Modules

- `Test2::API` - Primary interface for writing Test2 based testing tools.
- `Test2::AsyncSubtest` - Object representing an async subtest.
- `Test2::Bundle` - Documentation for bundles.
- `Test2::Compare` - Test2 extension for writing deep comparison tools.
- `Test2::Env` - Documentation for environment variables used or set by Test2.
- `Test2::Event` - Base class for events
- `Test2::EventFacet` - Base class for all event facets.
- `Test2::Formatter` - Namespace for formatters.
- `Test2::Handle` - Base class for Test2 handles used in V# bundles.
- `Test2::Hub` - The conduit through which all events flow.
- `Test2::IPC` - Turn on IPC for threading or forking support.
- `Test2::Manual` - Documentation hub for Test2 and Test2-Suite.
- `Test2::Mock` - Module for managing mocked classes and instances.
- `Test2::Plugin` - Documentation for plugins

- `Test2::Require` - Base class and documentation for skip-unless type test packages.
- `Test2::Suite` - Distribution with a rich set of tools built upon the Test2 framework.
- `Test2::Todo` - TODO extension for Test2.
- `Test2::Tools` - Documentation for Tools.
- `Test2::Util` - Tools used by Test2 and friends.
- `Test2::V0` - 0Th edition of the Test2 recommended bundle.
- `Test2::V1` - V1 edition of the Test2 recommended bundle.
- `Test2::Workflow` - A test workflow is a way of structuring tests using composable units.

Test2::API

Primary interface for writing Test2 based testing tools.

INTERNALS NOTE

The internals of this package are subject to change at any time! The public methods provided will not change in backwards-incompatible ways (once there is a stable release), but the underlying implementation details might. **Do not break encapsulation here!**

Currently the implementation is to create a single instance of the *Test2::API::Instance* Object. All class methods defer to the single instance. There is no public access to the singleton, and that is intentional. The class methods provided by this package provide the only functionality publicly exposed.

This is done primarily to avoid the problems Test::Builder had by exposing its singleton. We do not want anyone to replace this singleton, rebless it, or directly muck with its internals. If you need to do something and cannot because of the restrictions placed here, then please report it as an issue. If possible, we will create a way for you to implement your functionality without exposing things that should not be exposed.

DESCRIPTION

This package exports all the functions necessary to write and/or verify testing tools. Using these building blocks you can begin writing test tools very quickly. You are also provided with tools that help you to test the tools you write.

SYNOPSIS

WRITING A TOOL

The `context()` method is your primary interface into the Test2 framework.

```
package My::Ok;
use Test2::API qw/context/;

our @EXPORT = qw/my_ok/;
use base 'Exporter';

# Just like ok() from Test::More
sub my_ok($;$) {
    my ($bool, $name) = @_;
    my $ctx = context(); # Get a context
    $ctx->ok($bool, $name);
    $ctx->release; # Release the context
    return $bool;
}
```

See *Test2::API::Context* for a list of methods available on the context object.

TESTING YOUR TOOLS

The `intercept { ... }` tool lets you temporarily intercept all events generated by the test system:

```
use Test2::API qw/intercept/;

use My::Ok qw/my_ok/;

my $events = intercept {
    # These events are not displayed
    my_ok(1, "pass");
    my_ok(0, "fail");
};
```

As of version 1.302178 this now returns an arrayref that is also an instance of *Test2::API::InterceptResult*. See the *Test2::API::InterceptResult* documentation for details on how to best use it.

OTHER API FUNCTIONS

```
use Test2::API qw{
    test2_init_done
    test2_stack
    test2_set_is_end
    test2_get_is_end
    test2_ipc
    test2_formatter_set
    test2_formatter
    test2_is_testing_done
};

my $init  = test2_init_done();
```

(continues on next page)

(continued from previous page)

```
my $stack = test2_stack();
my $ipc   = test2_ipc();

test2_formatter_set($FORMATTER)
my $formatter = test2_formatter();

... And others ...
```

ENVIRONMENT VARIABLES

See *Test2::Env* for a list of meaningful environment variables.

MAIN API EXPORTS

All exports are optional. You must specify subs to import.

```
use Test2::API qw/context intercept run_subtest/;
```

This is the list of exports that are most commonly needed. If you are simply writing a tool, then this is probably all you need. If you need something and you cannot find it here, then you can also look at "OTHER API EXPORTS".

These exports lack the 'test2_' prefix because of how important/common they are. Exports in the "OTHER API EXPORTS" section have the 'test2_' prefix to ensure they stand out.

context(...)

Usage:

- $ctx = context()
- $ctx = context(%params)

The `context()` function will always return the current context. If there is already a context active, it will be returned. If there is not an active context, one will be generated. When a context is generated it will default to using the file and line number where the currently running sub was called from.

Please see *"CRITICAL DETAILS" in Test2::API::Context* for important rules about what you can and cannot do with a context once it is obtained.

Note This function will throw an exception if you ignore the context object it returns.

Note On perls 5.14+ a depth check is used to ensure there are no context leaks. This cannot be safely done on older perls due to https://rt.perl.org/Public/Bug/Display.html?id=127774 You can forcefully enable it either by setting `$ENV{T2_CHECK_DEPTH} = 1` or `$Test2::API::DO_DEPTH_CHECK = 1` **BEFORE** loading *Test2::API*.

OPTIONAL PARAMETERS

All parameters to `context` are optional.

- level => $int

  If you must obtain a context in a sub deeper than your entry point you can use this to tell it how many EXTRA stack frames to look back. If this option is not provided the default of `0` is used.

```
sub third_party_tool {
    my $sub = shift;
    ... # Does not obtain a context
    $sub->();
    ...
}

third_party_tool(sub {
    my $ctx = context(level => 1);
    ...
    $ctx->release;
});
```

- wrapped => $int

  Use this if you need to write your own tool that wraps a call to `context()` with the intent that it should return a context object.

```
sub my_context {
    my %params = ( wrapped => 0, @_ );
    $params{wrapped}++;
    my $ctx = context(%params);
    ...
    return $ctx;
}

sub my_tool {
    my $ctx = my_context();
    ...
    $ctx->release;
}
```

  If you do not do this, then tools you call that also check for a context will notice that the context they grabbed was created at the same stack depth, which will trigger protective measures that warn you and destroy the existing context.

- stack => $stack

  Normally `context()` looks at the global hub stack. If you are maintaining your own *Test2::API::Stack* instance you may pass it in to be used instead of the global one.

- hub => $hub

  Use this parameter if you want to obtain the context for a specific hub instead of

whatever one happens to be at the top of the stack.

- on_init => sub { ... }

  This lets you provide a callback sub that will be called **ONLY** if your call to `context()` generated a new context. The callback **WILL NOT** be called if `context()` is returning an existing context. The only argument passed into the callback will be the context object itself.

```
sub foo {
    my $ctx = context(on_init => sub { 'will run' });

    my $inner = sub {
        # This callback is not run since we are getting the
↪existing
        # context from our parent sub.
        my $ctx = context(on_init => sub { 'will NOT run' });
        $ctx->release;
    }
    $inner->();

    $ctx->release;
}
```

- on_release => sub { ... }

  This lets you provide a callback sub that will be called when the context instance is released. This callback will be added to the returned context even if an existing context is returned. If multiple calls to context add callbacks, then all will be called in reverse order when the context is finally released.

```
sub foo {
    my $ctx = context(on_release => sub { 'will run second' });

    my $inner = sub {
        my $ctx = context(on_release => sub { 'will run first' }
↪);

        # Neither callback runs on this release
        $ctx->release;
    }
    $inner->();

    # Both callbacks run here.
    $ctx->release;
}
```

release($;$)

Usage:

- release $ctx;
- release $ctx, ...;

This is intended as a shortcut that lets you release your context and return a value in one statement. This function will get your context, and an optional return value. It will release your context, then return your value. Scalar context is always assumed.

```
sub tool {
    my $ctx = context();
    ...

    return release $ctx, 1;
}
```

This tool is most useful when you want to return the value you get from calling a function that needs to see the current context:

```
my $ctx = context();
my $out = some_tool(...);
$ctx->release;
return $out;
```

We can combine the last 3 lines of the above like so:

```
my $ctx = context();
release $ctx, some_tool(...);
```

context_do(&;@)

Usage:

```
sub my_tool {
    context_do {
        my $ctx = shift;

        my (@args) = @_;

        $ctx->ok(1, "pass");

        ...

        # No need to call $ctx->release, done for you on scope exit.
    } @_;
}
```

Using this inside your test tool takes care of a lot of boilerplate for you. It will ensure a context is acquired. It will capture and rethrow any exception. It will ensure the context is released when you are done. It preserves the subroutine call context (list, scalar, void).

This is the safest way to write a test tool. The only two downsides to this are a slight performance decrease, and some extra indentation in your source. If the indentation is a problem for you then you can take a peek at the next section.

no_context(&;$)

Usage:

- no_context { ... };
- no_context { ... } $hid;

```
sub my_tool(&) {
    my $code = shift;
    my $ctx = context();
    ...

    no_context {
        # Things in here will not see our current context, they
↪get a new
        # one.

        $code->();
    };

    ...
    $ctx->release;
};
```

This tool will hide a context for the provided block of code. This means any tools run inside the block will get a completely new context if they acquire one. The new context will be inherited by tools nested below the one that acquired it.

This will normally hide the current context for the top hub. If you need to hide the context for a different hub you can pass in the optional `$hid` parameter.

intercept(&)

Usage:

```
my $events = intercept {
    ok(1, "pass");
    ok(0, "fail");
    ...
};
```

This function takes a codeblock as its only argument, and it has a prototype. It will execute the codeblock, intercepting any generated events in the process. It will return an array reference with all the generated event objects. All events should be subclasses of *Test2::Event*.

As of version 1.302178 the events array that is returned is blssed as an *Test2::API::InterceptResult* instance. *Test2::API::InterceptResult* Provides a helpful interface for filtering and/or inspecting the events list overall, or individual events within the list.

This is intended to help you test your test code. This is not intended for people simply writing tests.

run_subtest(...)

Usage:

```
run_subtest($NAME, \&CODE, $BUFFERED, @ARGS)

# or

run_subtest($NAME, \&CODE, \%PARAMS, @ARGS)
```

This will run the provided codeblock with the args in `@args`. This codeblock will be run as a subtest. A subtest is an isolated test state that is condensed into a single *Test2::Event::Subtest* event, which contains all events generated inside the subtest.

ARGUMENTS:

- $NAME

  The name of the subtest.

- \&CODE

  The code to run inside the subtest.

- $BUFFERED or \%PARAMS

  If this is a simple scalar then it will be treated as a boolean for the 'buffered' setting. If this is a hash reference then it will be used as a parameters hash. The param hash will be used for hub construction (with the specified keys removed).

  Keys that are removed and used by run_subtest:

  - 'buffered' => $bool

    Toggle buffered status.

  - 'inherit_trace' => $bool

    Normally the subtest hub is pushed and the sub is allowed to generate its own root context for the hub. When this setting is turned on a root context will be created for the hub that shares the same trace as the current context.

    Set this to true if your tool is producing subtests without user-specified subs.

  - 'no_fork' => $bool

    Defaults to off. Normally forking inside a subtest will actually fork the subtest, resulting in 2 final subtest events. This parameter will turn off that behavior, only the original process/thread will return a final subtest event.

- @ARGS

  Any extra arguments you want passed into the subtest code.

BUFFERED VS UNBUFFERED (OR STREAMED)

Normally all events inside and outside a subtest are sent to the formatter immediately by the hub. Sometimes it is desirable to hold off sending events within a subtest until the subtest is complete. This usually depends on the formatter being used.

- Things not affected by this flag

  In both cases events are generated and stored in an array. This array is eventually used to populate the `subevents` attribute on the *Test2::Event::Subtest* event that is generated at the end of the subtest. This flag has no effect on this part; it always happens.

  At the end of the subtest, the final *Test2::Event::Subtest* event is sent to the formatter.

- Things that are affected by this flag

  The `buffered` attribute of the *Test2::Event::Subtest* event will be set to the value of this flag. This means any formatter, listener, etc which looks at the event will know if it was buffered.

- Things that are formatter dependent

  Events within a buffered subtest may or may not be sent to the formatter as they happen. If a formatter fails to specify then the default is to **NOT SEND** the events as they are generated, instead the formatter can pull them from the `subevents` attribute.

  A formatter can specify by implementing the `hide_buffered()` method. If this method returns true then events generated inside a buffered subtest will not be sent independently of the final subtest event.

An example of how this is used is the *Test2::Formatter::TAP* formatter. For unbuffered subtests the events are rendered as they are generated. At the end of the subtest, the final subtest event is rendered, but the `subevents` attribute is ignored. For buffered subtests the opposite occurs, the events are NOT rendered as they are generated, instead the `subevents` attribute is used to render them all at once. This is useful when running subtests tests in parallel, since without it the output from subtests would be interleaved together.

OTHER API EXPORTS

Exports in this section are not commonly needed. These all have the 'test2_' prefix to help ensure they stand out. You should look at the "MAIN API EXPORTS" section before looking here. This section is one where "Great power comes with great responsibility". It is possible to break things badly if you are not careful with these.

All exports are optional. You need to list which ones you want at import time:

```
use Test2::API qw/test2_init_done .../;
```

STATUS AND INITIALIZATION STATE

These provide access to internal state and object instances.

- $bool = test2_init_done()

  This will return true if the stack and IPC instances have already been initialized. It will return false if they have not. Init happens as late as possible. It happens as soon as a tool requests the IPC instance, the formatter, or the stack.

- $bool = test2_load_done()

  This will simply return the boolean value of the loaded flag. If Test2 has finished loading this will be true, otherwise false. Loading is considered complete the first time a tool requests a context.

- test2_set_is_end()

- test2_set_is_end($bool)

  This is used to toggle Test2's belief that the END phase has already started. With no arguments this will set it to true. With arguments it will set it to the first argument's value.

  This is used to prevent the use of `caller()` in END blocks which can cause segfaults. This is only necessary in some persistent environments that may have multiple END phases.

- $bool = test2_get_is_end()

  Check if Test2 believes it is the END phase.

- $stack = test2_stack()

  This will return the global *Test2::API::Stack* instance. If this has not yet been initialized it will be initialized now.

- $bool = test2_is_testing_done()

  This will return true if testing is complete and no other events should be sent. This is useful in things like warning handlers where you might want to turn warnings into events, but need them to start acting like normal warnings when testing is done.

  ```
  $SIG{__WARN__} = sub {
      my ($warning) = @_;

      if (test2_is_testing_done()) {
          warn @_;
      }
      else {
          my $ctx = context();
          ...
          $ctx->release
      }
  }
  ```

- test2_ipc_disable

Disable IPC.

- $bool = test2_ipc_disabled

  Check if IPC is disabled.

- test2_ipc_wait_enable()
- test2_ipc_wait_disable()
- $bool = test2_ipc_wait_enabled()

  These can be used to turn IPC waiting on and off, or check the current value of the flag.

  Waiting is turned on by default. Waiting will cause the parent process/thread to wait until all child processes and threads are finished before exiting. You will almost never want to turn this off.

- $bool = test2_no_wait()
- test2_no_wait($bool)

  DISCOURAGED: This is a confusing interface, it is better to use `test2_ipc_wait_enable()`, `test2_ipc_wait_disable()` and `test2_ipc_wait_enabled()`.

  This can be used to get/set the no_wait status. Waiting is turned on by default. Waiting will cause the parent process/thread to wait until all child processes and threads are finished before exiting. You will almost never want to turn this off.

- $fh = test2_stdout()
- $fh = test2_stderr()

  These functions return the filehandles that test output should be written to. They are primarily useful when writing a custom formatter and code that turns events into actual output (TAP, etc.). They will return a dupe of the original filehandles that formatted output can be sent to regardless of whatever state the currently running test may have left STDOUT and STDERR in.

- test2_reset_io()

  Re-dupe the internal filehandles returned by `test2_stdout()` and `test2_stderr()` from the current STDOUT and STDERR. You shouldn't need to do this except in very peculiar situations (for example, you're testing a new formatter and you need control over where the formatter is sending its output.)

BEHAVIOR HOOKS

These are hooks that allow you to add custom behavior to actions taken by Test2 and tools built on top of it.

- test2_add_callback_exit(sub { ... })

  This can be used to add a callback that is called after all testing is done. This is too late to add additional results, the main use of this callback is to set the exit code.

```
test2_add_callback_exit(
    sub {
        my ($context, $exit, \$new_exit) = @_;
        ...
    }
);
```

The `$context` passed in will be an instance of *Test2::API::Context*. The `$exit` argument will be the original exit code before anything modified it. `$$new_exit` is a reference to the new exit code. You may modify this to change the exit code. Please note that `$$new_exit` may already be different from `$exit`

- test2_add_callback_post_load(sub { ... })

  Add a callback that will be called when Test2 is finished loading. This means the callback will be run once, the first time a context is obtained. If Test2 has already finished loading then the callback will be run immediately.

- test2_add_callback_testing_done(sub { ... })

  This adds your coderef as a follow-up to the root hub after Test2 is finished loading.

  This is essentially a helper to do the following:

```
test2_add_callback_post_load(sub {
    my $stack = test2_stack();
    $stack->top; # Ensure we have a hub
    my ($hub) = Test2::API::test2_stack->all;

    $hub->set_active(1);

    $hub->follow_up(sub { ... }); # <-- Your coderef here
});
```

- test2_add_callback_context_acquire(sub { ... })

  Add a callback that will be called every time someone tries to acquire a context. This will be called on EVERY call to `context()`. It gets a single argument, a reference to the hash of parameters being used the construct the context. This is your chance to change the parameters by directly altering the hash.

```
test2_add_callback_context_acquire(sub {
    my $params = shift;
    $params->{level}++;
});
```

  This is a very scary API function. Please do not use this unless you need to. This is here for *Test::Builder* and backwards compatibility. This has you directly manipulate the hash instead of returning a new one for performance reasons.

- test2_add_callback_context_init(sub { ... })

  Add a callback that will be called every time a new context is created. The callback will receive the newly created context as its only argument.

- test2_add_callback_context_release(sub { ... })

Add a callback that will be called every time a context is released. The callback will receive the released context as its only argument.

- test2_add_callback_pre_subtest(sub { ... })

  Add a callback that will be called every time a subtest is going to be run. The callback will receive the subtest name, coderef, and any arguments.

- @list = test2_list_context_acquire_callbacks()

  Return all the context acquire callback references.

- @list = test2_list_context_init_callbacks()

  Returns all the context init callback references.

- @list = test2_list_context_release_callbacks()

  Returns all the context release callback references.

- @list = test2_list_exit_callbacks()

  Returns all the exit callback references.

- @list = test2_list_post_load_callbacks()

  Returns all the post load callback references.

- @list = test2_list_pre_subtest_callbacks()

  Returns all the pre-subtest callback references.

- test2_add_uuid_via(sub { ... })

- $sub = test2_add_uuid_via()

  This allows you to provide a UUID generator. If provided UUIDs will be attached to all events, hubs, and contexts. This is useful for storing, tracking, and linking these objects.

  The sub you provide should always return a unique identifier. Most things will expect a proper UUID string, however nothing in Test2::API enforces this.

  The sub will receive exactly 1 argument, the type of thing being tagged 'context', 'hub', or 'event'. In the future additional things may be tagged, in which case new strings will be passed in. These are purely informative, you can (and usually should) ignore them.

- test2_add_pending_diag($diag)

- test2_add_pending_diag($diag1, $diag2)

  Add a diagnostics message that will be issued the next time a context in which a failure occurred is released.

  This can also be thought of like this: "If the next bit causes a failed assertion, add this diagnostics message".

- @diags = test2_get_pending_diags()

  Get all the current pending diagnostics messages.

- @diags = test2_clear_pending_diags()

  Clear any pending diagnostics, returning them.

IPC AND CONCURRENCY

These let you access, or specify, the IPC system internals.

- $bool = test2_has_ipc()

  Check if IPC is enabled.

- $ipc = test2_ipc()

  This will return the global *Test2::IPC::Driver* instance. If this has not yet been initialized it will be initialized now.

- test2_ipc_add_driver($DRIVER)

  Add an IPC driver to the list. This will add the driver to the start of the list.

- @drivers = test2_ipc_drivers()

  Get the list of IPC drivers.

- $bool = test2_ipc_polling()

  Check if polling is enabled.

- test2_ipc_enable_polling()

  Turn on polling. This will cull events from other processes and threads every time a context is created.

- test2_ipc_disable_polling()

  Turn off IPC polling.

- test2_ipc_enable_shm()

  Legacy, this is currently a no-op that returns 0;

- test2_ipc_set_pending($uniq_val)

  Tell other processes and events that an event is pending. `$uniq_val` should be a unique value no other thread/process will generate.

  Note: After calling this `test2_ipc_get_pending()` will return 1. This is intentional, and not avoidable.

- $pending = test2_ipc_get_pending()

  This returns -1 if there is no way to check (assume yes)

  This returns 0 if there are (most likely) no pending events.

  This returns 1 if there are (likely) pending events. Upon return it will reset, nothing else will be able to see that there were pending events.

- $timeout = test2_ipc_get_timeout()

- test2_ipc_set_timeout($timeout)

  Get/Set the timeout value for the IPC system. This timeout is how long the IPC system will wait for child processes and threads to finish before aborting.

  The default value is `30` seconds.

MANAGING FORMATTERS

These let you access, or specify, the formatters that can/should be used.

- $formatter = test2_formatter

  This will return the global formatter class. This is not an instance. By default the formatter is set to *Test2::Formatter::TAP*.

  You can override this default using the `T2_FORMATTER` environment variable.

  Normally 'Test2::Formatter::' is prefixed to the value in the environment variable:

```
$ T2_FORMATTER='TAP' perl test.t     # Use the␣
↪Test2::Formatter::TAP formatter
$ T2_FORMATTER='Foo' perl test.t     # Use the␣
↪Test2::Formatter::Foo formatter
```

  If you want to specify a full module name you use the '+' prefix:

```
$ T2_FORMATTER='+Foo::Bar' perl test.t     # Use the Foo::Bar␣
↪formatter
```

- test2_formatter_set($class_or_instance)

  Set the global formatter class. This can only be set once. **Note:** This will override anything specified in the 'T2_FORMATTER' environment variable.

- @formatters = test2_formatters()

  Get a list of all loaded formatters.

- test2_formatter_add($class_or_instance)

  Add a formatter to the list. Last formatter added is used at initialization. If this is called after initialization a warning will be issued.

TIME STAMPS

You can enable or disable timestamps in trace facets. They are disabled by default for compatibility and performance reasons.

- test2_enable_trace_stamps()

  Enable stamps in traces.

- test2_disable_trace_stamps()

  Disable stamps in traces.

- $bool = test2_trace_stamps_enabled()

  Check status of trace stamps.

OTHER EXAMPLES

See the `/Examples/` directory included in this distribution.

SEE ALSO

Test2::API::Context - Detailed documentation of the context object.

Test2::IPC - The IPC system used for threading/fork support.

Test2::Formatter - Formatters such as TAP live here.

Test2::Event - Events live in this namespace.

Test2::Hub - All events eventually funnel through a hub. Custom hubs are how `intercept()` and `run_subtest()` are implemented.

MAGIC

This package has an END block. This END block is responsible for setting the exit code based on the test results. This end block also calls the callbacks that can be added to this package.

SOURCE

The source code repository for Test2 can be found at https://github.com/Test-More/test-more/.

What breaks at what version

DESCRIPTION

This module provides lists of modules that are broken, or have been broken in the past, when upgrading *Test::Builder* to use *Test2*.

FUNCTIONS

These can be imported, or called as methods on the class.

-
- This returns key/value pairs. The key is the module name, the value is the version number. If the installed version of the module is at or below the specified one then an upgrade would be a good idea, but not strictly necessary.
-
- This returns key/value pairs. The key is the module name, the value is the version number. If the installed version of the module is at or below the specified one then an upgrade is required for the module to work properly.
-
- This returns key/value pairs. The key is the module name, the value is the version number. If the installed version of the module is at or below the specified one then the module will not work. A newer version may work, but is not tested or verified.

SOURCE

Test2::API::Context

Object to represent a testing context.

DESCRIPTION

The context object is the primary interface for authors of testing tools written with *Test2*. The context object represents the context in which a test takes place (File and Line Number), and provides a quick way to generate events from that context. The context object also takes care of sending events to the correct *Test2::Hub* instance.

SYNOPSIS

In general you will not be creating contexts directly. To obtain a context you should always use `context()` which is exported by the *Test2::API* module.

```
use Test2::API qw/context/;

sub my_ok {
    my ($bool, $name) = @_;
    my $ctx = context();

    if ($bool) {
        $ctx->pass($name);
    }
    else {
        $ctx->fail($name);
    }

    $ctx->release; # You MUST do this!
    return $bool;
}
```

Context objects make it easy to wrap other tools that also use context. Once you grab a context, any tool you call before releasing your context will inherit it:

```
sub wrapper {
    my ($bool, $name) = @_;
    my $ctx = context();
    $ctx->diag("wrapping my_ok");

    my $out = my_ok($bool, $name);
    $ctx->release; # You MUST do this!
    return $out;
}
```

CRITICAL DETAILS

- you MUST always use the context() sub from Test2::API

  Creating your own context via `Test2::API::Context->new()` will almost never produce a desirable result. Use `context()` which is exported by *Test2::API*.

  There are a handful of cases where a tool author may want to create a new context by hand, which is why the `new` method exists. Unless you really know what you are doing you should avoid this.

- You MUST always release the context when done with it

  Releasing the context tells the system you are done with it. This gives it a chance to run any necessary callbacks or cleanup tasks. If you forget to release the context it will try to detect the problem and warn you about it.

- You MUST NOT pass context objects around

  When you obtain a context object it is made specifically for your tool and any tools nested within. If you pass a context around you run the risk of polluting other tools with incorrect context information.

  If you are certain that you want a different tool to use the same context you may pass it a snapshot. `$ctx->snapshot` will give you a shallow clone of the context that is safe to pass around or store.

- You MUST NOT store or cache a context for later

  As long as a context exists for a given hub, all tools that try to get a context will get the existing instance. If you try to store the context you will pollute other tools with incorrect context information.

  If you are certain that you want to save the context for later, you can use a snapshot. `$ctx->snapshot` will give you a shallow clone of the context that is safe to pass around or store.

  `context()` has some mechanisms to protect you if you do cause a context to persist beyond the scope in which it was obtained. In practice you should not rely on these protections, and they are fairly noisy with warnings.

- You SHOULD obtain your context as soon as possible in a given tool

  You never know what tools you call from within your own tool will need a context. Obtaining the context early ensures that nested tools can find the context you want them to find.

METHODS

- $ctx->done_testing;

  Note that testing is finished. If no plan has been set this will generate a Plan event.

- $clone = $ctx->snapshot()

  This will return a shallow clone of the context. The shallow clone is safe to store for later.

- $ctx->release()

This will release the context. This runs cleanup tasks, and several important hooks. It will also restore `$!`, `$?`, and `$@` to what they were when the context was created.

Note: If a context is acquired more than once an internal refcount is kept. `release()` decrements the ref count, none of the other actions of `release()` will occur unless the refcount hits 0. This means only the last call to `release()` will reset `$?`, `$!`, `$@`, and run the cleanup tasks.

- $ctx->throw($message)

  This will throw an exception reporting to the file and line number of the context. This will also release the context for you.

- $ctx->alert($message)

  This will issue a warning from the file and line number of the context.

- $stack = $ctx->stack()

  This will return the *Test2::API::Stack* instance the context used to find the current hub.

- $hub = $ctx->hub()

  This will return the *Test2::Hub* instance the context recognizes as the current one to which all events should be sent.

- $dbg = $ctx->trace()

  This will return the *Test2::EventFacet::Trace* instance used by the context.

- $ctx->do_in_context(\&code, @args);

  Sometimes you have a context that is not current, and you want things to use it as the current one. In these cases you can call `$ctx->do_in_context(sub { ... })`. The codeblock will be run, and anything inside of it that looks for a context will find the one on which the method was called.

  This **DOES NOT** affect context on other hubs, only the hub used by the context will be affected.

```
my $ctx = ...;
$ctx->do_in_context(sub {
    my $ctx = context(); # returns the $ctx the sub is called on
});
```

  Note: The context will actually be cloned, the clone will be used instead of the original. This allows the thread id, process id, and error variables to be correct without modifying the original context.

- $ctx->restore_error_vars()

  This will set `$!`, `$?`, and `$@` to what they were when the context was created. There is no localization or anything done here, calling this method will actually set these vars.

- $! = $ctx->errno()

  The (numeric) value of `$!` when the context was created.

- $? = $ctx->child_error()

  The value of `$?` when the context was created.

- $@ = $ctx->eval_error()

  The value of `$@` when the context was created.

EVENT PRODUCTION METHODS

Which one do I use?

The `pass*` and `fail*` are optimal if they meet your situation, using one of them will always be the most optimal. That said they are optimal by eliminating many features.

Method such as ok, and `note` are shortcuts for generating common 1-task events based on the old API, however they are forward compatible, and easy to use. If these meet your needs then go ahead and use them, but please check back often for alternatives that may be added.

If you want to generate new style events, events that do many things at once, then you want the `*ev2*` methods. These let you directly specify which facets you wish to use.

- $event = $ctx->pass()
- $event = $ctx->pass($name)

  This will send and return an *Test2::Event::Pass* event. You may optionally provide a `$name` for the assertion.

  The *Test2::Event::Pass* is a specially crafted and optimized event, using this will help the performance of passing tests.

- $true = $ctx->pass_and_release()
- $true = $ctx->pass_and_release($name)

  This is a combination of `pass()` and `release()`. You can use this if you do not plan to do anything with the context after sending the event. This helps write more clear and compact code.

```
sub shorthand {
    my ($bool, $name) = @_;
    my $ctx = context();
    return $ctx->pass_and_release($name) if $bool;

    ... Handle a failure ...
}

sub longform {
    my ($bool, $name) = @_;
    my $ctx = context();

    if ($bool) {
        $ctx->pass($name);
        $ctx->release;
        return 1;
```

(continues on next page)

(continued from previous page)

```
    }

    ... Handle a failure ...
}
```

- my $event = $ctx->fail()
- my $event = $ctx->fail($name)
- my $event = $ctx->fail($name, @diagnostics)

  This lets you send an *Test2::Event::Fail* event. You may optionally provide a `$name` and `@diagnostics` messages.

  Diagnostics messages can be simple strings, data structures, or instances of *Test2::EventFacet::Info::Table* (which are converted inline into the *Test2::EventFacet::Info* structure).

- my $false = $ctx->fail_and_release()
- my $false = $ctx->fail_and_release($name)
- my $false = $ctx->fail_and_release($name, @diagnostics)

  This is a combination of `fail()` and `release()`. This can be used to write clearer and shorter code.

```
sub shorthand {
    my ($bool, $name) = @_;
    my $ctx = context();
    return $ctx->fail_and_release($name) unless $bool;

    ... Handle a success ...
}

sub longform {
    my ($bool, $name) = @_;
    my $ctx = context();

    unless ($bool) {
        $ctx->pass($name);
        $ctx->release;
        return 1;
    }

    ... Handle a success ...
}
```

- $event = $ctx->ok($bool, $name)
- $event = $ctx->ok($bool, $name, \@on_fail)

  NOTE: Use of this method is discouraged in favor of `pass()` and `fail()` which produce *Test2::Event::Pass* and *Test2::Event::Fail* events. These newer event types are faster and less crufty.

This will create an *Test2::Event::Ok* object for you. If `$bool` is false then an *Test2::Event::Diag* event will be sent as well with details about the failure. If you do not want automatic diagnostics you should use the `send_event()` method directly.

The third argument `\@on_fail`) is an optional set of diagnostics to be sent in the event of a test failure. Unlike with `fail()` these diagnostics must be plain strings, data structures are not supported.

- $event = $ctx->note($message)

  Send an *Test2::Event::Note*. This event prints a message to STDOUT.

- $event = $ctx->diag($message)

  Send an *Test2::Event::Diag*. This event prints a message to STDERR.

- $event = $ctx->plan($max)

- $event = $ctx->plan(0, 'SKIP', $reason)

  This can be used to send an *Test2::Event::Plan* event. This event usually takes either a number of tests you expect to run. Optionally you can set the expected count to 0 and give the 'SKIP' directive with a reason to cause all tests to be skipped.

- $event = $ctx->skip($name, $reason);

  Send an *Test2::Event::Skip* event.

- $event = $ctx->bail($reason)

  This sends an *Test2::Event::Bail* event. This event will completely terminate all testing.

- $event = $ctx->send_ev2(%facets)

  This lets you build and send a V2 event directly from facets. The event is returned after it is sent.

  This example sends a single assertion, a note (comment for stdout in Test::Builder talk) and sets the plan to 1.

```
my $event = $ctx->send_event(
    plan   => {count => 1},
    assert => {pass  => 1, details => "A passing assert"},
    info => [{tag => 'NOTE', details => "This is a note"}],
);
```

- $event = $ctx->build_e2(%facets)

  This is the same as `send_ev2()`, except it builds and returns the event without sending it.

- $event = $ctx->send_ev2_and_release($Type, %parameters)

  This is a combination of `send_ev2()` and `release()`.

```
sub shorthand {
    my $ctx = context();
    return $ctx->send_ev2_and_release(assert => {pass => 1,␣
↪details => 'foo'});
```

(continues on next page)

(continued from previous page)

```
}

sub longform {
    my $ctx = context();
    my $event = $ctx->send_ev2(assert => {pass => 1, details =>
↪'foo'});
    $ctx->release;
    return $event;
}
```

- $event = $ctx->send_event($Type, %parameters)

  It is better to use send_ev2() in new code.

  This lets you build and send an event of any type. The `$Type` argument should be the event package name with `Test2::Event::` left off, or a fully qualified package name prefixed with a '+'. The event is returned after it is sent.

```
my $event = $ctx->send_event('Ok', ...);
```

  or

```
my $event = $ctx->send_event('+Test2::Event::Ok', ...);
```

- $event = $ctx->build_event($Type, %parameters)

  It is better to use build_ev2() in new code.

  This is the same as `send_event()`, except it builds and returns the event without sending it.

- $event = $ctx->send_event_and_release($Type, %parameters)

  It is better to use send_ev2_and_release() in new code.

  This is a combination of `send_event()` and `release()`.

```
sub shorthand {
    my $ctx = context();
    return $ctx->send_event_and_release(Pass => { name => 'foo'␣
↪});
}

sub longform {
    my $ctx = context();
    my $event = $ctx->send_event(Pass => { name => 'foo' });
    $ctx->release;
    return $event;
}
```

HOOKS

There are 2 types of hooks, init hooks, and release hooks. As the names suggest, these hooks are triggered when contexts are created or released.

INIT HOOKS

These are called whenever a context is initialized. That means when a new instance is created. These hooks are **NOT** called every time something requests a context, just when a new one is created.

GLOBAL

This is how you add a global init callback. Global callbacks happen for every context for any hub or stack.

```
Test2::API::test2_add_callback_context_init(sub {
    my $ctx = shift;
    ...
});
```

PER HUB

This is how you add an init callback for all contexts created for a given hub. These callbacks will not run for other hubs.

```
$hub->add_context_init(sub {
    my $ctx = shift;
    ...
});
```

PER CONTEXT

This is how you specify an init hook that will only run if your call to `context()` generates a new context. The callback will be ignored if `context()` is returning an existing context.

```
my $ctx = context(on_init => sub {
    my $ctx = shift;
    ...
});
```

RELEASE HOOKS

These are called whenever a context is released. That means when the last reference to the instance is about to be destroyed. These hooks are **NOT** called every time `$ctx->release` is called.

GLOBAL

This is how you add a global release callback. Global callbacks happen for every context for any hub or stack.

```
Test2::API::test2_add_callback_context_release(sub {
    my $ctx = shift;
    ...
});
```

PER HUB

This is how you add a release callback for all contexts created for a given hub. These callbacks will not run for other hubs.

```
$hub->add_context_release(sub {
    my $ctx = shift;
    ...
});
```

PER CONTEXT

This is how you add release callbacks directly to a context. The callback will **ALWAYS** be added to the context that gets returned, it does not matter if a new one is generated, or if an existing one is returned.

```
my $ctx = context(on_release => sub {
    my $ctx = shift;
    ...
});
```

THIRD PARTY META-DATA

This object consumes *Test2::Util::ExternalMeta* which provides a consistent way for you to attach meta-data to instances of this class. This is useful for tools, plugins, and other extensions.

Test2::API::Instance

Object used by Test2::API under the hood

DESCRIPTION

This object encapsulates the global shared state tracked by *Test2*. A single global instance of this package is stored (and obscured) by the *Test2::API* package.

There is no reason to directly use this package. This package is documented for completeness. This package can change, or go away completely at any time. Directly using, or monkeypatching this package is not supported in any way shape or form.

SYNOPSIS

```
use Test2::API::Instance;

my $obj = Test2::API::Instance->new;
```

- $pid = $obj->pid

  PID of this instance.

- $obj->tid

  Thread ID of this instance.

- $obj->reset()

  Reset the object to defaults.

- $obj->load()

  Set the internal state to loaded, and run and stored post-load callbacks.

- $bool = $obj->loaded

  Check if the state is set to loaded.

- $arrayref = $obj->post_load_callbacks

  Get the post-load callbacks.

- $obj->add_post_load_callback(sub { ... })

  Add a post-load callback. If `load()` has already been called then the callback will be immediately executed. If `load()` has not been called then the callback will be stored and executed later when `load()` is called.

- $hashref = $obj->contexts()

  Get a hashref of all active contexts keyed by hub id.

- $arrayref = $obj->context_acquire_callbacks

  Get all context acquire callbacks.

- $arrayref = $obj->context_init_callbacks

  Get all context init callbacks.

- $arrayref = $obj->context_release_callbacks

  Get all context release callbacks.

- $arrayref = $obj->pre_subtest_callbacks

  Get all pre-subtest callbacks.

- $obj->add_context_init_callback(sub { ... })

  Add a context init callback. Subs are called every time a context is created. Subs get the newly created context as their only argument.

- $obj->add_context_release_callback(sub { ... })

  Add a context release callback. Subs are called every time a context is released. Subs get the released context as their only argument. These callbacks should not call release on the context.

- $obj->add_pre_subtest_callback(sub { ... })

  Add a pre-subtest callback. Subs are called every time a subtest is going to be run. Subs get the subtest name, coderef, and any arguments.

- $obj->set_exit()

  This is intended to be called in an `END { ... }` block. This will look at test state and set $?. This will also call any end callbacks, and wait on child processes/threads.

- $obj->set_ipc_pending($val)

  Tell other processes and threads there is a pending event. `$val` should be a unique value no other thread/process will generate.

  Note: This will also make the current process see a pending event.

- $pending = $obj->get_ipc_pending()

  This returns -1 if it is not possible to know.

  This returns 0 if there are no pending events.

  This returns 1 if there are pending events.

- $timeout = $obj->ipc_timeout;

- $obj->set_ipc_timeout($timeout);

  How long to wait for child processes and threads before aborting.

- $drivers = $obj->ipc_drivers

  Get the list of IPC drivers.

- $obj->add_ipc_driver($DRIVER_CLASS)

  Add an IPC driver to the list. The most recently added IPC driver will become the global one during initialization. If a driver is added after initialization has occurred a warning will be generated:

```
"IPC driver $driver loaded too late to be used as the global␣
↪ipc driver"
```

- $bool = $obj->ipc_polling

  Check if polling is enabled.

- $obj->enable_ipc_polling

  Turn on polling. This will cull events from other processes and threads every time a context is created.

- $obj->disable_ipc_polling

  Turn off IPC polling.

- $bool = $obj->no_wait

- $bool = $obj->set_no_wait($bool)

  Get/Set no_wait. This option is used to turn off process/thread waiting at exit.

- $arrayref = $obj->exit_callbacks

  Get the exit callbacks.

- $obj->add_exit_callback(sub { ... })

  Add an exit callback. This callback will be called by `set_exit()`.

- $bool = $obj->finalized

  Check if the object is finalized. Finalization happens when either `ipc()`, `stack()`, or `format()` are called on the object. Once finalization happens these fields are considered unchangeable (not enforced here, enforced by *Test2*).

- $ipc = $obj->ipc

  Get the one true IPC instance.

- $obj->ipc_disable

  Turn IPC off

- $bool = $obj->ipc_disabled

  Check if IPC is disabled

- $stack = $obj->stack

  Get the one true hub stack.

- $formatter = $obj->formatter

  Get the global formatter. By default this is the `'Test2::Formatter::TAP'` package. This could be any package that implements the `write()` method. This can also be an instantiated object.

- $bool = $obj->formatter_set()

  Check if a formatter has been set.

- $obj->add_formatter($class)

- $obj->add_formatter($obj)

  Add a formatter. The most recently added formatter will become the global one during initialization. If a formatter is added after initialization has occurred a warning will be generated:

```
"Formatter $formatter loaded too late to be used as the global␣
↪formatter"
```

- $obj->set_add_uuid_via(sub { ... })

- $sub = $obj->add_uuid_via()

  This allows you to provide a UUID generator. If provided UUIDs will be attached to all events, hubs, and contexts. This is useful for storing, tracking, and linking these objects.

  The sub you provide should always return a unique identifier. Most things will expect a proper UUID string, however nothing in Test2::API enforces this.

  The sub will receive exactly 1 argument, the type of thing being tagged 'context', 'hub', or 'event'. In the future additional things may be tagged, in which case new strings will be passed in. These are purely informative, you can (and usually should) ignore them.

Test2::API::InterceptResult

Representation of a list of events.

DESCRIPTION

This class represents a list of events, normally obtained using `intercept()` from *Test2::API*.

This class is intended for people who with to verify the results of test tools they write.

This class provides methods to normalize, summarize, or map the list of events. The output of these operations makes verifying your testing tools and the events they generate significantly easier. In most cases this spares you from needing a deep understanding of the event/facet model.

SYNOPSIS

Usually you get an instance of this class when you use `intercept()` from *Test2::API*.

```
use Test2::V1 '-iPp';
use Test2::API qw/intercept/;

my $events = intercept {
    ok(1, "pass");
    ok(0, "fail");
    todo "broken" => sub { ok(0, "fixme") };
    plan 3;
};

# This is typically the most useful construct
# squash_info() merges assertions and diagnostics that are␣
↪associated
#   (and returns a new instance with the modifications)
# flatten() condenses the facet data into the key details for each␣
↪event
#   (and returns those structures in an arrayref)
is(
    $events->squash_info->flatten(),
    [
        {
            causes_failure => 0,

            name => 'pass',
            pass => 1,

            trace_file => 'xxx.t',
            trace_line => 5,
        },
```

(continues on next page)

(continued from previous page)

```
        {
            causes_failure => 1,

            name => 'fail',
            pass => 0,

            trace_file => 'xxx.t',
            trace_line => 6,

            # There can be more than one diagnostics message so this
↪is
            # always an array when present.
            diag => ["Failed test 'fail'\nat xxx.t line 6."],
        },
        {
            causes_failure => 0,

            name => 'fixme',
            pass => 0,

            trace_file => 'xxx.t',
            trace_line => 7,

            # There can be more than one diagnostics message or todo
            # reason, so these are always an array when present.
            todo => ['broken'],

            # Diag message was turned into a note since the
↪assertion was
            # TODO
            note => ["Failed test 'fixme'\nat xxx.t line 7."],
        },
        {
            causes_failure => 0,

            plan => 3,

            trace_file => 'xxx.t',
            trace_line => 8,
        },
    ],
    "Flattened events look like we expect"
);
```

See *Test2::API::InterceptResult::Event* for a full description of what `flatten()` provides for each event.

METHODS

Please note that no methods modify the original instance unless asked to do so.

CONSTRUCTION

- $events = Test2::API::InterceptResult->new(@EVENTS)
- $events = Test2::API::InterceptResult->new_from_ref(\@EVENTS)

  These create a new instance of Test2::API::InterceptResult from the given events.

  In the first form a new blessed arrayref is returned. In the 'new_from_ref' form the reference you pass in is directly blessed.

  Both of these will throw an exception if called in void context. This is mainly important for the 'filtering' methods listed below which normally return a new instance, they throw an exception in such cases as it probably means someone meant to filter the original in place.

- $clone = $events->clone()

  Make a clone of the original events. Note that this is a deep copy, the entire structure is duplicated. This uses `dclone` from *Storable* to achieve the deep clone.

NORMALIZATION

- @events = $events->event_list

  This returns all the events in list-form.

- $hub = $events->hub

  This returns a new *Test2::Hub* instance that has processed all the events contained in the instance. This gives you a simple way to inspect the state changes your events cause.

- $state = $events->state

  This returns a summary of the state of a hub after processing all the events.

```
{
    count        => 2,      # Number of assertions made
    failed       => 1,      # Number of test failures seen
    is_passing   => 0,      # Boolean, true if the test would␣
↪be passing
                            # after the events are processed.

    plan         => 2,      # Plan, either a number, undef,
↪'SKIP', or 'NO PLAN'
    follows_plan => 1,      # True if there is a plan and it␣
↪was followed.
                            # False if the plan and assertions␣
↪did not
                            # match, undef if no plan was␣
↪present in the
```

                            # reason.
}
```

- $new = $events->upgrade
- $events->upgrade(in_place => $BOOL)

  Note: This normally returns a new instance, leaving the original unchanged. If you call it in void context it will throw an exception. If you want to modify the original you must pass in the `in_place => 1` option. You may call this in void context when you ask to modify it in place. The in-place form returns the instance that was modified so you can chain methods.

  This will create a clone of the list where all events have been converted into *Test2::API::InterceptResult::Event* instances. This is extremely helpful as *Test2::API::InterceptResult::Event* provide a much better interface for working with events. This allows you to avoid thinking about legacy event types.

  This also means your tests against the list are not fragile if the tool you are testing randomly changes what type of events it generates (IE Changing from *Test2::Event::Ok* to *Test2::Event::Pass*, both make assertions and both will normalize to identical (or close enough) *Test2::API::InterceptResult::Event* instances.

  Really you almost always want this, the only reason it is not done automatically is to make sure the `intercept()` tool is backwards compatible.

- $new = $events->squash_info
- $events->squash_info(in_place => $BOOL)

  Note: This normally returns a new instance, leaving the original unchanged. If you call it in void context it will throw an exception. If you want to modify the original you must pass in the `in_place => 1` option. You may call this in void context when you ask to modify it in place. The in-place form returns the instance that was modified so you can chain methods.

  Note: All events in the new or modified instance will be converted to *Test2::API::InterceptResult::Event* instances. There is no way to avoid this, the squash operation requires the upgraded event class.

  Test::More and many other legacy tools would send notes, diags, and assertions

as separate events. A subtest in *Test::More* would send a note with the subtest name, the subtest assertion, and finally a diagnostics event if the subtest failed. This method will normalize things by squashing the note and diag into the same event as the subtest (This is different from putting them into the subtest, which is not what happens).

FILTERING

Note: These normally return new instances, leaving the originals unchanged. If you call them in void context they will throw exceptions. If you want to modify the originals you must pass in the `in_place => 1` option. You may call these in void context when you ask to modify them in place. The in-place forms return the instance that was modified so you can chain methods.

%PARAMS

These all accept the same 2 optional parameters:

- in_place => $BOOL

  When true the method will modify the instance in place instead of returning a new instance.

- args => \@ARGS

  If you wish to pass parameters into the event method being used for filtering, you may do so here.

METHODS

- $events->grep($CALL, %PARAMS)

  This is essentially:

  ```
  Test2::API::InterceptResult->new(
      grep { $_->$CALL( @{$PARAMS{args}} ) } $self->event_list,
  );
  ```

  Note: that $CALL is called on an upgraded version of the event, though the events returned will be the original ones, not the upgraded ones.

  $CALL may be either the name of a method on *Test2::API::InterceptResult::Event*, or a coderef.

- $events->asserts(%PARAMS)

  This is essentially:

  ```
  $events->grep(has_assert => @{$PARAMS{args}})
  ```

  It returns a new instance containing only the events that made assertions.

- $events->subtests(%PARAMS)

  This is essentially:

```
$events->grep(has_subtest => @{$PARAMS{args}})
```

It returns a new instance containing only the events that have subtests.

- $events->diags(%PARAMS)

  This is essentially:

```
$events->grep(has_diags => @{$PARAMS{args}})
```

  It returns a new instance containing only the events that have diags.

- $events->notes(%PARAMS)

  This is essentially:

```
$events->grep(has_notes => @{$PARAMS{args}})
```

  It returns a new instance containing only the events that have notes.

- $events->errors(%PARAMS)

  Note: Errors are NOT failing assertions. Failing assertions are a different thing.

  This is essentially:

```
$events->grep(has_errors => @{$PARAMS{args}})
```

  It returns a new instance containing only the events that have errors.

- $events->plans(%PARAMS)

  This is essentially:

```
$events->grep(has_plan => @{$PARAMS{args}})
```

  It returns a new instance containing only the events that set the plan.

- $events->causes_fail(%PARAMS)
- $events->causes_failure(%PARAMS)

  These are essentially:

```
$events->grep(causes_fail    => @{$PARAMS{args}})
$events->grep(causes_failure => @{$PARAMS{args}})
```

  Note: `causes_fail()` and `causes_failure()` are both aliases for each other in events, so these methods are effectively aliases here as well.

  It returns a new instance containing only the events that cause failure.

MAPPING

These methods **ALWAYS** return an arrayref.

Note: No methods on *Test2::API::InterceptResult::Event* alter the event in any way.

Important Notes about Events:

Test2::API::InterceptResult::Event was tailor-made to be used in event-lists. Most methods that are not applicable to a given event will return an empty list, so you normally do not need to worry about unwanted undef values or exceptions being thrown. Mapping over event methods is an intended use, so it works well to produce lists.

Exceptions to the rule:

Some methods such as `causes_fail` always return a boolean true or false for all events. Any method prefixed with `the_` conveys the intent that the event should have exactly 1 of something, so those will throw an exception when that condition is not true.

- $arrayref = $events->map($CALL, %PARAMS)

  This is essentially:

```
[ map { $_->$CALL(@{ $PARAMS{args} }) } $events->upgrade->event_
↪list ];
```

  $CALL may be either the name of a method on *Test2::API::InterceptResult::Event*, or a coderef.

- $arrayref = $events->flatten(%PARAMS)

  This is essentially:

```
[ map { $_->flatten(@{ $PARAMS{args} }) } $events->upgrade->
↪event_list ];
```

  It returns a new list of flattened structures.

  See *Test2::API::InterceptResult::Event* for details on what `flatten()` returns.

- $arrayref = $events->briefs(%PARAMS)

  This is essentially:

```
[ map { $_->briefs(@{ $PARAMS{args} }) } $events->upgrade->
↪event_list ];
```

  It returns a new list of event briefs.

  See *Test2::API::InterceptResult::Event* for details on what `brief()` returns.

- $arrayref = $events->summaries(%PARAMS)

  This is essentially:

```
[ map { $_->summaries(@{ $PARAMS{args} }) } $events->upgrade->
↪event_list ];
```

  It returns a new list of event summaries.

  See *Test2::API::InterceptResult::Event* for details on what `summary()` returns.

- $arrayref = $events->subtest_results(%PARAMS)

  This is essentially:

```
[ map { $_->subtest_result(@{ $PARAMS{args} }) } $events->
↪upgrade->event_list ];
```

It returns a new list of event summaries.

See *Test2::API::InterceptResult::Event* for details on what `subtest_result()` returns.

- $arrayref = $events->diag_messages(%PARAMS)

  This is essentially:

```
[ map { $_->diag_messages(@{ $PARAMS{args} }) } $events->
↪upgrade->event_list ];
```

  It returns a new list of diagnostic messages (strings).

  See *Test2::API::InterceptResult::Event* for details on what `diag_messages()` returns.

- $arrayref = $events->note_messages(%PARAMS)

  This is essentially:

```
[ map { $_->note_messages(@{ $PARAMS{args} }) } $events->
↪upgrade->event_list ];
```

  It returns a new list of notification messages (strings).

  See *Test2::API::InterceptResult::Event* for details on what `note_messages()` returns.

- $arrayref = $events->error_messages(%PARAMS)

  This is essentially:

```
[ map { $_->error_messages(@{ $PARAMS{args} }) } $events->
↪upgrade->event_list ];
```

  It returns a new list of error messages (strings).

  See *Test2::API::InterceptResult::Event* for details on what `error_messages()` returns.

Modules

- `Test2::API::InterceptResult::Event` - Representation of an event for use in testing other test tools.
- `Test2::API::InterceptResult::Hub` - Hub used by InterceptResult.
- `Test2::API::InterceptResult::Squasher` - Encapsulation of the algorithm that squashes diags into assertions.

Test2::API::InterceptResult::Event

Representation of an event for use in testing other test tools.

DESCRIPTION

`intercept { ... }` from *Test2::API* returns an instance of *Test2::API::InterceptResult* which is a blessed arrayref of *Test2::API::InterceptResult::Event* objects.

This POD documents the methods of these events, which are mainly provided for you to use when testing your test tools.

SYNOPSIS

```
use Test2::V1 '-iPp';
use Test2::API qw/intercept/;

my $events = intercept {
    ok(1, "A passing assertion");
    plan(1);
};

# This will convert all events into instances of
# Test2::API::InterceptResult::Event. Until we do this they are the
# original Test::Event::* instances
$events->upgrade(in_place => 1);

# Now we can get individual events in this form
my $assert = $events->[0];
my $plan   = $events->[1];

# Or we can operate on all events at once:
my $flattened = $events->flatten;
```

(continues on next page)

(continued from previous page)

```
is(
    $flattened,
    [
      {
        causes_failure => 0,

        name => 'A passing assertion',
        pass => 1,

        trace_file => 'xxx.t',
        trace_line => 5,
      },
      {
        causes_failure => 0,

        plan => 1,

        trace_file => 'xxx.t',
        trace_line => 6,
      },
    ],
    "Flattened both events and returned an arrayref of the results
);
```

METHODS

!!! IMPORTANT NOTES ON DESIGN !!!

Please pay attention to what these return, many return a scalar when applicable or an empty list when not (as opposed to undef). Many also always return a list of 0 or more items. Some always return a scalar. Note that none of the methods care about context, their behavior is consistent regardless of scalar, list, or void context.

This was done because this class was specifically designed to be used in a list and generate more lists in bulk operations. Sometimes in a map you want nothing to show up for the event, and you do not want an undef in its place. In general single event instances are not going to be used alone, though that is allowed.

As a general rule any method prefixed with `the_` implies the event should have exactly 1 of the specified item, and and exception will be thrown if there are 0, or more than 1 of the item.

ATTRIBUTES

- $hashref = $event->facet_data

  This will return the facet data hashref, which is all Test2 cares about for any given event.

- $class = $event->result_class

This is normally *Test2::API::InterceptResult*. This is set at construction so that subtest results can be turned into instances of it on demand.

DUPLICATION

- $copy = $event->clone

  Create a deep copy of the event. Modifying either event will not affect the other.

CONDENSED MULTI-FACET DATA

- $bool = $event->causes_failure
- $bool = $event->causes_fail

  These are both aliases of the same functionality.

  This will always return either a true value, or a false value. This never returns a list.

  This method may be relatively slow (still super fast) because it determines pass or fail by creating an instance of *Test2::Hub* and asking it to process the event, and then asks the hub for its pass/fail state. This is slower than building in logic to do the check, but it is more reliable as it will always tell you what the hub thinks, so the logic will never be out of date relative to the Test2 logic that actually cares.

- STRING_OR_EMPTY_LIST = $event->brief

  Not all events have a brief, some events are not rendered by the formatter, others have no "brief" data worth seeing. When this is the case an empty list is returned. This is done intentionally so it can be used in a map operation without having `undef` being included in the result.

  When a brief can be generated it is always a single 1-line string, and is returned as-is, not in a list.

  Possible briefs:

```
# From control facets
"BAILED OUT"
"BAILED OUT: $why"

# From error facets
"ERROR"
"ERROR: $message"
"ERROR: $partial_message [...]"
"ERRORS: $first_error_message [...]"

# From assert facets
"PASS"
"FAIL"
"PASS with amnesty"
"FAIL with amnesty"

# From plan facets
```

(continues on next page)

(continued from previous page)

```
"PLAN $count"
"NO PLAN"
"SKIP ALL"
"SKIP ALL: $why"
```

Note that only the first applicable brief is returned. This is essentially a poor-mans TAP that only includes facets that could (but not necessarily do) cause a failure.

- $hashref = $event->flatten
- $hashref = $event->flatten(include_subevents => 1)

  This ALWAYS returns a hashref. This puts all the most useful data for the most interesting facets into a single hashref for easy validation.

  If there are no meaningful facets this will return an empty hashref.

  If given the 'include_subevents' parameter it will also include subtest data:

  Here is a list of EVERY possible field. If a field is not applicable it will not be present.

  – always present

  ```
  causes_failure => 1,    # Always present
  ```

  – Present if the event has a trace facet

  ```
  trace_line    => 42,
  trace_file    => 'Foo/Bar.pm',
  trace_details => 'Extra trace details',    # usually not␣
  ↪present
  ```

  – If an assertion is present

  ```
  pass => 0,
  name => "1 + 1 = 2, so math works",
  ```

  – If a plan is present:

  ```
  plan => $count_or_SKIP_ALL_or_NO_PLAN,
  ```

  – If amnesty facets are present

  You get an array for each type that is present.

  ```
  todo => [    # Yes you could be under multiple todos, this␣
  ↪will list them all.
      "I will fix this later",
      "I promise to fix these",
  ],

  skip => ["This will format the main drive, do not run"],

  ... => ["Other amnesty"]
  ```

– If Info (note/diag) facets are present

  You get an arrayref for any that are present, the key is not defined if they are not present.

```
diag => [
    "Test failed at Foo/Bar.pm line 42",
    "You forgot to tie your boots",
],

note => ["Your boots are red"],

...  => ["Other info"],
```

– If error facets are present

  Always an arrayref

```
error => [
    "non fatal error (does not cause test failure, just an␣
↪FYI",
    "FATAL: This is a fatal error (causes failure)",
],

# Errors can have alternative tags, but in practice are␣
↪always 'error',
# listing this for completeness.
... => [ ... ]
```

– Present if the event is a subtest

```
subtest => {
    count      => 2,    # Number of assertions made
    failed     => 1,    # Number of test failures seen
    is_passing => 0,    # Boolean, true if the test would be␣
↪passing
                        # after the events are processed.

    plan         => 2,  # Plan, either a number, undef, 'SKIP
↪', or 'NO PLAN'
    follows_plan => 1,  # True if there is a plan and it was␣
↪followed.
                        # False if the plan and assertions␣
↪did not
                        # match, undef if no plan was␣
↪present in the
                        # event list.

    bailed_out => "foo",    # if there was a bail-out in the
                            # events in this will be a␣
↪string explaining
                            # why there was a bailout, if no␣
```

(continues on next page)

(continued from previous page)

```
↪reason was
                                # given this will simply be set␣
↪to true (1).

    skip_reason => "foo",    # If there was a skip_all this␣
↪will give the
                                # reason.
},
```

if (`include_subtest => 1`) was provided as a parameter then the following will be included. This is the result of turning all subtest child events into an *Test2::API::InterceptResult* instance and calling the `flatten` method on it.

```
subevents => Test2::API::InterceptResult->new(@child_events)-
↪>flatten(...),
```

– If a bail-out is being requested

If no reason was given this will be set to 1.

```
bailed_out => "reason",
```

- $hashref = $event->summary()

This returns a limited summary. See `flatten()`, which is usually a better option.

```
{
    brief => $event->brief || '',

    causes_failure => $event->causes_failure,

    trace_line    => $event->trace_line,
    trace_file    => $event->trace_file,
    trace_tool    => $event->trace_subname,
    trace_details => $event->trace_details,

    facets => [ sort keys(%{$event->{+FACET_DATA}}) ],
}
```

DIRECT ARBITRARY FACET ACCESS

- @list_of_facets = $event->facet($name)

This always returns a list of 0 or more items. This fetches the facet instances from the event. For facets like 'assert' this will always return 0 or 1 item. For events like 'info' (diags, notes) this will return 0 or more instances, once for each instance of the facet.

These will be blessed into the proper *Test2::EventFacet* subclass. If no subclass can be found it will be blessed as an Test2::API::InterceptResult::Facet generic facet class.

- $undef_or_facet = $event->the_facet($name)

  If you know you will have exactly 1 instance of a facet you can call this.

  If you are correct and there is exactly one instance of the facet it will always return the hashref.

  If there are 0 instances of the facet this will return undef, not an empty list.

  If there are more than 1 instance this will throw an exception because your assumption was incorrect.

TRACE FACET

- @list_of_facets = $event->trace

  TODO

- $undef_or_hashref = $event->the_trace

  This returns the trace hashref, or undef if it is not present.

- $undef_or_arrayref = $event->frame

  If a trace is present, and has a caller frame, this will be an arrayref:

```
[$package, $file, $line, $subname]
```

  If the trace is not present, or has no caller frame this will return undef.

- $undef_or_string = $event->trace_details

  This is usually undef, but occasionally has a string that overrides the file/line number debugging a trace usually provides on test failure.

- $undef_or_string = $event->trace_package

  Same as `(caller())[0]`, the first element of the trace frame.

  Will be undef if not present.

- $undef_or_string = $event->trace_file

  Same as `(caller())[1]`, the second element of the trace frame.

  Will be undef if not present.

- $undef_or_integer = $event->trace_line

  Same as `(caller())[2]`, the third element of the trace frame.

  Will be undef if not present.

- $undef_or_string = $event->trace_subname

- $undef_or_string = $event->trace_tool

  Aliases for the same thing

  Same as `(caller($level))[4]`, the fourth element of the trace frame.

  Will be undef if not present.

- $undef_or_string = $event->trace_signature

  A string that is a unique signature for the trace. If a single context generates multiple events they will all have the same signature. This can be used to tie assertions and diagnostics sent as separate events together after the fact.

ASSERT FACET

- $bool = $event->has_assert

  Returns true if the event has an assert facet, false if it does not.

- $undef_or_hashref = $event->the_assert

  Returns the assert facet if present, undef if it is not.

- @list_of_facets = $event->assert

  TODO

- EMPTY_LIST_OR_STRING = $event->assert_brief

  Returns a string giving a brief of the assertion if an assertion is present. Returns an empty list if no assertion is present.

SUBTESTS (PARENT FACET)

- $bool = $event->has_subtest

  True if a subetest is present in this event.

- $undef_or_hashref = $event->the_subtest

  Get the one subtest if present, otherwise undef.

- @list_of_facets = $event->subtest

  TODO

- EMPTY_LIST_OR_OBJECT = $event->subtest_result

  Returns an empty list if there is no subtest.

  Get an instance of *Test2::API::InterceptResult* representing the subtest.

CONTROL FACET (BAILOUT, ENCODING)

- $bool = $event->has_bailout

  True if there was a bailout

- $undef_hashref = $event->the_bailout

  Return the control facet if it requested a bailout.

- EMPTY_LIST_OR_HASHREF = $event->bailout

  Get a list of 0 or 1 hashrefs. The hashref will be the control facet if a bail-out was requested.

- EMPTY_LIST_OR_STRING = $event->bailout_brief

  Get the brief of the bailout if present.

- EMPTY_LIST_OR_STRING = $event->bailout_reason

  Get the reason for the bailout, an empty string if no reason was provided, or an empty list if there was no bailout.

PLAN FACET

TODO

- $bool = $event->has_plan
- $undef_or_hashref = $event->the_plan
- @list_if_hashrefs = $event->plan
- EMPTY_LIST_OR_STRING $event->plan_brief

AMNESTY FACET (TODO AND SKIP)

TODO

- $event->has_amnesty
- $event->the_amnesty
- $event->amnesty
- $event->amnesty_reasons
- $event->has_todos
- $event->todos
- $event->todo_reasons
- $event->has_skips
- $event->skips
- $event->skip_reasons
- $event->has_other_amnesty
- $event->other_amnesty
- $event->other_amnesty_reasons

ERROR FACET (CAPTURED EXCEPTIONS)

TODO

- $event->has_errors
- $event->the_errors
- $event->errors
- $event->error_messages

- $event->error_brief

INFO FACET (DIAG, NOTE)

TODO

- $event->has_info
- $event->the_info
- $event->info
- $event->info_messages
- $event->has_diags
- $event->diags
- $event->diag_messages
- $event->has_notes
- $event->notes
- $event->note_messages
- $event->has_other_info
- $event->other_info
- $event->other_info_messages

Test2::API::Stack

Object to manage a stack of *Test2::Hub* instances.

INTERNALS NOTE

The internals of this package are subject to change at any time! The public methods provided will not change in backwards incompatible ways, but the underlying implementation details might. **Do not break encapsulation here!**

DESCRIPTION

This module is used to represent and manage a stack of *Test2::Hub* objects. Hubs are usually in a stack so that you can push a new hub into place that can intercept and handle events differently than the primary hub.

SYNOPSIS

```
my $stack = Test2::API::Stack->new;
my $hub = $stack->top;
```

METHODS

- $stack = Test2::API::Stack->new()

  This will create a new empty stack instance. All arguments are ignored.

- $hub = $stack->new_hub()
- $hub = $stack->new_hub(%params)
- $hub = $stack->new_hub(%params, class => $class)

  This will generate a new hub and push it to the top of the stack. Optionally you can provide arguments that will be passed into the constructor for the *Test2::Hub* object.

  If you specify the `'class' => $class` argument, the new hub will be an instance of the specified class.

  Unless your parameters specify `'formatter'` or `'ipc'` arguments, the formatter and IPC instance will be inherited from the current top hub. You can set the parameters to `undef` to avoid having a formatter or IPC instance.

  If there is no top hub, and you do not ask to leave IPC and formatter undef, then a new formatter will be created, and the IPC instance from *Test2::API* will be used.

- $hub = $stack->top()

  This will return the top hub from the stack. If there is no top hub yet this will create it.

- $hub = $stack->peek()

  This will return the top hub from the stack. If there is no top hub yet this will return undef.

- $stack->cull

  This will call `$hub->cull` on all hubs in the stack.

- @hubs = $stack->all

  This will return all the hubs in the stack as a list.

- $stack->clear

  This will completely remove all hubs from the stack. Normally you do not want to do this, but there are a few valid reasons for it.

- $stack->push($hub)

  This will push the new hub onto the stack.

- $stack->pop($hub)

  This will pop a hub from the stack, if the hub at the top of the stack does not match the hub you expect (passed in as an argument) it will throw an exception.

Test2::AsyncSubtest

Object representing an async subtest.

DESCRIPTION

Regular subtests have a limited scope, they start, events are generated, then they close and send an *Test2::Event::Subtest* event. This is a problem if you want the subtest to keep receiving events while other events are also being generated. This class implements subtests that stay open until you decide to close them.

This is mainly useful for tools that start a subtest in one process and then spawn children. In many cases it is nice to let the parent process continue instead of waiting on the children.

SYNOPSIS

```
use Test2::AsyncSubtest;

my $ast = Test2::AsyncSubtest->new(name => foo);

$ast->run(sub {
    ok(1, "Event in parent" );
});

ok(1, "Event outside of subtest");

$ast->run_fork(sub {
    ok(1, "Event in child process");
});

...

