR`, and the processing continues after the messages are printed. This being the opposite of the standard-conforming behaviour, it is strongly recommended to set `$Getopt::Std::STANDARD_HELP_VERSION` to true.

One can change the output file handle of the messages by setting `$Getopt::Std::OUTPUT_HELP_VERSION`. One can print the messages of `--help` (without the `Usage:` line) and `--version` by calling functions `help_mess()` and `version_mess()` with the switches string as an argument.

5.2.52 Guard

Guard - run a piece of code when a scope ends or an object goes away.

```
use Guard;

{
    scope_guard { print "leaving the block\n" };
    ...
}                       # prints here, however the block is left

my $g = guard { unlink $tempfile };
...
undef $g;               # runs now - or whenever the last copy goes
```

`scope_guard BLOCK` runs the block when the enclosing scope is left: at its end, through `return`, `last`, or an exception unwinding past it.

`guard BLOCK` returns an object that runs the block when it is destroyed - when the last reference to it goes away. It can be stored, passed around and kept in a data structure, and the code runs exactly once, when nothing holds it any more. `Guard::cancel($guard)` disarms one: its code will then never run.

The code runs with `$@` saved and restored, so a guard firing while an exception is on its way out does not overwrite it. If the guard's own code dies, the exception is handed to `$Guard::DIED`, which by default `warn`s it; the exception never escapes the guard.

This is a native implementation of the CPAN module Guard 1.023; its `Guard.pm` is used unchanged.

Differences from upstream

One, where perl 5.44 with Guard.xs fails: `Guard::cancel(\1)` - a reference to a plain number or undef - dies "Guard::cancel called on a non-guard object", as for every other non-guard; perl5 reads past the value and crashes some of the time (t/81-xs-native/Guard/300-guard-surface.t).

Functions

Other Functions

scope_guard

`scope_guard BLOCK`: run BLOCK when the enclosing scope is left - at its end, by `return`, `last`/`next`, or an exception passing through. Several in one scope run in reverse order of creation. Exported by default.

guard

`guard BLOCK`: an object that runs BLOCK when it is destroyed, that is when the last reference to it goes away - so the code's lifetime can be tied to a data structure rather than a scope. Exported by default.

cancel

`Guard::cancel($guard)`: disarm a guard object made by `guard` - its code will never run. Anything else dies "Guard::cancel called on a non-guard object". Not exported; it is also the method `$guard->cancel`.

scope_guard

`scope_guard BLOCK`: run BLOCK when the enclosing scope is left - at its end, by `return`, `last`/`next`, or an exception passing through. Several in one scope run in reverse order of creation. Exported by default.

```
{
    my $lock = acquire();
    scope_guard { release($lock) };
    work();                 # release runs even if this dies
}
```

5.2.53 HTML

Namespace containing the following modules:

- `HTML::Entities` - Encode or decode strings with HTML entities
- `HTML::Filter` - Filter HTML text through the parser
- `HTML::HeadParser` - Parse section of a HTML document
- `HTML::LinkExtor` - Extract links from an HTML document
- `HTML::Parser` - Parse HTML into events: start and end tags, text, comments, declarations, processing instructions.
- `HTML::PullParser` - Alternative HTML::Parser interface
- `HTML::Tagset` - data tables useful in parsing HTML
- `HTML::TokeParser` - Alternative HTML::Parser interface

HTML::Entities

Encode or decode strings with HTML entities

SYNOPSIS

```
use HTML::Entities;

$a = "V&aring;re norske tegn b&oslash;r &#230res";
decode_entities($a);
encode_entities($a, "\200-\377");
```

For example, this:

```
$input = "vis-à-vis Beyoncé's naïve\npapier-mâché résumé";
print encode_entities($input), "\n"
```

Prints this out:

```
vis-&agrave;-vis Beyonc&eacute;'s na&iuml;ve
papier-m&acirc;ch&eacute; r&eacute;sum&eacute;
```

DESCRIPTION

This module deals with encoding and decoding of strings with HTML character entities. The module provides the following functions:

- decode_entities($string, ...)

  This routine replaces HTML entities found in the $string with the corresponding Unicode character. Unrecognized entities are left alone.

  If multiple strings are provided as argument they are each decoded separately and the same number of strings are returned.

  If called in void context the arguments are decoded in-place.

  This routine is exported by default.

- _decode_entities($string, \%entity2char)

- _decode_entities($string, \%entity2char, $expand_prefix)

  This will in-place replace HTML entities in $string. The %entity2char hash must be provided. Named entities not found in the %entity2char hash are left alone. Numeric entities are expanded unless their value overflow.

  The keys in %entity2char are the entity names to be expanded and their values are what they should expand into. The values do not have to be single character strings. If a key has ";" as suffix, then occurrences in $string are only expanded if properly terminated with ";". Entities without ";" will be expanded regardless of how they are terminated for compatibility with how common browsers treat entities in the Latin-1 range.

  If $expand_prefix is TRUE then entities without trailing ";" in

  unrecognized name. The longest matching name in %entity2char will be used. This is mainly present for compatibility with an MSIE misfeature.

  ```
  $string = "foo&nbspbar";
  _decode_entities($string, { nb => "@", nbsp => "\xA0" }, 1);
  print $string;  # will print "foo bar"
  ```

  An entity whose value is the string being decoded expands to the value that string had when the call began. This routine does not scan replacement text again, so any entities inside it are left alone.

  Looking up a value can run Perl code, through a tied hash or an overloaded object. If that code modifies the string being decoded, this routine dies.

  This routine is exported by default.

- encode_entities($string)
- encode_entities($string, $unsafe_chars)

  This routine replaces unsafe characters in $string with their entity representation. A second argument can be given to specify which characters to consider unsafe. The unsafe characters is specified using the regular expression character class syntax (what you find within brackets in regular expressions).

  The default set of characters to encode are control chars, high-bit chars, and the <, &, >, ' and " characters. But this, for example, would encode *just* the <, &, >, and " characters:

```
$encoded = encode_entities($input, '<>&"');
```

  and this would only encode non-plain ASCII:

```
$encoded = encode_entities($input, '^\n\x20-\x25\x27-\x7e');
```

  This routine is exported by default.

- encode_entities_numeric($string)
- encode_entities_numeric($string, $unsafe_chars)

  This routine works just like encode_entities, except that the replacement entities are always &#x_hexnum_; and never &_entname_;. For example, `encode_entities("r\xF4le")` returns “rôle”, but `encode_entities_numeric("r\xF4le")` returns “rôle”.

  This routine is *not* exported by default. But you can always export it with `use HTML::Entities qw(encode_entities_numeric);` or even `use HTML::Entities qw(:DEFAULT encode_entities_numeric);`

All these routines modify the string passed as the first argument, if called in a void context. In scalar and array contexts, the encoded or decoded string is returned (without changing the input string).

If you prefer not to import these routines into your namespace, you can call them as:

```
use HTML::Entities ();
$decoded = HTML::Entities::decode($a);
$encoded = HTML::Entities::encode($a);
$encoded = HTML::Entities::encode_numeric($a);
```

The module can also export the %char2entity and the %entity2char hashes, which contain the mapping from all characters to the corresponding entities (and vice versa, respectively).

COPYRIGHT

Copyright 1995-2006 Gisle Aas. All rights reserved.

Functions

Entities

decode_entities

Replace the entities in the strings: in place in void context, else returning decoded copies.

UNICODE_SUPPORT

Always 1: entities decode to Unicode characters.

HTML::Filter

Filter HTML text through the parser

NOTE

This module is deprecated. The `HTML::Parser` now provides the functionally of `HTML::Filter` much more efficiently with the `default` handler.

SYNOPSIS

```
require HTML::Filter;
$p = HTML::Filter->new->parse_file("index.html");
```

DESCRIPTION

`HTML::Filter` is an HTML parser that by default prints the original text of each HTML element (a slow version of cat(1) basically). The callback methods may be overridden to modify the filtering for some HTML elements and you can override output() method which is called to print the HTML text.

`HTML::Filter` is a subclass of `HTML::Parser`. This means that the document should be given to the parser by calling the $p->parse() or $p->parse_file() methods.

EXAMPLES

The first example is a filter that will remove all comments from an HTML file. This is achieved by simply overriding the comment method to do nothing.

```
package CommentStripper;
require HTML::Filter;
@ISA=qw(HTML::Filter);
sub comment { }  # ignore comments
```

The second example shows a filter that will remove any s found in the HTML file. We specialize the start() and end() methods to count table tags and then make output not happen when inside a table.

```
package TableStripper;
require HTML::Filter;
@ISA=qw(HTML::Filter);
sub start
{
   my $self = shift;
   $self->{table_seen}++ if $_[0] eq "table";
   $self->SUPER::start(@_);
}

sub end
{
   my $self = shift;
   $self->SUPER::end(@_);
   $self->{table_seen}-- if $_[0] eq "table";
}

sub output
{
    my $self = shift;
    unless ($self->{table_seen}) {
        $self->SUPER::output(@_);
    }
}
```

If you want to collect the parsed text internally you might want to do something like this:

```
package FilterIntoString;
require HTML::Filter;
@ISA=qw(HTML::Filter);
sub output { push(@{$_[0]->{fhtml}}, $_[1]) }
sub filtered_html { join("", @{$_[0]->{fhtml}}) }
```

SEE ALSO

HTML::Parser

COPYRIGHT

Copyright 1997-1999 Gisle Aas.

This library is free software; you can redistribute it and/or modify it under the same terms as Perl itself.

HTML::HeadParser

Parse section of a HTML document

SYNOPSIS

```
require HTML::HeadParser;
$p = HTML::HeadParser->new;
$p->parse($text) and  print "not finished";

$p->header('Title')           # to access <title>....</title>
$p->header('Content-Base')    # to access <base href="http://...">
$p->header('Foo')             # to access <meta http-equiv="Foo"␣
↪content="...">
$p->header('X-Meta-Author')   # to access <meta name="author"␣
↪content="...">
$p->header('X-Meta-Charset') # to access <meta charset="...">
```

DESCRIPTION

The `HTML::HeadParser` is a specialized (and lightweight) `HTML::Parser` that will only parse the ...</HEAD> section of an HTML document. The parse() method will return a FALSE value as soon as some element or body text are found, and should not be called again after this.

Note that the `HTML::HeadParser` might get confused if raw undecoded UTF-8 is passed to the parse() method. Make sure the strings are properly decoded before passing them on.

The `HTML::HeadParser` keeps a reference to a header object, and the parser will update this header object as the various elements of the

- Content-Base:

  The *Content-Base* header is initialized from the <base href="..."> element.

- Title:

  The *Title* header is initialized from the <title>...</title> element.

- Isindex:

  The *Isindex* header will be added if there is a <isindex> element in the <head>. The header value is initialized from the *prompt* attribute if it is present. If no *prompt* attribute is given it will have '?' as the value.

- X-Meta-Foo:

  All <meta> elements containing a `name` attribute will result in headers using the prefix `X-Meta-` appended with the value of the `name` attribute as the name of the header, and the value of the `content` attribute as the pushed header value.

  <meta> elements containing a `http-equiv` attribute will result in headers as in above, but without the `X-Meta-` prefix in the header name.

  <meta> elements containing a `charset` attribute will result in an `X-Meta-Charset` header, using the value of the `charset` attribute as the pushed header value.

  The ':' character can't be represented in header field names, so if the meta element contains this char it's substituted with '-' before forming the field name.

METHODS

The following methods (in addition to those provided by the superclass) are available:

- $hp = HTML::HeadParser->new
- $hp = HTML::HeadParser->new($header)

  The object constructor. The optional $header argument should be a reference to an object that implement the header() and push_header() methods as defined by the `HTTP::Headers` class. Normally it will be of some class that is a or delegates to the `HTTP::Headers` class.

  If no $header is given `HTML::HeadParser` will create an `HTTP::Headers` object by itself (initially empty).

- $hp->header;

  Returns a reference to the header object.

- $hp->header($key)

  Returns a header value. It is just a shorter way to write `$hp->header->header($key)`.

EXAMPLE

```
$h = HTTP::Headers->new;
$p = HTML::HeadParser->new($h);
$p->parse(<<EOT);
<title>Stupid example</title>
<base href="http://www.linpro.no/lwp/">
Normal text starts here.
EOT
undef $p;
print $h->title;   # should print "Stupid example"
```

SEE ALSO

HTML::Parser, HTTP::Headers

The `HTTP::Headers` class is distributed as part of the *libwww-perl* package. If you don't have that distribution installed you need to provide the $header argument to the `HTML::HeadParser` constructor with your own object that implements the documented protocol.

HTML::LinkExtor

Extract links from an HTML document

SYNOPSIS

```
require HTML::LinkExtor;
$p = HTML::LinkExtor->new(\&cb, "http://www.perl.org/");
sub cb {
    my($tag, %links) = @_;
    print "$tag @{[%links]}\n";
}
$p->parse_file("index.html");
```

DESCRIPTION

HTML::LinkExtor is an HTML parser that extracts links from an HTML document. The *HTML::LinkExtor* is a subclass of *HTML::Parser*. This means that the document should be given to the parser by calling the $p->parse() or $p->parse_file() methods.

- $p = HTML::LinkExtor->new
- $p = HTML::LinkExtor->new($callback)
- $p = HTML::LinkExtor->new($callback, $base)

  The constructor takes two optional arguments. The first is a reference to a callback routine. It will be called as links are found. If a callback is not provided, then links are just accumulated internally and can be retrieved by calling the $p->links() method.

  The $base argument is an optional base URL used to absolutize all URLs found. You need to have the *URI* module installed if you provide $base.

  The callback is called with the lowercase tag name as first argument, and then all link attributes as separate key/value pairs. All non-link attributes are removed.

- $p->links

  Returns a list of all links found in the document. The returned values will be anonymous arrays with the following elements:

  ```
  [$tag, $attr => $url1, $attr2 => $url2,...]
  ```

  The $p->links method will also truncate the internal link list. This means that if the method is called twice without any parsing between them the second call will return an empty list.

  Also note that $p->links will always be empty if a callback routine was provided when the *HTML::LinkExtor* was created.

EXAMPLE

This is an example showing how you can extract links from a document received using LWP:

```
use LWP::UserAgent;
use HTML::LinkExtor;
use URI::URL;

$url = "http://www.perl.org/";  # for instance
$ua = LWP::UserAgent->new;

# Set up a callback that collect image links
my @imgs = ();
sub callback {
   my($tag, %attr) = @_;
   return if $tag ne 'img';  # we only look closer at <img ...>
   push(@imgs, values %attr);
}

# Make the parser.  Unfortunately, we don't know the base yet
# (it might be different from $url)
$p = HTML::LinkExtor->new(\&callback);

# Request document and parse it as it arrives
$res = $ua->request(HTTP::Request->new(GET => $url),
                    sub {$p->parse($_[0])});

# Expand all image URLs to absolute ones
my $base = $res->base;
@imgs = map { $_ = url($_, $base)->abs; } @imgs;

# Print them out
print join("\n", @imgs), "\n";
```

HTML::Parser

Parse HTML into events: start and end tags, text, comments, declarations, processing instructions.

`HTML::Parser` reads HTML the way browsers tolerate it - unquoted and unclosed attributes, stray <, comments that end at the first > in a damaged document - and reports what it finds to handlers you register, with exactly the pieces you ask for (`'tagname, attr'`, `'dtext'`, `'offset, length'`, ...). It parses incrementally: feed the document in chunks as it arrives, then `eof`. `HTML::Entities` decodes and encodes character entities, and `HTML::TokeParser`, `HTML::PullParser`, `HTML::LinkExtor`, `HTML::HeadParser` and `HTML::Filter` are built on the parser.

```
use HTML::Parser;
binmode STDOUT, ':utf8';

my $p = HTML::Parser->new(
    api_version => 3,
    start_h => [sub { print "start $_[0] @{[ %{$_[1]} ]}\n" },
↪'tagname, attr'],
    text_h  => [sub { print "text [$_[0]]\n" if $_[0] =~ /\S/ },
↪'dtext'],
);
$p->parse('<p class=x>caf&eacute; &amp; <b>bar</b></p>');
$p->eof;
# start p class x
# text [café & ]
# start b
# text [bar]
```

This is a native implementation of the XS half of HTML-Parser 3.86 (`hparser.c`, `util.c`, `Parser.xs`, with marked sections enabled as upstream builds them); its `HTML/Parser.pm`, `HTML/Entities.pm` and the other modules of the dist are used unchanged.

Differences from upstream

None in behaviour.

Functions

Parsing

parse

Parse a chunk of the document, or chunks from a code reference until it returns nothing. Returns the parser, or undef when a handler called `eof` meanwhile.

eof

End the document: flush what is buffered and report the end. Called from a handler, parsing stops after the current event.

Configuration

strict_comment

Get, and with an argument set, one of the boolean options: strict_comment, strict_names, xml_mode, unbroken_text, marked_sections, attr_encoded, case_sensitive, strict_end, closing_plaintext, utf8_mode, empty_element_tags, xml_pic, backquote.

Also available as HTML::Parser::strict_names, HTML::Parser::xml_mode, HTML::Parser::unbroken_text, HTML::Parser::marked_sections, HTML::Parser::attr_encoded, HTML::Parser::case_sensitive, HTML::Parser::strict_end, HTML::Parser::closing_plaintext, HTML::Parser::utf8_mode, HTML::Parser::empty_element_tags, HTML::Parser::xml_pic, HTML::Parser::backquote.

boolean_attribute_value

Get, and with an argument set, the value a boolean attribute (one written without =value) gets; by default its name.

report_tags

Set the tags whose events are reported (report_tags), those whose tags are ignored (ignore_tags), or those whose whole elements are (ignore_elements); no list clears it.

Also available as HTML::Parser::ignore_tags, HTML::Parser::ignore_elements.

Handlers

handler

Get the handler of an event; with more arguments set it (a code reference, a method name or an array to accumulate into) and the argspec naming what it is passed.

HTML::PullParser

Alternative HTML::Parser interface

SYNOPSIS

```
use HTML::PullParser;

$p = HTML::PullParser->new(file => "index.html",
                           start => 'event, tagname, @attr',
                           end   => 'event, tagname',
                           ignore_elements => [qw(script style)],
                          ) || die "Can't open: $!";
while (my $token = $p->get_token) {
    #...do something with $token
}
```

DESCRIPTION

The HTML::PullParser is an alternative interface to the HTML::Parser class. It basically turns the HTML::Parser inside out. You associate a file (or any IO::Handle object or string) with the parser at construction time and then repeatedly call $parser->get_token to obtain the tags and text found in the parsed document.

The following methods are provided:

- $p = HTML::PullParser->new(file => $file, %options)
- $p = HTML::PullParser->new(doc => \$doc, %options)

  A `HTML::PullParser` can be made to parse from either a file or a literal document based on whether the `file` or `doc` option is passed to the parser's constructor.

  The `file` passed in can either be a file name or a file handle object. If a file name is passed, and it can't be opened for reading, then the constructor will return an undefined value and `$!` will tell you why it failed. Otherwise the argument is taken to be some object that the `HTML::PullParser` can read() from when it needs more data. The stream will be read() until EOF, but not closed.

  A `doc` can be passed plain or as a reference to a scalar. If a reference is passed then the value of this scalar should not be changed before all tokens have been extracted.

  Next the information to be returned for the different token types must be set up. This is done by simply associating an argspec (as defined in *HTML::Parser*) with the events you have an interest in. For instance, if you want `start` tokens to be reported as the string `'S'` followed by the tagname and the attributes you might pass an `start`-option like this:

```
$p = HTML::PullParser->new(
       doc   => $document_to_parse,
       start => '"S", tagname, @attr',
       end   => '"E", tagname',
     );
```

  At last other `HTML::Parser` options, like `ignore_tags`, and `unbroken_text`, can be passed in. Note that you should not use the *event*_h options to set up parser handlers. That would confuse the inner logic of `HTML::PullParser`.

- $token = $p->get_token

  This method will return the next *token* found in the HTML document, or `undef` at the end of the document. The token is returned as an array reference. The content of this array match the argspec set up during `HTML::PullParser` construction.

- $p->unget_token(@tokens)

  If you find out you have read too many tokens you can push them back, so that they are returned again the next time $p->get_token is called.

EXAMPLES

The ‘eg/hform’ script shows how we might parse the form section of HTML::Documents using HTML::PullParser.

HTML::Tagset

data tables useful in parsing HTML

VERSION

Version 3.24

SYNOPSIS

```
use HTML::Tagset;
# Then use any of the items in the HTML::Tagset package
#  as need arises
```

DESCRIPTION

This module contains several data tables useful in various kinds of HTML parsing operations.

Note that all tag names used are lowercase.

In the following documentation, a “hashset” is a hash being used as a set – the hash conveys that its keys are there, and the actual values associated with the keys are not significant. (But what values are there, are always true.)

VARIABLES

Note that none of these variables are exported.

hashset %HTML::Tagset::emptyElement

This hashset has as values the tag-names (GIs) of elements that cannot have content. (For example, “base”, “br”, “hr”.) So `$HTML::Tagset::emptyElement{'hr'}` exists and is true. `$HTML::Tagset::emptyElement{'dl'}` does not exist, and so is not true.

hashset %HTML::Tagset::optionalEndTag

This hashset lists tag-names for elements that can have content, but whose end-tags are generally, "safely", omissible. Example: `$HTML::Tagset::emptyElement{'li'}` exists and is true.

hash %HTML::Tagset::linkElements

Values in this hash are tagnames for elements that might contain links, and the value for each is a reference to an array of the names of attributes whose values can be links.

hash %HTML::Tagset::boolean_attr

This hash (not hashset) lists what attributes of what elements can be printed without showing the value (for example, the "noshade" attribute of "hr" elements). For elements with only one such attribute, its value is simply that attribute name. For elements with many such attributes, the value is a reference to a hashset containing all such attributes.

hashset %HTML::Tagset::isPhraseMarkup

This hashset contains all phrasal-level elements.

hashset %HTML::Tagset::is_Possible_Strict_P_Content

This hashset contains all phrasal-level elements that be content of a P element, for a strict model of HTML.

hashset %HTML::Tagset::isHeadElement

This hashset contains all elements that elements that should be present only in the 'head' element of an HTML document.

hashset %HTML::Tagset::isList

This hashset contains all elements that can contain "li" elements.

hashset %HTML::Tagset::isTableElement

This hashset contains all elements that are to be found only in/under a "table" element.

hashset %HTML::Tagset::isFormElement

This hashset contains all elements that are to be found only in/under a "form" element.

hashset %HTML::Tagset::isBodyElement

This hashset contains all elements that are to be found only in/under the "body" element of an HTML document.

hashset %HTML::Tagset::isHeadOrBodyElement

This hashset includes all elements that I notice can fall either in the head or in the body.

hashset %HTML::Tagset::isKnown

This hashset lists all known HTML elements.

hashset %HTML::Tagset::canTighten

This hashset lists elements that might have ignorable whitespace as children or siblings.

array @HTML::Tagset::p_closure_barriers

This array has a meaning that I have only seen a need for in `HTML::TreeBuilder`, but I include it here on the off chance that someone might find it of use:

When we see a "<p>" token, we go lookup up the lineage for a p element we might have to minimize. At first sight, we might say that if there's a p anywhere in the lineage of this new p, it should be closed. But that's wrong. Consider this document:

```
<html>
  <head>
    <title>foo</title>
  </head>
  <body>
    <p>foo
      <table>
        <tr>
          <td>
             foo
             <p>bar
          </td>
        </tr>
      </table>
    </p>
  </body>
</html>
```

The second p is quite legally inside a much higher p.

My formalization of the reason why this is legal, but this:

```
<p>foo<p>bar</p></p>
```

isn't, is that something about the table constitutes a "barrier" to the application of the rule about what p must minimize.

So `@HTML::Tagset::p_closure_barriers` is the list of all such barrier-tags.

hashset %isCDATA_Parent

This hashset includes all elements whose content is CDATA.

CAVEATS

You may find it useful to alter the behavior of modules (like `HTML::Element` or `HTML::TreeBuilder`) that use `HTML::Tagset`'s data tables by altering the data tables themselves. You are welcome to try, but be careful; and be aware that different modules may or may react differently to the data tables being changed.

Note that it may be inappropriate to use these tables for *producing* HTML – for example, `%isHeadOrBodyElement` lists the tagnames for all elements that can appear either in the head or in the body, such as "script". That doesn't mean that I am saying your code that produces HTML should feel free to put script elements in either place! If you are producing programs that spit out HTML, you should be *intimately* familiar with the DTDs for HTML or XHTML (available at `http://www.w3.org/`), and you should slavishly obey them, not the data tables in this document.

BUGS

Please report any bugs or feature requests to `bug-html-tagset at rt.cpan.org`, or through the web interface at http://rt.cpan.org/NoAuth/ReportBug.html?Queue=HTML-Tagset. I will be notified, and then you'll automatically be notified of progress on your bug as I make changes.

HTML::TokeParser

Alternative HTML::Parser interface

SYNOPSIS

```
require HTML::TokeParser;
$p = HTML::TokeParser->new("index.html") ||
     die "Can't open: $!";
$p->empty_element_tags(1);  # configure its behaviour

while (my $token = $p->get_token) {
    #...
}
```

DESCRIPTION

The `HTML::TokeParser` is an alternative interface to the `HTML::Parser` class. It is an `HTML::PullParser` subclass with a predeclared set of token types. If you wish the tokens to be reported differently you probably want to use the `HTML::PullParser` directly.

The following methods are available:

- $p = HTML::TokeParser->new($filename, %opt);
- $p = HTML::TokeParser->new($filehandle, %opt);
- $p = HTML::TokeParser->new(\$document, %opt);

  The object constructor argument is either a file name, a file handle object, or the complete document to be parsed. Extra options can be provided as key/value pairs and are processed as documented by the base classes.

  If the argument is a plain scalar, then it is taken as the name of a file to be opened and parsed. If the file can't be opened for reading, then the constructor will return `undef` and `$!` will tell you why it failed.

  If the argument is a reference to a plain scalar, then this scalar is taken to be the literal document to parse. The value of this scalar should not be changed before all tokens have been extracted.

  Otherwise the argument is taken to be some object that the `HTML::TokeParser` can read() from when it needs more data. Typically it will be a filehandle of some kind. The stream will be read() until EOF, but not closed.

  A newly constructed `HTML::TokeParser` differ from its base classes by having the `unbroken_text` attribute enabled by default. See *HTML::Parser* for a description of this and other attributes that influence how the document is parsed. It is often a good idea to enable `empty_element_tags` behaviour.

  Note that the parsing result will likely not be valid if raw undecoded UTF-8 is used as a source. When parsing UTF-8 encoded files turn on UTF-8 decoding:

```
open(my $fh, "<:utf8", "index.html") || die "Can't open 'index.
 ↪html': $!";
my $p = HTML::TokeParser->new( $fh );
# ...
```

If a $filename is passed to the constructor the file will be opened in raw mode and the parsing result will only be valid if its content is Latin-1 or pure ASCII.

If parsing from an UTF-8 encoded string buffer decode it first:

```
utf8::decode($document);
my $p = HTML::TokeParser->new( \$document );
# ...
```

- $p->get_token

  This method will return the next *token* found in the HTML document, or `undef` at the end of the document. The token is returned as an array reference. The first element of the array will be a string denoting the type of this token: "S" for start tag, "E" for end tag, "T" for text, "C" for comment, "D" for declaration, and "PI" for process instructions. The rest of the token array depend on the type like this:

```
["S",  $tag, $attr, $attrseq, $text]
["E",  $tag, $text]
["T",  $text, $is_data]
["C",  $text]
["D",  $text]
["PI", $token0, $text]
```

  where $attr is a hash reference, $attrseq is an array reference and the rest are plain scalars. The *"Argspec" in HTML::Parser* explains the details.

- $p->unget_token(@tokens)

  If you find you have read too many tokens you can push them back, so that they are returned the next time $p->get_token is called.

- $p->get_tag

- $p->get_tag(@tags)

  This method returns the next start or end tag (skipping any other tokens), or `undef` if there are no more tags in the document. If one or more arguments are given, then we skip tokens until one of the specified tag types is found. For example:

```
$p->get_tag("font", "/font");
```

  will find the next start or end tag for a font-element.

  The tag information is returned as an array reference in the same form as for $p->get_token above, but the type code (first element) is missing. A start tag will be returned like this:

```
[$tag, $attr, $attrseq, $text]
```

  The tagname of end tags are prefixed with "/", i.e. end tag is returned like this:

```
["/$tag", $text]
```

- $p->get_text
- $p->get_text(@endtags)

  This method returns all text found at the current position. It will return a zero length string if the next token is not text. Any entities will be converted to their corresponding character.

  If one or more arguments are given, then we return all text occurring before the first of the specified tags found. For example:

```
$p->get_text("p", "br");
```

  will return the text up to either a paragraph of line break element.

  The text might span tags that should be *textified*. This is controlled by the $p->{textify} attribute, which is a hash that defines how certain tags can be treated as text. If the name of a start tag matches a key in this hash then this tag is converted to text. The hash value is used to specify which tag attribute to obtain the text from. If this tag attribute is missing, then the upper case name of the tag enclosed in brackets is returned, e.g. “[IMG]”. The hash value can also be a subroutine reference. In this case the routine is called with the start tag token content as its argument and the return value is treated as the text.

  The default $p->{textify} value is:

```
{img => "alt", applet => "alt"}
```

  This means that and tags are treated as text, and that the text to substitute can be found in the ALT attribute.

- $p->get_trimmed_text
- $p->get_trimmed_text(@endtags)

  Same as $p->get_text above, but will collapse any sequences of white space to a single space character. Leading and trailing white space is removed.

- $p->get_phrase

  This will return all text found at the current position ignoring any phrasal-level tags. Text is extracted until the first non phrasal-level tag. Textification of tags is the same as for get_text(). This method will collapse white space in the same way as get_trimmed_text() does.

  The definition of phrasal-level tags is obtained from the HTML::Tagset module.

EXAMPLES

This example extracts all links from a document. It will print one line for each link, containing the URL and the textual description between the ...</A> tags:

```
use HTML::TokeParser;
$p = HTML::TokeParser->new(shift||"index.html");

while (my $token = $p->get_tag("a")) {
    my $url = $token->[1]{href} || "-";
    my $text = $p->get_trimmed_text("/a");
    print "$url\t$text\n";
}
```

This example extract the from the document:

```
use HTML::TokeParser;
$p = HTML::TokeParser->new(shift||"index.html");
if ($p->get_tag("title")) {
    my $title = $p->get_trimmed_text;
    print "Title: $title\n";
}
```

5.2.54 HTTP

Namespace containing the following modules:

- `HTTP::Parser`
- `HTTP::Tiny` - A small, simple, correct HTTP/1.1 client

HTTP::Parser

Namespace containing the following modules:

- `HTTP::Parser::XS` - Parse an HTTP request or response head out of a byte buffer - the parser Plack, Starman and Twiggy sit on.

HTTP::Parser::XS

Parse an HTTP request or response head out of a byte buffer - the parser Plack, Starman and Twiggy sit on.

Two entry points, both non-blocking and both operating on a buffer the caller owns:

- `parse_http_request($buf, \%env)` fills `%env` with a PSGI environment and returns the number of bytes the request head occupies, `-2` if the head is not complete yet, `-1` if it is malformed. A server calls it again with more bytes on `-2`.
- `parse_http_response($buf, $format, \%special)` returns `($ret, $minor_version, $status, $message, $headers)` for a client.

```
use HTTP::Parser::XS qw(parse_http_request parse_http_response␣
↪HEADERS_AS_HASHREF);

my $req = "GET /search?q=perl%20glob HTTP/1.1\r\nHost: example.com\
↪r\n"
        . "X-Trace: 1\r\nX-Trace: 2\r\n\r\nbody";
my %env;
my $len = parse_http_request($req, \%env);
print "$len bytes of head; $env{REQUEST_METHOD} $env{PATH_INFO} ?
↪$env{QUERY_STRING}\n";
# 81 bytes of head; GET /search ? q=perl%20glob
print "host $env{HTTP_HOST}, trace '$env{HTTP_X_TRACE}'\n";   # host␣
↪example.com, trace '1, 2'
print parse_http_request("GET / HTTP/1.1\r\nHost:", {}), "\n";  # -
↪2: not complete yet

my ($ret, $minor, $status, $msg, $headers) =
    parse_http_response("HTTP/1.0 404 Not Found\r\nContent-Length:␣
↪0\r\n\r\n", HEADERS_AS_HASHREF);
print "$ret: HTTP/1.$minor $status $msg, length $headers->{'content-
↪length'}\n";
# 45: HTTP/1.0 404 Not Found, length 0
```

`$format` is `HEADERS_AS_HASHREF` (a hash of lower-cased names; a repeated header's values in an array reference), `HEADERS_AS_ARRAYREF` (name, value pairs in order) or `HEADERS_NONE`. This is a native implementation of HTTP::Parser::XS 0.17; its `XS.pm` is used unchanged, and nothing is exported by default.

The PSGI environment

`parse_http_request` writes `REQUEST_METHOD`, `REQUEST_URI`, `SCRIPT_NAME` (always `""`), `PATH_INFO`, `QUERY_STRING` and `SERVER_PROTOCOL`, then one key per header. Header names are upper-cased, `-` becomes `_`, and everything except `Content-Type` and `Content-Length` is prefixed `HTTP_`; those two land as `CONTENT_TYPE` and `CONTENT_LENGTH` with no prefix, as CGI and PSGI require. A header sent twice is joined with `", "`.

`REQUEST_URI` keeps the request target verbatim. `PATH_INFO` is the part before `?` with `%XX` escapes decoded, `QUERY_STRING` the part after; a `#` fragment and everything after it is dropped from both but not from `REQUEST_URI`.

Limits

At most 128 headers, and a header name of at most 1024 bytes. The two parsers differ on what happens past the name limit: the request parser fails the whole request (`-1`, and %env is cleared), the response parser silently skips the offending header and carries on.

$BACKEND

`'xs'`, set by XS.pm once XSLoader::load has loaded this native code. `PERL_ONLY=1` or `PERL_HTTP_PARSER_XS=pp` make XS.pm load the distribution's pure-Perl `HTTP::Parser::XS::PP` instead, and then it is `'pp'`.

Vectorised tokenizer

The byte scanners run AVX2 (32B/iteration) or SSE2 (16B) blocks before falling back to picohttpparser's own eight-way unrolled loop and then a byte tail. Upstream drives PCMPESTRI instead, but only under `-msse4.2`, which its Makefile.PL never passes - the shipped `.so` has no vector instruction in it at all - so every CPAN install runs the scalar loop.

Speed relative to the reference XS on a Skylake Xeon E3-1505M (`--release`, processes interleaved, min of 5 - sequential runs drift enough between processes to invent a 10% result):

workload	speedup vs perl5 XS (>1 = pperl faster)
64 KB header value, `HEADERS_NONE`	6.01x
64 KB header value	4.23x
4 KB header value	2.15x
1 KB header name	1.95x
4 KB request target	1.25x
realistic 10-header GET	**1.00x**
response, `HEADERS_AS_HASHREF`	0.88x

The long-value rows are where the vector scan pays. A realistic request is not bound by scanning: most of its cost is creating the hash entry and the string for each PSGI key, so there the two run at the same speed.

`PPERL_HTTP_PARSER_SIMD=avx2|sse2|scalar` forces a kernel, for example to compare them on one machine; all three give identical results.

Differences from upstream

None in what is parsed; only the speed differs.

Functions

Request parsing

parse_http_request

`parse_http_request($buf, \%env)` - XS.xs `parse_http_request`.

Response parsing

parse_http_response

`parse_http_response($buf, $header_format, \%special_headers)` - XS.xs parse_http_response.

HTTP::Tiny

A small, simple, correct HTTP/1.1 client

VERSION

version 0.096

SYNOPSIS

```
use HTTP::Tiny;

my $response = HTTP::Tiny->new->get('http://example.com/');

die "Failed!\n" unless $response->{success};

print "$response->{status} $response->{reason}\n";

while (my ($k, $v) = each %{$response->{headers}}) {
    for (ref $v eq 'ARRAY' ? @$v : $v) {
        print "$k: $_\n";
    }
}

print $response->{content} if length $response->{content};
```

DESCRIPTION

This is a very simple HTTP/1.1 client, designed for doing simple requests without the overhead of a large framework like LWP::UserAgent.

It is more correct and more complete than HTTP::Lite. It supports proxies and redirection. It also correctly resumes after EINTR.

If *IO::Socket::IP* 0.25 or later is installed, HTTP::Tiny will use it instead of *IO::Socket::INET* for transparent support for both IPv4 and IPv6.

Cookie support requires HTTP::CookieJar or an equivalent class.

METHODS

new

```
$http = HTTP::Tiny->new( %attributes );
```

This constructor returns a new HTTP::Tiny object. Valid attributes include:

- `agent` — A user-agent string (defaults to 'HTTP-Tiny/$VERSION'). If `agent` — ends in a space character, the default user-agent string is appended.
- `allow_credentialed_redirects` - If a `3XX` redirects to a different scheme, host or port, by default HTTP::Tiny will strip away caller-supplied `Authorization`, `Cookie` and `Proxy-Authorization` headers from the redirected request and from all subsequent requests in the chain. Set this to a true value to revert to the legacy behavior of forwarding those headers. Default is `false`.
- `allow_downgrade` — If a `3XX` redirect changes the scheme from `https` to plain `http`, HTTP::Tiny will by default refuse to follow it, returning the `3XX` response. Set this to a true value to revert to the legacy behavior of redirecting `https` to `http`. Default is `false`.
- `cookie_jar` — An instance of HTTP::CookieJar — or equivalent class that supports the `add` and `cookie_header` methods
- `default_headers` — A hashref of default headers to apply to requests
- `local_address` — The local IP address to bind to
- `keep_alive` — Whether to reuse the last connection (if for the same scheme, host and port) (defaults to 1)
- `keep_alive_timeout` — How many seconds to keep a connection available for after a request (defaults to 0, unlimited)
- `max_redirect` — Maximum number of redirects allowed (defaults to 5)
- `max_size` — Maximum response size in bytes (only when not using a data callback). If defined, requests with responses larger than this will return a 599 status code.
- `http_proxy` — URL of a proxy server to use for HTTP connections (default is `$ENV{http_proxy}` — if set)
- `https_proxy` — URL of a proxy server to use for HTTPS connections (default is `$ENV{https_proxy}` — if set)
- `proxy` — URL of a generic proxy server for both HTTP and HTTPS connections (default is `$ENV{all_proxy}` — if set)
- `no_proxy` — List of domain suffixes that should not be proxied. Must be a comma-separated string or an array reference. (default is `$ENV{no_proxy}` —)
- `timeout` — Request timeout in seconds (default is 60) If a socket open, read or write takes longer than the timeout, the request response status code will be 599.
- `verify_SSL` — A boolean that indicates whether to validate the TLS/SSL certificate of an `https` — connection (default is true). Changed from false to true in version 0.083.
- `SSL_options` — A hashref of `SSL_*` — options to pass through to *IO::Socket::SSL*

- `$ENV{PERL_HTTP_TINY_SSL_INSECURE_BY_DEFAULT}` - Changes the default certificate verification behavior to not check server identity if set to 1. Only effective if `verify_SSL` is not set. Added in version 0.083.

An accessor/mutator method exists for each attribute.

Passing an explicit `undef` for `proxy`, `http_proxy` or `https_proxy` will prevent getting the corresponding proxies from the environment.

Errors during request execution will result in a pseudo-HTTP status code of 599 and a reason of "Internal Exception". The content field in the response will contain the text of the error.

The `keep_alive` parameter enables a persistent connection, but only to a single destination scheme, host and port. If any connection-relevant attributes are modified via accessor, or if the process ID or thread ID change, the persistent connection will be dropped. If you want persistent connections across multiple destinations, use multiple HTTP::Tiny objects.

The `keep_alive_timeout` parameter allows you to control how long a keep alive connection will be considered for reuse. By setting this lower than the server keep alive time, this allows you to avoid race conditions where the server closes the connection while preparing to write the request on a reused persistent connection.

See "TLS/SSL SUPPORT" for more on the `verify_SSL` and `SSL_options` attributes.

get|head|put|post|patch|delete

```
$response = $http->get($url);
$response = $http->get($url, \%options);
$response = $http->head($url);
```

These methods are shorthand for calling `request()` for the given method. The URL must have unsafe characters escaped and international domain names encoded. See `request()` for valid options and a description of the response.

The `success` field of the response will be true if the status code is 2XX.

post_form

```
$response = $http->post_form($url, $form_data);
$response = $http->post_form($url, $form_data, \%options);
```

This method executes a `POST` request and sends the key/value pairs from a form data hash or array reference to the given URL with a `content-type` of `application/x-www-form-urlencoded`. If data is provided as an array reference, the order is preserved; if provided as a hash reference, the terms are sorted by key for consistency. See documentation for the `www_form_urlencode` method for details on the encoding.

The URL must have unsafe characters escaped and international domain names encoded. See `request()` for valid options and a description of the response. Any `content-type` header or content in the options hashref will be ignored.

The `success` field of the response will be true if the status code is 2XX.

mirror

```
$response = $http->mirror($url, $file, \%options)
if ( $response->{success} ) {
    print "$file is up to date\n";
}
```

Executes a `GET` request for the URL and saves the response body to the file name provided. The URL must have unsafe characters escaped and international domain names encoded. If the file already exists, the request will include an `If-Modified-Since` header with the modification timestamp of the file. You may specify a different `If-Modified-Since` header yourself in the `$options->{headers}` hash.

The `success` field of the response will be true if the status code is `2XX` or if the status code is `304` (unmodified).

If the file was modified and the server response includes a properly formatted `Last-Modified` header, the file modification time will be updated accordingly.

request

```
$response = $http->request($method, $url);
$response = $http->request($method, $url, \%options);
```

Executes an HTTP request of the given method type ('GET', 'HEAD', 'POST', 'PUT', etc.) on the given URL. The URL must have unsafe characters escaped and international domain names encoded.

NOTE: Method names are **case-sensitive** per the HTTP/1.1 specification. Don't use `get` when you really want `GET`. See "LIMITATIONS" for how this applies to redirection.

If the URL includes a "user:password" stanza, they will be used for Basic-style authorization headers. For example:

```
$http->request('GET', 'http://Aladdin:open sesame@example.com/');
```

If the "user:password" stanza contains reserved characters, they must be percent-escaped:

```
$http->request('GET', 'http://john%40example.com:password@example.
↪com/');
```

Caller-supplied `Authorization`, `Cookie` and `Proxy-Authorization` headers are stripped on cross-origin redirects. See "new"'s `allow_credentialed_redirects` attribute to opt out.

A hashref of options may be appended to modify the request.

Valid options are:

- `headers` — A hashref containing headers to include with the request. If the value for a header is an array reference, the header will be output multiple times with each value in the array. These headers over-write any default headers.

- `content` — A scalar to include as the body of the request OR a code reference that will be called iteratively to produce the body of the request
- `trailer_callback` — A code reference that will be called if it exists to provide a hashref of trailing headers (only used with chunked transfer-encoding)
- `data_callback` — A code reference that will be called for each chunks of the response body received.
- `peer` — Override host resolution and force all connections to go only to a specific peer address, regardless of the URL of the request. This will include any redirections! This options should be used with extreme caution (e.g. debugging or very special circumstances). It can be given as either a scalar or a code reference that will receive the hostname and whose response will be taken as the address.

The `Host` header is generated from the URL in accordance with RFC 2616. It is a fatal error to specify `Host` in the `headers` option. Other headers may be ignored or overwritten if necessary for transport compliance.

If the `content` option is a code reference, it will be called iteratively to provide the content body of the request. It should return the empty string or undef when the iterator is exhausted.

If the `content` option is the empty string, no `content-type` or `content-length` headers will be generated.

If the `data_callback` option is provided, it will be called iteratively until the entire response body is received. The first argument will be a string containing a chunk of the response body, the second argument will be the in-progress response hash reference, as described below. (This allows customizing the action of the callback based on the `status` or `headers` received prior to the content body.)

Content data in the request/response is handled as "raw bytes". Any encoding/decoding (with associated headers) are the responsibility of the caller.

The `request` method returns a hashref containing the response. The hashref will have the following keys:

- `success` — Boolean indicating whether the operation returned a 2XX status code
- `url` — URL that provided the response. This is the URL of the request unless there were redirections, in which case it is the last URL queried in a redirection chain
- `status` — The HTTP status code of the response
- `reason` — The response phrase returned by the server
- `content` — The body of the response. If the response does not have any content or if a data callback is provided to consume the response body, this will be the empty string
- `headers` — A hashref of header fields. All header field names will be normalized to be lower case. If a header is repeated, the value will be an arrayref; it will otherwise be a scalar string containing the value
- `protocol` - If this field exists, it is the protocol of the response such as HTTP/1.0 or HTTP/1.1

- `redirects` If this field exists, it is an arrayref of response hash references from redirects in the same order that redirections occurred. If it does not exist, then no redirections occurred.

On an error during the execution of the request, the `status` field will contain 599, and the `content` field will contain the text of the error.

www_form_urlencode

```
$params = $http->www_form_urlencode( $data );
$response = $http->get("http://example.com/query?$params");
```

This method converts the key/value pairs from a data hash or array reference into a `x-www-form-urlencoded` string. The keys and values from the data reference will be UTF-8 encoded and escaped per RFC 3986. If a value is an array reference, the key will be repeated with each of the values of the array reference. If data is provided as a hash reference, the key/value pairs in the resulting string will be sorted by key and value for consistent ordering.

can_ssl

```
$ok          = HTTP::Tiny->can_ssl;
($ok, $why) = HTTP::Tiny->can_ssl;
($ok, $why) = $http->can_ssl;
```

Indicates if SSL support is available. When called as a class object, it checks for the correct version of *Net::SSLeay* and *IO::Socket::SSL*. When called as an object methods, if `SSL_verify` is true or if `SSL_verify_mode` is set in `SSL_options`, it checks that a CA file is available.

In scalar context, returns a boolean indicating if SSL is available. In list context, returns the boolean and a (possibly multi-line) string of errors indicating why SSL isn't available.

connected

```
$host = $http->connected;
($host, $port) = $http->connected;
```

Indicates if a connection to a peer is being kept alive, per the `keep_alive` option.

In scalar context, returns the peer host and port, joined with a colon, or `undef` (if no peer is connected). In list context, returns the peer host and port or an empty list (if no peer is connected).

Note: This method cannot reliably be used to discover whether the remote host has closed its end of the socket.

TLS/SSL SUPPORT

Direct `https` connections are supported only if *IO::Socket::SSL* 1.56 or greater and *Net::SSLeay* 1.49 or greater are installed. An error will occur if new enough versions of these modules are not installed or if the TLS encryption fails. You can also use `HTTP::Tiny::can_ssl()` utility function that returns boolean to see if the required modules are installed.

An `https` connection may be made via an `http` proxy that supports the CONNECT command (i.e. RFC 2817). You may not proxy `https` via a proxy that itself requires `https` to communicate.

TLS/SSL provides two distinct capabilities:

- Encrypted communication channel
- Verification of server identity

By default, HTTP::Tiny verifies server identity.

This was changed in version 0.083 due to security concerns. The previous default behavior can be enabled by setting `$ENV{PERL_HTTP_TINY_SSL_INSECURE_BY_DEFAULT}` to 1.

Verification is done by checking that that the TLS/SSL connection has a valid certificate corresponding to the host name of the connection and that the certificate has been verified by a CA. Assuming you trust the CA, this will protect against machine-in-the-middle attacks.

Certificate verification requires a file or directory containing trusted CA certificates.

`IO::Socket::SSL::default_ca()` is called to detect the default location of your CA certificates. This also supports the environment variables `SSL_CERT_FILE` and `SSL_CERT_DIR`, and will fail over to Mozilla::CA if no certs are found.

If `IO::Socket::SSL::default_ca()` is not able to find usable CA certificates, HTTP::Tiny will search several well-known system-specific default locations for a CA certificate file as a last resort:

- /etc/ssl/certs/ca-certificates.crt
- /etc/pki/tls/certs/ca-bundle.crt
- /etc/ssl/ca-bundle.pem
- /etc/openssl/certs/ca-certificates.crt
- /etc/ssl/cert.pem
- /usr/local/share/certs/ca-root-nss.crt
- /etc/pki/tls/cacert.pem
- /etc/certs/ca-certificates.crt

An error will be occur if `verify_SSL` is true and no CA certificate file is available.

If you desire complete control over TLS/SSL connections, the `SSL_options` attribute lets you provide a hash reference that will be passed through to `IO::Socket::SSL::start_SSL()`, overriding any options set by HTTP::Tiny. For example, to provide your own trusted CA file:

```
SSL_options => {
    SSL_ca_file => $file_path,
}
```

The `SSL_options` attribute could also be used for such things as providing a client certificate for authentication to a server or controlling the choice of cipher used for the TLS/SSL connection. See *IO::Socket::SSL* documentation for details.

PROXY SUPPORT

HTTP::Tiny can proxy both `http` and `https` requests. Only Basic proxy authorization is supported and it must be provided as part of the proxy URL: `http://user:pass@proxy.example.com/`.