$ast->finish;

done_testing;
```

CONSTRUCTION

```
my $ast = Test2::AsyncSubtest->new( ... );
```

- name => $name (required)

  Name of the subtest. This construction argument is required.

- send_to => $hub (optional)

  Hub to which the final subtest event should be sent. This must be an instance of *Test2::Hub* or a subclass. If none is specified then the current top hub will be used.

- trace => $trace (optional)

File/Line to which errors should be attributed. This must be an instance of *Test2::Util::Trace*. If none is specified then the file/line where the constructor was called will be used.

- hub => $hub (optional)

  Use this to specify a hub the subtest should use. By default a new hub is generated. This must be an instance of *Test2::AsyncSubtest::Hub*.

METHODS

SIMPLE ACCESSORS

- $bool = $ast->active

  True if the subtest is active. The subtest is active if its hub appears in the global hub stack. This is true when `$ast->run(...)` us running.

- $arrayref = $ast->children

  Get an arrayref of child processes/threads. Numerical items are PIDs, blessed items are *threads* instances.

- $arrayref = $ast->events

  Get an arrayref of events that have been sent to the subtests hub.

- $bool = $ast->finished

  True if `finished()` has already been called.

- $hub = $ast->hub

  The hub created for the subtest.

- $int = $ast->id

  Attach/Detach counter. Used internally, not useful to users.

- $str = $ast->name

  Name of the subtest.

- $pid = $ast->pid

  PID in which the subtest was created.

- $tid = $ast->tid

  Thread ID in which the subtest was created.

- $hub = $ast->send_to

  Hub to which the final subtest event should be sent.

- $arrayref = $ast->stack

  Stack of async subtests at the time this one was created. This is mainly for internal use.

- $trace = $ast->trace

  Test2::Util::Trace instance used for error reporting.

INTERFACE

- $ast->attach($id)

  Attach a subtest in a child/process to the original.

  Note: `my $id = $ast->cleave` must have been called in the parent process/thread before the child was started, the id it returns must be used in the call to `$ast->attach($id)`

- $id = $ast->cleave

  Prepare a slot for a child process/thread to attach. This must be called BEFORE the child process or thread is started. The ID returned is used by `attach()`.

  This must only be called in the original process/thread.

- $ctx = $ast->context

  Get an *Test2::API::Context* instance that can be used to send events to the context in which the hub was created. This is not a canonical context, you should not call `$ctx->release` on it.

- $ast->detach

  Detach from the parent in a child process/thread. This should be called just before the child exits.

- $ast->finish

- $ast->finish(%options)

  Finish the subtest, wait on children, and send the final subtest event.

  This must only be called in the original process/thread.

  Note: This calls `$ast->wait`.

  These are the options:

  - collapse => 1

    This intelligently allows a subtest to be empty.

    If no events bump the test count then the subtest no final plan will be added. The subtest will not be considered a failure (normally an empty subtest is a failure).

    If there are no events at all the subtest will be collapsed into an *Test2::Event::Ok* event.

  - silent => 1

    This will prevent finish from generating a final *Test2::Event::Subtest* event. This effectively ends the subtest without it affecting the parent subtest (or top level test).

  - no_plan => 1

    This will prevent a final plan from being added to the subtest for you when none is directly specified.

  - skip => “reason”

    This will issue an *Test2::Event::Skip* instead of a subtest. This will throw an exception if any events have been seen, or if state implies events have occurred.

- $out = $ast->fork

  This is a slightly higher level interface to fork. Running it will fork your code in-place just like `fork()`. It will return a pid in the parent, and an *Test2::Util::Guard* instance in the child. An exception will be thrown if fork fails.

  It is recommended that you use `$ast->run_fork(sub { ... })` instead.

- $bool = $ast->pending

  True if there are child processes, threads, or subtests that depend on this one.

- $bool = $ast->ready

  This is essentially `!$ast->pending`.

- $ast->run(sub { ... })

  Run the provided codeblock inside the subtest. This will push the subtest hub onto the stack, run the code, then pop the hub off the stack.

- $pid = $ast->run_fork(sub { ... })

  Same as `$ast->run()`, except that the codeblock is run in a child process.

  You do not need to directly call `wait($pid)`, that will be done for you when `$ast->wait`, or `$ast->finish` are called.

- my $thr = $ast->run_thread(sub { ... });

  ** **DISCOURAGED** ** Threads cause problems. This method remains for anyone who REALLY wants it, but it is no longer supported. Tests for this functionality do not even run unless the AUTHOR_TESTING or T2_DO_THREAD_TESTS env vars are enabled.

  Same as `$ast->run()`, except that the codeblock is run in a child thread.

  You do not need to directly call `$thr->join`, that is done for you when `$ast->wait`, or `$ast->finish` are called.

- $passing = $ast->start

  Push the subtest hub onto the stack. Returns the current pass/fail status of the subtest.

- $ast->stop

  Pop the subtest hub off the stack. Returns the current pass/fail status of the subtest.

- $ast->wait

  Wait on all threads/processes that were started using `$ast->fork`, `$ast->run_fork`, or `$ast->run_thread`.

Modules

- `Test2::AsyncSubtest::Event`
- `Test2::AsyncSubtest::Hub` - Hub used by async subtests.

Test2::AsyncSubtest::Event

Namespace containing the following modules:

- `Test2::AsyncSubtest::Event::Attach` - Event to attach a subtest to the parent.
- `Test2::AsyncSubtest::Event::Detach` - Event to detach a subtest from the parent.

Test2::AsyncSubtest::Event::Attach

Event to attach a subtest to the parent.

DESCRIPTION

Used internally by *Test2::AsyncSubtest*. No user serviceable parts inside.

SOURCE

The source code repository for Test2-AsyncSubtest can be found at `https://github.com/Test-More/test-more/`.

Test2::AsyncSubtest::Hub

Hub used by async subtests.

DESCRIPTION

This is a subclass of *Test2::Hub::Subtest* used for async subtests.

SYNOPSIS

You should not use this directly.

METHODS

- $ast = $hub->ast

  Get the *Test2::AsyncSubtest* object to which this hub is bound.

SOURCE

The source code repository for Test2-AsyncSubtest can be found at `https://github.com/Test-More/test-more/`.

Test2::Bundle

Documentation for bundles.

DESCRIPTION

Bundles are collections of Tools and Plugins. Bundles should not provide any tools or behaviors of their own, they should simply combine the tools and behaviors of other packages.

FAQ

- Should my bundle subclass Test2::Bundle?

  No. Currently this class is empty. Eventually we may want to add behavior, in which case we do not want anyone to already be subclassing it.

HOW DO I WRITE A BUNDLE?

Writing a bundle can be very simple:

```
package Test2::Bundle::MyBundle;
use strict;
use warnings;

use Test2::Plugin::ExitSummary; # Load a plugin

use Test2::Tools::Basic qw/ok plan done_testing/;

# Re-export the tools
our @EXPORTS = qw/ok plan done_testing/;
use base 'Exporter';

1;
```

If you want to do anything more complex you should look into Import::Into and Symbol::Move.

SOURCE

The source code repository for Test2-Suite can be found at `https://github.com/Test-More/test-more/`.

MAINTAINERS

- Chad Granum exodist@cpan.org

AUTHORS

- Chad Granum exodist@cpan.org

COPYRIGHT

Copyright Chad Granum exodist@cpan.org.

This program is free software; you can redistribute it and/or modify it under the same terms as Perl itself.

See `http://dev.perl.org/licenses/`

Modules

- `Test2::Bundle::Extended` - Old name for Test2::V0
- `Test2::Bundle::More` - ALMOST a drop-in replacement for Test::More.
- `Test2::Bundle::Simple` - ALMOST a drop-in replacement for Test::Simple.

Test2::Bundle::Extended

Old name for Test2::V0

*** DEPRECATED ***

This bundle has been renamed to *Test2::V0*, in which the `':v1'` tag has been removed as unnecessary.

Note: *Test2::V1* is the latest bundle, you probably want to look at that.

DESCRIPTION

This is the big-daddy bundle. This bundle includes nearly every tool, and several plugins, that the Test2 author uses. This bundle is used extensively to test *Test2::Suite* itself.

SYNOPSIS

```
use Test2::Bundle::Extended ':v1';

ok(1, "pass");

...

done_testing;
```

RESOLVING CONFLICTS WITH MOOSE

```
use Test2::Bundle::Extended '!meta';
```

Moose and *Test2::Bundle::Extended* both export very different `meta()` subs. Adding `'!meta'` to the import args will prevent the sub from being imported. This bundle also exports the sub under the name `meta_check()` so you can use that spelling as an alternative.

TAGS

- :v1
- :DEFAULT

  The following are all identical:

```
use Test2::Bundle::Extended;

use Test2::Bundle::Extended ':v1';

use Test2::Bundle::Extended ':DEFAULT';
```

RENAMING ON IMPORT

```
use Test2::Bundle::Extended ':v1', '!ok', ok => {-as => 'my_ok'};
```

This bundle uses Importer for exporting, as such you can use any arguments it accepts.

Explanation:

- ':v1'

  Use the default tag, all default exports.

- '!ok'

  Do not export `ok()`

- ok => {-as => 'my_ok'}

  Actually, go ahead and import `ok()` but under the name `my_ok()`.

If you did not add the `'!ok'` argument then you would have both `ok()` and `my_ok()`

PRAGMAS

All of these can be disabled via individual import arguments, or by the `-no_pragmas` argument.

```
use Test2::Bundle::Extended -no_pragmas => 1;
```

STRICT

strict is turned on for you. You can disable this with the `-no_strict` or `-no_pragmas` import arguments:

```
use Test2::Bundle::Extended -no_strict => 1;
```

WARNINGS

warnings are turned on for you. You can disable this with the `-no_warnings` or `-no_pragmas` import arguments:

```
use Test2::Bundle::Extended -no_warnings => 1;
```

UTF8

This is actually done via the *Test2::Plugin::UTF8* plugin, see the "PLUGINS" section for details.

Note: `-no_pragmas => 1` will turn off the entire plugin.

PLUGINS

SRAND

See *Test2::Plugin::SRand*.

This will set the random seed to today's date. You can provide an alternate seed with the `-srand` import option:

```
use Test2::Bundle::Extended -srand => 1234;
```

UTF8

See *Test2::Plugin::UTF8*.

This will set the file, and all output handles (including formatter handles), to utf8. This will turn on the utf8 pragma for the current scope.

This can be disabled using the `-no_utf8 => 1` or `-no_pragmas => 1` import arguments.

```
use Test2::Bundle::Extended -no_utf8 => 1;
```

EXIT SUMMARY

See *Test2::Plugin::ExitSummary*.

This plugin has no configuration.

API FUNCTIONS

See *Test2::API* for these

- $ctx = context()
- $events = intercept { ... }

TOOLS

TARGET

See *Test2::Tools::Target*.

You can specify a target class with the `-target` import argument. If you do not provide a target then `$CLASS` and `CLASS()` will not be imported.

```
use Test2::Bundle::Extended -target => 'My::Class';

print $CLASS;  # My::Class
print CLASS(); # My::Class
```

Or you can specify names:

```
use Test2::Bundle::Extended -target => { pkg => 'Some::Package' };

pkg()->xxx; # Call 'xxx' on Some::Package
$pkg->xxx;  # Same
```

- $CLASS

  Package variable that contains the target class name.

- $class = CLASS()

  Constant function that returns the target class name.

DEFER

See *Test2::Tools::Defer*.

- def $func => @args;
- do_def()

BASIC

See *Test2::Tools::Basic*.

- ok($bool, $name)
- pass($name)
- fail($name)
- diag($message)
- note($message)
- $todo = todo($reason)
- todo $reason => sub { ... }
- skip($reason, $count)
- plan($count)
- skip_all($reason)
- done_testing()
- bail_out($reason)

COMPARE

See *Test2::Tools::Compare*.

- is($got, $want, $name)
- isnt($got, $do_not_want, $name)
- like($got, qr/match/, $name)
- unlike($got, qr/mismatch/, $name)
- $check = match(qr/pattern/)
- $check = mismatch(qr/pattern/)
- $check = validator(sub { return $bool })
- $check = hash { ... }
- $check = array { ... }
- $check = bag { ... }
- $check = object { ... }
- $check = meta { ... }
- $check = number($num)
- $check = string($str)
- $check = check_isa($class_name)
- $check = in_set(@things)
- $check = not_in_set(@things)
- $check = check_set(@things)
- $check = item($thing)
- $check = item($idx => $thing)
- $check = field($name => $val)
- $check = call($method => $expect)
- $check = call_list($method => $expect)
- $check = call_hash($method => $expect)
- $check = prop($name => $expect)
- $check = check($thing)
- $check = T()
- $check = F()
- $check = D()
- $check = DF()
- $check = E()
- $check = DNE()

- $check = FDNE()
- $check = U()
- $check = L()
- $check = exact_ref($ref)
- end()
- etc()
- filter_items { grep { ... } @_ }
- $check = event $type => ...
- @checks = fail_events $type => ...

CLASSIC COMPARE

See *Test2::Tools::ClassicCompare*.

- cmp_ok($got, $op, $want, $name)

SUBTEST

See *Test2::Tools::Subtest*.

- subtest $name => sub { ... }

  (Note: This is called `subtest_buffered()` in the Tools module.)

CLASS

See *Test2::Tools::Class*.

- can_ok($thing, @methods)
- isa_ok($thing, @classes)
- DOES_ok($thing, @roles)

ENCODING

See *Test2::Tools::Encoding*.

- set_encoding($encoding)

EXPORTS

See *Test2::Tools::Exports*.

- imported_ok('function', '$scalar', ...)
- not_imported_ok('function', '$scalar', ...)

REF

See *Test2::Tools::Ref*.

- ref_ok($ref, $type)
- ref_is($got, $want)
- ref_is_not($got, $do_not_want)

MOCK

See *Test2::Tools::Mock*.

- $control = mock ...
- $bool = mocked($thing)

EXCEPTION

See *Test2::Tools::Exception*.

- $exception = dies { ... }
- $bool = lives { ... }
- $bool = try_ok { ... }

WARNINGS

See *Test2::Tools::Warnings*.

- $count = warns { ... }
- $warning = warning { ... }
- $warnings_ref = warnings { ... }
- $bool = no_warnings { ... }

SOURCE

Test2::Bundle::More

ALMOST a drop-in replacement for Test::More.

DESCRIPTION

This bundle is intended to be a (mostly) drop-in replacement for *Test::More*. See "KEY DIFFERENCES FROM Test::More" for details.

SYNOPSIS

```
use Test2::Bundle::More;

ok(1, "pass");

...

done_testing;
```

PLUGINS

This loads *Test2::Plugin::ExitSummary*.

TOOLS

These are from *Test2::Tools::Basic*. See *Test2::Tools::Basic* for details.

- ok($bool, $name)
- pass($name)
- fail($name)
- skip($why, $count)
- $todo = todo($why)
- diag($message)
- note($message)
- plan($count)
- skip_all($why)
- done_testing()

- BAIL_OUT($why)

These are from *Test2::Tools::ClassicCompare*. See *Test2::Tools::ClassicCompare* for details.

- is($got, $want, $name)
- isnt($got, $donotwant, $name)
- like($got, qr/match/, $name)
- unlike($got, qr/mismatch/, $name)
- is_deeply($got, $want, "Deep compare")
- cmp_ok($got, $op, $want, $name)

These are from *Test2::Tools::Class*. See *Test2::Tools::Class* for details.

- isa_ok($thing, @classes)
- can_ok($thing, @subs)

This is from *Test2::Tools::Subtest*. It is called `subtest_streamed()` in that package.

- subtest $name => sub { ... }

KEY DIFFERENCES FROM Test::More

- You cannot plan at import.

  THIS WILL **NOT** WORK:

  ```
  use Test2::Bundle::More tests => 5;
  ```

  Instead you must plan in a separate statement:

  ```
  use Test2::Bundle::More;
  plan 5;
  ```

- You have three subs imported for use in planning

  Use `plan($count)`, `skip_all($reason)`, or `done_testing()` for your planning.

- isa_ok accepts different arguments

  `isa_ok` in Test::More was:

  ```
  isa_ok($thing, $isa, $alt_thing_name);
  ```

  This was very inconsistent with tools like `can_ok($thing, @subs)`.

  In Test2::Bundle::More, `isa_ok()` takes a `$thing` and a list of `@isa`.

  ```
  isa_ok($thing, $class1, $class2, ...);
  ```

THESE FUNCTIONS AND VARIABLES HAVE BEEN REMOVED

- $TODO

  See `todo()`.

- use_ok()
- require_ok()

  These are not necessary. Use `use` and `require` directly. If there is an error loading the module the test will catch the error and fail.

- todo_skip()

  Not necessary.

- eq_array()
- eq_hash()
- eq_set()

  Discouraged in Test::More.

- explain()

  This started a fight between Test developers, who may now each write their own implementations in *Test2*. (See explain in Test::Most vs *Test::More*. Hint: Test::Most wrote it first, then Test::More added it, but broke compatibility).

- new_ok()

  Not necessary.

SOURCE

The source code repository for Test2-Suite can be found at `https://github.com/Test-More/test-more/`.

Test2::Bundle::Simple

ALMOST a drop-in replacement for Test::Simple.

DESCRIPTION

This bundle is intended to be a (mostly) drop-in replacement for *Test::Simple*. See "KEY DIFFERENCES FROM Test::Simple" for details.

SYNOPSIS

```
use Test2::Bundle::Simple;

ok(1, "pass");

done_testing;
```

PLUGINS

This loads *Test2::Plugin::ExitSummary*.

TOOLS

These are all from *Test2::Tools::Basic*.

- ok($bool, $name)

  Run a test. If bool is true, the test passes. If bool is false, it fails.

- plan($count)

  Tell the system how many tests to expect.

- skip_all($reason)

  Tell the system to skip all the tests (this will exit the script).

- done_testing();

  Tell the system that all tests are complete. You can use this instead of setting a plan.

KEY DIFFERENCES FROM Test::Simple

- You cannot plan at import.

  THIS WILL **NOT** WORK:

  ```
  use Test2::Bundle::Simple tests => 5;
  ```

  Instead you must plan in a separate statement:

  ```
  use Test2::Bundle::Simple;
  plan 5;
  ```

- You have three subs imported for use in planning

  Use `plan($count)`, `skip_all($reason)`, or `done_testing()` for your planning.

SOURCE

The source code repository for Test2-Suite can be found at `https://github.com/Test-More/test-more/`.

Test2::Compare

Test2 extension for writing deep comparison tools.

DESCRIPTION

This library is the driving force behind deep comparison tools such as `Test2::Tools::Compare::is()` and `Test2::Tools::ClassicCompare::is_deeply()`.

SYNOPSIS

```
package Test2::Tools::MyCheck;

use Test2::Compare::MyCheck;
use Test2::Compare qw/compare/;

sub MyCheck {
    my ($got, $exp, $name, @diag) = @_;
    my $ctx = context();

    my $delta = compare($got, $exp, \&convert);

    if ($delta) {
```

(continues on next page)

(continued from previous page)

```
        $ctx->fail($name, $delta->diag, @diag);
    }
    else {
        $ctx->ok(1, $name);
    }

    $ctx->release;
    return !$delta;
}

sub convert {
    my $thing = shift;
    return $thing if blessed($thing) && $thing->isa(
↪'Test2::Compare::MyCheck');

    return Test2::Compare::MyCheck->new(stuff => $thing);
}
```

See *Test2::Compare::Base* for details about writing a custom check.

EXPORTS

- $delta = compare($got, $expect, \&convert)

  This will compare the structures in `$got` with those in `$expect`, The convert sub should convert vanilla structures inside `$expect` into checks. If there are differences in the structures they will be reported back as an *Test2::Compare::Delta* tree.

- $build = get_build()

  Get the current global build, if any.

- push_build($build)

  Set the current global build.

- $build = pop_build($build)

  Unset the current global build. This will throw an exception if the build passed in is different from the current global.

- build($class, sub { ... })

  Run the provided codeblock with a new instance of `$class` as the current build. Returns the new build.

- $check = convert($thing)

- $check = convert($thing, $config)

  This convert function is used by `strict_convert()` and `relaxed_convert()` under the hood. It can also be used as the basis for other convert functions.

  If you want to use it with a custom configuration you should wrap it in another sub like so:

```
sub my_convert {
    my $thing_to_convert = shift;
    return convert(
        $thing_to_convert,
        { ... }
    );
}
```

Or the short variant:

```
sub my_convert { convert($_[0], { ... }) }
```

There are several configuration options, here they are with the default setting listed first:

- implicit_end => 1

  This option toggles array/hash boundaries. If this is true then no extra hash keys or array indexes will be allowed. This setting affects generated compare objects as well as any passed in.

- use_regex => 1

  This option toggles regex matching. When true (default) regexes are converted to checks such that values must match the regex. When false regexes will be compared to see if they are identical regexes.

- use_code => 0

  This option toggles code matching. When false (default) coderefs in structures must be the same coderef as specified. When true coderefs will be run to verify the value being checked.

- $check = strict_convert($thing)

  Convert `$thing` to an *Test2::Compare::** object. This will behave strictly which means it uses these settings:

  - implicit_end => 1

    Array bounds will be checked when this object is used in a comparison. No unexpected hash keys can be present.

  - use_code => 0

    Sub references will be compared as refs (IE are these sub refs the same ref?)

  - use_regex => 0

    Regexes will be compared directly (IE are the regexes the same?)

- $compare = relaxed_convert($thing)

  Convert `$thing` to an *Test2::Compare::** object. This will be relaxed which means it uses these settings:

  - implicit_end => 0

    Array bounds will not be checked when this object is used in a comparison. Unexpected hash keys can be present.

- use_code => 1

  Sub references will be run to verify a value.

- use_regex => 1

  Values will be checked against any regexes provided.

WRITING A VARIANT OF IS/LIKE

```
use Test2::Compare qw/compare convert/;

sub my_like($$;$@) {
    my ($got, $exp, $name, @diag) = @_;
    my $ctx = context();

    # A custom converter that does the same thing as the one used by like()
    my $convert = sub {
        my $thing = shift;
        return convert(
            $thing,
            {
                implicit_end => 0,
                use_code     => 1,
                use_regex    => 1,
            }
        );
    };

    my $delta = compare($got, $exp, $convert);

    if ($delta) {
        $ctx->fail($name, $delta->diag, @diag);
    }
    else {
        $ctx->ok(1, $name);
    }

    $ctx->release;
    return !$delta;
}
```

The work of a comparison tool is done by 3 entities:

- compare()

  The `compare()` function takes the structure you got, the specification you want to check against, and a `\&convert` sub that will convert anything that is not an instance of an *Test2::Compare::Base* subclass into one.

  This tool will use the `\&convert` function on the specification, and then produce an *Test2::Compare::Delta* structure that outlines all the ways the structure you got deviates from the specification.

- \&convert

  Converts anything that is not an instance of an *Test2::Compare::Base* subclass, and turns it into one. The objects this produces are able to check that a structure matches a specification.

- $delta

  An instance of *Test2::Compare::Delta* is ultimately returned. This object represents all the ways in with the structure you got deviated from the specification. The delta is a tree and may contain child deltas for nested structures.

  The delta is capable of rendering itself as a table, use `@lines = $delta->diag` to get the table (lines in `@lines` will not be terminated with `"\n"`).

The `convert()` function provided by this package contains all the specification behavior of `like()` and `is()`. It is intended to be wrapped in a sub that passes in a configuration hash, which allows you to control the behavior.

You are free to write your own `$check = compare($thing)` function, it just needs to accept a single argument, and produce a single instance of an *Test2::Compare::Base* subclass.

Modules

- `Test2::Compare::Array` - Internal representation of an array comparison.
- `Test2::Compare::Bag` - Internal representation of a bag comparison.
- `Test2::Compare::Base` - Base class for comparison classes.
- `Test2::Compare::Bool` - Compare two values as booleans
- `Test2::Compare::Custom` - Custom field check for comparisons.

- `Test2::Compare::DeepRef` - Ref comparison
- `Test2::Compare::Delta` - Representation of differences between nested data structures.
- `Test2::Compare::Event` - Event specific Object subclass.
- `Test2::Compare::EventMeta` - Meta class for events in deep comparisons
- `Test2::Compare::Float` - Compare two values as numbers with tolerance.
- `Test2::Compare::Hash` - Representation of a hash in a deep comparison.
- `Test2::Compare::Isa` - Check if the value is an instance of the class.
- `Test2::Compare::Meta` - Check library for meta-checks
- `Test2::Compare::Negatable` - Poor mans 'role' for compare objects that can be negated.
- `Test2::Compare::Number` - Compare two values as numbers
- `Test2::Compare::Object` - Representation of an object during deep comparison.
- `Test2::Compare::OrderedSubset` - Internal representation of an ordered subset.
- `Test2::Compare::Pattern` - Use a pattern to validate values in a deep comparison.
- `Test2::Compare::Ref` - Ref comparison
- `Test2::Compare::Regex` - Regex direct comparison
- `Test2::Compare::Scalar` - Representation of a Scalar Ref in deep comparisons
- `Test2::Compare::Set` - Allows a field to be matched against a set of checks.
- `Test2::Compare::String` - Compare two values as strings
- `Test2::Compare::Undef` - Check that something is undefined
- `Test2::Compare::Wildcard` - Placeholder check.

Test2::Compare::Array

Internal representation of an array comparison.

DESCRIPTION

This module is an internal representation of an array for comparison purposes.

METHODS

- $ref = $arr->inref()

  If the instance was constructed from an actual array, this will return the reference to that array.

- $bool = $arr->ending

- $arr->set_ending($bool)

  Set this to true if you would like to fail when the array being validated has more items than the check. That is, if you check indexes 0-3 but the array has values for indexes 0-4, it will fail and list that last item in the array as unexpected. If set to false then it is assumed you do not care about extra items.

- $hashref = $arr->items()

  Returns the hashref of `key => val` pairs to be checked in the array.

- $arr->set_items($hashref)

  Accepts a hashref to permit indexes to be skipped if desired.

  Note: that there is no validation when using `set_items`, it is better to use the `add_item` interface.

- $arrayref = $arr->order()

  Returns an arrayref of all indexes that will be checked, in order.

- $arr->set_order($arrayref)

  Sets the order in which indexes will be checked.

  Note: that there is no validation when using `set_order`, it is better to use the `add_item` interface.

- $name = $arr->name()

  Always returns the string `"<ARRAY>"`.

- $bool = $arr->verify(got => $got, exists => $bool)

  Check if `$got` is an array reference or not.

- $idx = $arr->top_index()

  Returns the topmost index which is checked. This will return undef if there are no items, or `0` if there is only 1 item.

- $arr->add_item($item)

  Push an item onto the list of values to be checked.

- $arr->add_item($idx => $item)

  Add an item to the list of values to be checked at the specified index.

- $arr->add_filter(sub { ... })

  Add a filter sub. The filter receives all remaining values of the array being checked, and should return the values that should still be checked. The filter will be run between the last item added and the next item added.

- @deltas = $arr->deltas(got => $got, convert => \&convert, seen => \%seen)

  Find the differences between the expected array values and those in the `$got` arrayref.

Test2::Compare::Bag

Internal representation of a bag comparison.

DESCRIPTION

This module is an internal representation of a bag for comparison purposes.

METHODS

- $bool = $arr->ending
- $arr->set_ending($bool)

  Set this to true if you would like to fail when the array being validated has more items than the check. That is, if you check for 4 items but the array has 5 values, it will fail and list that unmatched item in the array as unexpected. If set to false then it is assumed you do not care about extra items.

- $arrayref = $arr->items()

  Returns the arrayref of values to be checked in the array.

- $arr->set_items($arrayref)

  Accepts an arrayref.

  Note: that there is no validation when using `set_items`, it is better to use the `add_item` interface.

- $name = $arr->name()

  Always returns the string `"<BAG>"`.

- $bool = $arr->verify(got => $got, exists => $bool)

  Check if `$got` is an array reference or not.

- $arr->add_item($item)

  Push an item onto the list of values to be checked.

- @deltas = $arr->deltas(got => $got, convert => \&convert, seen => \%seen)

  Find the differences between the expected bag values and those in the `$got` arrayref.

Test2::Compare::Base

Base class for comparison classes.

DESCRIPTION

All comparison classes for Test2::Compare should inherit from this base class.

SYNOPSIS

```
package Test2::Compare::MyCheck;
use strict;
use warnings;

use base 'Test2::Compare::Base';
use Test2::Util::HashBase qw/stuff/;

sub name { 'STUFF' }

sub operator {
    my $self = shift;
    my ($got) = @_;
    return 'eq';
}

sub verify {
    my $self = shift;
    my $params = @_;

    # Always check if $got exists! This method must return false if no
    # value at all was received.
    return 0 unless $params{exists};

    my $got = $params{got};

    # Returns true if both values match. This includes undef, 0, and other
    # false-y values!
    return $got eq $self->stuff;
}
```

METHODS

Some of these must be overridden, others can be.

- $dclass = $check->delta_class

  Returns the delta subclass that should be used. By default *Test2::Compare::Delta* is used.

- @deltas = $check->deltas(id => $id, exists => $bool, got => $got, convert => \&convert, seen => \%seen)

  Should return child deltas.

- @lines = $check->got_lines($got)

  This is your chance to provide line numbers for errors in the `$got` structure.

- $op = $check->operator()

- $op = $check->operator($got)

Returns the operator that was used to compare the check with the received data in `$got`. If there was no value for got then there will be no arguments, undef will only be an argument if undef was seen in `$got`. This is how you can tell the difference between a missing value and an undefined one.

- $bool = $check->verify(id => $id, exists => $bool, got => $got, convert => \&convert, seen => \%seen)

  Return true if there is a shallow match, that is both items are arrayrefs, both items are the same string or same number, etc. This should not recurse, as deep checks are done in `$check->deltas()`.

- $name = $check->name

  Get the name of the check.

- $display = $check->render

  What should be displayed in a table for this check, usually the name or value.

- $delta = $check->run(id => $id, exists => $bool, got => $got, convert => \&convert, seen => \%seen)

  This is where the checking is done, first a shallow check using `$check->verify`, then checking `$check->deltas()`. `\%seen` is used to prevent cycles.

Test2::Compare::Bool

Compare two values as booleans

DESCRIPTION

Check if two values have the same boolean result (both true, or both false).

SOURCE

The source code repository for Test2-Suite can be found at `https://github.com/Test-More/test-more/`.

MAINTAINERS

- Chad Granum exodist@cpan.org

Test2::Compare::Custom

Custom field check for comparisons.

DESCRIPTION

Sometimes you want to do something complicated or unusual when validating a field nested inside a deep data structure. You could pull it out of the structure and test it separately, or you can use this to embed the check. This provides a way for you to write custom checks for fields in deep comparisons.

SYNOPSIS

```
my $cus = Test2::Compare::Custom->new(
    name => 'IsRef',
    operator => 'ref(...)',
    stringify_got => 1,
    code => sub {
        my %args = @_;
        return $args{got} ? 1 : 0;
    },
);

# Pass
```

(continues on next page)

(continued from previous page)

```
is(
    { a => 1, ref => {},   b => 2 },
    { a => 1, ref => $cus, b => 2 },
    "This will pass"
);

# Fail
is(
    {a => 1, ref => 'notref', b => 2},
    {a => 1, ref => $cus,     b => 2},
    "This will fail"
);
```

ARGUMENTS

Your custom sub will be passed 4 arguments in a hash:

```
code => sub {
    my %args = @_;
    # provides got, exists, operator, name
    return ref($args{got}) ? 1 : 0;
},
```

$_ is also localized to `got` to make it easier for those who need to use regexes.

- got
- $_

  The value to be checked.

- exists

  This will be a boolean. This will be true if `got` exists at all. If `exists` is false then it means `got` is not simply undef, but doesn't exist at all (think checking the value of a hash key that does not exist).

- operator

  The operator specified at construction.

- name

  The name provided at construction.

METHODS

- $code = $cus->code

  Returns the coderef provided at construction.

- $name = $cus->name

  Returns the name provided at construction.

- $op = $cus->operator

  Returns the operator provided at construction.

- $stringify = $cus->stringify_got

  Returns the stringify_got flag provided at construction.

- $bool = $cus->verify(got => $got, exists => $bool)

Test2::Compare::Delta

Representation of differences between nested data structures.

DESCRIPTION

This is used by *Test2::Compare*. When data structures are compared a delta will be returned. Deltas are a tree data structure that represent all the differences between two other data structures.

METHODS

CLASS METHODS

- $class->add_column($NAME => sub { ... })
- $class->add_column($NAME, %PARAMS)

  This can be used to add columns to the table that it produced when a comparison fails. The first argument should always be the column name, which must be unique.

  The first form simply takes a coderef that produces the value that should be displayed in the column for any given delta. The arguments passed into the sub are the delta, and the row ID.

```
Test2::Compare::Delta->add_column(
    Foo => sub {
        my ($delta, $id) = @_;
        return $delta->... ? 'foo' : 'bar'
    },
);
```

  The second form allows you some extra options. The `'value'` key is required, and must be a coderef. All other keys are optional.

```
Test2::Compare::Delta->add_column(
    'Foo',    # column name
    value => sub { ... },    # how to get the cell value
    alias       => 'FOO',    # Display name (used in table␣
↪header)
    no_collapse => $bool,    # Show column even if it has no␣
↪values?
);
```

- $bool = $class->remove_column($NAME)

  This will remove the specified column. This will return true if the column existed and was removed. This will return false if the column did not exist. No exceptions are thrown. If a missing column is a problem then you need to check the return yourself.

- $class->set_column_alias($NAME, $ALIAS)

  This can be used to change the table header, overriding the default column names with new ones.

ATTRIBUTES

- $bool = $delta->verified
- $delta->set_verified($bool)

  This will be true if the delta itself matched, if the delta matched then the problem is in the delta's children, not the delta itself.

- $aref = $delta->id
- $delta->set_id([$type, $name])

  ID for the delta, used to produce the path into the data structure. An example is `['HASH' => 'foo']` which means the delta is in the path `...->{'foo'}`. Valid types are `HASH`, `ARRAY`, `SCALAR`, `META`, and `METHOD`.

- $val = $delta->got
- $delta->set_got($val)

  Deltas are produced by comparing a received data structure 'got' against a check data structure 'check'. The 'got' attribute contains the value that was received for comparison.

- $check = $delta->chk
- $check = $delta->check
- $delta->set_chk($check)
- $delta->set_check($check)

  Deltas are produced by comparing a received data structure 'got' against a check data structure 'check'. The 'check' attribute contains the value that was expected in the comparison.

  `check` and `chk` are aliases for the same attribute.

- $aref = $delta->children
- $delta->set_children([$delta1, $delta2, ...])

  A Delta may have child deltas. If it does then this is an arrayref with those children.
- $dne = $delta->dne
- $delta->set_dne($dne)

  Sometimes a comparison results in one side or the other not existing at all, in which case this is set to the name of the attribute that does not exist. This can be set to 'got' or 'check'.
- $e = $delta->exception
- $delta->set_exception($e)

  This will be set to the exception in cases where the comparison failed due to an exception being thrown.

OTHER

- $string = $delta->render_got

  Renders the string that should be used in a table to represent the received value in a comparison.
- $string = $delta->render_check

  Renders the string that should be used in a table to represent the expected value in a comparison.
- $bool = $delta->should_show

  This will return true if the delta should be shown in the table. This is normally true for any unverified delta. This will also be true for deltas that contain extra useful debug information.
- $aref = $delta->filter_visible

  This will produce an arrayref of `[ $path => $delta ]` for all deltas that should be displayed in the table.
- $aref = $delta->table_header

  This returns an array ref of the headers for the table.
- $string = $delta->table_op

  This returns the operator that should be shown in the table.
- $string = $delta->table_check_lines

  This returns the defined lines (extra debug info) that should be displayed.
- $string = $delta->table_got_lines

  This returns the generated lines (extra debug info) that should be displayed.
- $aref = $delta->table_rows

  This returns an arrayref of table rows, each row is itself an arrayref.

- @table_lines = $delta->table

  Returns all the lines of the table that should be displayed.

Test2::Compare::EventMeta

Meta class for events in deep comparisons

DESCRIPTION

This is used in deep comparisons of event objects. You should probably never use this directly.

DEFINED CHECKS

- file

  File that generated the event.

- line

  Line where the event was generated.

- package

  Package that generated the event.

- subname

  Name of the tool that generated the event.

- debug

  The debug information that will be printed in event of a failure.

- tid

  Thread ID of the thread that generated the event.

- pid

  Process ID of the process that generated the event.

SOURCE

The source code repository for Test2-Suite can be found at `https://github.com/Test-More/test-more/`.

Test2::Compare::Float

Compare two values as numbers with tolerance.

DESCRIPTION

This is used to compare two numbers. You can also check that two numbers are not the same.

This is similar to Test2::Compare::Number, with extra checks to work around floating point representation issues.

The optional 'tolerance' parameter controls how close the two numbers must be to be considered equal. Tolerance defaults to 1e-08.

Note: This will fail if the received value is undefined. It must be a number.

Note: This will fail if the comparison generates a non-numeric value warning (which will not be shown). This is because it must get a number. The warning is not shown as it will report to a useless line and filename. However, the test diagnostics show both values.

SOURCE

Test2::Compare::Meta

Check library for meta-checks

DESCRIPTION

Sometimes in a deep comparison you want to run extra checks against an item down the chain. This library allows you to write a check that verifies several attributes of an item.

DEFINED CHECKS

- blessed

  Lets you check that an item is blessed, and that it is blessed into the expected class.

- reftype

  Lets you check the reftype of the item.

- isa

  Lets you check if the item is an instance of the expected class.

- this

  Lets you check the item itself.

- size

  Lets you check the size of the item. For an arrayref this is the number of elements. For a hashref this is the number of keys. For everything else this is undef.

SOURCE

The source code repository for Test2-Suite can be found at `https://github.com/Test-More/test-more/`.

Test2::Compare::Negatable

Poor mans 'role' for compare objects that can be negated.

DESCRIPTION

Using this package inside an *Test2::Compare::Base* subclass will overload `!$obj` and import `clone_negate()` and `toggle_negate()`.

WHY?

Until perl 5.18 the 'fallback' parameter to *overload* would not be inherited, so we cannot use inheritance for the behavior we actually want. This module works around the problem by emulating the `use overload` call we want for each consumer class.

ATTRIBUTES

- $bool = $obj->negate
- $obj->set_negate($bool)
- $attr = NEGATE()

  The NEGATE attribute will be added via *Test2::Util::HashBase*.

METHODS

- $clone = $obj->clone_negate()

  Create a shallow copy of the object, and call `toggle_negate` on it.

- $obj->toggle_negate()

  Toggle the negate attribute. If the attribute was on it will now be off, if it was off it will now be on.

SOURCE

Test2::Compare::Number

Compare two values as numbers

DESCRIPTION

This is used to compare two numbers. You can also check that two numbers are not the same.

Note: This will fail if the received value is undefined. It must be a number.

Note: This will fail if the comparison generates a non-numeric value warning (which will not be shown). This is because it must get a number. The warning is not shown as it will report to a useless line and filename. However, the test diagnostics show both values.

Test2::Compare::Object

Representation of an object during deep comparison.

DESCRIPTION

This class lets you specify an expected object in a deep comparison. You can check the fields/elements of the underlying reference, call methods to verify results, and do meta checks for object type and ref type.

METHODS

- $class = $obj->meta_class

  The meta-class to be used when checking the object type. This is mainly listed because it is useful to override for specialized object subclasses.

  This normally just returns *Test2::Compare::Meta*.

- $class = $obj->object_base

  The base-class to be expected when checking the object type. This is mainly listed because it is useful to override for specialized object subclasses.

  This normally just returns 'UNIVERSAL'.

- $obj->add_prop(...)

  Add a meta-property to check, see *Test2::Compare::Meta*. This method just delegates.

- $obj->add_field(...)

  Add a hash-field to check, see *Test2::Compare::Hash*. This method just delegates.

- $obj->add_item(...)

  Add an array item to check, see *Test2::Compare::Array*. This method just delegates.

- $obj->add_call($method, $check)

- $obj->add_call($method, $check, $name)

- $obj->add_call($method, $check, $name, $context)

  Add a method call check. This will call the specified method on your object and verify the result. `$method` may be a method name, an array ref, or a coderef.

  If it's an arrayref, the first element must be the method name, and the rest are arguments that will be passed to it.

In the case of a coderef it can be helpful to provide an alternate name. When no name is provided the name is either `$method` or the string '\&CODE'.

If `$context` is `'list'`, the method will be invoked in list context, and the result will be an arrayref.

If `$context` is `'hash'`, the method will be invoked in list context, and the result will be a hashref (this will warn if the method returns an odd number of values).

Test2::Compare::OrderedSubset

Internal representation of an ordered subset.

DESCRIPTION

This module is used to ensure an array has all the expected items int he expected order. It ignores any unexpected items mixed into the array. It only cares that all the expected values are present, and in order, everything else is noise.

METHODS

- $ref = $arr->inref()

  If the instance was constructed from an actual array, this will have the reference to that array.

- $arrayref = $arr->items()

- $arr->set_items($arrayref)

  All the expected items, in order.

- $name = $arr->name()

  Always returns the string "<ORDERED SUBSET>".

- $bool = $arr->verify(got => $got, exists => $bool)

  Check if $got is an array reference or not.

- $arr->add_item($item)

  Add an item to the list of values to check.

- @deltas = $arr->deltas(got => $got, convert => \&convert, seen => \%seen)

  Find the differences between the expected array values and those in the $got arrayref.

Test2::Compare::Pattern

Use a pattern to validate values in a deep comparison.

DESCRIPTION

This allows you to use a regex to validate a value in a deep comparison. Sometimes a value just needs to look right, it may not need to be exact. An example is a memory address that might change from run to run.

SOURCE

The source code repository for Test2-Suite can be found at https://github.com/Test-More/test-more/.

Test2::Compare::Ref

Ref comparison

DESCRIPTION

Used to compare two refs in a deep comparison.

SYNOPSIS

```
my $ref = {};
my $check = Test2::Compare::Ref->new(input => $ref);

# Passes
is( [$ref], [$check], "The array contains the exact ref we want" );

# Fails, they both may be empty hashes, but we are looking for a␣
↪specific
# reference.
is( [{}], [$check], "This will fail");
```

Test2::Compare::Scalar

Representation of a Scalar Ref in deep comparisons

DESCRIPTION

This is used in deep comparisons to represent a scalar reference.

SYNOPSIS

```
my $sr = Test2::Compare::Scalar->new(item => 'foo');

is([\'foo'], $sr, "pass");
is([\'bar'], $sr, "fail, different value");
is(['foo'],  $sr, "fail, not a ref");
```

Test2::Compare::String

Compare two values as strings

DESCRIPTION

This is used to compare two items after they are stringified. You can also check that two strings are not equal.

Note: This will fail if the received value is undefined, it must be defined.

SOURCE

The source code repository for Test2-Suite can be found at `https://github.com/Test-More/test-more/`.

MAINTAINERS

- Chad Granum exodist@cpan.org

Test2::Compare::Wildcard

Placeholder check.

DESCRIPTION

This module is used as a temporary placeholder for values that still need to be converted. This is necessary to carry forward the filename and line number which would be lost in the conversion otherwise.

SOURCE

The source code repository for Test2-Suite can be found at `https://github.com/Test-More/test-more/`.

Test2::Env

Documentation for environment variables used or set by Test2.

DESCRIPTION

This is a list of environment variables that are either set by, or read by Test2.

AUTHOR_TESTING

This env var is read by Test2. When set Test2 will run tests that are normally skipped unless a module author is doing extra author-specific testing.

AUTOMATED_TESTING

This env var is read by Test2. When set this indicates the tests are run by an automated system and no human interaction is possible.

See *Test2::Require::AuthorTesting*.

EXTENDED_TESTING

This env var is read by Test2. When set it indicates some extended testing that should normally be skipped will be run.

See *Test2::Require::ExtendedTesting*.

HARNESS_ACTIVE

This env var is read by Test2. It is usually set by `prove` (*Test::Harness*) or `yath` (App::Yath).

NONINTERACTIVE_TESTING

This env var is read by Test2. When set this indicates the testing will not be interactive.

See *Test2::Require::NonInteractiveTesting*.

RELEASE_TESTING

This env var is read by Test2. When set this indicates that release testing is being done, which may run more tests than normal.

See *Test2::Require::ReleaseTesting*.

T2_FORMATTER

This can be used to set the formatter that Test2 will use. If set to a string without a '+' prefix, then 'Test2::Formatter::' will be added to the start of the module name. If '+' is present it will be stripped and no further modification will be made to the module name.

T2_IN_PRELOAD

Test2 sets this when preload mode is active. This is mainly used by App::Yath and similar tools that preload Test2, then fork to run tests.

TABLE_TERM_SIZE

This is used to set a terminal width for things like diagnostic message tables.

TEST2_ACTIVE

Test2 sets this variable when tests are running.

TEST2_ENABLE_PLUGINS

This can be used to force plugins to be loaded when the Test2 API is loaded. It takes a list of one or more plugin names separated by comma. If the module name does not have a '+' in front of it then the `Test2::Plugin::` namespace is assumed and added. If a '+' is present at the start of a module name it will be stripped and no further modification will be made.

Examples:

```
TEST2_ENABLE_PLUGINS=BailOnFail
Test2_ENABLE_PLUGINS=SRand,+My::Plugin::Name
```

TEST_ACTIVE

Set by Test2 when tests are running.

TS_MAX_DELTA

Used to determine how many max lines of output will be provided when is() finds a deep data structure mismatch.

SOURCE

The source code repository for Test2-Suite can be found at `https://github.com/Test-More/test-more/`.

Test2::Event

Base class for events

DESCRIPTION

Base class for all event objects that get passed through *Test2*.

SYNOPSIS

```
package Test2::Event::MyEvent;
use strict;
use warnings;

# This will make our class an event subclass (required)
use base 'Test2::Event';

# Add some accessors (optional)
# You are not obligated to use HashBase, you can use any object tool␣
 ↪you
# want, or roll your own accessors.
use Test2::Util::HashBase qw/foo bar baz/;

# Use this if you want the legacy API to be written for you, for␣
 ↪this to
# work you will need to implement a facet_data() method.
use Test2::Util::Facets2Legacy;
```

(continues on next page)

(continued from previous page)

```
# Chance to initialize some defaults
sub init {
    my $self = shift;
    # no other args in @_

    $self->set_foo('xxx') unless defined $self->foo;

    ...
}

# This is the new way for events to convey data to the Test2 system
sub facet_data {
    my $self = shift;

    # Get common facets such as 'about', 'trace' 'amnesty', and
↪'meta'
    my $facet_data = $self->common_facet_data();

    # Are you making an assertion?
    $facet_data->{assert} = {pass => 1, details => 'my assertion'};
    ...

    return $facet_data;
}

1;
```

METHODS

GENERAL

- $trace = $e->trace

  Get a snapshot of the *Test2::EventFacet::Trace* as it was when this event was generated

- $bool_or_undef = $e->related($e2)

  Check if 2 events are related. In this case related means their traces share a signature meaning they were created with the same context (or at the very least by contexts which share an id, which is the same thing unless someone is doing something very bad).

  This can be used to reliably link multiple events created by the same tool. For instance a failing test like `ok(0, "fail"` will generate 2 events, one being a *Test2::Event::Ok*, the other being a *Test2::Event::Diag*, both of these events are related having been created under the same context and by the same initial tool (though multiple tools may have been nested under the initial one).

  This will return `undef` if the relationship cannot be checked, which happens if either event has an incomplete or missing trace. This will return `0` if the traces are complete, but do not match. 1 will be returned if there is a match.

- $e->add_amnesty({tag => $TAG, details => $DETAILS});

  This can be used to add amnesty to this event. Amnesty only affects failing assertions in most cases, but some formatters may display them for passing assertions, or even non-assertions as well.

  Amnesty will prevent a failed assertion from causing the overall test to fail. In other words it marks a failure as expected and allowed.

  Note: This is how 'TODO' is implemented under the hood. TODO is essentially amnesty with the 'TODO' tag. The details are the reason for the TODO.

- $uuid = $e->uuid

  If UUID tagging is enabled (See Test::API) then any event that has made its way through a hub will be tagged with a UUID. A newly created event will not yet be tagged in most cases.

- $class = $e->load_facet($name)

  This method is used to load a facet by name (or key). It will attempt to load the facet class, if it succeeds it will return the class it loaded. If it fails it will return `undef`. This caches the result at the class level so that future calls will be faster.

  The `$name` variable should be the key used to access the facet in a facets hashref. For instance the assertion facet has the key 'assert', the information facet has the 'info' key, and the error facet has the key 'errors'. You may include or omit the 's' at the end of the name, the method is smart enough to try both the 's' and no-'s' forms, it will check what you provided first, and if that is not found it will add or strip the 's and try again.

- @classes = $e->FACET_TYPES()

- @classes = Test2::Event->FACET_TYPES()

  This returns a list of all facets that have been loaded using the `load_facet()` method. This will not return any classes that have not been loaded, or have been loaded directly without a call to `load_facet()`.

  Note: The core facet types are automatically loaded and populated in this list.

NEW API

- $hashref = $e->common_facet_data();

  This can be used by subclasses to generate a starting facet data hashref. This will populate the hashref with the trace, meta, amnesty, and about facets. These facets are nearly always produced the same way for all events.

- $hashref = $e->facet_data()

  If you do not override this then the default implementation will attempt to generate facets from the legacy API. This generation is limited only to what the legacy API can provide. It is recommended that you override this method and write out explicit facet data.

- $hashref = $e->facets()

This takes the hashref from `facet_data()` and blesses each facet into the proper `Test2::EventFacet::*` subclass. If no class can be found for any given facet it will be passed along unchanged.

- @errors = $e->validate_facet_data();
- @errors = $e->validate_facet_data(%params);
- @errors = $e->validate_facet_data(\%facets, %params);
- @errors = Test2::Event->validate_facet_data(%params);
- @errors = Test2::Event->validate_facet_data(\%facets, %params);

  This method will validate facet data and return a list of errors. If no errors are found this will return an empty list.

  This can be called as an object method with no arguments, in which case the `facet_data()` method will be called to get the facet data to be validated.

  When used as an object method the `\%facet_data` argument may be omitted.

  When used as a class method the `\%facet_data` argument is required.

  Remaining arguments will be slurped into a `%params` hash.

  Currently only 1 parameter is defined:

  – require_facet_class => $BOOL

    When set to true (default is false) this will reject any facets where a facet class cannot be found. Normally facets without classes are assumed to be custom and are ignored.

WHAT ARE FACETS?

Facets are how events convey their purpose to the Test2 internals and formatters. An event without facets will have no intentional effect on the overall test state, and will not be displayed at all by most formatters, except perhaps to say that an event of an unknown type was seen.

Facets are produced by the `facet_data()` subroutine, which you should nearly-always override. `facet_data()` is expected to return a hashref where each key is the facet type, and the value is either a hashref with the data for that facet, or an array of hashrefs. Some facets must be defined as single hashrefs, some must be defined as an array of hashrefs, No facets allow both.

`facet_data()` **MUST NOT** bless the data it returns, the main hashref, and nested facet hashrefs **MUST** be bare, though items contained within each facet may be blessed. The data returned by this method **should** also be copies of the internal data in order to prevent accidental state modification.

`facets()` takes the data from `facet_data()` and blesses it into the `Test2::EventFacet::*` packages. This is rarely used however, the EventFacet packages are primarily for convenience and documentation. The EventFacet classes are not used at all internally, instead the raw data is used.

Here is a list of facet types by package. The packages are not used internally, but are where the documentation for each type is kept.

Note: Every single facet type has the `'details'` field. This field is always intended for human consumption, and when provided, should explain the 'why' for the facet. All other fields are facet specific.

- about => {...}

  Test2::EventFacet::About

  This contains information about the event itself such as the event package name. The `details` field for this facet is an overall summary of the event.

- assert => {...}

  Test2::EventFacet::Assert

  This facet is used if an assertion was made. The `details` field of this facet is the description of the assertion.

- control => {...}

  Test2::EventFacet::Control

  This facet is used to tell the *Test2::Hub* about special actions the event causes. Things like halting all testing, terminating the current test, etc. In this facet the `details` field explains why any special action was taken.

  Note: This is how bail-out is implemented.

- meta => {...}

  Test2::EventFacet::Meta

  The meta facet contains all the meta-data attached to the event. In this case the `details` field has no special meaning, but may be present if something sets the 'details' meta-key on the event.

- parent => {...}

  Test2::EventFacet::Parent

  This facet contains nested events and similar details for subtests. In this facet the `details` field will typically be the name of the subtest.

- plan => {...}

  Test2::EventFacet::Plan

  This facet tells the system that a plan has been set. The `details` field of this is usually left empty, but when present explains why the plan is what it is, this is most useful if the plan is to skip-all.

- trace => {...}

  Test2::EventFacet::Trace

  This facet contains information related to when and where the event was generated. This is how the test file and line number of a failure is known. This facet can also help you to tell if tests are related.

  In this facet the `details` field overrides the "failed at test_file.t line 42." message provided on assertion failure.

- amnesty => [{...}, ...]

  Test2::EventFacet::Amnesty

  The amnesty facet is a list instead of a single item, this is important as amnesty can come from multiple places at once.

  For each instance of amnesty the `details` field explains why amnesty was granted.

  Note: Outside of formatters amnesty only acts to forgive a failing assertion.

- errors => [{...}, ...]

  Test2::EventFacet::Error

  The errors facet is a list instead of a single item, any number of errors can be listed. In this facet `details` describes the error, or may contain the raw error message itself (such as an exception). In perl exception may be blessed objects, as such the raw data for this facet may contain nested items which are blessed.

  Not all errors are considered fatal, there is a `fail` field that must be set for an error to cause the test to fail.

  Note: This facet is unique in that the field name is 'errors' while the package is 'Error'. This is because this is the only facet type that is both a list, and has a name where the plural is not the same as the singular. This may cause some confusion, but I feel it will be less confusing than the alternative.

- info => [{...}, ...]

  Test2::EventFacet::Info

  The 'info' facet is a list instead of a single item, any quantity of extra information can be attached to an event. Some information may be critical diagnostics, others may be simply commentary in nature, this is determined by the debug flag.

  For this facet the `details` flag is the info itself. This info may be a string, or it may be a data structure to display. This is one of the few facet types that may contain blessed items.

LEGACY API

- $bool = $e->causes_fail

  Returns true if this event should result in a test failure. In general this should be false.

- $bool = $e->increments_count

  Should be true if this event should result in a test count increment.

- $e->callback($hub)

  If your event needs to have extra effects on the *Test2::Hub* you can override this method.

  This is called **BEFORE** your event is passed to the formatter.

- $num = $e->nested

  If this event is nested inside of other events, this should be the depth of nesting. (This is mainly for subtests)

- $bool = $e->global

  Set this to true if your event is global, that is ALL threads and processes should see it no matter when or where it is generated. This is not a common thing to want, it is used by bail-out and skip_all to end testing.

- $code = $e->terminate

  This is called **AFTER** your event has been passed to the formatter. This should normally return undef, only change this if your event should cause the test to exit immediately.

  If you want this event to cause the test to exit you should return the exit code here. Exit code of 0 means exit success, any other integer means exit with failure.

  This is used by *Test2::Event::Plan* to exit 0 when the plan is 'skip_all'. This is also used by Test2::Event:Bail to force the test to exit with a failure.

  This is called after the event has been sent to the formatter in order to ensure the event is seen and understood.

- $msg = $e->summary

  This is intended to be a human readable summary of the event. This should ideally only be one line long, but you can use multiple lines if necessary. This is intended for human consumption. You do not need to make it easy for machines to understand.

  The default is to simply return the event package name.

- ($count, $directive, $reason) = $e->sets_plan()

  Check if this event sets the testing plan. It will return an empty list if it does not. If it does set the plan it will return a list of 1 to 3 items in order: Expected Test Count, Test Directive, Reason for directive.

- $bool = $e->diagnostics

  True if the event contains diagnostics info. This is useful because a non-verbose harness may choose to hide events that are not in this category. Some formatters may choose to send these to STDERR instead of STDOUT to ensure they are seen.

- $bool = $e->no_display

  False by default. This will return true on events that should not be displayed by formatters.

- $id = $e->in_subtest

  If the event is inside a subtest this should have the subtest ID.

- $id = $e->subtest_id

  If the event is a final subtest event, this should contain the subtest ID.

THIRD PARTY META-DATA

This object consumes *Test2::Util::ExternalMeta* which provides a consistent way for you to attach meta-data to instances of this class. This is useful for tools, plugins, and other extensions.

Modules

- `Test2::Event::Bail` - Bailout!
- `Test2::Event::Diag` - Diag event type
- `Test2::Event::Encoding` - Set the encoding for the output stream
- `Test2::Event::Exception` - Exception event
- `Test2::Event::Fail` - Event for a simple failed assertion
- `Test2::Event::Generic` - Generic event type.
- `Test2::Event::Note` - Note event type
- `Test2::Event::Ok` - Ok event type
- `Test2::Event::Pass` - Event for a simple passing assertion
- `Test2::Event::Plan` - The event of a plan
- `Test2::Event::Skip` - Skip event type
- `Test2::Event::Subtest` - Event for subtest types
- `Test2::Event::TAP`
- `Test2::Event::V2` - Second generation event.
- `Test2::Event::Waiting` - Tell all procs/threads it is time to be done

Test2::Event::Bail

Bailout!

DESCRIPTION

The bailout event is generated when things go horribly wrong and you need to halt all testing in the current file.

SYNOPSIS

```
use Test2::API qw/context/;
use Test2::Event::Bail;

my $ctx = context();
my $event = $ctx->bail('Stuff is broken');
```

METHODS

Inherits from *Test2::Event*. Also defines:

- $reason = $e->reason

  The reason for the bailout.

Test2::Event::Diag

Diag event type

DESCRIPTION

Diagnostics messages, typically rendered to STDERR.

SYNOPSIS

```
use Test2::API qw/context/;
use Test2::Event::Diag;

my $ctx = context();
my $event = $ctx->diag($message);
```

ACCESSORS

- $diag->message

  The message for the diag.

Test2::Event::Encoding

Set the encoding for the output stream

DESCRIPTION

The encoding event is generated when a test file wants to specify the encoding to be used when formatting its output. This event is intended to be produced by formatter classes and used for interpreting test names, message contents, etc.

SYNOPSIS

```
use Test2::API qw/context/;
use Test2::Event::Encoding;

my $ctx = context();
my $event = $ctx->send_event('Encoding', encoding => 'UTF-8');
```

METHODS

Inherits from *Test2::Event*. Also defines:

- $encoding = $e->encoding

  The encoding being specified.

SOURCE

The source code repository for Test2 can be found at https://github.com/Test-More/test-more/.

Test2::Event::Exception

Exception event

DESCRIPTION

An exception event will display to STDERR, and will prevent the overall test file from passing.

SYNOPSIS

```
use Test2::API qw/context/;
use Test2::Event::Exception;

my $ctx = context();
my $event = $ctx->send_event('Exception', error => 'Stuff is broken
 ↪');
```

METHODS

Inherits from *Test2::Event*. Also defines:

- $reason = $e->error

  The reason for the exception.

CAVEATS

Be aware that all exceptions are stringified during construction.

Test2::Event::Fail

Event for a simple failed assertion

DESCRIPTION

This is an optimal representation of a failed assertion.

SYNOPSIS

```
use Test2::API qw/context/;

sub fail {
    my ($name) = @_;
    my $ctx = context();
    $ctx->fail($name);
    $ctx->release;
}
```

Test2::Event::Generic

Generic event type.

DESCRIPTION

This is a generic event that lets you customize all fields in the event API. This is useful if you have need for a custom event that does not make sense as a published reusable event subclass.

SYNOPSIS

```
use Test2::API qw/context/;

sub send_custom_fail {
    my $ctx = shift;

    $ctx->send_event('Generic', causes_fail => 1, summary => 'The
 ↪sky is falling');

    $ctx->release;
}

send_custom_fail();
```

METHODS

- $e->facet_data($data)
- $data = $e->facet_data

  Get or set the facet data (see *Test2::Event*). If no facet_data is set then `Test2::Event->facet_data` will be called to produce facets from the other data.

- $e->callback($hub)

  Call the custom callback if one is set, otherwise this does nothing.

- $e->set_callback(sub { ... })

  Set the custom callback. The custom callback must be a coderef. The first argument to your callback will be the event itself, the second will be the *Test2::Hub* that is using the callback.

- $bool = $e->causes_fail
- $e->set_causes_fail($bool)

  Get/Set the `causes_fail` attribute. This defaults to `0`.

- $bool = $e->diagnostics
- $e->set_diagnostics($bool)

  Get/Set the `diagnostics` attribute. This defaults to `0`.

- $bool_or_undef = $e->global
- @bool_or_empty = $e->global
- $e->set_global($bool_or_undef)

  Get/Set the `diagnostics` attribute. This defaults to an empty list which is undef in scalar context.

- $bool = $e->increments_count
- $e->set_increments_count($bool)

  Get/Set the `increments_count` attribute. This defaults to `0`.

- $bool = $e->no_display
- $e->set_no_display($bool)

  Get/Set the `no_display` attribute. This defaults to `0`.

- @plan = $e->sets_plan

  Get the plan if this event sets one. The plan is a list of up to 3 items: `($count, $directive, $reason)`. `$count` must be defined, the others may be undef, or may not exist at all.

- $e->set_sets_plan(\@plan)

  Set the plan. You must pass in an arrayref with up to 3 elements.

- $summary = $e->summary
- $e->set_summary($summary_or_undef)

  Get/Set the summary. This will default to the event package `'Test2::Event::Generic'`. You can set it to any value. Setting this to `undef` will reset it to the default.

- $int_or_undef = $e->terminate
- @int_or_empty = $e->terminate
- $e->set_terminate($int_or_undef)

  This will get/set the `terminate` attribute. This defaults to undef in scalar context, or an empty list in list context. Setting this to undef will clear it completely. This must be set to a positive integer (0 or larger).

Test2::Event::Note

Note event type

DESCRIPTION

Notes, typically rendered to STDOUT.

SYNOPSIS

```
use Test2::API qw/context/;
use Test2::Event::Note;

my $ctx = context();
my $event = $ctx->Note($message);
```

ACCESSORS

- $note->message

  The message for the note.

Test2::Event::Ok

Ok event type

DESCRIPTION

Ok events are generated whenever you run a test that produces a result. Examples are `ok()`, and `is()`.

SYNOPSIS

```
use Test2::API qw/context/;
use Test2::Event::Ok;

my $ctx = context();
my $event = $ctx->ok($bool, $name, \@diag);
```

or:

```
my $ctx   = context();
my $event = $ctx->send_event(
    'Ok',
    pass => $bool,
    name => $name,
);
```

ACCESSORS

- $rb = $e->pass

  The original true/false value of whatever was passed into the event (but reduced down to 1 or 0).

- $name = $e->name

  Name of the test.

- $b = $e->effective_pass

  This is the true/false value of the test after TODO and similar modifiers are taken into account.

SOURCE

Test2::Event::Pass

Event for a simple passing assertion

DESCRIPTION

This is an optimal representation of a passing assertion.

SYNOPSIS

```
use Test2::API qw/context/;

sub pass {
    my ($name) = @_;
    my $ctx = context();
    $ctx->pass($name);
    $ctx->release;
}
```

SOURCE

Test2::Event::Plan

The event of a plan

DESCRIPTION

Plan events are fired off whenever a plan is declared, done testing is called, or a subtext completes.

SYNOPSIS

```
use Test2::API qw/context/;
use Test2::Event::Plan;

my $ctx = context();

# Plan for 10 tests to run
my $event = $ctx->plan(10);

# Plan to skip all tests (will exit 0)
$ctx->plan(0, skip_all => "These tests need to be skipped");
```

ACCESSORS

- $num = $plan->max

  Get the number of expected tests

- $dir = $plan->directive

  Get the directive (such as TODO, skip_all, or no_plan).

- $reason = $plan->reason

  Get the reason for the directive.

SOURCE

Test2::Event::Skip

Skip event type

DESCRIPTION

Skip events bump test counts just like *Test2::Event::Ok* events, but they can never fail.

SYNOPSIS

```
use Test2::API qw/context/;
use Test2::Event::Skip;

my $ctx = context();
my $event = $ctx->skip($name, $reason);
```

or:

```
my $ctx   = context();
my $event = $ctx->send_event(
    'Skip',
    name   => $name,
    reason => $reason,
);
```

ACCESSORS

- $reason = $e->reason

  The original true/false value of whatever was passed into the event (but reduced down to 1 or 0).

SOURCE

The source code repository for Test2 can be found at https://github.com/Test-More/test-more/.

Test2::Event::Subtest

Event for subtest types

DESCRIPTION

This class represents a subtest. This class is a subclass of *Test2::Event::Ok*.

ACCESSORS

This class inherits from *Test2::Event::Ok*.

- $arrayref = $e->subevents

  Returns the arrayref containing all the events from the subtest

- $bool = $e->buffered

  True if the subtest is buffered, that is all subevents render at once. If this is false it means all subevents render as they are produced.

SOURCE

The source code repository for Test2 can be found at https://github.com/Test-More/test-more/.

Test2::Event::TAP

Namespace containing the following modules:

- `Test2::Event::TAP::Version` - Event for TAP version.

Test2::Event::TAP::Version

Event for TAP version.

DESCRIPTION

This event is used if a TAP formatter wishes to set a version.

SYNOPSIS

```
use Test2::API qw/context/;
use Test2::Event::Encoding;

my $ctx = context();
my $event = $ctx->send_event('TAP::Version', version => 42);
```

METHODS

Inherits from *Test2::Event*. Also defines:

- $version = $e->version

  The TAP version being parsed.

SOURCE

The source code repository for Test2 can be found at https://github.com/Test-More/test-more/.

Test2::Event::V2

Second generation event.

DESCRIPTION

This is the event type that should be used instead of *Test2::Event* or its legacy subclasses.

SYNOPSIS

USING A CONTEXT

```
use Test2::API qw/context/;

sub my_tool {
    my $ctx = context();

    my $event = $ctx->send_ev2(info => [{tag => 'NOTE', details =>
 ↪"This is a note"}]);

    $ctx->release;

    return $event;
}
```

USING THE CONSTRUCTOR

```
use Test2::Event::V2;

my $e = Test2::Event::V2->new(
    trace => {frame => [$PKG, $FILE, $LINE, $SUBNAME]},
    info  => [{tag => 'NOTE', details => "This is a note"}],
);
```

METHODS

This class inherits from *Test2::Event*.

- $fd = $e->facet_data()

  This will return a hashref of facet data. Each facet hash will be a shallow copy of the original.

- $about = $e->about()

  This will return the 'about' facet hashref.

  NOTE: This will return the internal hashref, not a copy.

- $trace = $e->trace()

  This will return the 'trace' facet, normally blessed (but this is not enforced when the trace is set using `set_trace()`.

  NOTE: This will return the internal trace, not a copy.

MUTATION

- $e->add_amnesty({...})

  Inherited from *Test2::Event*. This can be used to add 'amnesty' facets to an existing event. Each new item is added to the **END** of the list.

  NOTE: Items **ARE** blessed when added.

- $e->add_hub({...})

  Inherited from *Test2::Event*. This is used by hubs to stamp events as they pass through. New items are added to the **START** of the list.

  NOTE: Items **ARE NOT** blessed when added.

- $e->set_uuid($UUID)

  Inherited from *Test2::Event*, overridden to also vivify/mutate the 'about' facet.

- $e->set_trace($trace)

  Inherited from *Test2::Event* which allows you to change the trace.

  Note: This method does not bless/clone the trace for you. Many things will expect the trace to be blessed, so you should probably do that.

LEGACY SUPPORT METHODS

These are all imported from *Test2::Util::Facets2Legacy*, see that module or *Test2::Event* for documentation on what they do.

- causes_fail
- diagnostics
- global
- increments_count
- no_display
- sets_plan
- subtest_id
- summary
- terminate

THIRD PARTY META-DATA

This object consumes *Test2::Util::ExternalMeta* which provides a consistent way for you to attach meta-data to instances of this class. This is useful for tools, plugins, and other extensions.

Test2::Event::Waiting

Tell all procs/threads it is time to be done

DESCRIPTION

This event has no data of its own. This event is sent out by the IPC system when the main process/thread is ready to end.

SOURCE

The source code repository for Test2 can be found at https://github.com/Test-More/test-more/.

MAINTAINERS

Test2::EventFacet

Base class for all event facets.

DESCRIPTION

Base class for all event facets.

METHODS

- $key = $facet_class->facet_key()

  This will return the key for the facet in the facet data hash.

- $bool = $facet_class->is_list()

  This will return true if the facet should be in a list instead of a single item.

- $clone = $facet->clone()

- $clone = $facet->clone(%replace)

  This will make a shallow clone of the facet. You may specify fields to override as arguments.

SOURCE

See https://dev.perl.org/licenses/

Modules

- `Test2::EventFacet::About` - Facet with event details.
- `Test2::EventFacet::Amnesty` - Facet for assertion amnesty.
- `Test2::EventFacet::Assert` - Facet representing an assertion.
- `Test2::EventFacet::Control` - Facet for hub actions and behaviors.
- `Test2::EventFacet::Error` - Facet for errors that need to be shown.
- `Test2::EventFacet::Hub` - Facet for the hubs an event passes through.
- `Test2::EventFacet::Info` - Facet for information a developer might care about.
- `Test2::EventFacet::Meta` - Facet for meta-data
- `Test2::EventFacet::Parent` - Facet for events contains other events
- `Test2::EventFacet::Plan` - Facet for setting the plan
- `Test2::EventFacet::Render` - Facet that dictates how to render an event.
- `Test2::EventFacet::Trace` - Debug information for events

Test2::EventFacet::About

Facet with event details.

DESCRIPTION

This facet has information about the event, such as event package.

FIELDS

- $string = $about->{details}
- $string = $about->details()

  Summary about the event.
- $package = $about->{package}
- $package = $about->package()

  Event package name.
- $bool = $about->{no_display}

- $bool = $about->no_display()

  True if the event should be skipped by formatters.

- $uuid = $about->{uuid}
- $uuid = $about->uuid()

  Will be set to a uuid if uuid tagging was enabled.

- $uuid = $about->{eid}
- $uuid = $about->eid()

  A unique (for the test job) identifier for the event.

SOURCE

The source code repository for Test2 can be found at https://github.com/Test-More/test-more/.

See https://dev.perl.org/licenses/

Test2::EventFacet::Amnesty

Facet for assertion amnesty.

DESCRIPTION

This package represents what is expected in units of amnesty.

NOTES

This facet appears in a list instead of being a single item.

FIELDS

- $string = $amnesty->{details}
- $string = $amnesty->details()

  Human readable explanation of why amnesty was granted.

  Example: *Not implemented yet, will fix*

- $short_string = $amnesty->{tag}
- $short_string = $amnesty->tag()

  Short string (usually 10 characters or less, not enforced, but may be truncated by renderers) categorizing the amnesty.

- $bool = $amnesty->{inherited}
- $bool = $amnesty->inherited()

  This will be true if the amnesty was granted to a parent event and inherited by this event, which is a child, such as an assertion within a subtest that is marked todo.

SOURCE

The source code repository for Test2 can be found at https://github.com/Test-More/test-more/.

MAINTAINERS

See https://dev.perl.org/licenses/

Test2::EventFacet::Assert

Facet representing an assertion.

DESCRIPTION

The assertion facet is provided by any event representing an assertion that was made.

FIELDS

- $string = $assert->{details}
- $string = $assert->details()

  Human readable description of the assertion.

- $bool = $assert->{pass}
- $bool = $assert->pass()

  True if the assertion passed.

- $bool = $assert->{no_debug}
- $bool = $assert->no_debug()

  Set this to true if you have provided custom diagnostics and do not want the defaults to be displayed.

- $int = $assert->{number}
- $int = $assert->number()

  (Optional) assertion number. This may be omitted or ignored. This is usually only useful when parsing/processing TAP.

  Note: This is not set by the Test2 system, assertion number is not known until AFTER the assertion has been processed. This attribute is part of the spec only for harnesses.

SOURCE

Test2::EventFacet::Control

Facet for hub actions and behaviors.

DESCRIPTION

This facet is used when the event needs to give instructions to the Test2 internals.

FIELDS

- $string = $control->{details}
- $string = $control->details()

  Human readable explanation for the special behavior.
- $bool = $control->{global}
- $bool = $control->global()

  True if the event is global in nature and should be seen by all hubs.
- $exit = $control->{terminate}
- $exit = $control->terminate()

  Defined if the test should immediately exit, the value is the exit code and may be `0`.
- $bool = $control->{halt}
- $bool = $control->halt()

  True if all testing should be halted immediately.
- $bool = $control->{has_callback}
- $bool = $control->has_callback()

  True if the `callback($hub)` method on the event should be called.
- $encoding = $control->{encoding}
- $encoding = $control->encoding()

  This can be used to change the encoding from this event onward.
- $phase = $control->{phase}
- $phase = $control->phase()

  Used to signal that a phase change has occurred. Currently only the perl END phase is signaled.

SOURCE

Test2::EventFacet::Error

Facet for errors that need to be shown.

DESCRIPTION

This facet is used when an event needs to convey errors.

NOTES

This facet has the hash key `'errors'`, and is a list of facets instead of a single item.

FIELDS

- $string = $error->{details}
- $string = $error->details()

  Explanation of the error, or the error itself (such as an exception). In perl exceptions may be blessed objects, so this field may contain a blessed object.

- $short_string = $error->{tag}
- $short_string = $error->tag()

  Short tag to categorize the error. This is usually 10 characters or less, formatters may truncate longer tags.

- $bool = $error->{fail}
- $bool = $error->fail()

  Not all errors are fatal, some are displayed having already been handled. Set this to true if you want the error to cause the test to fail. Without this the error is simply a diagnostics message that has no effect on the overall pass/fail result.

SOURCE

Test2::EventFacet::Hub

Facet for the hubs an event passes through.

DESCRIPTION

These are a record of the hubs an event passes through. Most recent hub is the first one in the list.

FACET FIELDS

- $string = $trace->{details}
- $string = $trace->details()

  The hub class or subclass
- $int = $trace->{pid}
- $int = $trace->pid()

  PID of the hub this event was sent to.
- $int = $trace->{tid}
- $int = $trace->tid()

  The thread ID of the hub the event was sent to.
- $hid = $trace->{hid}
- $hid = $trace->hid()

  The ID of the hub that the event was send to.

- $huuid = $trace->{huuid}
- $huuid = $trace->huuid()

  The UUID of the hub that the event was sent to.
- $int = $trace->{nested}
- $int = $trace->nested()

  How deeply nested the hub was.
- $bool = $trace->{buffered}
- $bool = $trace->buffered()

  True if the event was buffered and not sent to the formatter independent of a parent (This should never be set when nested is `0` or `undef`).

SOURCE

Test2::EventFacet::Info

Facet for information a developer might care about.

DESCRIPTION

This facet represents messages intended for humans that will help them either understand a result, or diagnose a failure.

NOTES

This facet appears in a list instead of being a single item.

FIELDS

- $string_or_structure = $info->{details}
- $string_or_structure = $info->details()

  Human readable string or data structure, this is the information to display. Formatters are free to render the structures however they please. This may contain a blessed object.

  If the `table` attribute (see below) is set then a renderer may choose to display the table instead of the details.

- $structure = $info->{table}
- $structure = $info->table()

  If the data the `info` facet needs to convey can be represented as a table then the data may be placed in this attribute in a more raw form for better display. The data must also be represented in the `details` attribute for renderers which do not support rendering tables directly.

  The table structure:

```
my %table = {
    header => [ 'column 1 header', 'column 2 header', ... ], #␣
↪Optional

    rows => [
        ['row 1 column 1', 'row 1, column 2', ... ],
        ['row 2 column 1', 'row 2, column 2', ... ],
        ...
    ],

    # Allow the renderer to hide empty columns when true,␣
↪Optional
    collapse => $BOOL,

    # List by name or number columns that should never be␣
↪collapsed
    no_collapse => \@LIST,
}
```

- $short_string = $info->{tag}
- $short_string = $info->tag()

  Short tag to categorize the info. This is usually 10 characters or less, formatters may truncate longer tags.

- $bool = $info->{debug}
- $bool = $info->debug()

Set this to true if the message is critical, or explains a failure. This is info that should be displayed by formatters even in less-verbose modes.

When false the information is not considered critical and may not be rendered in less-verbose modes.

- $bool = $info->{important}
- $bool = $info->important

  This should be set for non debug messages that are still important enough to show when a formatter is in quiet mode. A formatter should send these to STDOUT not STDERR, but should show them even in non-verbose mode.

Modules

- `Test2::EventFacet::Info::Table` - Intermediary representation of a table.

Test2::EventFacet::Info::Table

Intermediary representation of a table.

DESCRIPTION

Intermediary representation of a table for use in specialized *Test2::API::Context* methods which generate *Test2::EventFacet::Info* facets.

SYNOPSIS

```
use Test2::EventFacet::Info::Table;
use Test2::API qw/context/;

sub my_tool {
    my $ctx = context();

    ...