HTTP::Tiny supports the following proxy environment variables:

- http_proxy or HTTP_PROXY
- https_proxy or HTTPS_PROXY
- all_proxy or ALL_PROXY

If the `REQUEST_METHOD` environment variable is set, then this might be a CGI process and `HTTP_PROXY` would be set from the `Proxy:` header, which is a security risk. If `REQUEST_METHOD` is set, `HTTP_PROXY` (the upper case variant only) is ignored, but `CGI_HTTP_PROXY` is considered instead.

Tunnelling `https` over an `http` proxy using the CONNECT method is supported. If your proxy uses `https` itself, you can not tunnel `https` over it.

Be warned that proxying an `https` connection opens you to the risk of a man-in-the-middle attack by the proxy server.

The `no_proxy` environment variable is supported in the format of a comma-separated list of domain extensions proxy should not be used for.

Proxy arguments passed to `new` will override their corresponding environment variables.

LIMITATIONS

HTTP::Tiny is *conditionally compliant* with the HTTP/1.1 specifications:

- “Message Syntax and Routing” [RFC7230]
- “Semantics and Content” [RFC7231]
- “Conditional Requests” [RFC7232]
- “Range Requests” [RFC7233]
- “Caching” [RFC7234]
- “Authentication” [RFC7235]

It attempts to meet all “MUST” requirements of the specification, but does not implement all “SHOULD” requirements. (Note: it was developed against the earlier RFC 2616 speci-

fication and may not yet meet the revised RFC 7230-7235 spec.) Additionally, HTTP::Tiny supports the PATCH method of RFC 5789.

Some particular limitations of note include:

- HTTP::Tiny focuses on correct transport. Users are responsible for ensuring that user-defined headers and content are compliant with the HTTP/1.1 specification.
- Users must ensure that URLs are properly escaped for unsafe characters and that international domain names are properly encoded to ASCII. See URI::Escape, URI::_punycode and Net::IDN::Encode.
- Redirection is very strict against the specification. Redirection is only automatic for response codes 301, 302, 307 and 308 if the request method is 'GET' or 'HEAD'. Response code 303 is always converted into a 'GET' redirection, as mandated by the specification. There is no automatic support for status 305 ("Use proxy") redirections.
- There is no provision for delaying a request body using an Expect header. Unexpected 1XX responses are silently ignored as per the specification.
- Only 'chunked' Transfer-Encoding is supported.
- There is no support for a Request-URI of '*' for the 'OPTIONS' request.
- Headers mentioned in the RFCs and some other, well-known headers are generated with their canonical case. Other headers are sent in the case provided by the user. Except for control headers (which are sent first), headers are sent in arbitrary order.

Despite the limitations listed above, HTTP::Tiny is considered feature-complete. New feature requests should be directed to HTTP::Tiny::UA.

5.2.55 Hash

Namespace containing the following modules:

- `Hash::Util` - General-utility hash subroutines - lock and unlock keys or values, inspect bucket layout, and seed the hash function.

Hash::Util

General-utility hash subroutines - lock and unlock keys or values, inspect bucket layout, and seed the hash function.

A *restricted* hash is an ordinary hash that rejects new keys and, optionally, refuses writes to its values. You build one by calling `lock_keys` on a populated hash; from that point on a write to any key not already present croaks. Locking individual values with `lock_value`, or the whole hash with `lock_hash`, makes the existing values immutable as well. Every lock has a matching unlock.

Alongside the locking primitives the module exposes a handful of introspection helpers: `bucket_ratio`, `num_buckets`, `used_buckets`, `bucket_info`, `bucket_array`, and the summary reports `bucket_stats` and `bucket_stats_formatted`. They report how the hash is laid out internally and are useful when tuning the size of very large hashes.

`hash_seed` and `hash_value` expose the hash function itself - the random per-process seed, and the integer hash of a given string under that seed (or a caller-supplied seed). Both are sensitive: handing them to untrusted code enables algorithmic-complexity attacks against any hash in the program.

Every `ref`-suffixed variant (`lock_ref_keys`, `lock_hashref`, `hashref_locked`, `legal_ref_keys`, `hidden_ref_keys`, etc.) does the same work as its plain counterpart but takes an already-taken hash reference rather than relying on the `\%` prototype.

Synopsis

```
use Hash::Util qw(lock_keys unlock_keys lock_value hash_locked␣
 ↪hidden_keys);

my %h = (foo => 1, bar => 2);
lock_keys(%h);                      # fix the keyset
$h{foo} = 10;                       # ok
eval { $h{baz} = 99 };              # croaks - attempt to access␣
 ↪disallowed key

lock_value(%h, 'foo');              # make $h{foo} immutable too
print hash_locked(%h) ? "yes" : "no";   # yes

unlock_keys(%h);                    # lift the keyset restriction
```

Locking keys

`lock_keys(%hash)` restricts the hash to its current keys; `lock_keys(%hash, @keys)` restricts it to `@keys`. Afterwards, assigning to a key outside the set croaks with `Attempt to access disallowed key '...' in a restricted hash`. With an explicit list, an existing key that is not in the list makes the call croak with `Hash has key '...' which is not in the new key set`; keys in the list that are not present yet become hidden placeholders, legal to assign to later. Every key is compared as a string, so `lock_keys(%h, 1)` allows the key `"1"`.

`delete` and `exists` still work on a locked hash and do not change the legal keyset: a deleted key can be assigned again, a new key still cannot. A locked hash cannot be

`blessed`; bless it first.

`unlock_keys(%hash)` lifts the keyset restriction. Values locked with `lock_value` stay locked, and placeholders stay in place until the next `lock_keys`, which clears them before it locks.

`lock_keys_plus(%hash, @additional_keys)` locks the hash to its current keys plus `@additional_keys` - the same as `lock_keys(%hash, @additional_keys, keys %hash)`.

All of them return a reference to the hash.

Locking values

`lock_value(%hash, $key)` makes the value under `$key` read-only: a later assignment croaks with `Modification of a read-only value attempted`. Unless the keyset is locked too, the key can still be deleted, and a later assignment then creates a fresh writable value; for that reason, with warnings enabled, locking a value in an unlocked hash warns `Cannot usefully lock values in an unlocked hash`. `unlock_value(%hash, $key)` makes the value writable again.

`lock_hash(%hash)` locks the keyset and every value; `unlock_hash` undoes both. `lock_hash_recurse` and `unlock_hash_recurse` do the same and descend into every value that is a hash reference - only into hashes, so a hash of arrays of hashes has only its outermost hash locked.

All of them return a reference to the hash.

Querying the lock state

`hash_locked(%hash)` is true when the keyset is locked and `hash_unlocked(%hash)` is its negation. Both return Perl's boolean true and false values, so a false result prints as the empty string. Value locks alone do not count.

`legal_keys(%hash)` lists every key the hash may carry - the visible keys plus the hidden placeholders - and `hidden_keys(%hash)` lists the placeholders only: legal keys that fail both `exists` and `defined`. On an unrestricted hash `legal_keys` equals `keys %hash` and `hidden_keys` is empty.

Hash-reference forms

Each function above has a form that takes a hash reference instead of relying on the `\%` prototype: `lock_ref_keys`, `unlock_ref_keys`, `lock_ref_keys_plus`, `lock_ref_value`, `unlock_ref_value`, `lock_hashref`, `unlock_hashref`, `lock_hashref_recurse`, `unlock_hashref_recurse`, `hashref_locked`, `hashref_unlocked`, `legal_ref_keys` and `hidden_ref_keys`.

Bucket statistics

`bucket_stats(\%hash)` extends `bucket_info` with derived quantities:

```
my ($keys, $buckets, $used, $quality, $utilization_ratio,
    $collision_pct, $mean, $stddev, @length_counts)
    = bucket_stats(\%hash);
```

`$quality` is the Red Dragon quality score (ideal `1.0`, acceptable around `0.95` to `1.05`), `$utilization_ratio` the fraction of used buckets, `$collision_pct` the fraction of keys that share a bucket, and `$mean` and `$stddev` describe the chain lengths of the used buckets. For an empty hash only the first three values are returned.

`bucket_stats_formatted(\%hash)` renders the same data as a report: a summary with the quality score read as "Good", "Poor" or "Bad", then two bar charts - chain lengths, which is what a failed lookup costs, and key positions within their chains, which is what a successful one costs. Useful when deciding whether to pre-size a large hash with `keys(%h) = N`.

Security

`hash_seed`, `hash_value`, and `bucket_array` reveal enough about the hash function to enable collision attacks. Do not expose their output to code you do not trust.

This is a native implementation of the XS half of Hash::Util 0.32; its `Hash/Util.pm` is used unchanged. Nothing is exported by default.

Differences from upstream

None.

Modules

- `Hash::Util::FieldHash` - Support for inside-out classes: hashes keyed by the identity of a reference, whose entries go away with the object.

Functions

Hash locking

`all_keys`

Split a restricted hash's keys into visible and hidden sets, writing the results into the caller's arrays.

`hidden_ref_keys`

List the hidden placeholder keys of a restricted hash - legal keys that currently have no value.

`legal_ref_keys`

List every key a restricted hash is allowed to carry - the visible keys plus the hidden placeholders.

Synopsis

```
my @legal = legal_ref_keys(\%hash);
my @legal = legal_keys(%hash);          # the \% form
```

On an unrestricted hash this is equivalent to `keys %hash`.

hv_store

Install an *alias* from `$hash{$key}` to an existing scalar, instead of copying its value in the usual way.

lock_keys

Restrict a hash to its current keys, or to an explicit list.

unlock_keys

Lift the keyset restriction imposed by `lock_keys`.

lock_ref_keys

Hash-reference variant of `lock_keys`.

unlock_ref_keys

Hash-reference variant of `unlock_keys`.

lock_ref_keys_plus

Lock the hash to the union of its current keys and a given extra list.

lock_value

Make the value under a given key immutable.

unlock_value

Undo a previous `lock_value`, making the value at `$key` writable again.

lock_ref_value

Hash-reference variant of `lock_value`.

Synopsis

```
lock_ref_value($href, $key);
```

Same behaviour as `lock_value` but takes a hash reference.

unlock_ref_value

Hash-reference variant of unlock_value.

Synopsis

```
unlock_ref_value($href, $key);
```

Same behaviour as unlock_value but takes a hash reference.

lock_hash

Lock the whole hash: both its keyset and every value.

unlock_hash

Undo a previous lock_hash, making every key and value writable again.

Synopsis

```
unlock_hash(%hash);
```

Clears the read-only flag on each existing value and lifts the keyset restriction. Returns a reference to the hash.

lock_hashref

Hash-reference variant of lock_hash.

Synopsis

```
lock_hashref($href);
```

Same behaviour as lock_hash but takes a hash reference.

unlock_hashref

Hash-reference variant of unlock_hash.

Synopsis

```
unlock_hashref($href);
```

Same behaviour as unlock_hash but takes a hash reference.

lock_hash_recurse

Lock a hash and every nested hash it references, transitively.

unlock_hash_recurse

Undo a previous `lock_hash_recurse`, unlocking every nested hash it touched.

Synopsis

```
unlock_hash_recurse(%hash);
```

Traverses the same subset of references as `lock_hash_recurse` - hash-valued entries only. Returns a reference to the hash.

lock_hashref_recurse

Hash-reference variant of `lock_hash_recurse`.

Synopsis

```
lock_hashref_recurse($href);
```

Same behaviour as `lock_hash_recurse` but takes a hash reference.

unlock_hashref_recurse

Hash-reference variant of `unlock_hash_recurse`.

Synopsis

```
unlock_hashref_recurse($href);
```

Same behaviour as `unlock_hash_recurse` but takes a hash reference.

hash_locked

Report whether the hash's keyset is currently locked.

hash_unlocked

Report whether the hash's keyset is *not* currently locked.

hashref_locked

Hash-reference variant of `hash_locked`.

Synopsis

```
hashref_locked($href) and print "restricted\n";
```

Same behaviour as `hash_locked` but takes a hash reference.

hashref_unlocked

Hash-reference variant of hash_unlocked.

Synopsis

```
hashref_unlocked($href) and print "open\n";
```

Same behaviour as hash_unlocked but takes a hash reference.

hidden_keys

List the “hidden” placeholder keys of a restricted hash - legal keys that currently have no value assigned.

legal_keys

List every key the restricted hash *is allowed to carry* - visible keys plus hidden placeholders.

Bucket introspection

hash_traversal_mask

Read or set the per-hash bucket-traversal mask used by keys, values, and each.

bucket_info

Return a flat list summarising the hash’s bucket layout.

bucket_array

Return a packed array-of-arrays describing which key lives in which bucket.

bucket_ratio

Return a "used/total" string describing how many of the hash’s internal buckets hold at least one key.

num_buckets

Return the total number of buckets the hash holds (or would hold if its bucket array were allocated).

used_buckets

Return the count of buckets that currently hold at least one key.

bucket_stats

Return a rich statistical summary of the hash's bucket layout.

bucket_stats_formatted

Return a multi-line human-readable report of `bucket_stats`, complete with ASCII bar-charts.

Hash function

hash_seed

Return the per-process random bytes that seed the hash function.

hash_value

Return the integer hash value of a string under the current (or a supplied) seed.

Hash::Util::FieldHash

Support for inside-out classes: hashes keyed by the identity of a reference, whose entries go away with the object.

A *field hash* takes a reference as a key and stores it under the reference's id, so the key survives stringification overloads and re-blessing. When the object is destroyed, its entry disappears from every field hash it was used in. That is the bookkeeping an inside-out class needs: each attribute is one field hash, keyed by the object.

An *idhash* only replaces a reference key by its id; registering the object with `register` adds the garbage collection.

Synopsis

```
use Hash::Util::FieldHash qw(fieldhash id id_2obj register idhash);

package Person;
fieldhash my %name;
sub new  { my $self = bless \ do { my $o }, shift; $name{$self} =␣
 ↪shift; $self }
sub name { $name{$_[0]} }

package main;
my $p = Person->new('Ada');
print $p->name, "\n";                # Ada
my $id = id($p);                     # the key %name stores it under
print id_2obj($id) == $p ? "same\n" : "other\n";
undef $p;                            # %name is empty again
```

Functions

`fieldhash(%h)` and `fieldhashes(\%a, \%b, ...)` turn hashes into field hashes; `idhash` and `idhashes` turn them into idhashes. Each returns a reference to the hash, or nothing when the argument is not a hash. A hash that already is one of the two keeps its kind.

`id($ref)` is the id of a reference, the number a field hash stores it under; a non-reference comes back unchanged. `id_2obj($id)` is the registered object with that id, or `undef`. `register($obj, @hashrefs)` registers `$obj` and marks each hash in `@hashrefs` for the cleanup of its id; it returns a new reference to `$obj`.

This is a native implementation of the XS half of Hash::Util::FieldHash 1.27; its `Hash/Util/FieldHash.pm` is used unchanged. Nothing is exported by default.

Differences from upstream

None.

Functions

Field hashes

`register`

Register an object for garbage collection in the given hashes.

Object ids

`id`

The id of a reference: the number a field hash stores it under.

`id_2obj`

The registered object that has a given id.

id

The id of a reference: the number a field hash stores it under.

Synopsis

```
use Hash::Util::FieldHash qw(id);
my $id = id($obj);
```

What you get back

For a reference, the address of what it points to, as a number - the same value `Scalar::Util::refaddr` gives. The id stays the object's for its lifetime. Anything that is not a reference comes back unchanged, where `refaddr` gives `undef`.

id_2obj

The registered object that has a given id.

Synopsis

```
use Hash::Util::FieldHash qw(id id_2obj);
my $obj = id_2obj($id);
```

What you get back

A new reference to the object whose `id` is `$id`, or `undef`. Only objects that have been used as a field hash key or passed to `register` are known; for any other id, and once the object is gone, the answer is `undef`.

register

Register an object for garbage collection in the given hashes.

Synopsis

```
use Hash::Util::FieldHash qw(id register);
my %name;
register($obj, \%name);
$name{id $obj} = 'Ada';     # deleted when $obj goes away
```

What you get back

A new reference to the object. Every hash reference after the first argument is marked, so that the object's entry is deleted from it when the object is destroyed; arguments that are not hash references are ignored. Field hashes do this themselves; `register` is for idhashes and ordinary hashes keyed by `id`. A first argument that is not a reference dies with `Attempt to register a non-ref`.

all_keys

Split a restricted hash's keys into visible and hidden sets, writing the results into the caller's arrays.

Synopsis

```
all_keys(%hash, @visible, @hidden);
```

Clears both arrays first, then fills `@visible` with every key that passes `exists` and `@hidden` with every legal-but-unassigned placeholder key. Returns a reference to the hash.

On an unrestricted hash `@hidden` comes back empty and `@visible` matches `keys %hash`. Like `hidden_keys`, the behaviour is experimental and depends on the current restricted-hash implementation.

hidden_ref_keys

List the hidden placeholder keys of a restricted hash - legal keys that currently have no value.

Synopsis

```
my @hidden = hidden_ref_keys(\%hash);
my @hidden = hidden_keys(%hash);        # the \% form
```

A hidden key is allowed by the hash's keyset but fails both `exists` and `defined` - typically the ghost left behind by a `delete` on a locked hash, or a key reserved in advance by `lock_keys_plus`. Assigning to it brings it into the visible keyset.

Returns the empty list on an unrestricted hash. The feature is experimental and closely tied to the current restricted-hash implementation; do not build durable contracts on top of it.

hv_store

Install an *alias* from `$hash{$key}` to an existing scalar, instead of copying its value in the usual way.

Synopsis

```
my $sv = 0;
hv_store(%hash, $key, $sv) or die "store failed";
$hash{$key} = 1;
print $sv;          # prints 1 - $sv and $hash{$key} share one
 ↪scalar
```

After the call, `$sv` and `$hash{$key}` refer to the same scalar: a later assignment through either name is visible through the other. Returns true on success and false if the store was rejected.

This is a low-level primitive with narrow uses; ordinary code should assign through the hash normally.

hash_seed

Return the per-process random bytes that seed the hash function.

Synopsis

```
my $seed = hash_seed();
```

The result is a byte string whose length depends on the hash function the interpreter is built with: 32 bytes for pperl, as for a default build of perl 5.44. Two interpreters started from the same program see different values; a single run sees the same value throughout its life.

The seed is sensitive. Anyone who learns it can construct keys that collide in your hashes and mount an algorithmic-complexity attack. Keep it out of logs and error messages.

hash_value

Return the integer hash value of a string under the current (or a supplied) seed.

Synopsis

```
my $h = hash_value($string);
my $h = hash_value($string, $seed);
```

With one argument, hashes `$string` with the interpreter's per-process seed - the same seed reported by `hash_seed`. With a second argument, hashes it with `$seed` instead, letting you compute what the hash value *would* be under a different seed. The custom seed must be at least as long as `hash_seed` produces; a shorter `$seed` croaks with `seed len must be at least N long only got M bytes`.

`$string` is used as a string whatever it holds, so `hash_value(42)` equals `hash_value("42")`.

The one-argument value is stable for the lifetime of a single interpreter and unstable across runs, Perl versions, build options, and architectures. Do not persist it.

Like `hash_seed`, the result is sensitive information that can be used to engineer collisions. Treat it accordingly.

hash_traversal_mask

Read or set the per-hash bucket-traversal mask used by `keys`, `values`, and `each`.

Synopsis

```
my $mask = hash_traversal_mask(\%hash);
hash_traversal_mask(\%hash, 1234);
```

Every hash carries a U32 mask that is XOR'd with each bucket index during iteration, so two hashes with the same contents still visit their keys in different orders. Called with one argument, the function returns the current mask. Called with two, it sets the mask - pinning the iteration order of that particular hash for reproducible test output.

Pinning the mask does not make two *different* hashes iterate identically: keys that collide into the same bucket may still appear in different orders because chain order depends on insertion history.

Returns undef for a hash that has never been given a mask, and nothing at all for an argument that is not a reference to a plain hash.

bucket_info

Return a flat list summarising the hash's bucket layout.

Synopsis

```
my ($keys, $buckets, $used, @length_counts) = bucket_info(\%hash);
```

The first three values are the number of keys, the total bucket count, and the number of used buckets. Each `$length_counts[$n]` that follows is the number of buckets holding exactly `$n` keys, so `$length_counts[0]` is the empty-bucket count, `$length_counts[1]` the count of single-key buckets, and so on.

Given undef, it reports on the interpreter's shared string table. Returns the empty list for any other argument that is not a reference to a plain, non-magical hash. When the hash's bucket array has not been allocated yet, only the three leading values are returned.

bucket_array

Return a packed array-of-arrays describing which key lives in which bucket.

Synopsis

```
my $array = bucket_array(\%hash);
```

Each element of the returned array reference is either an integer `$n` - meaning `$n` consecutive empty buckets at that position - or an array reference listing the keys stored in a single bucket. Placeholder keys are reported as normal keys. The order within a bucket is Perl's insert-first chain order and changes across rehashes.

Intended for debugging and diagnostics only. The layout reveals enough about the hash function to support collision attacks, so do not leak the output to untrusted code.

Given undef, it reports on the interpreter's shared string table. Returns nothing when the argument is not a reference to a plain hash, or when the hash has no bucket array yet.

bucket_ratio

Return a `"used/total"` string describing how many of the hash's internal buckets hold at least one key.

Synopsis

```
my $r = bucket_ratio(%hash);     # e.g. "5/8"
```

Behaves like the pre-5.25 `scalar(%hash)`: for a tied hash it calls the SCALAR tie method; for a normal empty hash it returns `0`; otherwise it reports the count of non-empty buckets followed by a slash followed by the total bucket count.

num_buckets

Return the total number of buckets the hash holds (or would hold if its bucket array were allocated).

Synopsis

```
my $n = num_buckets(%hash);
```

A freshly created hash may report a non-zero bucket count even before its bucket array has been materialised - Perl allocates buckets lazily. The value is always a power of two.

used_buckets

Return the count of buckets that currently hold at least one key.

Synopsis

```
my $used = used_buckets(%hash);
```

The value is computed from scratch on every call by walking the bucket array - there is no cache. Avoid calling it inside a hot loop on a large hash.

bucket_stats

Return a rich statistical summary of the hash's bucket layout.

Synopsis

```
my ($keys, $buckets, $used, $quality, $utilization_ratio,
    $collision_pct, $mean, $stddev, @length_counts)
    = bucket_stats(\%hash);
```

Extends `bucket_info` with derived quantities: `$quality` is the Red-Dragon quality score (ideal `1.0`, acceptable around `0.95` to `1.05`, worse as the number grows), `$utilization_ratio` is the fraction of used buckets, `$collision_pct` is the fraction of keys that are not first in their bucket chain (`($keys - $used) / $keys`), and `$mean` and `$stddev` describe the bucket-chain-length distribution over used buckets.

For an empty hash, only `$keys`, `$buckets`, and `$used` are returned - the statistical block is skipped.

bucket_stats_formatted

Return a multi-line human-readable report of `bucket_stats`, complete with ASCII bar-charts.

Synopsis

```
print bucket_stats_formatted(\%hash);
```

The first paragraph of the report gives the summary line (key count, used buckets, total buckets, quality score translated into “Good”, “Poor”, or “Bad”), followed by utilisation and collision percentages and the chain-length mean and standard deviation. Two bar-charts follow: one showing the distribution of bucket chain lengths (how costly a missed lookup is), and one showing how many keys sit at each position in their chain (how costly a found lookup is).

Useful when deciding whether to pre-size a large hash with `keys(%h) = N` to cut collisions.

lock_keys

Restrict a hash to its current keys, or to an explicit list.

Synopsis

```
lock_keys(%hash);              # pin the current keyset
lock_keys(%hash, @keys);       # pin to the given keyset
```

With one argument, subsequent attempts to assign to a key not already in `%hash` croak with `Attempt to access disallowed key '...' in a restricted hash`. With more arguments, the extra keys specify the allowed set; existing keys that do not appear in that set make the call croak with `Hash has key '...' which is not in the new key set`. Keys in the allowed set that are not yet present are accepted later (their slots start as hidden placeholders).

`delete` and `exists` still work on a locked hash and do not change the legal keyset - a deleted key can be reassigned, but a brand-new key still cannot. Returns a reference to the hash.

A locked hash cannot be `blessed`; bless before locking if you need both.

unlock_keys

Lift the keyset restriction imposed by `lock_keys`.

Synopsis

```
unlock_keys(%hash);
```

Any keys locked with `lock_value` or `lock_hash` remain locked - this undoes only the keyset restriction. Hidden placeholder keys introduced while the hash was locked stay

in place; use `hidden_keys` to see them and ordinary assignment to bring them into the visible keyset.

Returns a reference to the hash.

lock_ref_keys

Hash-reference variant of `lock_keys`.

Synopsis

```
lock_ref_keys($href);
lock_ref_keys($href, @keys);
```

Exactly the same effect as `lock_keys`, but takes an already-taken hash reference rather than relying on the `\%` prototype. Useful when the hash only exists as a reference - for example, an anonymous hash or a field on an object.

unlock_ref_keys

Hash-reference variant of `unlock_keys`.

Synopsis

```
unlock_ref_keys($href);
```

Lifts the keyset restriction on the referenced hash. See `unlock_keys` for the full story on placeholders and values that remain locked.

lock_ref_keys_plus

Lock the hash to the union of its current keys and a given extra list.

Synopsis

```
lock_ref_keys_plus($href, @additional_keys);
lock_keys_plus(%hash, @additional_keys);      # plain-hash form
```

Equivalent to `lock_keys($hash, @additional_keys, keys %hash)` without having to list the existing keys yourself. Extra keys that are not yet present in the hash become hidden placeholders - they are legal to assign to later but do not yet appear in `keys`.

Returns a reference to the hash.

lock_value

Make the value under a given key immutable.

Synopsis

```
lock_value(%hash, $key);
```

Any subsequent attempt to overwrite `$hash{$key}` croaks with `Modification of a read-only value attempted`. The key itself remains deletable unless `lock_keys` has also been applied - once the key is deleted, a later assignment creates a fresh (writable) value. A key not already present is created with a read-only `undef` value, or croaks if a locked keyset does not allow it. On a hash whose keyset is not locked, `lock_value` warns `Cannot usefully lock values in an unlocked hash` when warnings are enabled.

Returns a reference to the hash.

unlock_value

Undo a previous `lock_value`, making the value at `$key` writable again.

Synopsis

```
unlock_value(%hash, $key);
```

Does nothing (silently) if the value was never locked; an absent key is created with an `undef` value, or croaks if a locked keyset does not allow it. Returns a reference to the hash.

lock_hash

Lock the whole hash: both its keyset and every value.

Synopsis

```
lock_hash(%hash);
```

Equivalent to `lock_keys(%hash)` followed by `lock_value` on each existing key. After the call, no key may be added and no value overwritten, and because every value is read-only, `delete` croaks with “Attempt to delete readonly key”.

Returns a reference to the hash.

lock_hash_recurse

Lock a hash and every nested hash it references, transitively.

Synopsis

```
lock_hash_recurse(%hash);
```

Recurses only through hash-valued entries - a hash-of-hashes is locked throughout, but a hash-of-arrays-of-hashes has only the outermost hash locked because the recursion

does not descend into arrays. Reach for `Data::Visitor` or write your own walker if you need deeper traversal.

Returns a reference to the hash.

hash_locked

Report whether the hash's keyset is currently locked.

Synopsis

```
hash_locked(%hash) and print "restricted\n";
```

Returns 1 when `lock_keys` (or an equivalent) has been applied to the hash, the empty string otherwise. Value-level locks alone do not count - this only reports the keyset restriction.

hash_unlocked

Report whether the hash's keyset is *not* currently locked.

Synopsis

```
hash_unlocked(%hash) and print "open\n";
```

The logical inverse of `hash_locked`: returns 1 on an unlocked hash, the empty string on a locked one. Handy in conditions where testing for the open state reads more naturally than negating the locked one.

hidden_keys

List the "hidden" placeholder keys of a restricted hash - legal keys that currently have no value assigned.

Synopsis

```
my @hidden = hidden_keys(%hash);
```

A hidden key is one that is allowed by the hash's keyset but fails both `exists` and `defined` - typically the ghost left behind after a `delete` on a locked hash, or a key reserved in advance by `lock_keys_plus`. Assigning to a hidden key brings it into the visible keyset.

Returns the empty list on a hash that was never restricted; placeholders left by an earlier lock are still listed after `unlock_keys`. The feature is experimental and closely tied to the current restricted-hash implementation; do not build durable contracts on top of it.

legal_keys

List every key the restricted hash *is allowed to carry* - visible keys plus hidden placeholders.

Synopsis

```
my @legal = legal_keys(%hash);
```

On a hash that was never restricted this is equivalent to `keys %hash`. On a restricted hash it is the visible keys (`keys %hash`) merged with whatever `hidden_keys` would report.

5.2.56 I18N

Namespace containing the following modules:

- `I18N::Collate` - compare 8-bit scalar data according to the current locale
- `I18N::LangTags` - functions for dealing with RFC3066-style language tags
- `I18N::Langinfo` - Query locale information - country, language, and cultural conventions from the current locale.

I18N::Collate

compare 8-bit scalar data according to the current locale

SYNOPSIS

```
use I18N::Collate;
setlocale(LC_COLLATE, 'locale-of-your-choice');
$s1 = I18N::Collate->new("scalar_data_1");
$s2 = I18N::Collate->new("scalar_data_2");
```

DESCRIPTION

```
***

WARNING: starting from the Perl version 5.003_06
the I18N::Collate interface for comparing 8-bit scalar data
according to the current locale

      HAS BEEN DEPRECATED

That is, please do not use it anymore for any new applications
and please migrate the old applications away from it because its
functionality was integrated into the Perl core language in the
release 5.003_06.

```

(continues on next page)

(continued from previous page)

```
See the perllocale manual page for further information.

***
```

This module provides you with objects that will collate according to your national character set, provided that the POSIX setlocale() function is supported on your system.

You can compare $s1 and $s2 above with

```
$s1 le $s2
```

to extract the data itself, you'll need a dereference: $$s1

This module uses POSIX::setlocale(). The basic collation conversion is done by strxfrm() which terminates at NUL characters being a decent C routine. collate_xfrm() handles embedded NUL characters gracefully.

The available locales depend on your operating system; try whether `locale -a` shows them or man pages for "locale" or "nlsinfo" or the direct approach `ls /usr/lib/nls/loc` or `ls /usr/lib/nls` or `ls /usr/lib/locale`. Not all the locales that your vendor supports are necessarily installed: please consult your operating system's documentation and possibly your local system administration. The locale names are probably something like `xx_XX.(ISO)?8859-N` or `xx_XX.(ISO)?8859N`, for example `fr_CH.ISO8859-1` is the Swiss (CH) variant of French (fr), ISO Latin (8859) 1 (-1) which is the Western European character set.

I18N::LangTags

functions for dealing with RFC3066-style language tags

SYNOPSIS

```
use I18N::LangTags();
```

...or specify whichever of those functions you want to import, like so:

```
use I18N::LangTags qw(implicate_supers similarity_language_tag);
```

All the exportable functions are listed below – you're free to import only some, or none at all. By default, none are imported. If you say:

```
use I18N::LangTags qw(:ALL)
```

...then all are exported. (This saves you from having to use something less obvious like `use I18N::LangTags qw(/./)`.)

If you don't import any of these functions, assume a `&I18N::LangTags::` in front of all the function names in the following examples.

DESCRIPTION

Language tags are a formalism, described in RFC 3066 (obsoleting 1766), for declaring what language form (language and possibly dialect) a given chunk of information is in.

This library provides functions for common tasks involving language tags as they are needed in a variety of protocols and applications.

Please see the "See Also" references for a thorough explanation of how to correctly use language tags.

- the function is_language_tag($lang1)

  Returns true iff $lang1 is a formally valid language tag.

```
is_language_tag("fr")           is TRUE
is_language_tag("x-jicarilla")   is FALSE
    (Subtags can be 8 chars long at most -- 'jicarilla' is 9)

is_language_tag("sgn-US")    is TRUE
    (That's American Sign Language)

is_language_tag("i-Klikitat")    is TRUE
    (True without regard to the fact noone has actually
     registered Klikitat -- it's a formally valid tag)

is_language_tag("fr-patois")     is TRUE
    (Formally valid -- altho descriptively weak!)

is_language_tag("Spanish")       is FALSE
is_language_tag("french-patois") is FALSE
    (No good -- first subtag has to match
     /^([xXiI]|[a-zA-Z]{2,3})$/ -- see RFC3066)

is_language_tag("x-borg-prot2532") is TRUE
    (Yes, subtags can contain digits, as of RFC3066)
```

- the function extract_language_tags($whatever)

  Returns a list of whatever looks like formally valid language tags in $whatever. Not very smart, so don't get too creative with what you want to feed it.

```
extract_language_tags("fr, fr-ca, i-mingo")
  returns:   ('fr', 'fr-ca', 'i-mingo')

extract_language_tags("It's like this: I'm in fr -- French!")
  returns:   ('It', 'in', 'fr')
(So don't just feed it any old thing.)
```

  The output is untainted. If you don't know what tainting is, don't worry about it.

- the function same_language_tag($lang1, $lang2)

  Returns true iff $lang1 and $lang2 are acceptable variant tags representing the same language-form.

```
same_language_tag('x-kadara', 'i-kadara')  is TRUE
   (The x/i- alternation doesn't matter)
same_language_tag('X-KADARA', 'i-kadara')  is TRUE
   (...and neither does case)
same_language_tag('en',       'en-US')     is FALSE
   (all-English is not the SAME as US English)
same_language_tag('x-kadara', 'x-kadar')   is FALSE
   (these are totally unrelated tags)
same_language_tag('no-bok',    'nb')       is TRUE
   (no-bok is a legacy tag for nb (Norwegian Bokmal))
```

same_language_tag works by just seeing whether encode_language_tag($lang1) is the same as encode_language_tag($lang2).

(Yes, I know this function is named a bit oddly. Call it historic reasons.)

- the function similarity_language_tag($lang1, $lang2)

  Returns an integer representing the degree of similarity between tags $lang1 and $lang2 (the order of which does not matter), where similarity is the number of common elements on the left, without regard to case and to x/i- alternation.

```
similarity_language_tag('fr', 'fr-ca')          is 1
   (one element in common)
similarity_language_tag('fr-ca', 'fr-FR')       is 1
   (one element in common)

similarity_language_tag('fr-CA-joual',
                        'fr-CA-PEI')            is 2
similarity_language_tag('fr-CA-joual', 'fr-CA')  is 2
   (two elements in common)

similarity_language_tag('x-kadara', 'i-kadara')  is 1
   (x/i- doesn't matter)

similarity_language_tag('en',       'x-kadar')   is 0
similarity_language_tag('x-kadara', 'x-kadar')   is 0
   (unrelated tags -- no similarity)

similarity_language_tag('i-cree-syllabic',
                        'i-cherokee-syllabic')   is 0
   (no B<leftmost> elements in common!)
```

- the function is_dialect_of($lang1, $lang2)

  Returns true iff language tag $lang1 represents a subform of language tag $lang2.

  Get the order right! It doesn't work the other way around!

```
is_dialect_of('en-US', 'en')           is TRUE
  (American English IS a dialect of all-English)

is_dialect_of('fr-CA-joual', 'fr-CA')   is TRUE
```

(continues on next page)

(continued from previous page)

```
is_dialect_of('fr-CA-joual', 'fr')      is TRUE
  (Joual is a dialect of (a dialect of) French)

is_dialect_of('en', 'en-US')            is FALSE
  (all-English is a NOT dialect of American English)

is_dialect_of('fr', 'en-CA')            is FALSE

is_dialect_of('en',    'en'   )         is TRUE
is_dialect_of('en-US', 'en-US')         is TRUE
  (B<Note:> these are degenerate cases)

is_dialect_of('i-mingo-tom', 'x-Mingo') is TRUE
  (the x/i thing doesn't matter, nor does case)

is_dialect_of('nn', 'no')               is TRUE
  (because 'nn' (New Norse) is aliased to 'no-nyn',
   as a special legacy case, and 'no-nyn' is a
   subform of 'no' (Norwegian))
```

- the function super_languages($lang1)

  Returns a list of language tags that are superordinate tags to $lang1 – it gets this by removing subtags from the end of $lang1 until nothing (or just “i” or “x”) is left.

```
super_languages("fr-CA-joual")  is  ("fr-CA", "fr")

super_languages("en-AU")  is  ("en")

super_languages("en")  is  empty-list, ()

super_languages("i-cherokee")  is  empty-list, ()
 ...not ("i"), which would be illegal as well as pointless.
```

  If $lang1 is not a valid language tag, returns empty-list in a list context, undef in a scalar context.

  A notable and rather unavoidable problem with this method: “x-mingo-tom” has an “x” because the whole tag isn’t an IANA-registered tag – but super_languages(‘x-mingo-tom’) is (‘x-mingo’) – which isn’t really right, since ‘i-mingo’ is registered. But this module has no way of knowing that. (But note that same_language_tag(‘x-mingo’, ‘i-mingo’) is TRUE.)

  More importantly, you assume *at your peril* that superordinates of $lang1 are mutually intelligible with $lang1. Consider this carefully.

- the function locale2language_tag($locale_identifier)

  This takes a locale name (like “en”, “en_US”, or “en_US.ISO8859-1”) and maps it to a language tag. If it’s not mappable (as with, notably, “C” and “POSIX”), this returns empty-list in a list context, or undef in a scalar context.

```
locale2language_tag("en") is "en"

locale2language_tag("en_US") is "en-US"

locale2language_tag("en_US.ISO8859-1") is "en-US"

locale2language_tag("C") is undef or ()

locale2language_tag("POSIX") is undef or ()

locale2language_tag("POSIX") is undef or ()
```

I'm not totally sure that locale names map satisfactorily to language tags. Think REAL hard about how you use this. YOU HAVE BEEN WARNED.

The output is untainted. If you don't know what tainting is, don't worry about it.

- the function encode_language_tag($lang1)

  This function, if given a language tag, returns an encoding of it such that:

  * tags representing different languages never get the same encoding.

  * tags representing the same language always get the same encoding.

  * an encoding of a formally valid language tag always is a string value that is defined, has length, and is true if considered as a boolean.

  Note that the encoding itself is **not** a formally valid language tag. Note also that you cannot, currently, go from an encoding back to a language tag that it's an encoding of.

  Note also that you **must** consider the encoded value as atomic; i.e., you should not consider it as anything but an opaque, unanalysable string value. (The internals of the encoding method may change in future versions, as the language tagging standard changes over time.)

  `encode_language_tag` returns undef if given anything other than a formally valid language tag.

  The reason `encode_language_tag` exists is because different language tags may represent the same language; this is normally treatable with `same_language_tag`, but consider this situation:

  You have a data file that expresses greetings in different languages. Its format is "[language tag]=[how to say 'Hello']", like:

```
en-US=Hiho
fr=Bonjour
i-mingo=Hau'
```

  And suppose you write a program that reads that file and then runs as a daemon, answering client requests that specify a language tag and then expect the string that says how to greet in that language. So an interaction looks like:

```
greeting-client asks:    fr
greeting-server answers: Bonjour
```

So far so good. But suppose the way you're implementing this is:

```
my %greetings;
die unless open(IN, "<", "in.dat");
while(<IN>) {
  chomp;
  next unless /^([^=]+)=(.+)/s;
  my($lang, $expr) = ($1, $2);
  $greetings{$lang} = $expr;
}
close(IN);
```

at which point %greetings has the contents:

```
"en-US"   => "Hiho"
"fr"      => "Bonjour"
"i-mingo" => "Hau'"
```

And suppose then that you answer client requests for language $wanted by just looking up $greetings{$wanted}.

If the client asks for "fr", that will look up successfully in

"i-mingo", that will look up successfully in %greetings, to the value "Hau'".

But if the client asks for "i-Mingo" or "x-mingo", or "Fr", then the lookup in %greetings fails. That's the Wrong Thing.

You could instead do lookups on $wanted with:

```
use I18N::LangTags qw(same_language_tag);
my $response = '';
foreach my $l2 (keys %greetings) {
  if(same_language_tag($wanted, $l2)) {
    $response = $greetings{$l2};
    last;
  }
}
```

But that's rather inefficient. A better way to do it is to start your program with:

```
use I18N::LangTags qw(encode_language_tag);
my %greetings;
die unless open(IN, "<", "in.dat");
while(<IN>) {
  chomp;
  next unless /^([^=]+)=(.+)/s;
  my($lang, $expr) = ($1, $2);
  $greetings{
             encode_language_tag($lang)
```

(continues on next page)

(continued from previous page)

```
            } = $expr;
}
close(IN);
```

and then just answer client requests for language $wanted by just looking up

```
$greetings{encode_language_tag($wanted)}
```

And that does the Right Thing.

- the function alternate_language_tags($lang1)

  This function, if given a language tag, returns all language tags that are alternate forms of this language tag. (I.e., tags which refer to the same language.) This is meant to handle legacy tags caused by the minor changes in language tag standards over the years; and the x-/i- alternation is also dealt with.

  Note that this function does *not* try to equate new (and never-used, and unusable) ISO639-2 three-letter tags to old (and still in use) ISO639-1 two-letter equivalents – like “ara” -> “ar” – because “ara” has *never* been in use as an Internet language tag, and RFC 3066 stipulates that it never should be, since a shorter tag (“ar”) exists.

  Examples:

```
alternate_language_tags('no-bok')       is ('nb')
alternate_language_tags('nb')           is ('no-bok')
alternate_language_tags('he')           is ('iw')
alternate_language_tags('iw')           is ('he')
alternate_language_tags('i-hakka')      is ('zh-hakka', 'x-hakka
↪')
alternate_language_tags('zh-hakka')     is ('i-hakka', 'x-hakka
↪')
alternate_language_tags('en')           is ()
alternate_language_tags('x-mingo-tom')  is ('i-mingo-tom')
alternate_language_tags('x-klikitat')   is ('i-klikitat')
alternate_language_tags('i-klikitat')   is ('x-klikitat')
```

  This function returns empty-list if given anything other than a formally valid language tag.

- the function @langs = panic_languages(@accept_languages)

  This function takes a list of 0 or more language tags that constitute a given user’s Accept-Language list, and returns a list of tags for *other* (non-super) languages that are probably acceptable to the user, to be used *if all else fails*.

  For example, if a user accepts only ‘ca’ (Catalan) and ‘es’ (Spanish), and the documents/interfaces you have available are just in German, Italian, and Chinese, then the user will most likely want the Italian one (and not the Chinese or German one!), instead of getting nothing. So `panic_languages('ca', 'es')` returns a list containing ‘it’ (Italian).

  English (‘en’) is *always* in the return list, but whether it’s at the very end or not depends on the input languages. This function works by consulting an internal table that stipulates what common languages are “close” to each other.

A useful construct you might consider using is:

```
@fallbacks = super_languages(@accept_languages);
push @fallbacks, panic_languages(
  @accept_languages, @fallbacks,
);
```

- the function implicate_supers(...languages...)

  This takes a list of strings (which are presumed to be language-tags; strings that aren't, are ignored); and after each one, this function inserts super-ordinate forms that don't already appear in the list. The original list, plus these insertions, is returned.

  In other words, it takes this:

```
pt-br de-DE en-US fr pt-br-janeiro
```

  and returns this:

```
pt-br pt de-DE de en-US en fr pt-br-janeiro
```

  This function is most useful in the idiom

```
implicate_supers( I18N::LangTags::Detect::detect() );
```

  (See *I18N::LangTags::Detect*.)

- the function implicate_supers_strictly(...languages...)

  This works like `implicate_supers` except that the implicated forms are added to the end of the return list.

  In other words, implicate_supers_strictly takes a list of strings (which are presumed to be language-tags; strings that aren't, are ignored) and after the whole given list, it inserts the super-ordinate forms of all given tags, minus any tags that already appear in the input list.

  In other words, it takes this:

```
pt-br de-DE en-US fr pt-br-janeiro
```

  and returns this:

```
pt-br de-DE en-US fr pt-br-janeiro pt de en
```

  The reason this function has "_strictly" in its name is that when you're processing an Accept-Language list according to the RFCs, if you interpret the RFCs quite strictly, then you would use implicate_supers_strictly, but for normal use (i.e., common-sense use, as far as I'm concerned) you'd use implicate_supers.

ABOUT LOWERCASING

I've considered making all the above functions that output language tags return all those tags strictly in lowercase. Having all your language tags in lowercase does make some things easier. But you might as well just lowercase as you like, or call `encode_language_tag($lang1)` where appropriate.

ABOUT UNICODE PLAINTEXT LANGUAGE TAGS

In some future version of I18N::LangTags, I plan to include support for RFC2482-style language tags – which are basically just normal language tags with their ASCII characters shifted into Plane 14.

Modules

- `I18N::LangTags::Detect` - detect the user's language preferences
- `I18N::LangTags::List` - tags and names for human languages

I18N::LangTags::Detect

detect the user's language preferences

SYNOPSIS

```
use I18N::LangTags::Detect;
my @user_wants = I18N::LangTags::Detect::detect();
```

DESCRIPTION

It is a common problem to want to detect what language(s) the user would prefer output in.

FUNCTIONS

This module defines one public function, `I18N::LangTags::Detect::detect()`. This function is not exported (nor is even exportable), and it takes no parameters.

In scalar context, the function returns the most preferred language tag (or undef if no preference was seen).

In list context (which is usually what you want), the function returns a (possibly empty) list of language tags representing (best first) what languages the user apparently would accept output in. You will probably want to pass the output of this through `I18N::LangTags::implicate_supers_tightly(...)` or `I18N::LangTags::implicate_supers(...)`, like so:

```
my @languages =
  I18N::LangTags::implicate_supers_tightly(
    I18N::LangTags::Detect::detect()
  );
```

ENVIRONMENT

This module looks at several environment variables: REQUEST_METHOD, HTTP_ACCEPT_LANGUAGE, LANGUAGE, LC_ALL, LC_MESSAGES, and LANG.

It will also use the Win32::Locale module, if it's installed and IGNORE_WIN32_LOCALE is not set to a true value in the environment.

SEE ALSO

I18N::LangTags, Win32::Locale, *Locale::Maketext*.

(This module's core code started out as a routine in Locale::Maketext; but I moved it here once I realized it was more generally useful.)

I18N::LangTags::List

tags and names for human languages

SYNOPSIS

```
use I18N::LangTags::List;
print "Parlez-vous... ", join(', ',
    I18N::LangTags::List::name('elx') || 'unknown_language',
    I18N::LangTags::List::name('ar-Kw') || 'unknown_language',
    I18N::LangTags::List::name('en') || 'unknown_language',
    I18N::LangTags::List::name('en-CA') || 'unknown_language',
  ), "?\n";
```

prints:

```
Parlez-vous... Elamite, Kuwait Arabic, English, Canadian English?
```

DESCRIPTION

This module provides a function `I18N::LangTags::List::name( _langtag_ )` that takes a language tag (see *I18N::LangTags*) and returns the best attempt at an English name for it, or undef if it can't make sense of the tag.

The function I18N::LangTags::List::name(...) is not exported.

This module also provides a function `I18N::LangTags::List::is_decent( _langtag_ )` that returns true iff the language tag is syntactically valid and is for general use (like "fr" or "fr-ca", below). That is, it returns false for tags that are syntactically invalid and for tags, like "aus", that are listed in brackets below. This function is not exported.

The map of tags-to-names that it uses is accessible as

that follows in this documentation, which should be useful to you even if you don't use this module.

ABOUT LANGUAGE TAGS

Internet language tags, as defined in RFC 3066, are a formalism for denoting human languages. The two-letter ISO 639-1 language codes are well known (as "en" for English), as are their forms when qualified by a country code ("en-US"). Less well-known are the arbitrary-length non-ISO codes (like "i-mingo"), and the recently (in 2001) introduced three-letter ISO-639-2 codes.

Remember these important facts:

- Language tags are not locale IDs. A locale ID is written with a "_" instead of a "-", (almost?) always matches `m/^\w\w_\w\w\b/`, and *means* something different than a language tag. A language tag denotes a language. A locale ID denotes a language *as used in* a particular place, in combination with non-linguistic location-specific information such as what currency is used there. Locales *also* often denote character set information, as in "en_US.ISO8859-1".
- Language tags are not for computer languages.
- "Dialect" is not a useful term, since there is no objective criterion for establishing when two language-forms are dialects of eachother, or are separate languages.
- Language tags are not case-sensitive. en-US, en-us, En-Us, etc., are all the same tag, and denote the same language.
- Not every language tag really refers to a single language. Some language tags refer to conditions: i-default (system-message text in English plus maybe other languages), und (undetermined language). Others (notably lots of the three-letter codes) are bibliographic tags that classify whole groups of languages, as with cus "Cushitic (Other)" (i.e., a language that has been classed as Cushtic, but which has no more specific code) or the even less linguistically coherent sai for "South American Indian (Other)". Though useful in bibliography, **SUCH TAGS ARE NOT FOR GENERAL USE**. For further guidance, email me.
- Language tags are not country codes. In fact, they are often distinct codes, as with language tag ja for Japanese, and ISO 3166 country code `.jp` for Japan.