    $ctx->fail(
        $name,
        "failure diag message",
        Test2::EventFacet::Info::Table->new(
            # Required
            rows => [['a', 'b'], ['c', 'd'], ...],

            # Strongly Recommended
            as_string => "... string to print when table cannot be
↪rendered ...",

            # Optional
            header => ['col1', 'col2'],
            collapse => $bool,
            no_collapse => ['col1', ...],
        ),
    );

    ...

    $ctx->release;
}

my_tool();
```

ATTRIBUTES

- $header_aref = $t->header()
- $rows_aref = $t->rows()
- $bool = $t->collapse()
- $aref = $t->no_collapse()

  The above are all directly tied to the table hashref structure described in *Test2::EventFacet::Info*.

- $str = $t->as_string()

  This returns the string form of the table if it was set, otherwise it returns the string `"<TABLE NOT DISPLAYED>"`.

- $href = $t->as_hash()

This returns the data structure used for tables by *Test2::EventFacet::Info*.

- This returns the arguments that should be used to construct the proper *Test2::EventFacet::Info* structure.

```
return (table => $t->as_hash(), details => $t->as_string());
```

Test2::EventFacet::Meta

Facet for meta-data

DESCRIPTION

This facet can contain any random meta-data that has been attached to the event.

METHODS AND FIELDS

Any/all fields and accessors are autovivified into existence. There is no way to know what metadata may be added, so any is allowed.

- $anything = $meta->{anything}
- $anything = $meta->anything()

SOURCE

The source code repository for Test2 can be found at https://github.com/Test-More/test-more/.

Test2::EventFacet::Parent

Facet for events contains other events

DESCRIPTION

This facet is used when an event contains other events, such as a subtest.

FIELDS

- $string = $parent->{details}
- $string = $parent->details()

  Human readable description of the event.
- $hid = $parent->{hid}
- $hid = $parent->hid()

  Hub ID of the hub that is represented in the parent-child relationship.
- $arrayref = $parent->{children}
- $arrayref = $parent->children()

  Arrayref containing the facet-data hashes of events nested under this one.

  To get the actual events you need to get them from the parent event directly
- $bool = $parent->{buffered}
- $bool = $parent->buffered()

  True if the subtest is buffered (meaning the formatter has probably not seen them yet).

Test2::EventFacet::Plan

Facet for setting the plan

DESCRIPTION

Events use this facet when they need to set the plan.

FIELDS

- $string = $plan->{details}
- $string = $plan->details()

  Human readable explanation for the plan being set. This is normally not rendered by most formatters except when the `skip` field is also set.

- $positive_int = $plan->{count}
- $positive_int = $plan->count()

  Set the number of expected assertions. This should usually be set to `0` when `skip` or none are also set.

- $bool = $plan->{skip}
- $bool = $plan->skip()

  When true the entire test should be skipped. This is usually paired with an explanation in the `details` field, and a `control` facet that has `terminate` set to `0`.

- $bool = $plan->{none}

- $bool = $plan->none()

  This is mainly used by legacy *Test::Builder* tests which set the plan to `no plan`, a construct that predates the much better `done_testing()`.

  If you are using this in non-legacy code you may need to reconsider the course of your life, maybe a hermitage would suite you?

Test2::EventFacet::Render

Facet that dictates how to render an event.

DESCRIPTION

This facet is used to dictate how the event should be rendered by the standard test2 rendering tools. If this facet is present then ONLY what is specified by it will be rendered. It is assumed that anything important or note-worthy will be present here, no other facets will be considered for rendering/display.

This facet is a list type, you can add as many items as needed.

FIELDS

- $string = $render->[#]->{details}
- $string = $render->[#]->details()

  Human readable text for display.

- $string = $render->[#]->{tag}

- $string = $render->[#]->tag()

  Tag that should prefix/identify the main text.

- $string = $render->[#]->{facet}
- $string = $render->[#]->facet()

  Optional, if the display text was generated from another facet this should state what facet it was.

- $mode = $render->[#]->{mode}
- $mode = $render->[#]->mode()
  - calculated

    Calculated means the facet was generated from another facet. Calculated facets may be cleared and regenerated whenever the event state changes.

  - replace

    Replace means the facet is intended to replace the normal rendering of the event.

Test2::EventFacet::Trace

Debug information for events

DESCRIPTION

The *Test2::API::Context* object, as well as all *Test2::Event* types need to have access to information about where they were created. This object represents that information.

SYNOPSIS

```
use Test2::EventFacet::Trace;

my $trace = Test2::EventFacet::Trace->new(
    frame => [$package, $file, $line, $subname],
);
```

FACET FIELDS

- $string = $trace->{details}
- $string = $trace->details()

  Used as a custom trace message that will be used INSTEAD of `at <FILE> line <LINE>` when calling `$trace->debug`.
- $frame = $trace->{frame}
- $frame = $trace->frame()

  Get the call frame arrayref.

  ```
  [$package, $file, $line, $subname]
  ```
- $int = $trace->{pid}
- $int = $trace->pid()

  The process ID in which the event was generated.
- $int = $trace->{tid}
- $int = $trace->tid()

  The thread ID in which the event was generated.
- $id = $trace->{cid}
- $id = $trace->cid()

  The ID of the context that was used to create the event.
- $uuid = $trace->{uuid}
- $uuid = $trace->uuid()

  The UUID of the context that was used to create the event. (If uuid tagging was enabled)
- ($pkg, $file, $line, $subname) = $trace->call

  Get the basic call info as a list.
- @caller = $trace->full_call

  Get the full caller(N) results.
- $warning_bits = $trace->warning_bits

  Get index 9 from the full caller info. This is the warnings_bits field.

The value of this is not portable across perl versions or even processes. However it can be used in the process that generated it to reproduce the warnings settings in a new scope.

```
eval <<EOT;
BEGIN { ${^WARNING_BITS} = $trace->warning_bits };
... context's warning settings apply here ...
EOT
```

DISCOURAGED HUB RELATED FIELDS

These fields were not always set properly by tools. These are **MOSTLY** deprecated by the *Test2::EventFacet::Hub* facets. These fields are not required, and may only reflect the hub that was current when the event was created, which is not necessarily the same as the hub the event was sent through.

Some tools did do a good job setting these to the correct hub, but you cannot always rely on that. Use the 'hubs' facet list instead.

- $hid = $trace->{hid}
- $hid = $trace->hid()

  The ID of the hub that was current when the event was created.

- $huuid = $trace->{huuid}
- $huuid = $trace->huuid()

  The UUID of the hub that was current when the event was created. (If uuid tagging was enabled).

- $int = $trace->{nested}
- $int = $trace->nested()

  How deeply nested the event is.

- $bool = $trace->{buffered}
- $bool = $trace->buffered()

  True if the event was buffered and not sent to the formatter independent of a parent (This should never be set when nested is `0` or `undef`).

METHODS

Note: All facet frames are also methods.

- $trace->set_detail($msg)
- $msg = $trace->detail

  Used to get/set a custom trace message that will be used INSTEAD of `at <FILE> line <LINE>` when calling `$trace->debug`.

  `detail()` is an alias to the `details` facet field for backwards compatibility.

- $str = $trace->debug

  Typically returns the string `at <FILE> line <LINE>`. If `detail` is set then its value will be returned instead.

- $trace->alert($MESSAGE)

  This issues a warning at the frame (filename and line number where errors should be reported).

- $trace->throw($MESSAGE)

  This throws an exception at the frame (filename and line number where errors should be reported).

- ($package, $file, $line, $subname) = $trace->call()

  Get the caller details for the debug-info. This is where errors should be reported.

- $pkg = $trace->package

  Get the debug-info package.

- $file = $trace->file

  Get the debug-info filename.

- $line = $trace->line

  Get the debug-info line number.

- $subname = $trace->subname

  Get the debug-info subroutine name.

- $sig = trace->signature

  Get a signature string that identifies this trace. This is used to check if multiple events are related. The signature includes pid, tid, file, line number, and the cid.

Test2::Formatter

Namespace for formatters.

DESCRIPTION

This is the namespace for formatters. This is an empty package.

CREATING FORMATTERS

A formatter is any package or object with a `write($event, $num)` method.

```
package Test2::Formatter::Foo;
use strict;
use warnings;

sub write {
    my $self_or_class = shift;
    my ($event, $assert_num) = @_;
    ...
}

sub hide_buffered { 1 }

sub terminate { }

sub finalize { }

sub supports_tables { return $BOOL }

sub new_root {
    my $class = shift;
    ...
    $class->new(@_);
}

1;
```

The `write` method is a method, so it either gets a class or instance. The two arguments are the `$event` object it should record, and the `$assert_num` which is the number of the current assertion (ok), or the last assertion if this event is not itself an assertion. The assertion number may be any integer 0 or greater, and may be undefined in some cases.

The `hide_buffered()` method must return a boolean. This is used to tell buffered subtests whether or not to send it events as they are being buffered. See *"run_subtest(...)" in Test2::API* for more information.

The `terminate` and `finalize` methods are optional methods called that you can implement if the format you're generating needs to handle these cases, for example if you are generating XML and need close open tags.

The `terminate` method is called when an event's `terminate` method returns true, for example when a *Test2::Event::Plan* has a `'skip_all'` plan, or when a *Test2::Event::Bail* event is sent. The `terminate` method is passed a single argument, the *Test2::Event* object which triggered the terminate.

The `finalize` method is always the last thing called on the formatter, *except when* `terminate` *is called for a Bail event*. It is passed the following arguments:

The `supports_tables` method should be true if the formatter supports directly rendering table data from the `info` facets. This is a newer feature and many older formatters may not support it. When not supported the formatter falls back to rendering `detail` instead of the `table` data.

The `new_root` method is used when constructing a root formatter. The default is to just delegate to the regular `new()` method, most formatters can ignore this.

- The number of tests that were planned
- The number of tests actually seen
- The number of tests which failed
- A boolean indicating whether or not the test suite passed
- A boolean indicating whether or not this call is for a subtest

The `new_root` method is called when `Test2::API::Stack` Initializes the root hub for the first time. Most formatters will simply have this call `$class->new`, which is the default behavior. Some formatters however may want to take extra action during construction of the root formatter, this is where they can do that.

Modules

- `Test2::Formatter::TAP` - Standard TAP formatter

Test2::Formatter::TAP

Standard TAP formatter

DESCRIPTION

This is what takes events and turns them into TAP.

SYNOPSIS

```
use Test2::Formatter::TAP;
my $tap = Test2::Formatter::TAP->new();

# Switch to utf8
$tap->encoding('utf8');

$tap->write($event, $number); # Output an event
```

METHODS

- $bool = $tap->no_numbers
- $tap->set_no_numbers($bool)

  Use to turn numbers on and off.
- $arrayref = $tap->handles
- $tap->set_handles(\@handles);

  Can be used to get/set the filehandles. Indexes are identified by the `OUT_STD` and `OUT_ERR` constants.
- $encoding = $tap->encoding
- $tap->encoding($encoding)

  Get or set the encoding. By default no encoding is set, the original settings of STDOUT and STDERR are used.

  This directly modifies the stored filehandles, it does not create new ones.
- $tap->write($e, $num)

  Write an event to the console.

Test2::Handle

Base class for Test2 handles used in V# bundles.

DESCRIPTION

This is what you interact with when you use the `T2()` function in a test that uses *Test2::V1*.

SYNOPSIS

RECOMMENDED

```
use Test2::V1;

my $handle = T2();

$handle->ok(1, "Passing Test");
```

WITHOUT SUGAR

```
use Test2::Handle();

my $handle = Test2::Handle->new(base => 'Test2::V1::Base');

$handle->ok(1, "Passing test");
```

METHODS

Most methods are delegated to the base class provided at construction. There are however a few methods that are defined by this package itself.

- $base = $class_or_inst->DEFAULT_HANDLE_BASE

  Get the default handle base. This throws an exception on the base handle class, you should override it in a subclass.

- $base = $inst->HANDLE_BASE

  In this base class this method always throws an exception. In a subclass it should return the default base class to use for that subclass.

- $namespace = $inst->HANDLE_NAMESPACE

  Get the namespace used to store function we wrap as methods.

- @sub_names = $inst->HANDLE_SUBS

  Get a list of all subs available in the handle namespace.

- $inst->HANDLE_INCLUDE($package, @subs)

  Import the specified subs from the specified package into our internal namespace.

- $inst = $class->import()

  Used to create a `T2()` sub in your namsepace at import.

- $inst->init()

  Internally used to intialize and validate the handle object.

- AUTOLOAD

  Internally used to wrap functions as methods.

SOURCE

The source code repository for Test2-Suite can be found at `https://github.com/Test-More/test-more/`.

Test2::Hub

The conduit through which all events flow.

SYNOPSIS

```
use Test2::Hub;

my $hub = Test2::Hub->new();
$hub->send(...);
```

DESCRIPTION

The hub is the place where all events get processed and handed off to the formatter. The hub also tracks test state, and provides several hooks into the event pipeline.

COMMON TASKS

SENDING EVENTS

```
$hub->send($event)
```

The `send()` method is used to issue an event to the hub. This method will handle thread/fork sync, filters, listeners, TAP output, etc.

ALTERING OR REMOVING EVENTS

You can use either `filter()` or `pre_filter()`, depending on your needs. Both have identical syntax, so only `filter()` is shown here.

```
$hub->filter(sub {
    my ($hub, $event) = @_;

    my $action = get_action($event);

    # No action should be taken
    return $event if $action eq 'none';

    # You want your filter to remove the event
    return undef if $action eq 'delete';

    if ($action eq 'do_it') {
        my $new_event = copy_event($event);
        ... Change your copy of the event ...
        return $new_event;
    }

    die "Should not happen";
});
```

By default, filters are not inherited by child hubs. That means if you start a subtest, the subtest will not inherit the filter. You can change this behavior with the `inherit` parameter:

```
$hub->filter(sub { ... }, inherit => 1);
```

LISTENING FOR EVENTS

```
$hub->listen(sub {
    my ($hub, $event, $number) = @_;

    ... do whatever you want with the event ...

    # return is ignored
});
```

By default listeners are not inherited by child hubs. That means if you start a subtest, the subtest will not inherit the listener. You can change this behavior with the `inherit` parameter:

```
$hub->listen(sub { ... }, inherit => 1);
```

POST-TEST BEHAVIORS

```
$hub->follow_up(sub {
    my ($trace, $hub) = @_;

    ... do whatever you need to ...

    # Return is ignored
});
```

follow_up subs are called only once, either when done_testing is called, or in an END block.

SETTING THE FORMATTER

By default an instance of *Test2::Formatter::TAP* is created and used.

```
my $old = $hub->format(My::Formatter->new);
```

Setting the formatter will REPLACE any existing formatter. You may set the formatter to undef to prevent output. The old formatter will be returned if one was already set. Only one formatter is allowed at a time.

METHODS

- $hub->send($event)

  This is where all events enter the hub for processing.

- $hub->process($event)

  This is called by send after it does any IPC handling. You can use this to bypass the IPC process, but in general you should avoid using this.

- $old = $hub->format($formatter)

  Replace the existing formatter instance with a new one. Formatters must be objects that implement a `$formatter->write($event)` method.

- $sub = $hub->listen(sub { ... }, %optional_params)

  You can use this to record all events AFTER they have been sent to the formatter. No changes made here will be meaningful, except possibly to other listeners.

```
$hub->listen(sub {
    my ($hub, $event, $number) = @_;

    ... do whatever you want with the event ...

    # return is ignored
});
```

  Normally listeners are not inherited by child hubs such as subtests. You can add the `inherit => 1` parameter to allow a listener to be inherited.

- $hub->unlisten($sub)

  You can use this to remove a listen callback. You must pass in the coderef returned by the `listen()` method.

- $sub = $hub->filter(sub { ... }, %optional_params)

- $sub = $hub->pre_filter(sub { ... }, %optional_params)

  These can be used to add filters. Filters can modify, replace, or remove events before anything else can see them.

```
$hub->filter(
    sub {
        my ($hub, $event) = @_;

        return $event;    # No Changes
        return;           # Remove the event

        # Or you can modify an event before returning it.
        $event->modify;
        return $event;
    }
);
```

If you are not using threads, forking, or IPC then the only difference between a `filter` and a `pre_filter` is that `pre_filter` subs run first. When you are using threads, forking, or IPC, pre_filters happen to events before they are sent to their destination proc/thread, ordinary filters happen only in the destination hub/thread.

You cannot add a regular filter to a hub if the hub was created in another process or thread. You can always add a pre_filter.

- $hub->unfilter($sub)
- $hub->pre_unfilter($sub)

  These can be used to remove filters and pre_filters. The `$sub` argument is the reference returned by `filter()` or `pre_filter()`.

- $hub->follow_up(sub { ... })

  Use this to add behaviors that are called just before the hub is finalized. The only argument to your codeblock will be a *Test2::EventFacet::Trace* instance.

```
$hub->follow_up(sub {
    my ($trace, $hub) = @_;

    ... do whatever you need to ...

    # Return is ignored
});
```

  follow_up subs are called only once, ether when done_testing is called, or in an END block.

- $sub = $hub->add_context_acquire(sub { ... });

  Add a callback that will be called every time someone tries to acquire a context. It gets a single argument, a reference of the hash of parameters being used the construct the context. This is your chance to change the parameters by directly altering the hash.

```
test2_add_callback_context_acquire(sub {
    my $params = shift;
    $params->{level}++;
});
```

  This is a very scary API function. Please do not use this unless you need to. This is here for *Test::Builder* and backwards compatibility. This has you directly manipulate the hash instead of returning a new one for performance reasons.

  Note Using this hook could have a huge performance impact.

  The coderef you provide is returned and can be used to remove the hook later.

- $hub->remove_context_acquire($sub);

  This can be used to remove a context acquire hook.

- $sub = $hub->add_context_init(sub { ... });

This allows you to add callbacks that will trigger every time a new context is created for the hub. The only argument to the sub will be the *Test2::API::Context* instance that was created.

Note Using this hook could have a huge performance impact.

The coderef you provide is returned and can be used to remove the hook later.

- $hub->remove_context_init($sub);

  This can be used to remove a context init hook.

- $sub = $hub->add_context_release(sub { ... });

  This allows you to add callbacks that will trigger every time a context for this hub is released. The only argument to the sub will be the *Test2::API::Context* instance that was released. These will run in reverse order.

  Note Using this hook could have a huge performance impact.

  The coderef you provide is returned and can be used to remove the hook later.

- $hub->remove_context_release($sub);

  This can be used to remove a context release hook.

- $hub->cull()

  Cull any IPC events (and process them).

- $pid = $hub->pid()

  Get the process id under which the hub was created.

- $tid = $hub->tid()

  Get the thread id under which the hub was created.

- $hud = $hub->hid()

  Get the identifier string of the hub.

- $uuid = $hub->uuid()

  If UUID tagging is enabled (see *Test2::API*) then the hub will have a UUID.

- $ipc = $hub->ipc()

  Get the IPC object used by the hub.

- $hub->set_no_ending($bool)
- $bool = $hub->no_ending

  This can be used to disable auto-ending behavior for a hub. The auto-ending behavior is triggered by an end block and is used to cull IPC events, and output the final plan if the plan was 'NO PLAN'.

- $bool = $hub->active
- $hub->set_active($bool)

  These are used to get/set the 'active' attribute. When true this attribute will force `hub->finalize()` to take action even if there is no plan, and no tests have been

run. This flag is useful for plugins that add follow-up behaviors that need to run even if no events are seen.

STATE METHODS

- $hub->reset_state()

  Reset all state to the start. This sets the test count to 0, clears the plan, removes the failures, etc.

- $num = $hub->count

  Get the number of tests that have been run.

- $num = $hub->failed

  Get the number of failures (Not all failures come from a test fail, so this number can be larger than the count).

- $bool = $hub->ended

  True if the testing has ended. This MAY return the stack frame of the tool that ended the test, but that is not guaranteed.

- $bool = $hub->is_passing

- $hub->is_passing($bool)

  Check if the overall test run is a failure. Can also be used to set the pass/fail status.

- $hub->plan($plan)

- $plan = $hub->plan

  Get or set the plan. The plan must be an integer larger than 0, the string 'NO PLAN', or the string 'SKIP'.

- $bool = $hub->check_plan

  Check if the plan and counts match, but only if the tests have ended. If tests have not ended this will return undef, otherwise it will be a true/false.

THIRD PARTY META-DATA

This object consumes *Test2::Util::ExternalMeta* which provides a consistent way for you to attach meta-data to instances of this class. This is useful for tools, plugins, and other extensions.

Test2::Hub::Subtest

Hub used by subtests

DESCRIPTION

Subtests make use of this hub to route events.

TOGGLES

- $bool = $hub->manual_skip_all
- $hub->set_manual_skip_all($bool)

  The default is false.

  Normally a skip-all plan event will cause a subtest to stop executing. This is accomplished via `last LABEL` to a label inside the subtest code. Most of the time this is perfectly fine. There are times however where this flow control causes bad things to happen.

This toggle lets you turn off the abort logic for the hub. When this is toggled to true **you** are responsible for ensuring no additional events are generated.

Test2::IPC

Turn on IPC for threading or forking support.

SYNOPSIS

You should `use Test2::IPC;` as early as possible in your test file. If you import this module after API initialization it will attempt to retrofit IPC onto the existing hubs.

DISABLING IT

You can use `no Test2::IPC;` to disable IPC for good. You can also use the T2_NO_IPC env var.

EXPORTS

All exports are optional.

- cull()

  Cull allows you to collect results from other processes or threads on demand.

SOURCE

Modules

- `Test2::IPC::Driver` - Base class for Test2 IPC drivers.

Test2::IPC::Driver

Base class for Test2 IPC drivers.

SYNOPSIS

```
package Test2::IPC::Driver::MyDriver;

use base 'Test2::IPC::Driver';

...
```

METHODS

- $self->abort($msg)

  If an IPC encounters a fatal error it should use this. This will print the message to STDERR with `'IPC Fatal Error: '` prefixed to it, then it will forcefully exit 255. IPC errors may occur in threads or processes other than the main one, this method provides the best chance of the harness noticing the error.

- $self->abort_trace($msg)

  This is the same as `$ipc->abort($msg)` except that it uses `Carp::longmess` to add a stack trace to the message.

LOADING DRIVERS

Test2::IPC::Driver has an `import()` method. All drivers inherit this import method. This import method registers the driver.

In most cases you just need to load the desired IPC driver to make it work. You should load this driver as early as possible. A warning will be issued if you load it too late for it to be effective.

```
use Test2::IPC::Driver::MyDriver;
...
```

WRITING DRIVERS

```
package Test2::IPC::Driver::MyDriver;
use strict;
use warnings;

use base 'Test2::IPC::Driver';

sub is_viable {
    return 0 if $^O eq 'win32'; # Will not work on windows.
    return 1;
}

sub add_hub {
    my $self = shift;
    my ($hid) = @_;

    ... # Make it possible to contact the hub
}

sub drop_hub {
    my $self = shift;
    my ($hid) = @_;

    ... # Nothing should try to reach the hub anymore.
}

sub send {
    my $self = shift;
    my ($hid, $e, $global) = @_;

    ... # Send the event to the proper hub.

    # This may notify other procs/threads that there is a pending␣
↪event.
    Test2::API::test2_ipc_set_pending($uniq_val);
}
```

(continues on next page)

(continued from previous page)

```
sub cull {
    my $self = shift;
    my ($hid) = @_;

    my @events = ...; # Here is where you get the events for the hub

    return @events;
}

sub waiting {
    my $self = shift;

    ... # Notify all listening procs and threads that the main
    ... # process/thread is waiting for them to finish.
}

1;
```

METHODS SUBCLASSES MUST IMPLEMENT

- $ipc->is_viable

  This should return true if the driver works in the current environment. This should return false if it does not. This is a CLASS method.

- $ipc->add_hub($hid)

  This is used to alert the driver that a new hub is expecting events. The driver should keep track of the process and thread ids, the hub should only be dropped by the proc+thread that started it.

  ```
  sub add_hub {
      my $self = shift;
      my ($hid) = @_;

      ... # Make it possible to contact the hub
  }
  ```

- $ipc->drop_hub($hid)

  This is used to alert the driver that a hub is no longer accepting events. The driver should keep track of the process and thread ids, the hub should only be dropped by the proc+thread that started it (This is the drivers responsibility to enforce).

  ```
  sub drop_hub {
      my $self = shift;
      my ($hid) = @_;

      ... # Nothing should try to reach the hub anymore.
  }
  ```

- $ipc->send($hid, $event);

- $ipc->send($hid, $event, $global);

  Used to send events from the current process/thread to the specified hub in its process+thread.

```
sub send {
    my $self = shift;
    my ($hid, $e) = @_;

    ... # Send the event to the proper hub.

    # This may notify other procs/threads that there is a
↪pending event.
    Test2::API::test2_ipc_set_pending($uniq_val);
}
```

  If `$global` is true then the driver should send the event to all hubs in all processes and threads.

- @events = $ipc->cull($hid)

  Used to collect events that have been sent to the specified hub.

```
sub cull {
    my $self = shift;
    my ($hid) = @_;

    my @events = ...; # Here is where you get the events for
↪the hub

    return @events;
}
```

- $ipc->waiting()

  This is called in the parent process when it is complete and waiting for all child processes and threads to complete.

```
sub waiting {
    my $self = shift;

    ... # Notify all listening procs and threads that the main
    ... # process/thread is waiting for them to finish.
}
```

METHODS SUBCLASSES MAY IMPLEMENT OR OVERRIDE

- $ipc->driver_abort($msg)

  This is a hook called by `Test2::IPC::Driver->abort()`. This is your chance to cleanup when an abort happens. You cannot prevent the abort, but you can gracefully except it.

Modules

- `Test2::IPC::Driver::Files` - Temp dir + Files concurrency model.

Test2::IPC::Driver::Files

Temp dir + Files concurrency model.

DESCRIPTION

This is the default, and fallback concurrency model for *Test2*. This sends events between processes and threads using serialized files in a temporary directory. This is not particularly fast, but it works everywhere.

SYNOPSIS

```
use Test2::IPC::Driver::Files;

# IPC is now enabled
```

ENVIRONMENT VARIABLES

- T2_KEEP_TEMPDIR=0

  When true, the tempdir used by the IPC driver will not be deleted when the test is done.

- T2_TEMPDIR_TEMPLATE='test2-XXXXXX'

  This can be used to set the template for the IPC temp dir. The template should follow template specifications from *File::Temp*.

SEE ALSO

Test2::Manual

Documentation hub for Test2 and Test2-Suite.

DESCRIPTION

This is the hub for *Test2* and *Test2::Suite* documentation.

WRITING TESTS

The *Test2::Manual::Testing* POD is the hub for documentation related to writing tests.

WRITING TOOLS

The *Test2::Manual::Tooling* POD is the hub for documentation related to writing new tools.

GUTS AND INNER WORKINGS

The *Test2::Manual::Anatomy* POD is the hub for documentation of the inner workings of Test2 components.

A NOTE ON CONCURRENCY (SUPPORT FOR FORKING AND THREADING)

The *Test2::Manual::Concurrency* POD documents the concurrency support policy for *Test2*.

CONTRIBUTING

The *Test2::Manual::Contributing* POD is for people who want to contribute to *Test2* or *Test2::Suite* directly.

SEE ALSO

Test2 - Test2 itself.

Test2::Suite - Initial tools built using *Test2*.

SOURCE

Test2::Manual::Anatomy

The hub for documentation of the inner workings of Test2 components.

DESCRIPTION

This section covers internals of the Test2 architecture. This is useful information for toolbuilder, but is essential information for maintainers of Test2 itself.

END TO END

The *Test2::Manual::Anatomy::EndToEnd* document is an overview of Test2 from load to finish.

EVENTS

The *Test2::Manual::Anatomy::Event* document explains the internals of events.

THE CONTEXT

The *Test2::Manual::Anatomy::Context* document explains how the *Test2::API::Context* object works.

THE API AND THE API INSTANCE

The *Test2::Manual::Anatomy::API* document explains the inner workings of the Test2 API.

HUBS

The *Test2::Manual::Anatomy::Hubs* document explains the inner working of the Test2 hub stack, and the hubs therein.

THE IPC SYSTEM

The *Test2::Manual::Anatomy::IPC* document describes the IPC system.

INTERNAL UTILITIES

The *Test2::Manual::Anatomy::Utilities* document describes various utilities provided by the Test2 system.

Test2::Manual::Anatomy::API

Internals documentation for the API.

DESCRIPTION

This document covers some of the internals of *Test2::API*.

IMPLEMENTATION DETAILS

Test2::API

Test2::API provides a functional interface to any test2 global state. This API should be preserved regardless of internal details of how and where the global state is stored.

This module itself does not store any state (with a few minor exceptions) but instead relies on *Test2::API::Instance* to store state. This module is really intended to be the layer between the consumer and the implementation details. Ideally the implementation details can change any way they like, and this module can be updated to use the new details without breaking anything.

Test2::API::Instance

Test2::API::Instance is where the global state is actually managed. This is an implementation detail, and should not be relied upon. It is entirely possible that *Test2::API::Instance* could be removed completely, or changed in incompatible ways. Really these details are free to change so long as *Test2::API* is not broken.

Test2::API::Instance is fairly well documented, so no additionally documentation is needed for this manual page.

Test2::Manual::Anatomy::Context

Internals documentation for the Context objects.

DESCRIPTION

This document explains how the *Test2::API::Context* object works.

WHAT IS THE CONTEXT OBJECT?

The context object is one of the key components of Test2, and makes many features possible that would otherwise be impossible. Every test tool starts by getting a context, and ends by releasing the context. A test tool does all its work between getting and releasing the context. The context instance is the primary interface for sending events to the Test2 stack. Finally the context system is responsible for tracking what file and line number a tool operates on, which is critical for debugging.

PRIMARY INTERFACE FOR TEST TOOLS

Nearly every Test2 based tool should start by calling `$ctx = Test2::API::context()` in order to get a context object, and should end by calling `$ctx->release()`. Once a tool has its context object it can call methods on the object to send events or have other effects. Nearly everything a test tool needs to do should be done through the context object.

TRACK FILE AND LINE NUMBERS FOR ERROR REPORTING

When you call `Test2::API::Context` a new context object will be returned. If there is already a context object in effect (from a different point in the stack) you will get a clone of the existing one. If there is not already a current context then a completely new one will be generated. When a new context is generated Test2 will determine the file name and line number for your test code, these will be used when reporting any failures.

Typically the file and line number will be determined using `caller()` to look at your tools caller. The `$Test::Builder::Level` will be respected if detected, but is discouraged in favor of just using context objects at every level.

When calling `Test2::API::Context()` you can specify the `level => $count` arguments if you need to look at a deeper caller.

PRESERVE $?, $!, $^E AND $@

When you call `Test2::API::context()` the current values of `$?`, `$!`, `$^E`, and `$@` are stored in the context object itself. Whenever the context is released the original values of these variables will be restored. This protects the variables from any side effects caused by testing tools.

FINALIZE THE API STATE

Test2::API works via a hidden singleton instance of *Test2::API::Instance*. The singleton has some state that is not set in stone until the last possible minute. The last possible minute happens to be the first time a context is acquired. State includes IPC instance, Formatter class, Root PID, etc.

FIND/CREATE THE CURRENT/ROOT HUB

Test2 has a stack of hubs, the stack can be accessed via *Test2::API::test2_stack*. When you get a context it will find the current hub, if there is no current hub then the root one will be initialized.

PROVIDE HOOKS

There are hooks that run when contexts are created, found, and released. See *Test2::API* for details on these hooks and how to use them.

SEE ALSO

Test2::Manual - Primary index of the manual.

SOURCE

The source code repository for Test2-Manual can be found at `https://github.com/Test-More/test-more/`.

Test2::Manual::Anatomy::EndToEnd

Overview of Test2 from load to finish.

DESCRIPTION

This is a high level overview of everything from loading Test2 through the end of a test script.

WHAT HAPPENS WHEN I LOAD THE API?

```
use Test2::API qw/context/;
```

- A singleton instance of Test2::API::Instance is created.

  You have no access to this, it is an implementation detail.

- Several API functions are defined that use the singleton instance.

  You can import these functions, or use them directly.

- Then what?

  It waits...

  The API intentionally does as little as possible. At this point something can still change the formatter, load *Test2::IPC*, or have other global effects that need to be done before the first *Test2::API::Context* is created. Once the first *Test2::API::Context* is created the API will finish initialization.

  See "WHAT HAPPENS WHEN I ACQUIRE A CONTEXT?" for more information.

WHAT HAPPENS WHEN I USE A TOOL?

This section covers the basic workflow all tools such as `ok()` must follow.

```
sub ok($$) {
    my ($bool, $name) = @_;

    my $ctx = context();

    my $event = $ctx->send_event('Ok', pass => $bool, name =>
↪$name);

    ...

    $ctx->release;
    return $bool;
}

ok(1, "1 is true");
```

- A tool function is run.

  ```
  ok(1, "1 is true");
  ```

- The tool acquires a context object.

```
my $ctx = context();
```

See “WHAT HAPPENS WHEN I ACQUIRE A CONTEXT?” for more information.

- The tool uses the context object to create, send, and return events.

  See “WHAT HAPPENS WHEN I SEND AN EVENT?” for more information.

```
my $event = $ctx->send_event('Ok', pass => $bool, name =>
↪$name);
```

- When done the tool MUST release the context.

  See “WHAT HAPPENS WHEN I RELEASE A CONTEXT?” for more information.

```
$ctx->release();
```

- The tool returns.

```
return $bool;
```

WHAT HAPPENS WHEN I ACQUIRE A CONTEXT?

```
my $ctx = context();
```

These actions may not happen exactly in this order, but that is an implementation detail. For the purposes of this document this order is used to help the reader understand the flow.

- $!, $@, $? and $^E are captured and preserved.

  Test2 makes a point to preserve the values of $!, $@, $? and $^E such that the test tools do not modify these variables unexpectedly. They are captured first thing so that they can be restored later.

- The API state is changed to ‘loaded’.

  The ‘loaded’ state means that test tools have already started running. This is important as some plugins need to take effect before any tests are run. This state change only happens the first time a context is acquired, and may trigger some hooks defined by plugins to run.

- The current hub is found.

  A context attaches itself to the current *Test2::Hub*. If there is no current hub then the root hub will be initialized. This will also initialize the hub stack if necessary.

- Context acquire hooks fire.

  It is possible to create global, or hub-specific hooks that fire whenever a context is acquired, these hooks will fire now. These hooks fire even if there is an existing context.

- Any existing context is found.

If the current hub already has a context then a clone of it will be used instead of a completely new context. This is important because it allows nested tools to inherit the context used by parent tools.

- Stack depth is measured.

  Test2 makes a point to catch mistakes in how the context is used. The stack depth is used to accomplish this. If there is an existing context the depth will be checked against the one found here. If the old context has the same stack depth, or a shallower one, it means a tool is misbehaving and did not clean up the context when it was done, in which case the old context will be cleaned up, and a warning issued.

- A new context is created (if no existing context was found)

  If there is no existing context, a new one will be created using the data collected so far.

- Context init hooks fire (if no existing context was found)

  If a new context was created, context-creation hooks will fire.

- $!, $@, $?, and $^E are restored.

  We make sure $!, $@, $?, and $^E are unchanged at this point so that changes we made will not affect anything else. This is done in case something inside the context construction accidentally changed these vars.

- The context is returned.

  You have a shiny new context object, or a clone of the existing context.

WHAT HAPPENS WHEN I SEND AN EVENT?

```
my $event = $ctx->send_event('Ok', pass => $bool, name => $name);
```

- The Test2::Event::Ok module is loaded.

  The `send_event()` method will automatically load any Event package necessary. Normally `send_event()` will assume the first argument is an event class without the `Test2::Event::` prefix, which it will add for you. If you want to use an event class that is in a different namespace you can prefix the class name with a `+` to tell the tool that you are giving a fully qualified class name:

  ```
  my $event = $ctx->send_event('+Fully::Qualified::Event', pass =>
  ↪ $bool, name => $name);
  ```

- A new instance of Test2::Event::Ok is created.

  The event object is instantiated using the provided parameters.

- The event object is sent to the hub.

  The hub takes over from here.

- The hub runs the event through any filters.

  Filters are able to modify or remove events. Filters are run first, before the event can modify global test state.

- The global test state is updated to reflect the event.

  If the event affects test count then the count will be incremented. If the event causes failure then the failure count will be incremented. There are a few other ways the global state can be affected as well.

- The event is sent to the formatter

  After the state is changed the hub will send the event to the formatter for rendering. This is where TAP is normally produced.

- The event is sent to all listeners.

  There can be any number of listeners that take action when events are processed, this happens now.

WHAT HAPPENS WHEN I RELEASE A CONTEXT?

```
$ctx->release;
```

- The current context clone is released.

  If your tool is nested inside another, then releasing will simply destroy the copy of the context, nothing else will happen.

- If this was the canonical context, it will actually release

  When a context is created it is considered 'canon'. Any context obtained by a nested tool will be considered a child context linked to the canonical one. Releasing child contexts does not do anything of note (but is still required).

- Release hooks are called

  Release hooks are the main motivation behind making the `release()` method, and making it a required action on the part of test tools. These are hooks that we can have called when a tool is complete. This is how plugins like *Test2::Plugin::DieOnFail* are implemented. If we simply had a destructor call the hooks then we would be unable to write this plugin as a `die` inside of a destructor is useless.

- The context is cleared

  The main context data is cleared allowing the next tool to create a new context. This is important as the next tool very likely has a new line number.

- $!, $@, $?, and $^E are restored

  When a Test2 tool is complete it will restore $@, $!, $? and $^E to avoid action at a distance.

WHAT HAPPENS WHEN I USE done_testing()?

```
done_testing();
```

- Any pending IPC events will be culled.

  If IPC is turned on, a final culling will take place.

- Follow-up hooks are run

  The follow-up hooks are a way to run actions when a hub is complete. This is useful for adding cleanup tasks, or final tests to the end of a test.

- The final plan event is generated and processed.

  The final plan event will be produced using the current test count as the number of tests planned.

- The current hub is finalized.

  This will mark the hub is complete, and will not allow new events to be processed.

WHAT HAPPENS WHEN A TEST SCRIPT IS DONE?

Test2 has some behaviors it runs in an `END { ... }` block after tests are done running. This end block does some final checks to warn you if something went wrong. This end block also sets the exit value of the script.

- API Versions are checked.

  A warning will be produced if *Test::Builder* is loaded, but has a different version compared to *Test2::API*. This situation can happen if you downgrade to an older Test-Simple distribution, and is a bad situation.

- Any remaining context objects are cleaned up.

  If there are leftover context objects they will need to be cleaned up. A leftover context is never a good thing, and usually requires a warning. A leftover context could also be the result of an exception being thrown which terminates the script, *Test2* is fairly good at noticing this and not warning in these cases as the warning would simply be noise.

- Child processes are sent a 'waiting' event.

  If IPC is active, a waiting event is sent to all child processes.

- The script will wait for all child processes and/or threads to complete.

  This happens only when IPC is loaded, but Test::Builder is not. This behavior is useful, but would break compatibility for legacy tests.

- The hub stack is cleaned up.

  All hubs are finalized starting from the top. Leftover hubs are usually a bad thing, so a warning is produced if any are found.

- The root hub is finalized.

  This step is a no-op if `done_testing()` was used. If needed this will mark the root hub as finished.

- Exit callbacks are called.

  This is a chance for plugins to modify the final exit value of the script.

- The scripts exit value ($?) is set.

  If the test encountered any failures this will be set to a non-zero value. If possible this will be set to the number of failures, or 255 if the number is larger than 255 (the max value allowed).

- Broken module diagnostics

  Test2 is aware of many modules which were broken by Test2's release. At this point the script will check if any known-broken modules were loaded, and warn you if they were.

  Note: This only happens if there were test failures. No broken module warnings are produced on a success.

Test2::Manual::Anatomy::Event

The internals of events

DESCRIPTION

Events are how tools affect global state, and pass information along to the harness, or the human running the tests.

HISTORY

Before proceeding it is important that you know some history of events. Initially there was an event API, and an event would implement the API to produce an effect. This API proved to be lossy and inflexible. Recently the 'facet' system was introduced, and makes up for the shortcoming and inflexibility of the old API.

All events must still implement the old API, but that can be largely automated if you use the facet system effectively. Likewise essential facets can often be deduced from events that only implement the old API, though their information maybe less complete.

THE EVENT OBJECT

All event objects must subclass *Test2::Event*. If you inherit from this base class, and implement the old API properly, facets will be generated for you for free. On the other hand you can inherit from this, and also import *Test2::Util::Facets2Legacy* which will instead rely on your facet data, and deduce the old API from them.

All new events MUST implement both APIs one way or the other. A common way to do this is to simply implement both APIs directly in your event.

Here is a good template for a new event:

```
package Test2::Event::Mine;
use strict;
use warnings;

use parent 'Test2::Event';
use Test2::Util::Facets2Legacy ':ALL';

sub facet_data {
    my $self = shift;

    # Adds 'about', 'amnesty', and 'trace' facets
    my $out = $self->common_facet_data;

    # Add any additional facets to the $out hashref
    ...

    return $out;
}

1;
```

THE FACET API

The new API is a single method: `facet_data()`. This method must return a hashref where each key is specific to a facet type, and the value is either a facet hashref, or an array of hashrefs. Some facets MUST be lone hashrefs, others MUST be hashrefs inside an arrayref.

The *standard* facet types are as follows:

- assert => {details => $name, pass => $bool, no_debug => $bool, number => $maybe_int}

  Documented in *Test2::EventFacet::Assert*. An event may only have one.

  The 'details' key is the name of the assertion.

  The 'pass' key denotes a passing or failing assertion.

The 'no_debug' key tells any harness or formatter that diagnostics should not be added automatically to a failing assertion (used when there are custom diagnostics instead).

The 'number' key is for harness use, never set it yourself.

- about => {details => $string, no_display => $bool, package => $pkg}

  Documented in *Test2::EventFacet::About*. An event may only have one.

  'details' is a human readable string describing the overall event.

  'no_display' means that a formatter/harness should hide the event.

  'package' is the package of the event the facet describes (IE: *Test2::Event::Ok*)

- amnesty => [{details => $string, tag => $short_string, inherited => $bool}]

  Documented in *Test2::EventFacet::Amnesty*. An event may have multiple.

  This event is how things like 'todo' are implemented. Amnesty prevents a failing assertion from causing a global test failure.

  'details' is a human readable description of why the failure is being granted amnesty (IE The 'todo' reason)

  'tag' is a short human readable string, or category for the amnesty. This is typically 'TODO' or 'SKIP'.

  'inherited' is true if the amnesty was applied in a parent context (true if this test is run in a subtest that is marked todo).

- control => {details => $string, global => $bool, terminate => $maybe_int, halt => $bool, has_callback => $bool, encoding => $enc}

  Documented in *Test2::EventFacet::Control*. An event may have one.

  This facet is used to apply extra behavior when the event is processed.

  'details' is a human readable explanation for the behavior.

  'global' true if this event should be forwarded to, and processed by, all hubs everywhere. (bail-out uses this)

  'terminate' this should either be undef, or an integer. When defined this will cause the test to exit with the specific exit code.

  'halt' is used to signal any harness that no further test files should be run (bail-out uses this).

  'has_callback' is set to true if the event has a callback sub defined.

  'encoding' used to tell the formatter what encoding to use.

- errors => [{details => $string, tag => $short_string, fail => $bool}]

  Documented in *Test2::EventFacet::Error*. An event may have multiple.

  'details' is a human readable explanation of the error.

  'tag' is a short human readable category for the error.

  'fail' is true if the error should cause test failure. If this is false the error is simply informative, but not fatal.

- info => [{details => $string, tag => $short_string, debug => $bool, important => $bool}]

  Documented in *Test2::EventFacet::Info*. An event may have multiple.

  This is how diag and note are implemented.

  'details' human readable message.

  'tag' short category for the message, such as 'diag' or 'note'.

  'debug' is true if the message is diagnostics in nature, this is the main difference between a note and a diag.

  'important' is true if the message is not diagnostics, but is important to have it shown anyway. This is primarily used to communicate with a harness.

- parent => {details => $string, hid => $hid, children => [...], buffered => 1}

  Documented in *Test2::EventFacet::Parent*. An event may have one.

  This is used by subtests.

  'details' human readable name of the subtest.

  'hid' subtest hub id.

  'children' an arrayref containing facet_data instances from all child events.

  'buffered' true if it was a buffered subtest.

- plan => {details => $string, count => $int, skip => $bool, none => $bool}

  Documented in *Test2::EventFacet::Plan*. An event may have one.

  'details' is a human readable string describing the plan (for instance, why a test is skipped)

  'count' is the number of expected assertions (0 for skip)

  'skip' is true if the plan is to skip the test.

  'none' used for Test::More's 'no_plan' plan.

- trace => {details => $string, frame => [$pkg, $file, $line, $sub], pid => $int, tid => $int, cid => $cid, hid => $hid, nested => $int, buffered => $bool}

  Documented in *Test2::EventFacet::Trace*. An event may have one.

  This is how debugging information is tracked. This is taken from the context object at event creation.

  'details' human readable debug message (otherwise generated from frame)

  'frame' first 4 fields returned by caller: `[$package, $file, $line, $subname]`.

  'pid' the process id in which the event was created.

  'tid' the thread is in which the event was created.

  'cid' the id of the context used to create the event.

  'hid' the id of the hub to which the event was sent.

  'nest' subtest nesting depth of the event.

'buffered' is true if the event was generated inside a buffered subtest.

Note that ALL facet types have a 'details' key that may have a string. This string should always be human readable, and should be an explanation for the facet. For an assertion this is the test name. For a plan this is the reason for the plan (such as skip reason). For info it is the human readable diagnostics message.

CUSTOM FACETS

You can write custom facet types as well, simply add a new key to the hash and populated it. The general rule is that any code looking at the facets should ignore any it does not understand.

Optionally you can also create a package to document your custom facet. The package should be proper object, and may have additional methods to help work with your facet.

```
package Test2::EventFacet::MyFacet;

use parent 'Test2::EventFacet';

sub facet_key { 'myfacet' }
sub is_list { 0 }

1;
```

Your facet package should always be under the Test2::EventFacet:: namespace if you want any tools to automatically find it. The last part of the namespace should be the non-plural name of your facet with only the first word capitalized.

- $string = $facet_class->facet_key

  The key for your facet should be the same as the last section of the namespace, but all lowercase. You *may* append 's' to the key if your facet is a list type.

- $bool = $facet_class->is_list

  True if an event should put these facets in a list:

  ```
  { myfacet => [{}, {}] }
  ```

  False if an event may only have one of this type of facet at a time:

  ```
  { myfacet => {} }
  ```

EXAMPLES

The assert facet is not a list type, so its implementation would look like this:

```
package Test2::EventFacet::Assert;
sub facet_key { 'assert' }
sub is_list { 0 }
```

The amnesty facet is a list type, but amnesty does not need 's' appended to make it plural:

```
package Test2::EventFacet::Amnesty;
sub facet_key { 'amnesty' }
sub is_list { 1 }
```

The error facet is a list type, and appending 's' makes error plural as errors. This means the package name is '::Error', but the key is 'errors'.

```
package Test2::EventFacet::Error;
sub facet_key { 'errors' }
sub is_list { 1 }
```

Note2: In practice most tools completely ignore the facet packages, and work with the facet data directly in its raw structure. This is by design and recommended. The facet data is intended to be serialized frequently and passed around. When facets are concerned, data is important, classes and methods are not.

THE OLD API

The old API was simply a set of methods you were required to implement:

- $bool = $e->causes_fail

  Returns true if this event should result in a test failure. In general this should be false.

- $bool = $e->increments_count

  Should be true if this event should result in a test count increment.

- $e->callback($hub)

  If your event needs to have extra effects on the *Test2::Hub* you can override this method.

  This is called **BEFORE** your event is passed to the formatter.

- $num = $e->nested

  If this event is nested inside of other events, this should be the depth of nesting. (This is mainly for subtests)

- $bool = $e->global

  Set this to true if your event is global, that is ALL threads and processes should see it no matter when or where it is generated. This is not a common thing to want, it is used by bail-out and skip_all to end testing.

- $code = $e->terminate

  This is called **AFTER** your event has been passed to the formatter. This should normally return undef, only change this if your event should cause the test to exit immediately.

  If you want this event to cause the test to exit you should return the exit code here. Exit code of 0 means exit success, any other integer means exit with failure.

  This is used by *Test2::Event::Plan* to exit 0 when the plan is 'skip_all'. This is also used by *Test2::Event::Bail* to force the test to exit with a failure.

This is called after the event has been sent to the formatter in order to ensure the event is seen and understood.

- $msg = $e->summary

  This is intended to be a human readable summary of the event. This should ideally only be one line long, but you can use multiple lines if necessary. This is intended for human consumption. You do not need to make it easy for machines to understand.

  The default is to simply return the event package name.

- ($count, $directive, $reason) = $e->sets_plan()

  Check if this event sets the testing plan. It will return an empty list if it does not. If it does set the plan it will return a list of 1 to 3 items in order: Expected Test Count, Test Directive, Reason for directive.

- $bool = $e->diagnostics

  True if the event contains diagnostics info. This is useful because a non-verbose harness may choose to hide events that are not in this category. Some formatters may choose to send these to STDERR instead of STDOUT to ensure they are seen.

- $bool = $e->no_display

  False by default. This will return true on events that should not be displayed by formatters.

Test2::Manual::Anatomy::Hubs

Internals documentation for the hub stack, and hubs.

DESCRIPTION

This document describes the hub stack, and the hubs it contains. It explains why we have a stack, and when to add/remove hubs from it.

WHAT IS A HUB?

Test2 is an event system, tools generate events, those events are then processed to modify the testing state (number of tests, number of failures, etc). The hub is responsible for receiving and processing events to record the change in state. All events should eventually reach a destination hub.

The base hub is *Test2::Hub*. All hub classes should inherit from the base hub class. The base hub class provides several hooks that allow you to monitor or modify events. Hubs are also responsible for forwarding events to the output formatter.

WHY DO WE HAVE A HUB STACK?

There are cases where it makes sense to have more than one hub:

- subtests

  In Test2 subtests are implemented using the hub stack. When you start a subtest a new *Test2::Hub::Subtest* instance is created and pushed to the stack. Once this is done all calls to `Test2::API::context` will find the new hub and send all events to it. When the subtest tool is complete it will remove the new hub, and send a final subtest event to the parent hub.

- testing your test tools

  `Test2::API::intercept()` is implemented using the hub stack. The `Test2::API::intercept()` function will add an *Test2::Hub::Interceptor* instance to the stack, any calls to Test2::API::context() will find the new hub, and send it all events. The intercept hub is special in that is has no connection to the parent hub, and usually does not have a formatter.

WHEN SHOULD I ADD A HUB TO THE STACK?

Any time you want to intercept or block events from affecting the test state. Adding a new hub is essentially a way to create a sandbox where you have absolute control over what events do. Adding a new hub insures that the main test state will not be affected.

WHERE IS THE STACK?

The stack is an instance of *Test2::API::Stack*. You can access the global hub stack using `Test2::API::test2_stack`.

WHAT ABOUT THE ROOT HUB?

The root hub is created automatically as needed. A call to `Test2::API::test2_stack->top()` will create the root hub if it does not already exist.

HOW DO HUBS HANDLE IPC?

If the IPC system (*Test2::IPC*) was not loaded, then IPC is not handled at all. Forking or creating new threads without the IPC system can cause unexpected problems.

All hubs track the PID and Thread ID that was current when they were created. If an event is sent to a hub in a new process/thread the hub will detect this and try to forward the event along to the correct process/thread. This is accomplished using the IPC system.

Test2::Manual::Anatomy::IPC

Manual for the IPC system.

DESCRIPTION

This document describes the IPC system.

WHAT IS THE IPC SYSTEM

The IPC system is activated by loading *Test2::IPC*. This makes hubs process/thread aware, and makes them forward events along to the parent process/thread as necessary.

HOW DOES THE IPC SYSTEM AFFECT EVERYTHING?

Test2::API and *Test2::API::Instance* have some behaviors that trigger if *Test2::IPC* is loaded before the global state is initialized. Mainly an IPC driver will be initiated and stored in the global state.

If an IPC driver is initialized then all hubs will be initialized with a reference to the driver instance. If a hub has an IPC driver instance it will use it to forward events to parent processes and threads.

WHAT DOES AN IPC DRIVER DO?

An *Test2::IPC::Driver* provides a way to send event data to a destination process+thread+hub (or to all globally). The driver must also provide a way for a process/thread/hub to read in any pending events that have been sent to it.

HOW DOES THE DEFAULT IPC DRIVER WORK?

The default IPC driver is *Test2::IPC::Driver::Files*. This default driver, when initialized, starts by creating a temporary directory. Any time an event needs to be sent to another process/thread/hub, the event will be written to a file using *Storable*. The file is written with the destination process, thread, and hub as part of the filename. All hubs will regularly check for pending IPC events and will process them.

This driver is further optimized using a small chunk of SHM. Any time a new event is sent via IPC the shm is updated to have a new value. Hubs will not bother checking for new IPC events unless the shm value has changed since their last poll. A result of this is that the IPC system is surprisingly fast, and does not waste time polling the hard drive when there are no pending events.

Test2::Manual::Anatomy::Utilities

Overview of utilities for Test2.

DESCRIPTION

This is a brief overview of the utilities provided by Test2.

Test2::Util

Test2::Util provides functions to help you find out about the current system, or to run generic tasks that tend to be Test2 specific.

This utility provides things like an internal `try {...}` implementation, and constants for things like threading and forking support.

Test2::Util::ExternalMeta

Test2::Util::ExternalMeta allows you to quickly and easily attach meta-data to an object class.

Test2::Util::Facets2Legacy

Test2::Util::Facets2Legacy is a set of functions you can import into a more recent event class to provide the classic event API.

Test2::Util::HashBase

Test2::Util::HashBase is a local copy of Object::HashBase. All object classes provided by *Test2* use this to generate methods and accessors.

Test2::Manual::Concurrency

Documentation for Concurrency support.

FORKING

Test2

Test2 supports forking. For forking to work you need to load *Test2::IPC*.

Test::Builder

Test::Builder Did not used to support forking, but now that it is based on *Test2* it does. *Test2::IPC* must be loaded just as with *Test2*.

Test2::Suite

Test2::Suite tools should all work fine with *true* forking unless otherwise noted. Pseudo-fork via threads (Windows and a few others) is not supported, but may work.

Patches will be accepted to repair any pseudo-fork issues, but for these to be used or tested they must be requested. Fork tests should not run on pseudo-fork systems unless they are requested with an environment var, or the AUTHOR_TESTING var. Pseudo-fork is fragile, and we do not want to block install due to a pseudo-fork flaw.

Test::SharedFork

Test::SharedFork is currently support and maintained, though it is no longer necessary thanks to *Test2::IPC*. If usage ever drops off then the module may be deprecated, but for now the policy is to not let it break. Currently it simply loads *Test2::IPC* if it can, and falls back to the old methods on legacy installs.

Others

Individual authors are free to support or not support forking as they see fit.

THREADING

Note This only applies to ithreads.

Test2

The core of Test2 supports threading so long as *Test2::IPC* is loaded. Basic threading support (making sure events make it to the parent thread) is fully supported, and must not be broken.

Some times perl installs have broken threads (Some 5.10 versions compiled on newer gcc's will segv by simply starting a thread). This is beyond Test2's control, and not solvable in Test2. That said we strive for basic threading support on perl 5.8.1+.

If Test2 fails for threads on any perl 5.8 or above, and it is reasonably possible for Test2 to work around the issue, it should. (Patches and bug reports welcome).

Test::Builder

Test::Builder has had thread support for a long time. With Test2 the mechanism for thread support was switched to *Test2::IPC*. *Test::Builder* should still support threads as much as it did before the switch to Test2. Support includes auto-enabling thread support if *threads* is loaded before Test::Builder.

If there is a deviation between the new and old threading behavior then it is a bug (unless the old behavior itself can be classified as a bug.) Please report (or patch!) any such threading issues.

Test2::Suite

Tools in *Test2::Suite* have minimal threading support. Most of these tools do not care/notice threading and simply work because *Test2::IPC* handles it. Feel free to report any thread related bugs in Test2::Suite. Be aware though that these tools are not legacy, and have no pre-existing thread support, we reserve the right to refuse adding thread support to them.

Test2::Workflow

Test2::Workflow has been merged into *Test2::Suite*, so it gets addressed by this policy.

Test2::Workflow has thread support, but you must ask for it. Thread tests for Test2::Workflow do not event run without setting either the AUTHOR_TESTING env var, or the T2_DO_THREAD_TESTS env var.

To use threads with Test2::Workflow you must set the T2_WORKFLOW_USE_THREADS env var.

If you do rely on threads with Test2::Workflow and find a bug please report it, but it will be given an ultra-low priority. Merging patches that fix threading issues will be given normal priority.

Test2::Manual::Contributing

How to contribute to the Test2 project.

DESCRIPTION

This is a short manual page dedicated to helping people who wish to contribute to the Test2 project.

WAYS TO HELP

REPORT BUGS

The easiest way to help is to report bugs when you find them. Bugs are a fact of life when writing or using software. If you use Test2 long enough you are likely to find a bug. When you find such a bug it would help us out if you would submit a ticket.

BUG TRACKERS

Always try to find the preferred bug tracker for the module that has the bug. Here are the big 3 for the main Test2 project:

- Test2/Test-Builder/Test-More/test-more

  https://github.com/Test-More/test-more/issues

- Test2-Harness

  https://github.com/Test-More/Test2-Harness/issues

SUBMIT PATCHES

You are welcome to fix bugs you find, or from the tracker. We also often accept patches that add new features or update documentation. The preferred method of submitting patches is a github pull request, that said we also accept patches via email.

ADD/UPDATE DOCUMENTATION

Documentation can be flawed just like code can be. Documentation can also become outdated. If you see some incorrect documentation, or documentation that is missing, we would love to get a patch to fix it!

ANSWER QUESTIONS ON IRC/SLACK

We are always hanging out on irc://irc.perl.org, the #perl-qa and #toolchain channels are a good place to find us.

There is also a Test2 slack channel: https://perl-test2.slack.com.

WRITE NEW TOOLS USING TEST2

Writing a new tool using Test2 is always a good way to contribute. When you write a tool that you think is useful, it is nice to share it by putting it on CPAN.

PORT OLD TOOLS TO TEST2

The `Test::*` namespace has been around for a long time, and has a LOT of tools. The `Test2::Tools::*` namespace is fairly young, and has less tools. Finding a useful old tool with no modern equivalent, and writing a port is a very good use of your time.

Test2::Manual::Testing

Hub for documentation about writing tests with Test2.

DESCRIPTION

This document outlines all the tutorials and POD that cover writing tests. This section does not cover any Test2 internals, nor does it cover how to write new tools, for that see *Test2::Manual::Tooling*.

NAMESPACE MAP

When writing tests there are a couple namespaces to focus on:

- Test2::Tools::*

  This is where toolsets can be found. A toolset exports functions that help you make assertions about your code. Toolsets will only export functions, they should not ever have extra/global effects.

- Test2::Plugins::*

  This is where plugins live. Plugins should not export anything, but instead will introduce or alter behaviors for Test2 in general. These behaviors may be lexically scoped, or they may be global.

- Test2::Bundle::*

  Bundles combine toolsets and plugins together to reduce your boilerplate. First time test writers are encouraged to start with the *Test2::V1* bundle (which is an exception to the namespace rule as it does not live under `Test2::Bundle::`). If you find yourself loading several plugins and toolsets over and over again you could benefit from writing your own bundle.

- Test2::Require::*

  This namespace contains modules that will cause a test to skip if specific conditions are not met. Use this if you have tests that only run on specific perl versions, or require external libraries that may not always be available.

LISTING DEPENDENCIES

When you use *Test2*, specifically things included in *Test2::Suite* you need to list them in your modules test dependencies. It is important to note that you should list the tools/plugins/bundles you need, you should not simply list *Test2::Suite* as your dependency. *Test2::Suite* is a living distribution intended to represent the "current" best practices. As tools, plugins, and bundles evolve, old ones will become discouraged and potentially be moved from *Test2::Suite* into their own distributions.

One goal of *Test2::Suite* is to avoid breaking backwards compatibility. Another goal is to always improve by replacing bad designs with better ones. When necessary *Test2::Suite* will break old modules out into separate dists and define new ones, typically with a new bundle. In short, if we feel the need to break something we will do so by creating a new bundle, and discouraging the old one, but we will not break the old one.

So for example, if you use *Test2::V1*, and Dist::Zilla you should have this in your config:

```
[Prereqs / TestRequires]
Test2::V1 = 0.000060
```

You **SHOULD NOT** do this:

```
[Prereqs / TestRequires]
Test2::Suite = 0.000060
```

Because *Test2::V1* might not always be part of *Test2::Suite*.

When writing new tests you should often check *Test2::Suite* to see what the current recommended bundle is.

Dist::Zilla

```
[Prereqs / TestRequires]
Test2::V1 = 0.000060
```

ExtUtils::MakeMaker

```
my %WriteMakefileArgs = (
  ...,
  "TEST_REQUIRES" => {
    "Test2::V1" => "0.000060"
  },
  ...
);
```

Module::Install

```
test_requires 'Test2::V1' => '0.000060';
```

Module::Build

```
my $build = Module::Build->new(
    ...,
    test_requires => {
        "Test2::V1" => "0.000060",
    },
    ...
);
```

TUTORIALS

SIMPLE/INTRODUCTION TUTORIAL

Test2::Manual::Testing::Introduction is an introduction to writing tests using the *Test2* tools.

MIGRATING FROM TEST::BUILDER and TEST::MORE

Test2::Manual::Testing::Migrating Is a tutorial for converting old tests that use *Test::Builder* or *Test::More* to the newer *Test2* way of doing things.

ADVANCED PLANNING

Test2::Manual::Testing::Planning is a tutorial on the many ways to set a plan.

TODO TESTS

Test2::Manual::Testing::Todo is a tutorial for markings tests as TODO.

Test2::Manual::Testing::Introduction

Introduction to testing with Test2.

DESCRIPTION

This tutorial is a beginners introduction to testing. This will take you through writing a test file, making assertions, and running your test.

BOILERPLATE

THE TEST FILE

Test files typically are placed inside the `t/` directory, and end with the `.t` file extension.

`t/example.t`:

```
use Test2::V1 -ipP;

# Assertions will go here

done_testing;
```

This is all the boilerplate you need.

- use Test2::V1 -ipP;

  This loads a collection of testing tools that will be described later in the tutorial. See *Test2::V1* for more details, but for starters '-ipP' is a good set of import flags.

  If you do not like importing a ton of symbols or enabling pragmas/plugins all in one swoop you can do `use Test2::V1;`. If you do this you will need to use the T2() function to access tools, and load any pragmas/plugins manually:

  ```
  use Test2::V1;
  use strict;
  use warnings;
  use Test2::Plugin::UTF8;
  use Test2::Plugin::SRand;

  T2->ok(1, "pass");
  T2->is(5, 5, "5 is 5");

  T2->done_testing;
  ```

- done_testing;

  This should always be at the end of your test files. This tells *Test2* that you are done making assertions. This is important as `test2` will assume the test did not complete successfully without this, or some other form of test "plan".

DIST CONFIG

You should always list bundles and tools directly. You should not simply list *Test2::Suite* and call it done, bundles and tools may be moved out of *Test2::Suite* to their own dists at any time.

Dist::Zilla

```
[Prereqs / TestRequires]
Test2::V1 = 0.000060
```

ExtUtils::MakeMaker

```
my %WriteMakefileArgs = (
  ...,
  "TEST_REQUIRES" => {
    "Test2::V1" => "0.000060"
  },
  ...
);
```

Module::Install

```
test_requires 'Test2::V1' => '0.000060';
```

Module::Build

```
my $build = Module::Build->new(
    ...,
    test_requires => {
        "Test2::V1" => "0.000060",
    },
    ...
);
```

MAKING ASSERTIONS

The most simple tool for making assertions is `ok()`. `ok()` lets you assert that a condition is true.

```
ok($CONDITION, "Description of the condition");
```

Here is a complete `t/example.t`:

```
use Test2::V1 -import;

ok(1, "1 is true, so this will pass");

done_testing;
```

If you are doing it without imports:

```
use Test2::V1;

T2->ok(1, "1 is true, so this will pass");

T2->done_testing;
```

RUNNING THE TEST

Test files are simply scripts. Just like any other script you can run the test directly with perl. Another option is to use a test "harness" which runs the test for you, and provides extra information and checks the scripts exit value for you.

RUN DIRECTLY

```
$ perl -Ilib t/example.t
```

Which should produce output like this:

```
# Seeded srand with seed '20161028' from local date.
ok 1 - 1 is true, so this will pass
1..1
```

If the test had failed (`ok(0, ...)`) it would look like this:

```
# Seeded srand with seed '20161028' from local date.
not ok 1 - 0 is false, so this will fail
1..1
```

Test2 will also set the exit value of the script, a successful run will have an exit value of 0, a failed run will have a non-zero exit value.

USING YATH

The `yath` command line tool is provided by Test2::Harness which you may need to install yourself from cpan. `yath` is the harness written specifically for *Test2*.

```
$ yath -Ilib t/example.t
```

This will produce output similar to this:

```
( PASSED )  job  1    t/example.t

================================================================================

Run ID: 1508027909

All tests were successful!
```

You can also request verbose output with the `-v` flag:

```
$ yath -Ilib -v t/example.t
```

Which produces:

```
( LAUNCH )  job  1    example.t
(  NOTE  )  job  1    Seeded srand with seed '20171014' from local␣
 ↪date.
[  PASS  ]  job  1  + 1 is true, so this will pass
[  PLAN  ]  job  1    Expected assertions: 1
( PASSED )  job  1    example.t

================================================================================

Run ID: 1508028002

All tests were successful!
```

USING PROVE

The `prove` command line tool is provided by the *Test::Harness* module which comes with most versions of perl. *Test::Harness* is dual-life, which means you can also install the latest version from cpan.

```
$ prove -Ilib t/example.t
```

This will produce output like this:

```
example.t .. ok
All tests successful.
Files=1, Tests=1,  0 wallclock secs ( 0.01 usr  0.00 sys +  0.05␣
 ↪cusr  0.00 csys =  0.06 CPU)
Result: PASS
```

You can also request verbose output with the `-v` flag:

```
$ prove -Ilib -v t/example.t
```

The verbose output looks like this:

```
example.t ..
# Seeded srand with seed '20161028' from local date.
```

(continues on next page)

(continued from previous page)

```
ok 1 - 1 is true, so this will pass
1..1
ok
All tests successful.
Files=1, Tests=1,  0 wallclock secs ( 0.02 usr  0.00 sys +  0.06
↪cusr  0.00 csys =  0.08 CPU)
Result: PASS
```

THE "PLAN"

All tests need a "plan". The job of a plan is to make sure you ran all the tests you expected. The plan prevents a passing result from a test that exits before all the tests are run.

There are 2 primary ways to set the plan:

- done_testing()
- T2->done_testing()

  The most common, and recommended way to set a plan is to add `done_testing` at the end of your test file. This will automatically calculate the plan for you at the end of the test. If the test were to exit early then `done_testing` would not run and no plan would be found, forcing a failure.

- plan($COUNT)
- T2->plan($COUNT)

  The `plan()` function allows you to specify an exact number of assertions you want to run. If you run too many or too few assertions then the plan will not match and it will be counted as a failure. The primary problem with this way of planning is that you need to add up the number of assertions, and adjust the count whenever you update the test file.

  `plan()` must be used before all assertions, or after all assertions, it cannot be done in the middle of making assertions.

ADDITIONAL ASSERTION TOOLS

The *Test2::V1* bundle provides a lot more than `ok()`, `plan()`, and `done_testing()`. The biggest tools to note are:

- is($a, $b, $description)
- T2->is($a, $b, $description)

  `is()` allows you to compare 2 structures and insure they are identical. You can use it for simple string comparisons, or even deep data structure comparisons.

  ```
  is("foo", "foo", "Both strings are identical");

  is(["foo", 1], ["foo", 1], "Both arrays contain the same
  ↪elements");
  ```

- like($a, $b, $description)

- T2->like($a, $b, $description)

  `like()` is similar to `is()` except that it only checks items listed on the right, it ignores any extra values found on the left.

```
like([1, 2, 3, 4], [1, 2, 3], "Passes, the extra element on the␣
↪left is ignored");
```

  You can also used regular expressions on the right hand side:

```
like("foo bar baz", qr/bar/, "The string matches the regex,␣
↪this passes");
```

  You can also nest the regexes:

```
like([1, 2, 'foo bar baz', 3], [1, 2, qr/bar/], "This passes");
```

Test2::Manual::Testing::Migrating

How to migrate existing tests from Test::More to Test2.

DESCRIPTION

This tutorial covers the conversion of an existing test. This tutorial assumes you have a test written using *Test::More*.

LEGACY TEST

This tutorial will be converting this example test one section at a time:

`t/example.t`:

```
#####################
# Boilerplate

use strict;
use warnings;

use Test::More tests => 14;

use_ok 'Scalar::Util';
require_ok 'Exporter';

####################
# Simple assertions (no changes)

ok(1, "pass");

is("apple", "apple", "Simple string compare");

like("foo bar baz", qr/bar/, "Regex match");

####################
# Todo

{
    local $TODO = "These are todo";

    ok(0, "oops");
}

####################
# Deep comparisons

is_deeply([1, 2, 3], [1, 2, 3], "Deep comparison");

####################
# Comparing references

my $ref = [1];
is($ref, $ref, "Check that we have the same ref both times");
```

(continues on next page)

(continued from previous page)

```
####################
# Things that are gone

ok(eq_array([1], [1]), "array comparison");
ok(eq_hash({a => 1}, {a => 1}), "hash comparison");
ok(eq_set([1, 3, 2], [1, 2, 3]), "set comparison");

note explain([1, 2, 3]);

{
    package THING;
    sub new { bless({}, shift) }
}

my $thing = new_ok('THING');

####################
# Tools that changed

isa_ok($thing, 'THING', '$thing');

can_ok(__PACKAGE__, qw/ok is/);
```

BOILERPLATE

BEFORE:

```
use strict;
use warnings;

use Test::More tests => 14;

use_ok 'Scalar::Util';
require_ok 'Exporter';
```

AFTER:

```
use strict;
use warnings;

use Test2::V1 '-import';
plan(11);

use Scalar::Util;
require Exporter;
```

- Replace Test::More with Test2::V1

  Test2::V1 is the recommended bundle. In a full migration you will want to replace *Test::More* with the *Test2::V1* bundle.

Note: You should always double check the latest *Test2* to see if there is a new recommended bundle. When writing a new test you should always use the newest Test::V# module. Higher numbers are newer version.

You probably want the `-import` argument when using *Test2::V0* as it will populate your namespace with all the tools you expect from a test helper module. However if you want your namespace left clean you can omit the argument, in which case `T2()` is the only thing added to your namespace, and it can be used to access the tools:

```
use Test2::V1;

T2->ok(1, "pass");

T2->done_testing;
```

- NOTE: srand

  When srand is on (not default in V1, but Default in older V0) it can cause problems with things like *File::Temp* which will end up attempting the same "random" filenames for every test process started on a given day (or sharing the same seed).

  If this is a problem for you then please disable srand when loading

  For *Test2::V0*:

  ```
  use Test2::V0 -no_srand => 1;
  ```

  For *Test2::V1* simply do not use the `-P`, or `-Plugins` import option and it will not be loaded.

- Stop using use_ok()

  `use_ok()` has been removed. a `use MODULE` statement will throw an exception on failure anyway preventing the test from passing.

  If you *REALLY* want/need to assert that the file loaded you can use the *ok* module:

  ```
  use ok 'Scalar::Util';
  ```

  The main difference here is that there is a space instead of an underscore.

- Stop using require_ok()

  `require_ok` has been removed just like `use_ok`. There is no *ok* module equivalent here. Just use `require`.

- (optional) remove strict/warnings

  In the *Test2::V0* bundle turns strict and warnings on for you.

  In the *Test2::V1* bundle you must ask for strict and warnings with one of the following import args: `-p`, `-pragmas`, `-strict`, `-warnings`.

- Change where the plan is set

  Test2 does not allow you to set the plan at import. In the old code you would pass `tests => 11` as an import argument. In *Test2* you either need to use the `plan()` function to set the plan, or use `done_testing()` at the end of the test.

If your test already uses `done_testing()` you can keep that and no plan changes are necessary.

Note: We are also changing the plan from 14 to 11, that is because we dropped `use_ok`, `require_ok`, and we will be dropping one more later on. This is why `done_testing()` is recommended over a set plan.

SIMPLE ASSERTIONS

The vast majority of assertions will not need any changes:

```
####################
# Simple assertions (no changes)

ok(1, "pass");

is("apple", "apple", "Simple string compare");

like("foo bar baz", qr/bar/, "Regex match");
```

TODO

```
{
    local $TODO = "These are todo";

    ok(0, "oops");
}
```

The `$TODO` package variable is gone. You now have a `todo()` function.

There are 2 ways this can be used:

- todo $reason => sub { ... }

  ```
  todo "These are todo" => sub {
      ok(0, "oops");
  };
  ```

  This is the cleanest way to do a todo. This will make all assertions inside the code-block into TODO assertions.

- { my $TODO = todo $reason; ... }

  ```
  {
      my $TODO = todo "These are todo";

      ok(0, "oops");
  }
  ```

  This is a system that emulates the old way. Instead of modifying a global `$TODO` variable you create a todo object with the `todo()` function and assign it to a lexical variable. Once the todo object falls out of scope the TODO ends.

DEEP COMPARISONS

```
is_deeply([1, 2, 3], [1, 2, 3], "Deep comparison");
```

Deep comparisons are easy, simply replace `is_deeply()` with `is()`.

```
is([1, 2, 3], [1, 2, 3], "Deep comparison");
```

COMPARING REFERENCES

```
my $ref = [1];
is($ref, $ref, "Check that we have the same ref both times");
```

The `is()` function provided by *Test::More* forces both arguments into strings, which makes this a comparison of the reference addresses. *Test2*'s `is()` function is a deep comparison, so this will still pass, but fails to actually test what we want (that both references are the same exact ref, not just identical structures.)

We now have the `ref_is()` function that does what we really want, it ensures both references are the same reference. This function does the job better than the original, which could be thrown off by string overloading.

```
my $ref = [1];
ref_is($ref, $ref, "Check that we have the same ref both times");
```

TOOLS THAT ARE GONE

```
ok(eq_array([1], [1]), "array comparison");
ok(eq_hash({a => 1}, {a => 1}), "hash comparison");
ok(eq_set([1, 3, 2], [1, 2, 3]), "set comparison");

note explain([1, 2, 3]);

{
    package THING;
    sub new { bless({}, shift) }
}

my $thing = new_ok('THING');
```

`eq_array`, `eq_hash` and `eq_set` have been considered deprecated for a very long time, *Test2* does not provide them at all. Instead you can just use `is()`:

```
is([1], [1], "array comparison");
is({a => 1}, {a => 1}, "hash comparison");
```

`eq_set` is a tad more complicated, see *Test2::Tools::Compare* for an explanation:

```
is([1, 3, 2], bag { item 1; item 2; item 3; end }, "set comparison
↪");
```

`explain()` has a rocky history. There have been arguments about how it should work. *Test2* decided to simply not include `explain()` to avoid the arguments. You can instead directly use Data::Dumper:

```
use Data::Dumper;
note Dumper([1, 2, 3]);
```

`new_ok()` is gone. The implementation was complicated, and did not add much value:

```
{
    package THING;
    sub new { bless({}, shift) }
}

my $thing = THING->new;
ok($thing, "made a new thing");
```

The complete section after the conversion is:

```
is([1], [1], "array comparison");
is({a => 1}, {a => 1}, "hash comparison");
is([1, 3, 2], bag { item 1; item 2; item 3; end }, "set comparison
 ↪");

use Data::Dumper;
note Dumper([1, 2, 3]);

{
    package THING;
    sub new { bless({}, shift) }
}

my $thing = THING->new;
ok($thing, "made a new thing");
```

TOOLS THAT HAVE CHANGED

```
isa_ok($thing, 'THING', '$thing');

can_ok(__PACKAGE__, qw/ok is/);
```

In *Test::More* these functions are very confusing, and most people use them wrong!

`isa_ok()` from *Test::More* takes a thing, a class/reftype to check, and then uses the third argument as an alternative display name for the first argument (NOT a test name!).

`can_ok()` from *Test::More* is not consistent with `isa_ok` as all arguments after the first are subroutine names.

Test2 fixes this by making both functions consistent and obvious:

```
isa_ok($thing, ['THING'], 'got a THING');

can_ok(__PACKAGE__, [qw/ok is/], "have expected subs");
```

You will note that both functions take a thing, an arrayref as the second argument, then a test name as the third argument.

FINAL VERSION

IMPORTS

```

Test2::Manual::Testing::Planning

The many ways to set a plan.

DESCRIPTION

This tutorial covers the many ways of setting a plan.

TEST COUNT

The `plan()` function is provided by *Test2::Tools::Basic*. This function lets you specify an exact number of tests to run. This can be done at the start of testing, or at the end. This cannot be done partway through testing.

```
use Test2::Tools::Basic;
plan(10); # 10 tests expected

...
```

DONE TESTING

The done_testing() function is provided by *Test2::Tools::Basic*. This function will automatically set the plan to the number of tests that were run. This must be used at the very end of testing.

```
use Test2::Tools::Basic;

...

done_testing();
```

SKIP ALL

The skip_all() function is provided by *Test2::Tools::Basic*. This function will set the plan to 0, and exit the test immediately. You may provide a skip reason that explains why the test should be skipped.

```
use Test2::Tools::Basic;
skip_all("This test will not run here") if ...;

...
```

CUSTOM PLAN EVENT

A plan is simply an *Test2::Event::Plan* event that gets sent to the current hub. You could always write your own tool to set the plan.

```
use Test2::API qw/context/;

sub set_plan {
    my $count = @_;

    my $ctx = context();
    $ctx->send_event('Plan', max => $count);
    $ctx->release;

    return $count;
}
```

Test2::Manual::Testing::Todo

Tutorial for marking tests as TODO.

DESCRIPTION

This tutorial covers the process of marking tests as TODO. It also describes how TODO works under the hood.

THE TOOL

```
use Test2::Tools::Basic qw/todo/;
```

TODO BLOCK

This form is low-magic. All tests inside the block are marked as todo, tests outside the block are not todo. You do not need to do any variable management. The flaw with this form is that it adds a couple levels to the stack, which can break some high-magic tests.

Overall this is the preferred form unless you have a special case that requires the variable form.

```
todo "Reason for the todo" => sub {
    ok(0, "fail but todo");
    ...
};
```

TODO VARIABLE

This form maintains the todo scope for the life of the variable. This is useful for tests that are sensitive to scope changes. This closely emulates the *Test::More* style which localized the `$TODO` package variable. Once the variable is destroyed (set it to undef, scope end, etc) the TODO state ends.

```
my $todo = todo "Reason for the todo";
ok(0, "fail but todo");
...
$todo = undef;
```

MANUAL TODO EVENTS

```
use Test2::API qw/context/;

sub todo_ok {
    my ($bool, $name, $todo) = @_;

    my $ctx = context();
    $ctx->send_event('Ok', pass => $bool, effective_pass => 1, todo
 ↪=> $todo);
    $ctx->release;

    return $bool;
}
```

The *Test2::Event::Ok* event has a `todo` field which should have the todo reason. The event also has the `pass` and `effective_pass` fields. The `pass` field is the actual pass/fail value. The `effective_pass` is used to determine if the event is an actual failure (should always be set tot true with todo).

HOW THE TODO TOOLS WORK UNDER THE HOOD

The *Test2::Todo* library gets the current *Test2::Hub* instance and adds a filter. The filter that is added will set the `todo` and `effective_pass` fields on any *Test2::Event::Ok* events that pass through the hub. The filter also converts *Test2::Event::Diag* events into *Test2::Event::Note* events.

Test2::Manual::Tooling

Manual page for tool authors.

DESCRIPTION

This section covers writing new tools, plugins, and other Test2 components.

TOOL TUTORIALS

FIRST TOOL

Test2::Manual::Tooling::FirstTool - Introduction to writing tools by cloning ok().

MOVING FROM Test::Builder

Test2::Manual::Tooling::TestBuilder - This section maps Test::Builder methods to Test2 concepts.

NESTING TOOLS

Test2::Manual::Tooling::Nesting - How to call other tools from your tool.

TOOLS WITH SUBTESTS

Test2::Manual::Tooling::Subtest - How write tools that make use of subtests.

TESTING YOUR TEST TOOLS

Test2::Manual::Tooling::Testing - How to write tests for your test tools.

PLUGIN TUTORIALS

TAKING ACTION WHEN A NEW TOOL STARTS

Test2::Manual::Tooling::Plugin::ToolStarts - How to add behaviors that occur when a tool starts work.

TAKING ACTION AFTER A TOOL IS DONE

Test2::Manual::Tooling::Plugin::ToolCompletes - How to add behaviors that occur when a tool completes work.

TAKING ACTION AT THE END OF TESTING

Test2::Manual::Tooling::Plugin::TestingDone - How to add behaviors that occur when testing is complete (IE done_testing, or end of test).

TAKING ACTION JUST BEFORE EXIT

Test2::Manual::Tooling::Plugin::TestExit - How to safely add pre-exit behaviors.

WRITING A SIMPLE JSONL FORMATTER

Test2::Manual::Tooling::Formatter - How to write a custom formatter, in our case a JSONL formatter.

WHERE TO FIND HOOKS AND APIS

- global API

  Test2::API is the global API. This is primarily used by plugins that provide global behavior.

- In hubs

  Test2::Hub is the base class for all hubs. This is where hooks for manipulating events, or running things at the end of testing live.

SEE ALSO

Test2::Manual - Primary index of the manual.

SOURCE

The source code repository for Test2-Manual can be found at `https://github.com/Test-More/test-more/`.

- `Test2::Manual::Tooling::TestBuilder` - This section maps Test::Builder methods to Test2 concepts.
- `Test2::Manual::Tooling::Testing` - Tutorial on how to test your testing tools.

Test2::Manual::Tooling::FirstTool

Write your first tool with Test2.

DESCRIPTION

This tutorial will help you write your very first tool by cloning the `ok()` tool.

COMPLETE CODE UP FRONT

```
package Test2::Tools::MyOk;
use strict;
use warnings;

use Test2::API qw/context/;

```

(continues on next page)

(continued from previous page)

```
use base 'Exporter';
our @EXPORT = qw/ok/;

sub ok($;$@) {
    my ($bool, $name, @diag) = @_;

    my $ctx = context();

    return $ctx->pass_and_release($name) if $bool;
    return $ctx->fail_and_release($name, @diag);
}

1;
```

LINE BY LINE

- sub ok($;$@) {

  In this case we are emulating the `ok()` function exported by *Test2::Tools::Basic*.

  `ok()` and similar test tools use prototypes to enforce argument parsing. Your test tools do not necessarily need prototypes, like any perl function you need to make the decision based on how it is used.

  The prototype requires at least 1 argument, which will be forced into a scalar context. The second argument is optional, and is also forced to be scalar, it is the name of the test. Any remaining arguments are treated as diagnostics messages that will only be used if the test failed.

- my ($bool, $name, @diag) = @_;

  This line does not need much explanation, we are simply grabbing the args.

- my $ctx = context();

  This is a vital line in **ALL** tools. The context object is the primary API for test tools. You **MUST** get a context if you want to issue any events, such as making assertions. Further, the context is responsible for making sure failures are attributed to the correct file and line number.

  Note: A test function **MUST** always release the context when it is done, you cannot simply let it fall out of scope and be garbage collected. Test2 does a pretty good job of yelling at you if you make this mistake.

  Note: You **MUST NOT** ever store or pass around a *real* context object. If you wish to hold on to a context for any reason you must use clone to make a copy `my $copy = $ctx->clone`. The copy may be passed around or stored, but the original **MUST** be released when you are done with it.

- return $ctx->pass_and_release($name) if $bool;

  When `$bool` is true, this line uses the context object to issue a *Test2::Event::Pass* event. Along with issuing the event this will also release the context object and return true.

This is short form for:

```
if($bool) {
    $ctx->pass($name);
    $ctx->release;
    return 1;
}
```

- return $ctx->fail_and_release($name, @diag);

  This line issues a *Test2::Event::Fail* event, releases the context object, and returns false. The fail event will include any diagnostics messages from the `@diag` array.

  This is short form for:

```
$ctx->fail($name, @diag);
$ctx->release;
return 0;
```

CONTEXT OBJECT DOCUMENTATION

Test2::API::Context is the place to read up on what methods the context provides.

Test2::Manual::Tooling::Formatter

How to write a custom formatter, in our case a JSONL formatter.

DESCRIPTION

This tutorial explains a minimal formatter that outputs each event as a json string on its own line. A true formatter will probably be significantly more complicated, but this will give you the basics needed to get started.

COMPLETE CODE UP FRONT

```
package Test2::Formatter::MyFormatter;
use strict;
use warnings;

use JSON::MaybeXS qw/encode_json/;

use base qw/Test2::Formatter/;

sub new { bless {}, shift }

sub encoding {};

sub write {
    my ($self, $e, $num, $f) = @_;
    $f ||= $e->facet_data;

    print encode_json($f), "\n";
}

1;
```

LINE BY LINE

- use base qw/Test2::Formatter/;

  All formatters should inherit from *Test2::Formatter*.

- sub new { bless {}, shift }

  Formatters need to be instantiable objects, this is a minimal `new()` method.

- sub encoding {};

  For this example we leave this sub empty. In general you should implement this sub to make sure you honor situations where the encoding is set. *Test2::V0* itself will try to set the encoding to UTF8.

- sub write { ... }

  The `write()` method is the most important, each event is sent here.

- my ($self, $e, $num, $f) = @_;

The `write()` method receives 3 or 4 arguments, the fourth is optional.

- $self

  The formatter itself.

- $e

  The event being written

- $num

  The most recent assertion number. If the event being processed is an assertion then this will have been bumped by 1 since the last call to write. For non assertions this number is set to the most recent assertion.

- $f

  This MAY be a hashref containing all the facet data from the event. More often then not this will be undefined. This is only set if the facet data was needed by the hub, and it usually is not.

- $f ||= $e->facet_data;

  We want to dump the event facet data. This will set `$f` to the facet data unless we already have the facet data.

- print encode_json($f), "\n";

  This line prints the JSON encoded facet data, and a newline.

Test2::Manual::Tooling::Nesting

Tutorial for using other tools within your own.

DESCRIPTION

Sometimes you find yourself writing the same test pattern over and over, in such cases you may want to encapsulate the logic in a new test function that calls several tools together. This sounds easy enough, but can cause headaches if not done correctly.

NAIVE WAY

Lets say you find yourself writing the same test pattern over and over for multiple objects:

```
my $obj1 = $class1->new;
is($obj1->foo, 'foo', "got foo");
is($obj1->bar, 'bar', "got bar");

my $obj2 = $class1->new;
is($obj2->foo, 'foo', "got foo");
is($obj2->bar, 'bar', "got bar");

... 10x more times for classes 2-12
```

The naive way to do this is to write a `check_class()` function like this:

```
sub check_class {
    my $class = shift;
    my $obj = $class->new;
    is($obj->foo, 'foo', "got foo");
    is($obj->bar, 'bar', "got bar");
}

check_class($class1);
check_class($class2);
check_class($class3);
...
```

This will appear to work fine, and you might not notice any problems, *so long as the tests are passing.*

WHAT'S WRONG WITH IT?

The problems with the naive approach become obvious if things start to fail. The diagnostics that tell you what file and line the failure occurred on will be wrong. The failure will be reported to the line *inside* `check_class`, not to the line where `check_class()` was called. This is problem because it leaves you with no idea which class is failing.

HOW TO FIX IT

Luckily this is extremely easy to fix. You need to acquire a context object at the start of your function, and release it at the end... yes it is that simple.

```
use Test2::API qw/context/;

sub check_class {
    my $class = shift;

    my $ctx = context();

    my $obj = $class->new;
    is($obj->foo, 'foo', "got foo");
    is($obj->bar, 'bar', "got bar");

    $ctx->release;
}
```

See, that was easy. With these 2 additional lines we know have proper file+line reporting. The nested tools will find the context we acquired here, and know to use its file and line numbers.

THE OLD WAY (DO NOT DO THIS ANYMORE)

With *Test::Builder* there was a global variables called `$Test::Builder::Level` which helped solve this problem:

```
sub check_class {
    my $class = shift;

    local $Test::Builder::Level = $Test::Builder::Level + 1;

    my $obj = $class->new;
    is($obj->foo, 'foo', "got foo");
    is($obj->bar, 'bar', "got bar");
}
```

This variable worked well enough (and will still work) but was not very discoverable. Another problem with this variable is that it becomes cumbersome if you have a more deeply nested code structure called the nested tools, you might need to count stack frames, and hope they never change due to a third party module. The context solution has no such caveats.

Test2::Manual::Tooling::Plugin

Namespace containing the following modules:

- `Test2::Manual::Tooling::Plugin::TestExit` - How to safely add pre-exit behaviors.
- `Test2::Manual::Tooling::Plugin::TestingDone` - Run code when the test file is finished, or when done_testing is called.
- `Test2::Manual::Tooling::Plugin::ToolCompletes` - How to add behaviors that occur when a tool completes work.
- `Test2::Manual::Tooling::Plugin::ToolStarts` - How to add behaviors that occur when a tool starts work.

Test2::Manual::Tooling::Plugin::TestExit

How to safely add pre-exit behaviors.

DESCRIPTION

This describes the correct/safe way to add pre-exit behaviors to tests via a custom plugin.

The naive way to attempt this would be to add an `END { ... }` block. That can work, and may not cause problems.... On the other hand there are a lot of ways that can bite you. Describing all the potential problems of an END block, and how it might conflict with Test2 (Which has its own END block) is beyond the scope of this document.

COMPLETE CODE UP FRONT

```
package Test2::Plugin::MyPlugin;

use Test2::API qw{test2_add_callback_exit};

sub import {
    my $class = shift;

    test2_add_callback_exit(sub {
        my ($ctx, $orig_code, $new_exit_code_ref) = @_;

        return if $orig_code == 42;

        $$new_exit_code_ref = 42;
    });
}

1;
```

LINE BY LINE

- use Test2::API qw{test2_add_callback_exit};

  This imports the `(test2_add_callback_exit)` callback.

- test2_add_callback_exit(sub { ... });

  This adds our callback to be called before exiting.

- my ($ctx, $orig_code, $new_exit_code_ref) = @_

  The callback gets 3 arguments. First is a context object you may use. The second is the original exit code of the END block Test2 is using. The third argument is a scalar reference which you may use to get the current exit code, or set a new one.

- return if $orig_code == 42

  This is a short-cut to do nothing if the original exit code was already 42.

- $$new_exit_code_ref = 42

  This changes the exit code to 42.

Test2::Manual::Tooling::Plugin::TestingDone

Run code when the test file is finished, or when done_testing is called.

DESCRIPTION

This is a way to add behavior to the end of a test file. This code is run either when done_testing() is called, or when the test file has no more run-time code to run.

When triggered by done_testing() this will be run BEFORE the plan is calculated and sent. This means it IS safe to make test assertions in this callback.

COMPLETE CODE UP FRONT

```
package Test2::Plugin::MyPlugin;

use Test2::API qw{test2_add_callback_testing_done};

sub import {
    my $class = shift;

    test2_add_callback_testing_done(sub {
        ok(!$some_global, '$some_global was not set');
        print "The test file is done, or done_testing was just
 ↪called\n"
    });
}

1;
```

LINE BY LINE

- use Test2::API qw{test2_add_callback_testing_done};

  This imports the `test2_add_callback_testing_done()` callback.

- test2_add_callback_testing_done(sub { ... });

  This adds our callback to be called when testing is done.

- ok(!$some_global, '$some_global was not set')

  It is safe to make assertions in this type of callback. This code simply asserts that some global was never set over the course of the test.

- print "The test file is done, or done_testing was just called\n"

  This prints a message when the callback is run.

UNDER THE HOOD

Before test2_add_callback_testing_done() this kind of thing was still possible, but it was hard to get right, here is the code to do it:

```
test2_add_callback_post_load(sub {
    my $stack = test2_stack();

    # Insure we have at least one hub, but we do not necessarily␣
↪want the
    # one this returns.
    $stack->top;

    # We want the root hub, not the top one.
    my ($root) = Test2::API::test2_stack->all;

    # Make sure the hub does not believe nothing has happened.
    $root->set_active(1);

    # Now we can add our follow-up code
    $root->follow_up(sub {
        # Your callback code here
    });
});
```

SEE ALSO

Test2::Manual::Tooling::Plugin::ToolCompletes

How to add behaviors that occur when a tool completes work.

DESCRIPTION

This tutorial helps you understand how to add behaviors that occur when a tool is done with its work. All tools need to acquire and then release a context, for this tutorial we make use of the release hooks that are called every time a tool releases the context object.

COMPLETE CODE UP FRONT

```
package Test2::Plugin::MyPlugin;

use Test2::API qw{test2_add_callback_context_release};

sub import {
    my $class = shift;

    test2_add_callback_context_release(sub {
        my $ctx_ref = shift;

        print "Context was released\n";
    });
}

1;
```

LINE BY LINE

- use Test2::API qw{test2_add_callback_context_release};

  This imports the `test2_add_callback_context_release()` callback.

- test2_add_callback_context_release(sub { ... })

- my $ctx_ref = shift

  The coderefs for test2_add_callback_context_release() will receive exactly 1 argument, the context being released.

- print "Context was released\n"

  Print a notification whenever the context is released.

SEE ALSO

Test2::Manual - Primary index of the manual.

Test2::Manual::Tooling::Plugin::ToolStarts

How to add behaviors that occur when a tool starts work.

DESCRIPTION

This tutorial will help you write plugins that have behavior when a tool starts. All tools should start by acquiring a context object. This tutorial shows you the hooks you can use to take advantage of the context acquisition.

COMPLETE CODE UP FRONT

```
package Test2::Plugin::MyPlugin;

use Test2::API qw{
    test2_add_callback_context_init
```

(continues on next page)

(continued from previous page)

```
    test2_add_callback_context_acquire
};

sub import {
    my $class = shift;

    # Let us know every time a tool requests a context, and give us␣
↪a
    # chance to modify the parameters before we find it.
    test2_add_callback_context_acquire(sub {
        my $params_ref = shift;

        print "A tool has requested the context\n";
    });

    # Callback every time a new context is created, not called if an
    # existing context is found.
    test2_add_callback_context_init(sub {
        my $ctx_ref = shift;

        print "A new context was created\n";
    });
}

1;
```

LINE BY LINE

- use Test2::API qw{test2_add_callback_context_init test2_add_callback_context_acquire};

  This imports the `test2_add_callback_context_init()` and `test2_add_callback_context_acquire()` callbacks.

- test2_add_callback_context_acquire(sub { ... })

  This is where we add our callback for context acquisition. Every time `Test2::API::context()` is called the callback will be run.

- my $params_ref = shift

  In the test2_add_callback_context_acquire() callbacks we get exactly 1 argument, a reference to the parameters that `context()` will use to find the context.

- print “A tool has requested the context\n”

  Print a notification whenever a tool asks for a context.

- test2_add_callback_context_init(sub { ... })

  Add our context init callback. These callbacks are triggered whenever a completely new context is created. This is not called if an existing context is found. In short this only fires off for the top level tool, not nested tools.

- my $ctx_ref = shift

  The coderefs for test2_add_callback_context_init() will receive exactly 1 argument, the newly created context.

- print “A new context was created\n”

  Print a notification whenever a new context is created.

Test2::Manual::Tooling::Subtest

How to implement a tool that makes use of subtests.

DESCRIPTION

Subtests are a nice way of making related events visually, and architecturally distinct.

WHICH TYPE OF SUBTEST DO I NEED?

There are 2 types of subtest. The first type is subtests with user-supplied coderefs, such as the `subtest()` function itself. The second type is subtest that do not have any user supplied coderefs.

So which type do you need? The answer to that is simple, if you are going to let the user define the subtest with their own codeblock, you have the first type, otherwise you have the second.

In either case, you will still need use the same API function: `Test2::API::run_subtest`.

SUBTEST WITH USER SUPPLIED CODEREF

This example will emulate the `subtest` function.

```
use Test2::API qw/context run_subtest/;

sub my_subtest {
    my ($name, $code) = @_;

    # Like any other tool, you need to acquire a context, if you do not then
    # things will not report the correct file and line number.
    my $ctx = context();

    my $bool = run_subtest($name, $code);

    $ctx->release;

    return $bool;
}
```

This looks incredibly simple... and it is. `run_subtest()` does all the hard work for you. This will issue an *Test2::Event::Subtest* event with the results of the subtest. The subtest event itself will report to the proper file and line number due to the context you acquired (even though it does not *look* like you used the context.

`run_subtest()` can take additional arguments:

```
run_subtest($name, $code, \%params, @args);
```

- @args

  This allows you to pass arguments into the codeblock that gets run.

- \%params

  This is a hashref of parameters. Currently there are 3 possible parameters:

  - buffered => $bool

    This will turn the subtest into the new style buffered subtest. This type of subtest is recommended, but not default.

  - inherit_trace => $bool

    This is used for tool-side coderefs.

  - no_fork => $bool

    react to forking/threading inside the subtest itself. In general you are unlikely to need/want this parameter.

SUBTEST WITH TOOL-SIDE CODEREF

This is particularly useful if you want to turn a tool that wraps other tools into a subtest. For this we will be using the tool we created in *Test2::Manual::Tooling::Nesting*.

```
use Test2::API qw/context run_subtest/;

sub check_class {
    my $class = shift;

    my $ctx = context();

    my $code = sub {
        my $obj = $class->new;
        is($obj->foo, 'foo', "got foo");
        is($obj->bar, 'bar', "got bar");
    };

    my $bool = run_subtest($class, $code, {buffered => 1, inherit_
↪trace => 1});

    $ctx->release;

    return $bool;
}
```

The `run_subtest()` function does all the heavy lifting for us. All we need to do is give the function a name, a coderef to run, and the `inherit_trace => 1` parameter. The `buffered => 1` parameter is optional, but recommended.

The `inherit_trace` parameter tells the subtest tool that the contexts acquired inside the nested tools should use the same trace as the subtest itself. For user-supplied codeblocks you do not use inherit_trace because you want errors to report to the user-supplied file+line.

Test2::Manual::Tooling::TestBuilder

This section maps Test::Builder methods to Test2 concepts.

DESCRIPTION

With Test::Builder tools were encouraged to use methods on the Test::Builder singleton object. Test2 has a different approach, every tool should get a new *Test2::API::Context* object, and call methods on that. This document maps several concepts from Test::Builder to Test2.

CONTEXT

First thing to do, stop using the Test::Builder singleton, in fact stop using or even loading Test::Builder. Instead of Test::Builder each tool you write should follow this template:

```
use Test2::API qw/context/;

sub my_tool {
    my $ctx  = context();

    ... do work ...

    $ctx->ok(1, "a passing assertion");

    $ctx->release;

    return $whatever;
}
```

The original Test::Builder style was this:

```
use Test::Builder;
my $tb = Test::Builder->new; # gets the singleton

sub my_tool {
    ... do work ...
```

(continues on next page)

(continued from previous page)

```
    $tb->ok(1, "a passing assertion");

    return $whatever;
}
```

TEST BUILDER METHODS

- $tb->BAIL_OUT($reason)

  The context object has a 'bail' method:

  ```
  $ctx->bail($reason)
  ```

- $tb->diag($string)
- $tb->note($string)

  The context object has diag and note methods:

  ```
  $ctx->diag($string);
  $ctx->note($string);
  ```

- $tb->done_testing

  The context object has a done_testing method:

  ```
  $ctx->done_testing;
  ```

  Unlike the Test::Builder version, no arguments are allowed.

- $tb->like
- $tb->unlike

  These are not part of context, instead look at *Test2::Compare* and *Test2::Tools::Compare*.

- $tb->ok($bool, $name)

  ```
  # Preferred
  $ctx->pass($name);
  $ctx->fail($name, @diag);

  # Discouraged, but supported:
  $ctx->ok($bool, $name, \@failure_diags)
  ```

- $tb->subtest

  use the `Test2::API::run_subtest()` function instead. See *Test2::API* for documentation.

- $tb->todo_start
- $tb->todo_end

  See *"skip($why)" in Test2::Tools::Basic*, and *Test2::Todo* instead.

- $tb->output, $tb->failure_output, and $tb->todo_output

  These are handled via formatters now. See *Test2::Formatter* and *Test2::Formatter::TAP*.

LEVEL

Test::Builder had the `$Test::Builder::Level` variable that you could modify in order to set the stack depth. This was useful if you needed to nest tools and wanted to make sure your file and line number were correct. It was also frustrating and prone to errors. Some people never even discovered the level variable and always had incorrect line numbers when their tools would fail.

Test2 uses the context system, which solves the problem a better way. The top-most tool get a context, and holds on to it until it is done. Any tool nested under the first will find and use the original context instead of generating a new one. This means the level problem is solved for free, no variables to mess with.

Test2 is also smart enough to honor `$Test::Builder::Level` if it is set.

TODO

Test::Builder used the `$TODO` package variable to set the TODO state. This was confusing, and easy to get wrong. See Test2::Tools::Todo for the modern way to accomplish a TODO state.

Test2::Manual::Tooling::Testing

Tutorial on how to test your testing tools.

DESCRIPTION

Testing your test tools used to be a complex and difficult prospect. The old tools such as *Test::Tester* and *Test::Builder::Tester* were limited, and fragile. Test2 on the other hand was designed from the very start to be easily tested! This tutorial shows you how.

THE HOLY GRAIL OF TESTING YOUR TOOLS

The key to making Test2 easily testable (specially when compared to Test::Builder) is the `intercept` function.

```
use Test2::API qw/intercept/;

my $events = intercept {
    ok(1, "pass");
    ok(0, "fail");

    diag("A diag");
};
```

The intercept function lets you use any test tools you want inside a codeblock. No events or contexts generated within the intercept codeblock will have any effect on the outside testing state. The `intercept` function completely isolates the tools called within.

Note: Plugins and things that affect global API state may not be fully isolated. `intercept` is intended specifically for event isolation.

The `intercept` function will return an arrayref containing all the events that were generated within the codeblock. You can now make any assertions you want about the events you expected your tools to generate.

```
[
    bless({...}, 'Test2::Event::Ok'),   # pass
    bless({...}, 'Test2::Event::Ok'),   # fail
    bless({...}, 'Test2::Event::Diag'), # Failure diagnostics (not␣
↪always a second event)
    bless({...}, 'Test2::Event::Diag'), # custom 'A diag' message
]
```

Most test tools eventually produce one or more events. To effectively verify the events you get from intercept you really should read up on how events work *Test2::Manual::Anatomy::Event*. Once you know about events you can move on to the next section which points you at some helpers.

ADDITIONAL HELPERS

Test2::Tools::Tester

This is the most recent set of tools to help you test your events. To really understand these you should familiarize yourself with *Test2::Manual::Anatomy::Event*. If you are going to be writing anything more than the most simple of tools you should know how events work.

The *Test2::Tools::Tester* documentation is a good place for further reading.

Test2::Tools::HarnessTester

The Test2::Tools::HarnessTester can export the `summarize_events()` tool. This tool lets you run your event arrayref through Test2::Harness so that you can get a pass/fail summary.

```
my $summary = summarize_events($events);
```

The summary looks like this:

```
{
    plan       => $plan_facet,          # the plan event facet
    pass       => $bool,                # true if the events result␣
↪in a pass
    fail       => $bool,                # true if the events result␣
↪in a fail
    errors     => $error_count,         # Number of error facets seen
    failures   => $failure_count,       # Number of failing␣
↪assertions seen
    assertions => $assertion_count,     # Total number of assertions␣
↪seen
}
```

Test2::Tools::Compare

DEPRECATED These tools were written before the switch to faceted events. These will still work, but are no longer the recommended way to test your tools.

The *Test2::Tools::Compare* library exports a handful of extras to help test events.

- event $TYPE => ...

  Use in an array check against $events to check for a specific type of event with the properties you specify.

- fail_events $TYPE => ...

  Use when you expect a failing assertion of $TYPE. This will automatically check that the next event following it is a diagnostics message with the default failure text.

  Note: This is outdated as a single event may now possess both the failing assertion AND the failing text, such events will fail this test.

Test2::Mock

Module for managing mocked classes and instances.

DESCRIPTION

This module lets you add and override methods for any package temporarily. When the instance is destroyed it will restore the package to its original state.

SYNOPSIS

```
use Test2::Mock;
use MyClass;

my $mock = Test2::Mock->new(
    track => $BOOL, # enable call tracking if desired
    class => 'MyClass',
    override => [
        name => sub { 'fred' },
        ...
    ],
    add => [
        is_mocked => sub { 1 }
        ...
```

(continues on next page)

(continued from previous page)

```
    ],
    ...
);

# Unmock the 'name' sub
$mock->restore('name');

...

$mock = undef; # Will remove all the mocking
```

CONSTRUCTION

METHODS

- $mock = Test2::Mock->new(class => $CLASS, ...)

  This will create a new instance of *Test2::Mock* that manages mocking for the specified `$CLASS`.

  Any `Test2::Mock` method can be used as a constructor argument, each should be followed by an arrayref of arguments to be used within the method. For instance the `add()` method:

  ```
  my $mock = Test2::Mock->new(
      class => 'AClass',
      add => [foo => sub { 'foo' }],
  );
  ```

  is identical to this:

  ```
  my $mock = Test2::Mock->new(
      class => 'AClass',
  );
  $mock->add(foo => sub { 'foo' });
  ```

- $mock->track($bool)

  Turn tracking on or off. Any sub added/overridden/set when tracking is on will log every call in a hash retrievable via `$mock->tracking`. Changing the tracking toggle will not affect subs already altered, but will affect any additional alterations.

- $hashref = $mock->sub_tracking

  The tracking data looks like this:

  ```
  {
      sub_name => [
          {sub_name => $sub_name, sub_ref => $mock_subref, args =>
  ↪ [... copy of @_ from the call ... ]},
          ...,
          ...,
  ```

(continues on next page)

(continued from previous page)

```
    ],
}
```

Unlike call_tracking, this lists all calls by sub, so you can choose to only look at the sub specific calls.

Please note: The hashref items with the subname and args are shared with call_tracking, modifying one modifies the other, so copy first!

- $arrayref = $mock->call_tracking

  The tracking data looks like this:

```
[
    {sub_name => $sub_name, sub_ref => $mock_subref, args => [..
↪. copy of @_ from the call ... ]},
    ...,
    ...,
]
```

  Unlike sub_tracking this lists all calls to any mocked sub, in the order they were called. To filter by sub use sub_tracking.

  Please note: The hashref items with the subname and args are shared with sub_tracking, modifying one modifies the other, so copy first!

- $mock->clear_sub_tracking()
- $mock->clear_sub_tracking(\@subnames)

  Clear tracking data. With no arguments ALL tracking data is cleared. When arguments are provided then only those specific keys will be cleared.

- $mock->clear_call_tracking()

  Clear all items from call_tracking.

- $mock->add('symbol' => ..., 'symbol2' => ...)
- $mock->override('symbol1' => ..., 'symbol2' => ...)
- $mock->set('symbol1' => ..., 'symbol2' => ...)

  `add()` and `override()` are the primary ways to add/modify methods for a class. Both accept the exact same type of arguments. The difference is that `override` will fail unless the symbol you are overriding already exists, `add` on the other hand will fail if the symbol does already exist.

  `set()` was more recently added for cases where you may not know if the sub already exists. These cases are rare, and set should be avoided (think of it like 'no strict'). However there are valid use cases, so it was added.

  Note: Think of override as a push operation. If you call override on the same symbol multiple times it will track that. You can use `restore()` as a pop operation to go back to the previous mock. `reset` can be used to remove all the mocking for a symbol.

Arguments must be a symbol name, with optional sigil, followed by a new specification of the symbol. If no sigil is specified then '&' (sub) is assumed. A simple example of overriding a sub:

```
$mock->override(foo => sub { 'overridden foo' });
my $val = $class->foo; # Runs our override
# $val is now set to 'overridden foo'
```

You can also simply provide a value and it will be wrapped in a sub for you:

```
$mock->override( foo => 'foo' );
```

The example above will generate a sub that always returns the string 'foo'.

There are three *special* values that can be used to generate accessors:

```
$mock->add(
    name => 'rw',   # Generates a read/write accessor
    age  => 'ro',   # Generates a read only accessor
    size => 'wo',   # Generates a write only accessor
);
```

If you want to have a sub that actually returns one of the three special strings, or that returns a coderef, you can use a hashref as the spec:

```
my $ref = sub { 'my sub' };
$mock->add(
    rw_string => { val => 'rw' },
    ro_string => { val => 'ro' },
    wo_string => { val => 'wo' },
    coderef   => { val => $ref }, # the coderef method returns
 ↪$ref each time
);
```

You can also override/add other symbol types, such as hash:

```
package Foo;
...

$mock->add('%foo' => {a => 1});

print $Foo::foo{a}; # prints '1'
```

You can also tell mock to deduce the symbol type for the add/override from the reference, rules are similar to glob assignments:

```
$mock->add(
    -foo => sub { 'foo' },     # Adds the &foo sub to the␣
 ↪package
    -foo => { foo => 1 },      # Adds the %foo hash to the␣
 ↪package
    -foo => [ 'f', 'o', 'o' ], # Adds the @foo array to the␣
```

(continues on next page)

(continued from previous page)

```
↪package
    -foo => \"foo",            # Adds the $foo scalar to the␣
↪package
);
```

- $mock->restore($SYMBOL)

  Restore the symbol to what it was before the last override. If the symbol was recently added this will remove it. If the symbol has been overridden multiple times this will ONLY restore it to the previous state. Think of `override` as a push operation, and `restore` as the pop operation.

- $mock->reset($SYMBOL)

  Remove all mocking of the symbol and restore the original symbol. If the symbol was initially added then it will be completely removed.

- $mock->orig($SYMBOL)

  This will return the original symbol, before any mocking. For symbols that were added this will return undef.

- $mock->current($SYMBOL)

  This will return the current symbol.

- $mock->reset_all

  Remove all added symbols, and restore all overridden symbols to their originals.

- $mock->add_constructor($NAME => $TYPE)

- $mock->override_constructor($NAME => $TYPE)

  This can be used to inject constructors. The first argument should be the name of the constructor. The second argument specifies the constructor type.

  The `hash` type is the most common, all arguments are used to create a new hash that is blessed.

```
hash => sub  {
    my ($class, %params) = @_;
    return bless \%params, $class;
};
```

  The `array` type is similar to the hash type, but accepts a list instead of key/value pairs:

```
array => sub {
    my ($class, @params) = @_;
    return bless \@params, $class;
};
```

  The `ref` type takes a reference and blesses it. This will modify your original input argument.

```
ref => sub {
    my ($class, $params) = @_;
    return bless $params, $class;
};
```

The `ref_copy` type will copy your reference and bless the copy:

```
ref_copy => sub {
    my ($class, $params) = @_;
    my $type = reftype($params);

    return bless {%$params}, $class
        if $type eq 'HASH';

    return bless [@$params], $class
        if $type eq 'ARRAY';

    croak "Not sure how to construct a '$class' from '$params'";
};
```

- $mock->before($NAME, sub { ... })

  This will replace the original sub `$NAME` with a new sub that calls your custom code just before calling the original method. The return from your custom sub is ignored. Your sub and the original both get the unmodified arguments.

- $mock->after($NAME, sub { ... })

  This is similar to before, except your callback runs after the original code. The return from your callback is ignored.

- $mock->around($NAME, sub { ... })

  This gives you the chance to wrap the original sub:

```
$mock->around(foo => sub {
    my $orig = shift;
    my $self = shift;
    my (@args) = @_;

    ...
    $self->$orig(@args);
    ...

    return ...;
});
```

  The original sub is passed in as the first argument, even before `$self`. You are responsible for making sure your wrapper sub returns the correct thing.

- $mock->autoload

  This will inject an `AUTOLOAD` sub into the class. This autoload will automatically generate read-write accessors for any sub called that does not already exist.

- $mock->block_load

  This will prevent the real class from loading until the mock is destroyed. This will fail if the class is already loaded. This will let you mock a class completely without loading the original module.

- $pm_file = $mock->file

  This returns the relative path to the file for the module. This corresponds to the `%INC` entry.

- $bool = $mock->purge_on_destroy($bool)

  When true, this will cause the package stash to be completely obliterated when the mock object falls out of scope or is otherwise destroyed. You do not normally want this.

- $stash = $mock->stash

  This returns the stash for the class being mocked. This is the equivalent of:

  ```
  my $stash = \%{"${class}\::"};
  ```

  This saves you from needing to turn off strict.

- $class = $mock->class

  The class being mocked by this instance.

- $p = $mock->parent

  If you mock a class twice the first instance is the parent, the second is the child. This prevents the parent from being destroyed before the child, which would lead to a very unpleasant situation.

- $c = $mock->child

  Returns the child mock, if any.

Test2::Plugin

Documentation for plugins

DESCRIPTION

Plugins are packages that cause behavior changes, or other side-effects for the test file that loads them. They should not export any functions, or provide any tools. Plugins should be distinct units of functionality.

If you wish to combine behavior changes with tools then you should write a Plugin, a Tools module, and a bundle that loads them both.

FAQ

- Should I subclass Test2::Plugin?

  No. Currently this class is empty. Eventually we may want to add behavior, in which case we do not want anyone to already be subclassing it.

HOW DO I WRITE A PLUGIN?

Writing a plugin is not as simple as writing an *Test2::Bundle*, or writing *Test2::Tools*. Plugins alter behavior, or cause desirable side-effects. To accomplish this you typically need a custom `import()` method that calls one or more functions provided by the *Test2::API* package.

If you want to write a plugin you should look at existing plugins, as well as the *Test2::API* and *Test2::Hub* documentation. There is no formula for a Plugin, they are generally unique, however consistent rules are that they should not load other plugins, or export any functions.

Modules

- `Test2::Plugin::BailOnFail` - Automatically bail out of testing on the first test failure.
- `Test2::Plugin::DieOnFail` - Automatically die on the first test failure.
- `Test2::Plugin::ExitSummary` - Add extra diagnostics on failure at the end of the test.
- `Test2::Plugin::SRand` - Control the random seed for more controlled test environments.
- `Test2::Plugin::Times` - Output timing data at the end of the test.
- `Test2::Plugin::UTF8` - Test2 plugin to test with utf8.

Test2::Plugin::BailOnFail

Automatically bail out of testing on the first test failure.

DESCRIPTION

This module will issue a bailout event after the first test failure. This will prevent your tests from continuing. The bailout runs when the context is released; that is, it will run when the test function you are using, such as `ok()`, returns. This gives the tools the ability to output any extra diagnostics they may need.

SYNOPSIS

```
use Test2::V1;
use Test2::Plugin::BailOnFail;

T2->ok(1, "pass");
T2->ok(0, "fail");
T2->ok(1, "Will not run");
```

SOURCE

The source code repository for Test2-Suite can be found at `https://github.com/Test-More/test-more/`.

See `http://dev.perl.org/licenses/`

Test2::Plugin::DieOnFail

Automatically die on the first test failure.

DESCRIPTION

This module will die after the first test failure. This will prevent your tests from continuing. The exception is thrown when the context is released, that is it will run when the test function you are using, such as `ok()`, returns. This gives the tools the ability to output any extra diagnostics they may need.

SYNOPSIS

```
use Test2::V1;
use Test2::Plugin::DieOnFail;

T2->ok(1, "pass");
T2->ok(0, "fail");
T2->ok(1, "Will not run");
```

SOURCE

The source code repository for Test2-Suite can be found at `https://github.com/Test-More/test-more/`.

Test2::Plugin::ExitSummary

Add extra diagnostics on failure at the end of the test.

DESCRIPTION

This will provide some diagnostics after a failed test. These diagnostics can range from telling you how you deviated from your plan, warning you if there was no plan, etc. People used to *Test::More* generally expect these diagnostics.

SYNOPSIS

```
use Test2::Plugin::ExitSummary;
```

SOURCE

The source code repository for Test2-Suite can be found at `https://github.com/Test-More/test-more/`.

Test2::Plugin::SRand

Control the random seed for more controlled test environments.

DESCRIPTION

This module gives you control over the random seed used for your unit tests. In some testing environments the random seed can play a major role in results.

The default configuration for this module will seed srand with the local date. Using the date as the seed means that on any given day the random seed will always be the same, this means behavior will not change from run to run on a given day. However the seed is different on different days allowing you to be sure the code still works with actual randomness.

The seed is printed for you on failure, or when the harness is verbose. You can use the `T2_RAND_SEED` environment variable to specify the seed. You can also provide a specific seed as a load-time argument to the plugin.

SYNOPSIS

Loading the plugin is easy, and the defaults are sane:

```
use Test2::Plugin::SRand;
```

Custom seed:

```
use Test2::Plugin::SRand seed => 42;
```

NOTE ON LOAD ORDER

If you use this plugin you probably want to use it as the first, or near-first plugin. `srand` is not called until the plugin is loaded, so other plugins loaded first may already be making use of random numbers before your seed takes effect.

CAVEATS

When srand is on (default) it can cause problems with things like *File::Temp* which will end up attempting the same "random" filenames for every test process started on a given day (or sharing the same seed).

SOURCE

The source code repository for Test2-Suite can be found at `https://github.com/Test-More/test-more/`.

MAINTAINERS

- Chad Granum exodist@cpan.org

AUTHORS

- Chad Granum exodist@cpan.org

Test2::Plugin::Times

Output timing data at the end of the test.

CAVEAT

It is important to note that this timing data does not include global destruction. This data is only collected up until the point done_testing() is called. If your program takes time for END blocks, garbage collection, and similar, then this timing data will fall short of reality.

DESCRIPTION

This plugin will output a diagnostics message at the end of testing that tells you how much time elapsed, and how hard the system worked on the test.

This will produce a string like one of these (Note these numbers are completely made up). *Which string is used depends on the time elapsed.*

```
0.12345s on wallclock (0.05 usr 0.00 sys + 0.00 cusr 0.00 csys = 0.
↪05 CPU)

11.1234s on wallclock (0.05 usr 0.00 sys + 0.00 cusr 0.00 csys = 0.
↪05 CPU)

01m:54.45s on wallclock (0.05 usr 0.00 sys + 0.00 cusr 0.00 csys =␣
↪0.05 CPU)

18h:22m:54.45s on wallclock (0.05 usr 0.00 sys + 0.00 cusr 0.00 csys␣
↪= 0.05 CPU)

04d:18h:22m:54.45s on wallclock (0.05 usr 0.00 sys + 0.00 cusr 0.00␣
↪csys = 0.05 CPU)
```

SYNOPSIS

```
use Test2::Plugin::Times;
```

This is also useful at the command line for 1-time use:

```
$ perl -MTest2::Plugin::Times path/to/test.t
```

SOURCE

The source code repository for Test2-Suite can be found at `https://github.com/Test-More/test-more/`.

Test2::Plugin::UTF8

Test2 plugin to test with utf8.

DESCRIPTION

When used, this plugin will make tests work with utf8. This includes turning on the utf8 pragma and updating the Test2 output formatter to use utf8.

SYNOPSIS

```
use Test2::Plugin::UTF8;
```

This is similar to:

```
use utf8;
BEGIN {
    require Test2::Tools::Encoding;
    Test2::Tools::Encoding::set_encoding('utf8');
}
```

You can also disable the utf8 import by using 'encoding_only' to only enable utf8 encoding on the output format.

```
use Test2::Plugin::UTF8 qw(encoding_only);
```

import options

encoding_only

Does not import utf8 in your test and only enables the encoding mode on the output.

NOTES

This module currently sets output handles to have the ':utf8' output layer. Some might prefer ':encoding(utf-8)' which is more strict about verifying characters. There is a debate about whether or not encoding to utf8 from perl internals can ever fail, so it may not matter. This was also chosen because the alternative causes threads to segfault, see perlbug 31923.

Test2::Require

Base class and documentation for skip-unless type test packages.

DESCRIPTION

Test2::Require::* packages are packages you load to ensure your test file is skipped unless a specific requirement is met. Modules in this namespace may subclass *Test2::Require* if they wish, but it is not strictly necessary to do so.

HOW DO I WRITE A 'REQUIRE' MODULE?

AS A SUBCLASS

```
package Test2::Require::Widget;
use strict;
use warnings;

use base 'Test2::Require';

sub HAVE_WIDGETS { ... };

sub skip {
    my $class = shift;
    my @import_args = @_;

    if (HAVE_WIDGETS()) {
        # We have widgets, do not skip
        return undef;
    }
    else {
        # No widgets, skip the test
        return "Skipped because there are no widgets" unless HAVE_
↪WIDGETS();
    }
}

1;
```

A subclass of *Test2::Require* simply needs to implement a `skip()` method. This method will receive all import arguments. This method should return undef if the test should run, and should return a reason for skipping if the test should be skipped.

STAND-ALONE

If you do not wish to subclass *Test2::Require* then you should write an `import()` method:

```
package Test2::Require::Widget;
use strict;
use warnings;

use Test2::API qw/context/;

sub HAVE_WIDGETS { ... };

sub import {
    my $class = shift;

    # Have widgets, should run.
    return if HAVE_WIDGETS();
```

(continues on next page)

(continued from previous page)

```
    # Use the context object to create the event
    my $ctx = context();
    $ctx->plan(0, SKIP => "Skipped because there are no widgets");
    $ctx->release;
}

1;
```

Modules

- `Test2::Require::AuthorTesting` - Only run a test when the AUTHOR_TESTING environment variable is set.
- `Test2::Require::AutomatedTesting` - Only run a test when the AUTOMATED_TESTING environment variable is set.
- `Test2::Require::EnvVar` - Only run a test when a specific environment variable is set.
- `Test2::Require::ExtendedTesting` - Only run a test when the EXTENDED_TESTING environment variable is set.
- `Test2::Require::Fork` - Skip a test file unless the system supports forking
- `Test2::Require::Module` - Skip tests if certain packages are not installed, or insufficient versions.
- `Test2::Require::NonInteractiveTesting` - Only run a test when the NONINTERACTIVE_TESTING environment variable is set.

- `Test2::Require::Perl` - Skip the test unless the necessary version of Perl is installed.
- `Test2::Require::RealFork` - Skip a test file unless the system supports true forking
- `Test2::Require::ReleaseTesting` - Only run a test when the RELEASE_TESTING environment variable is set.
- `Test2::Require::Threads` - Skip a test file unless the system supports threading

Test2::Require::AuthorTesting

Only run a test when the AUTHOR_TESTING environment variable is set.

DESCRIPTION

It is common practice to write tests that are only run when the AUTHOR_TESTING environment variable is set. This module automates the (admittedly trivial) work of creating such a test.

SYNOPSIS

```
use Test2::Require::AuthorTesting;

...

done_testing;
```

SOURCE

The source code repository for Test2-Suite can be found at `https://github.com/Test-More/test-more/`.

Test2::Require::AutomatedTesting

Only run a test when the AUTOMATED_TESTING environment variable is set.

DESCRIPTION

It is common practice to write tests that are only run when the AUTOMATED_TESTING environment variable is set. This module automates the (admittedly trivial) work of creating such a test.

SYNOPSIS

```
use Test2::Require::AutomatedTesting;

...

done_testing;
```

SOURCE

The source code repository for Test2-Suite can be found at `https://github.com/Test-More/test-more/`.

Test2::Require::EnvVar

Only run a test when a specific environment variable is set.

DESCRIPTION

It is common practice to write tests that are only run when an environment variable is set. This module automates the (admittedly trivial) work of creating such a test.

SYNOPSIS

```
use Test2::Require::EnvVar 'SOME_VAR';

...

done_testing;
```

SOURCE

The source code repository for Test2-Suite can be found at `https://github.com/Test-More/test-more/`.

See `http://dev.perl.org/licenses/`

Test2::Require::ExtendedTesting

Only run a test when the EXTENDED_TESTING environment variable is set.

DESCRIPTION

It is common practice to write tests that are only run when the EXTENDED_TESTING environment variable is set. This module automates the (admittedly trivial) work of creating such a test.

SYNOPSIS

```
use Test2::Require::ExtendedTesting;

...

done_testing;
```

SOURCE

Test2::Require::Fork

Skip a test file unless the system supports forking

DESCRIPTION

It is fairly common to write tests that need to fork. Not all systems support forking. This library does the hard work of checking if forking is supported on the current system. If forking is not supported then this will skip all tests and exit true.

SYNOPSIS

```
use Test2::Require::Fork;

... Code that forks ...
```

EXPLANATION

Checking if the current system supports forking is not simple. Here is an example of how to do it:

```
use Config;

sub CAN_FORK {
    return 1 if $Config{d_fork};

    # Some platforms use ithreads to mimic forking
    return 0 unless $^O eq 'MSWin32' || $^O eq 'NetWare';
```

(continues on next page)

(continued from previous page)

```
    return 0 unless $Config{useithreads};
    return 0 unless $Config{ccflags} =~ /-DPERL_IMPLICIT_SYS/;

    # Threads are not reliable before 5.008001
    return 0 unless $] >= 5.008001;

    # Devel::Cover currently breaks with threads
    return 0 if $INC{'Devel/Cover.pm'};
    return 1;
}
```

Duplicating this non-trivial code in all tests that need to fork is error-prone. It is easy to forget bits, or get it wrong. On top of these checks, you also need to tell the harness that no tests should run and why.

SEE ALSO

- *Test2::Require::RealFork*

  Similar to this module, but will skip on any perl that only has fork emulation.

- *Test2::Require::Threads*

  Skip the test file if the system does not support threads.

SOURCE

The source code repository for Test2-Suite can be found at `https://github.com/Test-More/test-more/`.

Test2::Require::Module

Skip tests if certain packages are not installed, or insufficient versions.