LIST OF LANGUAGES

The first part of each item is the language tag, between {...}. It is followed by an English name for the language or language-group. Language tags that I judge to be not for general use, are bracketed.

This list is in alphabetical order by English name of the language.

- {ab} : Abkhazian

  eq Abkhaz
- {ace} : Achinese
- {ach} : Acoli

- {ada} : Adangme
- {ady} : Adyghe

  eq Adygei
- {aa} : Afar
- {afh} : Afrihili

  (Artificial)
- {af} : Afrikaans
- [{afa} : Afro-Asiatic (Other)]
- {ak} : Akan

  (Formerly “aka”.)
- {akk} : Akkadian

  (Historical)
- {sq} : Albanian
- {ale} : Aleut
- [{alg} : Algonquian languages]

  NOT Algonquin!
- [{tut} : Altaic (Other)]
- {am} : Amharic

  NOT Aramaic!
- {i-ami} : Ami

  eq Amis. eq ‘Amis. eq Pangca.
- [{apa} : Apache languages]
- {ar} : Arabic

  Many forms are mutually un-intelligible in spoken media. Notable forms: {ar-ae} UAE Arabic; {ar-bh} Bahrain Arabic; {ar-dz} Algerian Arabic; {ar-eg} Egyptian Arabic; {ar-iq} Iraqi Arabic; {ar-jo} Jordanian Arabic; {ar-kw} Kuwait Arabic; {ar-lb} Lebanese Arabic; {ar-ly} Libyan Arabic; {ar-ma} Moroccan Arabic; {ar-om} Omani Arabic; {ar-qa} Qatari Arabic; {ar-sa} Sauda Arabic; {ar-sy} Syrian Arabic; {ar-tn} Tunisian Arabic; {ar-ye} Yemen Arabic.
- {arc} : Aramaic

  NOT Amharic! NOT Samaritan Aramaic!
- {arp} : Arapaho
- {arn} : Araucanian
- {arw} : Arawak
- {hy} : Armenian

- [{cai} : Central American Indian (Other)]
- {chg} : Chagatai

  (Historical?)
- [{cmc} : Chamic languages]
- {ch} : Chamorro
- {ce} : Chechen
- {chr} : Cherokee

  eq Tsalagi
- {chy} : Cheyenne

- {chb} : Chibcha

  (Historical) NOT Chibchan (which is a language family).

- {ny} : Chichewa

  eq Nyanja. eq Chinyanja.

- {zh} : Chinese

  Many forms are mutually un-intelligible in spoken media. Notable forms: {zh-hans} Chinese, in simplified script; {zh-hant} Chinese, in traditional script; {zh-tw} Taiwan Chinese; {zh-cn} PRC Chinese; {zh-sg} Singapore Chinese; {zh-mo} Macau Chinese; {zh-hk} Hong Kong Chinese; {zh-guoyu} Mandarin [Putonghua/Guoyu]; {zh-hakka} Hakka [formerly "i-hakka"]; {zh-min} Hokkien; {zh-min-nan} Southern Hokkien; {zh-wuu} Shanghaiese; {zh-xiang} Hunanese; {zh-gan} Gan; {zh-yue} Cantonese.

- {chn} : Chinook Jargon

  eq Chinook Wawa.

- {chp} : Chipewyan
- {cho} : Choctaw
- {cu} : Church Slavic

  eq Old Church Slavonic.

- {chk} : Chuukese

  eq Trukese. eq Chuuk. eq Truk. eq Ruk.

- {cv} : Chuvash
- {cop} : Coptic
- {kw} : Cornish
- {co} : Corsican

  eq Corse.

- {cr} : Cree

  NOT Creek! (Formerly "cre".)

- {mus} : Creek

  NOT Cree!

- [{cpe} : English-based Creoles and pidgins (Other)]
- [{cpf} : French-based Creoles and pidgins (Other)]
- [{cpp} : Portuguese-based Creoles and pidgins (Other)]
- [{crp} : Creoles and pidgins (Other)]
- {hr} : Croatian

  eq Croat.

- [{cus} : Cushitic (Other)]

- {cs} : Czech
- {dak} : Dakota

  eq Nakota. eq Latoka.
- {da} : Danish
- {dar} : Dargwa
- {day} : Dayak
- {i-default} : Default (Fallthru) Language

  Defined in RFC 2277, this is for tagging text (which must include English text, and might/should include text in other appropriate languages) that is emitted in a context where language-negotiation wasn't possible – in SMTP mail failure messages, for example.
- {del} : Delaware
- {din} : Dinka
- {dv} : Divehi

  eq Maldivian. (Formerly "div".)
- {doi} : Dogri

  NOT Dogrib!
- {dgr} : Dogrib

  NOT Dogri!
- [{dra} : Dravidian (Other)]
- {dua} : Duala
- {nl} : Dutch

  eq Netherlander. Notable forms: {nl-nl} Netherlands Dutch; {nl-be} Belgian Dutch.
- {dum} : Middle Dutch (ca.1050-1350)

  (Historical)
- {dyu} : Dyula
- {dz} : Dzongkha
- {efi} : Efik
- {egy} : Ancient Egyptian

  (Historical)
- {eka} : Ekajuk
- {elx} : Elamite

  (Historical)
- {en} : English

  Notable forms: {en-au} Australian English; {en-bz} Belize English; {en-ca} Canadian English; {en-gb} UK English; {en-ie} Irish English; {en-jm} Jamaican English;

{en-nz} New Zealand English; {en-ph} Philippine English; {en-tt} Trinidad English; {en-us} US English; {en-za} South African English; {en-zw} Zimbabwe English.

- {enm} : Old English (1100-1500)

  (Historical)

- {ang} : Old English (ca.450-1100)

  eq Anglo-Saxon. (Historical)

- {i-enochian} : Enochian (Artificial)
- {myv} : Erzya
- {eo} : Esperanto

  (Artificial)

- {et} : Estonian
- {ee} : Ewe

  (Formerly “ewe”.)

- {ewo} : Ewondo
- {fan} : Fang
- {fat} : Fanti
- {fo} : Faroese
- {fj} : Fijian
- {fi} : Finnish
- [{fiu} : Finno-Ugrian (Other)]

  eq Finno-Ugric. NOT Ugaritic!

- {fon} : Fon
- {fr} : French

  Notable forms: {fr-fr} France French; {fr-be} Belgian French; {fr-ca} Canadian French; {fr-ch} Swiss French; {fr-lu} Luxembourg French; {fr-mc} Monaco French.

- {frm} : Middle French (ca.1400-1600)

  (Historical)

- {fro} : Old French (842-ca.1400)

  (Historical)

- {fy} : Frisian
- {fur} : Friulian
- {ff} : Fulah

  (Formerly “ful”.)

- {gaa} : Ga

- {gd} : Scots Gaelic

  NOT Scots!

- {gl} : Gallegan

  eq Galician

- {lg} : Ganda

  (Formerly “lug”.)

- {gay} : Gayo
- {gba} : Gbaya
- {gez} : Geez

  eq Ge’ez

- {ka} : Georgian
- {de} : German

  Notable forms: {de-at} Austrian German; {de-be} Belgian German; {de-ch} Swiss German; {de-de} Germany German; {de-li} Liechtenstein German; {de-lu} Luxembourg German.

- {gmh} : Middle High German (ca.1050-1500)

  (Historical)

- {goh} : Old High German (ca.750-1050)

  (Historical)

- [{gem} : Germanic (Other)]
- {gil} : Gilbertese
- {gon} : Gondi
- {gor} : Gorontalo
- {got} : Gothic

  (Historical)

- {grb} : Grebo
- {grc} : Ancient Greek

  (Historical) (Until 15th century or so.)

- {el} : Modern Greek

  (Since 15th century or so.)

- {gn} : Guarani

  Guaraní

- {gu} : Gujarati
- {gwi} : Gwich’in

  eq Gwichin

- {hai} : Haida
- {ht} : Haitian

  eq Haitian Creole
- {ha} : Hausa
- {haw} : Hawaiian

  Hawai'ian
- {he} : Hebrew

  (Formerly "iw".)
- {hz} : Herero
- {hil} : Hiligaynon
- {him} : Himachali
- {hi} : Hindi
- {ho} : Hiri Motu
- {hit} : Hittite

  (Historical)
- {hmn} : Hmong
- {hu} : Hungarian
- {hup} : Hupa
- {iba} : Iban
- {is} : Icelandic
- {io} : Ido

  (Artificial)
- {ig} : Igbo

  (Formerly "ibo".)
- {ijo} : Ijo
- {ilo} : Iloko
- [{inc} : Indic (Other)]
- [{ine} : Indo-European (Other)]
- {id} : Indonesian

  (Formerly "in".)
- {inh} : Ingush
- {ia} : Interlingua (International Auxiliary Language Association)

  (Artificial) NOT Interlingue!

- {ie} : Interlingue

  (Artificial) NOT Interlingua!
- {iu} : Inuktitut

  A subform of “Eskimo”.
- {ik} : Inupiaq

  A subform of “Eskimo”.
- [{ira} : Iranian (Other)]
- {ga} : Irish
- {mga} : Middle Irish (900-1200)

  (Historical)
- {sga} : Old Irish (to 900)

  (Historical)
- [{iro} : Iroquoian languages]
- {it} : Italian

  Notable forms: {it-it} Italy Italian; {it-ch} Swiss Italian.
- {ja} : Japanese

  (NOT “jp”!)
- {jv} : Javanese

  (Formerly “jw” because of a typo.)
- {jrb} : Judeo-Arabic
- {jpr} : Judeo-Persian
- {kbd} : Kabardian
- {kab} : Kabyle
- {kac} : Kachin
- {kl} : Kalaallisut

  eq Greenlandic “Eskimo”
- {xal} : Kalmyk
- {kam} : Kamba
- {kn} : Kannada

  eq Kanarese. NOT Canadian!
- {kr} : Kanuri

  (Formerly “kau”.)
- {krc} : Karachay-Balkar
- {kaa} : Kara-Kalpak

- {kar} : Karen
- {ks} : Kashmiri
- {csb} : Kashubian

  eq Kashub
- {kaw} : Kawi
- {kk} : Kazakh
- {kha} : Khasi
- {km} : Khmer

  eq Cambodian. eq Kampuchean.
- [{khi} : Khoisan (Other)]
- {kho} : Khotanese
- {ki} : Kikuyu

  eq Gikuyu.
- {kmb} : Kimbundu
- {rw} : Kinyarwanda
- {ky} : Kirghiz
- {i-klingon} : Klingon
- {kv} : Komi
- {kg} : Kongo

  (Formerly “kon”.)
- {kok} : Konkani
- {ko} : Korean
- {kos} : Kosraean
- {kpe} : Kpelle
- {kro} : Kru
- {kj} : Kuanyama
- {kum} : Kumyk
- {ku} : Kurdish
- {kru} : Kurukh
- {kut} : Kutenai
- {lad} : Ladino

  eq Judeo-Spanish. NOT Ladin (a minority language in Italy).
- {lah} : Lahnda

  NOT Lamba!

- {lam} : Lamba

  NOT Lahnda!
- {lo} : Lao

  eq Laotian.
- {la} : Latin

  (Historical) NOT Ladin! NOT Ladino!
- {lv} : Latvian

  eq Lettish.
- {lb} : Letzeburgesch

  eq Luxemburgian, eq Luxemburger. (Formerly “i-lux”.)
- {lez} : Lezghian
- {li} : Limburgish

  eq Limburger, eq Limburgan. NOT Letzeburgesch!
- {ln} : Lingala
- {lt} : Lithuanian
- {nds} : Low German

  eq Low Saxon. eq Low German. eq Low Saxon.
- {art-lojban} : Lojban (Artificial)
- {loz} : Lozi
- {lu} : Luba-Katanga

  (Formerly “lub”.)
- {lua} : Luba-Lulua
- {lui} : Luiseno

  eq Luiseño.
- {lun} : Lunda
- {luo} : Luo (Kenya and Tanzania)
- {lus} : Lushai
- {mk} : Macedonian

  eq the modern Slavic language spoken in what was Yugoslavia. NOT the form of Greek spoken in Greek Macedonia!
- {mad} : Madurese
- {mag} : Magahi
- {mai} : Maithili
- {mak} : Makasar
- {mg} : Malagasy

- {ms} : Malay

  NOT Malayalam!
- {ml} : Malayalam

- {gv} : Manx
- {mi} : Maori

  NOT Mari!
- {mr} : Marathi
- {chm} : Mari

  NOT Maori!
- {mh} : Marshall

  eq Marshallese.
- {mwr} : Marwari
- {mas} : Masai
- [{myn} : Mayan languages]
- {men} : Mende
- {mic} : Micmac
- {min} : Minangkabau
- {i-mingo} : Mingo

  eq the Irquoian language West Virginia Seneca. NOT New York Seneca!
- [{mis} : Miscellaneous languages]

  Don't use this.
- {moh} : Mohawk
- {mdf} : Moksha
- {mo} : Moldavian

  eq Moldovan.

- [{mkh} : Mon-Khmer (Other)]
- {lol} : Mongo
- {mn} : Mongolian

  eq Mongol.
- {mos} : Mossi
- [{mul} : Multiple languages]

  Not for normal use.
- [{mun} : Munda languages]
- {nah} : Nahuatl
- {nap} : Neapolitan
- {na} : Nauru
- {nv} : Navajo

  eq Navaho. (Formerly “i-navajo”.)
- {nd} : North Ndebele
- {nr} : South Ndebele
- {ng} : Ndonga
- {ne} : Nepali

  eq Nepalese. Notable forms: {ne-np} Nepal Nepali; {ne-in} India Nepali.
- {new} : Newari
- {nia} : Nias
- [{nic} : Niger-Kordofanian (Other)]
- [{ssa} : Nilo-Saharan (Other)]
- {niu} : Niuean
- {nog} : Nogai
- {non} : Old Norse

  (Historical)
- [{nai} : North American Indian]

  Do not use this.
- {no} : Norwegian

  Note the two following forms:
- {nb} : Norwegian Bokmal

  eq Bokmål, (A form of Norwegian.) (Formerly “no-bok”.)
- {nn} : Norwegian Nynorsk

  (A form of Norwegian.) (Formerly “no-nyn”.)

- [{nub} : Nubian languages]
- {nym} : Nyamwezi
- {nyn} : Nyankole
- {nyo} : Nyoro
- {nzi} : Nzima
- {oc} : Occitan (post 1500)

  eq Provençal, eq Provencal
- {oj} : Ojibwa

  eq Ojibwe. (Formerly “oji”.)
- {or} : Oriya
- {om} : Oromo
- {osa} : Osage
- {os} : Ossetian; Ossetic
- [{oto} : Otomian languages]

  Group of languages collectively called “Otomí”.
- {pal} : Pahlavi

  eq Pahlevi
- {i-pwn} : Paiwan

  eq Pariwan
- {pau} : Palauan
- {pi} : Pali

  (Historical?)
- {pam} : Pampanga
- {pag} : Pangasinan
- {pa} : Panjabi

  eq Punjabi
- {pap} : Papiamento

  eq Papiamentu.
- [{paa} : Papuan (Other)]
- {fa} : Persian

  eq Farsi. eq Iranian.
- {peo} : Old Persian (ca.600-400 B.C.)
- [{phi} : Philippine (Other)]

- {phn} : Phoenician

  (Historical)

- {pon} : Pohnpeian

  NOT Pompeiian!

- {pl} : Polish

- {pt} : Portuguese

  eq Portugese. Notable forms: {pt-pt} Portugal Portuguese; {pt-br} Brazilian Portuguese.

- [{pra} : Prakrit languages]

- {pro} : Old Provencal (to 1500)

  eq Old Provençal. (Historical.)

- {ps} : Pushto

  eq Pashto. eq Pushtu.

- {qu} : Quechua

  eq Quecha.

- {rm} : Raeto-Romance

  eq Romansh.

- {raj} : Rajasthani

- {rap} : Rapanui

- {rar} : Rarotongan

- [{qaa - qtz} : Reserved for local use.]

- [{roa} : Romance (Other)]

  NOT Romanian! NOT Romany! NOT Romansh!

- {ro} : Romanian

  eq Rumanian. NOT Romany!

- {rom} : Romany

  eq Rom. NOT Romanian!

- {rn} : Rundi

- {ru} : Russian

  NOT White Russian! NOT Rusyn!

- [{sal} : Salishan languages]

  Large language group.

- {sam} : Samaritan Aramaic

  NOT Aramaic!

- {se} : Northern Sami

  eq Lappish. eq Lapp. eq (Northern) Saami.
- {sma} : Southern Sami
- {smn} : Inari Sami
- {smj} : Lule Sami
- {sms} : Skolt Sami
- [{smi} : Sami languages (Other)]
- {sm} : Samoan
- {sad} : Sandawe
- {sg} : Sango
- {sa} : Sanskrit

  (Historical)
- {sat} : Santali
- {sc} : Sardinian

  eq Sard.
- {sas} : Sasak
- {sco} : Scots

  NOT Scots Gaelic!
- {sel} : Selkup
- [{sem} : Semitic (Other)]
- {sr} : Serbian

  eq Serb. NOT Sorbian.

  Notable forms: {sr-cyrl} : Serbian in Cyrillic script; {sr-latn} : Serbian in Latin script.
- {srr} : Serer
- {shn} : Shan
- {sn} : Shona
- {sid} : Sidamo
- {sgn-...} : Sign Languages

  Always use with a subtag. Notable forms: {sgn-gb} British Sign Language (BSL); {sgn-ie} Irish Sign Language (ESL); {sgn-ni} Nicaraguan Sign Language (ISN); {sgn-us} American Sign Language (ASL).

  (And so on with other country codes as the subtag.)
- {bla} : Siksika

  eq Blackfoot. eq Pikanii.

- {sd} : Sindhi
- {si} : Sinhalese

  eq Sinhala.
- [{sit} : Sino-Tibetan (Other)]
- [{sio} : Siouan languages]
- {den} : Slave (Athapascan)

  ("Slavey" is a subform.)
- [{sla} : Slavic (Other)]
- {sk} : Slovak

  eq Slovakian.
- {sl} : Slovenian

  eq Slovene.
- {sog} : Sogdian
- {so} : Somali
- {son} : Songhai
- {snk} : Soninke
- {wen} : Sorbian languages

  eq Wendish. eq Sorb. eq Lusatian. eq Wend. NOT Venda! NOT Serbian!
- {nso} : Northern Sotho
- {st} : Southern Sotho

  eq Sutu. eq Sesotho.
- [{sai} : South American Indian (Other)]
- {es} : Spanish

  Notable forms: {es-ar} Argentine Spanish; {es-bo} Bolivian Spanish; {es-cl} Chilean Spanish; {es-co} Colombian Spanish; {es-do} Dominican Spanish; {es-ec} Ecuadorian Spanish; {es-es} Spain Spanish; {es-gt} Guatemalan Spanish; {es-hn} Honduran Spanish; {es-mx} Mexican Spanish; {es-pa} Panamanian Spanish; {es-pe} Peruvian Spanish; {es-pr} Puerto Rican Spanish; {es-py} Paraguay Spanish; {es-sv} Salvadoran Spanish; {es-us} US Spanish; {es-uy} Uruguayan Spanish; {es-ve} Venezuelan Spanish.
- {suk} : Sukuma
- {sux} : Sumerian

  (Historical)
- {su} : Sundanese
- {sus} : Susu

- {sw} : Swahili

  eq Kiswahili
- {ss} : Swati
- {sv} : Swedish

  Notable forms: {sv-se} Sweden Swedish; {sv-fi} Finland Swedish.
- {syr} : Syriac
- {tl} : Tagalog
- {ty} : Tahitian
- [{tai} : Tai (Other)]

  NOT Thai!
- {tg} : Tajik
- {tmh} : Tamashek
- {ta} : Tamil
- {i-tao} : Tao

  eq Yami.
- {tt} : Tatar
- {i-tay} : Tayal

  eq Atayal. eq Atayan.
- {te} : Telugu
- {ter} : Tereno
- {tet} : Tetum
- {th} : Thai

  NOT Tai!
- {bo} : Tibetan
- {tig} : Tigre
- {ti} : Tigrinya
- {tem} : Timne

  eq Themne. eq Timene.
- {tiv} : Tiv
- {tli} : Tlingit
- {tpi} : Tok Pisin
- {tkl} : Tokelau
- {tog} : Tonga (Nyasa)

  NOT Tsonga!

- {to} : Tonga (Tonga Islands)

  (Pronounced “Tong-a”, not “Tong-ga”)

  NOT Tsonga!
- {tsi} : Tsimshian

  eq Sm’algyax
- {ts} : Tsonga

  NOT Tonga!
- {i-tsu} : Tsou
- {tn} : Tswana

  Same as Setswana.
- {tum} : Tumbuka
- [{tup} : Tupi languages]
- {tr} : Turkish

  (Typically in Roman script)
- {ota} : Ottoman Turkish (1500-1928)

  (Typically in Arabic script) (Historical)
- {crh} : Crimean Turkish

  eq Crimean Tatar
- {tk} : Turkmen

  eq Turkmeni.
- {tvl} : Tuvalu
- {tyv} : Tuvinian

  eq Tuvan. eq Tuvin.
- {tw} : Twi
- {udm} : Udmurt
- {uga} : Ugaritic

  NOT Ugric!
- {ug} : Uighur
- {uk} : Ukrainian
- {umb} : Umbundu
- {und} : Undetermined

  Not a tag for normal use.
- {ur} : Urdu

- {uz} : Uzbek

  eq Özbek

  Notable forms: {uz-cyrl} Uzbek in Cyrillic script; {uz-latn} Uzbek in Latin script.
- {vai} : Vai
- {ve} : Venda

  NOT Wendish! NOT Wend! NOT Avestan! (Formerly “ven”.)
- {vi} : Vietnamese

  eq Viet.
- {vo} : Volapuk

  eq Volapük. (Artificial)
- {vot} : Votic

  eq Votian. eq Vod.
- [{wak} : Wakashan languages]
- {wa} : Walloon
- {wal} : Walamo

  eq Wolaytta.
- {war} : Waray

  Presumably the Philippine language Waray-Waray (Samareño), not the smaller Philippine language Waray Sorsogon, nor the extinct Australian language Waray.
- {was} : Washo

  eq Washoe
- {cy} : Welsh
- {wo} : Wolof
- {x-...} : Unregistered (Semi-Private Use)

  “x-” is a prefix for language tags that are not registered with ISO or IANA. Example, x-double-dutch
- {xh} : Xhosa
- {sah} : Yakut
- {yao} : Yao

  (The Yao in Malawi?)
- {yap} : Yapese

  eq Yap
- {ii} : Sichuan Yi
- {yi} : Yiddish

  Formerly “ji”. Usually in Hebrew script.

Notable forms: {yi-latn} Yiddish in Latin script

- {yo} : Yoruba
- [{ypk} : Yupik languages]

  Several “Eskimo” languages.
- {znd} : Zande
- [{zap} : Zapotec]

  (A group of languages.)
- {zen} : Zenaga

  NOT Zend.
- {za} : Zhuang
- {zu} : Zulu
- {zun} : Zuni

  eq Zuñi

I18N::Langinfo

Query locale information - country, language, and cultural conventions from the current locale.

Exports `langinfo()` together with the item constants it takes: the character set name, the date and time formats, the day and month names, the numeric and currency separators, the era formats, the locale’s yes/no expressions, and glibc’s `_NL_*` extension items (postal address, identification, measurement, name, paper and telephone formats).

```
use I18N::Langinfo qw(langinfo CODESET DAY_1 MON_1 RADIXCHAR␣
 ↪YESEXPR);
use POSIX qw(setlocale LC_ALL);

setlocale(LC_ALL, "C");
printf "%s | %s %s | radix '%s' | yes %s\n",
    langinfo(CODESET), langinfo(DAY_1), langinfo(MON_1),␣
 ↪langinfo(RADIXCHAR), langinfo(YESEXPR);
# ANSI_X3.4-1968 | Sunday January | radix '.' | yes ^[yY]
```

The answers are the C library's for the locale in effect, so they change with `setlocale`. This is a native implementation of the XS half of I18N::Langinfo 0.24; its `.pm` is used unchanged, and `use I18N::Langinfo` exports `langinfo` alone - the item constants are imported by name.

Differences from upstream

None.

Functions

Other Functions

`langinfo`

`langinfo($item)` - the string the current locale gives for one `nl_langinfo` item code.

langinfo

`langinfo($item)` - the string the current locale gives for one `nl_langinfo` item code.

`$item` is one of the constants this module exports - `CODESET`, `D_FMT`, `T_FMT`, `DAY_1` .. `DAY_7`, `MON_1` .. `MON_12`, `RADIXCHAR`, `THOUSEP`, `CRNCYSTR`, `YESEXPR` and the rest. The answer comes from the locale in effect, so it follows `setlocale`; `RADIXCHAR` and `THOUSEP` come from the underlying `LC_NUMERIC` locale even though Perl keeps the radix a dot. A string that is UTF-8 in a UTF-8 locale comes back with the UTF-8 flag on. Called with no argument it uses `$_`. An item the C library has nothing for yields the empty string.

5.2.57 IO

Load the core IO modules - `IO::Handle`, `IO::File`, `IO::Seekable`, `IO::Pipe`, `IO::Socket`, `IO::Dir` - in one `use`.

This is the module every `IO::` class rests on: `IO::Handle`, `IO::File`, `IO::Seekable`, `IO::Dir`, `IO::Socket` and `IO::Pipe` all require it, so `use IO;` is enough to have the whole family available.

`IO` itself defines nothing you call as `IO::something`. Every method lives in the class it belongs to - `IO::Seekable`, `IO::File`, `IO::Handle`, `IO::Socket`, `IO::Poll` - and `use IO qw(File Handle)` simply loads the named subset.

It also defines the numeric constants those classes need: `POLLIN`, `POLLPRI`, `POLLOUT`, `POLLRDNORM`, `POLLWRNORM`, `POLLRDBAND`, `POLLWRBAND`, `POLLNORM`, `POLLERR`, `POLLHUP`

and POLLNVAL in IO::Poll, and _IOFBF, _IOLBF, _IONBF, SEEK_SET, SEEK_CUR and SEEK_END in IO::Handle.

```
use strict;
use IO qw(Handle File Seekable);
use IO::Seekable;                  # exports SEEK_SET, SEEK_CUR,␣
 ↪SEEK_END

my $fh = IO::File->new($path, "w+") or die $!;
$fh->autoflush(1);
$fh->print("hello\n");
$fh->seek(0, SEEK_SET);
print "read back: ", $fh->getline;                # read back: hello
printf "SEEK_END %d, _IONBF %d\n", SEEK_END, IO::Handle::_IONBF;   #␣
 ↪2, 2
```

This is a native implementation of the XS half of IO 1.56 - the handle methods that need C (blocking, ungetc, error, clearerr, untaint, flush, sync, setbuf, setvbuf, getline/getlines/gets, IO::Seekable's getpos/setpos, IO::File->new_tmpfile, IO::Poll's _poll and IO::Socket's sockatmark). Every IO::* module's Perl is upstream's, unchanged.

Differences from upstream

None.

Modules

- IO::Compress - read/write compressed data in multiple formats
- IO::Dir - supply object methods for directory handles
- IO::File - supply object methods for filehandles
- IO::Handle - supply object methods for I/O handles
- IO::Pipe - supply object methods for pipes
- IO::Poll - Object interface to system poll call
- IO::Pty - Pseudo TTY object class
- IO::Seekable - supply seek based methods for I/O objects
- IO::Select - OO interface to the select system call
- IO::Socket - Object interface to socket communications
- IO::Tty - Pseudo-terminals and the terminal constants: the compiled part under IO::Pty (a pty master and its slave as handles) and IO::Tty.
- IO::Uncompress
- IO::Zlib - IO:: style interface to *Compress::Zlib*

IO::Compress

read/write compressed data in multiple formats

DESCRIPTION

This is a stub module. It contains no code.

IO::Compress::Base

Base Class for IO::Compress modules

SYNOPSIS

```
use IO::Compress::Base ;
```

DESCRIPTION

This module is not intended for direct use in application code. Its sole purpose is to be sub-classed by IO::Compress modules.

SUPPORT

General feedback/questions/bug reports should be sent to https://github.com/pmqs/IO-Compress/issues (preferred) or https://rt.cpan.org/Public/Dist/Display.html?Name=IO-Compress.

IO::Compress::Bzip2

Write bzip2 files/buffers

SYNOPSIS

```
use IO::Compress::Bzip2 qw(bzip2 $Bzip2Error) ;

my $status = bzip2 $input => $output [,OPTS]
    or die "bzip2 failed: $Bzip2Error\n";

my $z = IO::Compress::Bzip2->new( $output [,OPTS] )
    or die "bzip2 failed: $Bzip2Error\n";

$z->print($string);
$z->printf($format, $string);
$z->write($string);
$z->syswrite($string [, $length, $offset]);
$z->flush();
$z->tell();
$z->eof();
$z->seek($position, $whence);
```

(continues on next page)

(continued from previous page)

```
$z->binmode();
$z->fileno();
$z->opened();
$z->autoflush();
$z->input_line_number();
$z->newStream( [OPTS] );

$z->close() ;

$Bzip2Error ;

# IO::File mode

print $z $string;
printf $z $format, $string;
tell $z
eof $z
seek $z, $position, $whence
binmode $z
fileno $z
close $z ;
```

DESCRIPTION

This module provides a Perl interface that allows writing bzip2 compressed data to files or buffer.

For reading bzip2 files/buffers, see the companion module *IO::Uncompress::Bunzip2*.

Functional Interface

A top-level function, `bzip2`, is provided to carry out "one-shot" compression between buffers and/or files. For finer control over the compression process, see the "OO Interface" section.

```
use IO::Compress::Bzip2 qw(bzip2 $Bzip2Error) ;

bzip2 $input_filename_or_reference => $output_filename_or_reference␣
 ↪[,OPTS]
    or die "bzip2 failed: $Bzip2Error\n";
```

The functional interface needs Perl5.005 or better.

bzip2 $input_filename_or_reference => $output_filename_or_reference [, OPTS]

`bzip2` expects at least two parameters, `$input_filename_or_reference` and `$output_filename_or_reference` and zero or more optional parameters (see "Optional Parameters")

The `$input_filename_or_reference` parameter

The parameter, `$input_filename_or_reference`, is used to define the source of the uncompressed data.

It can take one of the following forms:

- A filename

  If the `$input_filename_or_reference` parameter is a simple scalar, it is assumed to be a filename. This file will be opened for reading and the input data will be read from it.

- A filehandle

  If the `$input_filename_or_reference` parameter is a filehandle, the input data will be read from it. The string '-' can be used as an alias for standard input.

- A scalar reference

  If `$input_filename_or_reference` is a scalar reference, the input data will be read from `$$input_filename_or_reference`.

- An array reference

  If `$input_filename_or_reference` is an array reference, each element in the array must be a filename.

  The input data will be read from each file in turn.

  The complete array will be walked to ensure that it only contains valid filenames before any data is compressed.

- An Input FileGlob string

  If `$input_filename_or_reference` is a string that is delimited by the characters "<" and ">" `bzip2` will assume that it is an *input fileglob string*. The input is the list of files that match the fileglob.

  See *File::GlobMapper* for more details.

If the `$input_filename_or_reference` parameter is any other type, `undef` will be returned.

The `$output_filename_or_reference` parameter

The parameter `$output_filename_or_reference` is used to control the destination of the compressed data. This parameter can take one of these forms.

- A filename

  If the `$output_filename_or_reference` parameter is a simple scalar, it is assumed to be a filename. This file will be opened for writing and the compressed data will be written to it.

- A filehandle

  If the `$output_filename_or_reference` parameter is a filehandle, the compressed data will be written to it. The string '-' can be used as an alias for standard output.

- A scalar reference

  If `$output_filename_or_reference` is a scalar reference, the compressed data will be stored in `$$output_filename_or_reference`.

- An Array Reference

  If `$output_filename_or_reference` is an array reference, the compressed data will be pushed onto the array.

- An Output FileGlob

  If `$output_filename_or_reference` is a string that is delimited by the characters "<" and ">" `bzip2` will assume that it is an *output fileglob string*. The output is the list of files that match the fileglob.

  When `$output_filename_or_reference` is an fileglob string, `$input_filename_or_reference` must also be a fileglob string. Anything else is an error.

  See *File::GlobMapper* for more details.

If the `$output_filename_or_reference` parameter is any other type, `undef` will be returned.

Notes

When `$input_filename_or_reference` maps to multiple files/buffers and `$output_filename_or_reference` is a single file/buffer the input files/buffers will be stored in `$output_filename_or_reference` as a concatenated series of compressed data streams.

Optional Parameters

The optional parameters for the one-shot function `bzip2` are (for the most part) identical to those used with the OO interface defined in the "Constructor Options" section. The exceptions are listed below

- `AutoClose => 0|1`

  This option applies to any input or output data streams to `bzip2` that are filehandles.

  If `AutoClose` is specified, and the value is true, it will result in all input and/or output filehandles being closed once `bzip2` has completed.

  This parameter defaults to 0.

- `BinModeIn => 0|1`

  This option is now a no-op. All files will be read in binmode.

- `Append => 0|1`

  The behaviour of this option is dependent on the type of output data stream.

  - A Buffer

    If Append is enabled, all compressed data will be append to the end of the output buffer. Otherwise the output buffer will be cleared before any compressed data is written to it.

- A Filename

  If Append is enabled, the file will be opened in append mode. Otherwise the contents of the file, if any, will be truncated before any compressed data is written to it.

- A Filehandle

  If Append is enabled, the filehandle will be positioned to the end of the file via a call to `seek` before any compressed data is written to it. Otherwise the file pointer will not be moved.

When Append is specified, and set to true, it will *append* all compressed data to the output data stream.

So when the output is a filehandle it will carry out a seek to the eof before writing any compressed data. If the output is a filename, it will be opened for appending. If the output is a buffer, all compressed data will be appended to the existing buffer.

Conversely when Append is not specified, or it is present and is set to false, it will operate as follows.

When the output is a filename, it will truncate the contents of the file before writing any compressed data. If the output is a filehandle its position will not be changed. If the output is a buffer, it will be wiped before any compressed data is output.

Defaults to 0.

Oneshot Examples

Here are a few example that show the capabilities of the module.

Streaming

This very simple command line example demonstrates the streaming capabilities of the module. The code reads data from STDIN, compresses it, and writes the compressed data to STDOUT.

```
$ echo hello world | perl -MIO::Compress::Bzip2=bzip2 -e 'bzip2 \
↪*STDIN => \*STDOUT' >output.bz2
```

The special filename "-" can be used as a standin for both `\*STDIN` and `\*STDOUT`, so the above can be rewritten as

```
$ echo hello world | perl -MIO::Compress::Bzip2=bzip2 -e 'bzip2 "-"␣
↪=> "-"' >output.bz2
```

Compressing a file from the filesystem

To read the contents of the file `file1.txt` and write the compressed data to the file `file1.txt.bz2`.

```
use strict ;
use warnings ;
```

(continues on next page)

(continued from previous page)

```
use IO::Compress::Bzip2 qw(bzip2 $Bzip2Error) ;

my $input = "file1.txt";
bzip2 $input => "$input.bz2"
    or die "bzip2 failed: $Bzip2Error\n";
```

Reading from a Filehandle and writing to an in-memory buffer

To read from an existing Perl filehandle, `$input`, and write the compressed data to a buffer, `$buffer`.

```
use strict ;
use warnings ;
use IO::Compress::Bzip2 qw(bzip2 $Bzip2Error) ;
use IO::File ;

my $input = IO::File->new( "<file1.txt" )
    or die "Cannot open 'file1.txt': $!\n" ;
my $buffer ;
bzip2 $input => \$buffer
    or die "bzip2 failed: $Bzip2Error\n";
```

Compressing multiple files

To compress all files in the directory “/my/home” that match “*.txt” and store the compressed data in the same directory

```
use strict ;
use warnings ;
use IO::Compress::Bzip2 qw(bzip2 $Bzip2Error) ;

bzip2 '</my/home/*.txt>' => '<*.bz2>'
    or die "bzip2 failed: $Bzip2Error\n";
```

and if you want to compress each file one at a time, this will do the trick

```
use strict ;
use warnings ;
use IO::Compress::Bzip2 qw(bzip2 $Bzip2Error) ;

for my $input ( glob "/my/home/*.txt" )
{
    my $output = "$input.bz2" ;
    bzip2 $input => $output
        or die "Error compressing '$input': $Bzip2Error\n";
}
```

OO Interface

Constructor

The format of the constructor for `IO::Compress::Bzip2` is shown below

```
my $z = IO::Compress::Bzip2->new( $output [,OPTS] )
    or die "IO::Compress::Bzip2 failed: $Bzip2Error\n";
```

The constructor takes one mandatory parameter, `$output`, defined below and zero or more `OPTS`, defined in "Constructor Options".

It returns an `IO::Compress::Bzip2` object on success and `undef` on failure. The variable `$Bzip2Error` will contain an error message on failure.

If you are running Perl 5.005 or better the object, `$z`, returned from IO::Compress::Bzip2 can be used exactly like an *IO::File* filehandle. This means that all normal output file operations can be carried out with `$z`. For example, to write to a compressed file/buffer you can use either of these forms

```
$z->print("hello world\n");
print $z "hello world\n";
```

Below is a simple exaple of using the OO interface to create an output file `myfile.bz2` and write some data to it.

```
my $filename = "myfile.bz2";
my $z = IO::Compress::Bzip2->new($filename)
    or die "IO::Compress::Bzip2 failed: $Bzip2Error\n";

$z->print("abcde");
$z->close();
```

See the "Examples" for more.

The mandatory parameter `$output` is used to control the destination of the compressed data. This parameter can take one of these forms.

- A filename

  If the `$output` parameter is a simple scalar, it is assumed to be a filename. This file will be opened for writing and the compressed data will be written to it.

- A filehandle

  If the `$output` parameter is a filehandle, the compressed data will be written to it. The string '-' can be used as an alias for standard output.

- A scalar reference

  If `$output` is a scalar reference, the compressed data will be stored in `$$output`.

If the `$output` parameter is any other type, `IO::Compress::Bzip2`::new will return undef.

Constructor Options

`OPTS` is any combination of zero or more the following options:

- `AutoClose => 0|1`

  This option is only valid when the `$output` parameter is a filehandle. If specified, and the value is true, it will result in the `$output` being closed once either the `close` method is called or the `IO::Compress::Bzip2` object is destroyed.

  This parameter defaults to 0.

- `Append => 0|1`

  Opens `$output` in append mode.

  The behaviour of this option is dependent on the type of `$output`.

  - A Buffer

    If `$output` is a buffer and Append is enabled, all compressed data will be append to the end of `$output`. Otherwise `$output` will be cleared before any data is written to it.

  - A Filename

    If `$output` is a filename and Append is enabled, the file will be opened in append mode. Otherwise the contents of the file, if any, will be truncated before any compressed data is written to it.

  - A Filehandle

    If `$output` is a filehandle, the file pointer will be positioned to the end of the file via a call to `seek` before any compressed data is written to it. Otherwise the file pointer will not be moved.

  This parameter defaults to 0.

- `BlockSize100K => number`

  Specify the number of 100K blocks bzip2 uses during compression.

  Valid values are from 1 to 9, where 9 is best compression.

  The default is 1.

- `WorkFactor => number`

  Specifies how much effort bzip2 should take before resorting to a slower fallback compression algorithm.

  Valid values range from 0 to 250, where 0 means use the default value 30.

  The default is 0.

- `Strict => 0|1`

  This is a placeholder option.

Examples

Streaming

This very simple command line example demonstrates the streaming capabilities of the module. The code reads data from STDIN or all the files given on the commandline, compresses it, and writes the compressed data to STDOUT.

```
use strict ;
use warnings ;
use IO::Compress::Bzip2 qw(bzip2 $Bzip2Error) ;

my $z = IO::Compress::Bzip2->new("-", Stream => 1)
    or die "IO::Compress::Bzip2 failed: $Bzip2Error\n";

while (<>) {
    $z->print("abcde");
}
$z->close();
```

Note the use of `"-"` to means `STDOUT`. Alternatively you can use `\*STDOUT`.

Compressing a file from the filesystem

To read the contents of the file `file1.txt` and write the compressed data to the file `file1.txt.bz2` there are a few options

Start by creating the compression object and opening the input file

```
use strict ;
use warnings ;
use IO::Compress::Bzip2 qw(bzip2 $Bzip2Error) ;

my $input = "file1.txt";
my $z = IO::Compress::Bzip2->new("file1.txt.bz2")
    or die "IO::Compress::Bzip2 failed: $Bzip2Error\n";

# open the input file
open my $fh, "<", "file1.txt"
    or die "Cannot open file1.txt: $!\n";

# loop through the input file & write to the compressed file
while (<$fh>) {
    $z->print($_);
}

# not forgetting to close the compressed file
$z->close();
```

Methods

print

Usage is

```
$z->print($data)
print $z $data
```

Compresses and outputs the contents of the `$data` parameter. This has the same behaviour as the `print` built-in.

Returns true if successful.

printf

Usage is

```
$z->printf($format, $data)
printf $z $format, $data
```

Compresses and outputs the contents of the `$data` parameter.

Returns true if successful.

syswrite

Usage is

```
$z->syswrite $data
$z->syswrite $data, $length
$z->syswrite $data, $length, $offset
```

Compresses and outputs the contents of the `$data` parameter.

Returns the number of uncompressed bytes written, or `undef` if unsuccessful.

write

Usage is

```
$z->write $data
$z->write $data, $length
$z->write $data, $length, $offset
```

Compresses and outputs the contents of the `$data` parameter.

Returns the number of uncompressed bytes written, or `undef` if unsuccessful.

flush

Usage is

```
$z->flush;
```

Flushes any pending compressed data to the output file/buffer.

TODO

Returns true on success.

tell

Usage is

```
$z->tell()
tell $z
```

Returns the uncompressed file offset.

eof

Usage is

```
$z->eof();
eof($z);
```

Returns true if the `close` method has been called.

seek

```
$z->seek($position, $whence);
seek($z, $position, $whence);
```

Provides a sub-set of the `seek` functionality, with the restriction that it is only legal to seek forward in the output file/buffer. It is a fatal error to attempt to seek backward.

Empty parts of the file/buffer will have NULL (0x00) bytes written to them.

The `$whence` parameter takes one the usual values, namely SEEK_SET, SEEK_CUR or SEEK_END.

Returns 1 on success, 0 on failure.

binmode

Usage is

```
$z->binmode
binmode $z ;
```

This is a noop provided for completeness.

opened

```
$z->opened()
```

Returns true if the object currently refers to a opened file/buffer.

autoflush

```
my $prev = $z->autoflush()
my $prev = $z->autoflush(EXPR)
```

If the `$z` object is associated with a file or a filehandle, this method returns the current autoflush setting for the underlying filehandle. If `EXPR` is present, and is non-zero, it will enable flushing after every write/print operation.

If `$z` is associated with a buffer, this method has no effect and always returns `undef`.

Note that the special variable `$|` **cannot** be used to set or retrieve the autoflush setting.

input_line_number

```
$z->input_line_number()
$z->input_line_number(EXPR)
```

This method always returns `undef` when compressing.

fileno

```
$z->fileno()
fileno($z)
```

If the `$z` object is associated with a file or a filehandle, `fileno` will return the underlying file descriptor. Once the `close` method is called `fileno` will return `undef`.

If the `$z` object is associated with a buffer, this method will return `undef`.

close

```
$z->close() ;
close $z ;
```

Flushes any pending compressed data and then closes the output file/buffer.

For most versions of Perl this method will be automatically invoked if the IO::Compress::Bzip2 object is destroyed (either explicitly or by the variable with the reference to the object going out of scope). The exceptions are Perl versions 5.005 through 5.00504 and 5.8.0. In these cases, the `close` method will be called automatically, but not until global destruction of all live objects when the program is terminating.

Therefore, if you want your scripts to be able to run on all versions of Perl, you should call `close` explicitly and not rely on automatic closing.

Returns true on success, otherwise 0.

If the `AutoClose` option has been enabled when the IO::Compress::Bzip2 object was created, and the object is associated with a file, the underlying file will also be closed.

newStream([OPTS])

Usage is

```
$z->newStream( [OPTS] )
```

Closes the current compressed data stream and starts a new one.

OPTS consists of any of the options that are available when creating the `$z` object.

See the "Constructor Options" section for more details.

Importing

No symbolic constants are required by IO::Compress::Bzip2 at present.

- :all

  Imports `bzip2` and `$Bzip2Error`. Same as doing this

  ```
  use IO::Compress::Bzip2 qw(bzip2 $Bzip2Error) ;
  ```

IO::Compress::Deflate

Write RFC 1950 files/buffers

SYNOPSIS

```
use IO::Compress::Deflate qw(deflate $DeflateError) ;

my $status = deflate $input => $output [,OPTS]
    or die "deflate failed: $DeflateError\n";

my $z = IO::Compress::Deflate->new( $output [,OPTS] )
    or die "deflate failed: $DeflateError\n";

$z->print($string);
$z->printf($format, $string);
$z->write($string);
$z->syswrite($string [, $length, $offset]);
$z->flush();
$z->tell();
$z->eof();
$z->seek($position, $whence);
$z->binmode();
$z->fileno();
$z->opened();
$z->autoflush();
$z->input_line_number();
$z->newStream( [OPTS] );
```

(continues on next page)

(continued from previous page)

```
$z->deflateParams();

$z->close() ;

$DeflateError ;

# IO::File mode

print $z $string;
printf $z $format, $string;
tell $z
eof $z
seek $z, $position, $whence
binmode $z
fileno $z
close $z ;
```

DESCRIPTION

This module provides a Perl interface that allows writing compressed data to files or buffer as defined in RFC 1950.

For reading RFC 1950 files/buffers, see the companion module *IO::Uncompress::Inflate*.

Functional Interface

A top-level function, `deflate`, is provided to carry out "one-shot" compression between buffers and/or files. For finer control over the compression process, see the "OO Interface" section.

```
use IO::Compress::Deflate qw(deflate $DeflateError) ;

deflate $input_filename_or_reference => $output_filename_or_
 ↪reference [,OPTS]
    or die "deflate failed: $DeflateError\n";
```

The functional interface needs Perl5.005 or better.

deflate $input_filename_or_reference => $output_filename_or_reference [, OPTS]

`deflate` expects at least two parameters, `$input_filename_or_reference` and `$output_filename_or_reference` and zero or more optional parameters (see "Optional Parameters")

The $input_filename_or_reference parameter

The parameter, $input_filename_or_reference, is used to define the source of the uncompressed data.

It can take one of the following forms:

- A filename

  If the $input_filename_or_reference parameter is a simple scalar, it is assumed to be a filename. This file will be opened for reading and the input data will be read from it.

- A filehandle

  If the $input_filename_or_reference parameter is a filehandle, the input data will be read from it. The string '-' can be used as an alias for standard input.

- A scalar reference

  If $input_filename_or_reference is a scalar reference, the input data will be read from $$input_filename_or_reference.

- An array reference

  If $input_filename_or_reference is an array reference, each element in the array must be a filename.

  The input data will be read from each file in turn.

  The complete array will be walked to ensure that it only contains valid filenames before any data is compressed.

- An Input FileGlob string

  If $input_filename_or_reference is a string that is delimited by the characters "<" and ">" deflate will assume that it is an *input fileglob string*. The input is the list of files that match the fileglob.

  See *File::GlobMapper* for more details.

If the $input_filename_or_reference parameter is any other type, undef will be returned.

The $output_filename_or_reference parameter

The parameter $output_filename_or_reference is used to control the destination of the compressed data. This parameter can take one of these forms.

- A filename

  If the $output_filename_or_reference parameter is a simple scalar, it is assumed to be a filename. This file will be opened for writing and the compressed data will be written to it.

- A filehandle

  If the $output_filename_or_reference parameter is a filehandle, the compressed data will be written to it. The string '-' can be used as an alias for standard output.

- A scalar reference

  If `$output_filename_or_reference` is a scalar reference, the compressed data will be stored in `$$output_filename_or_reference`.

- An Array Reference

  If `$output_filename_or_reference` is an array reference, the compressed data will be pushed onto the array.

- An Output FileGlob

  If `$output_filename_or_reference` is a string that is delimited by the characters "<" and ">" `deflate` will assume that it is an *output fileglob string*. The output is the list of files that match the fileglob.

  When `$output_filename_or_reference` is an fileglob string, `$input_filename_or_reference` must also be a fileglob string. Anything else is an error.

  See *File::GlobMapper* for more details.

If the `$output_filename_or_reference` parameter is any other type, `undef` will be returned.

Notes

When `$input_filename_or_reference` maps to multiple files/buffers and `$output_filename_or_reference` is a single file/buffer the input files/buffers will be stored in `$output_filename_or_reference` as a concatenated series of compressed data streams.

Optional Parameters

The optional parameters for the one-shot function `deflate` are (for the most part) identical to those used with the OO interface defined in the "Constructor Options" section. The exceptions are listed below

- `AutoClose => 0|1`

  This option applies to any input or output data streams to `deflate` that are filehandles.

  If `AutoClose` is specified, and the value is true, it will result in all input and/or output filehandles being closed once `deflate` has completed.

  This parameter defaults to 0.

- `BinModeIn => 0|1`

  This option is now a no-op. All files will be read in binmode.

- `Append => 0|1`

  The behaviour of this option is dependent on the type of output data stream.

  - A Buffer

    If Append is enabled, all compressed data will be append to the end of the output buffer. Otherwise the output buffer will be cleared before any compressed data is written to it.

- A Filename

  If Append is enabled, the file will be opened in append mode. Otherwise the contents of the file, if any, will be truncated before any compressed data is written to it.

- A Filehandle

  If Append is enabled, the filehandle will be positioned to the end of the file via a call to `seek` before any compressed data is written to it. Otherwise the file pointer will not be moved.

When Append is specified, and set to true, it will *append* all compressed data to the output data stream.

So when the output is a filehandle it will carry out a seek to the eof before writing any compressed data. If the output is a filename, it will be opened for appending. If the output is a buffer, all compressed data will be appended to the existing buffer.

Conversely when Append is not specified, or it is present and is set to false, it will operate as follows.

When the output is a filename, it will truncate the contents of the file before writing any compressed data. If the output is a filehandle its position will not be changed. If the output is a buffer, it will be wiped before any compressed data is output.

Defaults to 0.

Oneshot Examples

Here are a few example that show the capabilities of the module.

Streaming

This very simple command line example demonstrates the streaming capabilities of the module. The code reads data from STDIN, compresses it, and writes the compressed data to STDOUT.

```
$ echo hello world | perl -MIO::Compress::Deflate=deflate -e
↪'deflate \*STDIN => \*STDOUT' >output.1950
```

The special filename "-" can be used as a standin for both `\*STDIN` and `\*STDOUT`, so the above can be rewritten as

```
$ echo hello world | perl -MIO::Compress::Deflate=deflate -e
↪'deflate "-" => "-"' >output.1950
```

Compressing a file from the filesystem

To read the contents of the file `file1.txt` and write the compressed data to the file `file1.txt.1950`.

```
use strict ;
use warnings ;
```

(continues on next page)

(continued from previous page)

```
use IO::Compress::Deflate qw(deflate $DeflateError) ;

my $input = "file1.txt";
deflate $input => "$input.1950"
    or die "deflate failed: $DeflateError\n";
```

Reading from a Filehandle and writing to an in-memory buffer

To read from an existing Perl filehandle, `$input`, and write the compressed data to a buffer, `$buffer`.

```
use strict ;
use warnings ;
use IO::Compress::Deflate qw(deflate $DeflateError) ;
use IO::File ;

my $input = IO::File->new( "<file1.txt" )
    or die "Cannot open 'file1.txt': $!\n" ;
my $buffer ;
deflate $input => \$buffer
    or die "deflate failed: $DeflateError\n";
```

Compressing multiple files

To compress all files in the directory “/my/home” that match “*.txt” and store the compressed data in the same directory

```
use strict ;
use warnings ;
use IO::Compress::Deflate qw(deflate $DeflateError) ;

deflate '</my/home/*.txt>' => '<*.1950>'
    or die "deflate failed: $DeflateError\n";
```

and if you want to compress each file one at a time, this will do the trick

```
use strict ;
use warnings ;
use IO::Compress::Deflate qw(deflate $DeflateError) ;

for my $input ( glob "/my/home/*.txt" )
{
    my $output = "$input.1950" ;
    deflate $input => $output
        or die "Error compressing '$input': $DeflateError\n";
}
```

OO Interface

Constructor

The format of the constructor for `IO::Compress::Deflate` is shown below

```
my $z = IO::Compress::Deflate->new( $output [,OPTS] )
    or die "IO::Compress::Deflate failed: $DeflateError\n";
```

The constructor takes one mandatory parameter, `$output`, defined below and zero or more `OPTS`, defined in "Constructor Options".

It returns an `IO::Compress::Deflate` object on success and `undef` on failure. The variable `$DeflateError` will contain an error message on failure.

If you are running Perl 5.005 or better the object, `$z`, returned from IO::Compress::Deflate can be used exactly like an *IO::File* filehandle. This means that all normal output file operations can be carried out with `$z`. For example, to write to a compressed file/buffer you can use either of these forms

```
$z->print("hello world\n");
print $z "hello world\n";
```

Below is a simple exaple of using the OO interface to create an output file `myfile.1950` and write some data to it.

```
my $filename = "myfile.1950";
my $z = IO::Compress::Deflate->new($filename)
    or die "IO::Compress::Deflate failed: $DeflateError\n";

$z->print("abcde");
$z->close();
```

See the "Examples" for more.

The mandatory parameter `$output` is used to control the destination of the compressed data. This parameter can take one of these forms.

- A filename

  If the `$output` parameter is a simple scalar, it is assumed to be a filename. This file will be opened for writing and the compressed data will be written to it.

- A filehandle

  If the `$output` parameter is a filehandle, the compressed data will be written to it. The string '-' can be used as an alias for standard output.

- A scalar reference

  If `$output` is a scalar reference, the compressed data will be stored in `$$output`.

If the `$output` parameter is any other type, `IO::Compress::Deflate`::new will return undef.

Constructor Options

`OPTS` is any combination of zero or more the following options:

- `AutoClose => 0|1`

  This option is only valid when the `$output` parameter is a filehandle. If specified, and the value is true, it will result in the `$output` being closed once either the `close` method is called or the `IO::Compress::Deflate` object is destroyed.

  This parameter defaults to 0.

- `Append => 0|1`

  Opens `$output` in append mode.

  The behaviour of this option is dependent on the type of `$output`.

  - A Buffer

    If `$output` is a buffer and Append is enabled, all compressed data will be append to the end of `$output`. Otherwise `$output` will be cleared before any data is written to it.

  - A Filename

    If `$output` is a filename and Append is enabled, the file will be opened in append mode. Otherwise the contents of the file, if any, will be truncated before any compressed data is written to it.

  - A Filehandle

    If `$output` is a filehandle, the file pointer will be positioned to the end of the file via a call to `seek` before any compressed data is written to it. Otherwise the file pointer will not be moved.

  This parameter defaults to 0.

- `Merge => 0|1`

  This option is used to compress input data and append it to an existing compressed data stream in `$output`. The end result is a single compressed data stream stored in `$output`.

  It is a fatal error to attempt to use this option when `$output` is not an RFC 1950 data stream.

  There are a number of other limitations with the `Merge` option:

  1. This module needs to have been built with zlib 1.2.1 or better to work. A fatal error will be thrown if `Merge` is used with an older version of zlib.

  2. If `$output` is a file or a filehandle, it must be seekable.

  This parameter defaults to 0.

- -Level

  Defines the compression level used by zlib. The value should either be a number between 0 and 9 (0 means no compression and 9 is maximum compression), or one of the symbolic constants defined below.

```
Z_NO_COMPRESSION
Z_BEST_SPEED
Z_BEST_COMPRESSION
Z_DEFAULT_COMPRESSION
```

The default is Z_DEFAULT_COMPRESSION.

Note, these constants are not imported by `IO::Compress::Deflate` by default.

```
use IO::Compress::Deflate qw(:strategy);
use IO::Compress::Deflate qw(:constants);
use IO::Compress::Deflate qw(:all);
```

- -Strategy

  Defines the strategy used to tune the compression. Use one of the symbolic constants defined below.

  ```
  Z_FILTERED
  Z_HUFFMAN_ONLY
  Z_RLE
  Z_FIXED
  Z_DEFAULT_STRATEGY
  ```

  The default is Z_DEFAULT_STRATEGY.

- `Strict => 0|1`

  This is a placeholder option.

Examples

Streaming

This very simple command line example demonstrates the streaming capabilities of the module. The code reads data from STDIN or all the files given on the commandline, compresses it, and writes the compressed data to STDOUT.

```
use strict ;
use warnings ;
use IO::Compress::Deflate qw(deflate $DeflateError) ;

my $z = IO::Compress::Deflate->new("-", Stream => 1)
    or die "IO::Compress::Deflate failed: $DeflateError\n";

while (<>) {
    $z->print("abcde");
}
$z->close();
```

Note the use of `"-"` to means `STDOUT`. Alternatively you can use `\*STDOUT`.

Compressing a file from the filesystem

To read the contents of the file `file1.txt` and write the compressed data to the file `file1.txt.1950` there are a few options

Start by creating the compression object and opening the input file

```
use strict ;
use warnings ;
use IO::Compress::Deflate qw(deflate $DeflateError) ;

my $input = "file1.txt";
my $z = IO::Compress::Deflate->new("file1.txt.1950")
    or die "IO::Compress::Deflate failed: $DeflateError\n";

# open the input file
open my $fh, "<", "file1.txt"
    or die "Cannot open file1.txt: $!\n";

# loop through the input file & write to the compressed file
while (<$fh>) {
    $z->print($_);
}

# not forgetting to close the compressed file
$z->close();
```

Methods

print

Usage is

```
$z->print($data)
print $z $data
```

Compresses and outputs the contents of the `$data` parameter. This has the same behaviour as the `print` built-in.

Returns true if successful.

printf

Usage is

```
$z->printf($format, $data)
printf $z $format, $data
```

Compresses and outputs the contents of the `$data` parameter.

Returns true if successful.

syswrite

Usage is

```
$z->syswrite $data
$z->syswrite $data, $length
$z->syswrite $data, $length, $offset
```

Compresses and outputs the contents of the `$data` parameter.

Returns the number of uncompressed bytes written, or `undef` if unsuccessful.

write

Usage is

```
$z->write $data
$z->write $data, $length
$z->write $data, $length, $offset
```

Compresses and outputs the contents of the `$data` parameter.

Returns the number of uncompressed bytes written, or `undef` if unsuccessful.

flush

Usage is

```
$z->flush;
$z->flush($flush_type);
```

Flushes any pending compressed data to the output file/buffer.

This method takes an optional parameter, `$flush_type`, that controls how the flushing will be carried out. By default the `$flush_type` used is `Z_FINISH`. Other valid values for `$flush_type` are `Z_NO_FLUSH`, `Z_SYNC_FLUSH`, `Z_FULL_FLUSH` and `Z_BLOCK`. It is strongly recommended that you only set the `flush_type` parameter if you fully understand the implications of what it does - overuse of `flush` can seriously degrade the level of compression achieved. See the `zlib` documentation for details.

Returns true on success.

tell

Usage is

```
$z->tell()
tell $z
```

Returns the uncompressed file offset.

eof

Usage is

```
$z->eof();
eof($z);
```

Returns true if the `close` method has been called.

seek

```
$z->seek($position, $whence);
seek($z, $position, $whence);
```

Provides a sub-set of the `seek` functionality, with the restriction that it is only legal to seek forward in the output file/buffer. It is a fatal error to attempt to seek backward.

Empty parts of the file/buffer will have NULL (0x00) bytes written to them.

The `$whence` parameter takes one the usual values, namely SEEK_SET, SEEK_CUR or SEEK_END.

Returns 1 on success, 0 on failure.

binmode

Usage is

```
$z->binmode
binmode $z ;
```

This is a noop provided for completeness.

opened

```
$z->opened()
```

Returns true if the object currently refers to a opened file/buffer.

autoflush

```
my $prev = $z->autoflush()
my $prev = $z->autoflush(EXPR)
```

If the `$z` object is associated with a file or a filehandle, this method returns the current autoflush setting for the underlying filehandle. If `EXPR` is present, and is non-zero, it will enable flushing after every write/print operation.

If `$z` is associated with a buffer, this method has no effect and always returns `undef`.

Note that the special variable `$|` **cannot** be used to set or retrieve the autoflush setting.

input_line_number

```
$z->input_line_number()
$z->input_line_number(EXPR)
```

This method always returns undef when compressing.

fileno

```
$z->fileno()
fileno($z)
```

If the $z object is associated with a file or a filehandle, fileno will return the underlying file descriptor. Once the close method is called fileno will return undef.

If the $z object is associated with a buffer, this method will return undef.

close

```
$z->close() ;
close $z ;
```

Flushes any pending compressed data and then closes the output file/buffer.

For most versions of Perl this method will be automatically invoked if the IO::Compress::Deflate object is destroyed (either explicitly or by the variable with the reference to the object going out of scope). The exceptions are Perl versions 5.005 through 5.00504 and 5.8.0. In these cases, the close method will be called automatically, but not until global destruction of all live objects when the program is terminating.

Therefore, if you want your scripts to be able to run on all versions of Perl, you should call close explicitly and not rely on automatic closing.

Returns true on success, otherwise 0.

If the AutoClose option has been enabled when the IO::Compress::Deflate object was created, and the object is associated with a file, the underlying file will also be closed.

newStream([OPTS])

Usage is

```
$z->newStream( [OPTS] )
```

Closes the current compressed data stream and starts a new one.

OPTS consists of any of the options that are available when creating the $z object.

See the “Constructor Options” section for more details.

deflateParams

Usage is

```
$z->deflateParams
```

TODO

Importing

A number of symbolic constants are required by some methods in `IO::Compress::Deflate`. None are imported by default.

- :all

  Imports `deflate`, `$DeflateError` and all symbolic constants that can be used by `IO::Compress::Deflate`. Same as doing this

  ```
  use IO::Compress::Deflate qw(deflate $DeflateError :constants) ;
  ```

- :constants

  Import all symbolic constants. Same as doing this

  ```
  use IO::Compress::Deflate qw(:flush :level :strategy) ;
  ```

- :flush

  These symbolic constants are used by the `flush` method.

  ```
  Z_NO_FLUSH
  Z_PARTIAL_FLUSH
  Z_SYNC_FLUSH
  Z_FULL_FLUSH
  Z_FINISH
  Z_BLOCK
  ```

- :level

  These symbolic constants are used by the `Level` option in the constructor.

  ```
  Z_NO_COMPRESSION
  Z_BEST_SPEED
  Z_BEST_COMPRESSION
  Z_DEFAULT_COMPRESSION
  ```

- :strategy

  These symbolic constants are used by the `Strategy` option in the constructor.

  ```
  Z_FILTERED
  Z_HUFFMAN_ONLY
  Z_RLE
  Z_FIXED
  Z_DEFAULT_STRATEGY
  ```

IO::Compress::Gzip

Write RFC 1952 files/buffers

SYNOPSIS

```
use IO::Compress::Gzip qw(gzip $GzipError) ;

my $status = gzip $input => $output [,OPTS]
    or die "gzip failed: $GzipError\n";

my $z = IO::Compress::Gzip->new( $output [,OPTS] )
    or die "gzip failed: $GzipError\n";

$z->print($string);
$z->printf($format, $string);
$z->write($string);
$z->syswrite($string [, $length, $offset]);
$z->flush();
$z->tell();
$z->eof();
$z->seek($position, $whence);
$z->binmode();
$z->fileno();
$z->opened();
$z->autoflush();
$z->input_line_number();
$z->newStream( [OPTS] );

$z->deflateParams();

$z->close() ;

$GzipError ;

# IO::File mode

print $z $string;
printf $z $format, $string;
tell $z
eof $z
seek $z, $position, $whence
binmode $z
```

(continues on next page)

(continued from previous page)

```
fileno $z
close $z ;
```

DESCRIPTION

This module provides a Perl interface that allows writing compressed data to files or buffer as defined in RFC 1952.

All the gzip headers defined in RFC 1952 can be created using this module.

For reading RFC 1952 files/buffers, see the companion module *IO::Uncompress::Gunzip*.

Functional Interface

A top-level function, `gzip`, is provided to carry out "one-shot" compression between buffers and/or files. For finer control over the compression process, see the "OO Interface" section.

```
use IO::Compress::Gzip qw(gzip $GzipError) ;

gzip $input_filename_or_reference => $output_filename_or_reference␣
↪[,OPTS]
    or die "gzip failed: $GzipError\n";
```

The functional interface needs Perl5.005 or better.

gzip $input_filename_or_reference => $output_filename_or_reference [, OPTS]

`gzip` expects at least two parameters, `$input_filename_or_reference` and `$output_filename_or_reference` and zero or more optional parameters (see "Optional Parameters")

The `$input_filename_or_reference` parameter

The parameter, `$input_filename_or_reference`, is used to define the source of the uncompressed data.

It can take one of the following forms:

- A filename

  If the `$input_filename_or_reference` parameter is a simple scalar, it is assumed to be a filename. This file will be opened for reading and the input data will be read from it.

- A filehandle

  If the `$input_filename_or_reference` parameter is a filehandle, the input data will be read from it. The string '-' can be used as an alias for standard input.

- A scalar reference

  If `$input_filename_or_reference` is a scalar reference, the input data will be read from `$$input_filename_or_reference`.

- An array reference

  If `$input_filename_or_reference` is an array reference, each element in the array must be a filename.

  The input data will be read from each file in turn.

  The complete array will be walked to ensure that it only contains valid filenames before any data is compressed.

- An Input FileGlob string

  If `$input_filename_or_reference` is a string that is delimited by the characters "<" and ">" `gzip` will assume that it is an *input fileglob string*. The input is the list of files that match the fileglob.

  See *File::GlobMapper* for more details.

If the `$input_filename_or_reference` parameter is any other type, `undef` will be returned.

In addition, if `$input_filename_or_reference` is a simple filename, the default values for the `Name` and `Time` options will be sourced from that file.

If you do not want to use these defaults they can be overridden by explicitly setting the `Name` and `Time` options or by setting the `Minimal` parameter.

The `$output_filename_or_reference` parameter

The parameter `$output_filename_or_reference` is used to control the destination of the compressed data. This parameter can take one of these forms.

- A filename

  If the `$output_filename_or_reference` parameter is a simple scalar, it is assumed to be a filename. This file will be opened for writing and the compressed data will be written to it.

- A filehandle

  If the `$output_filename_or_reference` parameter is a filehandle, the compressed data will be written to it. The string '-' can be used as an alias for standard output.

- A scalar reference

  If `$output_filename_or_reference` is a scalar reference, the compressed data will be stored in `$$output_filename_or_reference`.

- An Array Reference

  If `$output_filename_or_reference` is an array reference, the compressed data will be pushed onto the array.

- An Output FileGlob

  If `$output_filename_or_reference` is a string that is delimited by the characters "<" and ">" `gzip` will assume that it is an *output fileglob string*. The output is the list of files that match the fileglob.

When `$output_filename_or_reference` is an fileglob string, `$input_filename_or_reference` must also be a fileglob string. Anything else is an error.

See *File::GlobMapper* for more details.

If the `$output_filename_or_reference` parameter is any other type, `undef` will be returned.

Notes

When `$input_filename_or_reference` maps to multiple files/buffers and `$output_filename_or_reference` is a single file/buffer the input files/buffers will be stored in `$output_filename_or_reference` as a concatenated series of compressed data streams.

Optional Parameters

The optional parameters for the one-shot function `gzip` are (for the most part) identical to those used with the OO interface defined in the "Constructor Options" section. The exceptions are listed below

- `AutoClose => 0|1`

  This option applies to any input or output data streams to `gzip` that are filehandles.

  If `AutoClose` is specified, and the value is true, it will result in all input and/or output filehandles being closed once `gzip` has completed.

  This parameter defaults to 0.

- `BinModeIn => 0|1`

  This option is now a no-op. All files will be read in binmode.

- `Append => 0|1`

  The behaviour of this option is dependent on the type of output data stream.

  - A Buffer

    If Append is enabled, all compressed data will be append to the end of the output buffer. Otherwise the output buffer will be cleared before any compressed data is written to it.

  - A Filename

    If Append is enabled, the file will be opened in append mode. Otherwise the contents of the file, if any, will be truncated before any compressed data is written to it.

  - A Filehandle

    If Append is enabled, the filehandle will be positioned to the end of the file via a call to `seek` before any compressed data is written to it. Otherwise the file pointer will not be moved.

  When Append is specified, and set to true, it will *append* all compressed data to the output data stream.

So when the output is a filehandle it will carry out a seek to the eof before writing any compressed data. If the output is a filename, it will be opened for appending. If the output is a buffer, all compressed data will be appended to the existing buffer.

Conversely when Append is not specified, or it is present and is set to false, it will operate as follows.

When the output is a filename, it will truncate the contents of the file before writing any compressed data. If the output is a filehandle its position will not be changed. If the output is a buffer, it will be wiped before any compressed data is output.

Defaults to 0.

Oneshot Examples

Here are a few example that show the capabilities of the module.

Streaming

This very simple command line example demonstrates the streaming capabilities of the module. The code reads data from STDIN, compresses it, and writes the compressed data to STDOUT.

```
$ echo hello world | perl -MIO::Compress::Gzip=gzip -e 'gzip \*STDIN
 ↪=> \*STDOUT' >output.gz
```

The special filename "-" can be used as a standin for both `\*STDIN` and `\*STDOUT`, so the above can be rewritten as

```
$ echo hello world | perl -MIO::Compress::Gzip=gzip -e 'gzip "-" =>
 ↪"-"' >output.gz
```

Compressing a file from the filesystem

To read the contents of the file `file1.txt` and write the compressed data to the file `file1.txt.gz`.

```
use strict ;
use warnings ;
use IO::Compress::Gzip qw(gzip $GzipError) ;

my $input = "file1.txt";
gzip $input => "$input.gz"
    or die "gzip failed: $GzipError\n";
```

Reading from a Filehandle and writing to an in-memory buffer

To read from an existing Perl filehandle, `$input`, and write the compressed data to a buffer, `$buffer`.

```
use strict ;
use warnings ;
use IO::Compress::Gzip qw(gzip $GzipError) ;
use IO::File ;

my $input = IO::File->new( "<file1.txt" )
    or die "Cannot open 'file1.txt': $!\n" ;
my $buffer ;
gzip $input => \$buffer
    or die "gzip failed: $GzipError\n";
```

Compressing multiple files

To compress all files in the directory "/my/home" that match "*.txt" and store the compressed data in the same directory

```
use strict ;
use warnings ;
use IO::Compress::Gzip qw(gzip $GzipError) ;

gzip '</my/home/*.txt>' => '<*.gz>'
    or die "gzip failed: $GzipError\n";
```

and if you want to compress each file one at a time, this will do the trick

```
use strict ;
use warnings ;
use IO::Compress::Gzip qw(gzip $GzipError) ;

for my $input ( glob "/my/home/*.txt" )
{
    my $output = "$input.gz" ;
    gzip $input => $output
        or die "Error compressing '$input': $GzipError\n";
}
```

OO Interface

Constructor

The format of the constructor for `IO::Compress::Gzip` is shown below

```
my $z = IO::Compress::Gzip->new( $output [,OPTS] )
    or die "IO::Compress::Gzip failed: $GzipError\n";
```

The constructor takes one mandatory parameter, `$output`, defined below and zero or more `OPTS`, defined in "Constructor Options".

It returns an `IO::Compress::Gzip` object on success and `undef` on failure. The variable `$GzipError` will contain an error message on failure.

If you are running Perl 5.005 or better the object, `$z`, returned from IO::Compress::Gzip can be used exactly like an *IO::File* filehandle. This means that all normal output file operations can be carried out with `$z`. For example, to write to a compressed file/buffer you can use either of these forms

```
$z->print("hello world\n");
print $z "hello world\n";
```

Below is a simple exaple of using the OO interface to create an output file `myfile.gz` and write some data to it.

```
my $filename = "myfile.gz";
my $z = IO::Compress::Gzip->new($filename)
    or die "IO::Compress::Gzip failed: $GzipError\n";

$z->print("abcde");
$z->close();
```

See the "Examples" for more.

The mandatory parameter `$output` is used to control the destination of the compressed data. This parameter can take one of these forms.

- A filename

  If the `$output` parameter is a simple scalar, it is assumed to be a filename. This file will be opened for writing and the compressed data will be written to it.

- A filehandle

  If the `$output` parameter is a filehandle, the compressed data will be written to it. The string '-' can be used as an alias for standard output.

- A scalar reference

  If `$output` is a scalar reference, the compressed data will be stored in `$$output`.

If the `$output` parameter is any other type, `IO::Compress::Gzip`::new will return undef.

Constructor Options

`OPTS` is any combination of zero or more the following options:

- `AutoClose => 0|1`

  This option is only valid when the `$output` parameter is a filehandle. If specified, and the value is true, it will result in the `$output` being closed once either the `close` method is called or the `IO::Compress::Gzip` object is destroyed.

  This parameter defaults to 0.

- `Append => 0|1`

  Opens `$output` in append mode.

  The behaviour of this option is dependent on the type of `$output`.

- A Buffer

  If `$output` is a buffer and Append is enabled, all compressed data will be append to the end of `$output`. Otherwise `$output` will be cleared before any data is written to it.

- A Filename

  If `$output` is a filename and Append is enabled, the file will be opened in append mode. Otherwise the contents of the file, if any, will be truncated before any compressed data is written to it.

- A Filehandle

  If `$output` is a filehandle, the file pointer will be positioned to the end of the file via a call to `seek` before any compressed data is written to it. Otherwise the file pointer will not be moved.

This parameter defaults to 0.

- `Merge => 0|1`

  This option is used to compress input data and append it to an existing compressed data stream in `$output`. The end result is a single compressed data stream stored in `$output`.

  It is a fatal error to attempt to use this option when `$output` is not an RFC 1952 data stream.

  There are a number of other limitations with the `Merge` option:

  1. This module needs to have been built with zlib 1.2.1 or better to work. A fatal error will be thrown if `Merge` is used with an older version of zlib.
  2. If `$output` is a file or a filehandle, it must be seekable.

  This parameter defaults to 0.

- -Level

  Defines the compression level used by zlib. The value should either be a number between 0 and 9 (0 means no compression and 9 is maximum compression), or one of the symbolic constants defined below.

```
Z_NO_COMPRESSION
Z_BEST_SPEED
Z_BEST_COMPRESSION
Z_DEFAULT_COMPRESSION
```

  The default is Z_DEFAULT_COMPRESSION.

  Note, these constants are not imported by `IO::Compress::Gzip` by default.

```
use IO::Compress::Gzip qw(:strategy);
use IO::Compress::Gzip qw(:constants);
use IO::Compress::Gzip qw(:all);
```

- -Strategy

Defines the strategy used to tune the compression. Use one of the symbolic constants defined below.

```
Z_FILTERED
Z_HUFFMAN_ONLY
Z_RLE
Z_FIXED
Z_DEFAULT_STRATEGY
```

The default is Z_DEFAULT_STRATEGY.

- `Minimal => 0|1`

  If specified, this option will force the creation of the smallest possible compliant gzip header (which is exactly 10 bytes long) as defined in RFC 1952.

  See the section titled “Compliance” in RFC 1952 for a definition of the values used for the fields in the gzip header.

  All other parameters that control the content of the gzip header will be ignored if this parameter is set to 1.

  This parameter defaults to 0.

- `Comment => $comment`

  Stores the contents of `$comment` in the COMMENT field in the gzip header. By default, no comment field is written to the gzip file.

  If the `-Strict` option is enabled, the comment can only consist of ISO 8859-1 characters plus line feed.

  If the `-Strict` option is disabled, the comment field can contain any character except NULL. If any null characters are present, the field will be truncated at the first NULL.

- `Name => $string`

  Stores the contents of `$string` in the gzip NAME header field. If `Name` is not specified, no gzip NAME field will be created.

  If the `-Strict` option is enabled, `$string` can only consist of ISO 8859-1 characters.

  If `-Strict` is disabled, then `$string` can contain any character except NULL. If any null characters are present, the field will be truncated at the first NULL.

- `Time => $number`

  Sets the MTIME field in the gzip header to $number.

  This field defaults to the time the `IO::Compress::Gzip` object was created if this option is not specified.

- `TextFlag => 0|1`

  This parameter controls the setting of the FLG.FTEXT bit in the gzip header. It is used to signal that the data stored in the gzip file/buffer is probably text.

  The default is 0.

- `HeaderCRC => 0|1`

  When true this parameter will set the FLG.FHCRC bit to 1 in the gzip header and set the CRC16 header field to the CRC of the complete gzip header except the CRC16 field itself.

  Note that gzip files created with the `HeaderCRC` flag set to 1 cannot be read by most, if not all, of the standard gunzip utilities, most notably gzip version 1.2.4. You should therefore avoid using this option if you want to maximize the portability of your gzip files.

  This parameter defaults to 0.

- `OS_Code => $value`

  Stores `$value` in the gzip OS header field. A number between 0 and 255 is valid.

  If not specified, this parameter defaults to the OS code of the Operating System this module was built on. The value 3 is used as a catch-all for all Unix variants and unknown Operating Systems.

- `ExtraField => $data`

  This parameter allows additional metadata to be stored in the ExtraField in the gzip header. An RFC 1952 compliant ExtraField consists of zero or more subfields. Each subfield consists of a two byte header followed by the subfield data.

  The list of subfields can be supplied in any of the following formats

```
-ExtraField => [$id1, $data1,
                $id2, $data2,
                ...
               ]
-ExtraField => [ [$id1 => $data1],
                 [$id2 => $data2],
                 ...
               ]
-ExtraField => { $id1 => $data1,
                 $id2 => $data2,
                 ...
               }
```

  Where `$id1`, `$id2` are two byte subfield ID's. The second byte of the ID cannot be 0, unless the `Strict` option has been disabled.

  If you use the hash syntax, you have no control over the order in which the Extra-SubFields are stored, plus you cannot have SubFields with duplicate ID.

  Alternatively the list of subfields can by supplied as a scalar, thus

```
-ExtraField => $rawdata
```

  If you use the raw format, and the `Strict` option is enabled, `IO::Compress::Gzip` will check that `$rawdata` consists of zero or more conformant sub-fields. When `Strict` is disabled, `$rawdata` can consist of any arbitrary byte stream.

  The maximum size of the Extra Field 65535 bytes.

- `ExtraFlags => $value`

  Sets the XFL byte in the gzip header to `$value`.

  If this option is not present, the value stored in XFL field will be determined by the setting of the `Level` option.

  If `Level => Z_BEST_SPEED` has been specified then XFL is set to 2. If `Level => Z_BEST_COMPRESSION` has been specified then XFL is set to 4. Otherwise XFL is set to 0.

- `Strict => 0|1`

  `Strict` will optionally police the values supplied with other options to ensure they are compliant with RFC1952.

  This option is enabled by default.

  If `Strict` is enabled the following behaviour will be policed:

  – The value supplied with the `Name` option can only contain ISO 8859-1 characters.

  – The value supplied with the `Comment` option can only contain ISO 8859-1 characters plus line-feed.

  – The values supplied with the `-Name` and `-Comment` options cannot contain multiple embedded nulls.

  – If an `ExtraField` option is specified and it is a simple scalar, it must conform to the sub-field structure as defined in RFC 1952.

  – If an `ExtraField` option is specified the second byte of the ID will be checked in each subfield to ensure that it does not contain the reserved value 0x00.

  When `Strict` is disabled the following behaviour will be policed:

  – The value supplied with `-Name` option can contain any character except NULL.

  – The value supplied with `-Comment` option can contain any character except NULL.

  – The values supplied with the `-Name` and `-Comment` options can contain multiple embedded nulls. The string written to the gzip header will consist of the characters up to, but not including, the first embedded NULL.

  – If an `ExtraField` option is specified and it is a simple scalar, the structure will not be checked. The only error is if the length is too big.

  – The ID header in an `ExtraField` sub-field can consist of any two bytes.

Examples

Streaming

This very simple command line example demonstrates the streaming capabilities of the module. The code reads data from STDIN or all the files given on the commandline, compresses it, and writes the compressed data to STDOUT.

```
use strict ;
use warnings ;
use IO::Compress::Gzip qw(gzip $GzipError) ;

my $z = IO::Compress::Gzip->new("-", Stream => 1)
    or die "IO::Compress::Gzip failed: $GzipError\n";

while (<>) {
    $z->print("abcde");
}
$z->close();
```

Note the use of `"-"` to means STDOUT. Alternatively you can use `\*STDOUT`.

Compressing a file from the filesystem

To read the contents of the file `file1.txt` and write the compressed data to the file `file1.txt.gz` there are a few options

Start by creating the compression object and opening the input file

```
use strict ;
use warnings ;
use IO::Compress::Gzip qw(gzip $GzipError) ;

my $input = "file1.txt";
my $z = IO::Compress::Gzip->new("file1.txt.gz")
    or die "IO::Compress::Gzip failed: $GzipError\n";

# open the input file
open my $fh, "<", "file1.txt"
    or die "Cannot open file1.txt: $!\n";

# loop through the input file & write to the compressed file
while (<$fh>) {
    $z->print($_);
}

# not forgetting to close the compressed file
$z->close();
```

Methods

print

Usage is

```
$z->print($data)
print $z $data
```

Compresses and outputs the contents of the `$data` parameter. This has the same behaviour as the `print` built-in.

Returns true if successful.

printf

Usage is

```
$z->printf($format, $data)
printf $z $format, $data
```

Compresses and outputs the contents of the `$data` parameter.

Returns true if successful.

syswrite

Usage is

```
$z->syswrite $data
$z->syswrite $data, $length
$z->syswrite $data, $length, $offset
```

Compresses and outputs the contents of the `$data` parameter.

Returns the number of uncompressed bytes written, or `undef` if unsuccessful.

write

Usage is

```
$z->write $data
$z->write $data, $length
$z->write $data, $length, $offset
```

Compresses and outputs the contents of the `$data` parameter.

Returns the number of uncompressed bytes written, or `undef` if unsuccessful.

flush

Usage is

```
$z->flush;
$z->flush($flush_type);
```

Flushes any pending compressed data to the output file/buffer.

This method takes an optional parameter, `$flush_type`, that controls how the flushing will be carried out. By default the `$flush_type` used is `Z_FINISH`. Other valid values for `$flush_type` are `Z_NO_FLUSH`, `Z_SYNC_FLUSH`, `Z_FULL_FLUSH` and `Z_BLOCK`. It is

strongly recommended that you only set the `flush_type` parameter if you fully understand the implications of what it does - overuse of `flush` can seriously degrade the level of compression achieved. See the `zlib` documentation for details.

Returns true on success.

tell

Usage is

```
$z->tell()
tell $z
```

Returns the uncompressed file offset.

eof

Usage is

```
$z->eof();
eof($z);
```

Returns true if the `close` method has been called.

seek

```
$z->seek($position, $whence);
seek($z, $position, $whence);
```

Provides a sub-set of the `seek` functionality, with the restriction that it is only legal to seek forward in the output file/buffer. It is a fatal error to attempt to seek backward.

Empty parts of the file/buffer will have NULL (0x00) bytes written to them.

The `$whence` parameter takes one the usual values, namely SEEK_SET, SEEK_CUR or SEEK_END.

Returns 1 on success, 0 on failure.

binmode

Usage is

```
$z->binmode
binmode $z ;
```

This is a noop provided for completeness.

opened

```
$z->opened()
```

Returns true if the object currently refers to a opened file/buffer.

autoflush

```
my $prev = $z->autoflush()
my $prev = $z->autoflush(EXPR)
```

If the `$z` object is associated with a file or a filehandle, this method returns the current autoflush setting for the underlying filehandle. If `EXPR` is present, and is non-zero, it will enable flushing after every write/print operation.

If `$z` is associated with a buffer, this method has no effect and always returns `undef`.

Note that the special variable `$|` **cannot** be used to set or retrieve the autoflush setting.

input_line_number

```
$z->input_line_number()
$z->input_line_number(EXPR)
```

This method always returns `undef` when compressing.

fileno

```
$z->fileno()
fileno($z)
```

If the `$z` object is associated with a file or a filehandle, `fileno` will return the underlying file descriptor. Once the `close` method is called `fileno` will return `undef`.

If the `$z` object is associated with a buffer, this method will return `undef`.

close

```
$z->close() ;
close $z ;
```

Flushes any pending compressed data and then closes the output file/buffer.

For most versions of Perl this method will be automatically invoked if the IO::Compress::Gzip object is destroyed (either explicitly or by the variable with the reference to the object going out of scope). The exceptions are Perl versions 5.005 through 5.00504 and 5.8.0. In these cases, the `close` method will be called automatically, but not until global destruction of all live objects when the program is terminating.

Therefore, if you want your scripts to be able to run on all versions of Perl, you should call `close` explicitly and not rely on automatic closing.

Returns true on success, otherwise 0.

If the `AutoClose` option has been enabled when the IO::Compress::Gzip object was created, and the object is associated with a file, the underlying file will also be closed.

newStream([OPTS])

Usage is

```
$z->newStream( [OPTS] )
```

Closes the current compressed data stream and starts a new one.

OPTS consists of any of the options that are available when creating the `$z` object.

See the "Constructor Options" section for more details.

deflateParams

Usage is

```
$z->deflateParams
```

TODO

Importing

A number of symbolic constants are required by some methods in `IO::Compress::Gzip`. None are imported by default.

- :all

  Imports `gzip`, `$GzipError` and all symbolic constants that can be used by `IO::Compress::Gzip`. Same as doing this

  ```
  use IO::Compress::Gzip qw(gzip $GzipError :constants) ;
  ```

- :constants

  Import all symbolic constants. Same as doing this

  ```
  use IO::Compress::Gzip qw(:flush :level :strategy) ;
  ```

- :flush

  These symbolic constants are used by the `flush` method.

  ```
  Z_NO_FLUSH
  Z_PARTIAL_FLUSH
  Z_SYNC_FLUSH
  Z_FULL_FLUSH
  Z_FINISH
  Z_BLOCK
  ```

- :level

  These symbolic constants are used by the `Level` option in the constructor.

```
Z_NO_COMPRESSION
Z_BEST_SPEED
Z_BEST_COMPRESSION
Z_DEFAULT_COMPRESSION
```

- :strategy

  These symbolic constants are used by the `Strategy` option in the constructor.

```
Z_FILTERED
Z_HUFFMAN_ONLY
Z_RLE
Z_FIXED
Z_DEFAULT_STRATEGY
```

IO::Compress::RawDeflate

Write RFC 1951 files/buffers

SYNOPSIS

```
use IO::Compress::RawDeflate qw(rawdeflate $RawDeflateError) ;

my $status = rawdeflate $input => $output [,OPTS]
    or die "rawdeflate failed: $RawDeflateError\n";

my $z = IO::Compress::RawDeflate->new( $output [,OPTS] )
    or die "rawdeflate failed: $RawDeflateError\n";

$z->print($string);
$z->printf($format, $string);
$z->write($string);
$z->syswrite($string [, $length, $offset]);
$z->flush();
$z->tell();
$z->eof();
$z->seek($position, $whence);
$z->binmode();
$z->fileno();
$z->opened();
$z->autoflush();
$z->input_line_number();
$z->newStream( [OPTS] );

$z->deflateParams();
```

(continues on next page)

(continued from previous page)

```
$z->close() ;

$RawDeflateError ;

# IO::File mode

print $z $string;
printf $z $format, $string;
tell $z
eof $z
seek $z, $position, $whence
binmode $z
fileno $z
close $z ;
```

DESCRIPTION

This module provides a Perl interface that allows writing compressed data to files or buffer as defined in RFC 1951.

Note that RFC 1951 data is not a good choice of compression format to use in isolation, especially if you want to auto-detect it.

For reading RFC 1951 files/buffers, see the companion module *IO::Uncompress::RawInflate*.

Functional Interface

A top-level function, `rawdeflate`, is provided to carry out "one-shot" compression between buffers and/or files. For finer control over the compression process, see the "OO Interface" section.

```
use IO::Compress::RawDeflate qw(rawdeflate $RawDeflateError) ;

rawdeflate $input_filename_or_reference => $output_filename_or_
 ↪reference [,OPTS]
    or die "rawdeflate failed: $RawDeflateError\n";
```

The functional interface needs Perl5.005 or better.

rawdeflate $input_filename_or_reference => $output_filename_or_reference [, OPTS]

`rawdeflate` expects at least two parameters, `$input_filename_or_reference` and `$output_filename_or_reference` and zero or more optional parameters (see "Optional Parameters")

The `$input_filename_or_reference` parameter

The parameter, `$input_filename_or_reference`, is used to define the source of the uncompressed data.

It can take one of the following forms:

- A filename

  If the `$input_filename_or_reference` parameter is a simple scalar, it is assumed to be a filename. This file will be opened for reading and the input data will be read from it.

- A filehandle

  If the `$input_filename_or_reference` parameter is a filehandle, the input data will be read from it. The string '-' can be used as an alias for standard input.

- A scalar reference

  If `$input_filename_or_reference` is a scalar reference, the input data will be read from `$$input_filename_or_reference`.

- An array reference

  If `$input_filename_or_reference` is an array reference, each element in the array must be a filename.

  The input data will be read from each file in turn.

  The complete array will be walked to ensure that it only contains valid filenames before any data is compressed.

- An Input FileGlob string

  If `$input_filename_or_reference` is a string that is delimited by the characters "<" and ">" `rawdeflate` will assume that it is an *input fileglob string*. The input is the list of files that match the fileglob.

  See *File::GlobMapper* for more details.

If the `$input_filename_or_reference` parameter is any other type, `undef` will be returned.

The `$output_filename_or_reference` parameter

The parameter `$output_filename_or_reference` is used to control the destination of the compressed data. This parameter can take one of these forms.

- A filename

  If the `$output_filename_or_reference` parameter is a simple scalar, it is assumed to be a filename. This file will be opened for writing and the compressed data will be written to it.

- A filehandle

  If the `$output_filename_or_reference` parameter is a filehandle, the compressed data will be written to it. The string '-' can be used as an alias for standard output.

- A scalar reference

  If `$output_filename_or_reference` is a scalar reference, the compressed data will be stored in `$$output_filename_or_reference`.

- An Array Reference

  If `$output_filename_or_reference` is an array reference, the compressed data will be pushed onto the array.

- An Output FileGlob

  If `$output_filename_or_reference` is a string that is delimited by the characters "<" and ">" `rawdeflate` will assume that it is an *output fileglob string*. The output is the list of files that match the fileglob.

  When `$output_filename_or_reference` is an fileglob string, `$input_filename_or_reference` must also be a fileglob string. Anything else is an error.

  See *File::GlobMapper* for more details.

If the `$output_filename_or_reference` parameter is any other type, `undef` will be returned.

Notes

When `$input_filename_or_reference` maps to multiple files/buffers and `$output_filename_or_reference` is a single file/buffer the input files/buffers will be stored in `$output_filename_or_reference` as a concatenated series of compressed data streams.

Optional Parameters

The optional parameters for the one-shot function `rawdeflate` are (for the most part) identical to those used with the OO interface defined in the "Constructor Options" section. The exceptions are listed below

- `AutoClose => 0|1`

  This option applies to any input or output data streams to `rawdeflate` that are filehandles.

  If `AutoClose` is specified, and the value is true, it will result in all input and/or output filehandles being closed once `rawdeflate` has completed.

  This parameter defaults to 0.

- `BinModeIn => 0|1`

  This option is now a no-op. All files will be read in binmode.

- `Append => 0|1`

  The behaviour of this option is dependent on the type of output data stream.

  - A Buffer

    If Append is enabled, all compressed data will be append to the end of the output buffer. Otherwise the output buffer will be cleared before any compressed data is written to it.

- A Filename

  If Append is enabled, the file will be opened in append mode. Otherwise the contents of the file, if any, will be truncated before any compressed data is written to it.

- A Filehandle

  If Append is enabled, the filehandle will be positioned to the end of the file via a call to `seek` before any compressed data is written to it. Otherwise the file pointer will not be moved.

When Append is specified, and set to true, it will *append* all compressed data to the output data stream.

So when the output is a filehandle it will carry out a seek to the eof before writing any compressed data. If the output is a filename, it will be opened for appending. If the output is a buffer, all compressed data will be appended to the existing buffer.

Conversely when Append is not specified, or it is present and is set to false, it will operate as follows.

When the output is a filename, it will truncate the contents of the file before writing any compressed data. If the output is a filehandle its position will not be changed. If the output is a buffer, it will be wiped before any compressed data is output.

Defaults to 0.

Oneshot Examples

Here are a few example that show the capabilities of the module.

Streaming

This very simple command line example demonstrates the streaming capabilities of the module. The code reads data from STDIN, compresses it, and writes the compressed data to STDOUT.

```
$ echo hello world | perl -MIO::Compress::RawDeflate=rawdeflate -e
↪'rawdeflate \*STDIN => \*STDOUT' >output.1951
```

The special filename "-" can be used as a standin for both `\*STDIN` and `\*STDOUT`, so the above can be rewritten as

```
$ echo hello world | perl -MIO::Compress::RawDeflate=rawdeflate -e
↪'rawdeflate "-" => "-"' >output.1951
```

Compressing a file from the filesystem

To read the contents of the file `file1.txt` and write the compressed data to the file `file1.txt.1951`.

```
use strict ;
use warnings ;
```

(continues on next page)

(continued from previous page)

```
use IO::Compress::RawDeflate qw(rawdeflate $RawDeflateError) ;

my $input = "file1.txt";
rawdeflate $input => "$input.1951"
    or die "rawdeflate failed: $RawDeflateError\n";
```

Reading from a Filehandle and writing to an in-memory buffer

To read from an existing Perl filehandle, `$input`, and write the compressed data to a buffer, `$buffer`.

```
use strict ;
use warnings ;
use IO::Compress::RawDeflate qw(rawdeflate $RawDeflateError) ;
use IO::File ;

my $input = IO::File->new( "<file1.txt" )
    or die "Cannot open 'file1.txt': $!\n" ;
my $buffer ;
rawdeflate $input => \$buffer
    or die "rawdeflate failed: $RawDeflateError\n";
```

Compressing multiple files

To compress all files in the directory “/my/home” that match “*.txt” and store the compressed data in the same directory

```
use strict ;
use warnings ;
use IO::Compress::RawDeflate qw(rawdeflate $RawDeflateError) ;

rawdeflate '</my/home/*.txt>' => '<*.1951>'
    or die "rawdeflate failed: $RawDeflateError\n";
```

and if you want to compress each file one at a time, this will do the trick

```
use strict ;
use warnings ;
use IO::Compress::RawDeflate qw(rawdeflate $RawDeflateError) ;

for my $input ( glob "/my/home/*.txt" )
{
    my $output = "$input.1951" ;
    rawdeflate $input => $output
        or die "Error compressing '$input': $RawDeflateError\n";
}
```

OO Interface

Constructor

The format of the constructor for `IO::Compress::RawDeflate` is shown below

```
my $z = IO::Compress::RawDeflate->new( $output [,OPTS] )
    or die "IO::Compress::RawDeflate failed: $RawDeflateError\n";
```

The constructor takes one mandatory parameter, `$output`, defined below and zero or more `OPTS`, defined in "Constructor Options".

It returns an `IO::Compress::RawDeflate` object on success and `undef` on failure. The variable `$RawDeflateError` will contain an error message on failure.

If you are running Perl 5.005 or better the object, `$z`, returned from IO::Compress::RawDeflate can be used exactly like an *IO::File* filehandle. This means that all normal output file operations can be carried out with `$z`. For example, to write to a compressed file/buffer you can use either of these forms

```
$z->print("hello world\n");
print $z "hello world\n";
```

Below is a simple exaple of using the OO interface to create an output file `myfile.1951` and write some data to it.

```
my $filename = "myfile.1951";
my $z = IO::Compress::RawDeflate->new($filename)
    or die "IO::Compress::RawDeflate failed: $RawDeflateError\n";

$z->print("abcde");
$z->close();
```

See the "Examples" for more.

The mandatory parameter `$output` is used to control the destination of the compressed data. This parameter can take one of these forms.

- A filename

  If the `$output` parameter is a simple scalar, it is assumed to be a filename. This file will be opened for writing and the compressed data will be written to it.

- A filehandle

  If the `$output` parameter is a filehandle, the compressed data will be written to it. The string '-' can be used as an alias for standard output.

- A scalar reference

  If `$output` is a scalar reference, the compressed data will be stored in `$$output`.

If the `$output` parameter is any other type, `IO::Compress::RawDeflate`::new will return undef.

Constructor Options

`OPTS` is any combination of zero or more the following options:

- `AutoClose => 0|1`

  This option is only valid when the `$output` parameter is a filehandle. If specified, and the value is true, it will result in the `$output` being closed once either the `close` method is called or the `IO::Compress::RawDeflate` object is destroyed.

  This parameter defaults to 0.

- `Append => 0|1`

  Opens `$output` in append mode.

  The behaviour of this option is dependent on the type of `$output`.

  - A Buffer

    If `$output` is a buffer and Append is enabled, all compressed data will be append to the end of `$output`. Otherwise `$output` will be cleared before any data is written to it.

  - A Filename

    If `$output` is a filename and Append is enabled, the file will be opened in append mode. Otherwise the contents of the file, if any, will be truncated before any compressed data is written to it.

  - A Filehandle

    If `$output` is a filehandle, the file pointer will be positioned to the end of the file via a call to `seek` before any compressed data is written to it. Otherwise the file pointer will not be moved.

  This parameter defaults to 0.

- `Merge => 0|1`

  This option is used to compress input data and append it to an existing compressed data stream in `$output`. The end result is a single compressed data stream stored in `$output`.