DESCRIPTION

Sometimes you have tests that are nice to run, but depend on tools that may not be available. Instead of adding the tool as a dep, or making the test always skip, it is common to make the test run conditionally. This package helps make that possible.

This module is modeled after Test::Requires. The difference is that this module is based on *Test2* directly, and does not go through *Test::Builder*. Another difference is that the packages you check for are not imported into your namespace for you. This is intentional.

SYNOPSIS

```
# The test will be skipped unless Some::Module is installed, any␣
 ↪version.
use Test2::Require::Module 'Some::Module';

# The test will be skipped unless 'Other::Module' is installed and␣
 ↪at
# version '5.555' or greater.
use Test2::Require::Module 'Other::Module' => '5.555';

# We now need to use them directly, Test2::Require::Module does not␣
 ↪import
# them for us.
use Some::Module;
use Other::Module;
```

SOURCE

The source code repository for Test2-Suite can be found at `https://github.com/Test-More/test-more/`.

Test2::Require::NonInteractiveTesting

Only run a test when the NONINTERACTIVE_TESTING environment variable is set.

DESCRIPTION

It is common practice to write tests that are only run when the NONINTERACTIVE_TESTING environment variable is set. This module automates the (admittedly trivial) work of creating such a test.

SYNOPSIS

```
use Test2::Require::NonInteractiveTesting;

...

done_testing;
```

SOURCE

The source code repository for Test2-Suite can be found at https://github.com/Test-More/test-more/.

Test2::Require::Perl

Skip the test unless the necessary version of Perl is installed.

DESCRIPTION

Sometimes you have tests that are nice to run, but depend on a certain version of Perl. This package lets you run the test conditionally, depending on if the correct version of Perl is available.

SYNOPSIS

```
# Skip the test unless perl 5.10 or greater is installed.
use Test2::Require::Perl 'v5.10';

# Enable 5.10 features.
use v5.10;
```

SOURCE

The source code repository for Test2-Suite can be found at `https://github.com/Test-More/test-more/`.

Test2::Require::RealFork

Skip a test file unless the system supports true forking

DESCRIPTION

It is fairly common to write tests that need to fork. Not all systems support forking. This library does the hard work of checking if forking is supported on the current system. If forking is not supported then this will skip all tests and exit true.

SYNOPSIS

```
use Test2::Require::RealFork;

... Code that forks ...
```

SEE ALSO

- *Test2::Require::Fork*

  Similar to this module, but will allow fork emulation.

- *Test2::Require::Threads*

  Skip the test file if the system does not support threads.

SOURCE

The source code repository for Test2-Suite can be found at `https://github.com/Test-More/test-more/`.

Test2::Require::ReleaseTesting

Only run a test when the RELEASE_TESTING environment variable is set.

DESCRIPTION

It is common practice to write tests that are only run when the RELEASE_TESTING environment variable is set. This module automates the (admittedly trivial) work of creating such a test.

SYNOPSIS

```
use Test2::Require::ReleaseTesting;

...

done_testing;
```

SOURCE

The source code repository for Test2-Suite can be found at `https://github.com/Test-More/test-more/`.

Test2::Require::Threads

Skip a test file unless the system supports threading

DESCRIPTION

It is fairly common to write tests that need to use threads. Not all systems support threads. This library does the hard work of checking if threading is supported on the current system. If threading is not supported then this will skip all tests and exit true.

SYNOPSIS

```
use Test2::Require::Threads;

... Code that uses threads ...
```

EXPLANATION

Checking if the current system supports threading is not simple, here is an example of how to do it:

```
use Config;

sub CAN_THREAD {
    # Threads are not reliable before 5.008001
    return 0 unless $] >= 5.008001;
    return 0 unless $Config{'useithreads'};

    # Devel::Cover currently breaks with threads
    return 0 if $INC{'Devel/Cover.pm'};
    return 1;
}
```

Duplicating this non-trivial code in all tests that need to use threads is error-prone. It is easy to forget bits, or get it wrong. On top of these checks you also need to tell the harness that no tests should run and why.

SEE ALSO

- *Test2::Require::Fork*

  Skip the test file if the system does not support forking.

- *Test2*

  Test2::Require::Threads uses *Test2* under the hood.

Test2::Suite

Distribution with a rich set of tools built upon the Test2 framework.

DESCRIPTION

Rich set of tools, plugins, bundles, etc built upon the *Test2* testing library. If you are interested in writing tests, this is the distribution for you.

WHAT ARE TOOLS, PLUGINS, AND BUNDLES?

- TOOLS

  Tools are packages that export functions for use in test files. These functions typically generate events. Tools **SHOULD NEVER** alter behavior of other tools, or the system in general.

- PLUGINS

  Plugins are packages that produce effects, or alter behavior of tools. An example would be a plugin that causes the test to bail out after the first failure. Plugins **SHOULD NOT** export anything.

- BUNDLES

  Bundles are collections of tools and plugins. A bundle should load and re-export functions from Tool packages. A bundle may also load and configure any number of plugins.

If you want to write something that both exports new functions, and affects behavior, you should write both a Tools distribution, and a Plugin distribution, then a Bundle that loads them both. This is important as it helps avoid the problem where a package exports much-desired tools, but also produces undesirable side-effects.

INCLUDED BUNDLES

- Test2::V#

  These do not live in the bundle namespace as they are the primary ways to use Test2::Suite.

  The current latest is *Test2::V1*.

  ```
  use Test2::V1;

  T2->ok(...);

  # Note: is does deep checking, unlike the 'is' from Test::More.
  $T2->is(...);

  ...

  T2->done_testing;
  ```

  See *Test2::V1* for complete documentation.

- Extended

  ** **Deprecated** ** See *Test2::V0* or *Test2::V1*.

```
use Test2::Bundle::Extended;
# strict and warnings are on for you now.

ok(...);

# Note: is does deep checking, unlike the 'is' from Test::More.
is(...);

...

done_testing;
```

  This bundle includes every tool listed in the "INCLUDED TOOLS" section below, except for *Test2::Tools::ClassicCompare*. This bundle provides most of what anyone writing tests could need. This is also the preferred bundle/toolset of the *Test2* author.

  See *Test2::Bundle::Extended* for complete documentation.

- More

```
use Test2::Bundle::More;
use strict;
use warnings;

plan 3; # Or you can use done_testing at the end

ok(...);

is(...); # Note: String compare

is_deeply(...);

...

done_testing; # Use instead of plan
```

  This bundle is meant to be a *mostly* drop-in replacement for *Test::More*. There are some notable differences to be aware of however. Some exports are missing: `eq_array`, `eq_hash`, `eq_set`, `$TODO`, `explain`, `use_ok`, `require_ok`. As well it is no longer possible to set the plan at import: `use .. tests => 5`. `$TODO` has been replaced by the `todo()` function. Planning is done using `plan`, `skip_all`, or `done_testing`.

  See *Test2::Bundle::More* for complete documentation.

- Simple

```
use Test2::Bundle::Simple;
use strict;
```

(continues on next page)

(continued from previous page)

```
use warnings;

plan 1;

ok(...);
```

This bundle is meant to be a *mostly* drop-in replacement for *Test::Simple*. See *Test2::Bundle::Simple* for complete documentation.

INCLUDED TOOLS

- Basic

  Basic provides most of the essential tools previously found in *Test::More*. However it does not export any tools used for comparison. The basic `pass`, `fail`, `ok` functions are present, as are functions for planning.

  See *Test2::Tools::Basic* for complete documentation.

- Compare

  This provides `is`, `like`, `isnt`, `unlike`, and several additional helpers. **Note:** These are all *deep* comparison tools and work like a combination of *Test::More*'s `is` and `is_deeply`.

  See *Test2::Tools::Compare* for complete documentation.

- ClassicCompare

  This provides *Test::More* flavored `is`, `like`, `isnt`, `unlike`, and `is_deeply`. It also provides `cmp_ok`.

  See *Test2::Tools::ClassicCompare* for complete documentation.

- Class

  This provides functions for testing objects and classes, things like `isa_ok`.

  See *Test2::Tools::Class* for complete documentation.

- Defer

  This provides functions for writing test functions in one place, but running them later. This is useful for testing things that run in an altered state.

  See *Test2::Tools::Defer* for complete documentation.

- Encoding

  This exports a single function that can be used to change the encoding of all your test output.

  See *Test2::Tools::Encoding* for complete documentation.

- Exports

  This provides tools for verifying exports. You can verify that functions have been imported, or that they have not been imported.

  See *Test2::Tools::Exports* for complete documentation.

- Mock

  This provides tools for mocking objects and classes. This is based largely on Mock::Quick, but several interface improvements have been added that cannot be added to Mock::Quick itself without breaking backwards compatibility.

  See *Test2::Tools::Mock* for complete documentation.

- Ref

  This exports tools for validating and comparing references.

  See *Test2::Tools::Ref* for complete documentation.

- Spec

  This is an RSPEC implementation with concurrency support.

  See *Test2::Tools::Spec* for more details.

- Subtest

  This exports tools for running subtests.

  See *Test2::Tools::Subtest* for complete documentation.

- Target

  This lets you load the package(s) you intend to test, and alias them into constants/package variables.

  See *Test2::Tools::Target* for complete documentation.

INCLUDED PLUGINS

- BailOnFail

  The much requested “bail-out on first failure” plugin. When this plugin is loaded, any failure will cause the test to bail out immediately.

  See *Test2::Plugin::BailOnFail* for complete documentation.

- DieOnFail

  The much requested “die on first failure” plugin. When this plugin is loaded, any failure will cause the test to die immediately.

  See *Test2::Plugin::DieOnFail* for complete documentation.

- ExitSummary

  This plugin gives you statistics and diagnostics at the end of your test in the event of a failure.

  See *Test2::Plugin::ExitSummary* for complete documentation.

- SRand

  Use this to set the random seed to a specific seed, or to the current date.

  See *Test2::Plugin::SRand* for complete documentation.

- UTF8

  Turn on utf8 for your testing. This sets the current file to be utf8, it also sets STDERR, STDOUT, and your formatter to all output utf8.

  See *Test2::Plugin::UTF8* for complete documentation.

INCLUDED REQUIREMENT CHECKERS

- AuthorTesting

  Using this package will cause the test file to be skipped unless the AUTHOR_TESTING environment variable is set.

  See *Test2::Require::AuthorTesting* for complete documentation.

- EnvVar

  Using this package will cause the test file to be skipped unless a custom environment variable is set.

  See *Test2::Require::EnvVar* for complete documentation.

- Fork

  Using this package will cause the test file to be skipped unless the system is capable of forking (including emulated forking).

  See *Test2::Require::Fork* for complete documentation.

- RealFork

  Using this package will cause the test file to be skipped unless the system is capable of true forking.

  See *Test2::Require::RealFork* for complete documentation.

- Module

  Using this package will cause the test file to be skipped unless the specified module is installed (and optionally at a minimum version).

  See *Test2::Require::Module* for complete documentation.

- Perl

  Using this package will cause the test file to be skipped unless the specified minimum perl version is met.

  See *Test2::Require::Perl* for complete documentation.

- Threads

  Using this package will cause the test file to be skipped unless the system has threading enabled.

  Note: This will not turn threading on for you.

  See *Test2::Require::Threads* for complete documentation.

SEE ALSO

See the *Test2* documentation for a namespace map. Everything in this distribution uses *Test2*.

Test2::Manual is the Test2 Manual.

CONTACTING US

Many Test2 developers and users lurk on irc://irc.perl.org/#perl. We also have a slack team that can be joined by anyone with an `@cpan.org` email address https://perl-test2.slack.com/ If you do not have an `@cpan.org` email you can ask for a slack invite by emailing Chad Granum exodist@cpan.org.

Test2::Todo

TODO extension for Test2.

DESCRIPTION

This is an object that lets you create and manage TODO states for tests. This is an extension, not a plugin or a tool. This library can be used by plugins and tools to manage todo states.

If you simply want to write a todo test then you should look at the `todo` function provided by *Test2::Tools::Basic*.

SYNOPSIS

```
use Test2::Todo;

# Start the todo
my $todo = Test2::Todo->new(reason => 'Fix later');

# Will be considered todo, so suite still passes
ok(0, "oops");

# End the todo
$todo->end;

# TODO has ended, this test will actually fail.
ok(0, "oops");
```

CONSTRUCTION OPTIONS

- reason (required)

  The reason for the todo, this can be any defined value.

- hub (optional)

  The hub to which the TODO state should be applied. If none is provided then the current global hub is used.

INSTANCE METHODS

- $todo->end

  End the todo state.

CLASS METHODS

- $count = Test2::Todo->hub_in_todo($hub)

  If the hub has any todo objects this will return the total number of them. If the hub has no todo objects it will return 0.

OTHER NOTES

How it works

When an instance is created a filter sub is added to the *Test2::Hub*. This filter will set the `todo` and `diag_todo` attributes on all events as they come in. When the instance is destroyed, or `end()` is called, the filter is removed.

When a new hub is pushed (such as when a subtest is started) the new hub will inherit the filter, but it will only set `diag_todo`, it will not set `todo` on events in child hubs.

$todo->end is called at destruction

If your `$todo` object falls out of scope and gets garbage collected, the todo will end.

Can I use multiple instances?

Yes. The most recently created one that is still active will win.

Test2::Tools

Documentation for Tools.

DESCRIPTION

Tools are packages that export test functions, typically all related to a specific aspect of testing. If you have a couple different categories of exports then you may want to break them into separate modules.

Tools should export testing functions. Loading tools **should not** have side- effects, or alter the behavior of other tools. If you want to alter behaviors or create side-effects then you probably want to write a *Test2::Plugin*.

FAQ

- Why is it called Test2::Tools, and not Test2::Tool?

  This question arises since Tools is the only namespace in the plural. This is because each Plugin should be a distinct unit of functionality, but a Tools dist can (and usually should) export several tools. A bundle is also typically described as a single unit. Nobody would like Test2::Bundles::Foo.

- Should my tools subclass Test2::Tools?

  No. Currently this class is empty. Eventually we may want to add behavior, in which case we do not want anyone to already be subclassing it.

HOW DO I WRITE A 'TOOLS' MODULE?

It is very easy to write tools:

```
package Test2::Tools::Mine
use strict;
use warnings;

# All tools should use the context() function.
use Test2::API qw/context/;

our @EXPORTS = qw/ok plan/;
use base 'Exporter';

sub ok($;$) {
    my ($bool, $name) = @_;

    # All tool functions should start by grabbing a context
    my $ctx = context();

    # The context is the primary interface for generating events
    $ctx->ok($bool, $name);

    # When you are done you release the context
    $ctx->release;

    return $bool ? 1 : 0;
}

sub plan {
    my ($max) = @_;
    my $ctx = context();
    $ctx->plan($max);
    $ctx->release;
}

1;
```

See *Test2::API::Context* for documentation on what the `$ctx` object can do.

Modules

- `Test2::Tools::AsyncSubtest` - Tools for writing async subtests.
- `Test2::Tools::Basic` - Test2 implementation of the basic testing tools.
- `Test2::Tools::Class` - Test2 implementation of the tools for testing classes.
- `Test2::Tools::ClassicCompare` - Classic (Test::More style) comparison tools.
- `Test2::Tools::Compare` - Tools for comparing deep data structures.
- `Test2::Tools::Defer` - Write tests that get executed at a later time
- `Test2::Tools::Encoding` - Tools for managing the encoding of *Test2* based tests.
- `Test2::Tools::Event` - Tools for generating test events.
- `Test2::Tools::Exception` - Test2 based tools for checking exceptions
- `Test2::Tools::Exports` - Tools for validating exporters.
- `Test2::Tools::GenTemp` - Tool for generating a populated temp directory.
- `Test2::Tools::Grab` - Temporarily intercept all events without adding a scope level.
- `Test2::Tools::Mock` - Class/Instance mocking for Test2.
- `Test2::Tools::Ref` - Tools for validating references.
- `Test2::Tools::Refcount` - assert reference counts on objects
- `Test2::Tools::Spec` - RSPEC implementation on top of Test2::Workflow
- `Test2::Tools::Subtest` - Tools for writing subtests
- `Test2::Tools::Target` - Alias the testing target package.
- `Test2::Tools::Tester` - Tools to help you test other testing tools.
- `Test2::Tools::Tiny` - Tiny set of tools for unfortunate souls who cannot use *Test2::Suite*.
- `Test2::Tools::Warnings` - Tools to verify warnings.

Test2::Tools::AsyncSubtest

Tools for writing async subtests.

DESCRIPTION

These are tools for writing async subtests. Async subtests are subtests which can be started and stashed so that they can continue to receive events while other events are also being generated.

SYNOPSIS

```
use Test2::Bundle::Extended;
use Test2::Tools::AsyncSubtest;

my $ast1 = async_subtest local => sub {
    ok(1, "Inside subtest");
};

my $ast2 = fork_subtest child => sub {
    ok(1, "Inside subtest in another process");
};

# You must call finish on the subtests you create. Finish will wait/
 ↪join on
# any child processes and threads.
$ast1->finish;
$ast2->finish;

done_testing;
```

EXPORTS

Everything is exported by default.

- $ast = async_subtest $name
- $ast = async_subtest $name => sub { ... }
- $ast = async_subtest $name => \%hub_params, sub { ... }

  Create an async subtest. Run the codeblock if it is provided.
- $ast = fork_subtest $name => sub { ... }
- $ast = fork_subtest $name => \%hub_params, sub { ... }

  Create an async subtest. Run the codeblock in a forked process.
- $ast = thread_subtest $name => sub { ... }
- $ast = thread_subtest $name => \%hub_params, sub { ... }

  ** **DISCOURAGED** ** Threads are fragile. Thread tests are not even run unless the AUTHOR_TESTING or T2_DO_THREAD_TESTS env vars are enabled.

Create an async subtest. Run the codeblock in a thread.

NOTES

- Async Subtests are always buffered.

  Always buffered.

- Do not use done_testing() yourself.

  using done_testing() inside an async subtest will not work properly, the async subtest must be finalized by calling `$st->finish`.

SOURCE

The source code repository for Test2-AsyncSubtest can be found at `https://github.com/Test-More/test-more/`.

Test2::Tools::Basic

Test2 implementation of the basic testing tools.

DESCRIPTION

This is a *Test2* based implementation of the more basic tools originally provided by *Test::More*. Not all *Test::More* tools are provided by this package, only the basic/simple ones. Some tools have been modified for better diagnostics capabilities.

SYNOPSIS

```
use Test2::Tools::Basic;

ok($x, "simple test");
```

(continues on next page)

(continued from previous page)

```
if ($passing) {
    pass('a passing test');
}
else {
    fail('a failing test');
}

diag "This is a diagnostics message on STDERR";
note "This is a diagnostics message on STDOUT";

{
    my $todo = todo "Reason for todo";
    ok(0, "this test is todo");
}

ok(1, "this test is not todo");

todo "reason" => sub {
    ok(0, "this test is todo");
};

ok(1, "this test is not todo");

SKIP: {
    skip "This will wipe your drive";

    # This never gets run:
    ok(!system('sudo rm -rf /'), "Wipe drive");
}

done_testing;
```

EXPORTS

All subs are exported by default.

PLANNING

- plan($num)
- plan('tests' => $num)
- plan('skip_all' => $reason)

  Set the number of tests that are expected. This must be done first or last, never in the middle of testing.

  For legacy compatibility you can specify 'tests' as the first argument before the number. You can also use this to skip all with the 'skip_all' prefix, followed by a reason for skipping.

- skip_all($reason)

Set the plan to 0 with a reason, then exit true. This should be used before any tests are run.

- done_testing

  Used to mark the end of testing. This is a safe way to have a dynamic or unknown number of tests.

- bail_out($reason)

  Invoked when something has gone horribly wrong: stop everything, kill all threads and processes, end the process with a false exit status.

ASSERTIONS

- ok($bool)
- ok($bool, $name)
- ok($bool, $name, @diag)

  Simple assertion. If `$bool` is true the test passes, and if it is false the test fails. The test name is optional, and all arguments after the name are added as diagnostics message if and only if the test fails. If the test passes all the diagnostics arguments will be ignored.

- pass()
- pass($name)

  Fire off a passing test (a single Ok event). The name is optional

- fail()
- fail($name)
- fail($name, @diag)

  Fire off a failing test (a single Ok event). The name and diagnostics are optional.

DIAGNOSTICS

- diag(@messages)

  Write diagnostics messages. All items in `@messages` will be joined into a single string with no separator. When using TAP, diagnostics are sent to STDERR.

  Returns false, so as to preserve failure.

- note(@messages)

  Write note-diagnostics messages. All items in `@messages` will be joined into a single string with no separator. When using TAP, notes are sent to STDOUT.

META

- $todo = todo($reason)

- todo $reason => sub { ... }

  This is used to mark some results as TODO. TODO means that the test may fail, but will not cause the overall test suite to fail.

  There are two ways to use this. The first is to use a codeblock, and the TODO will only apply to the codeblock.

```
ok(1, "before"); # Not TODO

todo 'this will fail' => sub {
    # This is TODO, as is any other test in this block.
    ok(0, "blah");
};

ok(1, "after"); # Not TODO
```

  The other way is to use a scoped variable. TODO will end when the variable is destroyed or set to undef.

```
ok(1, "before"); # Not TODO

{
    my $todo = todo 'this will fail';

    # This is TODO, as is any other test in this block.
    ok(0, "blah");
};

ok(1, "after"); # Not TODO
```

  This is the same thing, but without the `{...}` scope.

```
ok(1, "before"); # Not TODO

my $todo = todo 'this will fail';

ok(0, "blah"); # TODO

$todo = undef;

ok(1, "after"); # Not TODO
```

- skip($why)
- skip($why, $count)

  This is used to skip some tests. This requires you to wrap your tests in a block labeled `SKIP:`. This is somewhat magical. If no `$count` is specified then it will issue a single result. If you specify `$count` it will issue that many results.

```
SKIP: {
    skip "This will wipe your drive";
```

(continues on next page)

(continued from previous page)

```
    # This never gets run:
    ok(!system('sudo rm -rf /'), "Wipe drive");
}
```

Test2::Tools::Class

Test2 implementation of the tools for testing classes.

DESCRIPTION

Test2 based tools for validating classes and objects. These are similar to some tools from *Test::More*, but they have a more consistent interface.

SYNOPSIS

```
use Test2::Tools::Class;

isa_ok($CLASS_OR_INSTANCE, $PARENT_CLASS1, $PARENT_CLASS2, ...);
isa_ok($CLASS_OR_INSTANCE, [$PARENT_CLASS1, $PARENT_CLASS2, ...],
 ↪"Test Name");

can_ok($CLASS_OR_INSTANCE, $METHOD1, $METHOD2, ...);
can_ok($CLASS_OR_INSTANCE, [$METHOD1, $METHOD2, ...], "Test Name");

DOES_ok($CLASS_OR_INSTANCE, $ROLE1, $ROLE2, ...);
DOES_ok($CLASS_OR_INSTANCE, [$ROLE1, $ROLE2, ...], "Test Name");
```

EXPORTS

All subs are exported by default.

- can_ok($thing, @methods)
- can_ok($thing, \@methods, $test_name)

  This checks that `$thing` (either a class name, or a blessed instance) has the specified methods.

  If the second argument is an arrayref then it will be used as the list of methods leaving the third argument to be the test name.

- isa_ok($thing, @classes)
- isa_ok($thing, \@classes, $test_name)

  This checks that `$thing` (either a class name, or a blessed instance) is or subclasses the specified classes.

  If the second argument is an arrayref then it will be used as the list of classes leaving the third argument to be the test name.

- DOES_ok($thing, @roles)
- DOES_ok($thing, \@roles, $test_name)

  This checks that `$thing` (either a class name, or a blessed instance) does the specified roles.

  If the second argument is an arrayref then it will be used as the list of roles leaving the third argument to be the test name.

  Note 1: This uses the `$class->DOES(...)` method, not the `does()` method Moose provides.

  Note 2: Not all perls have the `DOES()` method, if you use this on those perls the test will be skipped.

Test2::Tools::ClassicCompare

Classic (Test::More style) comparison tools.

DESCRIPTION

This provides comparison functions that behave like they did in *Test::More*, unlike the *Test2::Tools::Compare* plugin which has modified them.

SYNOPSIS

```
use Test2::Tools::ClassicCompare qw/is is_deeply isnt like unlike␣
↪cmp_ok/;

is($got, $expect, "These are the same when stringified");
isnt($got, $unexpected, "These are not the same when stringified");

like($got, qr/.../, "'got' matches the pattern");
unlike($got, qr/.../, "'got' does not match the pattern");

is_deeply($got, $expect, "These structures are same when checked␣
↪deeply");

cmp_ok($GOT, $OP, $WANT, 'Compare these items using the specified␣
↪operatr');
```

EXPORTS

- $bool = is($got, $expect)
- $bool = is($got, $expect, $name)
- $bool = is($got, $expect, $name, @diag)

  This does a string comparison of the two arguments. If the two arguments are the same after stringification the test passes. The test will also pass if both arguments are undef.

  The test `$name` is optional.

  The test `@diag` is optional, it is extra diagnostics messages that will be displayed if the test fails. The diagnostics are ignored if the test passes.

  It is important to note that this tool considers `"1"` and `"1.0"` to not be equal as it uses a string comparison.

See *Test2::Tools::Compare* if you want an `is()` function that tries to be smarter for you.

- $bool = isnt($got, $dont_expect)
- $bool = isnt($got, $dont_expect, $name)
- $bool = isnt($got, $dont_expect, $name, @diag)

  This is the inverse of `is()`, it passes when the strings are not the same.

- $bool = like($got, $pattern)
- $bool = like($got, $pattern, $name)
- $bool = like($got, $pattern, $name, @diag)

  Check if `$got` matches the specified pattern. Will fail if it does not match.

  The test `$name` is optional.

  The test `@diag` is optional. It contains extra diagnostics messages that will be displayed if the test fails. The diagnostics are ignored if the test passes.

- $bool = unlike($got, $pattern)
- $bool = unlike($got, $pattern, $name)
- $bool = unlike($got, $pattern, $name, @diag)

  This is the inverse of `like()`. This will fail if `$got` matches `$pattern`.

- $bool = is_deeply($got, $expect)
- $bool = is_deeply($got, $expect, $name)
- $bool = is_deeply($got, $expect, $name, @diag)

  This does a deep check, comparing the structures in `$got` with those in `$expect`. It will recurse into hashrefs, arrayrefs, and scalar refs. All other values will be stringified and compared as strings. It is important to note that this tool considers `"1"` and `"1.0"` to not be equal as it uses a string comparison.

  This is the same as `Test2::Tools::Compare::is()`.

- cmp_ok($got, $op, $expect)
- cmp_ok($got, $op, $expect, $name)
- cmp_ok($got, $op, $expect, $name, @diag)

  Compare `$got` to `$expect` using the operator specified in `$op`. This is effectively an `eval "\$got $op \$expect"` with some other stuff to make it more sane. This is useful for comparing numbers, overloaded objects, etc.

  Overloading Note: Your input is passed as-is to the comparison. If the comparison fails between two overloaded objects, the diagnostics will try to show you the overload form that was used in comparisons. It is possible that the diagnostics will be wrong, though attempts have been made to improve them since *Test::More*.

  Exceptions: If the comparison results in an exception then the test will fail and the exception will be shown.

`cmp_ok()` has an internal list of operators it supports. If you provide an unsupported operator it will issue a warning. You can add operators to the `%Test2::Tools::ClassicCompare::OPS` hash, the key should be the operator, and the value should either be 'str' for string comparison operators, 'num' for numeric operators, or any other true value for other operators.

Supported operators:

- == (num)
- != (num)
- = (num)
- <= (num)
- (num)
- < (num)
- <=> (num)
- eq (str)
- ne (str)
- gt (str)
- lt (str)
- ge (str)
- le (str)
- cmp (str)
- !~ (str)
- =~ (str)
- &&
- ||
- xor
- or
- and
- //
- &
- |
- ~~

Test2::Tools::Compare

Tools for comparing deep data structures.

DESCRIPTION

Test::More had `is_deeply()`. This library is the *Test2* version that can be used to compare data structures, but goes a step further in that it provides tools for building a data structure specification against which you can verify your data. There are both 'strict' and 'relaxed' versions of the tools.

SYNOPSIS

```
use Test2::Tools::Compare;

# Hash for demonstration purposes
my $some_hash = {a => 1, b => 2, c => 3};

# Strict checking, everything must match
is(
    $some_hash,
    {a => 1, b => 2, c => 3},
    "The hash we got matches our expectations"
);

# Relaxed Checking, only fields we care about are checked, and we
 ↪can use a
# regex to approximate a field.
like(
    $some_hash,
    {a => 1, b => qr/\A[0-9]+\z/},
    "'a' is 1, 'b' is an integer, we don't care about 'c'."
);
```

ADVANCED

Declarative hash, array, and objects builders are available that allow you to generate specifications. These are more verbose than simply providing a hash, but have the advantage that every component you specify has a line number associated. This is helpful for debugging as the failure output will tell you not only which fields was incorrect, but also the line on which you declared the field.

```
use Test2::Tools::Compare qw{
    is like isnt unlike
    match mismatch validator
    hash array bag object meta number float rounded within string
 ↪subset bool
    in_set not_in_set check_set
    item field call call_list call_hash prop check all_items all_
 ↪keys all_vals all_values
    etc end filter_items
    T F D DF E DNE FDNE U L
    event fail_events
    exact_ref
};

is(
    $some_hash,
    hash {
        field a => 1;
        field b => 2;
        field c => 3;
    },
    "Hash matches spec"
);
```

COMPARISON TOOLS

- $bool = is($got, $expect)
- $bool = is($got, $expect, $name)
- $bool = is($got, $expect, $name, @diag)

  `$got` is the data structure you want to check. `$expect` is what you want `$got` to look like. `$name` is an optional name for the test. `@diag` is optional diagnostics messages that will be printed to STDERR in event of failure, they will not be displayed when the comparison is successful. The boolean true/false result of the comparison is returned.

  This is the strict checker. The strict checker requires a perfect match between `$got` and `$expect`. All hash fields must be specified, all array items must be present, etc. All non-scalar/hash/array/regex references must be identical (same memory address). Scalar, hash and array references will be traversed and compared. Regex references will be compared to see if they have the same pattern.

```
is(
    $some_hash,
    {a => 1, b => 2, c => 3},
    "The hash we got matches our expectations"
);
```

The only exception to strictness is when it is given an `$expect` object that was built from a specification, in which case the specification determines the strictness. Strictness only applies to literal values/references that are provided and converted to a specification for you.

```
is(
    $some_hash,
    hash {    # Note: the hash function is not exported by␣
↪default
        field a => 1;
        field b => match(qr/\A[0-9]+\z/);    # Note: The match␣
↪function is not exported by default
        # Don't care about other fields.
    },
    "The hash comparison is not strict"
);
```

This works for both deep and shallow structures. For instance you can use this to compare two strings:

```
is('foo', 'foo', "strings match");
```

Note: This is not the tool to use if you want to check if two references are the same exact reference, use `ref_is()` from the *Test2::Tools::Ref* plugin instead. *Most* of the time this will work as well, however there are problems if your reference contains a cycle and refers back to itself at some point. If this happens, an exception will be thrown to break an otherwise infinite recursion.

Note: Non-reference values will be compared as strings using eq, so that means strings '2.0' and '2' will not match, but numeric 2.0 and 2 will, since they are both stringified to '2'.

- $bool = isnt($got, $expect)
- $bool = isnt($got, $expect, $name)
- $bool = isnt($got, $expect, $name, @diag)

  Opposite of `is()`. Does all the same checks, but passes when there is a mismatch.

- $bool = like($got, $expect)
- $bool = like($got, $expect, $name)
- $bool = like($got, $expect, $name, @diag)

  `$got` is the data structure you want to check. `$expect` is what you want `$got` to look like. `$name` is an optional name for the test. `@diag` is optional diagnostics messages that will be printed to STDERR in event of failure, they will not be displayed

when the comparison is successful. The boolean true/false result of the comparison is returned.

This is the relaxed checker. This will ignore hash keys or array indexes that you do not actually specify in your `$expect` structure. In addition regex and sub references will be used as validators. If you provide a regex using `qr/.../`, the regex itself will be used to validate the corresponding value in the `$got` structure. The same is true for coderefs, the value is passed in as the first argument (and in `$_`) and the sub should return a boolean value. In this tool regexes will stringify the thing they are checking.

```
like(
    $some_hash,
    {a => 1, b => qr/\A[0-9]+\z/},
    "'a' is 1, 'b' is an integer, we don't care about other␣
↪fields"
);
```

This works for both deep and shallow structures. For instance you can use this to compare two strings:

```
like('foo bar', qr/^foo/, "string matches the pattern");
```

- $bool = unlike($got, $expect)
- $bool = unlike($got, $expect, $name)
- $bool = unlike($got, $expect, $name, @diag)

  Opposite of `like()`. Does all the same checks, but passes when there is a mismatch.

The `is()`, `isnt()`, `like()`, and `unlike()` functions can be made to dump `$got` using *Data::Dumper* when tests fail by setting the `T2_AUTO_DUMP` environment variable to "1". (Alternatively, `T2_AUTO_DUMP` can be set to the name of a Perl module providing a compatible `Dump()` method.) The `T2_AUTO_DEPARSE` environment variable can be used to enable Data::Dumper's deparsing of coderefs.

QUICK CHECKS

Note: None of these are exported by default. You need to request them.

Quick checks are a way to quickly generate a common value specification. These can be used in structures passed into `is` and `like` through the `$expect` argument.

Example:

```
is($foo, T(), '$foo has a true value');
```

- $check = T()

  This verifies that the value in the corresponding `$got` structure is true, any true value will do.

```
is($foo, T(), '$foo has a true value');
```

(continues on next page)

(continued from previous page)

```
is(
    { a => 'xxx' },
    { a => T() },
    "The 'a' key is true"
);
```

- $check = F()

  This verifies that the value in the corresponding `$got` structure is false, any false value will do, **but the value must exist**.

```
is($foo, F(), '$foo has a false value');

is(
    { a => 0 },
    { a => F() },
    "The 'a' key is false"
);
```

  It is important to note that a nonexistent value does not count as false. This check will generate a failing test result:

```
is(
    { a => 1 },
    { a => 1, b => F() },
    "The 'b' key is false"
);
```

  This will produce the following output:

```
not ok 1 - The b key is false
# Failed test "The 'b' key is false"
# at some_file.t line 10.
# +------+------------------+-------+---------+
# | PATH | GOT              | OP    | CHECK   |
# +------+------------------+-------+---------+
# | {b}  | <DOES NOT EXIST> | FALSE | FALSE() |
# +------+------------------+-------+---------+
```

  In Perl, you can have behavior that is different for a missing key vs. a false key, so it was decided not to count a completely absent value as false. See the `DNE()` shortcut below for checking that a field is missing.

  If you want to check for false and/or DNE use the `FDNE()` check.

- $check = D()

  This is to verify that the value in the `$got` structure is defined. Any value other than `undef` will pass.

  This will pass:

```
is('foo', D(), 'foo is defined');
```

This will fail:

```
is(undef, D(), 'foo is defined');
```

- $check = U()

  This is to verify that the value in the `$got` structure is undefined.

  This will pass:

```
is(undef, U(), 'not defined');
```

  This will fail:

```
is('foo', U(), 'not defined');
```

- $check = DF()

  This is to verify that the value in the `$got` structure is defined but false. Any false value other than `undef` will pass.

  This will pass:

```
is(0, DF(), 'foo is defined but false');
```

  These will fail:

```
is(undef, DF(), 'foo is defined but false');
is(1, DF(), 'foo is defined but false');
```

- $check = E()

  This can be used to check that a value exists. This is useful to check that an array has more values, or to check that a key exists in a hash, even if the value is undefined.

  These pass:

```
is(['a', 'b', undef], ['a', 'b', E()], "There is a third item␣
↪in the array");
is({a => 1, b => 2}, {a => 1, b => E()}, "The 'b' key exists in␣
↪the hash");
```

  These will fail:

```
is(['a', 'b'], ['a', 'b', E()], "Third item exists");
is({a => 1}, {a => 1, b => E()}, "'b' key exists");
```

- $check = DNE()

  This can be used to check that no value exists. This is useful to check the end bound of an array, or to check that a key does not exist in a hash.

  These pass:

```
is(['a', 'b'], ['a', 'b', DNE()], "There is no third item in␣
↪the array");
is({a => 1}, {a => 1, b => DNE()}, "The 'b' key does not exist␣
↪in the hash");
```

These will fail:

```
is(['a', 'b', 'c'], ['a', 'b', DNE()], "No third item");
is({a => 1, b => 2}, {a => 1, b => DNE()}, "No 'b' key");
```

- $check = FDNE()

  This is a combination of `F()` and `DNE()`. This will pass for a false value, or a nonexistent value.

- $check = L()

  This is to verify that the value in the `$got` structure is defined and has length. Any value other than `undef` or the empty string will pass (including references).

  These will pass:

```
is('foo', L(), 'value is defined and has length');
is([],    L(), 'value is defined and has length');
```

  These will fail:

```
is(undef, L(), 'value is defined and has length');
is('',    L(), 'value is defined and has length');
```

VALUE SPECIFICATIONS

Note: None of these are exported by default. You need to request them.

- $check = string "..."

  Verify that the value matches the given string using the eq operator.

- $check = !string "..."

  Verify that the value does not match the given string using the ne operator.

- $check = number ...;

  Verify that the value matches the given number using the == operator.

- $check = !number ...;

  Verify that the value does not match the given number using the != operator.

- $check = number_lt ...;
- $check = number_le ...;
- $check = number_ge ...;
- $check = number_gt ...;

Verify that the value is less than, less than or equal to, greater than or equal to, or greater than the given number.

- $check = float ...;

  Verify that the value is approximately equal to the given number.

  If a 'precision' parameter is specified, both operands will be rounded to 'precision' number of fractional decimal digits and compared with eq.

```
is($near_val, float($val, precision => 4), "Near 4 decimal␣
↪digits");
```

  Otherwise, the check will be made within a range of +/- 'tolerance', with a default 'tolerance' of 1e-08.

```
is( $near_val, float($val, tolerance => 0.01), "Almost there...
↪");
```

  See also `within` and `rounded`.

- $check = !float ...;

  Verify that the value is not approximately equal to the given number.

  If a 'precision' parameter is specified, both operands will be rounded to 'precision' number of fractional decimal digits and compared with eq.

  Otherwise, the check will be made within a range of +/- 'tolerance', with a default 'tolerance' of 1e-08.

  See also `!within` and `!rounded`.

- $check = within($num, $tolerance);

  Verify that the value approximately matches the given number, within a range of +/- `$tolerance`. Compared using the == operator.

  `$tolerance` is optional and defaults to 1e-08.

- $check = !within($num, $tolerance);

  Verify that the value does not approximately match the given number within a range of +/- `$tolerance`. Compared using the != operator.

  `$tolerance` is optional and defaults to 1e-08.

- $check = rounded($num, $precision);

  Verify that the value approximately matches the given number, when both are rounded to `$precision` number of fractional digits. Compared using the eq operator.

- $check = !rounded($num, $precision);

  Verify that the value does not approximately match the given number, when both are rounded to `$precision` number of fractional digits. Compared using the ne operator.

- $check = bool ...;

  Verify the value has the same boolean value as the given argument (XNOR).

- $check = !bool ...;

  Verify the value has a different boolean value from the given argument (XOR).

- $check = check_isa ...;

  Verify the value is an instance of the given class name.

- $check = !check_isa ...;

  Verify the value is not an instance of the given class name.

- $check = match qr/.../

- $check = !mismatch qr/.../

  Verify that the value matches the regex pattern. This form of pattern check will **NOT** stringify references being checked.

  Note: `!mismatch()` is documented for completion, please do not use it.

- $check = !match qr/.../

- $check = mismatch qr/.../

  Verify that the value does not match the regex pattern. This form of pattern check will **NOT** stringify references being checked.

  Note: `mismatch()` was created before overloading of `!` for `match()` was a thing.

- $check = validator(sub{ ... })

- $check = validator($NAME => sub{ ... })

- $check = validator($OP, $NAME, sub{ ... })

  The coderef is the only required argument. The coderef should check that the value is what you expect and return a boolean true or false. Optionally, you can specify a name and operator that are used in diagnostics. They are also provided to the sub itself as named parameters.

  Check the value using this sub. The sub gets the value in $_, and it receives the value and several other items as named parameters.

```
my $check = validator(sub {
    my %params = @_;

    # These both work:
    my $got = $_;
    my $got = $params{got};

    # Check if a value exists at all
    my $exists = $params{exists}

    # What $OP (if any) did we specify when creating the␣
↪validator
    my $operator = $params{operator};

    # What name (if any) did we specify when creating the␣
↪validator
```

(continues on next page)

(continued from previous page)

```
    my $name = $params{name};

    ...

    return $bool;
}
```

- $check = exact_ref($ref)

  Check that the value is exactly the same reference as the one provided.

SET BUILDERS

Note: None of these are exported by default. You need to request them.

- my $check = check_set($check1, $check2, ...)

  Check that the value matches ALL of the specified checks.

- my $check = in_set($check1, $check2, ...)

  Check that the value matches ONE OR MORE of the specified checks.

- not_in_set($check1, $check2, ...)

  Check that the value DOES NOT match ANY of the specified checks.

- check $thing

  Check that the value matches the specified thing.

HASH BUILDER

Note: None of these are exported by default. You need to request them.

```
$check = hash {
    field foo => 1;
    field bar => 2;

    # Ensure the 'baz' keys does not even exist in the hash.
    field baz => DNE();

    # Ensure the key exists, but is set to undef
    field bat => undef;

    # Any check can be used
    field boo => $check;

    # Set checks that apply to all keys or values. Can be done␣
↪multiple
    # times, and each call can define multiple checks, all will be␣
↪run.
    all_vals match qr/a/, match qr/b/;    # All values must have an
```

(continues on next page)

(continued from previous page)

```
↪'a' and a 'b'
    all_keys match qr/x/;                  # All keys must have an 'x
↪'

    ...

    end(); # optional, enforces that no other keys are present.
};
```

- $check = hash { ... }

  This is used to define a hash check.

- field $NAME => $VAL
- field $NAME => $CHECK

  Specify a field check. This will check the hash key specified by `$NAME` and ensure it matches the value in `$VAL`. You can put any valid check in `$VAL`, such as the result of another call to `array { ... }`, `DNE()`, etc.

  Note: This function can only be used inside a hash builder sub, and must be called in void context.

- all_keys($CHECK1, $CHECK2, ...)

  Add checks that apply to all keys. You can put this anywhere in the hash block, and can call it any number of times with any number of arguments.

- all_vals($CHECK1, $CHECK2, ...)
- all_values($CHECK1, $CHECK2, ...)

  Add checks that apply to all values. You can put this anywhere in the hash block, and can call it any number of times with any number of arguments.

- end()

  Enforce that no keys are found in the hash other than those specified. This is essentially the `use strict` of a hash check. This can be used anywhere in the hash builder, though typically it is placed at the end.

- etc()

  Ignore any extra keys found in the hash. This is the opposite of `end()`. This can be used anywhere in the hash builder, though typically it is placed at the end.

- DNE()

  This is a handy check that can be used with `field()` to ensure that a field (D)oes (N)ot (E)xist.

  ```
  field foo => DNE();
  ```

ARRAY BUILDER

Note: None of these are exported by default. You need to request them.

```
$check = array {
    # Uses the next index, in this case index 0;
    item 'a';

    # Gets index 1 automatically
    item 'b';

    # Specify the index
    item 2 => 'c';

    # We skipped index 3, which means we don't care what it is.
    item 4 => 'e';

    # Gets index 5.
    item 'f';

    # Remove any REMAINING items that contain 0-9.
    filter_items { grep {!m/[0-9]/} @_ };

    # Set checks that apply to all items. Can be done multiple
↪times, and
    # each call can define multiple checks, all will be run.
    all_items match qr/a/, match qr/b/;
    all_items match qr/x/;

    # Of the remaining items (after the filter is applied) the next
↪one
    # (which is now index 6) should be 'g'.
    item 6 => 'g';

    item 7 => DNE; # Ensure index 7 does not exist.

    end(); # Ensure no other indexes exist.
};
```

- $check = array { ... }
- item $VAL
- item $CHECK
- item $IDX, $VAL
- item $IDX, $CHECK

  Add an expected item to the array. If `$IDX` is not specified it will automatically calculate it based on the last item added. You can skip indexes, which means you do not want them to be checked.

  You can provide any value to check in `$VAL`, or you can provide any valid check object.

Note: Items MUST be added in order.

Note: This function can only be used inside an array, bag or subset builder sub, and must be called in void context.

- filter_items { my @remaining = @_; ...; return @filtered }

  This function adds a filter, all items remaining in the array from the point the filter is reached will be passed into the filter sub as arguments, the sub should return only the items that should be checked.

  Note: This function can only be used inside an array builder sub, and must be called in void context.

- all_items($CHECK1, $CHECK2, ...)

  Add checks that apply to all items. You can put this anywhere in the array block, and can call it any number of times with any number of arguments.

- end()

  Enforce that there are no indexes after the last one specified. This will not force checking of skipped indexes.

- etc()

  Ignore any extra items found in the array. This is the opposite of `end()`. This can be used anywhere in the array builder, though typically it is placed at the end.

- DNE()

  This is a handy check that can be used with `item()` to ensure that an index (D)oes (N)ot (E)xist.

```
item 5 => DNE();
```

BAG BUILDER

Note: None of these are exported by default. You need to request them.

```
$check = bag {
    item 'a';
    item 'b';

    end(); # Ensure no other elements exist.
};
```

A bag is like an array, but we don't care about the order of the items. In the example, `$check` would match both `['a','b']` and `['b','a']`.

- $check = bag { ... }
- item $VAL
- item $CHECK

  Add an expected item to the bag.

  You can provide any value to check in `$VAL`, or you can provide any valid check object.

Note: This function can only be used inside an array, bag or subset builder sub, and must be called in void context.

- all_items($CHECK1, $CHECK2, ...)

  Add checks that apply to all items. You can put this anywhere in the bag block, and can call it any number of times with any number of arguments.

- end()

  Enforce that there are no more items after the last one specified.

- etc()

  Ignore any extra items found in the array. This is the opposite of `end()`. This can be used anywhere in the bag builder, though typically it is placed at the end.

ORDERED SUBSET BUILDER

Note: None of these are exported by default. You need to request them.

```
$check = subset {
    item 'a';
    item 'b';
    item 'c';

    # Doesn't matter if the array has 'd', the check will skip past␣
↪any
    # unknown items until it finds the next one in our subset.

    item 'e';
    item 'f';
};
```

- $check = subset { ... }
- item $VAL
- item $CHECK

  Add an expected item to the subset.

  You can provide any value to check in `$VAL`, or you can provide any valid check object.

  Note: Items MUST be added in order.

  Note: This function can only be used inside an array, bag or subset builder sub, and must be called in void context.

META BUILDER

Note: None of these are exported by default. You need to request them.

```
my $check = meta {
    prop blessed => 'My::Module'; # Ensure value is blessed as our␣
```

(continues on next page)

(continued from previous page)

```
↪package
    prop reftype => 'HASH';       # Ensure value is a blessed hash
    prop isa     => 'My::Base';   # Ensure value is an instance of␣
↪our class
    prop size    => 4;            # Check the number of hash keys
    prop this    => ...;          # Check the item itself
};
```

- meta { ... }
- meta_check { ... }

  Build a meta check. If you are using *Moose* then the `meta()` function would conflict with the one exported by *Moose*, in such cases `meta_check()` is available. Neither is exported by default.

- prop $NAME => $VAL
- prop $NAME => $CHECK

  Check the property specified by `$name` against the value or check.

  Valid properties are:

  – 'blessed'

    What package (if any) the thing is blessed as.

  – 'reftype'

    Reference type (if any) the thing is.

  – 'isa'

    What class the thing is an instance of.

  – 'this'

    The thing itself.

  – 'size'

    For array references this returns the number of elements. For hashes this returns the number of keys. For everything else this returns undef.

OBJECT BUILDER

Note: None of these are exported by default. You need to request them.

```
my $check = object {
    call foo => 1; # Call the 'foo' method, check the result.

    # Call the specified sub-ref as a method on the object, check␣
↪the
    # result. This is useful for wrapping methods that return␣
↪multiple
    # values.
```

(continues on next page)

(continued from previous page)

```
    call sub { [ shift->get_list ] } => [...];

    # This can be used to ensure a method does not exist.
    call nope => DNE();

    # Check the hash key 'foo' of the underlying reference, this
↪only works
    # on blessed hashes.
    field foo => 1;

    # Check the value of index 4 on the underlying reference, this
↪only
    # works on blessed arrays.
    item 4 => 'foo';

    # Check the meta-property 'blessed' of the object.
    prop blessed => 'My::Module';

    # Check if the object is an instance of the specified class.
    prop isa => 'My::Base';

    # Ensure only the specified hash keys or array indexes are
↪present in
    # the underlying hash. Has no effect on meta-property checks or
↪method
    # checks.
    end();
};
```

- $check = object { ... }

  Specify an object check for use in comparisons.

- call $METHOD_NAME => $RESULT
- call $METHOD_NAME => $CHECK
- call [$METHOD_NAME, @METHOD_ARGS] => $RESULT
- call [$METHOD_NAME, @METHOD_ARGS] => $CHECK
- call sub { ... }, $RESULT
- call sub { ... }, $CHECK

  Call the specified method (or coderef) and verify the result. If you pass an arrayref, the first element must be the method name, the others are the arguments it will be called with.

  The coderef form is useful if you need to do something more complex.

```
my $ref = sub {
  local $SOME::GLOBAL::THING = 3;
  return [shift->get_values_for('thing')];
```

(continues on next page)

(continued from previous page)

```
};

call $ref => ...;
```

- call_list $METHOD_NAME => $RESULT
- call_list $METHOD_NAME => $CHECK
- call_list [$METHOD_NAME, @METHOD_ARGS] => $RESULT
- call_list [$METHOD_NAME, @METHOD_ARGS] => $CHECK
- call_list sub { ... }, $RESULT
- call_list sub { ... }, $CHECK

  Same as `call`, but the method is invoked in list context, and the result is always an arrayref.

```
call_list get_items => [ ... ];
```

- call_hash $METHOD_NAME => $RESULT
- call_hash $METHOD_NAME => $CHECK
- call_hash [$METHOD_NAME, @METHOD_ARGS] => $RESULT
- call_hash [$METHOD_NAME, @METHOD_ARGS] => $CHECK
- call_hash sub { ... }, $RESULT
- call_hash sub { ... }, $CHECK

  Same as `call`, but the method is invoked in list context, and the result is always a hashref. This will warn if the method returns an odd number of values.

```
call_hash get_items => { ... };
```

- field $NAME => $VAL

  Works just like it does for hash checks.

- item $VAL
- item $IDX, $VAL

  Works just like it does for array checks.

- prop $NAME => $VAL
- prop $NAME => $CHECK

  Check the property specified by `$name` against the value or check.

  Valid properties are:

  – 'blessed'

    What package (if any) the thing is blessed as.

  - 'reftype'

    Reference type (if any) the thing is.

  - 'isa'

    What class the thing is an instance of.

  - 'this'

    The thing itself.

  - 'size'

    For array references this returns the number of elements. For hashes this returns the number of keys. For everything else this returns undef.

- DNE()

  Can be used with `item`, or `field` to ensure the hash field or array index does not exist. Can also be used with `call` to ensure a method does not exist.

- end()

  Turn on strict array/hash checking, ensuring that no extra keys/indexes are present.

- etc()

  Ignore any extra items found in the hash/array. This is the opposite of `end()`. This can be used anywhere in the builder, though typically it is placed at the end.

EVENT BUILDERS

Note: None of these are exported by default. You need to request them.

Check that we got an event of a specified type:

```
my $check = event 'Ok';
```

Check for details about the event:

```
my $check = event Ok => sub {
    # Check for a failure
    call pass => 0;

    # Effective pass after TODO/SKIP are accounted for.
    call effective_pass => 1;

    # Check the diagnostics
    call diag => [ match qr/Failed test foo/ ];

    # Check the file the event reports to
    prop file => 'foo.t';

    # Check the line number the event reports to
    prop line => '42';
```

(continues on next page)

(continued from previous page)

```
    # You can check the todo/skip values as well:
    prop skip => 'broken';
    prop todo => 'fixme';

    # Thread-id and process-id where event was generated
    prop tid => 123;
    prop pid => 123;
};
```

You can also provide a fully qualified event package with the '+' prefix:

```
my $check = event '+My::Event' => sub { ... }
```

You can also provide a hashref instead of a sub to directly check hash values of the event:

```
my $check = event Ok => { pass => 1, ... };
```

USE IN OTHER BUILDERS

You can use these all in other builders, simply use them in void context to have their value(s) appended to the build.

```
my $check = array {
    event Ok => { ... };
    event Note => { ... };

    fail_events Ok => { pass => 0 };
    # Get a Diag for free.
};
```

SPECIFICS

- $check = event $TYPE;
- $check = event $TYPE => sub { ... };
- $check = event $TYPE => { ... };

  This works just like an object builder. In addition to supporting everything the object check supports, you also have to specify the event type, and many extra meta-properties are available.

  Extra properties are:

  - 'file'

    File name to which the event reports (for use in diagnostics).

  - 'line'

    Line number to which the event reports (for use in diagnostics).

  - 'package'

    Package to which the event reports (for use in diagnostics).

- 'subname'

  Sub that was called to generate the event (example: `ok()`).

- 'skip'

  Set to the skip value if the result was generated by skipping tests.

- 'todo'

  Set to the todo value if TODO was set when the event was generated.

- 'trace'

  The `at file foo.t line 42` string that will be used in diagnostics.

- 'tid'

  Thread ID in which the event was generated.

- 'pid'

  Process ID in which the event was generated.

NOTE: Event checks have an implicit `etc()` added. This means you need to use `end()` if you want to fail on unexpected hash keys or array indexes. This implicit `etc()` extends to all forms, including builder, hashref, and no argument.

- @checks = fail_events $TYPE;
- @checks = fail_events $TYPE => sub { ... };
- @checks = fail_events $TYPE => { ... };

  Just like `event()` documented above. The difference is that this produces two events, the one you specify, and a `Diag` after it. There are no extra checks in the Diag.

  Use this to validate a simple failure where you do not want to be bothered with the default diagnostics. It only adds a single Diag check, so if your failure has custom diagnostics you will need to add checks for them.

Test2::Tools::Defer

Write tests that get executed at a later time

DESCRIPTION

Sometimes you need to test things BEFORE loading the necessary functions. This module lets you do that. You can write tests, and then have them run later, after `Test2` is loaded. You tell it what test function to run, and what arguments to give it. The function name and arguments will be stored to be executed later. When ready, run `do_def()` to kick them off once the functions are defined.

SYNOPSIS

```
use strict;
use warnings;

use Test2::Tools::Defer;

BEGIN {
    def ok => (1, 'pass');
    def is => ('foo', 'foo', 'runs is');
    ...
}

use Test2::Tools::Basic;

do_def(); # Run the tests

# Declare some more tests to run later:
def ok => (1, "another pass");
...

do_def(); # run the new tests

done_testing;
```

EXPORTS

- def function => @args;

  This will store the function name, and the arguments to be run later. Note that each package has a separate store of tests to run.

- do_def()

  This will run all the stored tests. It will also reset the list to be empty so you can add more tests to run even later.

Test2::Tools::Encoding

Tools for managing the encoding of *Test2* based tests.

DESCRIPTION

This module exports a function that lets you dynamically change the output encoding at will.

SYNOPSIS

```
use Test2::Tools::Encoding;

set_encoding('utf8');
```

EXPORTS

All subs are exported by default.

- set_encoding($encoding)

  This will set the encoding to whatever you specify. This will only affect the output of the current formatter, which is usually your TAP output formatter.

SOURCE

The source code repository for Test2-Suite can be found at `https://github.com/Test-More/test-more/`.

Test2::Tools::Event

Tools for generating test events.

DESCRIPTION

This module provides tools for generating events quickly by bypassing the context/hub. This is particularly useful when testing other *Test2* packages.

EXPORTS

- $e = gen_event($TYPE)
- $e = gen_event($TYPE, %FIELDS)
- $e = gen_event 'Ok';
- $e = gen_event Ok => (...)
- $e = gen_event '+Test2::Event::Ok' => (...)

  This will produce an event of the specified type. `$TYPE` is assumed to be shorthand for `Test2::Event::$TYPE`, you can prefix `$TYPE` with a '+' to drop the assumption.

  An *Test2::Util::Trace* will be generated using `caller(0)` and will be put in the 'trace' field of your new event, unless you specified your own 'trace' field.

SOURCE

The source code repository for Test2-Suite can be found at `https://github.com/Test-More/test-more/`.

Test2::Tools::Exception

Test2 based tools for checking exceptions

DESCRIPTION

This is the *Test2* implementation of code used to test exceptions. This is similar to Test::Fatal, but it intentionally does much less.

SYNOPSIS

```
use Test2::Tools::Exception qw/dies lives/;

like(
    dies { die 'xxx' },
    qr/xxx/,
    "Got exception"
);

ok(lives { ... }, "did not die") or note($@);
```

EXPORTS

All subs are exported by default.

- $e = dies { ... }

  This will trap any exception the codeblock throws. If no exception is thrown the sub will return undef. If an exception is thrown it will be returned. This function preserves $@, it will not be altered from its value before the sub is called.

- $bool = lives { ... }

  This will trap any exception thrown in the codeblock. It will return true when there is no exception, and false when there is. $@ is preserved from before the sub

is called when there is no exception. When an exception is trapped `$@` will have the exception so that you can look at it.

- $bool = try_ok { ... }
- $bool = try_ok { ... } "Test Description"

  This will run the code block trapping any exception. If there is no exception a passing event will be issued. If the test fails a failing event will be issued, and the exception will be reported as diagnostics.

  Note: This function does not preserve `$@` on failure, it will be set to the exception the codeblock throws, this is by design so that you can obtain the exception if desired.

DIFFERENCES FROM TEST::FATAL

Test::Fatal sets `$Test::Builder::Level` such that failing tests inside the exception block will report to the line where `exception()` is called. I disagree with this, and think the actual line of the failing test is more important. Ultimately, though Test::Fatal cannot be changed, people probably already depend on that behavior.

Test2::Tools::Exports

Tools for validating exporters.

DESCRIPTION

These are tools for checking that symbols have been imported into your namespace.

SYNOPSIS

```
use Test2::Tools::Exports

use Data::Dumper;
imported_ok qw/Dumper/;
not_imported_ok qw/dumper/;
```

EXPORTS

All subs are exported by default.

- imported_ok(@SYMBOLS)

  Check that the specified symbols exist in the current package. This will not find inherited subs. This will only find symbols in the current package's symbol table. This **WILL NOT** confirm that the symbols were defined outside of the package itself.

  ```
  imported_ok( '$scalar', '@array', '%hash', '&sub', 'also_a_sub'␣
  ↪);
  ```

  `@SYMBOLS` can contain any number of symbols. Each item in the array must be a string. The string should be the name of a symbol. If a sigil is present then it will search for that specified type, if no sigil is specified it will be used as a sub name.

- not_imported_ok(@SYMBOLS)

  Check that the specified symbols do not exist in the current package. This will not find inherited subs. This will only look at symbols in the current package's symbol table.

  ```
  not_imported_ok( '$scalar', '@array', '%hash', '&sub', 'also_a_
  ↪sub' );
  ```

  `@SYMBOLS` can contain any number of symbols. Each item in the array must be a string. The string should be the name of a symbol. If a sigil is present, then it will search for that specified type. If no sigil is specified, it will be used as a sub name.

CAVEATS

Before Perl 5.10, it is very difficult to distinguish between a package scalar that is undeclared vs declared and undefined. Currently `imported_ok` and `not_imported_ok` cannot see package scalars declared using `our $var` unless the variable has been assigned a defined value.

This will pass on recent perls, but fail on perls older than 5.10:

```
use Test2::Tools::Exports;

our $foo;

# Fails on perl onlder than 5.10
imported_ok(qw/$foo/);
```

If `$foo` is imported from another module, or imported using `use vars qw/$foo/;` then it will work on all supported perl versions.

```
use Test2::Tools::Exports;

use vars qw/$foo/;
use Some::Module qw/$bar/;

# Always works
imported_ok(qw/$foo $bar/);
```

Test2::Tools::GenTemp

Tool for generating a populated temp directory.

DESCRIPTION

This exports a tool that helps you make a temporary directory, nested directories and text files within.

SYNOPSIS

```
use Test2::Tools::GenTemp qw/gen_temp/;

my $dir = gen_temp(
    a_file => "Contents of a_file",
    a_dir  => {
        'a_file' => 'Contents of a_dir/afile',
        a_nested_dir => { ... },
    },
    ...
);

done_testing;
```

EXPORTS

All subs are exported by default.

- gen_temp(file => 'content', subdir => [sub_dir_file => 'content', ...], ...)
- gen_temp(-tempdir => \@TEMPDIR_ARGS, file => 'content', subdir => [sub_dir_file => 'content', ...], ...)

  This will generate a new temporary directory with all the files and subdirs you specify, recursively. The initial temp directory is created using `File::Temp::tempdir()`, you may pass arguments to tempdir using the `-tempdir => [...]` argument.

Test2::Tools::Grab

Temporarily intercept all events without adding a scope level.

DESCRIPTION

This package provides a function that returns an object that grabs all events. Once the object is destroyed events will once again be sent to the main hub.

SYNOPSIS

```
use Test2::Tools::Grab;

my $grab = grab();

# Generate some events, they are intercepted.
ok(1, "pass");
ok(0, "fail");

my $events_a = $grab->flush;

# Generate some more events, they are intercepted.
ok(1, "pass");
ok(0, "fail");

my $events_b = $grab->finish;
```

EXPORTS

- $grab = grab()

  This lets you intercept all events for a section of code without adding anything to your call stack. This is useful for things that are sensitive to changes in the stack depth.

  ```
  my $grab = grab();
      ok(1, 'foo');
      ok(0, 'bar');

  my $events = $grab->finish;

  is(@$events, 2, "grabbed 2 events.");
  ```

  If the `$grab` object is destroyed without calling `finish()`, it will automatically clean up after itself and restore the parent hub.

  ```
  {
      my $grab = grab();
      # Things are grabbed
  }
  # Things are back to normal
  ```

By default the hub used has no_ending set to true. This will prevent the hub from enforcing that you issued a plan and ran at least 1 test. You can turn enforcement back one like this:

```
$grab->hub->set_no_ending(0);
```

With no_ending turned off, finish will run the post-test checks to enforce the plan and that tests were run. In many cases this will result in additional events in your events array.

Test2::Tools::Mock

Class/Instance mocking for Test2.

DESCRIPTION

Mocking is often an essential part of testing. This library covers some of the most common mocking needs. This plugin is heavily influenced by Mock::Quick, but with an improved API. This plugin is also intended to play well with other plugins in ways Mock::Quick would be unable to.

SYNOPSIS

```
my $mock = mock 'Some::Class' => (
    track => $BOOL, # Enable/Disable tracking on subs defined below

    add => [
        new_method => sub { ... },
    ],
    override => [
        replace_method => sub { ... },
    ],
    set => [
        replace_or_inject => sub { ... },
    ],

    track => $bool, # enable/disable tracking again to affect mocks
 ↪made after this point
    ..., # Argument keys may be repeated
);

Some::Class->new_method();        # Calls the newly injected method
Some::Class->replace_method();    # Calls our replacement method.

$mock->override(...) # Override some more

$mock = undef; # Undoes all the mocking, restoring all original
 ↪methods.

my $simple_mock = mock {} => (
    add => [
        is_active => sub { ... }
    ]
);

$simple_mock->is_active();        # Calls our newly mocked method.
```

EXPORTS

DEFAULT

- mock

  This is a one-stop shop function that delegates to one of the other methods depending on how it is used. If you are not comfortable with a function that has a lot of potential behaviors, you can use one of the other functions directly.

- @mocks = mocked($object)

- @mocks = mocked($class)

  Check if an object or class is mocked. If it is mocked the `$mock` object(s) (*Test2::Mock*) will be returned.

- $mock = mock $class => (...);
- $mock = mock $instance => (...)
- $mock = mock 'class', $class => (...)

  These forms delegate to `mock_class()` to mock a package. The third form is to be explicit about what type of mocking you want.

- $obj = mock()
- $obj = mock { ... }
- $obj = mock 'obj', ...;

  These forms delegate to `mock_obj()` to create instances of anonymous packages where methods are vivified into existence as needed.

- mock $mock => sub { ... }
- mock $method => (...)

  These forms go together, the first form will set `$mock` as the current mock build, then run the sub. Within the sub you can declare mock specifications using the second form. The first form delegates to `mock_build()`.

  The second form calls the specified method on the current build. This second form delegates to `mock_do()`.

BY REQUEST

DEFINING MOCKS

- $obj = mock_obj(...)
- $obj = mock_obj { ... } => (...)
- $obj = mock_obj sub { ... }
- $obj = mock_obj { ... } => sub { ... }

  This method lets you quickly generate a blessed object. The object will be an instance of a randomly generated package name. Methods will vivify as read/write accessors as needed.

  Arguments can be any method available to *Test2::Mock* followed by an argument. If the very first argument is a hashref then it will be blessed as your new object.

  If you provide a coderef instead of key/value pairs, the coderef will be run to build the mock. (See the "BUILDING MOCKS" section).

- $mock = mock_class $class => (...)
- $mock = mock_class $instance => (...)
- $mock = mock_class ... => sub { ... }

  This will create a new instance of *Test2::Mock* to control the package specified. If you give it a blessed reference it will use the class of the instance.

  Arguments can be any method available to *Test2::Mock* followed by an argument. If the very first argument is a hashref then it will be blessed as your new object.

If you provide a coderef instead of key/value pairs, the coderef will be run to build the mock. (See the "BUILDING MOCKS" section).

BUILDING MOCKS

- mock_build $mock => sub { ... }

  Set `$mock` as the current build, then run the specified code. `$mock` will no longer be the current build when the sub is complete.

- $mock = mock_building()

  Get the current building `$mock` object.

- mock_do $method => $args

  Run the specified method on the currently building object.

METHOD GENERATORS

- $sub = mock_accessor $field

  Generate a read/write accessor for the specified field. This will generate a sub like the following:

```
$sub = sub {
    my $self = shift;
    ($self->{$field}) = @_ if @_;
    return $self->{$field};
};
```

- $sub = mock_getter $field

  Generate a read only accessor for the specified field. This will generate a sub like the following:

```
$sub = sub {
    my $self = shift;
    return $self->{$field};
};
```

- $sub = mock_setter $field

  Generate a write accessor for the specified field. This will generate a sub like the following:

```
$sub = sub {
    my $self = shift;
    ($self->{$field}) = @_;
};
```

- Generates several read/write accessors at once, returns key/value pairs where the key is the field name, and the value is the coderef.
- Generates several read only accessors at once, returns key/value pairs where the key is the field name, and the value is the coderef.

- Generates several write accessors at once, returns key/value pairs where the key is the field name, and the value is the coderef.

MOCK CONTROL OBJECTS

```
my $mock = mock(...);
```

Mock objects are instances of *Test2::Mock*. See it for their methods.

Test2::Tools::Ref

Tools for validating references.

DESCRIPTION

This module contains tools that allow you to verify that something is a ref. It also has tools to check if two refs are the same exact ref, or different. None of the functions in this module do deep comparisons.

SYNOPSIS

```
use Test2::Tools::Ref;

# Ensure something is a ref.
ref_ok($ref);

# Check that $ref is a HASH reference
```

(continues on next page)

(continued from previous page)

```
ref_ok($ref, 'HASH', 'Must be a hash')

ref_is($refa, $refb, "Same exact reference");

ref_is_not($refa, $refb, "Not the same exact reference");
```

EXPORTS

All subs are exported by default.

- ref_ok($thing)
- ref_ok($thing, $type)
- ref_ok($thing, $type, $name)

  This checks that `$thing` is a reference. If `$type` is specified then it will check that `$thing` is that type of reference.

- ref_is($ref1, $ref2, $name)

  Verify that two references are the exact same reference.

- ref_is_not($ref1, $ref2, $name)

  Verify that two references are not the exact same reference.

Test2::Tools::Refcount

assert reference counts on objects

SYNOPSIS

```
use Test2::Tools::Refcount;

use Some::Class;
my $object = Some::Class->new();

is_oneref( $object, '$object has a refcount of 1' );

my $otherref = $object;

is_refcount( $object, 2, '$object now has 2 references' );
```

DESCRIPTION

The Perl garbage collector uses simple reference counting during the normal execution of a program. This means that cycles or unweakened references in other parts of code can keep an object around for longer than intended. To help avoid this problem, the reference count of a new object from its class constructor ought to be 1. This way, the caller can know the object will be properly DESTROYed when it drops all of its references to it.

This module provides two test functions to help ensure this property holds for an object class, so as to be polite to its callers.

If the assertion fails; that is, if the actual reference count is different to what was expected, either of the following two modules may be used to assist the developer in finding where the references are.

- If Devel::MAT is installed, this test module will use it to dump the state of the memory after a failure. It will create a `.pmat` file named the same as the unit test, but with the trailing `.t` suffix replaced with `-TEST.pmat` where `TEST` is the number of the test that failed (in case there was more than one).

See the examples below for more information.

FUNCTIONS

is_refcount

```
is_refcount( $object, $count, $name )
```

Test that $object has $count references to it.

is_oneref

```
is_oneref( $object, $name )
```

Assert that the $object has only 1 reference to it.

refcount

```
$count = refcount( $object )
```

Returns the reference count of the given object as used by the test functions. This is useful for making tests that don't care what the count is before they start, but simply assert that the count hasn't changed by the end.

```
use Test2::Tools::Refcount import => [qw( is_refcount refcount )];
{
   my $count = refcount( $object );

   do_something( $object );

   is_refcount( $object, $count, 'do_something() preserves refcount'
↪);
}
```

EXAMPLE

Suppose, having written a new class `MyBall`, you now want to check that its constructor and methods are well-behaved, and don't leak references. Consider the following test script:

```
use Test::More tests => 2;
use Test2::Tools::Refcount;

use MyBall;

my $ball = MyBall->new();
is_oneref( $ball, 'One reference after construct' );

$ball->bounce;

# Any other code here that might be part of the test script

is_oneref( $ball, 'One reference just before EOF' );
```

The first assertion is just after the constructor, to check that the reference returned by it is the only reference to that object. This fact is important if we ever want `DESTROY` to behave properly. The second call is right at the end of the file, just before the main scope closes. At this stage we expect the reference count also to be one, so that the object is properly cleaned up.

Suppose, when run, this produces the following output (presuming Devel::MAT::Dumper is available):

```
1..2
ok 1 - One reference after construct
not ok 2 - One reference just before EOF
#   Failed test 'One reference just before EOF'
#   at ex.pl line 26.
#   expected 1 references, found 2
# SV address is 0x55e14c310278
# Writing heap dump to ex-2.pmat
# Looks like you failed 1 test of 2.
```

This has written a `ex-2.pmat` file we can load using the `pmat` shell and use the `identify` command on the given address to find where it went:

```
$ pmat ex-2.pmat
Perl memory dumpfile from perl 5.28.1 threaded
Heap contains 25233 objects
pmat> identify 0x55e14c310278
HASH(0)=MyBall at 0x55e14c310278 is:
├─(via RV) the lexical $ball at depth 1 of CODE() at␣
 ↪0x55e14c3104a0=main_cv, which is:
│  └─the main code
└─(via RV) value {self} of HASH(2) at 0x55e14cacb860, which is (*A):
   └─(via RV) value {cycle} of HASH(2) at 0x55e14cacb860, which is:
     itself
```

(This document isn't intended to be a full tutorial on Devel::MAT and the `pmat` shell; for that see Devel::MAT::UserGuide).

From this output, we can see that the constructor was well-behaved, but that a reference was leaked by the end of the script - the reference count was 2, when we expected just 1. Reading the trace output, we can see that there were 2 references that could be found - one stored in the $ball lexical in the main program, and one stored in a HASH. Since we expected to find the $ball lexical variable, we know we are now looking for a leak in a hash somewhere in the code. From reading the test script, we can guess this leak is likely to be in the bounce() method. Furthermore, we know that the reference to the object will be stored in a HASH in a member called `self`.

By reading the code which implements the bounce() method, we can see this is indeed the case:

```
sub bounce
{
   my $self = shift;
   my $cycle = { self => $self };
   $cycle->{cycle} = $cycle;
}
```

From reading the tracing output, we find that the HASH this object is referenced in also contains a reference to itself, in a member called `cycle`. This comes from the last line in this function, a line that purposely created a cycle, to demonstrate the point. While a

real program probably wouldn't do anything quite this obvious, the trace would still be useful in finding the likely cause of the leak.

If `Devel::MAT::Dumper` is not available, then these detailed traces will not be produced. The basic reference count testing will still take place, but a smaller message will be produced:

```
1..2
ok 1 - One reference after construct
not ok 2 - One reference just before EOF
#   Failed test 'One reference just before EOF'
#   at demo.pl line 16.
#   expected 1 references, found 2
# Looks like you failed 1 test of 2.
```

BUGS

- Temporaries created on the stack

  Code which creates temporaries on the stack, to be released again when the called function returns does not work correctly on perl 5.8 (and probably before). Examples such as

  ```
  is_oneref( [] );
  ```

  may fail and claim a reference count of 2 instead.

  Passing a variable such as

  ```
  my $array = [];
  is_oneref( $array );
  ```

  works fine. Because of the intention of this test module; that is, to assert reference counts on some object stored in a variable during the lifetime of the test script, this is unlikely to cause any problems.

ACKNOWLEDGEMENTS

Peter Rabbitson ribasushi@cpan.org - for suggesting using core's `B` instead of `Devel::Refcount` to obtain refcounts

AUTHOR

Paul Evans leonerd@leonerd.org.uk

Test2::Tools::Spec

RSPEC implementation on top of Test2::Workflow

DESCRIPTION

This uses *Test2::Workflow* to implement an RSPEC variant. This variant supports isolation and/or concurrency via forking or threads.

SYNOPSIS

```
use Test2::Bundle::Extended;
use Test2::Tools::Spec;

describe foo => sub {
    before_all  once => sub { ... };
    before_each many => sub { ... };

    after_all  once => sub { ... };
    after_each many => sub { ... };

    case condition_a => sub { ... };
    case condition_b => sub { ... };

    tests foo => sub { ... };
    tests bar => sub { ... };
};

done_testing;
```

EXPORTS

All of these use the same argument pattern. The first argument must always be a name for the block. The last argument must always be a code reference. Optionally a configuration hash can be inserted between the name and the code reference.

```
FUNCTION "name" => sub { ... };

FUNCTION "name" => {...}, sub { ... };
```

- NAME

  The first argument to a Test2::Tools::Spec function MUST be a name. The name does not need to be unique.

- PARAMS

  This argument is optional. If present this should be a hashref.

  Here are the valid keys for the hashref:

  - flat => $bool

    If this is set to true then the block will not render as a subtest, instead the events will be inline with the parent subtest (or main test).

  - async => $bool

Set this to true to mark a block as being capable of running concurrently with other test blocks. This does not mean the block WILL be run concurrently, just that it can be.

- iso => $bool

  Set this to true if the block MUST be run in isolation. If this is true then the block will run in its own forked process.

  These tests will be skipped on any platform that does not have true forking, or working/enabled threads.

  Threads will ONLY be used if the T2_WORKFLOW_USE_THREADS env var is set. Thread tests are only run if the T2_DO_THREAD_TESTS env var is set.

- todo => $reason

  Use this to mark an entire block as TODO.

- skip => $reason

  Use this to prevent a block from running at all.

- CODEREF

  This argument is required. This should be a code reference that will run some assertions.

ESSENTIALS

- tests NAME => sub { ... }
- tests NAME => \%params, sub { ... }
- tests($NAME, \%PARAMS, \&CODE)
- it NAME => sub { ... }
- it NAME => \%params, sub { ... }
- it($NAME, \%PARAMS, \&CODE)

  This defines a test block. Test blocks are essentially subtests. All test blocks will be run, and are expected to produce events. Test blocks can run multiple times if the `case()` function is also used.

  `it()` is an alias to `tests()`.

  These ARE NOT inherited by nested describe blocks.

- case NAME => sub { ... }
- case NAME => \%params, sub { ... }
- case($NAME, \%PARAMS, \&CODE)

  This lets you specify multiple conditions in which the test blocks should be run. Every test block within the same group (`describe`) will be run once per case.

  These ARE NOT inherited by nested describe blocks, but nested describe blocks will be executed once per case.

- before_each NAME => sub { ... }

- before_each NAME => \%params, sub { ... }
- before_each($NAME, \%PARAMS, \&CODE)

  Specify a codeblock that should be run multiple times, once before each `tests()` block is run. These will run AFTER `case()` blocks but before `tests()` blocks.

  These ARE inherited by nested describe blocks.
- before_case NAME => sub { ... }
- before_case NAME => \%params, sub { ... }
- before_case($NAME, \%PARAMS, \&CODE)

  Same as `before_each()`, except these blocks run BEFORE `case()` blocks.

  These ARE NOT inherited by nested describe blocks.
- before_all NAME => sub { ... }
- before_all NAME => \%params, sub { ... }
- before_all($NAME, \%PARAMS, \&CODE)

  Specify a codeblock that should be run once, before all the test blocks run.

  These ARE NOT inherited by nested describe blocks.
- around_each NAME => sub { ... }
- around_each NAME => \%params, sub { ... }
- around_each($NAME, \%PARAMS, \&CODE)

  Specify a codeblock that should wrap around each test block. These blocks are run AFTER case blocks, but before test blocks.

```
around_each wrapit => sub {
    my $cont = shift;

    local %ENV = ( ... );

    $cont->();

    ...
};
```

  The first argument to the codeblock will be a callback that MUST be called somewhere inside the sub in order for nested items to run.

  These ARE inherited by nested describe blocks.
- around_case NAME => sub { ... }
- around_case NAME => \%params, sub { ... }
- around_case($NAME, \%PARAMS, \&CODE)

  Same as `around_each` except these run BEFORE case blocks.

  These ARE NOT inherited by nested describe blocks.

- around_all NAME => sub { ... }
- around_all NAME => \%params, sub { ... }
- around_all($NAME, \%PARAMS, \&CODE)

  Same as `around_each` except that it only runs once to wrap ALL test blocks.

  These ARE NOT inherited by nested describe blocks.
- after_each NAME => sub { ... }
- after_each NAME => \%params, sub { ... }
- after_each($NAME, \%PARAMS, \&CODE)

  Same as `before_each` except it runs right after each test block.

  These ARE inherited by nested describe blocks.
- after_case NAME => sub { ... }
- after_case NAME => \%params, sub { ... }
- after_case($NAME, \%PARAMS, \&CODE)

  Same as `after_each` except it runs right after the case block, and before the test block.

  These ARE NOT inherited by nested describe blocks.
- after_all NAME => sub { ... }
- after_all NAME => \%params, sub { ... }
- after_all($NAME, \%PARAMS, \&CODE)

  Same as `before_all` except it runs after all test blocks have been run.

  These ARE NOT inherited by nested describe blocks.

SHORTCUTS

These are shortcuts. Each of these is the same as `tests()` except some parameters are added for you.

These are NOT exported by default/.

- mini NAME => sub { ... }

  Same as:

  ```
  tests NAME => { flat => 1 }, sub { ... }
  ```

- iso NAME => sub { ... }

  Same as:

  ```
  tests NAME => { iso => 1 }, sub { ... }
  ```

- miso NAME => sub { ... }

  Same as:

```
tests NAME => { mini => 1, iso => 1 }, sub { ... }
```

- async NAME => sub { ... }

  Same as:

```
tests NAME => { async => 1 }, sub { ... }
```

  Note: This conflicts with the `async()` exported from *threads*. Don't import both.

- masync NAME => sub { ... }

  Same as:

```
tests NAME => { minit => 1, async => 1 }, sub { ... }
```

CUSTOM ATTRIBUTE DEFAULTS

Sometimes you want to apply default attributes to all `tests()` or `case()` blocks. This can be done, and is lexical to your describe or package root!

```
use Test2::Bundle::Extended;
use Test2::Tools::Spec ':ALL';

# All 'tests' blocks after this declaration will have C<<iso => 1>>␣
 ↪by default
spec_defaults tests => (iso => 1);

tests foo => sub { ... }; # isolated

tests foo, {iso => 0}, sub { ... }; # Not isolated

spec_defaults tests => (iso => 0); # Turn it off again
```

Defaults are inherited by nested describe blocks. You can also override the defaults for the scope of the describe:

```
spec_defaults tests => (iso => 1);

describe foo => sub {
    spec_defaults tests => (async => 1); # Scoped to this describe␣
 ↪and any child describes

    tests bar => sub { ... }; # both iso and async
};

tests baz => sub { ... }; # Just iso, no async.
```

You can apply defaults to any type of blocks:

```
spec_defaults case => (iso => 1); # All cases are 'iso';
```

Defaults are not inherited when a builder's return is captured.

```
spec_defaults tests => (iso => 1);

# Note we are not calling this in void context, that is the key␣
 ↪here.
my $d = describe foo => {
    tests bar => sub { ... }; # Not iso
};
```

EXECUTION ORDER

As each function is encountered it executes, just like any other function. The `describe()` function will immediately execute the codeblock it is given. All other functions will stash their codeblocks to be run later. When `done_testing()` is run the workflow will be compiled, at which point all other blocks will run.

Here is an overview of the order in which blocks get called once compiled (at `done_testing()`).

```
before_all
    for-each-case {
        before_case
            case
        after_case

        # AND/OR nested describes
        before_each
            tests
        after_each
    }
after_all
```

Test2::Tools::Subtest

Tools for writing subtests

DESCRIPTION

This package exports subs that let you write subtests.

There are two types of subtests, buffered and streamed. Streamed subtests mimic subtests from *Test::More* in that they render all events as soon as they are produced. Buffered subtests wait until the subtest completes before rendering any results.

The main difference is that streamed subtests are unreadable when combined with concurrency. Buffered subtests look fine with any number of concurrent threads and processes.

SYNOPSIS

BUFFERED

```
use Test2::Tools::Subtest qw/subtest_buffered/;

subtest_buffered my_test => sub {
    ok(1, "subtest event A");
    ok(1, "subtest event B");
};
```

This will produce output like this:

```
ok 1 - my_test {
    ok 1 - subtest event A
    ok 2 - subtest event B
    1..2
}
```

STREAMED

The default option is 'buffered'. If you want streamed subtests, the way *Test::Builder* does it, use this:

```
use Test2::Tools::Subtest qw/subtest_streamed/;

subtest_streamed my_test => sub {
    ok(1, "subtest event A");
    ok(1, "subtest event B");
};
```

This will produce output like this:

```
# Subtest: my_test
    ok 1 - subtest event A
    ok 2 - subtest event B
    1..2
ok 1 - Subtest: my_test
```

IMPORTANT NOTE

You can use `bail_out` or `skip_all` in a subtest, but not in a BEGIN block or `use` statement. This is due to the way flow control works within a BEGIN block. This is not normally an issue, but can happen in rare conditions using eval, or script files as subtests.

EXPORTS

- subtest_streamed $name => $sub
- subtest_streamed($name, $sub, @args)
- subtest_streamed $name => \%params, $sub
- subtest_streamed($name, \%params, $sub, @args)

  Run subtest coderef, stream events as they happen.

  `\%params` is a hashref with any arguments you wish to pass into hub construction.
- subtest_buffered $name => $sub
- subtest_buffered($name, $sub, @args)
- subtest_buffered $name => \%params, $sub
- subtest_buffered($name, \%params, $sub, @args)

  Run subtest coderef, render events all at once when subtest is complete.

  `\%params` is a hashref with any arguments you wish to pass into hub construction.

Test2::Tools::Target

Alias the testing target package.

DESCRIPTION

This lets you alias the package you are testing into a constant and a package variable.

SYNOPSIS

```
use Test2::Tools::Target 'Some::Package';

CLASS()->xxx; # Call 'xxx' on Some::Package
$CLASS->xxx;  # Same
```

Or you can specify names:

```
use Test2::Tools::Target pkg => 'Some::Package';

pkg()->xxx; # Call 'xxx' on Some::Package
$pkg->xxx;  # Same
```

Test2::Tools::Tester

Tools to help you test other testing tools.

DESCRIPTION

This is a collection of tools that are useful when testing other test tools.

SYNOPSIS

```
use Test2::Tools::Tester qw/event_groups filter_events facets/;

use Test2::Tools::Basic qw/plan pass ok/;
use Test2::Tools::Compare qw/is like/;

my $events = intercept {
    plan 11;

    pass('pass');
    ok(1, 'pass');

    is(1, 1, "pass");
    like(1, 1, "pass");
};

# Grab events generated by tools in Test2::Tools::Basic
my $basic = filter $events => 'Test2::Tools::Basic';

# Grab events generated by Test2::Tools::Basic;
my $compare = filter $events => 'Test2::Tools::Compare';

# Grab events generated by tools named 'ok'.
my $oks = filter $events => qr/.*::ok$/;

my $grouped = group_events $events;
# Breaks events into this structure:
{
    '__NA__' => [ ... ],
    'Test2::Tools::Basic' => {
        '__ALL__' => [ $events->[0], $events->[1], $events->[2] ],
        plan => [ $events->[0] ],
        pass => [ $events->[1] ],
        ok => [ $events->[2] ],
    },
    Test2::Tools::Compare => { ... },
}

# Get an arrayref of all the assert facets from the list of events.
my $assert_facets = facets assert => $events;
# [
```

(continues on next page)

(continued from previous page)

```
#   bless({ details => 'pass', pass => 1},
 ↪'Test2::EventFacet::Assert'),
#   bless({ details => 'pass', pass => 1},
 ↪'Test2::EventFacet::Assert'),
# ]

# Same, but for info facets
my $info_facets = facets info => $events;
```

EXPORTS

No subs are exported by default.

- $array_ref = filter $events => $PACKAGE
- $array_ref = filter $events => $PACKAGE1, $PACKAGE2
- $array_ref = filter $events => qr/match/
- $array_ref = filter $events => qr/match/, $PACKAGE

  This function takes an arrayref of events as the first argument. All additional arguments must either be a package name, or a regex. Any event that is generated by a tool in any of the package, or by a tool that matches any of the regexes, will be returned in an arrayref.

- $grouped = group_events($events)

  This function iterates all the events in the argument arrayref and splits them into groups. The resulting data structure is:

  ```
  { PACKAGE => { SUBNAME => [ $EVENT1, $EVENT2, ... }}
  ```

  If the package of an event is not known it will be put into and arrayref under the '__NA__' key at the root of the structure. If a sub name is not known it will typically go under the '__ANON__' key in under the package name.

  In addition there is an '__ALL__' key under each package which stores all of the events sorted into that group.

  A more complete example:

  ```
  {
      '__NA__' => [ $event->[3] ],
      'Test2::Tools::Basic' => {
          '__ALL__' => [ $events->[0], $events->[1], $events->[2],
   ↪],
          plan => [ $events->[0] ],
          pass => [ $events->[1] ],
          ok => [ $events->[2] ],
      },
  }
  ```

- $arrayref = facets TYPE => $events

This function will compile a list of all facets of the specified type that are found in the arrayref of events. If the facet has a `Test2::EventFacet::TYPE` package available then the facet will be constructed into an instance of the class, otherwise it is left as a hashref. Facet Order is preserved.

```
my $assert_facets = facets assert => $events;
# [
#   bless({ details => 'pass', pass => 1},
 ↪'Test2::EventFacet::Assert'),
#   bless({ details => 'pass', pass => 1},
 ↪'Test2::EventFacet::Assert'),
# ]
```

Test2::Tools::Tiny

Tiny set of tools for unfortunate souls who cannot use *Test2::Suite*.

DESCRIPTION

You should really look at *Test2::Suite*. This package is some very basic essential tools implemented using *Test2*. This exists only so that *Test2* and other tools required by *Test2::Suite* can be tested. This is the package *Test2* uses to test itself.

USE Test2::Suite INSTEAD

Use *Test2::Suite* if at all possible.

EXPORTS

- ok($bool, $name)
- ok($bool, $name, @diag)

  Run a simple assertion.
- is($got, $want, $name)
- is($got, $want, $name, @diag)

  Assert that 2 strings are the same.
- isnt($got, $do_not_want, $name)
- isnt($got, $do_not_want, $name, @diag)

  Assert that 2 strings are not the same.
- like($got, $regex, $name)
- like($got, $regex, $name, @diag)

  Check that the input string matches the regex.
- unlike($got, $regex, $name)
- unlike($got, $regex, $name, @diag)

  Check that the input string does not match the regex.
- is_deeply($got, $want, $name)
- is_deeply($got, $want, $name, @diag)

  Check 2 data structures. Please note that this is a *DUMB* implementation that compares the output of *Data::Dumper* against both structures.
- diag($msg)

  Issue a diagnostics message to STDERR.
- note($msg)

  Issue a diagnostics message to STDOUT.
- skip_all($reason)

  Skip all tests.
- todo $reason => sub { ... }

  Run a block in TODO mode.
- plan($count)

  Set the plan.
- done_testing()

  Set the plan to the current test count.
- $warnings = warnings { ... }

  Capture an arrayref of warnings from the block.

- $exception = exception { ... }

  Capture an exception.

- tests $name => sub { ... }

  Run a subtest.

- $output = capture { ... }

  Capture STDOUT and STDERR output.

  Result looks like this:

```
{
    STDOUT => "...",
    STDERR => "...",
}
```

Test2::Tools::Warnings

Tools to verify warnings.

DESCRIPTION

This is a collection of tools that can be used to test code that issues warnings.

SYNOPSIS

```
use Test2::Tools::Warnings qw/warns warning warnings no_warnings/;

ok(warns { warn 'a' }, "the code warns");
ok(!warns { 1 }, "The code does not warn");
is(warns { warn 'a'; warn 'b' }, 2, "got 2 warnings");

ok(no_warnings { ... }, "code did not warn");

like(
    warning { warn 'xxx' },
    qr/xxx/,
    "Got expected warning"
);

is(
    warnings { warn "a\n"; warn "b\n" },
    [
        "a\n",
        "b\n",
    ],
    "Got 2 specific warnings"
);
```

EXPORTS

All subs are exported by default.

- $count = warns { ... }

  Returns the count of warnings produced by the block. This will always return 0, or a positive integer.

- $warning = warning { ... }

  Returns the first warning generated by the block. If the block produces more than one warning, they will all be shown as notes, and an actual warning will tell you about it.

- $warnings_ref = warnings { ... }

  Returns an arrayref with all the warnings produced by the block. This will always return an array reference. If there are no warnings, this will return an empty array reference.

- $bool = no_warnings { ... }

  Return true if the block has no warnings. Returns false if there are warnings.

Test2::Util

Tools used by Test2 and friends.

DESCRIPTION

Collection of tools used by *Test2* and friends.

EXPORTS

All exports are optional. You must specify subs to import.

- ($success, $error) = try { ... }

  Eval the codeblock, return success or failure, and the error message. This code protects $@ and $!, they will be restored by the end of the run. This code also temporarily blocks $SIG{DIE} handlers.

- protect { ... }

  Similar to try, except that it does not catch exceptions. The idea here is to protect $@ and $! from changes. $@ and $! will be restored to whatever they were before the run so long as it is successful. If the run fails $! will still be restored, but $@ will contain the exception being thrown.

- CAN_FORK

  True if this system is capable of true or pseudo-fork.

- CAN_REALLY_FORK

  True if the system can really fork. This will be false for systems where fork is emulated.

- CAN_THREAD

  True if this system is capable of using threads.

- USE_THREADS

  Returns true if threads are enabled, false if they are not.

- get_tid

  This will return the id of the current thread when threads are enabled, otherwise it returns 0.

- my $file = pkg_to_file($package)

  Convert a package name to a filename.

- $string = ipc_separator()

  Get the IPC separator. Currently this is always the string `'~'`.

- $string = gen_uid()

  Generate a unique id (NOT A UUID). This will typically be the process id, the thread id, the time, and an incrementing integer all joined with the `ipc_separator()`.

  These ID's are unique enough for most purposes. For identical ids to be generated you must have 2 processes with the same PID generate IDs at the same time with the same current state of the incrementing integer. This is a perfectly reasonable thing to expect to happen across multiple machines, but is quite unlikely to happen on one machine.

  This can fail to be unique if a process generates an id, calls exec, and does it again after the exec and it all happens in less than a second. It can also happen if the systems process id's cycle in less than a second allowing 2 different programs that use this generator to run with the same PID in less than a second. Both these cases are sufficiently unlikely. If you need universally unique ids, or ids that are unique in these conditions, look at *Data::UUID*.

- ($ok, $err) = do_rename($old_name, $new_name)

  Rename a file, this wraps `rename()` in a way that makes it more reliable cross-platform when trying to rename files you recently altered.

- ($ok, $err) = do_unlink($filename)

  Unlink a file, this wraps `unlink()` in a way that makes it more reliable cross-platform when trying to unlink files you recently altered.

NOTES && CAVEATS

- 5.10.0

  Perl 5.10.0 has a bug when compiled with newer gcc versions. This bug causes a segfault whenever a new thread is launched. Test2 will attempt to detect this, and note that the system is not capable of forking when it is detected.

- Devel::Cover

  Devel::Cover does not support threads. CAN_THREAD will return false if Devel::Cover is loaded before the check is first run.

Modules

- `Test2::Util::ExternalMeta` - Allow third party tools to safely attach meta-data to your instances.
- `Test2::Util::Facets2Legacy` - Convert facet data to the legacy event API.
- `Test2::Util::Grabber` - Object used to temporarily intercept all events.
- `Test2::Util::Guard` - Inline copy of Scope::Guard
- `Test2::Util::HashBase` - Build hash based classes.
- `Test2::Util::Importer` - Inline copy of Importer.
- `Test2::Util::Ref` - Tools for inspecting or manipulating references.
- `Test2::Util::Sig` - Signal tools used by Test2 and friends.
- `Test2::Util::Stash` - Utilities for manipulating stashes and globs.
- `Test2::Util::Sub` - Tools for inspecting and manipulating subs.
- `Test2::Util::Table` - Format a header and rows into a table
- `Test2::Util::Times` - Format timing/benchmark information.
- `Test2::Util::Trace` - Legacy wrapper for *Test2::EventFacet::Trace*.

Test2::Util::ExternalMeta

Allow third party tools to safely attach meta-data to your instances.

DESCRIPTION

This package lets you define a clear, and consistent way to allow third party tools to attach meta-data to your instances. If your object consumes this package, and imports its methods, then third party meta-data has a safe place to live.

SYNOPSIS

```
package My::Object;
use strict;
use warnings;

use Test2::Util::ExternalMeta qw/meta get_meta set_meta delete_meta/
 ↪;

...
```

Now to use it:

```
my $inst = My::Object->new;

$inst->set_meta(foo => 'bar');
my $val = $inst->get_meta('foo');
```

WHERE IS THE DATA STORED?

This package assumes your instances are blessed hashrefs, it will not work if that is not true. It will store all meta-data in the `_meta` key on your objects hash. If your object makes use of the `_meta` key in its underlying hash, then there is a conflict and you cannot use this package.

EXPORTS

- $val = $obj->meta($key)
- $val = $obj->meta($key, $default)

  This will get the value for a specified meta `$key`. Normally this will return `undef` when there is no value for the `$key`, however you can specify a `$default` value to set when no value is already set.
- $val = $obj->get_meta($key)

  This will get the value for a specified meta `$key`. This does not have the `$default` overhead that `meta()` does.
- $val = $obj->delete_meta($key)

  This will remove the value of a specified meta `$key`. The old `$val` will be returned.

- $obj->set_meta($key, $val)

  Set the value of a specified meta `$key`.

META-KEY RESTRICTIONS

Meta keys must be defined, and must be true when used as a boolean. Keys may not be references. You are free to stringify a reference `"$ref"` for use as a key, but this package will not stringify it for you.

Test2::Util::Facets2Legacy

Convert facet data to the legacy event API.

DESCRIPTION

This module exports several subroutines from the older event API (see *Test2::Event*). These subroutines can be used as methods on any object that provides a custom `facet_data()` method. These subroutines can also be used as functions that take a facet data hashref as arguments.

SYNOPSIS

AS METHODS

```
package My::Event;

use Test2::Util::Facets2Legacy ':ALL';
```

(continues on next page)

(continued from previous page)

```
sub facet_data { return { ... } }
```

Then to use it:

```
my $e = My::Event->new(...);

my $causes_fail = $e->causes_fail;
my $summary     = $e->summary;
....
```

AS FUNCTIONS

```
use Test2::Util::Facets2Legacy ':ALL';

my $f = {
    assert => { ... },
    info => [{...}, ...],
    control => {...},
    ...
};

my $causes_fail = causes_fail($f);
my $summary     = summary($f);
```

NOTE ON CYCLES

When used as methods, all these subroutines call `$e->facet_data()`. The default `facet_data()` method in *Test2::Event* relies on the legacy methods this module emulates in order to work. As a result of this it is very easy to create infinite recursion bugs.

These methods have cycle detection and will throw an exception early if a cycle is detected. `uuid()` is currently the only subroutine in this library that has a fallback behavior when cycles are detected.

EXPORTS

Nothing is exported by default. You must specify which methods to import, or use the ':ALL' tag.

- $bool = $e->causes_fail()
- $bool = causes_fail($f)

  Check if the event or facets result in a failing state.

- $bool = $e->diagnostics()
- $bool = diagnostics($f)

  Check if the event or facets contain any diagnostics information.

- $bool = $e->global()
- $bool = global($f)

  Check if the event or facets need to be globally processed.
- $bool = $e->increments_count()
- $bool = increments_count($f)

  Check if the event or facets make an assertion.
- $bool = $e->no_display()
- $bool = no_display($f)

  Check if the event or facets should be rendered or hidden.
- ($max, $directive, $reason) = $e->sets_plan()
- ($max, $directive, $reason) = sets_plan($f)

  Check if the event or facets set a plan, and return the plan details.
- $id = $e->subtest_id()
- $id = subtest_id($f)

  Get the subtest id, if any.
- $string = $e->summary()
- $string = summary($f)

  Get the summary of the event or facets hash, if any.
- $undef_or_int = $e->terminate()
- $undef_or_int = terminate($f)

  Check if the event or facets should result in process termination, if so the exit code is returned (which could be 0). undef is returned if no termination is requested.
- $uuid = $e->uuid()
- $uuid = uuid($f)

  Get the UUID of the facets or event.

  Note: This will fall back to `$e->SUPER::uuid()` if a cycle is detected and an event is used as the argument.

Test2::Util::Grabber

Object used to temporarily intercept all events.

DESCRIPTION

Once created this object will intercept and stash all events sent to the shared *Test2::Hub* object. Once the object is destroyed, events will once again be sent to the shared hub.

SYNOPSIS

```
use Test2 qw/Core Grab/;

my $grab = grab();

# Generate some events, they are intercepted.
ok(1, "pass");
ok(0, "fail");

my $events_a = $grab->flush;

# Generate some more events, they are intercepted.
ok(1, "pass");
ok(0, "fail");

# Same as flush, except it destroys the grab object.
my $events_b = $grab->finish;
```

After calling `finish()` the grab object is destroyed and `$grab` is set to undef. `$events_a` is an arrayref with the first two events. `$events_b` is an arrayref with the second two events.

EXPORTS

- $grab = grab()

  This lets you intercept all events for a section of code without adding anything to your call stack. This is useful for things that are sensitive to changes in the stack depth.

```
my $grab = grab();
    ok(1, 'foo');
    ok(0, 'bar');

# $grab is magically undef after this.
my $events = $grab->finish;

is(@$events, 2, "grabbed two events.");
```

When you call `finish()` the `$grab` object will automagically undef itself, but only for the reference used in the method call. If you have other references to the `$grab` object they will not be set to undef.

If the `$grab` object is destroyed without calling `finish()`, it will automatically clean up after itself and restore the parent hub.

```
{
    my $grab = grab();
    # Things are grabbed
}
# Things are back to normal
```

By default the hub used has `no_ending` set to true. This will prevent the hub from enforcing that you issued a plan and ran at least one test. You can turn enforcement back one like this:

```
$grab->hub->set_no_ending(0);
```

With `no_ending` turned off, `finish` will run the post-test checks to enforce the plan and that tests were run. In many cases this will result in additional events in your events array.

METHODS

- $grab = $class->new()

  Create a new grab object, immediately starts intercepting events.

- $ar = $grab->flush()

  Get an arrayref of all the events so far, clearing the grab objects internal list.

- $ar = $grab->events()

  Get an arrayref of all events so far. Does not clear the internal list.

- $ar = $grab->finish()

  Get an arrayref of all the events, then destroy the grab object.

- $hub = $grab->hub()

  Get the hub that is used by the grab event.

ENDING BEHAVIOR

By default the hub used has no_ending set to true. This will prevent the hub from enforcing that you issued a plan and ran at least one test. You can turn enforcement back one like this:

```
$grab->hub->set_no_ending(0);
```

With no_ending turned off, `finish` will run the post-test checks to enforce the plan and that tests were run. In many cases this will result in additional events in your events array.

SEE ALSO

Test2::Tools::Intercept - Accomplish the same thing, but using blocks instead.

Test2::Util::HashBase

Build hash based classes.

SYNOPSIS

A class:

```
package My::Class;
use strict;
use warnings;

# Generate 3 accessors
use Test2::Util::HashBase qw/foo -bar ^baz <bat >ban +boo/;

# Chance to initialize defaults
sub init {
    my $self = shift;    # No other args
    $self->{+FOO} ||= "foo";
    $self->{+BAR} ||= "bar";
    $self->{+BAZ} ||= "baz";
    $self->{+BAT} ||= "bat";
    $self->{+BAN} ||= "ban";
    $self->{+BOO} ||= "boo";
}

sub print {
    print join ", " => map { $self->{$_} } FOO, BAR, BAZ, BAT, BAN,␣
 ↪BOO;
}
```

Subclass it

```
package My::Subclass;
use strict;
use warnings;

# Note, you should subclass before loading HashBase.
use base 'My::Class';
```

(continues on next page)

(continued from previous page)

```
use Test2::Util::HashBase qw/bub/;

sub init {
    my $self = shift;

    # We get the constants from the base class for free.
    $self->{+FOO} ||= 'SubFoo';
    $self->{+BUB} ||= 'bub';

    $self->SUPER::init();
}
```

use it:

```
package main;
use strict;
use warnings;
use My::Class;

# These are all functionally identical
my $one   = My::Class->new(foo => 'MyFoo', bar => 'MyBar');
my $two   = My::Class->new({foo => 'MyFoo', bar => 'MyBar'});
my $three = My::Class->new(['MyFoo', 'MyBar']);

# Readers!
my $foo = $one->foo;    # 'MyFoo'
my $bar = $one->bar;    # 'MyBar'
my $baz = $one->baz;    # Defaulted to: 'baz'
my $bat = $one->bat;    # Defaulted to: 'bat'
# '>ban' means setter only, no reader
# '+boo' means no setter or reader, just the BOO constant

# Setters!
$one->set_foo('A Foo');

#'-bar' means read-only, so the setter will throw an exception (but
 ↪is defined).
$one->set_bar('A bar');

# '^baz' means deprecated setter, this will warn about the setter
 ↪being
# deprecated.
$one->set_baz('A Baz');

# '<bat' means no setter defined at all
# '+boo' means no setter or reader, just the BOO constant

$one->{+FOO} = 'xxx';
```

DESCRIPTION

This package is used to generate classes based on hashrefs. Using this class will give you a `new()` method, as well as generating accessors you request. Generated accessors will be getters, `set_ACCESSOR` setters will also be generated for you. You also get constants for each accessor (all caps) which return the key into the hash for that accessor. Single inheritance is also supported.

THIS IS A BUNDLED COPY OF HASHBASE

This is a bundled copy of Object::HashBase. This file was generated using the `/home/exodist/perl5/perlbrew/perls/main/bin/hashbase_inc.pl` script.

METHODS

PROVIDED BY HASH BASE

- $it = $class->new(%PAIRS)
- $it = $class->new(\%PAIRS)
- $it = $class->new(\@ORDERED_VALUES)

  Create a new instance.

  HashBase will not export `new()` if there is already a `new()` method in your packages inheritance chain.

  If you do not want this method you can define your own you just have to declare it before loading *Test2::Util::HashBase*.

```
package My::Package;

# predeclare new() so that HashBase does not give us one.
sub new;

use Test2::Util::HashBase qw/foo bar baz/;

# Now we define our own new method.
sub new { ... }
```

  This makes it so that HashBase sees that you have your own `new()` method. Alternatively you can define the method before loading HashBase instead of just declaring it, but that scatters your use statements.

  The most common way to create an object is to pass in key/value pairs where each key is an attribute and each value is what you want assigned to that attribute. No checking is done to verify the attributes or values are valid, you may do that in `init()` if desired.

  If you would like, you can pass in a hashref instead of pairs. When you do so the hashref will be copied, and the copy will be returned blessed as an object. There is no way to ask HashBase to bless a specific hashref.

  In some cases an object may only have 1 or 2 attributes, in which case a hashref may be too verbose for your liking. In these cases you can pass in an arrayref with

only values. The values will be assigned to attributes in the order the attributes were listed. When there is inheritance involved the attributes from parent classes will come before subclasses.

HOOKS

- $self->init()

  This gives you the chance to set some default values to your fields. The only argument is `$self` with its indexes already set from the constructor.

  Note: Test2::Util::HashBase checks for an init using `$class->can('init')` during construction. It DOES NOT call `can()` on the created object. Also note that the result of the check is cached, it is only ever checked once, the first time an instance of your class is created. This means that adding an `init()` method AFTER the first construction will result in it being ignored.

ACCESSORS

READ/WRITE

To generate accessors you list them when using the module:

```
use Test2::Util::HashBase qw/foo/;
```

This will generate the following subs in your namespace:

- foo()

  Getter, used to get the value of the `foo` field.

- set_foo()

  Setter, used to set the value of the `foo` field.

- FOO()

  Constant, returns the field `foo`'s key into the class hashref. Subclasses will also get this function as a constant, not simply a method, that means it is copied into the subclass namespace.

  The main reason for using these constants is to help avoid spelling mistakes and similar typos. It will not help you if you forget to prefix the '+' though.

READ ONLY

```
use Test2::Util::HashBase qw/-foo/;
```

- set_foo()

  Throws an exception telling you the attribute is read-only. This is exported to override any active setters for the attribute in a parent class.

DEPRECATED SETTER

```
use Test2::Util::HashBase qw/^foo/;
```

- set_foo()

  This will set the value, but it will also warn you that the method is deprecated.

NO SETTER

```
use Test2::Util::HashBase qw/<foo/;
```

Only gives you a reader, no `set_foo` method is defined at all.

NO READER

```
use Test2::Util::HashBase qw/>foo/;
```

Only gives you a write (`set_foo`), no `foo` method is defined at all.

CONSTANT ONLY

```
use Test2::Util::HashBase qw/+foo/;
```

This does not create any methods for you, it just adds the `FOO` constant.

SUBCLASSING

You can subclass an existing HashBase class.

```
use base 'Another::HashBase::Class';
use Test2::Util::HashBase qw/foo bar baz/;
```

The base class is added to `@ISA` for you, and all constants from base classes are added to subclasses automatically.

GETTING A LIST OF ATTRIBUTES FOR A CLASS

Test2::Util::HashBase provides a function for retrieving a list of attributes for an Test2::Util::HashBase class.

- @list = Test2::Util::HashBase::attr_list($class)
- @list = $class->Test2::Util::HashBase::attr_list()

  Either form above will work. This will return a list of attributes defined on the object. This list is returned in the attribute definition order, parent class attributes are listed before subclass attributes. Duplicate attributes will be removed before the list is returned.

  Note: This list is used in the `$class->new(\@ARRAY)` constructor to determine the attribute to which each value will be paired.

Test2::Util::Ref

Tools for inspecting or manipulating references.

DESCRIPTION

These are used by *Test2::Tools* to inspect, render, or manipulate references.

EXPORTS

All exports are optional. You must specify subs to import.

- $type = rtype($ref)

  A normalization between `Scalar::Util::reftype()` and `ref()`.

  Always returns a string.

  Returns `'REGEXP'` for regex types

  Returns `''` for non-refs

  Otherwise returns what `Scalar::Util::reftype()` returns.

- $addr_str = render_ref($ref)

  Always returns a string. For unblessed references this returns something like `"SCALAR(0x...)"`. For blessed references it returns `"My::Thing=SCALAR(0x...)"`. The only difference between this and `$add_str = "$thing"` is that it ignores any overloading to ensure it is always the ref address.

Test2::Util::Sig

Signal tools used by Test2 and friends.

DESCRIPTION

Collection of signal tools used by *Test2* and friends.

EXPORTS

All exports are optional. You must specify subs to import.

- ($ok, $err) = try_sig_mask { ... }

  Complete an action with several signals masked, they will be unmasked at the end allowing any signals that were intercepted to get handled.

  This is primarily used when you need to make several actions atomic (against some signals anyway).

  Signals that are intercepted:

  - SIGINT
  - SIGALRM
  - SIGHUP
  - SIGTERM
  - SIGUSR1
  - SIGUSR2

Test2::Util::Stash

Utilities for manipulating stashes and globs.

DESCRIPTION

This is a collection of utilities for manipulating and inspecting package stashes and globs.

EXPORTS

- $stash = get_stash($package)

  Gets the package stash. This is the same as `$stash = \%Package::Name::`.

- $sym_spec = parse_symbol($symbol)
- $sym_spec = parse_symbol($symbol, $package)

  Parse a symbol name, and return a hashref with info about the symbol.

  `$symbol` can be a simple name, or a fully qualified symbol name. The sigil is optional, and & is assumed if none is provided. If `$symbol` is fully qualified, and `$package` is also provided, then the package of the symbol must match the `$package`.

  Returns a structure like this:

```
return {
    name    => 'BAZ',
    sigil   => '$',
    type    => 'SCALAR',
    symbol  => '&Foo::Bar::BAZ',
    package => 'Foo::Bar',
};
```

- $glob_ref = get_glob($symbol)
- $glob_ref = get_glob($symbol, $package)

  Get a glob ref. Arguments are the same as for `parse_symbol`.

- $ref = get_symbol($symbol)
- $ref = get_symbol($symbol, $package)

  Get a reference to the symbol. Arguments are the same as for `parse_symbol`.

- $ref = purge_symbol($symbol)
- $ref = purge_symbol($symbol, $package)

  Completely remove the symbol from the package symbol table. Arguments are the same as for `parse_symbol`. A reference to the removed symbol is returned.

- $sig = slot_to_sig($slot)

  Convert a slot (like 'SCALAR') to a sigil (like '$').

- $slot = sig_to_slot($sig)

  Convert a sigil (like '$') to a slot (like 'SCALAR').

SOURCE

Test2::Util::Sub

Tools for inspecting and manipulating subs.

DESCRIPTION

Utilities used by Test2::Tools to inspect and manipulate subroutines.

EXPORTS

All exports are optional, you must specify subs to import.

- $name = sub_name(\&sub)

  Get the name of the sub.

- my $hr = sub_info(\&code)

  This returns a hashref with information about the sub:

```
{
    ref        => \&code,
    cobj       => $cobj,
    name       => "Some::Mod::code",
    file       => "Some/Mod.pm",
    package    => "Some::Mod",
```

(continues on next page)

(continued from previous page)

```
    # Note: These have been adjusted based on guesswork.
    start_line => 22,
    end_line   => 42,
    lines      => [22, 42],

    # Not a bug, these lines are different!
    all_lines  => [23, 25, ..., 39, 41],
};
```

- $info->{ref} => \&code

  This is the original sub passed to `sub_info()`.

- $info->{cobj} => $cobj

  This is the c-object representation of the coderef.

- $info->{name} => "Some::Mod::code"

  This is the name of the coderef. For anonymous coderefs this may end with `'__ANON__'`. Also note that the package 'main' is special, and 'main::' may be omitted.

- $info->{file} => "Some/Mod.pm"

  The file in which the sub was defined.

- $info->{package} => "Some::Mod"

  The package in which the sub was defined.

- $info->{start_line} => 22

- $info->{end_line} => 42

- $info->{lines} => [22, 42]

  These three fields are the *adjusted* start line, end line, and array with both. It is important to note that these lines have been adjusted and may not be accurate.

  The lines are obtained by walking the ops. As such, the first line is the line of the first statement, and the last line is the line of the last statement. This means that in multi-line subs the lines are usually off by 1. The lines in these keys will be adjusted for you if it detects a multi-line sub.

- $info->{all_lines} => [23, 25, ..., 39, 41]

  This is an array with the lines of every statement in the sub. Unlike the other line fields, these have not been adjusted for you.

Test2::Util::Table

Format a header and rows into a table

DESCRIPTION

This is used by some failing tests to provide diagnostics about what has gone wrong. This module is able to generic format rows of data into tables.

SYNOPSIS

```
use Test2::Util::Table qw/table/;

my @table = table(
    max_width => 80,
    collapse => 1, # Do not show empty columns
    header => [ 'name', 'age', 'hair color' ],
    rows => [
        [ 'Fred Flinstone',  2000000, 'black' ],
        [ 'Wilma Flinstone', 1999995, 'red' ],
        ...,
    ],
);

# The @table array contains each line of the table, no newlines␣
↪added.
say $_ for @table;
```

This prints a table like this:

```
+-----------------+---------+------------+
| name            | age     | hair color |
```

(continues on next page)

(continued from previous page)

```
+-----------------+---------+------------+
| Fred Flinstone  | 2000000 | black      |
| Wilma Flinstone | 1999995 | red        |
| ...             | ...     | ...        |
+-----------------+---------+------------+
```

EXPORTS

@rows = table(...)

The function returns a list of lines, lines do not have the newline \n character appended.

Options:

- header => [...]

  If you want a header specify it here. This takes an arrayref with each columns heading.

- rows => [[...], [...], ...]

  This should be an arrayref containing an arrayref per row.

- collapse => $bool

  Use this if you want to hide empty columns, that is any column that has no data in any row. Having a header for the column will not effect collapse.

- max_width => $num

  Set the maximum width of the table, the table may not be this big, but it will be no bigger. If none is specified it will attempt to find the width of your terminal and use that, otherwise it falls back to 80.

- sanitize => $bool

  This will sanitize all the data in the table such that newlines, control characters, and all whitespace except for ASCII 20 ' ' are replaced with escape sequences. This prevents newlines, tabs, and similar whitespace from disrupting the table.

  Note: newlines are marked as '\n', but a newline is also inserted into the data so that it typically displays in a way that is useful to humans.

  Example:

```
my $field = "foo\nbar\nbaz\n";

print join "\n" => table(
    sanitize => 1,
    rows => [
        [$field,      'col2'     ],
        ['row2 col1', 'row2 col2']
    ]
);
```

  Prints:

```
+------------------+-----------+
| foo\n            | col2      |
| bar\n            |           |
| baz\n            |           |
|                  |           |
| row2 col1        | row2 col2 |
+------------------+-----------+
```

So it marks the newlines by inserting the escape sequence, but it also shows the data across as many lines as it would normally display.

- mark_tail => $bool

  This will replace the last whitespace character of any trailing whitespace with its escape sequence. This makes it easier to notice trailing whitespace when comparing values.

my $cols = term_size()

Attempts to find the width in columns (characters) of the current terminal. Returns 80 as a safe bet if it cannot find it another way.

NOTE ON UNICODE/WIDE CHARACTERS

Some unicode characters, such as 婧 (U+5A67) are wider than others. These will render just fine if you `use utf8;` as necessary, and *Unicode::GCString* is installed, however if the module is not installed there will be anomalies in the table:

```
+-----+-----+---+
| a   | b   | c |
+-----+-----+---+
| 婧 | x   | y |
| x   | y   | z |
| x   | 婧 | z |
+-----+-----+---+
```

Modules

- Test2::Util::Table::LineBreak - Break up lines for use in tables.

Test2::Util::Table::LineBreak

Break up lines for use in tables.

DESCRIPTION

This is meant for internal use. This package takes long lines of text and splits them so that they fit in table rows.

SYNOPSIS

```
use Test2::Util::Table::LineBreak;

my $lb = Test2::Util::Table::LineBreak->new(string => $STRING);

$lb->break($SIZE);
while (my $part = $lb->next) {
    ...
}
```

Test2::Util::Times

Format timing/benchmark information.

DESCRIPTION

This modules exports tools for rendering timing data at the end of tests.

EXPORTS

All exports are optional. You must specify subs to import.

- $str = render_bench($start, $end, $user, $system, $cuser, $csystem)
- $str = render_bench($start, time(), times())

  This will produce a string like one of these (Note these numbers are completely made up). *Which string is used depends on the time elapsed.*

```
0.12345s on wallclock (0.05 usr 0.00 sys + 0.00 cusr 0.00 csys␣
↪= 0.05 CPU)

11.1234s on wallclock (0.05 usr 0.00 sys + 0.00 cusr 0.00 csys␣
↪= 0.05 CPU)

01m:54.45s on wallclock (0.05 usr 0.00 sys + 0.00 cusr 0.00␣
↪csys = 0.05 CPU)

18h:22m:54.45s on wallclock (0.05 usr 0.00 sys + 0.00 cusr 0.00␣
↪csys = 0.05 CPU)

04d:18h:22m:54.45s on wallclock (0.05 usr 0.00 sys + 0.00 cusr␣
↪0.00 csys = 0.05 CPU)
```

  The first 2 arguments are the `$start` and `$end` times in seconds (as returned by `time()` or `Time::HiRes::time()`).

  The last 4 arguments are timing information as returned by the `times()` function.

Test2::V0

0Th edition of the Test2 recommended bundle.

V1 IS OUT NOW!

See *Test2::V1* for the most recent "Recommended" bundle.

DESCRIPTION

This is the big-daddy bundle. This bundle includes nearly every tool, and several plugins, that the Test2 author uses. This bundle is used extensively to test *Test2::Suite* itself.

NAMING, USING, DEPENDING

This bundle should not change in a *severely* incompatible way. Some minor breaking changes, specially bugfixes, may be allowed. If breaking changes are needed then a new `Test2::V#` module should be released instead.

As new V# modules are released old ones *may* be moved to different cpan distributions. You should always use a specific bundle version and list that version in your distributions testing requirements. You should never simply list *Test2::Suite* as your modules dep, instead list the specific bundle, or tools and plugins you use directly in your metadata.

SYNOPSIS

```
use Test2::V0;

ok(1, "pass");

...

done_testing;
```

RESOLVING CONFLICTS WITH MOOSE

```
use Test2::V0 '!meta';
```

Moose and *Test2::V0* both export very different `meta()` subs. Adding `'!meta'` to the import args will prevent the sub from being imported. This bundle also exports the sub under the name `meta_check()` so you can use that spelling as an alternative.

TAGS

- :DEFAULT

  The following are both identical:

```
use Test2::V0;

use Test2::V0 ':DEFAULT';
```

RENAMING ON IMPORT

```
use Test2::V0 ':DEFAULT', '!ok', ok => {-as => 'my_ok'};
```

This bundle uses *Test2::Util::Importer* for exporting, as such you can use any arguments it accepts.

Explanation:

- '!ok'

  Do not export `ok()`

- ok => {-as => 'my_ok'}

  Actually, go ahead and import `ok()` but under the name `my_ok()`.

If you did not add the `'!ok'` argument then you would have both `ok()` and `my_ok()`

PRAGMAS

All of these can be disabled via individual import arguments, or by the `-no_pragmas` argument.

```
use Test2::V0 -no_pragmas => 1;
```

STRICT

strict is turned on for you. You can disable this with the `-no_strict` or `-no_pragmas` import arguments:

```
use Test2::V0 -no_strict => 1;
```

WARNINGS

warnings are turned on for you. You can disable this with the `-no_warnings` or `-no_pragmas` import arguments:

```
use Test2::V0 -no_warnings => 1;
```

UTF8

This is actually done via the *Test2::Plugin::UTF8* plugin, see the "PLUGINS" section for details.

Note: `-no_pragmas => 1` will turn off the entire plugin.

PLUGINS

SRAND

See *Test2::Plugin::SRand*.

This will set the random seed to today's date. You can provide an alternate seed with the `-srand` import option:

```
use Test2::V0 -srand => 1234;
```

You can also disable this behavior:

```
use Test2::V0 -no_srand => 1;
```

Note When srand is on (default) it can cause problems with things like *File::Temp* which will end up attempting the same "random" filenames for every test process started on a given day (or sharing the same seed).

UTF8

See *Test2::Plugin::UTF8*.

This will set the file, and all output handles (including formatter handles), to utf8. This will turn on the utf8 pragma for the current scope.

This can be disabled using the `-no_utf8 => 1` or `-no_pragmas => 1` import arguments.

```
use Test2::V0 -no_utf8 => 1;
```

EXIT SUMMARY

See *Test2::Plugin::ExitSummary*.

This plugin has no configuration.

ENVIRONMENT VARIABLES

See *Test2::Env* for a list of meaningful environment variables.

API FUNCTIONS

See *Test2::API* for these

- $ctx = context()
- $events = intercept { ... }

TOOLS

TARGET

See *Test2::Tools::Target*.

You can specify a target class with the `-target` import argument. If you do not provide a target then `$CLASS` and `CLASS()` will not be imported.

```
use Test2::V0 -target => 'My::Class';

print $CLASS;  # My::Class
print CLASS(); # My::Class
```

Or you can specify names:

```
use Test2::V0 -target => { pkg => 'Some::Package' };

pkg()->xxx; # Call 'xxx' on Some::Package
$pkg->xxx;  # Same
```

- $CLASS

  Package variable that contains the target class name.

- $class = CLASS()

  Constant function that returns the target class name.

DEFER

See *Test2::Tools::Defer*.

- def $func => @args;
- do_def()

BASIC

See *Test2::Tools::Basic*.

- ok($bool, $name)
- ok($bool, $name, @diag)
- pass($name)
- pass($name, @diag)
- fail($name)
- fail($name, @diag)
- diag($message)
- note($message)
- $todo = todo($reason)
- todo $reason => sub { ... }

- skip($reason, $count)
- plan($count)
- skip_all($reason)
- done_testing()
- bail_out($reason)

COMPARE

See *Test2::Tools::Compare*.

Test2::V1

V1 edition of the Test2 recommended bundle.

DESCRIPTION

This is the first sequel to *Test2::V0*. This module is recommended over *Test2::V0* for new tests.

Key differences from *Test2::V0*

- Only 1 export by default: T2()
- No pragmas by default
- srand and utf8 are not enabled by default
- Easy to still import everything
- East to still enable pragmas

NAMING, USING, DEPENDING

This bundle should not change in a *severely* incompatible way. Some minor breaking changes, specially bugfixes, may be allowed. If breaking changes are needed then a new `Test2::V#` module should be released instead.

Adding new optional exports, and new methods on the T2() handle are not considered breaking changes, and are allowed without bumping the V# number. Adding new plugin shortcuts is also allowed, but they cannot be added to the `-P` or `-plugins` shortcuts without a bump in V# number.

As new V# modules are released old ones *may* be moved to different cpan distributions. You should always use a specific bundle version and list that version in your distributions testing requirements. You should never simply list *Test2::Suite* as your modules dep, instead list the specific bundle, or tools and plugins you use directly in your metadata.

See the "JUSTIFICATION" section for an explanation of why *Test2::V1* was created.

SYNOPSIS

RECOMMENDED

```
use Test2::V1 -utf8;

T2->ok(1, "pass");

T2->is({1 => 1}, {1 => 1}, "Structures Match");

# Note that prototypes do not work in method form:
my @foo = (1, 2, 3);
T2->is(scalar(@foo), 3, "Needed to force scalar context");

T2->done_testing;
```

WORK LIKE V0 DID

```
use Test2::V1 -ipP;

ok(1, "pass");

is({1 => 1}, {1 => 1}, "Structures Match");

my @foo = (1, 2, 3);
is(@foo, 3, "Prototype forces @foo into scalar context");

# You still have access to T2
T2->ok(1, "Another Pass");

done_testing;
```

The `-ipP` argument is short for `-include, -pragmas, -plugins` which together enable all pragmas, plugins, and import all symbols.

Note: The order in which `i`, `p`, and `P` appear is not important; `-Ppi` and `-piP` and any other order are all perfectly valid.

IMPORT ARGUMENT GUIDE

- `-P` or `-plugins`

  Shortcut to include the following plugins: *Test2::Plugin::UTF8*, *Test2::Plugin::SRand*, *Test2::Plugin::ExitSummary*.

- `-p` or `-pragmas`

  Shortcut to enable the following pragmas: `strict`, `warnings`.

- `-i` or `-import`

  Shortcut to import all possible exports.

- `-x`

  Shortcut to import any sub that has '&' in its prototype, things like `dies { ... }`, `warns { ... }`, etc.

  While these can be used in method form: `T2->dies(sub { ... })` it is a little less convenient than having them imported. '-x' will import all of these, and any added in the future or included via an `-include => ...` import argument.

- `-ipP`, `-pPi`, `-pP`, `-Pix`, etc..

  The `i`, `p`, `P`, and `x` short options may all be grouped in any order following a single dash.

- `@EXPORT_LIST`

  Any arguments provided that are not prefixed with a `-` will be assumed to be export requests. If there is an exported sub by the given name it will be imported into your namespace. If there is no such sub an exception will be thrown.

- `!EXPORT_NAME`

  You can prefix an export name with `!` to exclude it at import time. This is really only usedul when combined with `-import` or `-i`.

- `EXPORT_NAME => { -as => "ALT_NAME" }`
- `EXPORT_NAME => { -prefix => "PREFIX_" }`
- `EXPORT_NAME => { -postfix => "_POSTFIX" }`

  You may specify a hashref after an export name to rename it, or add a prefix/postfix to the name.

RENAMING IMPORTS

```
use Test2::V1 '-import', '!ok', ok => {-as => 'my_ok'};
```

Explanation:

- '-import'

  Bring in ALL imports, no need to list them all by hand.

- '!ok'

  Do not import `ok()` (remove it from the list added by '-import')

- ok => {-as => 'my_ok'}

  Actually, go ahead and import `ok()` but under the name `my_ok()`.

If you did not add the `'!ok'` argument then you would have both `ok()` and `my_ok()`

PRAGMAS AND PLUGINS

NO PRAGMAS ARE ENABLED BY DEFAULT ONLY THE EXIT SUMMARY PLUGIN IS STILL ENABLED BY DEFAULT

This is a significant departure from *Test2::V0*.

You can enable all of these with the `-pP` argument, which is short for `-plugins, -pragmas`. `P` is short for plugins, and `p` is short for pragmas. When using the single-letter form they may both be together following a single dash, and can be in any order. They may also be combined with `i` to bring in all imports. `-p` or `-P` ont heir own are also perfectly valid.

- strict

  You can enable this with any of these arguments: `-strict`, `-p`, `-pragmas`.

  This enables strict for you.

- warnings

  You can enable this with any of these arguments: `-warnings`, `-p`, `-pragmas`.

  This enables warnings for you.

- srand

  You can enable this in multiple ways:

  ```
  use Test2::V1 -srand
  use Test2::V1 -P
  use Test2::V1 -plugins
  ```

  See *Test2::Plugin::SRand*.

  This will set the random seed to today's date.

  You can also set a random seed:

  ```
  use Test2::V1 -srand => { seed => 'my seed' };
  ```

- utf8

  You can enable this in multiple ways:

  ```
  use Test2::V1 -utf8
  use Test2::V1 -P
  use Test2::V1 -plugins
  ```

  See *Test2::Plugin::UTF8*.

  This will set the file, and all output handles (including formatter handles), to utf8. This will turn on the utf8 pragma for the current scope.

- summary

  This is turned on by default.

  You can avoid enabling it at import this way:

  ```
  use Test2::V1 -summary => 0;
  ```

  See *Test2::Plugin::ExitSummary*.

  This plugin has no configuration.

ENVIRONMENT VARIABLES

See *Test2::Env* for a list of meaningful environment variables.

API FUNCTIONS

See *Test2::API* for these

- $ctx = T2->context()
- $events = T2->intercept(sub { ... });

THE T2() HANDLE

The `T2()` subroutine imported into your namespace returns an instance of *Test2::V1::Handle*. This gives you a handle on all the tools included by default. It also creates a completely new namespace for use by your test that can have additional tools added to it.

ADDING/OVERRIDING TOOLS IN YOUR T2 HANDLE

```
# Method 1
use Test2::V1 T2 => {
    include => [
        ['Test2::Tools::MyTool', 'my_tool', 'my_other_tool'],
        ['Data::Dumper', 'Dumper'],
    ],
};

# Method 2
use Test2::V1 T2 => {
    include => {
        'Test2::Tools::MyTool' => ['my_tool', 'my_other_tool'],
        'Data::Dumper'         => 'Dumper',
    },
};

# Method 3 (This also works with a hashref instead of an arrayref)
use Test2::V1 -include => [
    ['Test2::Tools::MyTool', 'my_tool', 'my_other_tool'],
```

(continues on next page)

(continued from previous page)

```
    ['Data::Dumper', 'Dumper'],
];

# Method 4
T2->include('Test2::Tools::MyTool', 'my_tool', 'my_other_tool');
T2->include('Data::Dumper', 'Dumper');

# Using them:

T2->my_tool(...);

T2->Dumper({hi => 'there'});
```

Note that you MAY override original tools such as ok(), note(), etc. by importing different copies this way. The first time you do this there should be no warnings or errors. If you pull in multiple tools of the same name an redefine warning is likely.

This also effects exports:

```
use Test2::V1 -import, -include => ['Data::Dumper'];

print Dumper("Dumper can be imported from your include!");
```

OTHER HANDLE OPTIONS

```
use Test2::V1 T2 => {
    include   => $ARRAYREF_OR_HASHREF,
    namespace => $NAMESPACE,
    base      => $BASE_PACKAGE // 'Test2::V1::Base',
    stomp     => $BOOL,
};
```

- include => $ARRAYREF_OR_HASHREF

  See “ADDING TOOLS TO YOUR T2 HANDLE”.

- namespace => $NAMESPACE

  Normally a new namespace will be generated for you. You **CANNOT** rely on the package name being anything specific unless you provide your own.

  The namespace here will be where any tools you ‘include’ will be imported into. It will also have its base class set to the base class you specify, or the *Test2::V1::Base* module if you do not provide any.

  If this namespace already has any symbols defined in it an exception will be thrown unless the `stomp` argument is set to true (not recommended).

- stomp => $BOOL

  Used to allow the handle to stomp on an existing namespace (NOT RECOMMENDED).

- base => $BASE

Set the base class from which functions should be inherited. Normally this is set to *Test2::V1::Base*.

Another interesting use case is to have multiple handles that use eachothers namespaces as base classes:

```
use Test2::V1;

use Test2::V1::Handle(
    'T3',
    base    => T2->HANDLE_NAMESPACE,
    include => {'Alt::Ok' => 'ok'};
);

T3->ok(1, "This uses ok() from Alt::Ok, but all other ->
↪methods are the original");
T3->done_testing(); # Uses the original done_testing
```

EXAMPLE USE CASES

OVERRIDING INCLUDED TOOLS WITH ALTERNATES

Lets say you want to use the Test2::Warnings version of `warning()`, `warnings()` instead of the *Test2::Tools::Warnings* versions, and also wanted to import everything else Test2::Warnings provides.

```
use Test2::V1 -import, -include => ['Test2::Warnings'];
```

The `-include => ['Test2::Warnings']` option means we want to import the default set of imports from Test2::Warnings into our `T2()` handle's private namespace. This will override any methods that were also previously defined by default.

The `-import` option means we want to import all subs into the current namespace. This includes anything we got from Test2::Warnings, and we will get the Test2::Warnings version of those subs.

```
like(
    warning { warn 'xxx' }, # This is the Test2::Warnings version of
↪'warning'
    qr/xxx/,
    "Got expected warning"
);
```

TOOLS

TARGET

Added to Test::V1 in 1.302217.

See *Test2::Tools::Target*.

You can specify a target class with the `-target` import argument. If you do not provide a target then `$CLASS` and `CLASS()` will not be imported.

```
use Test2::V1 -target => 'My::Class';

print $CLASS;  # My::Class
print CLASS(); # My::Class
```

Or you can specify names:

```
use Test2::V1 -target => { pkg => 'Some::Package' };

pkg()->xxx; # Call 'xxx' on Some::Package
$pkg->xxx;  # Same
```

- $CLASS

  Package variable that contains the target class name.

- $class = CLASS()

  Constant function that returns the target class name.

DEFER

See *Test2::Tools::Defer*.

- def $func => @args;

  Added to Test::V1 in 1.302217.

- do_def()

  Added to Test::V1 in 1.302217.

BASIC

See *Test2::Tools::Basic*.

- ok($bool, $name)
- ok($bool, $name, @diag)

  Added to Test::V1 in 1.302217.

- pass($name)
- pass($name, @diag)

  Added to Test::V1 in 1.302217.

- fail($name)
- fail($name, @diag)

  Added to Test::V1 in 1.302217.

- diag($message)

  Added to Test::V1 in 1.302217.

- note($message)

  Added to Test::V1 in 1.302217.

- $todo = todo($reason)
- todo $reason => sub { ... }

  Added to Test::V1 in 1.302217.
- skip($reason, $count)

  Added to Test::V1 in 1.302217.
- plan($count)

  Added to Test::V1 in 1.302217.
- skip_all($reason)

  Added to Test::V1 in 1.302217.
- done_testing()

  Added to Test::V1 in 1.302217.
- bail_out($reason)

  Added to Test::V1 in 1.302217.

COMPARE

See *Test2::Tools::Compare*.

- is($got, $want, $name)

  Added to Test::V1 in 1.302217.
- isnt($got, $do_not_want, $name)

  Added to Test::V1 in 1.302217.
- like($got, qr/match/, $name)

  Added to Test::V1 in 1.302217.
- unlike($got, qr/mismatch/, $name)

  Added to Test::V1 in 1.302217.
- $check = match(qr/pattern/)

  Added to Test::V1 in 1.302217.
- $check = mismatch(qr/pattern/)

  Added to Test::V1 in 1.302217.
- $check = validator(sub { return $bool })

  Added to Test::V1 in 1.302217.
- $check = hash { ... }

  Added to Test::V1 in 1.302217.

  Added to Test::V1 in 1.302217.
- $check = call($method => $expect)

  Added to Test::V1 in 1.302217.
- $check = call_list($method => $expect)

  Added to Test::V1 in 1.302217.
- $check = call_hash($method => $expect)

  Added to Test::V1 in 1.302217.
- $check = prop($name => $expect)

  Added to Test::V1 in 1.302217.

- $check = check($thing)

  Added to Test::V1 in 1.302217.
- $check = T()

  Added to Test::V1 in 1.302217.
- $check = F()

  Added to Test::V1 in 1.302217.
- $check = D()

  Added to Test::V1 in 1.302217.
- $check = DF()

  Added to Test::V1 in 1.302217.
- $check = E()

  Added to Test::V1 in 1.302217.
- $check = DNE()

  Added to Test::V1 in 1.302217.
- $check = FDNE()

  Added to Test::V1 in 1.302217.
- $check = U()

  Added to Test::V1 in 1.302217.
- $check = L()

  Added to Test::V1 in 1.302217.
- $check = exact_ref($ref)

  Added to Test::V1 in 1.302217.
- end()

  Added to Test::V1 in 1.302217.
- etc()

  Added to Test::V1 in 1.302217.
- filter_items { grep { ... } @_ }

  Added to Test::V1 in 1.302217.
- $check = event $type => ...