  It is a fatal error to attempt to use this option when `$output` is not an RFC 1951 data stream.

  There are a number of other limitations with the `Merge` option:

  1. This module needs to have been built with zlib 1.2.1 or better to work. A fatal error will be thrown if `Merge` is used with an older version of zlib.

  2. If `$output` is a file or a filehandle, it must be seekable.

  This parameter defaults to 0.

- -Level

  Defines the compression level used by zlib. The value should either be a number between 0 and 9 (0 means no compression and 9 is maximum compression), or one of the symbolic constants defined below.

```
Z_NO_COMPRESSION
Z_BEST_SPEED
Z_BEST_COMPRESSION
Z_DEFAULT_COMPRESSION
```

The default is Z_DEFAULT_COMPRESSION.

Note, these constants are not imported by `IO::Compress::RawDeflate` by default.

```
use IO::Compress::RawDeflate qw(:strategy);
use IO::Compress::RawDeflate qw(:constants);
use IO::Compress::RawDeflate qw(:all);
```

- -Strategy

  Defines the strategy used to tune the compression. Use one of the symbolic constants defined below.

  ```
  Z_FILTERED
  Z_HUFFMAN_ONLY
  Z_RLE
  Z_FIXED
  Z_DEFAULT_STRATEGY
  ```

  The default is Z_DEFAULT_STRATEGY.

- `Strict => 0|1`

  This is a placeholder option.

Examples

Streaming

This very simple command line example demonstrates the streaming capabilities of the module. The code reads data from STDIN or all the files given on the commandline, compresses it, and writes the compressed data to STDOUT.

```
use strict ;
use warnings ;
use IO::Compress::RawDeflate qw(rawdeflate $RawDeflateError) ;

my $z = IO::Compress::RawDeflate->new("-", Stream => 1)
    or die "IO::Compress::RawDeflate failed: $RawDeflateError\n";

while (<>) {
    $z->print("abcde");
}
$z->close();
```

Note the use of `"-"` to means STDOUT. Alternatively you can use `\*STDOUT`.

Compressing a file from the filesystem

To read the contents of the file `file1.txt` and write the compressed data to the file `file1.txt.1951` there are a few options

Start by creating the compression object and opening the input file

```
use strict ;
use warnings ;
use IO::Compress::RawDeflate qw(rawdeflate $RawDeflateError) ;

my $input = "file1.txt";
my $z = IO::Compress::RawDeflate->new("file1.txt.1951")
    or die "IO::Compress::RawDeflate failed: $RawDeflateError\n";

# open the input file
open my $fh, "<", "file1.txt"
    or die "Cannot open file1.txt: $!\n";

# loop through the input file & write to the compressed file
while (<$fh>) {
    $z->print($_);
}

# not forgetting to close the compressed file
$z->close();
```

Methods

print

Usage is

```
$z->print($data)
print $z $data
```

Compresses and outputs the contents of the `$data` parameter. This has the same behaviour as the `print` built-in.

Returns true if successful.

printf

Usage is

```
$z->printf($format, $data)
printf $z $format, $data
```

Compresses and outputs the contents of the `$data` parameter.

Returns true if successful.

syswrite

Usage is

```
$z->syswrite $data
$z->syswrite $data, $length
$z->syswrite $data, $length, $offset
```

Compresses and outputs the contents of the `$data` parameter.

Returns the number of uncompressed bytes written, or `undef` if unsuccessful.

write

Usage is

```
$z->write $data
$z->write $data, $length
$z->write $data, $length, $offset
```

Compresses and outputs the contents of the `$data` parameter.

Returns the number of uncompressed bytes written, or `undef` if unsuccessful.

flush

Usage is

```
$z->flush;
$z->flush($flush_type);
```

Flushes any pending compressed data to the output file/buffer.

This method takes an optional parameter, `$flush_type`, that controls how the flushing will be carried out. By default the `$flush_type` used is `Z_FINISH`. Other valid values for `$flush_type` are `Z_NO_FLUSH`, `Z_SYNC_FLUSH`, `Z_FULL_FLUSH` and `Z_BLOCK`. It is strongly recommended that you only set the `flush_type` parameter if you fully understand the implications of what it does - overuse of `flush` can seriously degrade the level of compression achieved. See the `zlib` documentation for details.

Returns true on success.

tell

Usage is

```
$z->tell()
tell $z
```

Returns the uncompressed file offset.

eof

Usage is

```
$z->eof();
eof($z);
```

Returns true if the `close` method has been called.

seek

```
$z->seek($position, $whence);
seek($z, $position, $whence);
```

Provides a sub-set of the `seek` functionality, with the restriction that it is only legal to seek forward in the output file/buffer. It is a fatal error to attempt to seek backward.

Empty parts of the file/buffer will have NULL (0x00) bytes written to them.

The `$whence` parameter takes one the usual values, namely SEEK_SET, SEEK_CUR or SEEK_END.

Returns 1 on success, 0 on failure.

binmode

Usage is

```
$z->binmode
binmode $z ;
```

This is a noop provided for completeness.

opened

```
$z->opened()
```

Returns true if the object currently refers to a opened file/buffer.

autoflush

```
my $prev = $z->autoflush()
my $prev = $z->autoflush(EXPR)
```

If the `$z` object is associated with a file or a filehandle, this method returns the current autoflush setting for the underlying filehandle. If `EXPR` is present, and is non-zero, it will enable flushing after every write/print operation.

If `$z` is associated with a buffer, this method has no effect and always returns `undef`.

Note that the special variable `$|` **cannot** be used to set or retrieve the autoflush setting.

input_line_number

```
$z->input_line_number()
$z->input_line_number(EXPR)
```

This method always returns undef when compressing.

fileno

```
$z->fileno()
fileno($z)
```

If the $z object is associated with a file or a filehandle, fileno will return the underlying file descriptor. Once the close method is called fileno will return undef.

If the $z object is associated with a buffer, this method will return undef.

close

```
$z->close() ;
close $z ;
```

Flushes any pending compressed data and then closes the output file/buffer.

For most versions of Perl this method will be automatically invoked if the IO::Compress::RawDeflate object is destroyed (either explicitly or by the variable with the reference to the object going out of scope). The exceptions are Perl versions 5.005 through 5.00504 and 5.8.0. In these cases, the close method will be called automatically, but not until global destruction of all live objects when the program is terminating.

Therefore, if you want your scripts to be able to run on all versions of Perl, you should call close explicitly and not rely on automatic closing.

Returns true on success, otherwise 0.

If the AutoClose option has been enabled when the IO::Compress::RawDeflate object was created, and the object is associated with a file, the underlying file will also be closed.

newStream([OPTS])

Usage is

```
$z->newStream( [OPTS] )
```

Closes the current compressed data stream and starts a new one.

OPTS consists of any of the options that are available when creating the $z object.

See the “Constructor Options” section for more details.

deflateParams

Usage is

```
$z->deflateParams
```

TODO

Importing

A number of symbolic constants are required by some methods in `IO::Compress::RawDeflate`. None are imported by default.

- :all

  Imports `rawdeflate`, `$RawDeflateError` and all symbolic constants that can be used by `IO::Compress::RawDeflate`. Same as doing this

  ```
  use IO::Compress::RawDeflate qw(rawdeflate $RawDeflateError␣
  ↪:constants) ;
  ```

- :constants

  Import all symbolic constants. Same as doing this

  ```
  use IO::Compress::RawDeflate qw(:flush :level :strategy) ;
  ```

- :flush

  These symbolic constants are used by the `flush` method.

  ```
  Z_NO_FLUSH
  Z_PARTIAL_FLUSH
  Z_SYNC_FLUSH
  Z_FULL_FLUSH
  Z_FINISH
  Z_BLOCK
  ```

- :level

  These symbolic constants are used by the `Level` option in the constructor.

  ```
  Z_NO_COMPRESSION
  Z_BEST_SPEED
  Z_BEST_COMPRESSION
  Z_DEFAULT_COMPRESSION
  ```

- :strategy

  These symbolic constants are used by the `Strategy` option in the constructor.

  ```
  Z_FILTERED
  Z_HUFFMAN_ONLY
  Z_RLE
  ```

(continues on next page)

(continued from previous page)

```
Z_FIXED
Z_DEFAULT_STRATEGY
```

IO::Compress::Zip

Write zip files/buffers

SYNOPSIS

```
use IO::Compress::Zip qw(zip $ZipError) ;

my $status = zip $input => $output [,OPTS]
    or die "zip failed: $ZipError\n";

my $z = IO::Compress::Zip->new( $output [,OPTS] )
    or die "zip failed: $ZipError\n";

$z->print($string);
$z->printf($format, $string);
$z->write($string);
$z->syswrite($string [, $length, $offset]);
$z->flush();
$z->tell();
$z->eof();
$z->seek($position, $whence);
$z->binmode();
$z->fileno();
$z->opened();
$z->autoflush();
$z->input_line_number();
$z->newStream( [OPTS] );

$z->deflateParams();

$z->close() ;

$ZipError ;

# IO::File mode

print $z $string;
printf $z $format, $string;
```

(continues on next page)

(continued from previous page)

```
tell $z
eof $z
seek $z, $position, $whence
binmode $z
fileno $z
close $z ;
```

DESCRIPTION

This module provides a Perl interface that allows writing zip compressed data to files or buffer.

The primary purpose of this module is to provide streaming write access to zip files and buffers.

At present the following compression methods are supported by IO::Compress::Zip

- Store (0)
- Deflate (8)
- Bzip2 (12)

  To write Bzip2 content, the module `IO::Uncompress::Bunzip2` must be installed.
- Lzma (14)

  To write LZMA content, the module `IO::Uncompress::UnLzma` must be installed.
- Zstandard (93)

  To write Zstandard content, the module `IO::Compress::Zstd` must be installed.
- Xz (95)

  To write Xz content, the module `IO::Uncompress::UnXz` must be installed.

For reading zip files/buffers, see the companion module *IO::Uncompress::Unzip*.

Functional Interface

A top-level function, `zip`, is provided to carry out "one-shot" compression between buffers and/or files. For finer control over the compression process, see the "OO Interface" section.

```
use IO::Compress::Zip qw(zip $ZipError) ;

zip $input_filename_or_reference => $output_filename_or_reference [,
↪OPTS]
    or die "zip failed: $ZipError\n";
```

The functional interface needs Perl5.005 or better.

zip $input_filename_or_reference => $output_filename_or_reference [, OPTS]

`zip` expects at least two parameters, `$input_filename_or_reference` and `$output_filename_or_reference` and zero or more optional parameters (see "Optional Parameters")

The `$input_filename_or_reference` parameter

The parameter, `$input_filename_or_reference`, is used to define the source of the uncompressed data.

It can take one of the following forms:

- A filename

  If the `$input_filename_or_reference` parameter is a simple scalar, it is assumed to be a filename. This file will be opened for reading and the input data will be read from it.

- A filehandle

  If the `$input_filename_or_reference` parameter is a filehandle, the input data will be read from it. The string '-' can be used as an alias for standard input.

- A scalar reference

  If `$input_filename_or_reference` is a scalar reference, the input data will be read from `$$input_filename_or_reference`.

- An array reference

  If `$input_filename_or_reference` is an array reference, each element in the array must be a filename.

  The input data will be read from each file in turn.

  The complete array will be walked to ensure that it only contains valid filenames before any data is compressed.

- An Input FileGlob string

  If `$input_filename_or_reference` is a string that is delimited by the characters "<" and ">" `zip` will assume that it is an *input fileglob string*. The input is the list of files that match the fileglob.

  See *File::GlobMapper* for more details.

If the `$input_filename_or_reference` parameter is any other type, `undef` will be returned.

In addition, if `$input_filename_or_reference` corresponds to a filename from the filesystem, a number of zip file header fields will be populated by default using the following attributes from the input file

- the full filename contained in `$input_filename_or_reference`
- the file protection attributes
- the UID/GID for the file
- the file timestamps

If you do not want to use these defaults they can be overridden by explicitly setting one, or more, of the `Name`, `Time`, `TextFlag`, `ExtAttr`, `exUnixN` and `exTime` options or by setting the `Minimal` parameter.

The `$output_filename_or_reference` parameter

The parameter `$output_filename_or_reference` is used to control the destination of the compressed data. This parameter can take one of these forms.

- A filename

  If the `$output_filename_or_reference` parameter is a simple scalar, it is assumed to be a filename. This file will be opened for writing and the compressed data will be written to it.

- A filehandle

  If the `$output_filename_or_reference` parameter is a filehandle, the compressed data will be written to it. The string '-' can be used as an alias for standard output.

- A scalar reference

  If `$output_filename_or_reference` is a scalar reference, the compressed data will be stored in `$$output_filename_or_reference`.

- An Array Reference

  If `$output_filename_or_reference` is an array reference, the compressed data will be pushed onto the array.

- An Output FileGlob

  If `$output_filename_or_reference` is a string that is delimited by the characters "<" and ">" `zip` will assume that it is an *output fileglob string*. The output is the list of files that match the fileglob.

  When `$output_filename_or_reference` is an fileglob string, `$input_filename_or_reference` must also be a fileglob string. Anything else is an error.

  See *File::GlobMapper* for more details.

If the `$output_filename_or_reference` parameter is any other type, `undef` will be returned.

Notes

When `$input_filename_or_reference` maps to multiple files/buffers and `$output_filename_or_reference` is a single file/buffer the input files/buffers will each be stored in `$output_filename_or_reference` as a distinct entry.

Optional Parameters

The optional parameters for the one-shot function `zip` are (for the most part) identical to those used with the OO interface defined in the "Constructor Options" section. The exceptions are listed below

- `AutoClose => 0|1`

  This option applies to any input or output data streams to `zip` that are filehandles.

  If `AutoClose` is specified, and the value is true, it will result in all input and/or output filehandles being closed once `zip` has completed.

  This parameter defaults to 0.

- `BinModeIn => 0|1`

  This option is now a no-op. All files will be read in binmode.

- `Append => 0|1`

  The behaviour of this option is dependent on the type of output data stream.

  - A Buffer

    If Append is enabled, all compressed data will be append to the end of the output buffer. Otherwise the output buffer will be cleared before any compressed data is written to it.

  - A Filename

    If Append is enabled, the file will be opened in append mode. Otherwise the contents of the file, if any, will be truncated before any compressed data is written to it.

  - A Filehandle

    If Append is enabled, the filehandle will be positioned to the end of the file via a call to `seek` before any compressed data is written to it. Otherwise the file pointer will not be moved.

  When Append is specified, and set to true, it will *append* all compressed data to the output data stream.

  So when the output is a filehandle it will carry out a seek to the eof before writing any compressed data. If the output is a filename, it will be opened for appending. If the output is a buffer, all compressed data will be appended to the existing buffer.

  Conversely when Append is not specified, or it is present and is set to false, it will operate as follows.

  When the output is a filename, it will truncate the contents of the file before writing any compressed data. If the output is a filehandle its position will not be changed. If the output is a buffer, it will be wiped before any compressed data is output.

  Defaults to 0.

Oneshot Examples

Here are a few example that show the capabilities of the module.

Streaming

This very simple command line example demonstrates the streaming capabilities of the module. The code reads data from STDIN, compresses it, and writes the compressed data to STDOUT.

```
$ echo hello world | perl -MIO::Compress::Zip=zip -e 'zip \*STDIN =>␣
↪\*STDOUT' >output.zip
```

The special filename "-" can be used as a standin for both `\*STDIN` and `\*STDOUT`, so the above can be rewritten as

```
$ echo hello world | perl -MIO::Compress::Zip=zip -e 'zip "-" => "-"
↪' >output.zip
```

One problem with creating a zip archive directly from STDIN can be demonstrated by looking at the contents of the zip file, output.zip, that we have just created.

```
$ unzip -l output.zip
Archive:  output.zip
Length      Date    Time    Name
---------  ---------- -----   ----
    12  2019-08-16 22:21
---------                     -------
    12                     1 file
```

The archive member (filename) used is the empty string.

If that doesn't suit your needs, you can explicitly set the filename used in the zip archive by specifying the Name option, like so

```
echo hello world | perl -MIO::Compress::Zip=zip -e 'zip "-" => "-",␣
↪Name => "hello.txt"' >output.zip
```

Now the contents of the zip file looks like this

```
$ unzip -l output.zip
Archive:  output.zip
Length      Date    Time    Name
---------  ---------- -----   ----
    12  2019-08-16 22:22   hello.txt
---------                     -------
    12                     1 file
```

Compressing a file from the filesystem

To read the contents of the file `file1.txt` and write the compressed data to the file `file1.txt.zip`.

```
use strict ;
use warnings ;
use IO::Compress::Zip qw(zip $ZipError) ;
```

(continues on next page)

(continued from previous page)

```
my $input = "file1.txt";
zip $input => "$input.zip"
    or die "zip failed: $ZipError\n";
```

Reading from a Filehandle and writing to an in-memory buffer

To read from an existing Perl filehandle, `$input`, and write the compressed data to a buffer, `$buffer`.

```
use strict ;
use warnings ;
use IO::Compress::Zip qw(zip $ZipError) ;
use IO::File ;

my $input = IO::File->new( "<file1.txt" )
    or die "Cannot open 'file1.txt': $!\n" ;
my $buffer ;
zip $input => \$buffer
    or die "zip failed: $ZipError\n";
```

Compressing multiple files

To create a zip file, `output.zip`, that contains the compressed contents of the files `alpha.txt` and `beta.txt`

```
use strict ;
use warnings ;
use IO::Compress::Zip qw(zip $ZipError) ;

zip [ 'alpha.txt', 'beta.txt' ] => 'output.zip'
    or die "zip failed: $ZipError\n";
```

Alternatively, rather than having to explicitly name each of the files that you want to compress, you could use a fileglob to select all the `txt` files in the current directory, as follows

```
use strict ;
use warnings ;
use IO::Compress::Zip qw(zip $ZipError) ;

my @files = <*.txt>;
zip \@files => 'output.zip'
    or die "zip failed: $ZipError\n";
```

or more succinctly

```
zip [ <*.txt> ] => 'output.zip'
    or die "zip failed: $ZipError\n";
```

OO Interface

Constructor

The format of the constructor for `IO::Compress::Zip` is shown below

```
my $z = IO::Compress::Zip->new( $output [,OPTS] )
    or die "IO::Compress::Zip failed: $ZipError\n";
```

The constructor takes one mandatory parameter, `$output`, defined below and zero or more `OPTS`, defined in "Constructor Options".

It returns an `IO::Compress::Zip` object on success and `undef` on failure. The variable `$ZipError` will contain an error message on failure.

If you are running Perl 5.005 or better the object, `$z`, returned from IO::Compress::Zip can be used exactly like an *IO::File* filehandle. This means that all normal output file operations can be carried out with `$z`. For example, to write to a compressed file/buffer you can use either of these forms

```
$z->print("hello world\n");
print $z "hello world\n";
```

Below is a simple exaple of using the OO interface to create an output file `myfile.zip` and write some data to it.

```
my $filename = "myfile.zip";
my $z = IO::Compress::Zip->new($filename)
    or die "IO::Compress::Zip failed: $ZipError\n";

$z->print("abcde");
$z->close();
```

See the "Examples" for more.

The mandatory parameter `$output` is used to control the destination of the compressed data. This parameter can take one of these forms.

- A filename

  If the `$output` parameter is a simple scalar, it is assumed to be a filename. This file will be opened for writing and the compressed data will be written to it.

- A filehandle

  If the `$output` parameter is a filehandle, the compressed data will be written to it. The string '-' can be used as an alias for standard output.

- A scalar reference

  If `$output` is a scalar reference, the compressed data will be stored in `$$output`.

If the `$output` parameter is any other type, `IO::Compress::Zip`::new will return undef.

Constructor Options

`OPTS` is any combination of zero or more the following options:

- `AutoClose => 0|1`

  This option is only valid when the `$output` parameter is a filehandle. If specified, and the value is true, it will result in the `$output` being closed once either the `close` method is called or the `IO::Compress::Zip` object is destroyed.

  This parameter defaults to 0.

- `Append => 0|1`

  Opens `$output` in append mode.

  The behaviour of this option is dependent on the type of `$output`.

  - A Buffer

    If `$output` is a buffer and Append is enabled, all compressed data will be append to the end of `$output`. Otherwise `$output` will be cleared before any data is written to it.

  - A Filename

    If `$output` is a filename and Append is enabled, the file will be opened in append mode. Otherwise the contents of the file, if any, will be truncated before any compressed data is written to it.

  - A Filehandle

    If `$output` is a filehandle, the file pointer will be positioned to the end of the file via a call to `seek` before any compressed data is written to it. Otherwise the file pointer will not be moved.

  This parameter defaults to 0.

File Naming Options

A quick bit of zip file terminology – A zip archive consists of one or more *archive members*, where each member has an associated filename, known as the *archive member name*.

The options listed in this section control how the *archive member name* (or filename) is stored the zip archive.

- `Name => $string`

  This option is used to explicitly set the *archive member name* in the zip archive to `$string`. Most of the time you don't need to make use of this option. By default when adding a filename to the zip archive, the *archive member name* will match the filename.

  You should only need to use this option if you want the *archive member name* to be different from the uncompressed filename or when the input is a filehandle or a buffer.

  The default behaviour for what *archive member name* is used when the `Name` option is *not* specified depends on the form of the `$input` parameter:

- If the `$input` parameter is a filename, the value of `$input` will be used for the *archive member name* .
- If the `$input` parameter is not a filename, the *archive member name* will be an empty string.

Note that both the `CanonicalName` and `FilterName` options can modify the value used for the *archive member name*.

Also note that you should set the `Efs` option to true if you are working with UTF8 filenames.

- `CanonicalName => 0|1`

  This option controls whether the *archive member name* is *normalized* into Unix format before being written to the zip file.

  It is recommended that you enable this option unless you really need to create a non-standard Zip file.

  This is what APPNOTE.TXT has to say on what should be stored in the zip filename header field.

```
The name of the file, with optional relative path.
The path stored should not contain a drive or
device letter, or a leading slash.  All slashes
should be forward slashes '/' as opposed to
backwards slashes '\' for compatibility with Amiga
and UNIX file systems etc.
```

  This option defaults to **false**.

- `FilterName => sub { ... }`

  This option allow the *archive member* name to be modified before it is written to the zip file.

  This option takes a parameter that must be a reference to a sub. On entry to the sub the `$_` variable will contain the name to be filtered. If no filename is available `$_` will contain an empty string.

  The value of `$_` when the sub returns will be used as the *archive member name*.

  Note that if `CanonicalName` is enabled, a normalized filename will be passed to the sub.

  If you use `FilterName` to modify the filename, it is your responsibility to keep the filename in Unix format.

  Although this option can be used with the OO interface, it is of most use with the one-shot interface. For example, the code below shows how `FilterName` can be used to remove the path component from a series of filenames before they are stored in `$zipfile`.

```
sub compressTxtFiles
{
    my $zipfile = shift ;
    my $dir     = shift ;
```

(continues on next page)

(continued from previous page)

```
    zip [ <$dir/*.txt> ] => $zipfile,
        FilterName => sub { s[^$dir/][] } ;
}
```

- `Efs => 0|1`

  This option controls setting of the "Language Encoding Flag" (EFS) in the zip archive. When set, the filename and comment fields for the zip archive MUST be valid UTF-8.

  If the string used for the filename and/or comment is not valid UTF-8 when this option is true, the script will die with a "wide character" error.

  Note that this option only works with Perl 5.8.4 or better.

  This option defaults to **false**.

Overall Zip Archive Structure

- `Minimal => 1|0`

  If specified, this option will disable the creation of all extra fields in the zip local and central headers. So the `exTime`, `exUnix2`, `exUnixN`, `ExtraFieldLocal` and `ExtraFieldCentral` options will be ignored.

  This parameter defaults to 0.

- `Stream => 0|1`

  This option controls whether the zip file/buffer output is created in streaming mode.

  Note that when outputting to a file with streaming mode disabled (`Stream` is 0), the output file must be seekable.

  The default is 1.

- `Zip64 => 0|1`

  Create a Zip64 zip file/buffer. This option is used if you want to store files larger than 4 Gig or store more than 64K files in a single zip archive.

  `Zip64` will be automatically set, as needed, if working with the one-shot interface when the input is either a filename or a scalar reference.

  If you intend to manipulate the Zip64 zip files created with this module using an external zip/unzip, make sure that it supports Zip64.

  In particular, if you are using Info-Zip you need to have zip version 3.x or better to update a Zip64 archive and unzip version 6.x to read a zip64 archive.

  The default is 0.

Deflate Compression Options

- -Level

  Defines the compression level used by zlib. The value should either be a number between 0 and 9 (0 means no compression and 9 is maximum compression), or one of the symbolic constants defined below.

```
Z_NO_COMPRESSION
Z_BEST_SPEED
Z_BEST_COMPRESSION
Z_DEFAULT_COMPRESSION
```

  The default is Z_DEFAULT_COMPRESSION.

  Note, these constants are not imported by `IO::Compress::Zip` by default.

```
use IO::Compress::Zip qw(:strategy);
use IO::Compress::Zip qw(:constants);
use IO::Compress::Zip qw(:all);
```

- -Strategy

  Defines the strategy used to tune the compression. Use one of the symbolic constants defined below.

```
Z_FILTERED
Z_HUFFMAN_ONLY
Z_RLE
Z_FIXED
Z_DEFAULT_STRATEGY
```

  The default is Z_DEFAULT_STRATEGY.

Bzip2 Compression Options

- `BlockSize100K => number`

  Specify the number of 100K blocks bzip2 uses during compression.

  Valid values are from 1 to 9, where 9 is best compression.

  This option is only valid if the `Method` is ZIP_CM_BZIP2. It is ignored otherwise.

  The default is 1.

- `WorkFactor => number`

  Specifies how much effort bzip2 should take before resorting to a slower fallback compression algorithm.

  Valid values range from 0 to 250, where 0 means use the default value 30.

  This option is only valid if the `Method` is ZIP_CM_BZIP2. It is ignored otherwise.

  The default is 0.

Lzma and Xz Compression Options

- `Preset => number`

  Used to choose the LZMA compression preset.

  Valid values are 0-9 and `LZMA_PRESET_DEFAULT`.

  0 is the fastest compression with the lowest memory usage and the lowest compression.

  9 is the slowest compression with the highest memory usage but with the best compression.

  This option is only valid if the `Method` is ZIP_CM_LZMA. It is ignored otherwise.

  Defaults to `LZMA_PRESET_DEFAULT` (6).

- `Extreme => 0|1`

  Makes LZMA compression a lot slower, but a small compression gain.

  This option is only valid if the `Method` is ZIP_CM_LZMA. It is ignored otherwise.

  Defaults to 0.

Other Options

- `Time => $number`

  Sets the last modified time field in the zip header to $number.

  This field defaults to the time the `IO::Compress::Zip` object was created if this option is not specified and the `$input` parameter is not a filename.

- `ExtAttr => $attr`

  This option controls the "external file attributes" field in the central header of the zip file. This is a 4 byte field.

  If you are running a Unix derivative this value defaults to

  ```
  0100644 << 16
  ```

  This should allow read/write access to any files that are extracted from the zip file/buffer`.

  For all other systems it defaults to 0.

- `exTime => [$atime, $mtime, $ctime]`

  This option expects an array reference with exactly three elements: `$atime`, `mtime` and `$ctime`. These correspond to the last access time, last modification time and creation time respectively.

  It uses these values to set the extended timestamp field (ID is "UT") in the local zip header using the three values, $atime, $mtime, $ctime. In addition it sets the extended timestamp field in the central zip header using `$mtime`.

  If any of the three values is `undef` that time value will not be used. So, for example, to set only the `$mtime` you would use this

```
exTime => [undef, $mtime, undef]
```

If the `Minimal` option is set to true, this option will be ignored.

By default no extended time field is created.

- `exUnix2 => [$uid, $gid]`

  This option expects an array reference with exactly two elements: `$uid` and `$gid`. These values correspond to the numeric User ID (UID) and Group ID (GID) of the owner of the files respectively.

  When the `exUnix2` option is present it will trigger the creation of a Unix2 extra field (ID is "Ux") in the local zip header. This will be populated with `$uid` and `$gid`. An empty Unix2 extra field will also be created in the central zip header.

  Note - The UID & GID are stored as 16-bit integers in the "Ux" field. Use `exUnixN` if your UID or GID are 32-bit.

  If the `Minimal` option is set to true, this option will be ignored.

  By default no Unix2 extra field is created.

- `exUnixN => [$uid, $gid]`

  This option expects an array reference with exactly two elements: `$uid` and `$gid`. These values correspond to the numeric User ID (UID) and Group ID (GID) of the owner of the files respectively.

  When the `exUnixN` option is present it will trigger the creation of a UnixN extra field (ID is "ux") in both the local and central zip headers. This will be populated with `$uid` and `$gid`. The UID & GID are stored as 32-bit integers.

  If the `Minimal` option is set to true, this option will be ignored.

  By default no UnixN extra field is created.

- `Comment => $comment`

  Stores the contents of `$comment` in the Central File Header of the zip file.

  Set the `Efs` option to true if you want to store a UTF8 comment.

  By default, no comment field is written to the zip file.

- `ZipComment => $comment`

  Stores the contents of `$comment` in the End of Central Directory record of the zip file.

  By default, no comment field is written to the zip file.

- `Method => $method`

  Controls which compression method is used. At present the compression methods supported are: Store (no compression at all), Deflate, Bzip2, Zstd, Xz and Lzma.

  The symbols ZIP_CM_STORE, ZIP_CM_DEFLATE, ZIP_CM_BZIP2, ZIP_CM_ZSTD, ZIP_CM_XZ and ZIP_CM_LZMA are used to select the compression method.

  These constants are not imported by `IO::Compress::Zip` by default.

```
use IO::Compress::Zip qw(:zip_method);
use IO::Compress::Zip qw(:constants);
use IO::Compress::Zip qw(:all);
```

Note that to create Bzip2 content, the module `IO::Compress::Bzip2` must be installed. A fatal error will be thrown if you attempt to create Bzip2 content when `IO::Compress::Bzip2` is not available.

Note that to create Lzma content, the module `IO::Compress::Lzma` must be installed. A fatal error will be thrown if you attempt to create Lzma content when `IO::Compress::Lzma` is not available.

Note that to create Xz content, the module `IO::Compress::Xz` must be installed. A fatal error will be thrown if you attempt to create Xz content when `IO::Compress::Xz` is not available.

Note that to create Zstd content, the module `IO::Compress::Zstd` must be installed. A fatal error will be thrown if you attempt to create Zstd content when `IO::Compress::Zstd` is not available.

The default method is ZIP_CM_DEFLATE.

- `TextFlag => 0|1`

  This parameter controls the setting of a bit in the zip central header. It is used to signal that the data stored in the zip file/buffer is probably text.

  In one-shot mode this flag will be set to true if the Perl `-T` operator thinks the file contains text.

  The default is 0.

- `ExtraFieldLocal => $data`
- `ExtraFieldCentral => $data`

  The `ExtraFieldLocal` option is used to store additional metadata in the local header for the zip file/buffer. The `ExtraFieldCentral` does the same for the matching central header.

  An extra field consists of zero or more subfields. Each subfield consists of a two byte header followed by the subfield data.

  The list of subfields can be supplied in any of the following formats

```
ExtraFieldLocal => [$id1, $data1,
                    $id2, $data2,
                    ...
                   ]

ExtraFieldLocal => [ [$id1 => $data1],
                     [$id2 => $data2],
                     ...
                   ]

ExtraFieldLocal => { $id1 => $data1,
                     $id2 => $data2,
```

(continues on next page)

(continued from previous page)

```
                    ...
                }
```

Where `$id1`, `$id2` are two byte subfield ID's.

If you use the hash syntax, you have no control over the order in which the Extra-SubFields are stored, plus you cannot have SubFields with duplicate ID.

Alternatively the list of subfields can by supplied as a scalar, thus

```
ExtraField => $rawdata
```

In this case `IO::Compress::Zip` will check that `$rawdata` consists of zero or more conformant sub-fields.

The Extended Time field (ID "UT"), set using the `exTime` option, and the Unix2 extra field (ID "Ux), set using the `exUnix2` option, are examples of extra fields.

If the `Minimal` option is set to true, this option will be ignored.

The maximum size of an extra field 65535 bytes.

- `Strict => 0|1`

  This is a placeholder option.

Examples

Streaming

This very simple command line example demonstrates the streaming capabilities of the module. The code reads data from STDIN or all the files given on the commandline, compresses it, and writes the compressed data to STDOUT.

```
use strict ;
use warnings ;
use IO::Compress::Zip qw(zip $ZipError) ;

my $z = IO::Compress::Zip->new("-", Stream => 1)
    or die "IO::Compress::Zip failed: $ZipError\n";

while (<>) {
    $z->print("abcde");
}
$z->close();
```

Note the use of `"-"` to means `STDOUT`. Alternatively you can use `\*STDOUT`.

One problem with creating a zip archive directly from STDIN can be demonstrated by looking at the contents of the zip file, output.zip, that we have just created (assumg you have redirected it to a file called `output.zip`).

```
$ unzip -l output.zip
Archive:  output.zip
```

(continues on next page)

(continued from previous page)

```
Length      Date    Time    Name
---------  ---------- -----   ----
    12  2019-08-16 22:21
---------                     -------
    12                    1 file
```

The archive member (filename) used is the empty string.

If that doesn't suit your needs, you can explicitly set the filename used in the zip archive by specifying the Name option, like so

```
my $z = IO::Compress::Zip->new("-", Name => "hello.txt", Stream =>␣
↪1)
```

Now the contents of the zip file looks like this

```
$ unzip -l output.zip
Archive:  output.zip
Length      Date    Time    Name
---------  ---------- -----   ----
    12  2019-08-16 22:22   hello.txt
---------                     -------
    12                    1 file
```

Compressing a file from the filesystem

To read the contents of the file `file1.txt` and write the compressed data to the file `file1.txt.zip` there are a few options

Start by creating the compression object and opening the input file

```
use strict ;
use warnings ;
use IO::Compress::Zip qw(zip $ZipError) ;

my $input = "file1.txt";
my $z = IO::Compress::Zip->new("file1.txt.zip")
    or die "IO::Compress::Zip failed: $ZipError\n";

# open the input file
open my $fh, "<", "file1.txt"
    or die "Cannot open file1.txt: $!\n";

# loop through the input file & write to the compressed file
while (<$fh>) {
    $z->print($_);
}

# not forgetting to close the compressed file
$z->close();
```

Compressing multiple files

To create a zip file, `output.zip`, that contains the compressed contents of the files `alpha.txt` and `beta.txt`

```
use strict ;
use warnings ;
use IO::Compress::Zip qw(zip $ZipError) ;

my $z = IO::Compress::Zip->new("output.zip", Name => "alpha.txt")
    or die "IO::Compress::Zip failed: $ZipError\n";

# open the input file
open my $fh, "<", "file1.txt"
    or die "Cannot open file1.txt: $!\n";

# loop through the input file & write to the compressed file
while (<$fh>) {
    $z->print($_);
}

# move to next file
$z->newStream(Name => "beta.txt")

while (<$fh>) {
    $z->print($_);
}

$z->close();
```

Methods

print

Usage is

```
$z->print($data)
print $z $data
```

Compresses and outputs the contents of the `$data` parameter. This has the same behaviour as the `print` built-in.

Returns true if successful.

printf

Usage is

```
$z->printf($format, $data)
printf $z $format, $data
```

Compresses and outputs the contents of the `$data` parameter.

Returns true if successful.

syswrite

Usage is

```
$z->syswrite $data
$z->syswrite $data, $length
$z->syswrite $data, $length, $offset
```

Compresses and outputs the contents of the `$data` parameter.

Returns the number of uncompressed bytes written, or `undef` if unsuccessful.

write

Usage is

```
$z->write $data
$z->write $data, $length
$z->write $data, $length, $offset
```

Compresses and outputs the contents of the `$data` parameter.

Returns the number of uncompressed bytes written, or `undef` if unsuccessful.

flush

Usage is

```
$z->flush;
$z->flush($flush_type);
```

Flushes any pending compressed data to the output file/buffer.

This method takes an optional parameter, `$flush_type`, that controls how the flushing will be carried out. By default the `$flush_type` used is `Z_FINISH`. Other valid values for `$flush_type` are `Z_NO_FLUSH`, `Z_SYNC_FLUSH`, `Z_FULL_FLUSH` and `Z_BLOCK`. It is strongly recommended that you only set the `flush_type` parameter if you fully understand the implications of what it does - overuse of `flush` can seriously degrade the level of compression achieved. See the `zlib` documentation for details.

Returns true on success.

tell

Usage is

```
$z->tell()
tell $z
```

Returns the uncompressed file offset.

eof

Usage is

```
$z->eof();
eof($z);
```

Returns true if the `close` method has been called.

seek

```
$z->seek($position, $whence);
seek($z, $position, $whence);
```

Provides a sub-set of the `seek` functionality, with the restriction that it is only legal to seek forward in the output file/buffer. It is a fatal error to attempt to seek backward.

Empty parts of the file/buffer will have NULL (0x00) bytes written to them.

The `$whence` parameter takes one the usual values, namely SEEK_SET, SEEK_CUR or SEEK_END.

Returns 1 on success, 0 on failure.

binmode

Usage is

```
$z->binmode
binmode $z ;
```

This is a noop provided for completeness.

opened

```
$z->opened()
```

Returns true if the object currently refers to a opened file/buffer.

autoflush

```
my $prev = $z->autoflush()
my $prev = $z->autoflush(EXPR)
```

If the `$z` object is associated with a file or a filehandle, this method returns the current autoflush setting for the underlying filehandle. If `EXPR` is present, and is non-zero, it will enable flushing after every write/print operation.

If `$z` is associated with a buffer, this method has no effect and always returns `undef`.

Note that the special variable `$|` **cannot** be used to set or retrieve the autoflush setting.

input_line_number

```
$z->input_line_number()
$z->input_line_number(EXPR)
```

This method always returns undef when compressing.

fileno

```
$z->fileno()
fileno($z)
```

If the $z object is associated with a file or a filehandle, fileno will return the underlying file descriptor. Once the close method is called fileno will return undef.

If the $z object is associated with a buffer, this method will return undef.

close

```
$z->close() ;
close $z ;
```

Flushes any pending compressed data and then closes the output file/buffer.

For most versions of Perl this method will be automatically invoked if the IO::Compress::Zip object is destroyed (either explicitly or by the variable with the reference to the object going out of scope). The exceptions are Perl versions 5.005 through 5.00504 and 5.8.0. In these cases, the close method will be called automatically, but not until global destruction of all live objects when the program is terminating.

Therefore, if you want your scripts to be able to run on all versions of Perl, you should call close explicitly and not rely on automatic closing.

Returns true on success, otherwise 0.

If the AutoClose option has been enabled when the IO::Compress::Zip object was created, and the object is associated with a file, the underlying file will also be closed.

newStream([OPTS])

Usage is

```
$z->newStream( [OPTS] )
```

Closes the current compressed data stream and starts a new one.

OPTS consists of any of the options that are available when creating the $z object.

See the “Constructor Options” section for more details.

deflateParams

Usage is

```
$z->deflateParams
```

TODO

Importing

A number of symbolic constants are required by some methods in `IO::Compress::Zip`. None are imported by default.

- :all

  Imports `zip`, `$ZipError` and all symbolic constants that can be used by `IO::Compress::Zip`. Same as doing this

  ```
  use IO::Compress::Zip qw(zip $ZipError :constants) ;
  ```

- :constants

  Import all symbolic constants. Same as doing this

  ```
  use IO::Compress::Zip qw(:flush :level :strategy :zip_method) ;
  ```

- :flush

  These symbolic constants are used by the `flush` method.

  ```
  Z_NO_FLUSH
  Z_PARTIAL_FLUSH
  Z_SYNC_FLUSH
  Z_FULL_FLUSH
  Z_FINISH
  Z_BLOCK
  ```

- :level

  These symbolic constants are used by the `Level` option in the constructor.

  ```
  Z_NO_COMPRESSION
  Z_BEST_SPEED
  Z_BEST_COMPRESSION
  Z_DEFAULT_COMPRESSION
  ```

- :strategy

  These symbolic constants are used by the `Strategy` option in the constructor.

  ```
  Z_FILTERED
  Z_HUFFMAN_ONLY
  Z_RLE
  Z_FIXED
  Z_DEFAULT_STRATEGY
  ```

- :zip_method

  These symbolic constants are used by the `Method` option in the constructor.

```
ZIP_CM_STORE
ZIP_CM_DEFLATE
ZIP_CM_BZIP2
```

IO::Dir

supply object methods for directory handles

SYNOPSIS

```
use IO::Dir;
my $d = IO::Dir->new(".");
if (defined $d) {
    while (defined($_ = $d->read)) { something($_); }
    $d->rewind;
    while (defined($_ = $d->read)) { something_else($_); }
    undef $d;
}

tie my %dir, 'IO::Dir', ".";
foreach (keys %dir) {
    print $_, " " , $dir{$_}->size,"\n";
}
```

DESCRIPTION

The IO::Dir package provides two interfaces to perl's directory reading routines.

The first interface is an object approach. IO::Dir provides an object constructor and methods, which are just wrappers around perl's built in directory reading routines.

- new ([DIRNAME])

  new is the constructor for IO::Dir objects. It accepts one optional argument which, if given, new will pass to open

The following methods are wrappers for the directory related functions built into perl (the trailing 'dir' has been removed from the names). See *perlfunc* for details of these functions.

- open (DIRNAME)

- read ()
- seek (POS)
- tell ()
- rewind ()
- close ()

`IO::Dir` also provides an interface to reading directories via a tied hash. The tied hash extends the interface beyond just the directory reading routines by the use of `lstat`, from the `File::stat` package, `unlink`, `rmdir` and `utime`.

- tie %hash, 'IO::Dir', DIRNAME [, OPTIONS]

The keys of the hash will be the names of the entries in the directory. Reading a value from the hash will be the result of calling `File::stat::lstat`. Deleting an element from the hash will delete the corresponding file or subdirectory, provided that `DIR_UNLINK` is included in the `OPTIONS`.

Assigning to an entry in the hash will cause the time stamps of the file to be modified. If the file does not exist then it will be created. Assigning a single integer to a hash element will cause both the access and modification times to be changed to that value. Alternatively a reference to an array of two values can be passed. The first array element will be used to set the access time and the second element will be used to set the modification time.

IO::File

supply object methods for filehandles

SYNOPSIS

```
use IO::File;

my $fh = IO::File->new();
if ($fh->open("< file")) {
```

(continues on next page)

(continued from previous page)

```
    print <$fh>;
    $fh->close;
}

my $fh = IO::File->new("> file");
if (defined $fh) {
    print $fh "bar\n";
    $fh->close;
}

my $fh = IO::File->new("file", "r");
if (defined $fh) {
    print <$fh>;
    undef $fh;       # automatically closes the file
}

my $fh = IO::File->new("file", O_WRONLY|O_APPEND);
if (defined $fh) {
    print $fh "corge\n";

    my $pos = $fh->getpos;
    $fh->setpos($pos);

    undef $fh;       # automatically closes the file
}

autoflush STDOUT 1;
```

DESCRIPTION

`IO::File` inherits from `IO::Handle` and `IO::Seekable`. It extends these classes with methods that are specific to file handles.

CONSTRUCTOR

- new (FILENAME [,MODE [,PERMS]])

  Creates an `IO::File`. If it receives any parameters, they are passed to the method open; if the open fails, the object is destroyed. Otherwise, it is returned to the caller.

- new_tmpfile

  Creates an `IO::File` opened for read/write on a newly created temporary file. On systems where this is possible, the temporary file is anonymous (i.e. it is unlinked after creation, but held open). If the temporary file cannot be created or opened, the `IO::File` object is destroyed. Otherwise, it is returned to the caller.

METHODS

- open(FILENAME [,MODE [,PERMS]])
- open(FILENAME, IOLAYERS)

  open accepts one, two or three parameters. With one parameter, it is just a front end for the built-in open function. With two or three parameters, the first parameter is a filename that may include whitespace or other special characters, and the second parameter is the open mode, optionally followed by a file permission value.

  If `IO::File::open` receives a Perl mode string (">", "+<", etc.) or an ANSI C fopen() mode string ("w", "r+", etc.), it uses the basic Perl open operator (but protects any special characters).

  If `IO::File::open` is given a numeric mode, it passes that mode and the optional permissions value to the Perl `sysopen` operator. The permissions default to 0666.

  If `IO::File::open` is given a mode that includes the `:` character, it passes all the three arguments to the three-argument open operator.

  For convenience, `IO::File` exports the O_XXX constants from the Fcntl module, if this module is available.

NOTE

Some operating systems may perform `IO::File::new()` or `IO::File::open()` on a directory without errors. This behavior is not portable and not suggested for use. Using `opendir()` and `readdir()` or `IO::Dir` are suggested instead.

HISTORY

Derived from FileHandle.pm by Graham Barr <gbarr@pobox.com>.

Functions

Other Functions

new_tmpfile

Open an anonymous temporary file and return it as an `IO::File`.

IO::Handle

supply object methods for I/O handles

SYNOPSIS

```
use IO::Handle;

my $io = IO::Handle->new();
if ($io->fdopen(fileno(STDIN),"r")) {
    print $io->getline;
    $io->close;
}

my $io = IO::Handle->new();
if ($io->fdopen(fileno(STDOUT),"w")) {
    $io->print("Some text\n");
}

# setvbuf is not available by default on Perls 5.8.0 and later.
use IO::Handle '_IOLBF';
$io->setvbuf(my $buffer_var, _IOLBF, 1024);

undef $io;       # automatically closes the file if it's open

autoflush STDOUT 1;
```

DESCRIPTION

`IO::Handle` is the base class for all other IO handle classes. It is not intended that objects of `IO::Handle` would be created directly, but instead `IO::Handle` is inherited from by several other classes in the IO hierarchy.

If you are reading this documentation, looking for a replacement for the `FileHandle` package, then I suggest you read the documentation for `IO::File` too.

CONSTRUCTOR

- new ()

  Creates a new `IO::Handle` object.

- new_from_fd (FD, MODE)

  Creates an `IO::Handle` like `new` does. It requires two parameters, which are passed to the method `fdopen`; if the fdopen fails, the object is destroyed. Otherwise, it is returned to the caller.

METHODS

See *perlfunc* for complete descriptions of each of the following supported `IO::Handle` methods, which are just front ends for the corresponding built-in functions:

```
$io->close
$io->eof
$io->fcntl( FUNCTION, SCALAR )
```

(continues on next page)

(continued from previous page)

```
$io->fileno
$io->format_write( [FORMAT_NAME] )
$io->getc
$io->ioctl( FUNCTION, SCALAR )
$io->read ( BUF, LEN, [OFFSET] )
$io->print ( ARGS )
$io->printf ( FMT, [ARGS] )
$io->say ( ARGS )
$io->stat
$io->sysread ( BUF, LEN, [OFFSET] )
$io->syswrite ( BUF, [LEN, [OFFSET]] )
$io->truncate ( LEN )
```

See *perlvar* for complete descriptions of each of the following supported `IO::Handle` methods. All of them return the previous value of the attribute and takes an optional single argument that when given will set the value. If no argument is given the previous value is unchanged (except for $io->autoflush will actually turn ON autoflush by default).

```
$io->autoflush ( [BOOL] )                    $|
$io->format_page_number( [NUM] )             $%
$io->format_lines_per_page( [NUM] )          $=
$io->format_lines_left( [NUM] )              $-
$io->format_name( [STR] )                    $~
$io->format_top_name( [STR] )                $^
$io->input_line_number( [NUM])               $.
```

The following methods are not supported on a per-filehandle basis.

```
IO::Handle->format_line_break_characters( [STR] ) $:
IO::Handle->format_formfeed( [STR])               $^L
IO::Handle->output_field_separator( [STR] )       $,
IO::Handle->output_record_separator( [STR] )      $\

IO::Handle->input_record_separator( [STR] )       $/
```

Furthermore, for doing normal I/O you might need these:

- $io->fdopen (FD, MODE)

  `fdopen` is like an ordinary open except that its first parameter is not a filename but rather a file handle name, an IO::Handle object, or a file descriptor number. (For the documentation of the open method, see *IO::File*.)

- $io->opened

  Returns true if the object is currently a valid file descriptor, false otherwise.

- $io->getline

  This works like <$io> described in *"I/O Operators" in perlop* except that it's more readable and can be safely called in a list context but still returns just one line. If used as the conditional within a `while` or C-style `for` loop, however, you will need to emulate the functionality of <$io> with `defined($_ = $io->getline)`.

- $io->getlines

  This works like <$io> when called in a list context to read all the remaining lines in a file, except that it's more readable. It will also croak() if accidentally called in a scalar context.

- $io->ungetc (ORD)

  Pushes a character with the given ordinal value back onto the given handle's input stream. Only one character of pushback per handle is guaranteed.

- $io->write (BUF, LEN [, OFFSET])

  This `write` is somewhat like `write` found in C, in that it is the opposite of read. The wrapper for the perl `write` function is called `format_write`. However, whilst the C `write` function returns the number of bytes written, this `write` function simply returns true if successful (like `print`). A more C-like `write` is `syswrite` (see above).