  Added to Test::V1 in 1.302217.
- @checks = fail_events $type => ...

  Added to Test::V1 in 1.302217.

CLASSIC COMPARE

See *Test2::Tools::ClassicCompare*.

- cmp_ok($got, $op, $want, $name)

  Added to Test::V1 in 1.302217.

SUBTEST

See *Test2::Tools::Subtest*.

- subtest $name => sub { ... };

  Added to Test::V1 in 1.302217.

  (Note: This is called `subtest_buffered()` in the Tools module.)

CLASS

See *Test2::Tools::Class*.

- can_ok($thing, @methods)

  Added to Test::V1 in 1.302217.

- isa_ok($thing, @classes)

  Added to Test::V1 in 1.302217.

- DOES_ok($thing, @roles)

  Added to Test::V1 in 1.302217.

ENCODING

See *Test2::Tools::Encoding*.

- set_encoding($encoding)

  Added to Test::V1 in 1.302217.

EXPORTS

See *Test2::Tools::Exports*.

- imported_ok('function', '$scalar', ...)

  Added to Test::V1 in 1.302217.

- not_imported_ok('function', '$scalar', ...)

  Added to Test::V1 in 1.302217.

REF

See *Test2::Tools::Ref*.

- ref_ok($ref, $type)

  Added to Test::V1 in 1.302217.

- ref_is($got, $want)

  Added to Test::V1 in 1.302217.

- ref_is_not($got, $do_not_want)

  Added to Test::V1 in 1.302217.

See *Test2::Tools::Refcount*.

- is_refcount($ref, $count, $description)

  Added to Test::V1 in 1.302217.

- is_oneref($ref, $description)

  Added to Test::V1 in 1.302217.

- $count = refcount($ref)

  Added to Test::V1 in 1.302217.

MOCK

See *Test2::Tools::Mock*.

- $control = mock ...

  Added to Test::V1 in 1.302217.

- $bool = mocked($thing)

  Added to Test::V1 in 1.302217.

EXCEPTION

See *Test2::Tools::Exception*.

- $exception = dies { ... }

  Added to Test::V1 in 1.302217.

- $bool = lives { ... }

  Added to Test::V1 in 1.302217.

- $bool = try_ok { ... }

  Added to Test::V1 in 1.302217.

WARNINGS

See *Test2::Tools::Warnings*.

- $count = warns { ... }

  Added to Test::V1 in 1.302217.

- $warning = warning { ... }

  Added to Test::V1 in 1.302217.

- $warnings_ref = warnings { ... }

  Added to Test::V1 in 1.302217.

- $bool = no_warnings { ... }

  Added to Test::V1 in 1.302217.

JUSTIFICATION

Test2::V0 is a rich set of tools. But it made several assumptions about how it would be used. The assumptions are fairly good for new users writing simple scripts, but they can get in the way in many cases.

PROBLEMS WITH V0

- Assumptions of strict/warnings

  Many people would put custom strict/warnings settings at the top of their tests, only to have them wiped out when they use *Test2::V0*.

- Assumptions of UTF8

  Occasionally you do not want this assumption. The way it impacts all your regular and test handles, as well as how your source is read, can be a problem if you are not working with UTF8, or have other plans entirly.

- Huge default set of exports, which can grow

  Sometimes you want to keep your namespace clean.

  Sometimes you import a tool that does not conflict with anything in *Test2::V0*, then we go and add a new tool which conflicts with yours! We make a point not to break/remove exports, but there is no such commitment about adding new ones.

  Now the only default export is `T2()` which gives you a handle where all the tools we expose are provided as methods. You can also use the T2 module (Not bundled with Test-Simple) for use with an identical number of keystrokes, which allow you to leverage the prototypes on the original tool subroutines.

Modules

- `Test2::V1::Base` - Base namespace used for *Test2::Handle* objects created via *Test2::V1*.
- `Test2::V1::Handle` - V1 subclass of *Test2::Handle*.

Test2::V1::Base

Base namespace used for *Test2::Handle* objects created via *Test2::V1*.

DESCRIPTION

This is the default set of functions/methods available in *Test2::V1*.

SYNOPSIS

See *Test2::V1*. This module is not typically used directly.

INCLUDED FUNCTIONALITY

See *"TOOLS" in Test2::V1* for documentation about the tools included here, and when they were added.

Documentation is not duplicated here as that would mean maintaining 2 locations for every change.

SOURCE

The source code repository for Test2-Suite can be found at `https://github.com/Test-More/test-more/`.

Test2::V1::Handle

V1 subclass of *Test2::Handle*.

DESCRIPTION

The *Test2::V1* subclass of the *Test2::Handle* object. This is what you interact with when you use the `T2()` function in a test.

SYNOPSIS

```
use Test2::V1::Handle;

my $t2 = Test2::V1::Handle->new();

$t2->ok(1, "Passing test");
```

SUBCLASS OVERRIDES

The default base class used is *Test2::V1::Base*.

SEE ALSO

See *Test2::Handle* for more information.

SOURCE

The source code repository for Test2-Suite can be found at `https://github.com/Test-More/test-more/`.

Test2::Workflow

A test workflow is a way of structuring tests using composable units.

DESCRIPTION

A test workflow is a way of structuring tests using composable units. A well known example of a test workflow is RSPEC. RSPEC is implemented using Test2::Workflow in *Test2::Tools::Spec* along with several extensions.

IMPORTANT CONCEPTS

BUILD

Test2::Workflow::Build

A Build is used to compose tasks. Usually a build object is pushed to the stack before running code that adds tasks to the build. Once the build sub is complete the build is popped and returned. Usually a build is converted into a root task or task group.

RUNNER

Test2::Workflow::Runner

A runner takes the composed tasks and executes them in the proper order.

TASK

Test2::Workflow::Task

A task is a unit of work to accomplish. There are 2 main types of task.

ACTION

An action is the most simple unit used in composition. An action is essentially a name and a codeblock to run.

GROUP

A group is a task that is composed of other tasks.

EXPORTS

All exports are optional, you must request the ones you want.

- $parsed = parse_args(args => \@args)
- $parsed = parse_args(args => \@args, level => $L)
- $parsed = parse_args(args => \@args, caller => [caller($L)])

  This will parse a "typical" task builders arguments. The `@args` array MUST contain a name (plain scalar containing text) and also a single CODE reference. The `@args` array MAY also contain any quantity of line numbers or hashrefs. The resulting data structure will be a single hashref with all the provided hashrefs squashed together, and the 'name', 'code', 'lines' and 'frame' keys set from other arguments.

```
{
    # All hashrefs from @args get squashed together:
    %squashed_input_hashref_data,

    # @args must have exactly 1 plaintext scalar that is not a␣
↪number, it
    # is considered the name:
    name => 'name from input args'

    # Integer values are treated as line numbers
    lines => [ 35, 44 ],

    # Exactly 1 coderef must be provided in @args:
    code => \&some_code,

    # 'frame' contains the 'caller' data. This may be passed in␣
↪directly,
    # obtained from the 'level' parameter, or automatically␣
↪deduced.
    frame => ['A::Package', 'a_file.pm', 42, ...],
}
```

- $build = init_root($pkg, %args)

  This will initialize (or return the existing) a build for the specified package. `%args` get passed into the *Test2::Workflow::Build* constructor. This uses the following defaults (which can be overridden using `%args`):

```
name    => $pkg,
flat    => 1,
iso     => 0,
async   => 0,
is_root => 1,
```

Note that `%args` is completely ignored if the package build has already been initialized.

- $build = root_build($pkg)

  This will return the root build for the specified package.

- $build = current_build()

  This will return the build currently at the top of the build stack (or undef).

- $build = build($name, \%params, sub { ... })

  This will push a new build object onto the build stash then run the provided codeblock. Once the codeblock has finished running the build will be popped off the stack and returned.

  See `parse_args()` for details about argument processing.

5.2.103 Text

Namespace containing the following modules:

- `Text::Abbrev` - abbrev - create an abbreviation table from a list
- `Text::Balanced` - Extract delimited text sequences from strings.
- `Text::CSV` - This section is taken from Text::CSV_XS.
- `Text::CSV_PP` - Text::CSV_XS compatible pure-Perl module
- `Text::LevenshteinXS` - The Levenshtein edit distance of two strings: the fewest insertions, deletions and substitutions that turn one into the other.
- `Text::LineFold` - Line Folding for Plain Text
- `Text::ParseWords` - parse text into an array of tokens or array of arrays
- `Text::Tabs` - expand and unexpand tabs like unix expand(1) and unexpand(1)
- `Text::Wrap` - line wrapping to form simple paragraphs

Text::Abbrev

abbrev - create an abbreviation table from a list

SYNOPSIS

```
use Text::Abbrev;
abbrev $hashref, LIST
```

DESCRIPTION

Stores all unambiguous truncations of each element of LIST as keys in the associative array referenced by `$hashref`. The values are the original list elements.

EXAMPLE

```
$hashref = abbrev qw(list edit send abort gripe);

%hash = abbrev qw(list edit send abort gripe);

abbrev $hashref, qw(list edit send abort gripe);

abbrev(*hash, qw(list edit send abort gripe));
```

Text::Balanced

Extract delimited text sequences from strings.

SYNOPSIS

```
use Text::Balanced qw (
    extract_delimited
    extract_bracketed
    extract_quotelike
    extract_codeblock
    extract_variable
    extract_tagged
    extract_multiple
    gen_delimited_pat
    gen_extract_tagged
);

# Extract the initial substring of $text that is delimited by
# two (unescaped) instances of the first character in $delim.

($extracted, $remainder) = extract_delimited($text,$delim);

# Extract the initial substring of $text that is bracketed
# with a delimiter(s) specified by $delim (where the string
# in $delim contains one or more of '(){}[]<>').

($extracted, $remainder) = extract_bracketed($text,$delim);

# Extract the initial substring of $text that is bounded by
# an XML tag.

($extracted, $remainder) = extract_tagged($text);

# Extract the initial substring of $text that is bounded by
# a C<BEGIN>...C<END> pair. Don't allow nested C<BEGIN> tags

($extracted, $remainder) =
    extract_tagged($text,"BEGIN","END",undef,{bad=>["BEGIN"]});

# Extract the initial substring of $text that represents a
# Perl "quote or quote-like operation"

($extracted, $remainder) = extract_quotelike($text);

# Extract the initial substring of $text that represents a block
# of Perl code, bracketed by any of character(s) specified by $delim
# (where the string $delim contains one or more of '(){}[]<>').

($extracted, $remainder) = extract_codeblock($text,$delim);
```

(continues on next page)

(continued from previous page)

```
# Extract the initial substrings of $text that would be extracted by
# one or more sequential applications of the specified functions
# or regular expressions

@extracted = extract_multiple($text,
                              [ \&extract_bracketed,
                                \&extract_quotelike,
                                \&some_other_extractor_sub,
                                qr/[xyz]*/,
                                'literal',
                              ]);

# Create a string representing an optimized pattern (a la Friedl)
# that matches a substring delimited by any of the specified␣
 ↪characters
# (in this case: any type of quote or a slash)

$patstring = gen_delimited_pat(q{'"`/});

# Generate a reference to an anonymous sub that is just like␣
 ↪extract_tagged
# but pre-compiled and optimized for a specific pair of tags, and
# consequently much faster (i.e. 3 times faster). It uses qr// for␣
 ↪better
# performance on repeated calls.

$extract_head = gen_extract_tagged('<HEAD>','</HEAD>');
($extracted, $remainder) = $extract_head->($text);
```

DESCRIPTION

The various `extract_...` subroutines may be used to extract a delimited substring, possibly after skipping a specified prefix string. By default, that prefix is optional whitespace (`/\s*/`), but you can change it to whatever you wish (see below).

The substring to be extracted must appear at the current `pos` location of the string's variable (or at index zero, if no `pos` position is defined). In other words, the `extract_...` subroutines *don't* extract the first occurrence of a substring anywhere in a string (like an unanchored regex would). Rather, they extract an occurrence of the substring appearing immediately at the current matching position in the string (like a `\G`-anchored regex would).

General Behaviour in List Contexts

In a list context, all the subroutines return a list, the first three elements of which are always:

- [0]

The extracted string, including the specified delimiters. If the extraction fails `undef` is returned.

- [1]

  The remainder of the input string (i.e. the characters after the extracted string). On failure, the entire string is returned.

- [2]

  The skipped prefix (i.e. the characters before the extracted string). On failure, `undef` is returned.

Note that in a list context, the contents of the original input text (the first argument) are not modified in any way.

However, if the input text was passed in a variable, that variable's `pos` value is updated to point at the first character after the extracted text. That means that in a list context the various subroutines can be used much like regular expressions. For example:

```
while ( $next = (extract_quotelike($text))[0] )
{
    # process next quote-like (in $next)
}
```

General Behaviour in Scalar and Void Contexts

In a scalar context, the extracted string is returned, having first been removed from the input text. Thus, the following code also processes each quote-like operation, but actually removes them from $text:

```
while ( $next = extract_quotelike($text) )
{
    # process next quote-like (in $next)
}
```

Note that if the input text is a read-only string (i.e. a literal), no attempt is made to remove the extracted text.

In a void context the behaviour of the extraction subroutines is exactly the same as in a scalar context, except (of course) that the extracted substring is not returned.

A Note About Prefixes

Prefix patterns are matched without any trailing modifiers (`/gimsox` etc.) This can bite you if you're expecting a prefix specification like '.*?(?=)' to skip everything up to the first tag. Such a prefix pattern will only succeed if the tag is on the current line, since . normally doesn't match newlines.

To overcome this limitation, you need to turn on /s matching within the prefix pattern, using the `(?s)` directive: '(?s).*?(?=)'

Functions

- `extract_delimited`

  The `extract_delimited` function formalizes the common idiom of extracting a single-character-delimited substring from the start of a string. For example, to extract a single-quote delimited string, the following code is typically used:

```
($remainder = $text) =~ s/\A('(\\.|[^'])*')//s;
$extracted = $1;
```

  but with `extract_delimited` it can be simplified to:

```
($extracted,$remainder) = extract_delimited($text, "'");
```

  `extract_delimited` takes up to four scalars (the input text, the delimiters, a prefix pattern to be skipped, and any escape characters) and extracts the initial substring of the text that is appropriately delimited. If the delimiter string has multiple characters, the first one encountered in the text is taken to delimit the substring. The third argument specifies a prefix pattern that is to be skipped (but must be present!) before the substring is extracted. The final argument specifies the escape character to be used for each delimiter.

  All arguments are optional. If the escape characters are not specified, every delimiter is escaped with a backslash (`\`). If the prefix is not specified, the pattern `'\s*'` - optional whitespace - is used. If the delimiter set is also not specified, the set `/["'`]/` is used. If the text to be processed is not specified either, `$_` is used.

  In list context, `extract_delimited` returns a array of three elements, the extracted substring (*including the surrounding delimiters*), the remainder of the text, and the skipped prefix (if any). If a suitable delimited substring is not found, the first element of the array is the empty string, the second is the complete original text, and the prefix returned in the third element is an empty string.

  In a scalar context, just the extracted substring is returned. In a void context, the extracted substring (and any prefix) are simply removed from the beginning of the first argument.

  Examples:

```
# Remove a single-quoted substring from the very beginning of
 ↪$text:

    $substring = extract_delimited($text, "'", '');

# Remove a single-quoted Pascalish substring (i.e. one in which
# doubling the quote character escapes it) from the very
# beginning of $text:

    $substring = extract_delimited($text, "'", '', "'");

# Extract a single- or double- quoted substring from the
# beginning of $text, optionally after some whitespace
# (note the list context to protect $text from modification):
```

(continues on next page)

(continued from previous page)

```
    ($substring) = extract_delimited $text, q{"'};

# Delete the substring delimited by the first '/' in $text:

    $text = join '', (extract_delimited($text,'/','[^/]*')[2,1];
```

Note that this last example is *not* the same as deleting the first quote-like pattern. For instance, if `$text` contained the string:

```
"if ('./cmd' =~ m/$UNIXCMD/s) { $cmd = $1; }"
```

then after the deletion it would contain:

```
"if ('.$UNIXCMD/s) { $cmd = $1; }"
```

not:

```
"if ('./cmd' =~ ms) { $cmd = $1; }"
```

See "extract_quotelike" for a (partial) solution to this problem.

- `extract_bracketed`

  Like `"extract_delimited"`, the `extract_bracketed` function takes up to three optional scalar arguments: a string to extract from, a delimiter specifier, and a prefix pattern. As before, a missing prefix defaults to optional whitespace and a missing text defaults to `$_`. However, a missing delimiter specifier defaults to `'{}()[]<>'` (see below).

  `extract_bracketed` extracts a balanced-bracket-delimited substring (using any one (or more) of the user-specified delimiter brackets: '(..)', '{..}', '[..]', or '<..>'). Optionally it will also respect quoted unbalanced brackets (see below).

  A "delimiter bracket" is a bracket in list of delimiters passed as `extract_bracketed`'s second argument. Delimiter brackets are specified by giving either the left or right (or both!) versions of the required bracket(s). Note that the order in which two or more delimiter brackets are specified is not significant.

  A "balanced-bracket-delimited substring" is a substring bounded by matched brackets, such that any other (left or right) delimiter bracket *within* the substring is also matched by an opposite (right or left) delimiter bracket *at the same level of nesting*. Any type of bracket not in the delimiter list is treated as an ordinary character.

  In other words, each type of bracket specified as a delimiter must be balanced and correctly nested within the substring, and any other kind of ("non-delimiter") bracket in the substring is ignored.

  For example, given the string:

```
$text = "{ an '[irregularly :-(] {} parenthesized >:-)' string }
 ↪";
```

  then a call to `extract_bracketed` in a list context:

```
@result = extract_bracketed( $text, '{}' );
```

would return:

```
( "{ an '[irregularly :-(] {} parenthesized >:-)' string }" , "
↪" , "" )
```

since both sets of `'{..}'` brackets are properly nested and evenly balanced. (In a scalar context just the first element of the array would be returned. In a void context, `$text` would be replaced by an empty string.)

Likewise the call in:

```
@result = extract_bracketed( $text, '{[' );
```

would return the same result, since all sets of both types of specified delimiter brackets are correctly nested and balanced.

However, the call in:

```
@result = extract_bracketed( $text, '{([<' );
```

would fail, returning:

```
( undef , "{ an '[irregularly :-(] {} parenthesized >:-)'␣
↪string }"  );
```

because the embedded pairs of `'(..)'`s and `'[..]'`s are "cross-nested" and the embedded `'>'` is unbalanced. (In a scalar context, this call would return an empty string. In a void context, `$text` would be unchanged.)

Note that the embedded single-quotes in the string don't help in this case, since they have not been specified as acceptable delimiters and are therefore treated as non-delimiter characters (and ignored).

However, if a particular species of quote character is included in the delimiter specification, then that type of quote will be correctly handled. for example, if `$text` is:

```
$text = '<A HREF=">>>>">link</A>';
```

then

```
@result = extract_bracketed( $text, '<">' );
```

returns:

```
( '<A HREF=">>>>">', 'link</A>', "" )
```

as expected. Without the specification of " as an embedded quoter:

```
@result = extract_bracketed( $text, '<>' );
```

the result would be:

```
( '<A HREF=">', '>>>">link</A>', "" )
```

In addition to the quote delimiters ', ", and `, full Perl quote-like quoting (i.e. q{string}, qq{string}, etc) can be specified by including the letter 'q' as a delimiter. Hence:

```
@result = extract_bracketed( $text, '<q>' );
```

would correctly match something like this:

```
$text = '<leftop: conj /and/ conj>';
```

See also: "extract_quotelike" and "extract_codeblock".

- extract_variable

  extract_variable extracts any valid Perl variable or variable-involved expression, including scalars, arrays, hashes, array accesses, hash look-ups, method calls through objects, subroutine calls through subroutine references, etc.

  The subroutine takes up to two optional arguments:

  1. A string to be processed ($_ if the string is omitted or undef)
  2. A string specifying a pattern to be matched as a prefix (which is to be skipped). If omitted, optional whitespace is skipped.

  On success in a list context, an array of 3 elements is returned. The elements are:

  – [0]

    the extracted variable, or variablish expression

  – [1]

    the remainder of the input text,

  – [2]

    the prefix substring (if any),

  On failure, all of these values (except the remaining text) are undef.

  In a scalar context, extract_variable returns just the complete substring that matched a variablish expression. undef is returned on failure. In addition, the original input text has the returned substring (and any prefix) removed from it.

  In a void context, the input text just has the matched substring (and any specified prefix) removed.

- extract_tagged

  extract_tagged extracts and segments text between (balanced) specified tags.

  The subroutine takes up to five optional arguments:

  1. A string to be processed ($_ if the string is omitted or undef)
  2. A string specifying a pattern (i.e. regex) to be matched as the opening tag. If the pattern string is omitted (or undef) then a pattern that matches any standard XML tag is used.

3. A string specifying a pattern to be matched at the closing tag. If the pattern string is omitted (or `undef`) then the closing tag is constructed by inserting a `/` after any leading bracket characters in the actual opening tag that was matched (*not* the pattern that matched the tag). For example, if the opening tag pattern is specified as `'{{\w+}}'` and actually matched the opening tag `"{{DATA}}"`, then the constructed closing tag would be `"{{/DATA}}"`.
4. A string specifying a pattern to be matched as a prefix (which is to be skipped). If omitted, optional whitespace is skipped.
5. A hash reference containing various parsing options (see below)

The various options that can be specified are:

- `reject => $listref`

  The list reference contains one or more strings specifying patterns that must *not* appear within the tagged text.

  For example, to extract an HTML link (which should not contain nested links) use:

```
extract_tagged($text, '<A>', '</A>', undef, {reject => ['<A>
↪']} );
```

- `ignore => $listref`

  The list reference contains one or more strings specifying patterns that are *not* to be treated as nested tags within the tagged text (even if they would match the start tag pattern).

  For example, to extract an arbitrary XML tag, but ignore "empty" elements:

```
extract_tagged($text, undef, undef, undef, {ignore => ['<[^>
↪]*/>']} );
```

  (also see "gen_delimited_pat" below).

- `fail => $str`

  The `fail` option indicates the action to be taken if a matching end tag is not encountered (i.e. before the end of the string or some `reject` pattern matches). By default, a failure to match a closing tag causes `extract_tagged` to immediately fail.

  However, if the string value associated with <reject> is "MAX", then `extract_tagged` returns the complete text up to the point of failure. If the string is "PARA", `extract_tagged` returns only the first paragraph after the tag (up to the first line that is either empty or contains only whitespace characters). If the string is "", the default behaviour (i.e. failure) is reinstated.

  For example, suppose the start tag "/para" introduces a paragraph, which then continues until the next "/endpara" tag or until another "/para" tag is encountered:

```
$text = "/para line 1\n\nline 3\n/para line 4";
```

(continues on next page)

(continued from previous page)

```
extract_tagged($text, '/para', '/endpara', undef,
                        {reject => '/para', fail => MAX );

# EXTRACTED: "/para line 1\n\nline 3\n"
```

Suppose instead, that if no matching "/endpara" tag is found, the "/para" tag refers only to the immediately following paragraph:

```
$text = "/para line 1\n\nline 3\n/para line 4";

extract_tagged($text, '/para', '/endpara', undef,
                 {reject => '/para', fail => MAX );

# EXTRACTED: "/para line 1\n"
```

Note that the specified `fail` behaviour applies to nested tags as well.

On success in a list context, an array of 6 elements is returned. The elements are:

– [0]

the extracted tagged substring (including the outermost tags),

– [1]

the remainder of the input text,

– [2]

the prefix substring (if any),

– [3]

the opening tag

– [4]

the text between the opening and closing tags

– [5]

the closing tag (or "" if no closing tag was found)

On failure, all of these values (except the remaining text) are `undef`.

In a scalar context, `extract_tagged` returns just the complete substring that matched a tagged text (including the start and end tags). `undef` is returned on failure. In addition, the original input text has the returned substring (and any prefix) removed from it.

In a void context, the input text just has the matched substring (and any specified prefix) removed.

- `gen_extract_tagged`

  `gen_extract_tagged` generates a new anonymous subroutine which extracts text between (balanced) specified tags. In other words, it generates a function identical in function to `extract_tagged`.

The difference between `extract_tagged` and the anonymous subroutines generated by `gen_extract_tagged`, is that those generated subroutines:

- do not have to reparse tag specification or parsing options every time they are called (whereas `extract_tagged` has to effectively rebuild its tag parser on every call);
- make use of the new qr// construct to pre-compile the regexes they use (whereas `extract_tagged` uses standard string variable interpolation to create tag-matching patterns).

The subroutine takes up to four optional arguments (the same set as `extract_tagged` except for the string to be processed). It returns a reference to a subroutine which in turn takes a single argument (the text to be extracted from).

In other words, the implementation of `extract_tagged` is exactly equivalent to:

```
sub extract_tagged
{
        my $text = shift;
        $extractor = gen_extract_tagged(@_);
        return $extractor->($text);
}
```

(although `extract_tagged` is not currently implemented that way).

Using `gen_extract_tagged` to create extraction functions for specific tags is a good idea if those functions are going to be called more than once, since their performance is typically twice as good as the more general-purpose `extract_tagged`.

- `extract_quotelike`

`extract_quotelike` attempts to recognize, extract, and segment any one of the various Perl quotes and quotelike operators (see perlop(3)) Nested backslashed delimiters, embedded balanced bracket delimiters (for the quotelike operators), and trailing modifiers are all caught. For example, in:

```
extract_quotelike 'q # an octothorpe: \# (not the end of the q!
↪) #'

extract_quotelike '  "You said, \"Use sed\"."  '

extract_quotelike ' s{([A-Z]{1,8}\.[A-Z]{3})} /\L$1\E/; '

extract_quotelike ' tr/\\\/\\\\/\\\\//ds; '
```

the full Perl quotelike operations are all extracted correctly.

Note too that, when using the /x modifier on a regex, any comment containing the current pattern delimiter will cause the regex to be immediately terminated. In other words:

```
'm /
        (?i)            # CASE INSENSITIVE
        [a-z_]          # LEADING ALPHABETIC/UNDERSCORE
```

(continues on next page)

(continued from previous page)

```
        [a-z0-9]*       # FOLLOWED BY ANY NUMBER OF␣
↪ALPHANUMERICS
  /x'
```

will be extracted as if it were:

```
'm /
        (?i)            # CASE INSENSITIVE
        [a-z_]          # LEADING ALPHABETIC/'
```

This behaviour is identical to that of the actual compiler.

`extract_quotelike` takes two arguments: the text to be processed and a prefix to be matched at the very beginning of the text. If no prefix is specified, optional whitespace is the default. If no text is given, `$_` is used.

In a list context, an array of 11 elements is returned. The elements are:

- [0]

  the extracted quotelike substring (including trailing modifiers),

- [1]

  the remainder of the input text,

- [2]

  the prefix substring (if any),

- [3]

  the name of the quotelike operator (if any),

- [4]

  the left delimiter of the first block of the operation,

- [5]

  the text of the first block of the operation (that is, the contents of a quote, the regex of a match or substitution or the target list of a translation),

- [6]

  the right delimiter of the first block of the operation,

- [7]

  the left delimiter of the second block of the operation (that is, if it is a `s`, `tr`, or `y`),

- [8]

  the text of the second block of the operation (that is, the replacement of a substitution or the translation list of a translation),

- [9]

  the right delimiter of the second block of the operation (if any),

– [10]

the trailing modifiers on the operation (if any).

For each of the fields marked "(if any)" the default value on success is an empty string. On failure, all of these values (except the remaining text) are undef.

In a scalar context, extract_quotelike returns just the complete substring that matched a quotelike operation (or undef on failure). In a scalar or void context, the input text has the same substring (and any specified prefix) removed.

Examples:

```
# Remove the first quotelike literal that appears in text

        $quotelike = extract_quotelike($text,'.*?');

# Replace one or more leading whitespace-separated quotelike
# literals in $_ with "<QLL>"

        do { $_ = join '<QLL>', (extract_quotelike)[2,1] }␣
↪until $@;

# Isolate the search pattern in a quotelike operation from $text

        ($op,$pat) = (extract_quotelike $text)[3,5];
        if ($op =~ /[ms]/)
        {
                print "search pattern: $pat\n";
        }
        else
        {
                print "$op is not a pattern matching operation\n
↪";
        }
```

- extract_quotelike

  extract_quotelike can successfully extract "here documents" from an input string, but with an important caveat in list contexts.

  Unlike other types of quote-like literals, a here document is rarely a contiguous substring. For example, a typical piece of code using here document might look like this:

```
<<'EOMSG' || die;
This is the message.
EOMSG
exit;
```

  Given this as an input string in a scalar context, extract_quotelike would correctly return the string "<<'EOMSG'\nThis is the message.\nEOMSG", leaving the string " || die;\nexit;" in the original variable. In other words, the two separate pieces of the here document are successfully extracted and concatenated.

In a list context, `extract_quotelike` would return the list

- [0]

  "<<'EOMSG'\nThis is the message.\nEOMSG\n" (i.e. the full extracted here document, including fore and aft delimiters),

- [1]

  " || die;\nexit;" (i.e. the remainder of the input text, concatenated),

- [2]

  "" (i.e. the prefix substring – trivial in this case),

- [3]

  "<<" (i.e. the "name" of the quotelike operator)

- [4]

  "'EOMSG'" (i.e. the left delimiter of the here document, including any quotes),

- [5]

  "This is the message.\n" (i.e. the text of the here document),

- [6]

  "EOMSG" (i.e. the right delimiter of the here document),

- [7..10]

  "" (a here document has no second left delimiter, second text, second right delimiter, or trailing modifiers).

However, the matching position of the input variable would be set to "exit;" (i.e. *after* the closing delimiter of the here document), which would cause the earlier " || die;\nexit;" to be skipped in any sequence of code fragment extractions.

To avoid this problem, when it encounters a here document whilst extracting from a modifiable string, `extract_quotelike` silently rearranges the string to an equivalent piece of Perl:

```
<<'EOMSG'
This is the message.
EOMSG
|| die;
exit;
```

in which the here document *is* contiguous. It still leaves the matching position after the here document, but now the rest of the line on which the here document starts is not skipped.

To prevent <extract_quotelike> from mucking about with the input in this way (this is the only case where a list-context `extract_quotelike` does so), you can pass the input variable as an interpolated literal:

```
$quotelike = extract_quotelike("$var");
```

- `extract_codeblock`

  `extract_codeblock` attempts to recognize and extract a balanced bracket delimited substring that may contain unbalanced brackets inside Perl quotes or quotelike operations. That is, `extract_codeblock` is like a combination of "`extract_bracketed`" and "`extract_quotelike`".

  `extract_codeblock` takes the same initial three parameters as `extract_bracketed`: a text to process, a set of delimiter brackets to look for, and a prefix to match first. It also takes an optional fourth parameter, which allows the outermost delimiter brackets to be specified separately (see below), and a fifth parameter used only by Parse::RecDescent.

  Omitting the first argument (input text) means process `$_` instead. Omitting the second argument (delimiter brackets) indicates that only '`{`' is to be used. Omitting the third argument (prefix argument) implies optional whitespace at the start. Omitting the fourth argument (outermost delimiter brackets) indicates that the value of the second argument is to be used for the outermost delimiters.

  Once the prefix and the outermost opening delimiter bracket have been recognized, code blocks are extracted by stepping through the input text and trying the following alternatives in sequence:

  1. Try and match a closing delimiter bracket. If the bracket was the same species as the last opening bracket, return the substring to that point. If the bracket was mismatched, return an error.
  2. Try to match a quote or quotelike operator. If found, call `extract_quotelike` to eat it. If `extract_quotelike` fails, return the error it returned. Otherwise go back to step 1.
  3. Try to match an opening delimiter bracket. If found, call `extract_codeblock` recursively to eat the embedded block. If the recursive call fails, return an error. Otherwise, go back to step 1.
  4. Unconditionally match a bareword or any other single character, and then go back to step 1.

  Examples:

```
# Find a while loop in the text

        if ($text =~ s/.*?while\s*\{/{/)
        {
                $loop = "while " . extract_codeblock($text);
        }

# Remove the first round-bracketed list (which may include
# round- or curly-bracketed code blocks or quotelike operators)

        extract_codeblock $text, "(){}", '[^(]*';
```

  The ability to specify a different outermost delimiter bracket is useful in some circumstances. For example, in the Parse::RecDescent module, parser actions which are to be performed only on a successful parse are specified using a `<defer:...>` directive. For example:

```
sentence: subject verb object
                <defer: {$::theVerb = $item{verb}} >
```

Parse::RecDescent uses `extract_codeblock($text, '{}<>')` to extract the code within the `<defer:...>` directive, but there's a problem.

A deferred action like this:

```
<defer: {if ($count>10) {$count--}} >
```

will be incorrectly parsed as:

```
<defer: {if ($count>
```

because the "less than" operator is interpreted as a closing delimiter.

But, by extracting the directive using `extract_codeblock($text, '{}', undef, '<>')` the '>' character is only treated as a delimited at the outermost level of the code block, so the directive is parsed correctly.

- `extract_multiple`

  The `extract_multiple` subroutine takes a string to be processed and a list of extractors (subroutines or regular expressions) to apply to that string.

  In an array context `extract_multiple` returns an array of substrings of the original string, as extracted by the specified extractors. In a scalar context, `extract_multiple` returns the first substring successfully extracted from the original string. In both scalar and void contexts the original string has the first successfully extracted substring removed from it. In all contexts `extract_multiple` starts at the current `pos` of the string, and sets that `pos` appropriately after it matches.

  Hence, the aim of a call to `extract_multiple` in a list context is to split the processed string into as many non-overlapping fields as possible, by repeatedly applying each of the specified extractors to the remainder of the string. Thus `extract_multiple` is a generalized form of Perl's `split` subroutine.

  The subroutine takes up to four optional arguments:

  1. A string to be processed (`$_` if the string is omitted or `undef`)
  2. A reference to a list of subroutine references and/or qr// objects and/or literal strings and/or hash references, specifying the extractors to be used to split the string. If this argument is omitted (or `undef`) the list:

     ```
     [
             sub { extract_variable($_[0], '') },
             sub { extract_quotelike($_[0],'') },
             sub { extract_codeblock($_[0],'{}','') },
     ]
     ```

     is used.
  3. An number specifying the maximum number of fields to return. If this argument is omitted (or `undef`), split continues as long as possible.

If the third argument is *N*, then extraction continues until *N* fields have been successfully extracted, or until the string has been completely processed.

Note that in scalar and void contexts the value of this argument is automatically reset to 1 (under `-w`, a warning is issued if the argument has to be reset).

4. A value indicating whether unmatched substrings (see below) within the text should be skipped or returned as fields. If the value is true, such substrings are skipped. Otherwise, they are returned.

The extraction process works by applying each extractor in sequence to the text string.

If the extractor is a subroutine it is called in a list context and is expected to return a list of a single element, namely the extracted text. It may optionally also return two further arguments: a string representing the text left after extraction (like $' for a pattern match), and a string representing any prefix skipped before the extraction (like $` in a pattern match). Note that this is designed to facilitate the use of other Text::Balanced subroutines with `extract_multiple`. Note too that the value returned by an extractor subroutine need not bear any relationship to the corresponding substring of the original text (see examples below).

If the extractor is a precompiled regular expression or a string, it is matched against the text in a scalar context with a leading '\G' and the gc modifiers enabled. The extracted value is either $1 if that variable is defined after the match, or else the complete match (i.e. $&).

If the extractor is a hash reference, it must contain exactly one element. The value of that element is one of the above extractor types (subroutine reference, regular expression, or string). The key of that element is the name of a class into which the successful return value of the extractor will be blessed.

If an extractor returns a defined value, that value is immediately treated as the next extracted field and pushed onto the list of fields. If the extractor was specified in a hash reference, the field is also blessed into the appropriate class,

If the extractor fails to match (in the case of a regex extractor), or returns an empty list or an undefined value (in the case of a subroutine extractor), it is assumed to have failed to extract. If none of the extractor subroutines succeeds, then one character is extracted from the start of the text and the extraction subroutines reapplied. Characters which are thus removed are accumulated and eventually become the next field (unless the fourth argument is true, in which case they are discarded).

For example, the following extracts substrings that are valid Perl variables:

```
@fields = extract_multiple($text,
                           [ sub { extract_variable($_[0]) } ],
                           undef, 1);
```

This example separates a text into fields which are quote delimited, curly bracketed, and anything else. The delimited and bracketed parts are also blessed to identify them (the "anything else" is unblessed):

```
@fields = extract_multiple($text,
          [
```

(continues on next page)

(continued from previous page)

```
                { Delim => sub { extract_delimited($_[0],q{'"}) }
↪,
                { Brack => sub { extract_bracketed($_[0],'{}') }
↪ },
            ]);
```

This call extracts the next single substring that is a valid Perl quotelike operator (and removes it from $text):

```
$quotelike = extract_multiple($text,
                              [
                                sub { extract_quotelike($_[0]) }
↪,
                              ], undef, 1);
```

Finally, here is yet another way to do comma-separated value parsing:

```
$csv_text = "a,'x b',c";
@fields = extract_multiple($csv_text,
                           [
                                 sub { extract_delimited($_[0],q{
↪'"}) },
                                 qr/([^,]+)/,
                           ],
                           undef,1);
# @fields is now ('a', "'x b'", 'c')
```

The list in the second argument means: *"Try and extract a ' or " delimited string, otherwise extract anything up to a comma..."*. The undef third argument means: *"...as many times as possible..."*, and the true value in the fourth argument means *"...discarding anything else that appears (i.e. the commas)"*.

If you wanted the commas preserved as separate fields (i.e. like split does if your split pattern has capturing parentheses), you would just make the last parameter undefined (or remove it).

- `gen_delimited_pat`

  The `gen_delimited_pat` subroutine takes a single (string) argument and builds a Friedl-style optimized regex that matches a string delimited by any one of the characters in the single argument. For example:

  ```
  gen_delimited_pat(q{'"})
  ```

  returns the regex:

  ```
  (?:\"(?:\\\"|(?!\").)*\"|\'(?:\\\'|(?!\').)*\')
  ```

  Note that the specified delimiters are automatically quotemeta'd.

  A typical use of `gen_delimited_pat` would be to build special purpose tags for `extract_tagged`. For example, to properly ignore "empty" XML elements (which might contain quoted strings):

```
my $empty_tag = '<(' . gen_delimited_pat(q{'"}) . '|.)+/>';

extract_tagged($text, undef, undef, undef, {ignore => [$empty_
↪tag]} );
```

gen_delimited_pat may also be called with an optional second argument, which specifies the "escape" character(s) to be used for each delimiter. For example to match a Pascal-style string (where ' is the delimiter and '' is a literal ' within the string):

```
gen_delimited_pat(q{'},q{'});
```

Different escape characters can be specified for different delimiters. For example, to specify that '/' is the escape for single quotes and '%' is the escape for double quotes:

```
gen_delimited_pat(q{'"},q{/%});
```

If more delimiters than escape chars are specified, the last escape char is used for the remaining delimiters. If no escape char is specified for a given specified delimiter, '' is used.

- `delimited_pat`

  Note that `gen_delimited_pat` was previously called `delimited_pat`. That name may still be used, but is now deprecated.

DIAGNOSTICS

In a list context, all the functions return `(undef,$original_text)` on failure. In a scalar context, failure is indicated by returning `undef` (in this case the input text is not modified in any way).

In addition, on failure in *any* context, the `$@` variable is set. Accessing `$@->{error}` returns one of the error diagnostics listed below. Accessing `$@->{pos}` returns the offset into the original string at which the error was detected (although not necessarily where it occurred!) Printing `$@` directly produces the error message, with the offset appended. On success, the `$@` variable is guaranteed to be `undef`.

The available diagnostics are:

- `Did not find a suitable bracket: "%s"`

  The delimiter provided to `extract_bracketed` was not one of `'()[]<>{}'`.

- `Did not find prefix: /%s/`

  A non-optional prefix was specified but wasn't found at the start of the text.

- `Did not find opening bracket after prefix: "%s"`

  `extract_bracketed` or `extract_codeblock` was expecting a particular kind of bracket at the start of the text, and didn't find it.

- `No quotelike operator found after prefix: "%s"`

`extract_quotelike` didn't find one of the quotelike operators `q`, `qq`, `qw`, `qx`, `s`, `tr` or `y` at the start of the substring it was extracting.

- `Unmatched closing bracket: "%c"`

  `extract_bracketed`, `extract_quotelike` or `extract_codeblock` encountered a closing bracket where none was expected.

- `Unmatched opening bracket(s): "%s"`

  `extract_bracketed`, `extract_quotelike` or `extract_codeblock` ran out of characters in the text before closing one or more levels of nested brackets.

- `Unmatched embedded quote (%s)`

  `extract_bracketed` attempted to match an embedded quoted substring, but failed to find a closing quote to match it.

- `Did not find closing delimiter to match '%s'`

  `extract_quotelike` was unable to find a closing delimiter to match the one that opened the quote-like operation.

- `Mismatched closing bracket: expected "%c" but found "%s"`

  `extract_bracketed`, `extract_quotelike` or `extract_codeblock` found a valid bracket delimiter, but it was the wrong species. This usually indicates a nesting error, but may indicate incorrect quoting or escaping.

- `No block delimiter found after quotelike "%s"`

  `extract_quotelike` or `extract_codeblock` found one of the quotelike operators `q`, `qq`, `qw`, `qx`, `s`, `tr` or `y` without a suitable block after it.

- `Did not find leading dereferencer`

  `extract_variable` was expecting one of '$', '@', or '%' at the start of a variable, but didn't find any of them.

- `Bad identifier after dereferencer`

  `extract_variable` found a '$', '@', or '%' indicating a variable, but that character was not followed by a legal Perl identifier.

- `Did not find expected opening bracket at %s`

  `extract_codeblock` failed to find any of the outermost opening brackets that were specified.

- `Improperly nested codeblock at %s`

  A nested code block was found that started with a delimiter that was specified as being only to be used as an outermost bracket.

- `Missing second block for quotelike "%s"`

  `extract_codeblock` or `extract_quotelike` found one of the quotelike operators `s`, `tr` or `y` followed by only one block.

- `No match found for opening bracket`

  `extract_codeblock` failed to find a closing bracket to match the outermost opening bracket.

- `Did not find opening tag: /%s/`

  `extract_tagged` did not find a suitable opening tag (after any specified prefix was removed).

- `Unable to construct closing tag to match: /%s/`

  `extract_tagged` matched the specified opening tag and tried to modify the matched text to produce a matching closing tag (because none was specified). It failed to generate the closing tag, almost certainly because the opening tag did not start with a bracket of some kind.

- `Found invalid nested tag: %s`

  `extract_tagged` found a nested tag that appeared in the "reject" list (and the failure mode was not "MAX" or "PARA").

- `Found unbalanced nested tag: %s`

  `extract_tagged` found a nested opening tag that was not matched by a corresponding nested closing tag (and the failure mode was not "MAX" or "PARA").

- `Did not find closing tag`

  `extract_tagged` reached the end of the text without finding a closing tag to match the original opening tag (and the failure mode was not "MAX" or "PARA").

EXPORTS

The following symbols are, or can be, exported by this module:

- Default Exports

  None.

- Optional Exports

  `extract_delimited`, `extract_bracketed`, `extract_quotelike`, `extract_codeblock`, `extract_variable`, `extract_tagged`, `extract_multiple`, `gen_delimited_pat`, `gen_extract_tagged`, `delimited_pat`.

- Export Tags

  - `:ALL`

    `extract_delimited`, `extract_bracketed`, `extract_quotelike`, `extract_codeblock`, `extract_variable`, `extract_tagged`, `extract_multiple`, `gen_delimited_pat`, `gen_extract_tagged`, `delimited_pat`.

KNOWN BUGS

See https://rt.cpan.org/Dist/Display.html?Status=Active&Queue=Text-Balanced.

FEEDBACK

Patches, bug reports, suggestions or any other feedback is welcome.

Patches can be sent as GitHub pull requests at https://github.com/steve-m-hay/Text-Balanced/pulls.

Bug reports and suggestions can be made on the CPAN Request Tracker at https://rt.cpan.org/Public/Bug/Report.html?Queue=Text-Balanced.

Currently active requests on the CPAN Request Tracker can be viewed at https://rt.cpan.org/Public/Dist/Display.html?Queue=Text-Balanced.

Please test this distribution. See CPAN Testers at https://www.cpantesters.org/ for details of how to get involved.

Previous test results on CPAN Testers can be viewed at https://www.cpantesters.org/distro/T/Text-Balanced.html and https://fast2-matrix.cpantesters.org/?dist=Text-Balanced.

AVAILABILITY

The latest version of this module is available from CPAN (see "CPAN" in perlmodlib for details) at

https://metacpan.org/release/Text-Balanced or

https://www.cpan.org/authors/id/S/SH/SHAY/ or

https://www.cpan.org/modules/by-module/Text/.

The latest source code is available from GitHub at https://github.com/steve-m-hay/Text-Balanced.

INSTALLATION

Text::CSV

SYNOPSIS

This section is taken from Text::CSV_XS.

```
# Functional interface
use Text::CSV qw( csv );

# Read whole file in memory
my $aoa = csv (in => "data.csv");    # as array of array
my $aoh = csv (in => "data.csv",
               headers => "auto");   # as array of hash

# Write array of arrays as csv file
csv (in => $aoa, out => "file.csv", sep_char => ";");

# Only show lines where "code" is odd
csv (in => "data.csv", filter => { code => sub { $_ % 2 }});

# Object interface
use Text::CSV;

my @rows;
# Read/parse CSV
my $csv = Text::CSV->new ({ binary => 1, auto_diag => 1 });
open my $fh, "<:encoding(utf8)", "test.csv" or die "test.csv: $!";
while (my $row = $csv->getline ($fh)) {
    $row->[2] =~ m/pattern/ or next; # 3rd field should match
    push @rows, $row;
    }
close $fh;

# and write as CSV
open $fh, ">:encoding(utf8)", "new.csv" or die "new.csv: $!";
$csv->say ($fh, $_) for @rows;
close $fh or die "new.csv: $!";
```

DESCRIPTION

Text::CSV is a thin wrapper for Text::CSV_XS-compatible modules now. All the backend modules provide facilities for the composition and decomposition of comma-separated values. Text::CSV uses Text::CSV_XS by default, and when Text::CSV_XS is not available, falls back on *Text::CSV_PP*, which is bundled in the same distribution as this module.

CHOOSING BACKEND

This module respects an environmental variable called `PERL_TEXT_CSV` when it decides a backend module to use. If this environmental variable is not set, it tries to load Text::CSV_XS, and if Text::CSV_XS is not available, falls back on Text::CSV_PP;

If you always don't want it to fall back on Text::CSV_PP, set the variable like this (`export` may be `setenv`, `set` and the likes, depending on your environment):

```
> export PERL_TEXT_CSV=Text::CSV_XS
```

If you prefer Text::CSV_XS to Text::CSV_PP (default), then:

```
> export PERL_TEXT_CSV=Text::CSV_XS,Text::CSV_PP
```

You may also want to set this variable at the top of your test files, in order not to be bothered with incompatibilities between backends (you need to wrap this in `BEGIN`, and set before actually `use`-ing Text::CSV module, as it decides its backend as soon as it's loaded):

```
BEGIN { $ENV{PERL_TEXT_CSV}='Text::CSV_PP'; }
use Text::CSV;
```

NOTES

This section is also taken from Text::CSV_XS.

Embedded newlines

Important Note: The default behavior is to accept only ASCII characters in the range from `0x20` (space) to `0x7E` (tilde). This means that the fields can not contain newlines. If your data contains newlines embedded in fields, or characters above `0x7E` (tilde), or binary data, you ***must*** set `binary => 1` in the call to "new". To cover the widest range of parsing options, you will always want to set binary.

But you still have the problem that you have to pass a correct line to the "parse" method, which is more complicated from the usual point of usage:

```
my $csv = Text::CSV->new ({ binary => 1, eol => $/ });
while (<>) {           #  WRONG!
    $csv->parse ($_);
    my @fields = $csv->fields ();
    }
```

this will break, as the `while` might read broken lines: it does not care about the quoting. If you need to support embedded newlines, the way to go is to **not** pass `eol` in the parser (it accepts `\n`, `\r`, **and** `\r\n` by default) and then

```
my $csv = Text::CSV->new ({ binary => 1 });
open my $fh, "<", $file or die "$file: $!";
while (my $row = $csv->getline ($fh)) {
    my @fields = @$row;
    }
```

The old(er) way of using global file handles is still supported

```
while (my $row = $csv->getline (*ARGV)) { ... }
```

Unicode

Unicode is only tested to work with perl-5.8.2 and up.

See also "BOM".

The simplest way to ensure the correct encoding is used for in- and output is by either setting layers on the filehandles, or setting the "encoding" argument for "csv".

```
 open my $fh, "<:encoding(UTF-8)", "in.csv"  or die "in.csv: $!";
or
 my $aoa = csv (in => "in.csv",     encoding => "UTF-8");

 open my $fh, ">:encoding(UTF-8)", "out.csv" or die "out.csv: $!";
or
 csv (in => $aoa, out => "out.csv", encoding => "UTF-8");
```

On parsing (both for "getline" and "parse"), if the source is marked being UTF8, then all fields that are marked binary will also be marked UTF8.

On combining ("print" and "combine"): if any of the combining fields was marked UTF8, the resulting string will be marked as UTF8. Note however that all fields *before* the first field marked UTF8 and contained 8-bit characters that were not upgraded to UTF8, these will be `bytes` in the resulting string too, possibly causing unexpected errors. If you pass data of different encoding, or you don't know if there is different encoding, force it to be upgraded before you pass them on:

```
$csv->print ($fh, [ map { utf8::upgrade (my $x = $_); $x } @data ]);
```

For complete control over encoding, please use Text::CSV::Encoded:

```
use Text::CSV::Encoded;
my $csv = Text::CSV::Encoded->new ({
    encoding_in  => "iso-8859-1", # the encoding comes into   Perl
    encoding_out => "cp1252",     # the encoding comes out of Perl
    });

$csv = Text::CSV::Encoded->new ({ encoding  => "utf8" });
```

(continues on next page)

(continued from previous page)

```
# combine () and print () accept *literally* utf8 encoded data
# parse () and getline () return *literally* utf8 encoded data

$csv = Text::CSV::Encoded->new ({ encoding  => undef }); # default
# combine () and print () accept UTF8 marked data
# parse () and getline () return UTF8 marked data
```

BOM

BOM (or Byte Order Mark) handling is available only inside the "header" method. This method supports the following encodings: `utf-8`, `utf-1`, `utf-32be`, `utf-32le`, `utf-16be`, `utf-16le`, `utf-ebcdic`, `scsu`, `bocu-1`, and `gb-18030`. See Wikipedia.

If a file has a BOM, the easiest way to deal with that is

```
my $aoh = csv (in => $file, detect_bom => 1);
```

All records will be encoded based on the detected BOM.

This implies a call to the "header" method, which defaults to also set the "column_names". So this is **not** the same as

```
my $aoh = csv (in => $file, headers => "auto");
```

which only reads the first record to set "column_names" but ignores any meaning of possible present BOM.

METHODS

This section is also taken from Text::CSV_XS.

version

(Class method) Returns the current module version.

new

(Class method) Returns a new instance of class Text::CSV. The attributes are described by the (optional) hash ref `\%attr`.

```
my $csv = Text::CSV->new ({ attributes ... });
```

The following attributes are available:

eol

```
my $csv = Text::CSV->new ({ eol => $/ });
          $csv->eol (undef);
my $eol = $csv->eol;
```

The end-of-line string to add to rows for "print" or the record separator for "getline".

When not passed in a **parser** instance, the default behavior is to accept `\n`, `\r`, and `\r\n`, so it is probably safer to not specify `eol` at all. Passing `undef` or the empty string behave the same.

When not passed in a **generating** instance, records are not terminated at all, so it is probably wise to pass something you expect. A safe choice for `eol` on output is either `$/` or `\r\n`.

Common values for `eol` are `"\012"` (`\n` or Line Feed), `"\015\012"` (`\r\n` or Carriage Return, Line Feed), and `"\015"` (`\r` or Carriage Return). The `eol` attribute cannot exceed 7 (ASCII) characters.

If both `$/` and `eol` equal `"\015"`, parsing lines that end on only a Carriage Return without Line Feed, will be "parse"d correct.

eol_type

```
my $eol = $csv->eol_type;
```

This read-only method returns the internal state of what is considered the valid EOL for parsing.

sep_char

```
my $csv = Text::CSV->new ({ sep_char => ";" });
          $csv->sep_char (";");
my $c = $csv->sep_char;
```

The char used to separate fields, by default a comma. (`,`). Limited to a single-byte character, usually in the range from `0x20` (space) to `0x7E` (tilde). When longer sequences are required, use `sep`.

The separation character can not be equal to the quote character or to the escape character.

sep

```
my $csv = Text::CSV->new ({ sep => "\N{FULLWIDTH COMMA}" });
          $csv->sep (";");
my $sep = $csv->sep;
```

The chars used to separate fields, by default undefined. Limited to 8 bytes.

When set, overrules `sep_char`. If its length is one byte it acts as an alias to `sep_char`.

quote_char

```
my $csv = Text::CSV->new ({ quote_char => "'" });
          $csv->quote_char (undef);
my $c = $csv->quote_char;
```

The character to quote fields containing blanks or binary data, by default the double quote character ("). A value of undef suppresses quote chars (for simple cases only). Limited to a single-byte character, usually in the range from 0x20 (space) to 0x7E (tilde). When longer sequences are required, use quote.

quote_char can not be equal to sep_char.

quote

```
my $csv = Text::CSV->new ({ quote => "\N{FULLWIDTH QUOTATION MARK}"␣
 ↪});
            $csv->quote ("'");
my $quote = $csv->quote;
```

The chars used to quote fields, by default undefined. Limited to 8 bytes.

When set, overrules quote_char. If its length is one byte it acts as an alias to quote_char.

This method does not support undef. Use quote_char to disable quotation.

escape_char

```
my $csv = Text::CSV->new ({ escape_char => "\\" });
        $csv->escape_char (":");
my $c = $csv->escape_char;
```

The character to escape certain characters inside quoted fields. This is limited to a single-byte character, usually in the range from 0x20 (space) to 0x7E (tilde).

The escape_char defaults to being the double-quote mark ("). In other words the same as the default quote_char. This means that doubling the quote mark in a field escapes it:

```
"foo","bar","Escape ""quote mark"" with two ""quote marks""","baz"
```

If you change the quote_char without changing the escape_char, the escape_char will still be the double-quote ("). If instead you want to escape the quote_char by doubling it you will need to also change the escape_char to be the same as what you have changed the quote_char to.

Setting escape_char to undef or "" will completely disable escapes and is greatly discouraged. This will also disable escape_null.

The escape character can not be equal to the separation character.

binary

```
my $csv = Text::CSV->new ({ binary => 1 });
        $csv->binary (0);
my $f = $csv->binary;
```

If this attribute is 1, you may use binary characters in quoted fields, including line feeds, carriage returns and NULL bytes. (The latter could be escaped as "0.) By default this feature is off.

If a string is marked UTF8, binary will be turned on automatically when binary characters other than CR and NL are encountered. Note that a simple string like "\x{00a0}" might still be binary, but not marked UTF8, so setting { binary => 1 } is still a wise option.

strict

```
my $csv = Text::CSV->new ({ strict => 1 });
        $csv->strict (0);
my $f = $csv->strict;
```

If this attribute is set to 1, any row that parses to a different number of fields than the previous row will cause the parser to throw error 2014.

Empty rows or rows that result in no fields (like comment lines) are exempt from these checks.

strict_eol

```
my $csv = Text::CSV->new ({ strict_eol => 1 });
        $csv->strict_eol (0);
my $f = $csv->strict_eol;
```

If this attribute is set to 0, no EOL consistency checks are done.

If this attribute is set to 1, any row that parses with a EOL other than the EOL from the first row will cause a warning. The error will be ignored and parsing continues. This warning is only thrown once. Note that in data with various different line endings, \r\r will still throw an error that cannot be ignored.

If this attribute is set to 2 or higher, any row that parses with a EOL other than the EOL from the first row will cause error 2016 to be thrown. The line being parsed to this error might not be stored in the result.

skip_empty_rows

```
my $csv = Text::CSV->new ({ skip_empty_rows => 1 });
        $csv->skip_empty_rows ("eof");
my $f = $csv->skip_empty_rows;
```

This attribute defines the behavior for empty rows: an “eol” immediately following the start of line. Default behavior is to return one single empty field.

This attribute is only used in parsing. This attribute is ineffective when using “parse” and “fields”.

Possible values for this attribute are

- 0 | undef

```
my $csv = Text::CSV->new ({ skip_empty_rows => 0 });
$csv->skip_empty_rows (undef);
```

No special action is taken. The result will be one single empty field.

- 1 | "skip"

```
my $csv = Text::CSV->new ({ skip_empty_rows => 1 });
$csv->skip_empty_rows ("skip");
```

The row will be skipped.

- 2 | "eof" | "stop"

```
my $csv = Text::CSV->new ({ skip_empty_rows => 2 });
$csv->skip_empty_rows ("eof");
```

The parsing will stop as if an "eof" was detected.

- 3 | "die"

```
my $csv = Text::CSV->new ({ skip_empty_rows => 3 });
$csv->skip_empty_rows ("die");
```

The parsing will stop. The internal error code will be set to 2015 and the parser will `die`.

- 4 | "croak"

```
my $csv = Text::CSV->new ({ skip_empty_rows => 4 });
$csv->skip_empty_rows ("croak");
```

The parsing will stop. The internal error code will be set to 2015 and the parser will `croak`.

- 5 | "error"

```
my $csv = Text::CSV->new ({ skip_empty_rows => 5 });
$csv->skip_empty_rows ("error");
```

The parsing will fail. The internal error code will be set to 2015.

- callback

```
my $csv = Text::CSV->new ({ skip_empty_rows => sub { [] } });
$csv->skip_empty_rows (sub { [ 42, $., undef, "empty" ] });
```

The callback is invoked and its result used instead. If you want the parse to stop after the callback, make sure to return a false value.

The returned value from the callback should be an array-ref. Any other type will cause the parse to stop, so these are equivalent in behavior:

```
csv (in => $fh, skip_empty_rows => "stop");
csv (in => $fh. skip_empty_rows => sub { 0; });
```

Without arguments, the current value is returned: `0`, `1`, `eof`, `die`, `croak` or the callback.

formula_handling

Alias for “formula”

formula

```
my $csv = Text::CSV->new ({ formula => "none" });
          $csv->formula ("none");
my $f = $csv->formula;
```

This defines the behavior of fields containing *formulas*. As formulas are considered dangerous in spreadsheets, this attribute can define an optional action to be taken if a field starts with an equal sign (=).

For purpose of code-readability, this can also be written as

```
my $csv = Text::CSV->new ({ formula_handling => "none" });
          $csv->formula_handling ("none");
my $f = $csv->formula_handling;
```

Possible values for this attribute are

- none

  Take no specific action. This is the default.

  ```
  $csv->formula ("none");
  ```

- die

  Cause the process to `die` whenever a leading = is encountered.

  ```
  $csv->formula ("die");
  ```

- croak

  Cause the process to `croak` whenever a leading = is encountered. (See *Carp*)

  ```
  $csv->formula ("croak");
  ```

- diag

  Report position and content of the field whenever a leading = is found. The value of the field is unchanged.

  ```
  $csv->formula ("diag");
  ```

- empty

  Replace the content of fields that start with a = with the empty string.

  ```
  $csv->formula ("empty");
  $csv->formula ("");
  ```

- undef

  Replace the content of fields that start with a = with undef.

```
$csv->formula ("undef");
$csv->formula (undef);
```

- a callback

  Modify the content of fields that start with a = with the return-value of the callback. The original content of the field is available inside the callback as $_;

```
# Replace all formula's with 42
$csv->formula (sub { 42; });

# same as $csv->formula ("empty") but slower
$csv->formula (sub { "" });

# Allow =4+12
$csv->formula (sub { s/^=(\d+\+\d+)$/$1/eer });

# Allow more complex calculations
$csv->formula (sub { eval { s{^=([-+*/0-9()]+)$}{$1}ee }; $_ });
```

All other values will give a warning and then fallback to diag.

decode_utf8

```
my $csv = Text::CSV->new ({ decode_utf8 => 1 });
        $csv->decode_utf8 (0);
my $f = $csv->decode_utf8;
```

This attributes defaults to TRUE.

While *parsing*, fields that are valid UTF-8, are automatically set to be UTF-8, so that

```
$csv->parse ("\xC4\xA8\n");
```

results in

```
PV("\304\250"\0) [UTF8 "\x{128}"]
```

Sometimes it might not be a desired action. To prevent those upgrades, set this attribute to false, and the result will be

```
PV("\304\250"\0)
```

auto_diag

```
my $csv = Text::CSV->new ({ auto_diag => 1 });
        $csv->auto_diag (2);
my $l = $csv->auto_diag;
```

Set this attribute to a number between 1 and 9 causes "error_diag" to be automatically called in void context upon errors.

In case of error `2012 - EOF`, this call will be void.

If `auto_diag` is set to a numeric value greater than 1, it will `die` on errors instead of `warn`. If set to anything unrecognized, it will be silently ignored.

Future extensions to this feature will include more reliable auto-detection of `autodie` being active in the scope of which the error occurred which will increment the value of `auto_diag` with 1 the moment the error is detected.

diag_verbose

```
my $csv = Text::CSV->new ({ diag_verbose => 1 });
        $csv->diag_verbose (2);
my $l = $csv->diag_verbose;
```

Set the verbosity of the output triggered by `auto_diag`. Currently only adds the current input-record-number (if known) to the diagnostic output with an indication of the position of the error.

blank_is_undef

```
my $csv = Text::CSV->new ({ blank_is_undef => 1 });
        $csv->blank_is_undef (0);
my $f = $csv->blank_is_undef;
```

Under normal circumstances, `CSV` data makes no distinction between quoted- and unquoted empty fields. These both end up in an empty string field once read, thus

```
1,"",," ",2
```

is read as

```
("1", "", "", " ", "2")
```

When *writing* `CSV` files with either `always_quote` or `quote_empty` set, the unquoted *empty* field is the result of an undefined value. To enable this distinction when *reading* `CSV` data, the `blank_is_undef` attribute will cause unquoted empty fields to be set to `undef`, causing the above to be parsed as

```
("1", "", undef, " ", "2")
```

Note that this is specifically important when loading `CSV` fields into a database that allows `NULL` values, as the perl equivalent for `NULL` is `undef` in *DBI* land.

empty_is_undef

```
my $csv = Text::CSV->new ({ empty_is_undef => 1 });
        $csv->empty_is_undef (0);
my $f = $csv->empty_is_undef;
```

Going one step further than `blank_is_undef`, this attribute converts all empty fields to `undef`, so

```
1,"",," ",2
```

is read as

```
(1, undef, undef, " ", 2)
```

Note that this affects only fields that are originally empty, not fields that are empty after stripping allowed whitespace. YMMV.

allow_whitespace

```
my $csv = Text::CSV->new ({ allow_whitespace => 1 });
        $csv->allow_whitespace (0);
my $f = $csv->allow_whitespace;
```

When this option is set to true, the whitespace (TAB's and SPACE's) surrounding the separation character is removed when parsing. If either TAB or SPACE is one of the three characters `sep_char`, `quote_char`, or `escape_char` it will not be considered whitespace.

Now lines like:

```
1 , "foo" , bar , 3 , zapp
```

are parsed as valid CSV, even though it violates the CSV specs.

Note that **all** whitespace is stripped from both start and end of each field. That would make it *more* than a *feature* to enable parsing bad CSV lines, as

```
1,   2.0,  3,   ape  , monkey
```

will now be parsed as

```
("1", "2.0", "3", "ape", "monkey")
```

even if the original line was perfectly acceptable CSV.

allow_loose_quotes

```
my $csv = Text::CSV->new ({ allow_loose_quotes => 1 });
        $csv->allow_loose_quotes (0);
my $f = $csv->allow_loose_quotes;
```

By default, parsing unquoted fields containing `quote_char` characters like

```
1,foo "bar" baz,42
```

would result in parse error 2034. Though it is still bad practice to allow this format, we cannot help the fact that some vendors make their applications spit out lines styled this way.

If there is **really** bad CSV data, like

```
1,"foo "bar" baz",42
```

or

```
1,""foo bar baz"",42
```

there is a way to get this data-line parsed and leave the quotes inside the quoted field as-is. This can be achieved by setting `allow_loose_quotes` **AND** making sure that the `escape_char` is *not* equal to `quote_char`.

allow_loose_escapes

```
my $csv = Text::CSV->new ({ allow_loose_escapes => 1 });
        $csv->allow_loose_escapes (0);
my $f = $csv->allow_loose_escapes;
```

Parsing fields that have `escape_char` characters that escape characters that do not need to be escaped, like:

```
my $csv = Text::CSV->new ({ escape_char => "\\" });
$csv->parse (qq{1,"my bar\'s",baz,42});
```

would result in parse error 2025. Though it is bad practice to allow this format, this attribute enables you to treat all escape character sequences equal.

allow_unquoted_escape

```
my $csv = Text::CSV->new ({ allow_unquoted_escape => 1 });
        $csv->allow_unquoted_escape (0);
my $f = $csv->allow_unquoted_escape;
```

A backward compatibility issue where `escape_char` differs from `quote_char` prevents `escape_char` to be in the first position of a field. If `quote_char` is equal to the default `"` and `escape_char` is set to `\`, this would be illegal:

```
1,\0,2
```

Setting this attribute to 1 might help to overcome issues with backward compatibility and allow this style.

always_quote

```
my $csv = Text::CSV->new ({ always_quote => 1 });
        $csv->always_quote (0);
my $f = $csv->always_quote;
```

By default the generated fields are quoted only if they *need* to be. For example, if they contain the separator character. If you set this attribute to 1 then *all* defined fields will

be quoted. (undef fields are not quoted, see "blank_is_undef"). This makes it quite often easier to handle exported data in external applications.

quote_space

```
my $csv = Text::CSV->new ({ quote_space => 1 });
          $csv->quote_space (0);
my $f = $csv->quote_space;
```

By default, a space in a field would trigger quotation. As no rule exists this to be forced in CSV, nor any for the opposite, the default is true for safety. You can exclude the space from this trigger by setting this attribute to 0.

quote_empty

```
my $csv = Text::CSV->new ({ quote_empty => 1 });
          $csv->quote_empty (0);
my $f = $csv->quote_empty;
```

By default the generated fields are quoted only if they *need* to be. An empty (defined) field does not need quotation. If you set this attribute to 1 then *empty* defined fields will be quoted. (undef fields are not quoted, see "blank_is_undef"). See also `always_quote`.

quote_binary

```
my $csv = Text::CSV->new ({ quote_binary => 1 });
          $csv->quote_binary (0);
my $f = $csv->quote_binary;
```

By default, all "unsafe" bytes inside a string cause the combined field to be quoted. By setting this attribute to `0`, you can disable that trigger for bytes `>= 0x7F`.

escape_null

```
my $csv = Text::CSV->new ({ escape_null => 1 });
          $csv->escape_null (0);
my $f = $csv->escape_null;
```

By default, a `NULL` byte in a field would be escaped. This option enables you to treat the `NULL` byte as a simple binary character in binary mode (the `{ binary => 1 }` is set). The default is true. You can prevent `NULL` escapes by setting this attribute to `0`.