- $io->error

  Returns a true value if the given handle has experienced any errors since it was opened or since the last call to `clearerr`, or if the handle is invalid. It only returns false for a valid handle with no outstanding errors.

- $io->clearerr

  Clear the given handle's error indicator. Returns -1 if the handle is invalid, 0 otherwise.

- $io->sync

  `sync` synchronizes a file's in-memory state with that on the physical medium. `sync` does not operate at the perlio api level, but operates on the file descriptor (similar to sysread, sysseek and systell). This means that any data held at the perlio api level will not be synchronized. To synchronize data that is buffered at the perlio api level you must use the flush method. `sync` is not implemented on all platforms. Returns "0 but true" on success, `undef` on error, `undef` for an invalid handle. See fsync(3c).

- $io->flush

  `flush` causes perl to flush any buffered data at the perlio api level. Any unread data in the buffer will be discarded, and any unwritten data will be written to the underlying file descriptor. Returns "0 but true" on success, `undef` on error.

- $io->printflush (ARGS)

  Turns on autoflush, print ARGS and then restores the autoflush status of the `IO::Handle` object. Returns the return value from print.

- $io->blocking ([BOOL])

  If called with an argument `blocking` will turn on non-blocking IO if `BOOL` is false, and turn it off if `BOOL` is true.

  `blocking` will return the value of the previous setting, or the current setting if `BOOL` is not given.

  If an error occurs `blocking` will return undef and `$!` will be set.

- binmode([LAYER])

  `binmode` sets `binmode` on the underlying `IO` object, as documented in `perldoc -f binmode`.

  `binmode` accepts one optional parameter, which is the layer to be passed on to the `binmode` call.

If the C functions setbuf() and/or setvbuf() are available, then `IO::Handle::setbuf` and `IO::Handle::setvbuf` set the buffering policy for an IO::Handle. The calling sequences for the Perl functions are the same as their C counterparts–including the constants `_IOFBF`, `_IOLBF`, and `_IONBF` for setvbuf()–except that the buffer parameter specifies a scalar variable to use as a buffer. You should only change the buffer before any I/O, or immediately after calling flush.

WARNING: The IO::Handle::setvbuf() is not available by default on Perls 5.8.0 and later because setvbuf() is rather specific to using the stdio library, while Perl prefers the new perlio subsystem instead.

WARNING: A variable used as a buffer by `setbuf` or `setvbuf` **must not be modified** in any way until the IO::Handle is closed or `setbuf` or `setvbuf` is called again, or memory corruption may result! Remember that the order of global destruction is undefined, so even if your buffer variable remains in scope until program termination, it may be undefined before the file IO::Handle is closed. Note that you need to import the constants `_IOFBF`, `_IOLBF`, and `_IONBF` explicitly. Like C, setbuf returns nothing. setvbuf returns "0 but true", on success, `undef` on failure.

Lastly, there is a special method for working under **-T** and setuid/gid scripts:

- $io->untaint

  Marks the object as taint-clean, and as such data read from it will also be considered taint-clean. Note that this is a very trusting action to take, and appropriate consideration for the data source and potential vulnerability should be kept in mind. Returns 0 on success, -1 if setting the taint-clean flag failed. (eg invalid handle)

NOTE

An `IO::Handle` object is a reference to a symbol/GLOB reference (see the *Symbol* package). Some modules that inherit from `IO::Handle` may want to keep object related variables in the hash table part of the GLOB. In an attempt to prevent modules trampling on each other I propose the that any such module should prefix its variables with its own name separated by _'s. For example the IO::Socket module keeps a `timeout` variable in 'io_socket_timeout'.

SEE ALSO

perlfunc, *"I/O Operators" in perlop*, *IO::File*

BUGS

Due to backwards compatibility, all filehandles resemble objects of class `IO::Handle`, or actually classes derived from that class. They actually aren't. Which means you can't derive your own class from `IO::Handle` and inherit those methods.

HISTORY

Derived from FileHandle.pm by Graham Barr <gbarr@pobox.com>

Functions

Other Functions

blocking

Query or set blocking mode on the handle.

ungetc

Push one character back onto the handle, to be read again next.

error

Report whether the handle's error indicator is set.

clearerr

Clear the handle's error and end-of-file indicators.

untaint

Mark the handle as a trusted source, so data read from it is not tainted.

flush

Write out any buffered data on the handle.

setbuf

Not available on this build: croaks when called on a handle open for writing.

setvbuf

Not available on this build: croaks when called.

sync

Flush the handle's data through to the storage device.

getlines

Read every remaining line from the handle and return them as a list.

getline

Read one line from the handle and return it, or undef at end of file.

gets

An old name for `getline`.

IO::Pipe

supply object methods for pipes

SYNOPSIS

```
use IO::Pipe;

$pipe = IO::Pipe->new();

if($pid = fork()) { # Parent
    $pipe->reader();

    while(<$pipe>) {
        ...
    }

}
elsif(defined $pid) { # Child
    $pipe->writer();

    print $pipe ...
}

or

$pipe = IO::Pipe->new();

$pipe->reader(qw(ls -l));

while(<$pipe>) {
    ...
}
```

DESCRIPTION

`IO::Pipe` provides an interface to creating pipes between processes.

CONSTRUCTOR

- new ([READER, WRITER])

  Creates an `IO::Pipe`, which is a reference to a newly created symbol (see the *Symbol* package). `IO::Pipe::new` optionally takes two arguments, which should be objects blessed into `IO::Handle`, or a subclass thereof. These two objects will be used for the system call to `pipe`. If no arguments are given then method `handles` is called on the new `IO::Pipe` object.

  These two handles are held in the array part of the GLOB until either `reader` or `writer` is called.

METHODS

- reader ([ARGS])

  The object is re-blessed into a sub-class of `IO::Handle`, and becomes a handle at the reading end of the pipe. If `ARGS` are given then `fork` is called and `ARGS` are passed to exec.

- writer ([ARGS])

  The object is re-blessed into a sub-class of `IO::Handle`, and becomes a handle at the writing end of the pipe. If `ARGS` are given then `fork` is called and `ARGS` are passed to exec.

- handles ()

  This method is called during construction by `IO::Pipe::new` on the newly created `IO::Pipe` object. It returns an array of two objects blessed into `IO::Pipe::End`, or a subclass thereof.

IO::Poll

Object interface to system poll call

SYNOPSIS

```
use IO::Poll qw(POLLRDNORM POLLWRNORM POLLIN POLLHUP);

$poll = IO::Poll->new();

$poll->mask($input_handle => POLLIN);
$poll->mask($output_handle => POLLOUT);

$poll->poll($timeout);

$ev = $poll->events($input);
```

DESCRIPTION

`IO::Poll` is a simple interface to the system level poll routine.

METHODS

- mask (IO [, EVENT_MASK])

  If EVENT_MASK is given, then, if EVENT_MASK is non-zero, IO is added to the list of file descriptors and the next call to poll will check for any event specified in EVENT_MASK. If EVENT_MASK is zero then IO will be removed from the list of file descriptors.

  If EVENT_MASK is not given then the return value will be the current event mask value for IO.

- poll ([TIMEOUT])

  Call the system level poll routine. If TIMEOUT is not specified then the call will block. Returns the number of handles which had events happen, or -1 on error.

- events (IO)

  Returns the event mask which represents the events that happened on IO during the last call to `poll`.

- remove (IO)

  Remove IO from the list of file descriptors for the next poll.

- handles([EVENT_MASK])

  Returns a list of handles. If EVENT_MASK is not given then a list of all handles known will be returned. If EVENT_MASK is given then a list of handles will be returned which had one of the events specified by EVENT_MASK happen during the last call to `poll`.

IO::Pty

Pseudo TTY object class

VERSION

1.31

SYNOPSIS

```
use IO::Pty;

$pty = IO::Pty->new;

$slave  = $pty->slave;

foreach $val (1..10) {
    print $pty "$val\n";
    $_ = <$slave>;
    print "$_";
}

close($slave);
```

DESCRIPTION

`IO::Pty` provides an interface to allow the creation of a pseudo tty.

`IO::Pty` inherits from *IO::Handle* and so provide all the methods defined by the *IO::Handle* package.

Please note that pty creation is very system-dependent. If you have problems, see *IO::Tty* for help.

CONSTRUCTOR

- new

  The new constructor takes no arguments and returns a new file object which is the master side of the pseudo tty.

METHODS

- ttyname()

  Returns the name of the slave pseudo tty. On UNIX machines this will be the pathname of the device. Use this name for informational purpose only, to get a slave filehandle, use slave().

- slave()

  The `slave` method will return the slave filehandle of the given master pty, opening it anew if necessary. If IO::Stty is installed, you can then call `$slave->stty()` to modify the terminal settings.

- close_slave()

  The slave filehandle will be closed and destroyed. This is necessary in the parent after forking to get rid of the open filehandle, otherwise the parent will not notice if the child exits. Subsequent calls of `slave()` will return a newly opened slave filehandle.

- make_slave_controlling_terminal()

  This will set the slave filehandle as the controlling terminal of the current process, which will become a session leader, so this should only be called by a child process after a fork(), e.g. in the callback to `sync_exec()` (see Proc::SyncExec). See the `try` script (also `test.pl`) for an example how to correctly spawn a subprocess.

- set_raw()

  Will set the pty to raw. Note that this is a one-way operation, you need IO::Stty to set the terminal settings to anything else.

  On some systems, the master pty is not a tty. This method checks for that and returns success anyway on such systems. Note that this method must be called on the slave, and probably should be called on the master, just to be sure, i.e.

```
$pty->slave->set_raw();
$pty->set_raw();
```

- clone_winsize_from(*FH)

  Gets the terminal size from filehandle FH (which must be a terminal) and transfers it to the pty. Returns true on success and undef on failure. Note that this must be called upon the *slave*, i.e.

```
$pty->slave->clone_winsize_from(\*STDIN);
```

  On some systems, the master pty also isatty. I actually have no idea if setting terminal sizes there is passed through to the slave, so if this method is called for a master that is not a tty, it silently returns OK.

See the `try` script for example code how to propagate SIGWINCH.

- get_winsize()

  Returns the terminal size, in a 4-element list.

```
($row, $col, $xpixel, $ypixel) = $tty->get_winsize()
```

- set_winsize($row, $col, $xpixel, $ypixel)

  Sets the terminal size. If not specified, `$xpixel` and `$ypixel` are set to 0. As with `clone_winsize_from`, this must be called upon the *slave*.

Functions

Pseudo-terminals

pty_allocate

A new pseudo-terminal: its master and slave descriptors and the slave's name.

pty_allocate

A new pseudo-terminal: its master and slave descriptors and the slave's name.

Synopsis

```
my ($master_fd, $slave_fd, $name) = IO::Pty::pty_allocate();
```

What you get back

Three values, both descriptors above 2 - or an empty list when no way of getting a pty worked. `IO::Pty->new` calls it; with `use warnings` each way that failed warns, and with `$IO::Tty::DEBUG` true each one tried is named on stderr.

IO::Seekable

supply seek based methods for I/O objects

SYNOPSIS

```
use IO::Seekable;
package IO::Something;
@ISA = qw(IO::Seekable);
```

DESCRIPTION

`IO::Seekable` does not have a constructor of its own as it is intended to be inherited by other `IO::Handle` based objects. It provides methods which allow seeking of the file descriptors.

- $io->getpos

  Returns an opaque value that represents the current position of the IO::File, or `undef` if this is not possible (eg an unseekable stream such as a terminal, pipe or socket). If the fgetpos() function is available in your C library it is used to implements getpos, else perl emulates getpos using C's ftell() function.

- $io->setpos

  Uses the value of a previous getpos call to return to a previously visited position. Returns “0 but true” on success, `undef` on failure.

See *perlfunc* for complete descriptions of each of the following supported `IO::Seekable` methods, which are just front ends for the corresponding built-in functions:

- $io->seek (POS, WHENCE)

  Seek the IO::File to position POS, relative to WHENCE:

  – WHENCE=0 (SEEK_SET)

    POS is absolute position. (Seek relative to the start of the file)

  – WHENCE=1 (SEEK_CUR)

    POS is an offset from the current position. (Seek relative to current)

  – WHENCE=2 (SEEK_END)

    POS is an offset from the end of the file. (Seek relative to end)

  The SEEK_* constants can be imported from the `Fcntl` module if you don’t wish to use the numbers `0` 1 or 2 in your code.

  Returns 1 upon success, `0` otherwise.

- $io->sysseek(POS, WHENCE)

  Similar to $io->seek, but sets the IO::File’s position using the system call lseek(2) directly, so will confuse most perl IO operators except sysread and syswrite (see *perlfunc* for full details)

  Returns the new position, or `undef` on failure. A position of zero is returned as the string `"0 but true"`

- $io->tell

  Returns the IO::File’s current position, or -1 on error.

SEE ALSO

perlfunc, *“I/O Operators” in perlop*, *IO::Handle IO::File*

HISTORY

Derived from FileHandle.pm by Graham Barr gbarr@pobox.com

Functions

Other Functions

getpos

Return an opaque marker for the handle’s current position.

setpos

Return the handle to a position previously recorded by `getpos`.

IO::Select

OO interface to the `select` system call

SYNOPSIS

```
use IO::Select;

my $s = IO::Select->new();

$s->add(\*STDIN);
$s->add($some_handle);

my @ready1 = $s->can_read($timeout);

my @ready2 = IO::Select->new(@handles)->can_read(0);
```

DESCRIPTION

The `IO::Select` package implements an object approach to the system `select` function call. It allows the user to see what IO handles, see *IO::Handle*, are ready for reading, writing or have an exception pending.

CONSTRUCTOR

- new ([HANDLES])

  The constructor creates a new object and optionally initialises it with a set of handles.

METHODS

- add (HANDLES)

  Add the list of handles to the `IO::Select` object. It is these values that will be returned when an event occurs. `IO::Select` keeps these values in a cache which is indexed by the `fileno` of the handle, so if more than one handle with the same `fileno` is specified then only the last one is cached.

  Each handle can be an `IO::Handle` object, an integer or an array reference where the first element is an `IO::Handle` or an integer.

- remove (HANDLES)

  Remove all the given handles from the object. This method also works by the `fileno` of the handles. So the exact handles that were added need not be passed, just handles that have an equivalent `fileno`

- exists (HANDLE)

  Returns a true value (actually the handle itself) if it is present. Returns undef otherwise.

- handles

  Return an array of all registered handles.

- can_read ([TIMEOUT])

  Return an array of handles that are ready for reading. `TIMEOUT` is the maximum amount of time to wait before returning an empty list (with `$!` unchanged), in seconds, possibly fractional. If `TIMEOUT` is not given and any handles are registered then the call will block indefinitely. Upon error, an empty list is returned, with `$!` set to indicate the error. To distinguish between timeout and error, set `$!` to zero before calling this method, and check it after an empty list is returned.

- can_write ([TIMEOUT])

  Same as `can_read` except check for handles that can be written to.

- has_exception ([TIMEOUT])

  Same as `can_read` except check for handles that have an exception condition, for example pending out-of-band data.

- count ()

  Returns the number of handles that the object will check for when one of the `can_` methods is called or the object is passed to the `select` static method.

- bits()

  Return the bit string suitable as argument to the core select() call.

- select (READ, WRITE, EXCEPTION [, TIMEOUT])

  `select` is a static method, that is you call it with the package name like `new`. `READ`, `WRITE` and `EXCEPTION` are either `undef` or `IO::Select` objects. `TIMEOUT` is optional and has the same effect as for the core select call.

  If at least one handle is ready for the specified kind of operation, the result will be an array of 3 elements, each a reference to an array which will hold the handles that are ready for reading, writing and have exceptions respectively. Upon timeout, an empty list is returned, with `$!` unchanged. Upon error, an empty list is returned, with `$!` set to indicate the error. To distinguish between timeout and error, set `$!` to zero before calling this method, and check it after an empty list is returned.

EXAMPLE

Here is a short example which shows how `IO::Select` could be used to write a server which communicates with several sockets while also listening for more connections on a listen socket

```
use IO::Select;
use IO::Socket;
```

(continues on next page)

(continued from previous page)

```
my $lsn = IO::Socket::INET->new(Listen => 1, LocalPort => 8080);
my $sel = IO::Select->new( $lsn );

while(my @ready = $sel->can_read) {
    foreach my $fh (@ready) {
        if($fh == $lsn) {
            # Create a new socket
            my $new = $lsn->accept;
            $sel->add($new);
        }
        else {
            # Process socket

            # Maybe we have finished with the socket
            $sel->remove($fh);
            $fh->close;
        }
    }
}
```

IO::Socket

Object interface to socket communications

SYNOPSIS

```
use strict;
use warnings;

use IO::Socket qw(AF_INET AF_UNIX);

# create a new AF_INET socket
my $sock = IO::Socket->new(Domain => AF_INET);
# which is the same as
$sock = IO::Socket::INET->new();

# create a new AF_UNIX socket
```

(continues on next page)

(continued from previous page)

```
$sock = IO::Socket->new(Domain => AF_UNIX);
# which is the same as
$sock = IO::Socket::UNIX->new();
```

DESCRIPTION

`IO::Socket` provides an object-oriented, *IO::Handle*-based interface to creating and using sockets via *Socket*, which provides a near one-to-one interface to the C socket library.

`IO::Socket` is a base class that really only defines methods for those operations which are common to all types of sockets. Operations which are specific to a particular socket domain have methods defined in subclasses of `IO::Socket`. See *IO::Socket::INET*, *IO::Socket::UNIX*, and *IO::Socket::IP* for examples of such a subclass.

`IO::Socket` will export all functions (and constants) defined by *Socket*.

CONSTRUCTOR ARGUMENTS

Given that `IO::Socket` doesn't have attributes in the traditional sense, the following arguments, rather than attributes, can be passed into the constructor.

Constructor arguments should be passed in `Key => 'Value'` pairs.

The only required argument is *"Domain" in IO::Socket*.

Blocking

```
my $sock = IO::Socket->new(..., Blocking => 1);
$sock = IO::Socket->new(..., Blocking => 0);
```

If defined but false, the socket will be set to non-blocking mode. If not specified it defaults to 1 (blocking mode).

Domain

```
my $sock = IO::Socket->new(Domain => IO::Socket::AF_INET);
$sock = IO::Socket->new(Domain => IO::Socket::AF_UNIX);
```

The socket domain will define which subclass of `IO::Socket` to use. The two options available along with this distribution are `AF_INET` and `AF_UNIX`.

`AF_INET` is for the internet address family of sockets and is handled via *IO::Socket::INET*. `AF_INET` sockets are bound to an internet address and port.

`AF_UNIX` is for the unix domain socket and is handled via *IO::Socket::UNIX*. `AF_UNIX` sockets are bound to the file system as their address name space.

This argument is **required**. All other arguments are optional.

Listen

```
my $sock = IO::Socket->new(..., Listen => 5);
```

Listen should be an integer value or left unset.

If provided, this argument will place the socket into listening mode. New connections can then be accepted using the *"accept" in IO::Socket* method. The value given is used as the `listen(2)` queue size.

If the `Listen` argument is given, but false, the queue size will be set to 5.

Timeout

```
my $sock = IO::Socket->new(..., Timeout => 5);
```

The timeout value, in seconds, for this socket connection. How exactly this value is utilized is defined in the socket domain subclasses that make use of the value.

Type

```
my $sock = IO::Socket->new(..., Type => IO::Socket::SOCK_STREAM);
```

The socket type that will be used. These are usually `SOCK_STREAM`, `SOCK_DGRAM`, or `SOCK_RAW`. If this argument is left undefined an attempt will be made to infer the type from the service name.

For example, you'll usually use `SOCK_STREAM` with a `tcp` connection and `SOCK_DGRAM` with a udp connection.

CONSTRUCTORS

`IO::Socket` extends the *IO::Handle* constructor.

new

```
my $sock = IO::Socket->new();

# get a new IO::Socket::INET instance
$sock = IO::Socket->new(Domain => IO::Socket::AF_INET);
# get a new IO::Socket::UNIX instance
$sock = IO::Socket->new(Domain => IO::Socket::AF_UNIX);

# Domain is the only required argument
$sock = IO::Socket->new(
    Domain => IO::Socket::AF_INET, # AF_INET, AF_UNIX
    Type => IO::Socket::SOCK_STREAM, # SOCK_STREAM, SOCK_DGRAM, ...
    Proto => 'tcp', # 'tcp', 'udp', IPPROTO_TCP, IPPROTO_UDP
    # and so on...
);
```

Creates an `IO::Socket`, which is a reference to a newly created symbol (see the *Symbol* package). `new` optionally takes arguments, these arguments are defined in *"CONSTRUCTOR ARGUMENTS" in IO::Socket*.

Any of the *"CONSTRUCTOR ARGUMENTS" in IO::Socket* may be passed to the constructor, but if any arguments are provided, then one of them must be the *"Domain" in IO::Socket* argument. The *"Domain" in IO::Socket* argument can, by default, be either `AF_INET` or `AF_UNIX`. Other domains can be used if a proper subclass for the domain family is registered. All other arguments will be passed to the `configuration` method of the package for that domain.

If the constructor fails it will return `undef` and set the `$errstr` package variable to contain an error message.

```
$sock = IO::Socket->new(...)
    or die "Cannot create socket - $IO::Socket::errstr\n";
```

For legacy reasons the error message is also set into the global `$@` variable, and you may still find older code which looks here instead.

```
$sock = IO::Socket->new(...)
    or die "Cannot create socket - $@\n";
```

METHODS

`IO::Socket` inherits all methods from *IO::Handle* and implements the following new ones.

accept

```
my $client_sock = $sock->accept();
my $inet_sock = $sock->accept('IO::Socket::INET');
```

The accept method will perform the system call `accept` on the socket and return a new object. The new object will be created in the same class as the listen socket, unless a specific package name is specified. This object can be used to communicate with the client that was trying to connect.

This differs slightly from the `accept` function in *perlfunc*.

In a scalar context the new socket is returned, or `undef` upon failure. In a list context a two-element array is returned containing the new socket and the peer address; the list will be empty upon failure.

atmark

```
my $integer = $sock->atmark();
# read in some data on a given socket
my $data;
$sock->read($data, 1024) until $sock->atmark;
```

(continues on next page)

(continued from previous page)

```
# or, export the function to use:
use IO::Socket 'sockatmark';
$sock->read($data, 1024) until sockatmark($sock);
```

True if the socket is currently positioned at the urgent data mark, false otherwise. If your system doesn't yet implement `sockatmark` this will throw an exception.

If your system does not support `sockatmark`, the `use` declaration will fail at compile time.

autoflush

```
# by default, autoflush will be turned on when referenced
$sock->autoflush(); # turns on autoflush
# turn off autoflush
$sock->autoflush(0);
# turn on autoflush
$sock->autoflush(1);
```

This attribute isn't overridden from *IO::Handle*'s implementation. However, since we turn it on by default, it's worth mentioning here.

bind

```
use Socket qw(pack_sockaddr_in);
my $port = 3000;
my $ip_address = '0.0.0.0';
my $packed_addr = pack_sockaddr_in($port, $ip_address);
$sock->bind($packed_addr);
```

Binds a network address to a socket, just as `bind(2)` does. Returns true if it succeeded, false otherwise. You should provide a packed address of the appropriate type for the socket.

connected

```
my $peer_addr = $sock->connected();
if ($peer_addr) {
    say "We're connected to $peer_addr";
}
```

If the socket is in a connected state, the peer address is returned. If the socket is not in a connected state, `undef` is returned.

Note that this method considers a half-open TCP socket to be "in a connected state". Specifically, it does not distinguish between the **ESTABLISHED** and **CLOSE-WAIT** TCP states; it returns the peer address, rather than `undef`, in either case. Thus, in general, it cannot be used to reliably learn whether the peer has initiated a graceful shutdown because in most cases (see below) the local TCP state machine remains in **CLOSE-WAIT**

until the local application calls *"shutdown" in IO::Socket* or `close`. Only at that point does this function return `undef`.

The "in most cases" hedge is because local TCP state machine behavior may depend on the peer's socket options. In particular, if the peer socket has `SO_LINGER` enabled with a zero timeout, then the peer's `close` will generate a `RST` segment. Upon receipt of that segment, the local TCP transitions immediately to **CLOSED**, and in that state, this method *will* return `undef`.

getsockopt

```
my $value = $sock->getsockopt(SOL_SOCKET, SO_REUSEADDR);
my $buf = $socket->getsockopt(SOL_SOCKET, SO_RCVBUF);
say "Receive buffer is $buf bytes";
```

Get an option associated with the socket. Levels other than `SOL_SOCKET` may be specified here. As a convenience, this method will unpack a byte buffer of the correct size back into a number.

listen

```
$sock->listen(5);
```

Does the same thing that the `listen(2)` system call does. Returns true if it succeeded, false otherwise. Listens to a socket with a given queue size.

peername

```
my $sockaddr_in = $sock->peername();
```

Returns the packed `sockaddr` address of the other end of the socket connection. It calls `getpeername`.

protocol

```
my $proto = $sock->protocol();
```

Returns the number for the protocol being used on the socket, if known. If the protocol is unknown, as with an `AF_UNIX` socket, zero is returned.

recv

```
my $buffer = "";
my $length = 1024;
my $flags = 0; # default. optional
$sock->recv($buffer, $length);
$sock->recv($buffer, $length, $flags);
```

Similar in functionality to *"recv" in perlfunc*.

Receives a message on a socket. Attempts to receive `$length` characters of data into `$buffer` from the specified socket. `$buffer` will be grown or shrunk to the length actually read. Takes the same flags as the system call of the same name. Returns the address of the sender if socket's protocol supports this; returns an empty string otherwise. If there's an error, returns `undef`. This call is actually implemented in terms of the `recvfrom(2)` system call.

Flags are ORed together values, such as `MSG_BCAST`, `MSG_OOB`, `MSG_TRUNC`. The default value for the flags is `0`.

The cached value of *"peername" in IO::Socket* is updated with the result of `recv`.

Note: In Perl v5.30 and newer, if the socket has been marked as `:utf8`, `recv` will throw an exception. The `:encoding(...)` layer implicitly introduces the `:utf8` layer. See *"binmode" in perlfunc*.

Note: In Perl versions older than v5.30, depending on the status of the socket, either (8-bit) bytes or characters are received. By default all sockets operate on bytes, but for example if the socket has been changed using *"binmode" in perlfunc* to operate with the `:encoding(UTF-8)` I/O layer (see the *"open" in perlfunc* pragma), the I/O will operate on UTF8-encoded Unicode characters, not bytes. Similarly for the `:encoding` layer: in that case pretty much any characters can be read.

send

```
my $message = "Hello, world!";
my $flags = 0; # defaults to zero
my $to = '0.0.0.0'; # optional destination
my $sent = $sock->send($message);
$sent = $sock->send($message, $flags);
$sent = $sock->send($message, $flags, $to);
```

Similar in functionality to *"send" in perlfunc*.

Sends a message on a socket. Attempts to send the scalar message to the socket. Takes the same flags as the system call of the same name. On unconnected sockets, you must specify a destination to send to, in which case it does a `sendto(2)` syscall. Returns the number of characters sent, or `undef` on error. The `sendmsg(2)` syscall is currently unimplemented.

The `flags` option is optional and defaults to `0`.

After a successful send with `$to`, further calls to `send` on an unconnected socket without `$to` will send to the same address, and `$to` will be used as the result of *"peername" in IO::Socket*.

Note: In Perl v5.30 and newer, if the socket has been marked as `:utf8`, `send` will throw an exception. The `:encoding(...)` layer implicitly introduces the `:utf8` layer. See *"binmode" in perlfunc*.

Note: In Perl versions older than v5.30, depending on the status of the socket, either (8-bit) bytes or characters are sent. By default all sockets operate on bytes, but for example if the socket has been changed using *"binmode" in perlfunc* to operate with the `:encoding(UTF-8)` I/O layer (see the *"open" in perlfunc* pragma), the I/O will operate

on UTF8-encoded Unicode characters, not bytes. Similarly for the `:encoding` layer: in that case pretty much any characters can be sent.

setsockopt

```
$sock->setsockopt(SOL_SOCKET, SO_REUSEADDR, 1);
$sock->setsockopt(SOL_SOCKET, SO_RCVBUF, 64*1024);
```

Set option associated with the socket. Levels other than `SOL_SOCKET` may be specified here. As a convenience, this method will convert a number into a packed byte buffer.

shutdown

```
$sock->shutdown(SHUT_RD); # we stopped reading data
$sock->shutdown(SHUT_WR); # we stopped writing data
$sock->shutdown(SHUT_RDWR); # we stopped using this socket
```

Shuts down a socket connection in the manner indicated by the value passed in, which has the same interpretation as in the syscall of the same name.

This is useful with sockets when you want to tell the other side you're done writing but not done reading, or vice versa. It's also a more insistent form of `close` because it also disables the file descriptor in any forked copies in other processes.

Returns `1` for success; on error, returns `undef` if the socket is not a valid filehandle, or returns `0` and sets `$!` for any other failure.

sockdomain

```
my $domain = $sock->sockdomain();
```

Returns the number for the socket domain type. For example, for an `AF_INET` socket the value of `&AF_INET` will be returned.

socket

```
my $sock = IO::Socket->new(); # no values given
# now let's actually get a socket with the socket method
# domain, type, and protocol are required
$sock = $sock->socket(AF_INET, SOCK_STREAM, 'tcp');
```

Opens a socket of the specified kind and returns it. Domain, type, and protocol are specified the same as for the syscall of the same name.

socketpair

```
my ($r, $w) = $sock->socketpair(AF_UNIX, SOCK_STREAM, PF_UNSPEC);
($r, $w) = IO::Socket::UNIX
    ->socketpair(AF_UNIX, SOCK_STREAM, PF_UNSPEC);
```

Will return a list of two sockets created (read and write), or an empty list on failure.

Differs slightly from `socketpair` in *perlfunc* in that the argument list is a bit simpler.

sockname

```
my $packed_addr = $sock->sockname();
```

Returns the packed `sockaddr` address of this end of the connection. It's the same as `getsockname(2)`.

sockopt

```
my $value = $sock->sockopt(SO_REUSEADDR);
$sock->sockopt(SO_REUSEADDR, 1);
```

Unified method to both set and get options in the `SOL_SOCKET` level. If called with one argument then *"getsockopt" in IO::Socket* is called, otherwise *"setsockopt" in IO::Socket* is called.

socktype

```
my $type = $sock->socktype();
```

Returns the number for the socket type. For example, for a `SOCK_STREAM` socket the value of `&SOCK_STREAM` will be returned.

timeout

```
my $seconds = $sock->timeout();
my $old_val = $sock->timeout(5); # set new and return old value
```

Set or get the timeout value (in seconds) associated with this socket. If called without any arguments then the current setting is returned. If called with an argument the current setting is changed and the previous value returned.

This method is available to all `IO::Socket` implementations but may or may not be used by the individual domain subclasses.

EXAMPLES

Let's create a TCP server on `localhost:3333`.

```
use strict;
use warnings;
use feature 'say';

use IO::Socket qw(AF_INET AF_UNIX SOCK_STREAM SHUT_WR);

my $server = IO::Socket->new(
```

(continues on next page)

(continued from previous page)

```
    Domain => AF_INET,
    Type => SOCK_STREAM,
    Proto => 'tcp',
    LocalHost => '0.0.0.0',
    LocalPort => 3333,
    ReusePort => 1,
    Listen => 5,
) || die "Can't open socket: $IO::Socket::errstr";
say "Waiting on 3333";

while (1) {
    # waiting for a new client connection
    my $client = $server->accept();

    # get information about a newly connected client
    my $client_address = $client->peerhost();
    my $client_port = $client->peerport();
    say "Connection from $client_address:$client_port";

    # read up to 1024 characters from the connected client
    my $data = "";
    $client->recv($data, 1024);
    say "received data: $data";

    # write response data to the connected client
    $data = "ok";
    $client->send($data);

    # notify client that response has been sent
    $client->shutdown(SHUT_WR);
}

$server->close();
```

A client for such a server could be

```
use strict;
use warnings;
use feature 'say';

use IO::Socket qw(AF_INET AF_UNIX SOCK_STREAM SHUT_WR);

my $client = IO::Socket->new(
    Domain => AF_INET,
    Type => SOCK_STREAM,
    proto => 'tcp',
    PeerPort => 3333,
    PeerHost => '0.0.0.0',
) || die "Can't open socket: $IO::Socket::errstr";
```

(continues on next page)

(continued from previous page)

```
say "Sending Hello World!";
my $size = $client->send("Hello World!");
say "Sent data of length: $size";

$client->shutdown(SHUT_WR);

my $buffer;
$client->recv($buffer, 1024);
say "Got back $buffer";

$client->close();
```

LIMITATIONS

On some systems, for an IO::Socket object created with `new_from_fd`, or created with *"accept" in IO::Socket* from such an object, the *"protocol" in IO::Socket*, *"sockdomain" in IO::Socket* and *"socktype" in IO::Socket* methods may return `undef`.

IO::Socket::INET

Object interface for AF_INET domain sockets

SYNOPSIS

```
use IO::Socket::INET;
```

DESCRIPTION

`IO::Socket::INET` provides an object interface to creating and using sockets in the AF_INET domain. It is built upon the *IO::Socket* interface and inherits all the methods defined by *IO::Socket*.

CONSTRUCTOR

- new ([ARGS])

  Creates an `IO::Socket::INET` object, which is a reference to a newly created symbol (see the *Symbol* package). new optionally takes arguments, these arguments are in key-value pairs.

  In addition to the key-value pairs accepted by *IO::Socket*, `IO::Socket::INET` provides.

```
PeerAddr    Remote host address          <hostname>[:<port>]
PeerHost    Synonym for PeerAddr
PeerPort    Remote port or service       <service>[(<no>)] |
 ↪<no>
LocalAddr   Local host bind address      hostname[:port]
LocalHost   Synonym for LocalAddr
LocalPort   Local host bind port         <service>[(<no>)] |
 ↪<no>
Proto       Protocol name (or number)    "tcp" | "udp" | ...
Type        Socket type              SOCK_STREAM | SOCK_DGRAM |␣
 ↪...
Listen      Queue size for listen
ReuseAddr   Set SO_REUSEADDR before binding
Reuse       Set SO_REUSEADDR before binding (deprecated,
                                          prefer ReuseAddr)
ReusePort   Set SO_REUSEPORT before binding
Broadcast   Set SO_BROADCAST before binding
Timeout     Timeout value for various operations
```

(continues on next page)

(continued from previous page)

```
MultiHomed  Try all addresses for multi-homed hosts
Blocking    Determine if connection will be blocking mode
```

If `Listen` is defined then a listen socket is created, else if the socket type, which is derived from the protocol, is SOCK_STREAM then connect() is called. If the `Listen` argument is given, but false, the queue size will be set to 5.

Although it is not illegal, the use of `MultiHomed` on a socket which is in non-blocking mode is of little use. This is because the first connect will never fail with a timeout as the connect call will not block.

The `PeerAddr` can be a hostname or the IP-address on the "xx.xx.xx.xx" form. The `PeerPort` can be a number or a symbolic service name. The service name might be followed by a number in parenthesis which is used if the service is not known by the system. The `PeerPort` specification can also be embedded in the `PeerAddr` by preceding it with a ":".

If `Proto` is not given and you specify a symbolic `PeerPort` port, then the constructor will try to derive `Proto` from the service name. As a last resort `Proto` "tcp" is assumed. The `Type` parameter will be deduced from `Proto` if not specified.

If the constructor is only passed a single argument, it is assumed to be a `PeerAddr` specification.

If `Blocking` is set to 0, the connection will be in nonblocking mode. If not specified it defaults to 1 (blocking mode).

Examples:

```
$sock = IO::Socket::INET->new(PeerAddr => 'www.perl.org',
                              PeerPort => 'http(80)',
                              Proto    => 'tcp');

$sock = IO::Socket::INET->new(PeerAddr => 'localhost:smtp(25)');

$sock = IO::Socket::INET->new(Listen    => 5,
                              LocalAddr => 'localhost',
                              LocalPort => 9000,
                              Proto     => 'tcp');

$sock = IO::Socket::INET->new('127.0.0.1:25');

$sock = IO::Socket::INET->new(
                        PeerPort  => 9999,
                        PeerAddr  => inet_ntoa(INADDR_
↪BROADCAST),
                        Proto     => 'udp',
                        LocalAddr => 'localhost',
                        Broadcast => 1 )
                      or die "Can't bind : $IO::Socket::errstr\n";
```

If the constructor fails it will return `undef` and set the `$IO::Socket::errstr` package variable to contain an error message.

```
$sock = IO::Socket::INET->new(...)
    or die "Cannot create socket - $IO::Socket::errstr\n";
```

For legacy reasons the error message is also set into the global $@ variable, and you may still find older code which looks here instead.

```
$sock = IO::Socket::INET->new(...)
    or die "Cannot create socket - $@\n";
```

METHODS

- sockaddr ()

  Return the address part of the sockaddr structure for the socket

- sockport ()

  Return the port number that the socket is using on the local host

- sockhost ()

  Return the address part of the sockaddr structure for the socket in a text form xx.xx.xx.xx

- peeraddr ()

  Return the address part of the sockaddr structure for the socket on the peer host

- peerport ()

  Return the port number for the socket on the peer host.

- peerhost ()

  Return the address part of the sockaddr structure for the socket on the peer host in a text form xx.xx.xx.xx

IO::Socket::IP

Family-neutral IP socket supporting both IPv4 and IPv6

SYNOPSIS

```
use IO::Socket::IP;

my $sock = IO::Socket::IP->new(
   PeerHost => "www.google.com",
   PeerPort => "http",
   Type     => SOCK_STREAM,
) or die "Cannot construct socket - $IO::Socket::errstr";

my $familyname = ( $sock->sockdomain == PF_INET6 ) ? "IPv6" :
                 ( $sock->sockdomain == PF_INET  ) ? "IPv4" :
                                                     "unknown";

printf "Connected to google via %s\n", $familyname;
```

DESCRIPTION

This module provides a protocol-independent way to use IPv4 and IPv6 sockets, intended as a replacement for *IO::Socket::INET*. Most constructor arguments and methods are provided in a backward-compatible way. For a list of known differences, see the `IO::Socket::INET` INCOMPATIBILITIES section below.

It uses the `getaddrinfo(3)` function to convert hostnames and service names or port numbers into sets of possible addresses to connect to or listen on. This allows it to work for IPv6 where the system supports it, while still falling back to IPv4-only on systems which don't.

REPLACING `IO::Socket` DEFAULT BEHAVIOUR

By placing `-register` in the import list to `IO::Socket::IP`, it will register itself with *IO::Socket* as the class that handles `PF_INET`. It will also ask to handle `PF_INET6` as well, provided that constant is available.

Changing `IO::Socket`'s default behaviour means that calling the `IO::Socket` constructor with either `PF_INET` or `PF_INET6` as the `Domain` parameter will yield an `IO::Socket::IP` object.

```
use IO::Socket::IP -register;

my $sock = IO::Socket->new(
   Domain    => PF_INET6,
   LocalHost => "::1",
   Listen    => 1,
) or die "Cannot create socket - $IO::Socket::errstr\n";

print "Created a socket of type " . ref($sock) . "\n";
```

Note that `-register` is a global setting that applies to the entire program; it cannot be applied only for certain callers, removed, or limited by lexical scope.

CONSTRUCTORS

new

```
$sock = IO::Socket::IP->new( %args )
```

Creates a new `IO::Socket::IP` object, containing a newly created socket handle according to the named arguments passed. The recognised arguments are:

- PeerHost => STRING
- PeerService => STRING

  Hostname and service name for the peer to `connect()` to. The service name may be given as a port number, as a decimal string.

- PeerAddr => STRING
- PeerPort => STRING

  For symmetry with the accessor methods and compatibility with `IO::Socket::INET`, these are accepted as synonyms for `PeerHost` and `PeerService` respectively.

- PeerAddrInfo => ARRAY

  Alternate form of specifying the peer to `connect()` to. This should be an array of the form returned by `Socket::getaddrinfo`.

  This parameter takes precedence over the `Peer*`, `Family`, `Type` and `Proto` arguments.

- LocalHost => STRING
- LocalService => STRING

  Hostname and service name for the local address to `bind()` to.

- LocalAddr => STRING
- LocalPort => STRING

  For symmetry with the accessor methods and compatibility with `IO::Socket::INET`, these are accepted as synonyms for `LocalHost` and `LocalService` respectively.

- LocalAddrInfo => ARRAY

  Alternate form of specifying the local address to `bind()` to. This should be an array of the form returned by `Socket::getaddrinfo`.

  This parameter takes precedence over the `Local*`, `Family`, `Type` and `Proto` arguments.

- Family => INT

The address family to pass to `getaddrinfo` (e.g. `AF_INET`, `AF_INET6`). Normally this will be left undefined, and `getaddrinfo` will search using any address family supported by the system.

- Type => INT

  The socket type to pass to `getaddrinfo` (e.g. `SOCK_STREAM`, `SOCK_DGRAM`). Normally defined by the caller; if left undefined `getaddrinfo` may attempt to infer the type from the service name.

- Proto => STRING or INT

  The IP protocol to use for the socket (e.g. `'tcp'`, `IPPROTO_TCP`, `'udp'`,`IPPROTO_UDP`). Normally this will be left undefined, and either `getaddrinfo` or the kernel will choose an appropriate value. May be given either in string name or numeric form.

- GetAddrInfoFlags => INT

  More flags to pass to the `getaddrinfo()` function. If not supplied, a default of `AI_ADDRCONFIG` will be used.

  These flags will be combined with `AI_PASSIVE` if the `Listen` argument is given. For more information see the documentation about `getaddrinfo()` in the *Socket* module.

- Listen => INT

  If defined, puts the socket into listening mode where new connections can be accepted using the `accept` method. The value given is used as the `listen(2)` queue size.

- ReuseAddr => BOOL

  If true, set the `SO_REUSEADDR` sockopt

- ReusePort => BOOL

  If true, set the `SO_REUSEPORT` sockopt (not all OSes implement this sockopt)

- Broadcast => BOOL

  If true, set the `SO_BROADCAST` sockopt

- Sockopts => ARRAY

  An optional array of other socket options to apply after the three listed above. The value is an ARRAY containing 2- or 3-element ARRAYrefs. Each inner array relates to a single option, giving the level and option name, and an optional value. If the value element is missing, it will be given the value of a platform-sized integer 1 constant (i.e. suitable to enable most of the common boolean options).

  For example, both options given below are equivalent to setting `ReuseAddr`.

```
Sockopts => [
   [ SOL_SOCKET, SO_REUSEADDR ],
   [ SOL_SOCKET, SO_REUSEADDR, pack( "i", 1 ) ],
]
```

- V6Only => BOOL

If defined, set the IPV6_V6ONLY sockopt when creating PF_INET6 sockets to the given value. If true, a listening-mode socket will only listen on the AF_INET6 addresses; if false it will also accept connections from AF_INET addresses.

If not defined, the socket option will not be changed, and default value set by the operating system will apply. For repeatable behaviour across platforms it is recommended this value always be defined for listening-mode sockets.

Note that not all platforms support disabling this option. Some, at least OpenBSD and MirBSD, will fail with EINVAL if you attempt to disable it. To determine whether it is possible to disable, you may use the class method

```
if( IO::Socket::IP->CAN_DISABLE_V6ONLY ) {
   ...
}
else {
   ...
}
```

If your platform does not support disabling this option but you still want to listen for both AF_INET and AF_INET6 connections you will have to create two listening sockets, one bound to each protocol.

- MultiHomed

  This IO::Socket::INET-style argument is ignored, except if it is defined but false. See the IO::Socket::INET INCOMPATIBILITIES section below.

  However, the behaviour it enables is always performed by IO::Socket::IP.

- Blocking => BOOL

  If defined but false, the socket will be set to non-blocking mode. Otherwise it will default to blocking mode. See the NON-BLOCKING section below for more detail.

- Timeout => NUM

  If defined, gives a maximum time in seconds to block per connect() call when in blocking mode. If missing, no timeout is applied other than that provided by the underlying operating system. When in non-blocking mode this parameter is ignored.

  Note that if the hostname resolves to multiple address candidates, the same timeout will apply to each connection attempt individually, rather than to the operation as a whole. Further note that the timeout does not apply to the initial hostname resolve operation, if connecting by hostname.

  This behaviour is copied inspired by IO::Socket::INET; for more fine grained control over connection timeouts, consider performing a nonblocking connect directly.

If neither Type nor Proto hints are provided, a default of SOCK_STREAM and IPPROTO_TCP respectively will be set, to maintain compatibility with IO::Socket::INET. Other named arguments that are not recognised are ignored.

If neither Family nor any hosts or addresses are passed, nor any *AddrInfo, then the constructor has no information on which to decide a socket family to create. In this

case, it performs a `getaddrinfo` call with the `AI_ADDRCONFIG` flag, no host name, and a service name of `"0"`, and uses the family of the first returned result.

If the constructor fails, it will set `$IO::Socket::errstr` and `$@` to an appropriate error message; this may be from `$!` or it may be some other string; not every failure necessarily has an associated `errno` value.

new (one arg)

```
$sock = IO::Socket::IP->new( $peeraddr )
```

As a special case, if the constructor is passed a single argument (as opposed to an even-sized list of key/value pairs), it is taken to be the value of the `PeerAddr` parameter. This is parsed in the same way, according to the behaviour given in the `PeerHost` AND `LocalHost` PARSING section below.

METHODS

As well as the following methods, this class inherits all the methods in *IO::Socket* and *IO::Handle*.

sockhost_service

```
( $host, $service ) = $sock->sockhost_service( $numeric );
```

Returns the hostname and service name of the local address (that is, the socket address given by the `sockname` method).

If `$numeric` is true, these will be given in numeric form rather than being resolved into names.

The following four convenience wrappers may be used to obtain one of the two values returned here. If both host and service names are required, this method is preferable to the following wrappers, because it will call `getnameinfo(3)` only once.

sockhost

```
$addr = $sock->sockhost;
```

Return the numeric form of the local address as a textual representation

sockport

```
$port = $sock->sockport;
```

Return the numeric form of the local port number

sockhostname

```
$host = $sock->sockhostname;
```

Return the resolved name of the local address

sockservice

```
$service = $sock->sockservice;
```

Return the resolved name of the local port number

sockaddr

```
$addr = $sock->sockaddr;
```

Return the local address as a binary octet string

peerhost_service

```
( $host, $service ) = $sock->peerhost_service( $numeric );
```

Returns the hostname and service name of the peer address (that is, the socket address given by the `peername` method), similar to the `sockhost_service` method.

The following four convenience wrappers may be used to obtain one of the two values returned here. If both host and service names are required, this method is preferable to the following wrappers, because it will call `getnameinfo(3)` only once.

peerhost

```
$addr = $sock->peerhost;
```

Return the numeric form of the peer address as a textual representation

peerport

```
$port = $sock->peerport;
```

Return the numeric form of the peer port number

peerhostname

```
$host = $sock->peerhostname;
```

Return the resolved name of the peer address

peerservice

```
$service = $sock->peerservice;
```

Return the resolved name of the peer port number

peeraddr

```
$addr = $peer->peeraddr;
```

Return the peer address as a binary octet string

as_inet

```
$inet = $sock->as_inet;
```

Returns a new *IO::Socket::INET* instance wrapping the same filehandle. This may be useful in cases where it is required, for backward-compatibility, to have a real object of `IO::Socket::INET` type instead of `IO::Socket::IP`. The new object will wrap the same underlying socket filehandle as the original, so care should be taken not to continue to use both objects concurrently. Ideally the original `$sock` should be discarded after this method is called.

This method checks that the socket domain is `PF_INET` and will throw an exception if it isn't.

NON-BLOCKING

If the constructor is passed a defined but false value for the `Blocking` argument then the socket is put into non-blocking mode. When in non-blocking mode, the socket will not be set up by the time the constructor returns, because the underlying `connect(2)` syscall would otherwise have to block.

The non-blocking behaviour is an extension of the `IO::Socket::INET` API, unique to `IO::Socket::IP`, because the former does not support multi-homed non-blocking connect.

When using non-blocking mode, the caller must repeatedly check for writeability on the filehandle (for instance using `select` or `IO::Poll`). Each time the filehandle is ready to write, the `connect` method must be called, with no arguments. Note that some operating systems, most notably `MSWin32` do not report a `connect()` failure using write-ready; so you must also `select()` for exceptional status.

While `connect` returns false, the value of `$!` indicates whether it should be tried again (by being set to the value `EINPROGRESS`, or `EWOULDBLOCK` on MSWin32), or whether a permanent error has occurred (e.g. `ECONNREFUSED`).

Once the socket has been connected to the peer, `connect` will return true and the socket will now be ready to use.

Note that calls to the platform's underlying `getaddrinfo(3)` function may block. If `IO::Socket::IP` has to perform this lookup, the constructor will block even when in non-blocking mode.

To avoid this blocking behaviour, the caller should pass in the result of such a lookup using the `PeerAddrInfo` or `LocalAddrInfo` arguments. This can be achieved by using Net::LibAsyncNS, or the `getaddrinfo(3)` function can be called in a child process.

```
use IO::Socket::IP;
use Errno qw( EINPROGRESS EWOULDBLOCK );

my @peeraddrinfo = ... # Caller must obtain the getaddrinfo result
 ↪here

my $socket = IO::Socket::IP->new(
   PeerAddrInfo => \@peeraddrinfo,
   Blocking     => 0,
) or die "Cannot construct socket - $@";

while( !$socket->connect and ( $! == EINPROGRESS || $! ==
 ↪EWOULDBLOCK ) ) {
   my $wvec = '';
   vec( $wvec, fileno $socket, 1 ) = 1;
   my $evec = '';
   vec( $evec, fileno $socket, 1 ) = 1;

   select( undef, $wvec, $evec, undef ) or die "Cannot select - $!";
}

die "Cannot connect - $!" if $!;

...
```

The example above uses `select()`, but any similar mechanism should work analogously. `IO::Socket::IP` takes care when creating new socket filehandles to preserve the actual file descriptor number, so such techniques as `poll` or `epoll` should be transparent to its reallocation of a different socket underneath, perhaps in order to switch protocol family between `PF_INET` and `PF_INET6`.

For another example using `IO::Poll` and `Net::LibAsyncNS`, see the `examples/nonblocking_libasyncns.pl` file in the module distribution.

PeerHost AND LocalHost PARSING

To support the `IO::Socket::INET` API, the host and port information may be passed in a single string rather than as two separate arguments.

If either `LocalHost` or `PeerHost` (or their `...Addr` synonyms) have any of the following special forms then special parsing is applied.

The value of the `...Host` argument will be split to give both the hostname and port (or service name):

```
hostname.example.org:http    # Host name
192.0.2.1:80                 # IPv4 address
[2001:db8::1]:80             # IPv6 address
```

In each case, the port or service name (e.g. `80`) is passed as the `LocalService` or `PeerService` argument.

Either of `LocalService` or `PeerService` (or their `...Port` synonyms) can be either a service name, a decimal number, or a string containing both a service name and number, in a form such as

```
http(80)
```

In this case, the name (`http`) will be tried first, but if the resolver does not understand it then the port number (`80`) will be used instead.

If the `...Host` argument is in this special form and the corresponding `...Service` or `...Port` argument is also defined, the one parsed from the `...Host` argument will take precedence and the other will be ignored.

split_addr

```
( $host, $port ) = IO::Socket::IP->split_addr( $addr )
```

Utility method that provides the parsing functionality described above. Returns a 2-element list, containing either the split hostname and port description if it could be parsed, or the given address and `undef` if it was not recognised.

```
IO::Socket::IP->split_addr( "hostname:http" );
                             # ( "hostname",  "http" )

IO::Socket::IP->split_addr( "192.0.2.1:80" );
                             # ( "192.0.2.1", "80"   )

IO::Socket::IP->split_addr( "[2001:db8::1]:80" );
                             # ( "2001:db8::1", "80" )

IO::Socket::IP->split_addr( "something.else" );
                             # ( "something.else", undef )
```

join_addr

```
$addr = IO::Socket::IP->join_addr( $host, $port )
```

Utility method that performs the reverse of `split_addr`, returning a string formed by joining the specified host address and port number. The host address will be wrapped in `[]` brackets if required (because it is a raw IPv6 numeric address).

This can be especially useful when combined with the `sockhost_service` or `peerhost_service` methods.

```
say "Connected to ", IO::Socket::IP->join_addr( $sock->peerhost_
↪service );
```

IO::Socket::INET INCOMPATIBILITIES

- The behaviour enabled by `MultiHomed` is in fact implemented by `IO::Socket::IP` as it is required to correctly support searching for a useable address from the results of the `getaddrinfo(3)` call. The constructor will ignore the value of this argument, except if it is defined but false. An exception is thrown in this case, because that would request it disable the `getaddrinfo(3)` search behaviour in the first place.
- `IO::Socket::IP` implements both the `Blocking` and `Timeout` parameters, but it implements the interaction of both in a different way.

  In `::INET`, supplying a timeout overrides the non-blocking behaviour, meaning that the `connect()` operation will still block despite that the caller asked for a non-blocking socket. This is not explicitly specified in its documentation, nor does this author believe that is a useful behaviour - it appears to come from a quirk of implementation.

  In `::IP` therefore, the `Blocking` parameter takes precedence - if a non-blocking socket is requested, no operation will block. The `Timeout` parameter here simply defines the maximum time that a blocking `connect()` call will wait, if it blocks at all.

  In order to specifically obtain the "blocking connect then non-blocking send and receive" behaviour of specifying this combination of options to `::INET` when using `::IP`, perform first a blocking connect, then afterwards turn the socket into nonblocking mode.

```
my $sock = IO::Socket::IP->new(
   PeerHost => $peer,
   Timeout => 20,
) or die "Cannot connect - $@";

$sock->blocking( 0 );
```

  This code will behave identically under both `IO::Socket::INET` and `IO::Socket::IP`.

TODO

- Investigate whether `POSIX::dup2` upsets BSD's kqueue watchers, and if so, consider what possible workarounds might be applied.

IO::Socket::SSL

SSL sockets with IO::Socket interface

SYNOPSIS

```
use strict;
use IO::Socket::SSL;

# simple client
my $cl = IO::Socket::SSL->new('www.google.com:443');
print $cl "GET / HTTP/1.0\r\n\r\n";
print <$cl>;

# simple server
my $srv = IO::Socket::SSL->new(
    LocalAddr => '0.0.0.0:1234',
    Listen => 10,
    SSL_cert_file => 'server-cert.pem',
    SSL_key_file => 'server-key.pem',
);
$srv->accept;
```

DESCRIPTION

IO::Socket::SSL makes using SSL/TLS much easier by wrapping the necessary functionality into the familiar *IO::Socket* interface and providing secure defaults whenever possible. This way, existing applications can be made SSL-aware without much effort, at least if you do blocking I/O and don't use select or poll.

But, under the hood, SSL is a complex beast. So there are lots of methods to make it do what you need if the default behavior is not adequate. Because it is easy to inadvertently introduce critical security bugs or just hard to debug problems, I would recommend studying the following documentation carefully.

The documentation consists of the following parts:

- "Essential Information About SSL/TLS"
- "Basic SSL Client"
- "Basic SSL Server"
- "Common Usage Errors"
- "Common Problems with SSL"
- "Using Non-Blocking Sockets"
- "Advanced Usage"
- "Integration Into Own Modules"
- "Description Of Methods"

Additional documentation can be found in

- *IO::Socket::SSL::Intercept* - Doing Man-In-The-Middle with SSL
- *IO::Socket::SSL::Utils* - Useful functions for certificates etc

Essential Information About SSL/TLS

SSL (Secure Socket Layer) or its successor TLS (Transport Layer Security) are protocols to facilitate end-to-end security. These protocols are used when accessing web sites (https), delivering or retrieving email, and in lots of other use cases. In the following documentation we will refer to both SSL and TLS as simply 'SSL'.

SSL enables end-to-end security by providing two essential functions:

- Encryption

  This part encrypts the data for transit between the communicating parties, so that nobody in between can read them. It also provides tamper resistance so that nobody in between can manipulate the data.

- Identification

  This part makes sure that you talk to the right peer. If the identification is done incorrectly it is easy to mount man-in-the-middle attacks, e.g. if Alice wants to talk to Bob it would be possible for Mallory to put itself in the middle, so that Alice talks to Mallory and Mallory to Bob. All the data would still be encrypted, but not end-to-end between Alice and Bob, but only between Alice and Mallory and then between Mallory and Bob. Thus Mallory would be able to read and modify all traffic between Alice and Bob.

Identification is the part which is the hardest to understand and the easiest to get wrong.

With SSL, the Identification is usually done with **certificates** inside a **PKI** (Public Key Infrastructure). These Certificates are comparable to an identity card, which contains information about the owner of the card. The card then is somehow **signed** by the **issuer** of the card, the **CA** (Certificate Agency).

To verify the identity of the peer the following must be done inside SSL:

- Get the certificate from the peer. If the peer does not present a certificate we cannot verify it.
- Check if we trust the certificate, e.g. make sure it's not a forgery.

  We believe that a certificate is not a fake if we either know the certificate already or if we **trust** the issuer (the CA) and can verify the issuers signature on the certificate. In reality there is often a hierarchy of certificate agencies and we only directly trust the root of this hierarchy. In this case the peer not only sends his own certificate, but also all **intermediate certificates**. Verification will be done by building a **trust path** from the trusted root up to the peers certificate and checking in each step if the we can verify the issuer's signature.

  This step often causes problems because the client does not know the necessary trusted root certificates. These are usually stored in a system dependent CA store, but often the browsers have their own CA store.

- Check if the certificate is still valid. Each certificate has a lifetime and should not be used after that time because it might be compromised or the underlying cryptography got broken in the mean time.
- Check if the subject of the certificate matches the peer. This is like comparing the picture on the identity card against the person representing the identity card.

When connecting to a server this is usually done by comparing the hostname used for connecting against the names represented in the certificate. A certificate might contain multiple names or wildcards, so that it can be used for multiple hosts (e.g. *.example.com and *.example.org).

Although nobody sane would accept an identity card where the picture does not match the person we see, it is a common implementation error with SSL to omit this check or get it wrong.

- Check if the certificate was revoked by the issuer. This might be the case if the certificate was compromised somehow and now somebody else might use it to claim the wrong identity. Such revocations happened a lot after the heartbleed attack.

  For SSL there are two ways to verify a revocation, CRL and OCSP. With CRLs (Certificate Revocation List) the CA provides a list of serial numbers for revoked certificates. The client somehow has to download the list (which can be huge) and keep it up to date. With OCSP (Online Certificate Status Protocol) the client can check a single certificate directly by asking the issuer.

  Revocation is the hardest part of the verification and none of today's browsers get it fully correct. But, they are still better than most other implementations which don't implement revocation checks or leave the hard parts to the developer.

When accessing a web site with SSL or delivering mail in a secure way the identity is usually only checked one way, e.g. the client wants to make sure it talks to the right server, but the server usually does not care which client it talks to. But, sometimes the server wants to identify the client too and will request a certificate from the client which the server must verify in a similar way.

Basic SSL Client

A basic SSL client is simple:

```
my $client = IO::Socket::SSL->new('www.example.com:443')
    or die "error=$!, ssl_error=$SSL_ERROR";
```

This will take the OpenSSL default CA store as the store for the trusted CA. This usually works on UNIX systems. If there are no certificates in the store it will try use Mozilla::CA which provides the default CAs of Firefox.

In the default settings, *IO::Socket::SSL* will use a safer cipher set and SSL version, do a proper hostname check against the certificate, and use SNI (server name indication) to send the hostname inside the SSL handshake. This is necessary to work with servers which have different certificates behind the same IP address. It will also check the revocation of the certificate with OCSP, but currently only if the server provides OCSP stapling (for deeper checks see `ocsp_resolver` method).

Lots of options can be used to change ciphers, SSL version, location of CA and much more. See documentation of methods for details.

With protocols like SMTP it is necessary to upgrade an existing socket to SSL. This can be done like this:

```
my $client = IO::Socket::INET->new('mx.example.com:25') or die $!;
# .. read greeting from server
```

(continues on next page)

(continued from previous page)

```
# .. send EHLO and read response
# .. send STARTTLS command and read response
# .. if response was successful we can upgrade the socket to SSL␣
 ↪now:
IO::Socket::SSL->start_SSL($client,
    # explicitly set hostname we should use for SNI
    SSL_hostname => 'mx.example.com'
) or die $SSL_ERROR;
```

A more complete example for a simple HTTP client:

```
my $client = IO::Socket::SSL->new(
    # where to connect
    PeerHost => "www.example.com",
    PeerPort => "https",

    # certificate verification - VERIFY_PEER is default
    SSL_verify_mode => SSL_VERIFY_PEER,

    # location of CA store
    # need only be given if default store should not be used
    SSL_ca_path => '/etc/ssl/certs', # typical CA path on Linux
    SSL_ca_file => '/etc/ssl/cert.pem', # typical CA file on BSD

    # or just use default path on system:
    IO::Socket::SSL::default_ca(), # either explicitly
    # or implicitly by not giving SSL_ca_*

    # easy hostname verification
    # It will use PeerHost as default name a verification
    # scheme as default, which is safe enough for most purposes.
    SSL_verifycn_name => 'foo.bar',
    SSL_verifycn_scheme => 'http',

    # SNI support - defaults to PeerHost
    SSL_hostname => 'foo.bar',

) or die "failed connect or ssl handshake: $!,$SSL_ERROR";

# send and receive over SSL connection
print $client "GET / HTTP/1.0\r\n\r\n";
print <$client>;
```

And to do revocation checks with OCSP (only available with OpenSSL 1.0.0 or higher and *Net::SSLeay* 1.59 or higher):

```
# default will try OCSP stapling and check only leaf certificate
my $client = IO::Socket::SSL->new($dst);

# better yet: require checking of full chain
```

(continues on next page)

(continued from previous page)

```
my $client = IO::Socket::SSL->new(
    PeerAddr => $dst,
    SSL_ocsp_mode => SSL_OCSP_FULL_CHAIN,
);

# even better: make OCSP errors fatal
# (this will probably fail with lots of sites because of bad OCSP␣
↪setups)
# also use common OCSP response cache
my $ocsp_cache = IO::Socket::SSL::OCSP_Cache->new;
my $client = IO::Socket::SSL->new(
    PeerAddr => $dst,
    SSL_ocsp_mode => SSL_OCSP_FULL_CHAIN|SSL_OCSP_FAIL_HARD,
    SSL_ocsp_cache => $ocsp_cache,
);

# disable OCSP stapling in case server has problems with it
my $client = IO::Socket::SSL->new(
    PeerAddr => $dst,
    SSL_ocsp_mode => SSL_OCSP_NO_STAPLE,
);

# check any certificates which are not yet checked by OCSP stapling␣
↪or
# where we have already cached results. For your own resolving␣
↪combine
# $ocsp->requests with $ocsp->add_response(uri,response).
my $ocsp = $client->ocsp_resolver();
my $errors = $ocsp->resolve_blocking();
if ($errors) {
    warn "OCSP verification failed: $errors";
    close($client);
}
```

Basic SSL Server

A basic SSL server looks similar to other *IO::Socket* servers, only that it also contains settings for certificate and key:

```
# simple server
my $server = IO::Socket::SSL->new(
    # where to listen
    LocalAddr => '127.0.0.1',
    LocalPort => 8080,
    Listen => 10,

    # which certificate to offer
    # with SNI support there can be different certificates per␣
↪hostname
```

(continues on next page)

(continued from previous page)

```
    SSL_cert_file => 'cert.pem',
    SSL_key_file => 'key.pem',
) or die "failed to listen: $!";

# accept client
my $client = $server->accept or die
    "failed to accept or ssl handshake: $!,$SSL_ERROR";
```

This will automatically use a secure set of ciphers and SSL version and also supports Forward Secrecy with (Elliptic-Curve) Diffie-Hellmann Key Exchange.

If you are doing a forking or threading server, we recommend that you do the SSL handshake inside the new process/thread so that the master is free for new connections. We recommend this because a client with improper or slow SSL handshake could make the server block in the handshake which would be bad to do on the listening socket:

```
# inet server
my $server = IO::Socket::INET->new(
    # where to listen
    LocalAddr => '127.0.0.1',
    LocalPort => 8080,
    Listen => 10,
);

# accept client
my $client = $server->accept or die;

# SSL upgrade client (in new process/thread)
IO::Socket::SSL->start_SSL($client,
    SSL_server => 1,
    SSL_cert_file => 'cert.pem',
    SSL_key_file => 'key.pem',
) or die "failed to ssl handshake: $SSL_ERROR";
```

Like with normal sockets, neither forking nor threading servers scale well. It is recommended to use non-blocking sockets instead, see “Using Non-Blocking Sockets”

Common Usage Errors

This is a list of typical errors seen with the use of *IO::Socket::SSL*:

- Disabling verification with `SSL_verify_mode`.

  As described in “Essential Information About SSL/TLS”, a proper identification of the peer is essential and failing to verify makes Man-In-The-Middle attacks possible.

  Nevertheless, lots of scripts and even public modules or applications disable verification, because it is probably the easiest way to make the thing work and usually nobody notices any security problems anyway.

  If the verification does not succeed with the default settings, one can do the following:

  - Make sure the needed CAs are in the store, maybe use `SSL_ca_file` or `SSL_ca_path` to specify a different CA store.
  - If the validation fails because the certificate is self-signed and that's what you expect, you can use the `SSL_fingerprint` option to accept specific leaf certificates by their certificate or pubkey fingerprint.
  - If the validation failed because the hostname does not match and you cannot access the host with the name given in the certificate, you can use `SSL_verifycn_name` to specify the hostname you expect in the certificate.

  A common error pattern is also to disable verification if they found no CA store (different modules look at different "default" places). Because *IO::Socket::SSL* is now able to provide a usable CA store on most platforms (UNIX, Mac OSX and Windows) it is better to use the defaults provided by *IO::Socket::SSL*. If necessary these can be checked with the `default_ca` method.

- Polling of SSL sockets (e.g. select, poll and other event loops).

  If you sysread one byte on a normal socket it will result in a syscall to read one byte. Thus, if more than one byte is available on the socket it will be kept in the network stack of your OS and the next select or poll call will return the socket as readable. But, with SSL you don't deliver single bytes. Multiple data bytes are packaged and encrypted together in an SSL frame. Decryption can only be done on the whole frame, so a sysread for one byte actually reads the complete SSL frame from the socket, decrypts it and returns the first decrypted byte. Further sysreads will return more bytes from the same frame until all bytes are returned and the next SSL frame will be read from the socket.

  Thus, in order to decide if you can read more data (e.g. if sysread will block) you must check if there are still data in the current SSL frame by calling `pending` and if there are no data pending you might check the underlying socket with select or poll. Another way might be if you try to sysread at least 16kByte all the time. 16kByte is the maximum size of an SSL frame and because sysread returns data from only a single SSL frame you can guarantee that there are no pending data.

  Additionally, contrary to plain sockets the data delivered on the socket are not necessarily application payload. It might be a TLS handshake, it might just be the beginning of a TLS record or it might be TLS session tickets which are send after the TLS handshake in TLS 1.3. In such situations select will return that data are available for read since it only looks at the plain socket. A sysread on the IO::Socket::SSL socket will not return any data though since it is an abstraction which only returns application data. This causes the sysread to hang in case the socket was blocking or to return an error with EAGAIN on non-blocking sockets. Applications using select or similar should therefore set the socket to non-blocking and also expect that the sysread might temporarily fail with EAGAIN.

  See also "Using Non-Blocking Sockets".

- Expecting exactly the same behavior as plain sockets.

  IO::Socket::SSL tries to emulate the usual socket behavior as good as possible, but full emulation can not be done. Specifically a read on the SSL socket might also result in a write on the TCP socket or a write on the SSL socket might result in a read on the TCP socket. Also `accept` and **close** on the SSL socket will result in writing and reading data to the TCP socket too.

Especially the hidden writes might result in a connection reset if the underlying TCP socket is already closed by the peer. Unless signal PIPE is explicitly handled by the application this will usually result in the application crashing. It is thus recommended to explicitly IGNORE signal PIPE so that the errors get propagated as EPIPE instead of causing a crash of the application.

- Set 'SSL_version' or 'SSL_cipher_list' to a "better" value.

  IO::Socket::SSL tries to set these values to reasonable, secure values which are compatible with the rest of the world. But, there are some scripts or modules out there which tried to be smart and get more secure or compatible settings. Unfortunately, they did this years ago and never updated these values, so they are still forced to do only 'TLSv1' (instead of also using TLSv12 or TLSv11). Or they set 'HIGH' as the cipher list and thought they were secure, but did not notice that 'HIGH' includes anonymous ciphers, e.g. without identification of the peer.

  So it is recommended to leave the settings at the secure defaults which *IO::Socket::SSL* sets and which get updated from time to time to better fit the real world.

- Make SSL settings inaccessible by the user, together with bad builtin settings.

  Some modules use *IO::Socket::SSL*, but don't make the SSL settings available to the user. This is often combined with bad builtin settings or defaults (like switching verification off).

  Thus the user needs to hack around these restrictions by using `set_args_filter_hack` or similar.

- Use of constants as strings.

  Constants like `SSL_VERIFY_PEER` or `SSL_WANT_READ` should be used as constants and not be put inside quotes, because they represent numerical values.

- Forking and handling the socket in parent and child.

  A **fork** of the process will duplicate the internal user space SSL state of the socket. If both master and child interact with the socket by using their own SSL state strange error messages will happen. Such interaction includes explicit or implicit **close** of the SSL socket. To avoid this the socket should be explicitly closed with **SSL_no_shutdown**.

- Forking and executing a new process.

  Since the SSL state is stored in user space it will be duplicated by a **fork** but it will be lost when doing **exec**. This means it is not possible to simply redirect stdin and stdout for the new process to the SSL socket by duplicating the relevant file handles. Instead explicitly exchanging plain data between child-process and SSL socket are needed.

Common Problems with SSL

SSL is a complex protocol with multiple implementations and each of these has their own quirks. While most of these implementations work together, it often gets problematic with older versions, minimal versions in load balancers, or plain wrong setups.

Unfortunately these problems are hard to debug. Helpful for debugging are a knowledge of SSL internals, wireshark and the use of the debug settings of *IO::Socket::SSL* and

Net::SSLeay, which can both be set with `$IO::Socket::SSL::DEBUG`. The following debugs levels are defined, but used not in any consistent way:

- 0 - No debugging (default).
- 1 - Print out errors from *IO::Socket::SSL* and ciphers from *Net::SSLeay*.
- 2 - Print also information about call flow from *IO::Socket::SSL*, progress information from *Net::SSLeay* and state information from OpenSSL.
- 3 - Print also some data dumps from *IO::Socket::SSL* and from *Net::SSLeay*.

Also, `analyze-ssl.pl` from the ssl-tools repository at https://github.com/noxxi/p5-ssl-tools might be a helpful tool when debugging SSL problems, as do the `openssl` command line tool and a check with a different SSL implementation (e.g. a web browser).

The following problems are not uncommon:

- Bad server setup: missing intermediate certificates.

  It is a regular problem that administrators fail to include all necessary certificates into their server setup, e.g. everything needed to build the trust chain from the trusted root. If they check the setup with the browser everything looks ok, because browsers work around these problems by caching any intermediate certificates and apply them to new connections if certificates are missing.

  But, fresh browser profiles which have never seen these intermediates cannot fill in the missing certificates and fail to verify; the same is true with *IO::Socket::SSL*.

- Old versions of servers or load balancers which do not understand specific TLS versions or croak on specific data.

  From time to time one encounters an SSL peer, which just closes the connection inside the SSL handshake. This can usually be worked around by downgrading the SSL version, e.g. by setting `SSL_version`. Modern Browsers usually deal with such servers by automatically downgrading the SSL version and repeat the connection attempt until they succeed.

  Worse servers do not close the underlying TCP connection but instead just drop the relevant packet. This is harder to detect because it looks like a stalled connection. But downgrading the SSL version often works here too.

  A cause of such problems are often load balancers or security devices, which have hardware acceleration and only a minimal (and less robust) SSL stack. They can often be detected because they support much fewer ciphers than other implementations.

- Bad or old OpenSSL versions.

  IO::Socket::SSL uses OpenSSL with the help of the *Net::SSLeay* library. It is recommend to have a recent version of this library, because it has more features and usually fewer known bugs.

- Validation of client certificates fail.

  Make sure that the purpose of the certificate allows use as ssl client (check with `openssl x509 -purpose`, that the necessary root certificate is in the path specified by `SSL_ca*` (or the default path) and that any intermediate certificates needed to build the trust chain are sent by the client.

- Validation of self-signed certificate fails even if it is given with `SSL_ca*` argument.

  The `SSL_ca*` arguments do not give a general trust store for arbitrary certificates but only specify a store for CA certificates which then can be used to verify other certificates. This especially means that certificates which are not a CA get simply ignored, notably self-signed certificates which do not also have the CA-flag set.

  This behavior of OpenSSL differs from the more general trust-store concept which can be found in browsers and where it is possible to simply added arbitrary certificates (CA or not) as trusted.

Using Non-Blocking Sockets

If you have a non-blocking socket, the expected behavior on read, write, accept or connect is to set `$!` to EWOULDBLOCK if the operation cannot be completed immediately. Note that EWOULDBLOCK is the same as EAGAIN on UNIX systems, but is different on Windows.

With SSL, handshakes might occur at any time, even within an established connection. In these cases it is necessary to finish the handshake before you can read or write data. This might result in situations where you want to read but must first finish the write of a handshake or where you want to write but must first finish a read. In these cases `$!` is set to EAGAIN like expected, and additionally `$SSL_ERROR` is set to either SSL_WANT_READ or SSL_WANT_WRITE. Thus if you get EWOULDBLOCK on a SSL socket you must check `$SSL_ERROR` for SSL_WANT_* and adapt your event mask accordingly.

Using readline on non-blocking sockets does not make much sense and I would advise against using it. And, while the behavior is not documented for other *IO::Socket* classes, it will try to emulate the behavior seen there, e.g. to return the received data instead of blocking, even if the line is not complete. If an unrecoverable error occurs it will return nothing, even if it already received some data.

Also, I would advise against using `accept` with a non-blocking SSL object because it might block and this is not what most would expect. The reason for this is that `accept` on a non-blocking TCP socket (e.g. *IO::Socket::IP*, *IO::Socket::INET*..) results in a new TCP socket which does not inherit the non-blocking behavior of the master socket. And thus, the initial SSL handshake on the new socket inside `IO::Socket::SSL::accept` will be done in a blocking way. To work around this you are safer by doing a TCP accept and later upgrade the TCP socket in a non-blocking way with `start_SSL` and `accept_SSL`.

```
my $cl = IO::Socket::SSL->new($dst);
$cl->blocking(0);
my $sel = IO::Select->new($cl);
while (1) {
    # with SSL a call for reading n bytes does not result in reading␣
↪of n
    # bytes from the socket, but instead it must read at least one␣
↪full SSL
    # frame. If the socket has no new bytes, but there are␣
↪unprocessed data
    # from the SSL frame can_read will block!

    # wait for data on socket
```

(continues on next page)

(continued from previous page)

```
    $sel->can_read();

    # new data on socket or eof
    READ:
    # this does not read only 1 byte from socket, but reads the␣
↪complete SSL
    # frame and then just returns one byte. On subsequent calls it␣
↪than
    # returns more byte of the same SSL frame until it needs to read␣
↪the
    # next frame.
    my $n = sysread( $cl,my $buf,1);
    if ( ! defined $n ) {
        die $! if not $!{EWOULDBLOCK};
        next if $SSL_ERROR == SSL_WANT_READ;
        if ( $SSL_ERROR == SSL_WANT_WRITE ) {
            # need to write data on renegotiation
            $sel->can_write;
            next;
        }
        die "something went wrong: $SSL_ERROR";
    } elsif ( ! $n ) {
        last; # eof
    } else {
        # read next bytes
        # we might have still data within the current SSL frame
        # thus first process these data instead of waiting on the␣
↪underlying
        # socket object
        goto READ if $cl->pending;    # goto sysread
        next;                         # goto $sel->can_read
    }
}
```

Additionally there are differences to plain sockets when using select, poll, kqueue or similar technologies to get notified if data are available. Relying only on these calls is not sufficient in all cases since unread data might be internally buffered in the SSL stack. To detect such buffering **pending()** need to be used. Alternatively the buffering can be avoided by using **sysread** with the maximum size of an SSL frame. See “Common Usage Errors” for details.

Advanced Usage

SNI Support

Newer extensions to SSL can distinguish between multiple hostnames on the same IP address using Server Name Indication (SNI).

Support for SNI on the client side was added somewhere in the OpenSSL 0.9.8 series, but with 1.0 a bug was fixed when the server could not decide about its hostname. Therefore client side SNI is only supported with OpenSSL 1.0 or higher in

IO::Socket::SSL. With a supported version, SNI is used automatically on the client side, if it can determine the hostname from `PeerAddr` or `PeerHost` (which are synonyms in the underlying IO::Socket:: classes and thus should never be set both or at least not to different values). On unsupported OpenSSL versions it will silently not use SNI. The hostname can also be given explicitly given with `SSL_hostname`, but in this case it will throw in error, if SNI is not supported. To check for support you might call `IO::Socket::SSL->can_client_sni()`.

On the server side, earlier versions of OpenSSL are supported, but only together with *Net::SSLeay* version >= 1.50. To check for support you might call `IO::Socket::SSL->can_server_sni()`. If server side SNI is supported, you might specify different certificates per host with `SSL_cert*` and `SSL_key*`, and check the requested name using `get_servername`.

Talk Plain and SSL With The Same Socket

It is often required to first exchange some plain data and then upgrade the socket to SSL after some kind of STARTTLS command. Protocols like FTPS even need a way to downgrade the socket again back to plain.

The common way to do this would be to create a normal socket and use `start_SSL` to upgrade and stop_SSL to downgrade:

```
my $sock = IO::Socket::INET->new(...) or die $!;
... exchange plain data on $sock until starttls command ...
IO::Socket::SSL->start_SSL($sock,%sslargs) or die $SSL_ERROR;
... now $sock is an IO::Socket::SSL object ...
... exchange data with SSL on $sock until stoptls command ...
$sock->stop_SSL or die $SSL_ERROR;
... now $sock is again an IO::Socket::INET object ...
```

But, lots of modules just derive directly from *IO::Socket::INET*. While this base class can be replaced with *IO::Socket::SSL*, these modules cannot easily support different base classes for SSL and plain data and switch between these classes on a starttls command.

To help in this case, *IO::Socket::SSL* can be reduced to a plain socket on startup, and connect_SSL/accept_SSL/start_SSL can be used to enable SSL and `stop_SSL` to talk plain again:

```
my $sock = IO::Socket::SSL->new(
    PeerAddr => ...
    SSL_startHandshake => 0,
    %sslargs
) or die $!;
... exchange plain data on $sock until starttls command ...
$sock->connect_SSL or die $SSL_ERROR;
... now $sock is an IO::Socket::SSL object ...
... exchange data with SSL on $sock until stoptls command ...
$sock->stop_SSL or die $SSL_ERROR;
... $sock is still an IO::Socket::SSL object ...
... but data exchanged again in plain ...
```

Integration Into Own Modules

IO::Socket::SSL behaves similarly to other *IO::Socket* modules and thus could be integrated in the same way, but you have to take special care when using non-blocking I/O (like for handling timeouts) or using select or poll. Please study the documentation on how to deal with these differences.

Also, it is recommended to not set or touch most of the `SSL_*` options, so that they keep their secure defaults. It is also recommended to let the user override these SSL specific settings without the need of global settings or hacks like `set_args_filter_hack`.

The notable exception is `SSL_verifycn_scheme`. This should be set to the hostname verification scheme required by the module or protocol.

Description Of Methods

IO::Socket::SSL inherits from another *IO::Socket* module. The choice of the super class depends on the installed modules:

- If *IO::Socket::IP* with at least version 0.20 is installed it will use this module as super class, transparently providing IPv6 and IPv4 support.
- If IO::Socket::INET6 is installed it will use this module as super class, transparently providing IPv6 and IPv4 support.
- Otherwise it will fall back to *IO::Socket::INET*, which is a perl core module. With *IO::Socket::INET* you only get IPv4 support.

Please be aware that with the IPv6 capable super classes, it will look first for the IPv6 address of a given hostname. If the resolver provides an IPv6 address, but the host cannot be reached by IPv6, there will be no automatic fallback to IPv4. To avoid these problems you can enforce IPv4 for a specific socket by using the `Domain` or `Family` option with the value AF_INET as described in *IO::Socket::IP*. Alternatively you can enforce IPv4 globally by loading *IO::Socket::SSL* with the option 'inet4', in which case it will use the IPv4 only class *IO::Socket::INET* as the super class.

IO::Socket::SSL will provide all of the methods of its super class, but sometimes it will override them to match the behavior expected from SSL or to provide additional arguments.

The new or changed methods are described below, but please also read the section about SSL specific error handling.

- Error Handling

  If an SSL specific error occurs, the global variable `$SSL_ERROR` will be set. If the error occurred on an existing SSL socket, the method `errstr` will give access to the latest socket specific error. Both `$SSL_ERROR` and the `errstr` method give a dualvar similar to `$!`, e.g. providing an error number in numeric context or an error description in string context.

- **new(...)**

  Creates a new *IO::Socket::SSL* object. You may use all the friendly options that came bundled with the super class (e.g. *IO::Socket::IP*, *IO::Socket::INET*, ...) plus (optionally) the ones described below. If you don't specify any SSL related options it will

do its best in using secure defaults, e.g. choosing good ciphers, enabling proper verification, etc.

- SSL_server

  Set this option to a true value if the socket should be used as a server. If this is not explicitly set it is assumed if the `Listen` parameter is given when creating the socket.

- SSL_hostname

  This can be given to specify the hostname used for SNI, which is needed if you have multiple SSL hostnames on the same IP address. If not given it will try to determine the hostname from `PeerAddr`, which will fail if only an IP was given or if this argument is used within `start_SSL`.

  If you want to disable SNI, set this argument to ‘’.

  Currently only supported for the client side and will be ignored for the server side.

  See section “SNI Support” for details of SNI the support.

- SSL_startHandshake

  If this option is set to false (defaults to true) it will not start the SSL handshake yet. This has to be done later with `accept_SSL` or `connect_SSL`. Before the handshake is started read/write/etc. can be used to exchange plain data.

- SSL_keepSocketOnError

  If this option is set to true (defaults to false) it will not close the underlying TCP socket on errors. In most cases there is no real use for this behavior since both sides of the TCP connection will probably have a different idea of the current state of the connection.

- SSL_ca | SSL_ca_file | SSL_ca_path

  Usually you want to verify that the peer certificate has been signed by a trusted certificate authority. In this case you should use this option to specify the file (`SSL_ca_file`) or directory (`SSL_ca_path`) containing the certificate(s) of the trusted certificate authorities.

  `SSL_ca_path` can also be an array or a string containing multiple path, where the path are separated by the platform specific separator. This separator is `;` on DOS, Windows, Netware, `,` on VMS and `:` for all the other systems. If multiple path are given at least one of these must be accessible.

  You can also give a list of X509* certificate handles (like you get from *Net::SSLeay* or IO::Socket::SSL::Utils::PEM_xxx2cert) with `SSL_ca`. These will be added to the CA store before path and file and thus take precedence. If neither SSL_ca, nor SSL_ca_file or SSL_ca_path are set it will use `default_ca()` to determine the user-set or system defaults. If you really don’t want to set a CA set SSL_ca_file or SSL_ca_path to `\undef` or SSL_ca to an empty list. (unfortunately `''` is used by some modules using *IO::Socket::SSL* when CA is not explicitly given).

- SSL_client_ca | SSL_client_ca_file

If verify_mode is VERIFY_PEER on the server side these options can be used to set the list of acceptable CAs for the client. This way the client can select they required certificate from a list of certificates. The value for these options is similar to `SSL_ca` and `SSL_ca_file`.

– SSL_fingerprint

Sometimes you have a self-signed certificate or a certificate issued by an unknown CA and you really want to accept it, but don't want to disable verification at all. In this case you can specify the fingerprint of the certificate as `'algo$hex_fingerprint'`. `algo` is a fingerprint algorithm supported by OpenSSL, e.g. 'sha1','sha256'... and `hex_fingerprint` is the hexadecimal representation of the binary fingerprint. Any colons inside the hex string will be ignored.

If you want to use the fingerprint of the pubkey inside the certificate instead of the certificate use the syntax `'algo$pub$hex_fingerprint'` instead. To get the fingerprint of an established connection you can use `get_fingerprint`.

It is also possible to skip `algo$`, i.e. only specify the fingerprint. In this case the likely algorithms will be automatically detected based on the length of the digest string.

Examples:

```
sha1$pub$f0f0c49b8a04a2dd2110e10f7806c97d87d0b26f  # pubkey␣
↪SHA-1
sha1$f0f0c49b8a04a2dd2110e10f7806c97d87d0b26f      #␣
↪certificate SHA-1
f0f0c49b8a04a2dd2110e10f7806c97d87d0b26f           #␣
↪certificate SHA-1
```

You can specify a list of fingerprints in case you have several acceptable certificates. If a fingerprint matches the topmost (i.e. leaf) certificate no additional validations can make the verification fail.

Note that the default behavior of SSL_fingerprint is to be an alternative to the normal validation. A mismatching fingerprint does not override a successful validation of the certificate, but a matching fingerprint can override an otherwise failed validation. To enforce a fingerprint see `SSL_force_fingerprint`.

– SSL_force_fingerprint

Set this to true to enforce strict certificate pinning: the connection will be rejected unless the peer certificate matches one of the fingerprints given in `SSL_fingerprint`, even if the certificate chain would otherwise be trusted.

Without this option, `SSL_fingerprint` acts as an alternative trust anchor — a matching fingerprint can unlock an otherwise-rejected certificate (e.g. self-signed or from an unknown CA), but a non-matching fingerprint does not block a certificate that passes normal chain validation. With this option, the fingerprint check is the sole trust decision: any certificate not in the fingerprint list is rejected regardless of CA trust.

– SSL_cert_file | SSL_cert | SSL_key_file | SSL_key

If you create a server you usually need to specify a server certificate which should be verified by the client. Same is true for client certificates, which should be verified by the server. The certificate can be given as a file with SSL_cert_file or as an internal representation of an X509* object (like you get from *Net::SSLeay* or IO::Socket::SSL::Utils::PEM_xxx2cert) with SSL_cert. If given as a file it will automatically detect the format. Supported file formats are PEM, DER and PKCS#12, where PEM and PKCS#12 can contain the certificate and the chain to use, while DER can only contain a single certificate.

If given as a list of X509* please note, that the all the chain certificates (e.g. all except the first) will be "consumed" by openssl and will be freed if the SSL context gets destroyed - so you should never free them yourself. But the servers certificate (e.g. the first) will not be consumed by openssl and thus must be freed by the application.

For each certificate a key is need, which can either be given as a file with SSL_key_file or as an internal representation of an EVP_PKEY* object with SSL_key (like you get from *Net::SSLeay* or IO::Socket::SSL::Utils::PEM_xxx2key). If a key was already given within the PKCS#12 file specified by SSL_cert_file it will ignore any SSL_key or SSL_key_file. If no SSL_key or SSL_key_file was given it will try to use the PEM file given with SSL_cert_file again, maybe it contains the key too.

If your SSL server should be able to use different certificates on the same IP address, depending on the name given by SNI, you can use a hash reference instead of a file with <hostname = cert_file>>.

If your SSL server should be able to use both RSA and ECDSA certificates for the same domain/IP a similar hash reference like with SNI is given. The domain names used to specify the additional certificates should be `hostname%whatever`, i.e. `hostname%ecc` or similar. This needs at least OpenSSL 1.0.2. To let the server pick the certificate based on the clients cipher preference `SSL_honor_cipher_order` should be set to false.

In case certs and keys are needed but not given it might fall back to builtin defaults, see "Defaults for Cert, Key and CA".

Examples:

```
SSL_cert_file => 'mycert.pem',
SSL_key_file => 'mykey.pem',

SSL_cert_file => {
   "foo.example.org" => 'foo-cert.pem',
   "foo.example.org%ecc" => 'foo-ecc-cert.pem',
   "bar.example.org" => 'bar-cert.pem',
   # used when nothing matches or client does not support SNI
   '' => 'default-cert.pem',
   '%ecc' => 'default-ecc-cert.pem',
},
SSL_key_file => {
   "foo.example.org" => 'foo-key.pem',
   "foo.example.org%ecc" => 'foo-ecc-key.pem',
   "bar.example.org" => 'bar-key.pem',
```

(continues on next page)

(continued from previous page)

```
    # used when nothing matches or client does not support SNI
    '' => 'default-key.pem',
    '%ecc' => 'default-ecc-key.pem',
}
```

– SSL_passwd_cb

  If your private key is encrypted, you might not want the default password prompt from Net::SSLeay. This option takes a reference to a subroutine that should return the password required to decrypt your private key.

– SSL_use_cert

  If this is true, it forces IO::Socket::SSL to use a certificate and key, even if you are setting up an SSL client. If this is set to 0 (the default), then you will only need a certificate and key if you are setting up a server.

  SSL_use_cert will implicitly be set if SSL_server is set. For convenience it is also set if it was not given but a cert was given for use (SSL_cert_file or similar).

– SSL_version

  Sets the version of the SSL protocol used to transmit data. 'SSLv23' uses a handshake compatible with SSL2.0, SSL3.0 and TLS1.x, while 'SSLv2', 'SSLv3', 'TLSv1', 'TLSv1_1', 'TLSv1_2', or 'TLSv1_3' restrict handshake and protocol to the specified version. All values are case-insensitive. Instead of 'TLSv1_1', 'TLSv1_2', and 'TLSv1_3' one can also use 'TLSv11', 'TLSv12', and 'TLSv13'. Which protocol versions are actually supported depend on the versions of OpenSSL and Net::SSLeay installed, but modern protocols like TLS 1.3 are supported by these for many years now.

  Independent from the handshake format you can limit to set of accepted SSL versions by adding !version separated by ':'.

  The default SSL_version is 'SSLv23:!TLSv1:!TLSv1_1:!SSLv3:!SSLv2'. This means, that the handshake format is compatible to SSL2.0 and higher, but that the successful handshake is limited to TLS1.2 and higher, that is no SSL2.0, SSL3.0, TLS 1.0 or TLS 1.1 because these versions have serious security issues and should not be used anymore.

  You can also use !TLSv1_1 and !TLSv1_2 to disable TLS versions 1.1 and 1.2 while still allowing TLS version 1.0. Setting the version instead to 'TLSv1' might break interaction with very old or broken clients, which expect a SSL2.0 compatible handshake. On the other side some broken clients just close the connection when they receive a TLS version 1.1 request. In this case setting the version to 'SSLv23:!SSLv2:!SSLv3:!TLSv1_1:!TLSv1_2' might help.

– SSL_cipher_list

  If this option is set the cipher list for the connection will be set to the given value, e.g. something like 'ALL:!LOW:!EXP:!aNULL'. This will only affect ciphers for TLS 1.2 and lower. See the OpenSSL documentation (https://www.openssl.org/docs/manmaster/man1/openssl-ciphers.html#CIPHER-STRINGS) for more details.

Unless you fail to contact your peer because of no shared ciphers it is recommended to leave this option at the default setting, which uses the system default but disables some insecure ciphers which might still be enabled on older systems.

In case different cipher lists are needed for different SNI hosts a hash can be given with the host as key and the cipher suite as value, similar to **SSL_cert***.

– SSL_ciphersuites

If this option is set the TLS 1.3 ciphersuites for the connection will be set to the given value. This is similar to SSL_cipher_list, but only for TLS 1.3 ciphers. See argument `-ciphersuites` in the OpenSSL documentation (https://www.openssl.org/docs/manmaster/man1/openssl-ciphers.html) for details.

Unless you fail to contact your peer because of no shared ciphers it is recommended to leave this option at the default setting, which uses the system default.

In case different cipher lists are needed for different SNI hosts a hash can be given with the host as key and the cipher suite as value, similar to **SSL_cert***.

– SSL_honor_cipher_order

If this option is true the cipher order the server specified is used instead of the order proposed by the client. This option defaults to true to make use of our secure cipher list setting.

– SSL_dh_file

To create a server which provides forward secrecy you need to either give the DH parameters or (better, because faster) the ECDH curve. This setting cares about DH parameters.

To support non-elliptic Diffie-Hellman key exchange a suitable file needs to be given here or the SSL_dh should be used with an appropriate value. See dhparam command in openssl for more information.

If neither `SSL_dh_file` nor `SSL_dh` are set a builtin DH parameter with a length of 2048 bit is used to offer DH key exchange by default. If you don't want this (e.g. disable DH key exchange) explicitly set this or the `SSL_dh` parameter to undef.

– SSL_dh

Like SSL_dh_file, but instead of giving a file you use a preloaded or generated DH*.

– SSL_ecdh_curve

To create a server which provides forward secrecy you need to either give the DH parameters or (better, because faster) the ECDH curve. This setting cares about the ECDH curve(s).

To support Elliptic Curve Diffie-Hellmann key exchange the OID or NID of at least one suitable curve needs to be provided here.

With OpenSSL 1.1.0+ this parameter defaults to `auto`, which means that it lets OpenSSL pick the best settings. If support for CTX_set_ecdh_auto is implemented in Net::SSLeay (needs at least version 1.86) it will use this to implement

the same default. Otherwise it will default to `prime256v1` (builtin of OpenSSL) in order to offer ECDH key exchange by default.

If setting groups or curves is supported by Net::SSLeay (needs at least version 1.86) then multiple curves can be given here in the order of the preference, i.e. `P-521:P-384:P-256`. When used at the client side this will include the supported curves as extension in the TLS handshake.

If you don't want to have ECDH key exchange this could be set to undef or set `SSL_ciphers` to exclude all of these ciphers.

You can check if ECDH support is available by calling `IO::Socket::SSL->can_ecdh`.

– SSL_verify_mode

This option sets the verification mode for the peer certificate. You may combine SSL_VERIFY_PEER (verify_peer), SSL_VERIFY_FAIL_IF_NO_PEER_CERT (fail verification if no peer certificate exists; ignored for clients), SSL_VERIFY_CLIENT_ONCE (verify client once; ignored for clients). Note that SSL_VERIFY_FAIL_IF_NO_PEER_CERT and SSL_VERIFY_CLIENT_ONCE must be used together with SSL_VERIFY_PEER. See OpenSSL man page for SSL_CTX_set_verify for more information.

The default is SSL_VERIFY_NONE for server (e.g. no check for client certificate) and SSL_VERIFY_PEER for client (check server certificate).

– SSL_verify_callback

If you want to verify certificates yourself, you can pass a sub reference along with this parameter to do so. When the callback is called, it will be passed:

1. a true/false value that indicates what OpenSSL thinks of the certificate,
2. a C-style memory address of the certificate store,
3. a string containing the certificate's issuer attributes and owner attributes, and
4. a string containing any errors encountered (0 if no errors).
5. a C-style memory address of the peer's own certificate (convertible to PEM form with Net::SSLeay::PEM_get_string_X509()).
6. The depth of the certificate in the chain. Depth 0 is the leaf certificate.

The function should return 1 or 0, depending on whether it thinks the certificate is valid or invalid. The default is to let OpenSSL do all of the busy work.

The callback will be called for each element in the certificate chain.

See the OpenSSL documentation for SSL_CTX_set_verify for more information.

– SSL_verifycn_scheme

The scheme is used to correctly verify the identity inside the certificate by using the hostname of the peer. See the information about the verification schemes in **verify_hostname**.

If you don't specify a scheme it will use 'default', but only complain loudly if the name verification fails instead of letting the whole certificate verification

fail. THIS WILL CHANGE, e.g. it will let the certificate verification fail in the future if the hostname does not match the certificate !!!! To override the name used in verification use **SSL_verifycn_name**.

The scheme 'default' is a superset of the usual schemes, which will accept the hostname in common name and subjectAltName and allow wildcards everywhere. While using this scheme is way more secure than no name verification at all you better should use the scheme specific to your application protocol, e.g. 'http', 'ftp'...

If you are really sure, that you don't want to verify the identity using the hostname you can use 'none' as a scheme. In this case you'd better have alternative forms of verification, like a certificate fingerprint or do a manual verification later by calling **verify_hostname** yourself.

– SSL_verifycn_publicsuffix

This option is used to specify the behavior when checking wildcards certificates for public suffixes, e.g. no wildcard certificates for *.com or *.co.uk should be accepted, while *.example.com or *.example.co.uk is ok.

If not specified it will simply use the builtin default of *IO::Socket::SSL::PublicSuffix*, you can create another object with from_string or from_file of this module.

To disable verification of public suffix set this option to `''`.

– SSL_verifycn_name

Set the name which is used in verification of hostname. If SSL_verifycn_scheme is set and no SSL_verifycn_name is given it will try to use SSL_hostname or PeerHost and PeerAddr settings and fail if no name can be determined. If SSL_verifycn_scheme is not set it will use a default scheme and warn if it cannot determine a hostname, but it will not fail.

Using PeerHost or PeerAddr works only if you create the connection directly with `IO::Socket::SSL->new`, if an IO::Socket::INET object is upgraded with **start_SSL** the name has to be given in **SSL_verifycn_name** or **SSL_hostname**.

– SSL_check_crl

If you want to verify that the peer certificate has not been revoked by the signing authority, set this value to true. OpenSSL will search for the CRL in your SSL_ca_path, or use the file specified by SSL_crl_file. See the Net::SSLeay documentation for more details.

– SSL_crl_file

If you want to specify the CRL file to be used, set this value to the pathname to be used. This must be used in addition to setting SSL_check_crl.

– SSL_ocsp_mode

Defines how certificate revocation is done using OCSP (Online Status Revocation Protocol). The default is to send a request for OCSP stapling to the server and if the server sends an OCSP response back the result will be used.

Any other OCSP checking needs to be done manually with `ocsp_resolver`.

The following flags can be combined with `|`:

* SSL_OCSP_NO_STAPLE

  Don't ask for OCSP stapling. This is the default if SSL_verify_mode is VERIFY_NONE.

* SSL_OCSP_TRY_STAPLE

  Try OCSP stapling, but don't fail if no usable stapled response is received. Both a missing staple and a broken or unverifiable staple are treated the same: the connection continues without OCSP revocation information from the staple. This is the default if SSL_verify_mode is VERIFY_PEER (the default).

* SSL_OCSP_MUST_STAPLE

  Require a valid stapled OCSP response; fail the connection if none is received. A broken or unverifiable staple is treated the same as a missing one — both cause the connection to fail with "did not receive the required stapled OCSP response". Most servers currently send no stapled OCSP response back.

* SSL_OCSP_FAIL_HARD

  Fail hard on response errors, default is to fail soft like the browsers do. Soft errors mean, that the OCSP response is not usable, e.g. no response, error response, no valid signature etc. Certificate revocations inside a verified response are considered hard errors in any case.

  Soft errors inside a stapled response are never considered hard, e.g. it is expected that in this case an OCSP request will be send to the responsible OCSP responder.

* SSL_OCSP_FULL_CHAIN

  This will set up the `ocsp_resolver` so that all certificates from the peer chain will be checked, otherwise only the leaf certificate will be checked against revocation.

– SSL_ocsp_staple_callback

  If this callback is defined, it will be called with the SSL object and the OCSP response handle obtained from the peer, e.g. `<$cb-($ssl,$resp)>>`. If the peer did not provide a stapled OCSP response the function will be called with `$resp=undef`. Because the OCSP response handle is no longer valid after leaving this function it should not by copied or freed. If access to the response is necessary after leaving this function it can be serialized with `Net::SSLeay::i2d_OCSP_RESPONSE`.

  If no such callback is provided, it will use the default one, which verifies the response and uses it to check if the certificate(s) of the connection got revoked.

– SSL_ocsp_cache

  With this option a cache can be given for caching OCSP responses, which could be shared between different SSL contexts. If not given a cache specific to the SSL context only will be used.

  You can either create a new cache with `IO::Socket::SSL::OCSP_Cache->new([size])` or implement your own cache, which needs to have methods `put($key,`

\%entry) and get($key) (returning \%entry) where entry is the hash representation of the OCSP response with fields like nextUpdate. The default implementation of the cache will consider responses valid as long as nextUpdate is less then the current time.

– SSL_psk

PSK to use instead of certificate. Requires the peer to use the same PSK.

On the client side the identity and psk need to be provided as array-ref with <[identity,psk]>. Alternatively only the psk might be provided, in which case io_socket_ssl is used as identity. On the server side a single psk might be given which will then be use no matter which identity hint was given by the client. Alternatively a hash-ref can be provided with identity as key and psk as value to serve clients with different psk based on the identity hint. The special identity '' is used to set a default psk.

To use PSK make sure to have the relevant ciphers enabled. With TLS 1.3 this is implicit, but with TLS 1.2 and lower explicitly add PSK to SSL_cipher_list since it is not enabled by default.

Note that the given psk is expected to be binary and not hexadecimal as some other tools do. To convert hex to binary use pack("H*",hexstring). Also note that the error messages one gets if either identity or psk don't match the configuration in the peer can be useless ("handshake failure") or misleading ("bad mac").

PSK support needs respective API functionality in Net::SSLeay, which was only fully included in 1.94. IO::Socket::SSL->can_psk() returns undef if functionality is not available and a hash-ref with details otherwise: key client in the hash signals support for using PSK in a SSL client (available since Net::SSLeay 1.82) while key server for support of PSK in SSL server (since Net::SSLeay 1.94).

– SSL_reuse_ctx

If you have already set the above options for a previous instance of IO::Socket::SSL, then you can reuse the SSL context of that instance by passing it as the value for the SSL_reuse_ctx parameter. You may also create a new instance of the IO::Socket::SSL::SSL_Context class, using any context options that you desire without specifying connection options, and pass that here instead.

If you use this option, all other context-related options that you pass in the same call to new() will be ignored unless the context supplied was invalid. Note that, contrary to versions of IO::Socket::SSL below v0.90, a global SSL context will not be implicitly used unless you use the set_default_context() function.

– SSL_create_ctx_callback

With this callback you can make individual settings to the context after it got created and the default setup was done. The callback will be called with the CTX object from Net::SSLeay as the single argument.

Example for limiting the server session cache size:

```
SSL_create_ctx_callback => sub {
    my $ctx = shift;
    Net::SSLeay::CTX_sess_set_cache_size($ctx,128);
}
```

– SSL_session_cache_size

  If you make repeated connections to the same host/port and the SSL renegotiation time is an issue, you can turn on client-side session caching with this option by specifying a positive cache size. For successive connections, pass the SSL_reuse_ctx option to the new() calls (or use set_default_context()) to make use of the cached sessions. The session cache size refers to the number of unique host/port pairs that can be stored at one time; the oldest sessions in the cache will be removed if new ones are added.

  This option does not effect the session cache a server has for it's clients, e.g. it does not affect SSL objects with SSL_server set.

  Note that session caching with TLS 1.3 needs at least Net::SSLeay 1.86.

– SSL_session_cache

  Specifies session cache object which should be used instead of creating a new. Overrules SSL_session_cache_size. This option is useful if you want to reuse the cache, but not the rest of the context.

  A session cache object can be created using `IO::Socket::SSL::Session_Cache->new( cachesize )`.

  Use set_default_session_cache() to set a global cache object.

– SSL_session_key

  Specifies a key to use for lookups and inserts into client-side session cache. Per default ip:port of destination will be used, but sometimes you want to share the same session over multiple ports on the same server (like with FTPS).

– SSL_session_id_context

  This gives an id for the servers session cache. It's necessary if you want clients to connect with a client certificate. If not given but SSL_verify_mode specifies the need for client certificate a context unique id will be picked.

– SSL_error_trap

  When using the accept() or connect() methods, it may be the case that the actual socket connection works but the SSL negotiation fails, as in the case of an HTTP client connecting to an HTTPS server. Passing a subroutine ref attached to this parameter allows you to gain control of the orphaned socket instead of having it be closed forcibly. The subroutine, if called, will be passed two parameters: a reference to the socket on which the SSL negotiation failed and the full text of the error message.

– SSL_npn_protocols

  If used on the server side it specifies list of protocols advertised by SSL server as an array ref, e.g. ['spdy/2','http1.1']. On the client side it specifies the

protocols offered by the client for NPN as an array ref. See also method `next_proto_negotiated`.

Next Protocol Negotiation (NPN) is available with Net::SSLeay 1.46+ and openssl-1.0.1+. NPN is unavailable in TLSv1.3 protocol. To check support you might call `IO::Socket::SSL->can_npn()`. If you use this option with an unsupported Net::SSLeay/OpenSSL it will throw an error.

– SSL_alpn_protocols

If used on the server side it specifies list of protocols supported by the SSL server as an array ref, e.g. ['http/2.0', 'spdy/3.1','http/1.1']. On the client side it specifies the protocols advertised by the client for ALPN as an array ref. See also method `alpn_selected`.

Application-Layer Protocol Negotiation (ALPN) is available with Net::SSLeay 1.56+ and openssl-1.0.2+. More details about the extension are in RFC7301. To check support you might call `IO::Socket::SSL->can_alpn()`. If you use this option with an unsupported Net::SSLeay/OpenSSL it will throw an error.

Note that some client implementations may encounter problems if both NPN and ALPN are specified. Since ALPN is intended as a replacement for NPN, try providing ALPN protocols then fall back to NPN if that fails.

– SSL_ticket_keycb => [$sub,$data] | $sub

This is a callback used for stateless session reuse (Session Tickets, RFC 5077).

This callback will be called as `$sub->($data,[$key_name])` where `$data` is the argument given to SSL_ticket_keycb (or undef) and `$key_name` depends on the mode:

* encrypt ticket

  If a ticket needs to be encrypted the callback will be called without `$key_name`. In this case it should return (`$current_key`, `$current_key_name`) where `$current_key` is the current key (32 byte random data) and `$current_key_name` the name associated with this key (exactly 16 byte). This `$current_key_name` will be incorporated into the ticket.

* decrypt ticket

  If a ticket needs to be decrypted the callback will be called with `$key_name` as found in the ticket. It should return (`$key`,`$current_key_name`) where `$key` is the key associated with the given `$key_name` and `$current_key_name` the name associated with the currently active key. If `$current_key_name` is different from the given `$key_name` the callback will be called again to re-encrypt the ticket with the currently active key.

  If no key can be found which matches the given `$key_name` then this function should return nothing (empty list).

  This mechanism should be used to limit the life time for each key encrypting the ticket. Compromise of a ticket encryption key might lead to decryption of SSL sessions which used session tickets protected by this key.

Example:

```
Net::SSLeay::RAND_bytes(my $oldkey,32);
Net::SSLeay::RAND_bytes(my $newkey,32);
my $oldkey_name = pack("a16",'oldsecret');
my $newkey_name = pack("a16",'newsecret');

my @keys = (
   [ $newkey_name, $newkey ], # current active key
   [ $oldkey_name, $oldkey ], # already expired
);

my $keycb = [ sub {
   my ($mykeys,$name) = @_;

   # return (current_key, current_key_name) if no name given
   return ($mykeys->[0][1],$mykeys->[0][0]) if ! $name;

   # return (matching_key, current_key_name) if we find a
 ↪key matching
   # the given name
   for(my $i = 0; $i<@$mykeys; $i++) {
       next if $name ne $mykeys->[$i][0];
       return ($mykeys->[$i][1],$mykeys->[0][0]);
   }

   # no matching key found
   return;
},\@keys ];

my $srv = IO::Socket::SSL->new(..., SSL_ticket_keycb =>
 ↪$keycb);
```

– SSL_on_peer_shutdown CODE

  This defines a callback which gets called on receiving SSL shutdown (close notify) from the peer. This can be used to override the default behavior, see `stop_SSL` for more.

– SSL_mode_release_buffers 1|0

  This enables or disables the SSL_MODE_RELEASE_BUFFERS option on the SSL object. With this option the read buffer will be released after each SSL_read but will need to be reallocated for each new SSL_read. If memory usage is a concern this might save lots of memory in the mean time though, about 34k per idle SSL connection according to the documentation in SSL_CTX_set_mode(3ssl).

– SSL_usebio 1|0

  If this option is used with `start_SSL` (not supported somewhere else) it will not upgrade the given IO handle but instead wrap it inside a new IO object and use openssl memory BIO's to manage exchange between TLS layer and socket layer. While this will add some overhead it makes it possible to stack TLS layers, i.e. first create an outer TLS connection (without or with SSL_use-

bio) and then create the inner TLS layer with SSL_usebio, using the outer TLS connection as the IO handle in `start_SSL`.

Example:

```
# create TLS connection to TLS enabled http proxy
my $outer = IO::Socket::SSL->new('proxy.test:3128');

# send proxy request
print $outer "CONNECT real-target.test:443 HTTP/1.0\r\n\r\n";
... # read and check response from proxy on $outer

# create an inner TLS connection to the server inside $outer
my $inner = IO::Socket::SSL->start_SSL($outer,
   SSL_usebio => 1,
   SSL_hostname => 'real-target.test', # SNI
);

# send request to server through proxy using $inner
print $inner "GET / HTTP/1.0\r\nHost: real-target.test\r\n\r\
 ↪n";
... # read response from server on $inner
```

- **accept**

  This behaves similar to the accept function of the underlying socket class, but additionally does the initial SSL handshake. But because the underlying socket class does return a blocking file handle even when accept is called on a non-blocking socket, the SSL handshake on the new file object will be done in a blocking way. Please see the section about non-blocking I/O for details. If you don't like this behavior you should do accept on the TCP socket and then upgrade it with `start_SSL` later.

- **connect(...)**

  This behaves similar to the connect function but also does an SSL handshake. Because you cannot give SSL specific arguments to this function, you should better either use `new` to create a connect SSL socket or `start_SSL` to upgrade an established TCP socket to SSL.

- **close(...)**

  Contrary to a close for a simple INET socket a close in SSL also mandates a proper shutdown of the SSL part. This is done by sending a close notify message by both peers.

  A naive implementation would thus wait until it receives the close notify message from the peer - which conflicts with the commonly expected semantic that a close will not block. The default behavior is thus to only send a close notify but not wait for the close notify of the peer. If it should instead wait for a close notify from the peer than `SSL_fast_shutdown` must be explicitly set to false:

  ```
  $self->close(SSL_fast_shutdown => 0);
  ```

  There are also cases where a SSL shutdown should not be done at all. This is true

for example when forking to let a child deal with the socket and closing the socket in the parent process. A naive explicit `close` or an implicit close when destroying the socket in the parent would send a close notify to the peer which would make the SSL socket in the client process unusable. In this case an explicit `close` with `SSL_no_shutdown` set to true should be done in the parent process:

```
$self->close(SSL_no_shutdown => 1);
```

For more details and other arguments see `stop_SSL` which gets called from `close` to shutdown the SSL state of the socket.

- **sysread(BUF, LEN, [OFFSET])**

  This function behaves from the outside the same as **sysread** in other *IO::Socket* objects, e.g. it returns at most LEN bytes of data. But in reality it reads not only LEN bytes from the underlying socket, but at a single SSL frame. It then returns up to LEN bytes it decrypted from this SSL frame. If the frame contained more data than requested it will return only LEN data, buffer the rest and return it on further read calls. This means, that it might be possible to read data, even if the underlying socket is not readable, so using poll or select might not be sufficient.

  sysread will only return data from a single SSL frame, e.g. either the pending data from the already buffered frame or it will read a frame from the underlying socket and return the decrypted data. It will not return data spanning several SSL frames in a single call.

  Also, calls to sysread might fail, because it must first finish an SSL handshake.

  To understand these behaviors is essential, if you write applications which use event loops and/or non-blocking sockets. Please read the specific sections in this documentation.

- **syswrite(BUF, [LEN, [OFFSET]])**

  This functions behaves from the outside the same as **syswrite** in other *IO::Socket* objects, e.g. it will write at most LEN bytes to the socket, but there is no guarantee, that all LEN bytes are written. It will return the number of bytes written. Because it basically just calls SSL_write from OpenSSL syswrite will write at most a single SSL frame. This means, that no more than 16.384 bytes, which is the maximum size of an SSL frame, will be written at once.

  For non-blocking sockets SSL specific behavior applies. Please read the specific section in this documentation.

- **peek(BUF, LEN, [OFFSET])**

  This function has exactly the same syntax as **sysread**, and performs nearly the same task but will not advance the read position so that successive calls to peek() with the same arguments will return the same results.

- **pending()**

  This function gives you the number of bytes available without reading from the underlying socket object. This function is essential if you work with event loops, please see the section about polling SSL sockets.

- **get_fingerprint([algo,certificate,pubkey])**

This methods returns the fingerprint of the given certificate in the form `algo$digest_hex`, where `algo` is the used algorithm, default 'sha256'. If no certificate is given the peer certificate of the connection is used. If `pubkey` is true it will not return the fingerprint of the certificate but instead the fingerprint of the pubkey inside the certificate as `algo$pub$digest_hex`.

- **get_fingerprint_bin([algo,certificate,pubkey])**

  This methods returns the binary fingerprint of the given certificate by using the algorithm `algo`, default 'sha256'. If no certificate is given the peer certificate of the connection is used. If `pubkey` is true it will not return the fingerprint of the certificate but instead the fingerprint of the pubkey inside the certificate.

- **get_cipher()**

  Returns the string form of the cipher that the IO::Socket::SSL object is using.

- **get_sslversion()**

  Returns the string representation of the SSL version of an established connection.

- **get_sslversion_int()**

  Returns the integer representation of the SSL version of an established connection.

- **get_session_reused()**

  This returns true if the session got reused and false otherwise. Note that with a reused session no certificates are send within the handshake and no ciphers are offered and thus functions which rely on this might not work.

- **dump_peer_certificate()**

  Returns a parsable string with select fields from the peer SSL certificate. This method directly returns the result of the dump_peer_certificate() method of Net::SSLeay.

- **peer_certificate($field;[$refresh])**

  If a peer certificate exists, this function can retrieve values from it. If no field is given the internal representation of certificate (X509 handle) from Net::SSLeay is returned, with reference owned internally (i.e. should not be freed). If refresh is true it will not used a cached version, but check again in case the certificate of the connection has changed due to renegotiation.

  The following fields can be queried:

  – authority (alias issuer)

    The certificate authority which signed the certificate.

  – owner (alias subject)

    The owner of the certificate.

  – commonName (alias cn) - only for Net::SSLeay version >=1.30

    The common name, usually the server name for SSL certificates.

  – subjectAltNames - only for Net::SSLeay version >=1.33

    Alternative names for the subject, usually different names for the same server, like example.org, example.com, *.example.com.

It returns a list of (typ,value) with typ GEN_DNS, GEN_IPADD etc (these constants are exported from IO::Socket::SSL). See Net::SSLeay::X509_get_subjectAltNames.

- **sock_certificate($field)**

  This is similar to `peer_certificate` but will return the sites own certificate. The same arguments for **$field** can be used. If no **$field** is given the X509 handle from the underlying OpenSSL will be returned. This handle is owned internally and will only be valid as long as the SSL connection exists. If used afterwards it might result in strange crashes of the application.

- **peer_certificates**

  This returns all the certificates send by the peer as X509 handles, e.g. first the peers own certificate and then the rest of the chain. You might use **CERT_asHash** from *IO::Socket::SSL::Utils* to inspect each of the certificates.

  Like with **sock_certificate** and **peer_certificates** the handles are owned internally and will only be valid as long as the SSL connection exists.

  This function depends on a version of Net::SSLeay >= 1.58 .

- **get_servername**

  This gives the name requested by the client if Server Name Indication (SNI) was used.

- **verify_hostname($hostname,$scheme,$publicsuffix)**

  This verifies the given hostname against the peer certificate using the given scheme. Hostname is usually what you specify within the PeerAddr. See the `SSL_verifycn_publicsuffix` parameter for an explanation of suffix checking and for the possible values.

  Verification of hostname against a certificate is different between various applications and RFCs. Some scheme allow wildcards for hostnames, some only in subjectAltNames, and even their different wildcard schemes are possible. RFC 6125 provides a good overview.

  To ease the verification the following schemes are predefined (both protocol name and rfcXXXX name can be used):

  – rfc2818, xmpp (rfc3920), ftp (rfc4217)

    Extended wildcards in subjectAltNames and common name are possible, e.g. *.example.org or even www*.example.org. The common name will be only checked if no DNS names are given in subjectAltNames.

  – http (alias www)

    While name checking is defined in rfc2818 the current browsers usually accept also an IP address (w/o wildcards) within the common name as long as no subjectAltNames are defined. Thus this is rfc2818 extended with this feature.

  – smtp (rfc2595), imap, pop3, acap (rfc4642), netconf (rfc5538), syslog (rfc5425), snmp (rfc5953)

    Simple wildcards in subjectAltNames are possible, e.g. *.example.org matches www.example.org but not lala.www.example.org. If nothing from subjectAlt-

Names match it checks against the common name, where wildcards are also allowed to match the full leftmost label.

- ldap (rfc4513)

  Simple wildcards are allowed in subjectAltNames, but not in common name. Common name will be checked even if subjectAltNames exist.

- sip (rfc5922)

  No wildcards are allowed and common name is checked even if subjectAltNames exist.

- gist (rfc5971)

  Simple wildcards are allowed in subjectAltNames and common name, but common name will only be checked if there are no DNS names in subjectAltNames.

- default

  This is a superset of all the rules and is automatically used if no scheme is given but a hostname (instead of IP) is known. Extended wildcards are allowed in subjectAltNames and common name and common name is checked always.

- none

  No verification will be done. Actually is does not make any sense to call verify_hostname in this case.

The scheme can be given either by specifying the name for one of the above predefined schemes, or by using a hash which can have the following keys and values:

- check_cn: 0|'always'|'when_only'

  Determines if the common name gets checked. If 'always' it will always be checked (like in ldap), if 'when_only' it will only be checked if no names are given in subjectAltNames (like in http), for any other values the common name will not be checked.

- wildcards_in_alt: 0|'full_label'|'anywhere'

  Determines if and where wildcards in subjectAltNames are possible. If 'full_label' only cases like *.example.org will be possible (like in ldap), for 'anywhere' www*.example.org is possible too (like http), dangerous things like but www.*.org or even '*' will not be allowed. For compatibility with older versions 'leftmost' can be given instead of 'full_label'.

- wildcards_in_cn: 0|'full_label'|'anywhere'

  Similar to wildcards_in_alt, but checks the common name. There is no predefined scheme which allows wildcards in common names.

- ip_in_cn: 0|1|4|6

  Determines if an IP address is allowed in the common name (no wildcards are allowed). If set to 4 or 6 it only allows IPv4 or IPv6 addresses, any other true value allows both.

- callback: \&coderef

If you give a subroutine for verification it will be called with the arguments ($hostname,$commonName,@subjectAltNames), where hostname is the name given for verification, commonName is the result from peer_certificate('cn') and subjectAltNames is the result from peer_certificate('subjectAltNames').

All other arguments for the verification scheme will be ignored in this case.

- **next_proto_negotiated()**

  This method returns the name of negotiated protocol - e.g. 'http/1.1'. It works for both client and server side of SSL connection.

  NPN support is available with Net::SSLeay 1.46+ and openssl-1.0.1+. To check support you might call `IO::Socket::SSL->can_npn()`.

- **alpn_selected()**

  Returns the protocol negotiated via ALPN as a string, e.g. 'http/1.1', 'http/2.0' or 'spdy/3.1'.

  ALPN support is available with Net::SSLeay 1.56+ and openssl-1.0.2+. To check support, use `IO::Socket::SSL->can_alpn()`.

- **errstr()**

  Returns the last error (in string form) that occurred. If you do not have a real object to perform this method on, call IO::Socket::SSL::errstr() instead.

  For read and write errors on non-blocking sockets, this method may include the string `SSL wants a read first!` or `SSL wants a write first!` meaning that the other side is expecting to read from or write to the socket and wants to be satisfied before you get to do anything. But with version 0.98 you are better comparing the global exported variable $SSL_ERROR against the exported symbols SSL_WANT_READ and SSL_WANT_WRITE.

- **opened()**

  This returns false if the socket could not be opened, 1 if the socket could be opened and the SSL handshake was successful done and -1 if the underlying IO::Handle is open, but the SSL handshake failed.

- **is_SSL()**

  This returns undefined if there is no SSL object associated with the socket. It will return `rw` if the state of the SSL object has SSL active for both directions, `r` if there was a locally initiated SSL shutdown (close notify), `w` if a remote SSL shutdown was received and `` (empty string but defined) if a bidirectional SSL shutdown was done.

- **IO::Socket::SSL->start_SSL($socket, ...)**

  This will convert a glob reference or a socket that you provide to an IO::Socket::SSL object. You may also pass parameters to specify context or connection options as with a call to new(). If you are using this function on an accept()ed socket, you must set the parameter "SSL_server" to 1, i.e. IO::Socket::SSL->start_SSL($socket, SSL_server => 1). If you have a class that inherits from IO::Socket::SSL and you want the $socket to be blessed into your own class instead, use MyClass->start_SSL($socket) to achieve the desired effect.

Note that if start_SSL() fails (wrong arguments, error in SSL negotiation ...), it will try to bless the socket back to its original class. This will fail if the given socket was not blessed, since there is no builtin "unbless". Therefore better use IO::Socket (or other IO::Handle) objects as `$socket` instead of creating unblessed sockets with `socket` or similar.

For non-blocking sockets you better just upgrade the socket to IO::Socket::SSL and call accept_SSL or connect_SSL and the upgraded object. To just upgrade the socket set **SSL_startHandshake** explicitly to 0. If you call start_SSL w/o this parameter it will revert to blocking behavior for accept_SSL and connect_SSL.

If given the parameter "Timeout" it will stop if after the timeout no SSL connection was established. This parameter is only used for blocking sockets, if it is not given the default Timeout from the underlying IO::Socket will be used.

- **stop_SSL(...)**

  This is the opposite of start_SSL(), connect_SSL() and accept_SSL(), e.g. it will shutdown the SSL connection and return to the class before start_SSL(). It gets the same arguments as close(), in fact close() calls stop_SSL() (but without downgrading the class).

  Will return true if it succeeded and undef if failed. This might be the case for non-blocking sockets. In this case $! is set to EWOULDBLOCK and the ssl error to SSL_WANT_READ or SSL_WANT_WRITE. In this case the call should be retried again with the same arguments once the socket is ready.

  For calling from `stop_SSL` `SSL_fast_shutdown` default to false, e.g. it waits for the close_notify of the peer. This is necessary in case you want to downgrade the socket and continue to use it as a plain socket. If `SSL_fast_shutdown` is set to true only the write direction will be shutdown for SSL and there can still be SSL data read. Read direction will then be closed either automatically when receiving a shutdown from the peer during read or by explicitly calling `stop_SSL` with `SSL_fast_shutdown` false.

  After a complete stop_SSL the socket can again be used to exchange plain data. Even if the SSL shutdown is only done for writing (`SSL_fast_shutdown`) plain data can be immediately written.

  If the SSL shutdown was initiated by the peer it will lead to an implicit SSL shutdown for reading and sysread will return with 0 in this case. It will also SSL shutdown the local side. After this the socket is ready to receive plain data from the peer and locally send data will also be transmitted in plain. To prevent accidental sending/receiving plain data after such implicit SSL shutdown, the read and write functions will return undef with $ERRNO set to EPERM until an explicit stop_SSL was done. If the peer directly closes the TCP connection ater the SSL shutdown without sending plain data this will still be detected though.

  If this default behavior is not wanted a callback can be setup using `SSL_on_peer_shutdown` which gets `$self` as first argument. The result from the callback will then be returned instead of 0 and no local SSL shutdown will be automatically initiated. Similar no explicit stop_SSL is needed before receiving plain data since the callback is considered explicit action enough.

- **connect_SSL, accept_SSL**

These functions should be used to do the relevant handshake, if the socket got created with `new` or upgraded with `start_SSL` and `SSL_startHandshake` was set to false. They will return undef until the handshake succeeded or an error got thrown. As long as the function returns undef and $! is set to EWOULDBLOCK one could retry the call after the socket got readable (SSL_WANT_READ) or writeable (SSL_WANT_WRITE).

- **set_msg_callback**

  This will add/remove a user defined callback for each message, internally using openssl SSL_set_msg_callback API. To make sure that the callback is active before the handshake starts, combine it with `SSL_startHandshake => 0` in the preceding setup of the SSL object. To remove callback explicitly call it with an empty callback function.

  Example:

```
$sock = IO::Socket::SSL->new( .... , SSL_startHandshake => 0);
# set callback
$sock->set_msg_callback(\&cb, $cbarg1, $cbarg2);
$sock->connect_SSL();

sub cb {
    my ($sock,
        # see SSL_set_msg_callback for the following args
        $direction, $ssl_ver, $content_type, $buf, $len, $ssl,
        $cbarg1, $cbarg2)
        = @_;
    ...
    if (no_longer_need_cb) {
        # disable callback
        $sock->set_msg_callback(undef);
    }
}
```

- **ocsp_resolver**

  This will create an OCSP resolver object, which can be used to create OCSP requests for the certificates of the SSL connection. Which certificates are verified depends on the setting of `SSL_ocsp_mode`: by default only the leaf certificate will be checked, but with SSL_OCSP_FULL_CHAIN all chain certificates will be checked.

  Because to create an OCSP request the certificate and its issuer certificate need to be known it is not possible to check certificates when the trust chain is incomplete or if the certificate is self-signed.

  The OCSP resolver gets created by calling `$ssl->ocsp_resolver` and provides the following methods:

  – hard_error

    This returns the hard error when checking the OCSP response. Hard errors are certificate revocations. With the `SSL_ocsp_mode` of SSL_OCSP_FAIL_HARD any soft error (e.g. failures to get signed information about the certificates) will be considered a hard error too.

The OCSP resolving will stop on the first hard error.

The method will return undef as long as no hard errors occurred and still requests to be resolved. If all requests got resolved and no hard errors occurred the method will return `''`.

– soft_error

This returns the soft error(s) which occurred when asking the OCSP responders.

– requests

This will return a hash consisting of `(url,request)`-tuples, e.g. which contain the OCSP request string and the URL where it should be sent too. The usual way to send such a request is as HTTP POST request with a content-type of `application/ocsp-request` or as a GET request with the base64 and url-encoded request is added to the path of the URL.

After you've handled all these requests and added the response with `add_response` you should better call this method again to make sure, that no more requests are outstanding. IO::Socket::SSL will combine multiple OCSP requests for the same server inside a single request, but some server don't give a response to all these requests, so that one has to ask again with the remaining requests.

– add_response($uri,$response)

This method takes the HTTP body of the response which got received when sending the OCSP request to `$uri`. If no response was received or an error occurred one should either retry or consider `$response` as empty which will trigger a soft error.

The method returns the current value of `hard_error`, e.g. a defined value when no more requests need to be done.

– resolve_blocking(%args)

This combines `requests` and `add_response` which *HTTP::Tiny* to do all necessary requests in a blocking way. `%args` will be given to *HTTP::Tiny* so that you can put proxy settings etc here. *HTTP::Tiny* will be called with `verify_SSL` of false, because the OCSP responses have their own signatures so no extra SSL verification is needed.

If you don't want to use blocking requests you need to roll your own user agent with `requests` and `add_response`.

- **IO::Socket::SSL->new_from_fd($fd, [mode], %sslargs)**

  This will convert a socket identified via a file descriptor into an SSL socket. Note that the argument list does not include a "MODE" argument; if you supply one, it will be thoughtfully ignored (for compatibility with IO::Socket::INET). Instead, a mode of '+<' is assumed, and the file descriptor passed must be able to handle such I/O because the initial SSL handshake requires bidirectional communication.

  Internally the given $fd will be upgraded to a socket object using the `new_from_fd` method of the super class (*IO::Socket::INET* or similar) and then `start_SSL` will be called using the given `%sslargs`. If `$fd` is already an IO::Socket object you should better call `start_SSL` directly.

- **IO::Socket::SSL::default_ca([path|dir| SSL_ca_file** = ..., SSL_ca_path => ...])>

  Determines or sets the default CA path. If existing path or dir or a hash is given it will set the default CA path to this value and never try to detect it automatically. If `undef` is given it will forget any stored defaults and continue with detection of system defaults. If no arguments are given it will start detection of system defaults, unless it has already stored user-set or previously detected values.

  The detection of system defaults works similar to OpenSSL, e.g. it will check the directory specified in environment variable SSL_CERT_DIR or the path OPENSSLDIR/certs (SSLCERTS: on VMS) and the file specified in environment variable SSL_CERT_FILE or the path OPENSSLDIR/cert.pem (SSLCERTS:cert.pem on VMS). Contrary to OpenSSL it will check if the SSL_ca_path contains PEM files with the hash as file name and if the SSL_ca_file looks like PEM. If no usable system default can be found it will try to load and use Mozilla::CA and if not available give up detection. The result of the detection will be saved to speed up future calls.

  The function returns the saved default CA as hash with SSL_ca_file and SSL_ca_path.

- **IO::Socket::SSL::set_default_context(...)**

  You may use this to make IO::Socket::SSL automatically re-use a given context (unless specifically overridden in a call to new()). It accepts one argument, which should be either an IO::Socket::SSL object or an IO::Socket::SSL::SSL_Context object. See the SSL_reuse_ctx option of new() for more details. Note that this sets the default context globally, so use with caution (esp. in mod_perl scripts).

- **IO::Socket::SSL::set_default_session_cache(...)**

  You may use this to make IO::Socket::SSL automatically re-use a given session cache (unless specifically overridden in a call to new()). It accepts one argument, which should be an IO::Socket::SSL::Session_Cache object or similar (e.g. something which implements get_session, add_session and del_session like IO::Socket::SSL::Session_Cache does). See the SSL_session_cache option of new() for more details. Note that this sets the default cache globally, so use with caution.

- **IO::Socket::SSL::set_defaults(%args)**

  With this function one can set defaults for all SSL_* parameter used for creation of the context, like the SSL_verify* parameter. Any SSL_* parameter can be given or the following short versions:

  - mode - SSL_verify_mode
  - callback - SSL_verify_callback
  - scheme - SSL_verifycn_scheme
  - name - SSL_verifycn_name

- **IO::Socket::SSL::set_client_defaults(%args)**

  Similar to `set_defaults`, but only sets the defaults for client mode.

- **IO::Socket::SSL::set_server_defaults(%args)**

  Similar to `set_defaults`, but only sets the defaults for server mode.

- **IO::Socket::SSL::set_args_filter_hack(\&code|'use_defaults')**

Sometimes one has to use code which uses unwanted or invalid arguments for SSL, typically disabling SSL verification or setting wrong ciphers or SSL versions. With this hack it is possible to override these settings and restore sanity. Example:

```
IO::Socket::SSL::set_args_filter_hack( sub {
    my ($is_server,$args) = @_;
    if ( ! $is_server ) {
        # client settings - enable verification with default CA
        # and fallback hostname verification etc
        delete @{$args}{qw(
            SSL_verify_mode
            SSL_ca_file
            SSL_ca_path
            SSL_verifycn_scheme
            SSL_version
        )};
        # and add some fingerprints for known certs which are␣
↪signed by
        # unknown CAs or are self-signed
        $args->{SSL_fingerprint} = ...
    }
});
```

With the short setting `set_args_filter_hack('use_defaults')` it will prefer the default settings in all cases. These default settings can be modified with `set_defaults`, `set_client_defaults` and `set_server_defaults`.

The following methods are unsupported (not to mention futile!) and IO::Socket::SSL will emit a large CROAK() if you are silly enough to use them:

- truncate
- stat
- ungetc
- setbuf
- setvbuf
- fdopen
- send/recv

  Note that send() and recv() cannot be reliably trapped by a tied filehandle (such as that used by IO::Socket::SSL) and so may send unencrypted data over the socket. Object-oriented calls to these functions will fail, telling you to use the print/printf/syswrite and read/sysread families instead.

ACCESS TO INTERNALS

`IO::Socket::SSL` uses internally `Net::SSLeay` which provides a lower level API to OpenSSL and provides functions which work directly with OpenSSL SSL and CTX handles. Sometimes it might be necessary to get direct access to these handles from `IO::Socket::SSL` in order to apply functionality available only with `Net::SSLeay`.

For this `_get_ssl_object` can be used on the `IO::Socket::SSL` object to get access to the OpenSSL SSL handle and `_get_ctx_object` can be used on `IO::Socket::SSL` and `IO::Socket::SSL_Context` objects to access the OpenSSL CTX handle. Use very carefully since OpenSSL memory/reference management must be done manually with `Net::SSLeay`.

DEPRECATIONS

The following functions are deprecated and are only retained for compatibility:

- context_init()

  use the SSL_reuse_ctx option if you want to re-use a context

- socketToSSL() and socket_to_SSL()

  use IO::Socket::SSL->start_SSL() instead

- kill_socket()

  use close() instead

- get_peer_certificate()

  use the peer_certificate() function instead. Used to return X509_Certificate with methods subject_name and issuer_name. Now simply returns $self which has these methods (although deprecated).

- issuer_name()

  use peer_certificate('issuer') instead

- subject_name()

  use peer_certificate('subject') instead

EXAMPLES

See the 'example' directory, the tests in 't' and also the tools in 'util'.

BUGS

If you use IO::Socket::SSL together with threads you should load it (e.g. use or require) inside the main thread before creating any other threads which use it. This way it is much faster because it will be initialized only once. Also there are reports that it might crash the other way.

Creating an IO::Socket::SSL object in one thread and closing it in another thread will not work.

IO::Socket::SSL does not work together with Storable::fd_retrieve/fd_store. See BUGS file for more information and how to work around the problem.

If you have a server and it looks like you have a memory leak you might check the size of your session cache. Default for Net::SSLeay seems to be 20480, see the example for SSL_create_ctx_callback for how to limit it.

TLS 1.3 support regarding session reuse is incomplete.

THANKS

Many thanks to all who added patches or reported bugs or helped IO::Socket::SSL another way. Please keep reporting bugs and help with patches, even if they just fix the documentation.

Special thanks to the team of Net::SSLeay for the good cooperation.

IO::Socket::SSL::Intercept

SSL interception (man in the middle)

SYNOPSIS

```
use IO::Socket::SSL::Intercept;
# create interceptor with proxy certificates
my $mitm = IO::Socket::SSL::Intercept->new(
    proxy_cert_file => 'proxy_cert.pem',
    proxy_key_file  => 'proxy_key.pem',
    ...
);
my $listen = IO::Socket::INET->new( LocalAddr => .., Listen => .. );
while (1) {
    # TCP accept new client
    my $client = $listen->accept or next;
    # SSL connect to server
    my $server = IO::Socket::SSL->new(
        PeerAddr => ..,
        SSL_verify_mode => ...,
        ...
    ) or die "ssl connect failed: $!,$SSL_ERROR";
    # clone server certificate
    my ($cert,$key) = $mitm->clone_cert( $server->peer_certificate
↪);
    # and upgrade client side to SSL with cloned certificate
    IO::Socket::SSL->start_SSL($client,
        SSL_server => 1,
        SSL_cert => $cert,
        SSL_key => $key
    ) or die "upgrade failed: $SSL_ERROR";
    # now transfer data between $client and $server and analyze
    # the unencrypted data
    ...
}
```

DESCRIPTION

This module provides functionality to clone certificates and sign them with a proxy certificate, thus making it easy to intercept SSL connections (man in the middle). It also manages a cache of the generated certificates.

How Intercepting SSL Works

Intercepting SSL connections is useful for analyzing encrypted traffic for security reasons or for testing. It does not break the end-to-end security of SSL, e.g. a properly written client will notice the interception unless you explicitly configure the client to trust your interceptor. Intercepting SSL works the following way:

- Create a new CA certificate, which will be used to sign the cloned certificates. This proxy CA certificate should be trusted by the client, or (a properly written client) will throw error messages or deny the connections because it detected a man in the middle attack. Due to the way the interception works there no support for client side certificates is possible.

  Using openssl such a proxy CA certificate and private key can be created with:

```
openssl genrsa -out proxy_key.pem 1024
openssl req -new -x509 -extensions v3_ca -key proxy_key.pem -
 ↪out proxy_cert.pem
# export as PKCS12 for import into browser
openssl pkcs12 -export -in proxy_cert.pem -inkey proxy_key.pem -
 ↪out proxy_cert.p12
```

- Configure client to connect to use intercepting proxy or somehow redirect connections from client to the proxy (e.g. packet filter redirects, ARP or DNS spoofing etc).
- Accept the TCP connection from the client, e.g. don't do any SSL handshakes with the client yet.
- Establish the SSL connection to the server and verify the servers certificate as usually. Then create a new certificate based on the original servers certificate, but signed by your proxy CA. This is the step where IO::Socket::SSL::Intercept helps.
- Upgrade the TCP connection to the client to SSL using the cloned certificate from the server. If the client trusts your proxy CA it will accept the upgrade to SSL.
- Transfer data between client and server. While the connections to client and server are both encrypted with SSL you will read/write the unencrypted data in your proxy application.

METHODS

IO::Socket::SSL::Intercept helps creating the cloned certificate with the following methods:

- **$mitm = IO::Socket::SSL::Intercept->new(%args)**

  This creates a new interceptor object. `%args` should be

  – proxy_cert X509 | proxy_cert_file filename

    This is the proxy certificate. It can be either given by an X509 object from *Net::SSLeay*s internal representation, or using a file in PEM format.

  – proxy_key EVP_PKEY | proxy_key_file filename

    This is the key for the proxy certificate. It can be either given by an EVP_PKEY object from *Net::SSLeay*s internal representation, or using a file in PEM format. The key should not have a passphrase.

  – cert_key EVP_PKEY | cert_key_file filename

    This optional argument specifies the public key used for the cloned certificate. It can be either given by an EVP_PKEY object from *Net::SSLeay*s internal representation, or using a file in PEM format. If not given it will create a new public key on each call of new.

- serial INTEGER|CODE

  This optional argument gives the starting point for the serial numbers of the newly created certificates. If not set the serial number will be created based on the digest of the original certificate. If the value is code it will be called with `serial(original_cert,CERT_asHash(original_cert))` and should return the new serial number.

- cache HASH | SUBROUTINE

  This optional argument gives a way to cache created certificates, so that they don't get recreated on future accesses to the same host. If the argument ist not given an internal HASH ist used.

  If the argument is a hash it will store for each generated certificate a hash reference with `cert` and `atime` in the hash, where `atime` is the time of last access (to expire unused entries) and `cert` is the certificate. Please note, that the certificate is in *Net::SSLeay*s internal X509 format and can thus not be simply dumped and restored. The key for the hash is an `ident` either given to `clone_cert` or generated from the original certificate.

  If the argument is a subroutine it will be called as `$cache->(ident,sub)`. This call should return either an existing (cached) `(cert,key)` or call `sub` without arguments to create a new `(cert,key)`, store it and return it. If called with `$cache->('type')` the function should just return 1 to signal that it supports the current type of cache. If it returns nothing instead the older cache interface is assumed for compatibility reasons.

- **($clone_cert,$key) = $mitm->clone_cert($original_cert,[$ident])**

  This clones the given certificate. An ident as the key into the cache can be given (like `host:port`), if not it will be created from the properties of the original certificate. It returns the cloned certificate and its key (which is the same for alle created certificates).

- **$string = $mitm->serialize**

  This creates a serialized version of the object (e.g. a string) which can then be used to persistently store created certificates over restarts of the application. The cache will only be serialized if it is a HASH. To work together with *Storable* the `STORABLE_freeze` function is defined to call `serialize`.

- **$mitm = IO::Socket::SSL::Intercept->unserialize($string)**

  This restores an Intercept object from a serialized string. To work together with *Storable* the `STORABLE_thaw` function is defined to call `unserialize`.

IO::Socket::SSL::PublicSuffix

provide access to Mozilla's list of effective TLD names

SYNOPSIS

```
   # use builtin default
   use IO::Socket::SSL::PublicSuffix;
   $ps = IO::Socket::SSL::PublicSuffix->default;

   # load from string
   $ps = IO::Socket::SSL::PublicSuffix->from_string("*.uk\n*");

   # load from file or file handle
   $ps = IO::Socket::SSL::PublicSuffix->from_file($filename);
   $ps = IO::Socket::SSL::PublicSuffix->from_file(\*STDIN);

   # --- string in -> string out
   # $rest -> whatever.host
   # $tld  -> co.uk
   my ($rest,$tld) = $ps->public_suffix('whatever.host.co.uk');
   my $tld = $ps->public_suffix('whatever.host.co.uk');

   # $root_domain -> host.co.uk
   my $root_domain = $ps->public_suffix('whatever.host.co.uk', 1);

   # --- array in -> array out
   # $rest -> [qw(whatever host)]
   # $tld  -> [qw(co uk)]
   my ($rest,$tld) = $ps->public_suffix([qw(whatever host co uk)]);

----

   # To update this file with the current list:
   perl -MIO::Socket::SSL::PublicSuffix -e
↪'IO::Socket::SSL::PublicSuffix::update_self_from_url()'
```

DESCRIPTION

This module uses the list of effective top level domain names from the mozilla project to determine the public top level domain for a given hostname.

Method

- class->default(%args)

  Returns object with builtin default. `min_suffix` can be given in `%args` to specify the minimal suffix, default is 1.

- class->from_string(string,%args)

  Returns object with configuration from string. See method `default` for `%args`.

- class->from_file(file name | file handle, %args)

Returns object with configuration from file or file handle. See method `default` for `%args`.

- $self->public_suffix($host|\@host, [$add])

  In array context the function returns the non-tld part and the tld part of the given hostname, in scalar context only the tld part. It adds `$add` parts of the non-tld part to the tld, e.g. with `$add=1` it will return the root domain.

  If there were no explicit matches against the public suffix configuration it will fall back to a suffix of length 1.

  The function accepts a string or an array-ref (e.g. host split by `.`). In the first case it will return string(s), in the latter case array-ref(s).

  International hostnames or labels can be in ASCII (IDNA form starting with `xn--`) or unicode. In the latter case an IDNA handling library needs to be available. URI is preferred, but Net::IDN:::Encode, Net::LibIDN are still supported.

- ($self|class)->can_idn

  Returns true if IDN support is available.

IO::Socket::SSL::Utils

loading, storing, creating certificates and keys

SYNOPSIS

```
use IO::Socket::SSL::Utils;

$cert = PEM_file2cert('cert.pem');      # load certificate from file
my $hash = CERT_asHash($cert);          # get details from␣
↪certificate
PEM_cert2file($cert,'cert.pem');        # write certificate to file
CERT_free($cert);                       # free memory within OpenSSL

@certs = PEM_file2certs('chain.pem');   # load multiple certificates␣
↪from file
PEM_certs2file('chain.pem', @certs);    # write multiple certificates␣
↪to file
CERT_free(@certs);                      # free memory for all within␣
↪OpenSSL

my $cert = PEM_string2cert($pem);       # load certificate from PEM␣
↪string
$pem = PEM_cert2string($cert);          # convert certificate to PEM␣
↪string

$key = KEY_create_rsa(2048);            # create new 2048-bit RSA key
PEM_key2file($key,"key.pem");           # and write it to file
KEY_free($key);                         # free memory within OpenSSL
```

DESCRIPTION

This module provides various utility functions to work with certificates and private keys, shielding some of the complexity of the underlying Net::SSLeay and OpenSSL.

FUNCTIONS

- Functions converting between string or file and certificates and keys. They croak if the operation cannot be completed.
  - PEM_file2cert(file) -> cert
  - PEM_cert2file(cert,file)
  - PEM_file2certs(file) -> @certs
  - PEM_certs2file(file,@certs)
  - PEM_string2cert(string) -> cert
  - PEM_cert2string(cert) -> string
  - PEM_file2key(file) -> key
  - PEM_key2file(key,file)
  - PEM_string2key(string) -> key
  - PEM_key2string(key) -> string

- Functions for cleaning up. Each loaded or created cert and key must be freed to not leak memory.
  - CERT_free(@certs)
  - KEY_free(@keys)
- KEY_create_rsa(bits) -> key

  Creates an RSA key pair, bits defaults to 2048.
- KEY_create_ec(curve) -> key

  Creates an EC key, curve defaults to `prime256v1`.
- CERT_asHash(cert,[digest_algo]) -> hash

  Extracts the information from the certificate into a hash and uses the given digest_algo (default: SHA-256) to determine digest of pubkey and cert. The resulting hash contains:
  - subject

    Hash with the parts of the subject, e.g. commonName, countryName, organizationName, stateOrProvinceName, localityName. If there are multiple values for any of these parts the hash value will be an array ref with the values in order instead of just a scalar.
  - subjectAltNames

    Array with list of alternative names. Each entry in the list is of `[type,value]`, where `type` can be OTHERNAME, EMAIL, DNS, X400, DIRNAME, EDIPARTY, URI, IP or RID.
  - issuer

    Hash with the parts of the issuer, e.g. commonName, countryName, organizationName, stateOrProvinceName, localityName. If there are multiple values for any of these parts the hash value will be an array ref with the values in order instead of just a scalar.
  - not_before, not_after

    The time frame, where the certificate is valid, as time_t, e.g. can be converted with localtime or similar functions.
  - serial

    The serial number
  - crl_uri

    List of URIs for CRL distribution.
  - ocsp_uri

    List of URIs for revocation checking using OCSP.
  - keyusage

    List of keyUsage information in the certificate.

- extkeyusage

  List of extended key usage information from the certificate. Each entry in this list consists of a hash with oid, nid, ln and sn.

- pubkey_digest_xxx

  Binary digest of the pubkey using the given digest algorithm, e.g. pubkey_digest_sha256 if (the default) SHA-256 was used.

- x509_digest_xxx

  Binary digest of the X.509 certificate using the given digest algorithm, e.g. x509_digest_sha256 if (the default) SHA-256 was used.

- fingerprint_xxx

  Fingerprint of the certificate using the given digest algorithm, e.g. fingerprint_sha256 if (the default) SHA-256 was used. Contrary to digest_* this is an ASCII string with a list if hexadecimal numbers, e.g. "73:59:75:5C:6D...".

- signature_alg

  Algorithm used to sign certificate, e.g. `sha256WithRSAEncryption`.

- ext

  List of extensions. Each entry in the list is a hash with oid, nid, sn, critical flag (boolean) and data (string representation given by X509V3_EXT_print).

- version

  Certificate version, usually 2 (x509v3)

- CERT_create(hash) -> (cert,key)

  Creates a certificate based on the given hash. If the issuer is not specified the certificate will be self-signed. The following keys can be given:

  - subject

    Hash with the parts of the subject, e.g. commonName, countryName, ... as described in `CERT_asHash`. Default points to IO::Socket::SSL.

  - not_before