When the `escape_char` attribute is set to undefined, this attribute will be set to false.

The default setting will encode "=\x00=" as

```
"="0="
```

With `escape_null` set, this will result in

```
"=\x00="
```

The default when using the `csv` function is `false`.

For backward compatibility reasons, the deprecated old name `quote_null` is still recognized.

keep_meta_info

```
my $csv = Text::CSV->new ({ keep_meta_info => 1 });
        $csv->keep_meta_info (0);
my $f = $csv->keep_meta_info;
```

By default, the parsing of input records is as simple and fast as possible. However, some parsing information - like quotation of the original field - is lost in that process. Setting this flag to true enables retrieving that information after parsing with the methods "meta_info", "is_quoted", and "is_binary" described below. Default is false for performance.

If you set this attribute to a value greater than 9, then you can control output quotation style like it was used in the input of the the last parsed record (unless quotation was added because of other reasons).

```
my $csv = Text::CSV->new ({
   binary         => 1,
   keep_meta_info => 1,
   quote_space    => 0,
   });

my $row = $csv->parse (q{1,,"", ," ",f,"g","h""h",help,"help"});

$csv->print (*STDOUT, \@row);
# 1,,, , ,f,g,"h""h",help,help
$csv->keep_meta_info (11);
$csv->print (*STDOUT, \@row);
# 1,,"", ," ",f,"g","h""h",help,"help"
```

undef_str

```
my $csv = Text::CSV->new ({ undef_str => "\\N" });
        $csv->undef_str (undef);
my $s = $csv->undef_str;
```

This attribute optionally defines the output of undefined fields. The value passed is not changed at all, so if it needs quotation, the quotation needs to be included in the value of the attribute. Use with caution, as passing a value like `" , " , , , , """` will for sure mess up your output. The default for this attribute is `undef`, meaning no special treatment.

This attribute is useful when exporting CSV data to be imported in custom loaders, like for MySQL, that recognize special sequences for `NULL` data.

This attribute has no meaning when parsing CSV data.

comment_str

```
my $csv = Text::CSV->new ({ comment_str => "#" });
        $csv->comment_str (undef);
my $s = $csv->comment_str;
```

This attribute optionally defines a string to be recognized as comment. If this attribute is defined, all lines starting with this sequence will not be parsed as CSV but skipped as comment.

This attribute has no meaning when generating CSV.

Comment strings that start with any of the special characters/sequences are not supported (so it cannot start with any of "sep_char", "quote_char", "escape_char", "sep", "quote", or "eol").

For convenience, `comment` is an alias for `comment_str`.

verbatim

```
my $csv = Text::CSV->new ({ verbatim => 1 });
        $csv->verbatim (0);
my $f = $csv->verbatim;
```

This is a quite controversial attribute to set, but makes some hard things possible.

The rationale behind this attribute is to tell the parser that the normally special characters newline (`NL`) and Carriage Return (`CR`) will not be special when this flag is set, and be dealt with as being ordinary binary characters. This will ease working with data with embedded newlines.

When `verbatim` is used with "getline", "getline" auto-`chomp`'s every line.

Imagine a file format like

```
M^^Hans^Janssen^Klas 2\n2A^Ja^11-06-2007#\r\n
```

where, the line ending is a very specific `"#\r\n"`, and the sep_char is a `^` (caret). None of the fields is quoted, but embedded binary data is likely to be present. With the specific line ending, this should not be too hard to detect.

By default, Text::CSV' parse function is instructed to only know about `"\n"` and `"\r"` to be legal line endings, and so has to deal with the embedded newline as a real `end-of-line`, so it can scan the next line if binary is true, and the newline is inside a quoted field. With this option, we tell "parse" to parse the line as if `"\n"` is just nothing more than a binary character.

For "parse" this means that the parser has no more idea about line ending and "getline" `chomp`s line endings on reading.

types

A set of column types; the attribute is immediately passed to the "types" method.

callbacks

See the "Callbacks" section below.

accessors

To sum it up,

```
$csv = Text::CSV->new ();
```

is equivalent to

```
$csv = Text::CSV->new ({
    eol                    => undef, # \r, \n, or \r\n
    sep_char               => ',',
    sep                    => undef,
    quote_char             => '"',
    quote                  => undef,
    escape_char            => '"',
    binary                 => 0,
    decode_utf8            => 1,
    auto_diag              => 0,
    diag_verbose           => 0,
    blank_is_undef         => 0,
    empty_is_undef         => 0,
    allow_whitespace       => 0,
    allow_loose_quotes     => 0,
    allow_loose_escapes    => 0,
    allow_unquoted_escape  => 0,
    always_quote           => 0,
    quote_empty            => 0,
    quote_space            => 1,
    escape_null            => 1,
    quote_binary           => 1,
    keep_meta_info         => 0,
    strict                 => 0,
    skip_empty_rows        => 0,
    formula                => 0,
    verbatim               => 0,
    undef_str              => undef,
    comment_str            => undef,
    types                  => undef,
    callbacks              => undef,
    });
```

For all of the above mentioned flags, an accessor method is available where you can inquire the current value, or change the value

```
my $quote = $csv->quote_char;
$csv->binary (1);
```

It is not wise to change these settings halfway through writing CSV data to a stream. If however you want to create a new stream using the available CSV object, there is no harm in changing them.

If the "new" constructor call fails, it returns undef, and makes the fail reason available through the "error_diag" method.

```
$csv = Text::CSV->new ({ ecs_char => 1 }) or
    die "".Text::CSV->error_diag ();
```

"error_diag" will return a string like

```
"INI - Unknown attribute 'ecs_char'"
```

known_attributes

```
@attr = Text::CSV->known_attributes;
@attr = Text::CSV::known_attributes;
@attr = $csv->known_attributes;
```

This method will return an ordered list of all the supported attributes as described above. This can be useful for knowing what attributes are valid in classes that use or extend Text::CSV.

print

```
$status = $csv->print ($fh, $colref);
```

Similar to "combine" + "string" + "print", but much more efficient. It expects an array ref as input (not an array!) and the resulting string is not really created, but immediately written to the $fh object, typically an IO handle or any other object that offers a "print" method.

For performance reasons print does not create a result string, so all "string", "status", "fields", and "error_input" methods will return undefined information after executing this method.

If $colref is undef (explicit, not through a variable argument) and "bind_columns" was used to specify fields to be printed, it is possible to make performance improvements, as otherwise data would have to be copied as arguments to the method call:

```
$csv->bind_columns (\($foo, $bar));
$status = $csv->print ($fh, undef);
```

A short benchmark

```
my @data = ("aa" .. "zz");
$csv->bind_columns (\(@data));
```

(continues on next page)

(continued from previous page)

```
$csv->print ($fh, [ @data ]);   # 11800 recs/sec
$csv->print ($fh,  \@data  );   # 57600 recs/sec
$csv->print ($fh,   undef  );   # 48500 recs/sec
```

say

```
$status = $csv->say ($fh, $colref);
```

Like `print`, but `eol` defaults to `$\`.

print_hr

```
$csv->print_hr ($fh, $ref);
```

Provides an easy way to print a `$ref` (as fetched with "getline_hr") provided the column names are set with "column_names".

It is just a wrapper method with basic parameter checks over

```
$csv->print ($fh, [ map { $ref->{$_} } $csv->column_names ]);
```

combine

```
$status = $csv->combine (@fields);
```

This method constructs a CSV record from `@fields`, returning success or failure. Failure can result from lack of arguments or an argument that contains an invalid character. Upon success, "string" can be called to retrieve the resultant CSV string. Upon failure, the value returned by "string" is undefined and "error_input" could be called to retrieve the invalid argument.

string

```
$line = $csv->string ();
```

This method returns the input to "parse" or the resultant CSV string of "combine", whichever was called more recently.

getline

```
$colref = $csv->getline ($fh);
```

This is the counterpart to "print", as "parse" is the counterpart to "combine": it parses a row from the `$fh` handle using the "getline" method associated with `$fh` and parses this row into an array ref. This array ref is returned by the function or `undef` for failure. When `$fh` does not support `getline`, you are likely to hit errors.

When fields are bound with “bind_columns” the return value is a reference to an empty list.

The “string”, “fields”, and “status” methods are meaningless again.

getline_all

```
$arrayref = $csv->getline_all ($fh);
$arrayref = $csv->getline_all ($fh, $offset);
$arrayref = $csv->getline_all ($fh, $offset, $length);
```

This will return a reference to a list of getline ($fh) results. In this call, `keep_meta_info` is disabled. If `$offset` is negative, as with `splice`, only the last `abs ($offset)` records of `$fh` are taken into consideration. Parameters `$offset` and `$length` are expected to be integers. Non-integer values are interpreted as integer without check.

Given a CSV file with 10 lines:

```
lines call
----- --------------------------------------------------------
0..9  $csv->getline_all ($fh)          # all
0..9  $csv->getline_all ($fh,  0)      # all
8..9  $csv->getline_all ($fh,  8)      # start at 8
-     $csv->getline_all ($fh,  0,  0) # start at 0 first 0 rows
0..4  $csv->getline_all ($fh,  0,  5) # start at 0 first 5 rows
4..5  $csv->getline_all ($fh,  4,  2) # start at 4 first 2 rows
8..9  $csv->getline_all ($fh, -2)      # last 2 rows
6..7  $csv->getline_all ($fh, -4,  2) # first 2 of last  4 rows
```

getline_hr

The “getline_hr” and “column_names” methods work together to allow you to have rows returned as hashrefs. You must call “column_names” first to declare your column names.

```
$csv->column_names (qw( code name price description ));
$hr = $csv->getline_hr ($fh);
print "Price for $hr->{name} is $hr->{price} EUR\n";
```

“getline_hr” will croak if called before “column_names”.

Note that “getline_hr” creates a hashref for every row and will be much slower than the combined use of “bind_columns” and “getline” but still offering the same easy to use hashref inside the loop:

```
my @cols = @{$csv->getline ($fh)};
$csv->column_names (@cols);
while (my $row = $csv->getline_hr ($fh)) {
    print $row->{price};
    }
```

Could easily be rewritten to the much faster:

```
my @cols = @{$csv->getline ($fh)};
my $row = {};
$csv->bind_columns (\@{$row}{@cols});
while ($csv->getline ($fh)) {
    print $row->{price};
    }
```

Your mileage may vary for the size of the data and the number of rows. With perl-5.14.2 the comparison for a 100_000 line file with 14 columns:

```
           Rate hashrefs getlines
hashrefs 1.00/s       --     -76%
getlines 4.15/s     313%       --
```

getline_hr_all

```
$arrayref = $csv->getline_hr_all ($fh);
$arrayref = $csv->getline_hr_all ($fh, $offset);
$arrayref = $csv->getline_hr_all ($fh, $offset, $length);
```

This will return a reference to a list of getline_hr ($fh) results. In this call, `keep_meta_info` is disabled.

parse

```
$status = $csv->parse ($line);
```

This method decomposes a CSV string into fields, returning success or failure. Failure can result from a lack of argument or the given CSV string is improperly formatted. Upon success, “fields” can be called to retrieve the decomposed fields. Upon failure calling “fields” will return undefined data and “error_input” can be called to retrieve the invalid argument.

You may use the “types” method for setting column types. See “types”’ description below.

The `$line` argument is supposed to be a simple scalar. Everything else is supposed to croak and set error 1500.

fragment

This function tries to implement RFC7111 (URI Fragment Identifiers for the text/csv Media Type) - https://datatracker.ietf.org/doc/html/rfc7111

```
my $AoA = $csv->fragment ($fh, $spec);
```

In specifications, `*` is used to specify the *last* item, a dash (`-`) to indicate a range. All indices are 1-based: the first row or column has index 1. Selections can be combined with the semi-colon (`;`).

When using this method in combination with “column_names”, the returned reference will point to a list of hashes instead of a list of lists. A disjointed cell-based combined

selection might return rows with different number of columns making the use of hashes unpredictable.

```
$csv->column_names ("Name", "Age");
my $AoH = $csv->fragment ($fh, "col=3;8");
```

If the “after_parse” callback is active, it is also called on every line parsed and skipped before the fragment.

- row

  ```
  row=4
  row=5-7
  row=6-*
  row=1-2;4;6-*
  ```

- col

  ```
  col=2
  col=1-3
  col=4-*
  col=1-2;4;7-*
  ```

- cell

  In cell-based selection, the comma (`,`) is used to pair row and column

  ```
  cell=4,1
  ```

  The range operator (`-`) using `cell`s can be used to define top-left and bottom-right `cell` location

  ```
  cell=3,1-4,6
  ```

  The `*` is only allowed in the second part of a pair

  ```
  cell=3,2-*,2    # row 3 till end, only column 2
  cell=3,2-3,*    # column 2 till end, only row 3
  cell=3,2-*,*    # strip row 1 and 2, and column 1
  ```

  Cells and cell ranges may be combined with `;`, possibly resulting in rows with different numbers of columns

  ```
  cell=1,1-2,2;3,3-4,4;1,4;4,1
  ```

  Disjointed selections will only return selected cells. The cells that are not specified will not be included in the returned set, not even as `undef`. As an example given a `CSV` like

  ```
  11,12,13,...19
  21,22,...28,29
  :             :
  91,...97,98,99
  ```

with `cell=1,1-2,2;3,3-4,4;1,4;4,1` will return:

```
11,12,14
21,22
33,34
41,43,44
```

Overlapping cell-specs will return those cells only once, So `cell=1,1-3,3;2,2-4,4;2,3;4,2` will return:

```
11,12,13
21,22,23,24
31,32,33,34
42,43,44
```

RFC7111 does **not** allow different types of specs to be combined (either `row` *or* `col` *or* `cell`). Passing an invalid fragment specification will croak and set error 2013.

column_names

Set the "keys" that will be used in the "getline_hr" calls. If no keys (column names) are passed, it will return the current setting as a list.

"column_names" accepts a list of scalars (the column names) or a single array_ref, so you can pass the return value from "getline" too:

```
$csv->column_names ($csv->getline ($fh));
```

"column_names" does **no** checking on duplicates at all, which might lead to unexpected results. Undefined entries will be replaced with the string `"\cAUNDEF\cA"`, so

```
$csv->column_names (undef, "", "name", "name");
$hr = $csv->getline_hr ($fh);
```

will set `$hr->{"\cAUNDEF\cA"}` to the 1st field, `$hr->{""}` to the 2nd field, and `$hr->{name}` to the 4th field, discarding the 3rd field.

"column_names" croaks on invalid arguments.

header

This method does NOT work in perl-5.6.x

Parse the CSV header and set `sep`, column_names and encoding.

```
my @hdr = $csv->header ($fh);
$csv->header ($fh, { sep_set => [ ";", ",", "|", "\t" ] });
$csv->header ($fh, { detect_bom => 1, munge_column_names => "lc" });
```

The first argument should be a file handle.

This method resets some object properties, as it is supposed to be invoked only once per file or stream. It will leave attributes `column_names` and `bound_columns` alone if

setting column names is disabled. Reading headers on previously process objects might fail on perl-5.8.0 and older.

Assuming that the file opened for parsing has a header, and the header does not contain problematic characters like embedded newlines, read the first line from the open handle then auto-detect whether the header separates the column names with a character from the allowed separator list.

If any of the allowed separators matches, and none of the *other* allowed separators match, set `sep` to that separator for the current CSV instance and use it to parse the first line, map those to lowercase, and use that to set the instance "column_names":

```
my $csv = Text::CSV->new ({ binary => 1, auto_diag => 1 });
open my $fh, "<", "file.csv";
binmode $fh; # for Windows
$csv->header ($fh);
while (my $row = $csv->getline_hr ($fh)) {
    ...
    }
```

If the header is empty, contains more than one unique separator out of the allowed set, contains empty fields, or contains identical fields (after folding), it will croak with error 1010, 1011, 1012, or 1013 respectively.

If the header contains embedded newlines or is not valid CSV in any other way, this method will croak and leave the parse error untouched.

A successful call to `header` will always set the `sep` of the `$csv` object. This behavior can not be disabled.

return value

On error this method will croak.

In list context, the headers will be returned whether they are used to set "column_names" or not.

In scalar context, the instance itself is returned. **Note**: the values as found in the header will effectively be **lost** if `set_column_names` is false.

Options

- sep_set

  ```
  $csv->header ($fh, { sep_set => [ ";", ",", "|", "\t" ] });
  ```

  The list of legal separators defaults to `[ ";", "," ]` and can be changed by this option. As this is probably the most often used option, it can be passed on its own as an unnamed argument:

  ```
  $csv->header ($fh, [ ";", ",", "|", "\t", "::", "\x{2063}" ]);
  ```

  Multi-byte sequences are allowed, both multi-character and Unicode. See `sep`.

- detect_bom

```
$csv->header ($fh, { detect_bom => 1 });
```

The default behavior is to detect if the header line starts with a BOM. If the header has a BOM, use that to set the encoding of `$fh`. This default behavior can be disabled by passing a false value to `detect_bom`.

Supported encodings from BOM are: UTF-8, UTF-16BE, UTF-16LE, UTF-32BE, and UTF-32LE. BOM also supports UTF-1, UTF-EBCDIC, SCSU, BOCU-1, and GB-18030 but *Encode* does not (yet). UTF-7 is not supported.

If a supported BOM was detected as start of the stream, it is stored in the object attribute `ENCODING`.

```
my $enc = $csv->{ENCODING};
```

The encoding is used with `binmode` on `$fh`.

If the handle was opened in a (correct) encoding, this method will **not** alter the encoding, as it checks the leading **bytes** of the first line. In case the stream starts with a decoded BOM (`U+FEFF`), `{ENCODING}` will be `""` (empty) instead of the default `undef`.

- munge_column_names

  This option offers the means to modify the column names into something that is most useful to the application. The default is to map all column names to lower case.

  ```
  $csv->header ($fh, { munge_column_names => "lc" });
  ```

  The following values are available:

  ```
  lc     - lower case
  uc     - upper case
  db     - valid DB field names
  none   - do not change
  \%hash - supply a mapping
  \&cb   - supply a callback
  ```

  – Lower case

    ```
    $csv->header ($fh, { munge_column_names => "lc" });
    ```

    The header is changed to all lower-case

    ```
    $_ = lc;
    ```

  – Upper case

    ```
    $csv->header ($fh, { munge_column_names => "uc" });
    ```

    The header is changed to all upper-case

    ```
    $_ = uc;
    ```

- Literal

```
$csv->header ($fh, { munge_column_names => "none" });
```

- Hash

```
$csv->header ($fh, { munge_column_names => { foo => "sombrero
↪" });
```

if a value does not exist, the original value is used unchanged

- Database

```
$csv->header ($fh, { munge_column_names => "db" });
```

* .

lower-case

* .

all sequences of non-word characters are replaced with an underscore

* .

all leading underscores are removed

```
$_ = lc (s/\W+/_/gr =~ s/^_+//r);
```

- Callback

```
$csv->header ($fh, { munge_column_names => sub { fc } });
$csv->header ($fh, { munge_column_names => sub { "column_".
↪$col++ } });
$csv->header ($fh, { munge_column_names => sub { lc (s/\W+/_/
↪gr) } });
```

As this callback is called in a `map`, you can use `$_` directly.

- set_column_names

```
$csv->header ($fh, { set_column_names => 1 });
```

The default is to set the instances column names using "column_names" if the method is successful, so subsequent calls to "getline_hr" can return a hash. Disable setting the header can be forced by using a false value for this option.

As described in "return value" above, content is lost in scalar context.

Validation

When receiving CSV files from external sources, this method can be used to protect against changes in the layout by restricting to known headers (and typos in the header fields).

```
my %known = (
    "record key" => "c_rec",
    "rec id"     => "c_rec",
    "id_rec"     => "c_rec",
    "kode"       => "code",
    "code"       => "code",
    "vaule"      => "value",
    "value"      => "value",
    );
my $csv = Text::CSV->new ({ binary => 1, auto_diag => 1 });
open my $fh, "<", $source or die "$source: $!";
$csv->header ($fh, { munge_column_names => sub {
    s/\s+$//;
    s/^\s+//;
    $known{lc $_} or die "Unknown column '$_' in $source";
    }});
while (my $row = $csv->getline_hr ($fh)) {
    say join "\t", $row->{c_rec}, $row->{code}, $row->{value};
    }
```

bind_columns

Takes a list of scalar references to be used for output with "print" or to store in the fields fetched by "getline". When you do not pass enough references to store the fetched fields in, "getline" will fail with error `3006`. If you pass more than there are fields to return, the content of the remaining references is left untouched. Under `strict` the two should match, otherwise "getline" will fail with error `2014`.

```
$csv->bind_columns (\$code, \$name, \$price, \$description);
while ($csv->getline ($fh)) {
    print "The price of a $name is \x{20ac} $price\n";
    }
```

To reset or clear all column binding, call "bind_columns" with the single argument `undef`. This will also clear column names.

```
$csv->bind_columns (undef);
```

If no arguments are passed at all, "bind_columns" will return the list of current bindings or `undef` if no binds are active.

Note that in parsing with `bind_columns`, the fields are set on the fly. That implies that if the third field of a row causes an error (or this row has just two fields where the previous row had more), the first two fields already have been assigned the values of the current row, while the rest of the fields will still hold the values of the previous row. If you want the parser to fail in these cases, use the `strict` attribute.

eof

```
$eof = $csv->eof ();
```

If "parse" or "getline" was used with an IO stream, this method will return true (1) if the last call hit end of file, otherwise it will return false ('). This is useful to see the difference between a failure and end of file.

Note that if the parsing of the last line caused an error, `eof` is still true. That means that if you are *not* using "auto_diag", an idiom like

```
while (my $row = $csv->getline ($fh)) {
    # ...
    }
$csv->eof or $csv->error_diag;
```

will *not* report the error. You would have to change that to

```
while (my $row = $csv->getline ($fh)) {
    # ...
    }
+$csv->error_diag and $csv->error_diag;
```

types

```
$csv->types (\@tref);
```

This method is used to force that (all) columns are of a given type. For example, if you have an integer column, two columns with doubles and a string column, then you might do a

```
$csv->types ([Text::CSV::IV (),
              Text::CSV::NV (),
              Text::CSV::NV (),
              Text::CSV::PV ()]);
```

Column types are used only for *decoding* columns while parsing, in other words by the "parse" and "getline" methods.

You can unset column types by doing a

```
$csv->types (undef);
```

or fetch the current type settings with

```
$types = $csv->types ();
```

- IV
- CSV_TYPE_IV

  Set field type to integer.
- NV

- CSV_TYPE_NV

  Set field type to numeric/float.

- PV
- CSV_TYPE_PV

  Set field type to string.

fields

```
@columns = $csv->fields ();
```

This method returns the input to "combine" or the resultant decomposed fields of a successful "parse", whichever was called more recently.

Note that the return value is undefined after using "getline", which does not fill the data structures returned by "parse".

meta_info

```
@flags = $csv->meta_info ();
```

This method returns the "flags" of the input to "combine" or the flags of the resultant decomposed fields of "parse", whichever was called more recently.

For each field, a meta_info field will hold flags that inform something about the field returned by the "fields" method or passed to the "combine" method. The flags are bit-wise-or'd like:

- 0x0001
- CSV_FLAGS_IS_QUOTED

  The field was quoted.

- 0x0002
- CSV_FLAGS_IS_BINARY

  The field was binary.

- 0x0004
- CSV_FLAGS_ERROR_IN_FIELD

  The field was invalid.

  Currently only used when allow_loose_quotes is active.

- 0x0010
- CSV_FLAGS_IS_MISSING

  The field was missing.

See the is_*** methods below.

is_quoted

```
my $quoted = $csv->is_quoted ($column_idx);
```

where `$column_idx` is the (zero-based) index of the column in the last result of "parse".

This returns a true value if the data in the indicated column was enclosed in `quote_char` quotes. This might be important for fields where content `,20070108,` is to be treated as a numeric value, and where `,"20070108",` is explicitly marked as character string data.

This method is only valid when "keep_meta_info" is set to a true value.

is_binary

```
my $binary = $csv->is_binary ($column_idx);
```

where `$column_idx` is the (zero-based) index of the column in the last result of "parse".

This returns a true value if the data in the indicated column contained any byte in the range `[\x00-\x08,\x10-\x1F,\x7F-\xFF]`.

This method is only valid when "keep_meta_info" is set to a true value.

is_missing

```
my $missing = $csv->is_missing ($column_idx);
```

where `$column_idx` is the (zero-based) index of the column in the last result of "getline_hr".

```
$csv->keep_meta_info (1);
while (my $hr = $csv->getline_hr ($fh)) {
    $csv->is_missing (0) and next; # This was an empty line
    }
```

When using "getline_hr", it is impossible to tell if the parsed fields are `undef` because they where not filled in the `CSV` stream or because they were not read at all, as **all** the fields defined by "column_names" are set in the hash-ref. If you still need to know if all fields in each row are provided, you should enable `keep_meta_info` so you can check the flags.

If `keep_meta_info` is `false`, `is_missing` will always return `undef`, regardless of `$column_idx` being valid or not. If this attribute is `true` it will return either `0` (the field is present) or 1 (the field is missing).

A special case is the empty line. If the line is completely empty - after dealing with the flags - this is still a valid CSV line: it is a record of just one single empty field. However, if `keep_meta_info` is set, invoking `is_missing` with index `0` will now return true.

status

```
$status = $csv->status ();
```

This method returns the status of the last invoked "combine" or "parse" call. Status is success (true: 1) or failure (false: undef or 0).

Note that as this only keeps track of the status of above mentioned methods, you are probably looking for error_diag instead.

error_input

```
$bad_argument = $csv->error_input ();
```

This method returns the erroneous argument (if it exists) of "combine" or "parse", whichever was called more recently. If the last invocation was successful, error_input will return undef.

Depending on the type of error, it *might* also hold the data for the last error-input of "getline".

error_diag

```
Text::CSV->error_diag ();
$csv->error_diag ();
$error_code  = 0  + $csv->error_diag ();
$error_str   = "" . $csv->error_diag ();
($cde, $str, $pos, $rec, $fld, $xs) = $csv->error_diag ();
```

If (and only if) an error occurred, this function returns the diagnostics of that error.

If called in void context, this will print the internal error code and the associated error message to STDERR.

If called in list context, this will return the error code and the error message in that order. If the last error was from parsing, the rest of the values returned are a best guess at the location within the line that was being parsed. Their values are 1-based. The position currently is index of the byte at which the parsing failed in the current record. It might change to be the index of the current character in a later release. The records is the index of the record parsed by the csv instance. The field number is the index of the field the parser thinks it is currently trying to parse. See examples/csv-check for how this can be used.

If called in scalar context, it will return the diagnostics in a single scalar, a-la $!. It will contain the error code in numeric context, and the diagnostics message in string context.

When called as a class method or a direct function call, the diagnostics are that of the last "new" call.

_cache_diag

Note: This is an internal function only, and output cannot be relied upon. Use at own risk.

If debugging beyond what "error_diag" is able to show, the internal cache can be shown with this function.

```
# Something failed ..
$csv->error_diag;
$csv->_cache_diag ();
```

record_number

```
$recno = $csv->record_number ();
```

Returns the records parsed by this csv instance. This value should be more accurate than `$.` when embedded newlines come in play. Records written by this instance are not counted.

SetDiag

```
$csv->SetDiag (0);
```

Use to reset the diagnostics if you are dealing with errors.

ADDITIONAL METHODS

- backend

  Returns the backend module name called by Text::CSV. `module` is an alias.

- is_xs

- is_pp

  Returns true value if Text::CSV uses a pure-Perl backend.

FUNCTIONS

This section is also taken from Text::CSV_XS.

csv

This function is not exported by default and should be explicitly requested:

```
use Text::CSV qw( csv );
```

This is a high-level function that aims at simple (user) interfaces. This can be used to read/parse a `CSV` file or stream (the default behavior) or to produce a file or write to a stream (define the `out` attribute). It returns an array- or hash-reference on parsing (or `undef` on fail) or the numeric value of "error_diag" on writing. When this function fails you can get to the error using the class call to "error_diag"

```
my $aoa = csv (in => "test.csv") or
    die Text::CSV->error_diag;
```

Note that failure here is the inability to start the parser, like when the input does not exist or the arguments are unknown or conflicting. Run-time parsing errors will return a valid reference, which can be empty, but still contains all results up till the error. See "on_error".

This function takes the arguments as key-value pairs. This can be passed as a list or as an anonymous hash:

```
my $aoa = csv (  in => "test.csv", sep_char => ";");
my $aoh = csv ({ in => $fh, headers => "auto" });
```

The arguments passed consist of two parts: the arguments to "csv" itself and the optional attributes to the CSV object used inside the function as enumerated and explained in "new".

If not overridden, the default option used for CSV is

```
auto_diag   => 1
escape_null => 0
strict_eol  => 1
```

The option that is always set and cannot be altered is

```
binary      => 1
```

As this function will likely be used in one-liners, it allows `quote` to be abbreviated as quo, and `escape_char` to be abbreviated as `esc` or `escape`.

Alternative invocations:

```
my $aoa = Text::CSV::csv (in => "file.csv");

my $csv = Text::CSV->new ();
my $aoa = $csv->csv (in => "file.csv");
```

In the latter case, the object attributes are used from the existing object and the attribute arguments in the function call are ignored:

```
my $csv = Text::CSV->new ({ sep_char => ";" });
my $aoh = $csv->csv (in => "file.csv", bom => 1);
```

will parse using `;` as `sep_char`, not `,`.

in

Used to specify the source. `in` can be a file name (e.g. `"file.csv"`), which will be opened for reading and closed when finished, a file handle (e.g. `$fh` or `FH`), a reference to a glob (e.g. `\*ARGV`), the glob itself (e.g. `*STDIN`), or a reference to a scalar (e.g. `\q{1,2,"csv"}`).

When used with "out", in should be a reference to a CSV structure (AoA or AoH) or a CODE-ref that returns an array-reference or a hash-reference. The code-ref will be invoked with no arguments.

```
my $aoa = csv (in => "file.csv");

open my $fh, "<", "file.csv";
my $aoa = csv (in => $fh);

my $csv = [ [qw( Foo Bar )], [ 1, 2 ], [ 2, 3 ]];
my $err = csv (in => $csv, out => "file.csv");
```

If called in void context without the "out" attribute, the resulting ref will be used as input to a subsequent call to csv:

```
csv (in => "file.csv", filter => { 2 => sub { length > 2 }})
```

will be a shortcut to

```
csv (in => csv (in => "file.csv", filter => { 2 => sub { length > 2␣
 ↪}}))
```

where, in the absence of the out attribute, this is a shortcut to

```
csv (in  => csv (in => "file.csv", filter => { 2 => sub { length > 2␣
 ↪}}),
     out => *STDOUT)
```

out

```
csv (in => $aoa,  out => "file.csv");
csv (in => $aoa,  out => $fh);
csv (in => $aoa,  out =>   STDOUT);
csv (in => $aoa,  out =>  *STDOUT);
csv (in => $aoa,  out => \*STDOUT);
csv (in => $aoa,  out => \my $data);
csv (in => $aoa,  out =>  undef);
csv (in => $aoa,  out => \"skip");

csv (in => $fh,   out => \@aoa);
csv (in => $fh,   out => \@aoh, bom => 1);
csv (in => $fh,   out => \%hsh, key => "key");

csv (in => $file, out => $file);
csv (in => $file, out => $fh);
csv (in => $fh,   out => $file);
csv (in => $fh,   out => $fh);
```

In output mode, the default CSV options when producing CSV are

```
eol       => "\r\n"
```

The “fragment” attribute is ignored in output mode.

`out` can be a file name (e.g. `"file.csv"`), which will be opened for writing and closed when finished, a file handle (e.g. `$fh` or `FH`), a reference to a glob (e.g. `\*STDOUT`), the glob itself (e.g. `*STDOUT`), or a reference to a scalar (e.g. `\my $data`).

```
csv (in => sub { $sth->fetch },            out => "dump.csv");
csv (in => sub { $sth->fetchrow_hashref }, out => "dump.csv",
     headers => $sth->{NAME_lc});
```

When a code-ref is used for `in`, the output is generated per invocation, so no buffering is involved. This implies that there is no size restriction on the number of records. The `csv` function ends when the coderef returns a false value.

If `out` is set to a reference of the literal string `"skip"`, the output will be suppressed completely, which might be useful in combination with a filter for side effects only.

```
my %cache;
csv (in    => "dump.csv",
     out   => \"skip",
     on_in => sub { $cache{$_[1][1]}++ });
```

Currently, setting `out` to any false value (`undef`, `""`, 0) will be equivalent to `\"skip"`.

If the `in` argument point to something to parse, and the `out` is set to a reference to an `ARRAY` or a `HASH`, the output is appended to the data in the existing reference. The result of the parse should match what exists in the reference passed. This might come handy when you have to parse a set of files with similar content (like data stored per period) and you want to collect that into a single data structure:

```
my %hash;
csv (in => $_, out => \%hash, key => "id") for sort glob "foo-[0-
↪9]*.csv";

my @list; # List of arrays
csv (in => $_, out => \@list)              for sort glob "foo-[0-
↪9]*.csv";

my @list; # List of hashes
csv (in => $_, out => \@list, bom => 1)    for sort glob "foo-[0-
↪9]*.csv";
```

Streaming

If **both** `in` and `out` are files, file handles or globs, streaming is enforced by injecting an `after_parse` callback that immediately uses the `say ()` method of the same instance to output the result and then rejects the record.

If a `after_parse` was already passed as attribute, that will be included in the injected call. If `on_in` was passed and `after_parse` was not, it will be used instead. If both were passed, `on_in` is ignored.

The EOL of the first record of the `in` source is consistently used as EOL for all records in the `out` destination.

The `filter` attribute is not available.

All other attributes are shared for `in` and `out`, so you cannot define different encodings for `in` and `out`. You need to pass a `$fh`, where `binmode` was used to apply the encoding layers.

Note that this is work in progress and things might change.

encoding

If passed, it should be an encoding accepted by the `:encoding()` option to open. There is no default value. This attribute does not work in perl 5.6.x. `encoding` can be abbreviated to `enc` for ease of use in command line invocations.

If `encoding` is set to the literal value `"auto"`, the method "header" will be invoked on the opened stream to check if there is a BOM and set the encoding accordingly. This is equal to passing a true value in the option `detect_bom`.

Encodings can be stacked, as supported by `binmode`:

```
# Using PerlIO::via::gzip
csv (in       => \@csv,
     out      => "test.csv:via.gz",
     encoding => ":via(gzip):encoding(utf-8)",
     );
$aoa = csv (in => "test.csv:via.gz",  encoding => ":via(gzip)");

# Using PerlIO::gzip
csv (in       => \@csv,
     out      => "test.csv:via.gz",
     encoding => ":gzip:encoding(utf-8)",
     );
$aoa = csv (in => "test.csv:gzip.gz", encoding => ":gzip");
```

detect_bom

If `detect_bom` is given, the method "header" will be invoked on the opened stream to check if there is a BOM and set the encoding accordingly.

`detect_bom` can be abbreviated to `bom`.

This is the same as setting `encoding` to `"auto"`.

Note that as the method "header" is invoked, its default is to also set the headers.

headers

If this attribute is not given, the default behavior is to produce an array of arrays.

If `headers` is supplied, it should be an anonymous list of column names, an anonymous hashref, a coderef, or a literal flag: `auto`, `lc`, `uc`, or `skip`.

- skip

  When `skip` is used, the header will not be included in the output.

```
my $aoa = csv (in => $fh, headers => "skip");
```

  `skip` is invalid/ignored in combinations with `detect_bom`.

- auto

  If `auto` is used, the first line of the CSV source will be read as the list of field headers and used to produce an array of hashes.

```
my $aoh = csv (in => $fh, headers => "auto");
```

- lc

  If `lc` is used, the first line of the CSV source will be read as the list of field headers mapped to lower case and used to produce an array of hashes. This is a variation of `auto`.

```
my $aoh = csv (in => $fh, headers => "lc");
```

- uc

  If `uc` is used, the first line of the CSV source will be read as the list of field headers mapped to upper case and used to produce an array of hashes. This is a variation of `auto`.

```
my $aoh = csv (in => $fh, headers => "uc");
```

- CODE

  If a coderef is used, the first line of the CSV source will be read as the list of mangled field headers in which each field is passed as the only argument to the coderef. This list is used to produce an array of hashes.

```
my $aoh = csv (in      => $fh,
               headers => sub { lc ($_[0]) =~ s/kode/code/gr });
```

  this example is a variation of using `lc` where all occurrences of kode are replaced with code.

- ARRAY

  If `headers` is an anonymous list, the entries in the list will be used as field names. The first line is considered data instead of headers.

```
my $aoh = csv (in => $fh, headers => [qw( Foo Bar )]);
csv (in => $aoa, out => $fh, headers => [qw( code description␣
 ↪price )]);
```

- HASH

  If `headers` is a hash reference, this implies `auto`, but header fields that exist as key in the hashref will be replaced by the value for that key. Given a CSV file like

```
post-kode,city,name,id number,fubble
1234AA,Duckstad,Donald,13,"X313DF"
```

using

```
csv (headers => { "post-kode" => "pc", "id number" => "ID" }, ..
 ↪.
```

will return an entry like

```
{ pc     => "1234AA",
  city   => "Duckstad",
  name   => "Donald",
  ID     => "13",
  fubble => "X313DF",
  }
```

See also `munge_column_names` and `set_column_names`.

munge_column_names

If `munge_column_names` is set, the method "header" is invoked on the opened stream with all matching arguments to detect and set the headers.

`munge_column_names` can be abbreviated to `munge`.

key

If passed, will default `headers` to `"auto"` and return a hashref instead of an array of hashes. Allowed values are simple scalars or array-references where the first element is the joiner and the rest are the fields to join to combine the key.

```
my $ref = csv (in => "test.csv", key => "code");
my $ref = csv (in => "test.csv", key => [ ":" => "code", "color" ]);
```

with test.csv like

```
code,product,price,color
1,pc,850,gray
2,keyboard,12,white
3,mouse,5,black
```

the first example will return

```
{ 1   => {
      code    => 1,
      color   => 'gray',
      price   => 850,
      product => 'pc'
      },
  2   => {
```

(continues on next page)

(continued from previous page)

```
      code    => 2,
      color   => 'white',
      price   => 12,
      product => 'keyboard'
      },
  3   => {
      code    => 3,
      color   => 'black',
      price   => 5,
      product => 'mouse'
      }
  }
```

the second example will return

```
{ "1:gray"    => {
      code    => 1,
      color   => 'gray',
      price   => 850,
      product => 'pc'
      },
  "2:white"   => {
      code    => 2,
      color   => 'white',
      price   => 12,
      product => 'keyboard'
      },
  "3:black"   => {
      code    => 3,
      color   => 'black',
      price   => 5,
      product => 'mouse'
      }
  }
```

The key attribute can be combined with `headers` for `CSV` date that has no header line, like

```
my $ref = csv (
    in      => "foo.csv",
    headers => [qw( c_foo foo bar description stock )],
    key     =>     "c_foo",
    );
```

value

Used to create key-value hashes.

Only allowed when `key` is valid. A `value` can be either a single column label or an anonymous list of column labels. In the first case, the value will be a simple scalar value,

in the latter case, it will be a hashref.

```
my $ref = csv (in => "test.csv", key   => "code",
                                 value => "price");
my $ref = csv (in => "test.csv", key   => "code",
                                 value => [ "product", "price" ]);
my $ref = csv (in => "test.csv", key   => [ ":" => "code", "color"
 ↪],
                                 value => "price");
my $ref = csv (in => "test.csv", key   => [ ":" => "code", "color"
 ↪],
                                 value => [ "product", "price" ]);
```

with test.csv like

```
code,product,price,color
1,pc,850,gray
2,keyboard,12,white
3,mouse,5,black
```

the first example will return

```
{ 1 => 850,
  2 =>  12,
  3 =>   5,
  }
```

the second example will return

```
{ 1   => {
      price   => 850,
      product => 'pc'
      },
  2   => {
      price   => 12,
      product => 'keyboard'
      },
  3   => {
      price   => 5,
      product => 'mouse'
      }
  }
```

the third example will return

```
{ "1:gray"    => 850,
  "2:white"   =>  12,
  "3:black"   =>   5,
  }
```

the fourth example will return

```
{ "1:gray"    => {
      price   => 850,
      product => 'pc'
      },
  "2:white"   => {
      price   => 12,
      product => 'keyboard'
      },
  "3:black"   => {
      price   => 5,
      product => 'mouse'
      }
  }
```

keep_headers

When using hashes, keep the column names into the arrayref passed, so all headers are available after the call in the original order.

```
my $aoh = csv (in => "file.csv", keep_headers => \my @hdr);
```

This attribute can be abbreviated to `kh` or passed as `keep_column_names`.

This attribute implies a default of `auto` for the `headers` attribute.

The headers can also be kept internally to keep stable header order:

```
csv (in      => csv (in => "file.csv", kh => "internal"),
     out     => "new.csv",
     kh      => "internal");
```

where `internal` can also be 1, `yes`, or `true`. This is similar to

```
my @h;
csv (in      => csv (in => "file.csv", kh => \@h),
     out     => "new.csv",
     headers => \@h);
```

fragment

Only output the fragment as defined in the "fragment" method. This option is ignored when *generating* CSV. See "out".

Combining all of them could give something like

```
use Text::CSV qw( csv );
my $aoh = csv (
    in       => "test.txt",
    encoding => "utf-8",
    headers  => "auto",
    sep_char => "|",
```

(continues on next page)

(continued from previous page)

```
    fragment => "row=3;6-9;15-*",
    );
say $aoh->[15]{Foo};
```

sep_set

If `sep_set` is set, the method "header" is invoked on the opened stream to detect and set `sep_char` with the given set.

`sep_set` can be abbreviated to `seps`. If neither `sep_set` not `seps` is given, but `sep` is defined, `sep_set` defaults to `[ sep ]`. This is only supported for perl version 5.10 and up.

Note that as the "header" method is invoked, its default is to also set the headers.

set_column_names

If `set_column_names` is passed, the method "header" is invoked on the opened stream with all arguments meant for "header".

If `set_column_names` is passed as a false value, the content of the first row is only preserved if the output is AoA:

With an input-file like

```
bAr,foo
1,2
3,4,5
```

This call

```
my $aoa = csv (in => $file, set_column_names => 0);
```

will result in

```
[[ "bar", "foo"     ],
 [ "1",   "2"       ],
 [ "3",   "4",  "5" ]]
```

and

```
my $aoa = csv (in => $file, set_column_names => 0, munge => "none");
```

will result in

```
[[ "bAr", "foo"     ],
 [ "1",   "2"       ],
 [ "3",   "4",  "5" ]]
```

csv

The *function* "csv" can also be called as a method or with an existing Text::CSV object. This could help if the function is to be invoked a lot of times and the overhead of creating the object internally over and over again would be prevented by passing an existing instance.

```
my $csv = Text::CSV->new ({ binary => 1, auto_diag => 1 });

my $aoa = $csv->csv (in => $fh);
my $aoa = csv (in => $fh, csv => $csv);
```

both act the same. Running this 20000 times on a 20 lines CSV file, showed a 53% speedup.

Callbacks

Callbacks enable actions triggered from the *inside* of Text::CSV.

While most of what this enables can easily be done in an unrolled loop as described in the "SYNOPSIS" callbacks can be used to meet special demands or enhance the "csv" function.

- error

  ```
  $csv->callbacks (error => sub { $csv->SetDiag (0) });
  ```

  the `error` callback is invoked when an error occurs, but *only* when "auto_diag" is set to a true value. A callback is invoked with the values returned by "error_diag":

  ```
  my ($c, $s);

  sub ignore3006 {
      my ($err, $msg, $pos, $recno, $fldno) = @_;
      if ($err == 3006) {
          # ignore this error
          ($c, $s) = (undef, undef);
          Text::CSV->SetDiag (0);
          }
      # Any other error
      return;
      } # ignore3006

  $csv->callbacks (error => \&ignore3006);
  $csv->bind_columns (\$c, \$s);
  while ($csv->getline ($fh)) {
      # Error 3006 will not stop the loop
      }
  ```

- after_parse

```
$csv->callbacks (after_parse => sub { push @{$_[1]}, "NEW" });
while (my $row = $csv->getline ($fh)) {
    $row->[-1] eq "NEW";
    }
```

This callback is invoked after parsing with "getline" only if no error occurred. The callback is invoked with two arguments: the current CSV parser object and an array reference to the fields parsed.

The return code of the callback is ignored unless it is a reference to the string "skip", in which case the record will be skipped in "getline_all".

```
sub add_from_db {
    my ($csv, $row) = @_;
    $sth->execute ($row->[4]);
    push @$row, $sth->fetchrow_array;
    } # add_from_db

my $aoa = csv (in => "file.csv", callbacks => {
    after_parse => \&add_from_db });
```

This hook can be used for validation:

- FAIL

  Die if any of the records does not validate a rule:

  ```
  after_parse => sub {
      $_[1][4] =~ m/^[0-9]{4}\s?[A-Z]{2}$/ or
          die "5th field does not have a valid Dutch zipcode";
      }
  ```

- DEFAULT

  Replace invalid fields with a default value:

  ```
  after_parse => sub { $_[1][2] =~ m/^\d+$/ or $_[1][2] = 0 }
  ```

- SKIP

  Skip records that have invalid fields (only applies to "getline_all"):

  ```
  after_parse => sub { $_[1][0] =~ m/^\d+$/ or return \"skip";
  ↪}
  ```

- before_print

```
my $idx = 1;
$csv->callbacks (before_print => sub { $_[1][0] = $idx++ });
$csv->print (*STDOUT, [ 0, $_ ]) for @members;
```

This callback is invoked before printing with "print" only if no error occurred. The callback is invoked with two arguments: the current CSV parser object and an array reference to the fields passed.

The return code of the callback is ignored.

```
sub max_4_fields {
    my ($csv, $row) = @_;
    @$row > 4 and splice @$row, 4;
    } # max_4_fields

csv (in => csv (in => "file.csv"), out => *STDOUT,
    callbacks => { before_print => \&max_4_fields });
```

This callback is not active for “combine”.

Callbacks for csv ()

```
csv (in        => "file.csv",
     callbacks => {
         filter       => { 6 => sub { $_ > 15 } },    # first
         after_parse  => sub { say "AFTER PARSE";  }, # first
         after_in     => sub { say "AFTER IN";     }, # second
         on_in        => sub { say "ON IN";        }, # third
         },
     );

csv (in        => $aoh,
     out       => "file.csv",
     callbacks => {
         on_in        => sub { say "ON IN";        }, # first
         before_out   => sub { say "BEFORE OUT";   }, # second
         before_print => sub { say "BEFORE PRINT"; }, # third
         },
     );
```

- filter

  This callback can be used to filter records. It is called just after a new record has been scanned. The callback accepts a:

  - hashref

    The keys are the index to the row (the field name or field number, 1-based) and the values are subs to return a true or false value.

    ```
    csv (in => "file.csv", filter => {
              3 => sub { m/a/ },       # third field should␣
    ↪contain an "a"
              5 => sub { length > 4 }, # length of the 5th␣
    ↪field minimal 5
              });

    csv (in => "file.csv", filter => { foo => sub { $_ > 4 }});
    ```

    If the keys to the filter hash contain any character that is not a digit it will also implicitly set “headers” to `"auto"` unless “headers” was already passed

as argument. When headers are active, returning an array of hashes, the filter is not applicable to the header itself.

All sub results should match, as in AND.

The context of the callback sets $_ localized to the field indicated by the filter. The two arguments are as with all other callbacks, so the other fields in the current row can be seen:

```
filter => { 3 => sub { $_ > 100 ? $_[1][1] =~ m/A/ : $_
↪[1][6] =~ m/B/ }}
```

If the context is set to return a list of hashes ("headers" is defined), the current record will also be available in the localized %_:

```
filter => { 3 => sub { $_ > 100 && $_{foo} =~ m/A/ && $_{bar}
↪ < 1000  }}
```

If the filter is used to *alter* the content by changing $_, make sure that the sub returns true in order not to have that record skipped:

```
filter => { 2 => sub { $_ = uc }}
```

will upper-case the second field, and then skip it if the resulting content evaluates to false. To always accept, end with truth:

```
filter => { 2 => sub { $_ = uc; 1 }}
```

– coderef

```
csv (in => "file.csv", filter => sub { $n++; 0; });
```

If the argument to `filter` is a coderef, it is an alias or shortcut to a filter on column 0:

```
csv (filter => sub { $n++; 0 });
```

is equal to

```
csv (filter => { 0 => sub { $n++; 0 });
```

– filter-name

```
csv (in => "file.csv", filter => "not_blank");
csv (in => "file.csv", filter => "not_empty");
csv (in => "file.csv", filter => "filled");
```

These are predefined filters

Given a file like (line numbers prefixed for doc purpose only):

```
1:1,2,3
2:
3:,
```

(continues on next page)

(continued from previous page)

```
4:""
5:,,
6:, ,
7:"",
8:" "
9:4,5,6
```

* not_blank

  Filter out the blank lines

  This filter is a shortcut for

  ```
  filter => { 0 => sub { @{$_[1]} > 1 or
              defined $_[1][0] && $_[1][0] ne "" } }
  ```

  Due to the implementation, it is currently impossible to also filter lines that consists only of a quoted empty field. These lines are also considered blank lines.

  With the given example, lines 2 and 4 will be skipped.

* not_empty

  Filter out lines where all the fields are empty.

  This filter is a shortcut for

  ```
  filter => { 0 => sub { grep { defined && $_ ne "" } @{$_
  ↪[1]} } }
  ```

  A space is not regarded being empty, so given the example data, lines 2, 3, 4, 5, and 7 are skipped.

* filled

  Filter out lines that have no visible data

  This filter is a shortcut for

  ```
  filter => { 0 => sub { grep { defined && m/\S/ } @{$_[1]}␣
  ↪} }
  ```

  This filter rejects all lines that *not* have at least one field that does not evaluate to the empty string.

  With the given example data, this filter would skip lines 2 through 8.

One could also use modules like Types::Standard:

```
use Types::Standard -types;

my $type   = Tuple[Str, Str, Int, Bool, Optional[Num]];
my $check  = $type->compiled_check;

# filter with compiled check and warnings
```

(continues on next page)

(continued from previous page)

```
my $aoa = csv (
   in     => \$data,
   filter => {
       0 => sub {
           my $ok = $check->($_[1]) or
               warn $type->get_message ($_[1]), "\n";
           return $ok;
           },
       },
   );
```

- after_in

  This callback is invoked for each record after all records have been parsed but before returning the reference to the caller. The hook is invoked with two arguments: the current CSV parser object and a reference to the record. The reference can be a reference to a HASH or a reference to an ARRAY as determined by the arguments.

  This callback can also be passed as an attribute without the `callbacks` wrapper.

- before_out

  This callback is invoked for each record before the record is printed. The hook is invoked with two arguments: the current CSV parser object and a reference to the record. The reference can be a reference to a HASH or a reference to an ARRAY as determined by the arguments.

  This callback can also be passed as an attribute without the `callbacks` wrapper.

  This callback makes the row available in %_ if the row is a hashref. In this case %_ is writable and will change the original row.

- on_in

  This callback acts exactly as the "after_in" or the "before_out" hooks.

  This callback can also be passed as an attribute without the `callbacks` wrapper.

  This callback makes the row available in %_ if the row is a hashref. In this case %_ is writable and will change the original row. So e.g. with

```
my $aoh = csv (
    in      => \"foo\n1\n2\n",
    headers => "auto",
    on_in   => sub { $_{bar} = 2; },
    );
```

  $aoh will be:

```
[ { foo => 1,
    bar => 2,
    }
  { foo => 2,
    bar => 2,
```

(continues on next page)

(continued from previous page)

```
    }
  ]
```

- on_error

  This callback acts exactly as the “error” hook.

```
my @err;
my $aoa = csv (in => $fh, on_error => sub { @err = @_ });
```

  is identical to

```
my $aoa = csv (in => $fh, callbacks => {
    error => sub { @err = @_ },
    });
```

  It can be used for ignoring errors as well as for just keeping the error in case of analysis after the `csv ()` function has returned.

```
my @err;
my $aoa = csv (in => "bad.csv, on_error => sub { @err = @_ });
die Text::CSV->error_diag if @err or !$aoa;
```

DIAGNOSTICS

This section is also taken from Text::CSV_XS.

Still under construction ...

If an error occurs, `$csv->error_diag` can be used to get information on the cause of the failure. Note that for speed reasons the internal value is never cleared on success, so using the value returned by “error_diag” in normal cases - when no error occurred - may cause unexpected results.

If the constructor failed, the cause can be found using “error_diag” as a class method, like `Text::CSV->error_diag`.

The `$csv->error_diag` method is automatically invoked upon error when the contractor was called with `auto_diag` set to 1 or 2, or when *autodie* is in effect. When set to 1, this will cause a `warn` with the error message, when set to 2, it will `die`. `2012 - EOF` is excluded from `auto_diag` reports.

Errors can be (individually) caught using the “error” callback.

The errors as described below are available. I have tried to make the error itself explanatory enough, but more descriptions will be added. For most of these errors, the first three capitals describe the error category:

- INI

  Initialization error or option conflict.

- ECR

  Carriage-Return related parse error.

- EOF

  End-Of-File related parse error.

- EIQ

  Parse error inside quotation.

- EIF

  Parse error inside field.

- ECB

  Combine error.

- EHR

  HashRef parse related error.

And below should be the complete list of error codes that can be returned:

- 1001 “INI - sep_char is equal to quote_char or escape_char”

  The separation character cannot be equal to the quotation character or to the escape character, as this would invalidate all parsing rules.

- 1002 “INI - allow_whitespace with escape_char or quote_char SP or TAB”

  Using the `allow_whitespace` attribute when either `quote_char` or `escape_char` is equal to `SPACE` or `TAB` is too ambiguous to allow.

- 1003 “INI - \r or \n in main attr not allowed”

  Using default `eol` characters in either `sep_char`, `quote_char`, or `escape_char` is not allowed.

- 1004 “INI - callbacks should be undef or a hashref”

  The `callbacks` attribute only allows one to be `undef` or a hash reference.

- 1005 “INI - EOL too long”

  The value passed for EOL is exceeding its maximum length (16).

- 1006 “INI - SEP too long”

  The value passed for SEP is exceeding its maximum length (16).

- 1007 “INI - QUOTE too long”

  The value passed for QUOTE is exceeding its maximum length (16).

- 1008 “INI - SEP undefined”

  The value passed for SEP should be defined and not empty.

- 1010 “INI - the header is empty”

  The header line parsed in the “header” is empty.

- 1011 “INI - the header contains more than one valid separator”

  The header line parsed in the “header” contains more than one (unique) separator character out of the allowed set of separators.

- 1012 “INI - the header contains an empty field”

  The header line parsed in the “header” contains an empty field.

- 1013 “INI - the header contains nun-unique fields”

  The header line parsed in the “header” contains at least two identical fields.

- 1014 “INI - header called on undefined stream”

  The header line cannot be parsed from an undefined source.

- 1500 “PRM - Invalid/unsupported argument(s)”

  Function or method called with invalid argument(s) or parameter(s).

- 1501 “PRM - The key attribute is passed as an unsupported type”

  The `key` attribute is of an unsupported type.

- 1502 “PRM - The value attribute is passed without the key attribute”

  The `value` attribute is only allowed when a valid key is given.

- 1503 “PRM - The value attribute is passed as an unsupported type”

  The `value` attribute is of an unsupported type.

- 2010 “ECR - QUO char inside quotes followed by CR not part of EOL”

  When `eol` has been set to anything but the default, like `"\r\t\n"`, and the `"\r"` is following the **second** (closing) `quote_char`, where the characters following the `"\r"` do not make up the `eol` sequence, this is an error.

- 2011 “ECR - Characters after end of quoted field”

  Sequences like `1,foo,"bar"baz,22,1` are not allowed. `"bar"` is a quoted field and after the closing double-quote, there should be either a new-line sequence or a separation character.

- 2012 “EOF - End of data in parsing input stream”

  Self-explaining. End-of-file while inside parsing a stream. Can happen only when reading from streams with “getline”, as using “parse” is done on strings that are not required to have a trailing `eol`.

- 2013 “INI - Specification error for fragments RFC7111”

  Invalid specification for URI “fragment” specification.

- 2014 “ENF - Inconsistent number of fields”

  Inconsistent number of fields under strict parsing.

- 2015 “ERW - Empty row”

  An empty row was not allowed.

- 2016 “EOL - Inconsistent EOL”

  Inconsistent End-Of-Line detected under strict_eol parsing.

- 2021 “EIQ - NL char inside quotes, binary off”

  Sequences like `1,"foo\nbar",22,1` are allowed only when the binary option has been selected with the constructor.

- 2022 “EIQ - CR char inside quotes, binary off”

  Sequences like `1,"foo\rbar",22,1` are allowed only when the binary option has been selected with the constructor.

- 2023 “EIQ - QUO character not allowed”

  Sequences like `"foo "bar" baz",qu` and `2023,",2008-04-05,"Foo, Bar",\n` will cause this error.

- 2024 “EIQ - EOF cannot be escaped, not even inside quotes”

  The escape character is not allowed as last character in an input stream.

- 2025 “EIQ - Loose unescaped escape”

  An escape character should escape only characters that need escaping.

  Allowing the escape for other characters is possible with the attribute “allow_loose_escapes”.

- 2026 “EIQ - Binary character inside quoted field, binary off”

  Binary characters are not allowed by default. Exceptions are fields that contain valid UTF-8, that will automatically be upgraded if the content is valid UTF-8. Set `binary` to 1 to accept binary data.

- 2027 “EIQ - Quoted field not terminated”

  When parsing a field that started with a quotation character, the field is expected to be closed with a quotation character. When the parsed line is exhausted before the quote is found, that field is not terminated.

- 2030 “EIF - NL char inside unquoted verbatim, binary off”
- 2031 “EIF - CR char is first char of field, not part of EOL”
- 2032 “EIF - CR char inside unquoted, not part of EOL”
- 2034 “EIF - Loose unescaped quote”
- 2035 “EIF - Escaped EOF in unquoted field”
- 2036 “EIF - ESC error”
- 2037 “EIF - Binary character in unquoted field, binary off”
- 2110 “ECB - Binary character in Combine, binary off”
- 2200 “EIO - print to IO failed. See errno”
- 3001 “EHR - Unsupported syntax for column_names ()”
- 3002 “EHR - getline_hr () called before column_names ()”
- 3003 “EHR - bind_columns () and column_names () fields count mismatch”
- 3004 “EHR - bind_columns () only accepts refs to scalars”
- 3006 “EHR - bind_columns () did not pass enough refs for parsed fields”
- 3007 “EHR - bind_columns needs refs to writable scalars”
- 3008 “EHR - unexpected error in bound fields”
- 3009 “EHR - print_hr () called before column_names ()”

- 3010 “EHR - print_hr () called with invalid arguments”

AUTHORS and MAINTAINERS

Alan Citterman <alan[at]mfgrtl.com> wrote the original Perl module. Please don’t send mail concerning Text::CSV to Alan, as he’s not a present maintainer.

Jochen Wiedmann <joe[at]ispsoft.de> rewrote the encoding and decoding in C by implementing a simple finite-state machine and added the variable quote, escape and separator characters, the binary mode and the print and getline methods. See ChangeLog releases 0.10 through 0.23.

H.Merijn Brand <h.m.brand[at]xs4all.nl> cleaned up the code, added the field flags methods, wrote the major part of the test suite, completed the documentation, fixed some RT bugs. See ChangeLog releases 0.25 and on.

Makamaka Hannyaharamitu, <makamaka[at]cpan.org> wrote Text::CSV_PP which is the pure-Perl version of Text::CSV_XS.

New Text::CSV (since 0.99) is maintained by Makamaka, and Kenichi Ishigaki since 1.91.

Text::CSV_PP

Text::CSV_XS compatible pure-Perl module

SYNOPSIS

This section is taken from Text::CSV_XS.

```
# Functional interface
use Text::CSV_PP qw( csv );

# Read whole file in memory
my $aoa = csv (in => "data.csv");    # as array of array
my $aoh = csv (in => "data.csv",
               headers => "auto");   # as array of hash

# Write array of arrays as csv file
csv (in => $aoa, out => "file.csv", sep_char => ";");

# Only show lines where "code" is odd
csv (in => "data.csv", filter => { code => sub { $_ % 2 }});

# Object interface
use Text::CSV_PP;

my @rows;
# Read/parse CSV
my $csv = Text::CSV_PP->new ({ binary => 1, auto_diag => 1 });
open my $fh, "<:encoding(utf8)", "test.csv" or die "test.csv: $!";
while (my $row = $csv->getline ($fh)) {
    $row->[2] =~ m/pattern/ or next; # 3rd field should match
    push @rows, $row;
    }
close $fh;

# and write as CSV
open $fh, ">:encoding(utf8)", "new.csv" or die "new.csv: $!";
$csv->say ($fh, $_) for @rows;
close $fh or die "new.csv: $!";
```

DESCRIPTION

Text::CSV_PP is a pure-perl module that provides facilities for the composition and decomposition of comma-separated values. This is (almost) compatible with much faster Text::CSV_XS, and mainly used as its fallback module when you use *Text::CSV* module without having installed Text::CSV_XS. If you don't have any reason to use this module directly, use Text::CSV for speed boost and portability (or maybe Text::CSV_XS when you write an one-off script and don't need to care about portability).

The following caveats are taken from the doc of Text::CSV_XS.

Embedded newlines

Important Note: The default behavior is to accept only ASCII characters in the range from `0x20` (space) to `0x7E` (tilde). This means that the fields can not contain newlines. If your data contains newlines embedded in fields, or characters above `0x7E` (tilde), or binary data, you ***must*** set `binary => 1` in the call to "new". To cover the widest range of parsing options, you will always want to set binary.

But you still have the problem that you have to pass a correct line to the "parse" method, which is more complicated from the usual point of usage:

```
my $csv = Text::CSV_PP->new ({ binary => 1, eol => $/ });
while (<>) {            #  WRONG!
    $csv->parse ($_);
    my @fields = $csv->fields ();
    }
```

this will break, as the `while` might read broken lines: it does not care about the quoting. If you need to support embedded newlines, the way to go is to **not** pass `eol` in the parser (it accepts `\n`, `\r`, **and** `\r\n` by default) and then

```
my $csv = Text::CSV_PP->new ({ binary => 1 });
open my $fh, "<", $file or die "$file: $!";
while (my $row = $csv->getline ($fh)) {
    my @fields = @$row;
    }
```

The old(er) way of using global file handles is still supported

```
while (my $row = $csv->getline (*ARGV)) { ... }
```

Unicode

Unicode is only tested to work with perl-5.8.2 and up.

See also "BOM".

The simplest way to ensure the correct encoding is used for in- and output is by either setting layers on the filehandles, or setting the "encoding" argument for "csv".

```
 open my $fh, "<:encoding(UTF-8)", "in.csv"  or die "in.csv: $!";
or
 my $aoa = csv (in => "in.csv",     encoding => "UTF-8");

 open my $fh, ">:encoding(UTF-8)", "out.csv" or die "out.csv: $!";
or
 csv (in => $aoa, out => "out.csv", encoding => "UTF-8");
```

On parsing (both for "getline" and "parse"), if the source is marked being UTF8, then all fields that are marked binary will also be marked UTF8.

On combining ("print" and "combine"): if any of the combining fields was marked UTF8, the resulting string will be marked as UTF8. Note however that all fields *before* the first field marked UTF8 and contained 8-bit characters that were not upgraded to UTF8, these

will be `bytes` in the resulting string too, possibly causing unexpected errors. If you pass data of different encoding, or you don't know if there is different encoding, force it to be upgraded before you pass them on:

```
$csv->print ($fh, [ map { utf8::upgrade (my $x = $_); $x } @data ]);
```

For complete control over encoding, please use Text::CSV::Encoded:

```
use Text::CSV::Encoded;
my $csv = Text::CSV::Encoded->new ({
    encoding_in  => "iso-8859-1", # the encoding comes into   Perl
    encoding_out => "cp1252",     # the encoding comes out of Perl
    });

$csv = Text::CSV::Encoded->new ({ encoding  => "utf8" });
# combine () and print () accept *literally* utf8 encoded data
# parse () and getline () return *literally* utf8 encoded data

$csv = Text::CSV::Encoded->new ({ encoding  => undef }); # default
# combine () and print () accept UTF8 marked data
# parse () and getline () return UTF8 marked data
```

BOM

BOM (or Byte Order Mark) handling is available only inside the "header" method. This method supports the following encodings: `utf-8`, `utf-1`, `utf-32be`, `utf-32le`, `utf-16be`, `utf-16le`, `utf-ebcdic`, `scsu`, `bocu-1`, and `gb-18030`. See Wikipedia.

If a file has a BOM, the easiest way to deal with that is

```
my $aoh = csv (in => $file, detect_bom => 1);
```

All records will be encoded based on the detected BOM.

This implies a call to the "header" method, which defaults to also set the "column_names". So this is **not** the same as

```
my $aoh = csv (in => $file, headers => "auto");
```

which only reads the first record to set "column_names" but ignores any meaning of possible present BOM.

METHODS

This section is also taken from Text::CSV_XS.

version

(Class method) Returns the current module version.

new

(Class method) Returns a new instance of class Text::CSV_PP. The attributes are described by the (optional) hash ref `\%attr`.

```
my $csv = Text::CSV_PP->new ({ attributes ... });
```

The following attributes are available:

eol

```
my $csv = Text::CSV_PP->new ({ eol => $/ });
          $csv->eol (undef);
my $eol = $csv->eol;
```

The end-of-line string to add to rows for "print" or the record separator for "getline".

When not passed in a **parser** instance, the default behavior is to accept `\n`, `\r`, and `\r\n`, so it is probably safer to not specify `eol` at all. Passing `undef` or the empty string behave the same.

When not passed in a **generating** instance, records are not terminated at all, so it is probably wise to pass something you expect. A safe choice for `eol` on output is either `$/` or `\r\n`.

Common values for `eol` are `"\012"` (`\n` or Line Feed), `"\015\012"` (`\r\n` or Carriage Return, Line Feed), and `"\015"` (`\r` or Carriage Return). The `eol` attribute cannot exceed 7 (ASCII) characters.

If both `$/` and `eol` equal `"\015"`, parsing lines that end on only a Carriage Return without Line Feed, will be "parse"d correct.

eol_type

```
my $eol = $csv->eol_type;
```

This read-only method returns the internal state of what is considered the valid EOL for parsing.

sep_char

```
my $csv = Text::CSV_PP->new ({ sep_char => ";" });
          $csv->sep_char (";");
my $c = $csv->sep_char;
```

The char used to separate fields, by default a comma. (`,`). Limited to a single-byte character, usually in the range from `0x20` (space) to `0x7E` (tilde). When longer sequences are required, use `sep`.

The separation character can not be equal to the quote character or to the escape character.

sep

```
my $csv = Text::CSV_PP->new ({ sep => "\N{FULLWIDTH COMMA}" });
          $csv->sep (";");
my $sep = $csv->sep;
```

The chars used to separate fields, by default undefined. Limited to 8 bytes.

When set, overrules `sep_char`. If its length is one byte it acts as an alias to `sep_char`.

quote_char

```
my $csv = Text::CSV_PP->new ({ quote_char => "'" });
        $csv->quote_char (undef);
my $c = $csv->quote_char;
```

The character to quote fields containing blanks or binary data, by default the double quote character (`"`). A value of undef suppresses quote chars (for simple cases only). Limited to a single-byte character, usually in the range from `0x20` (space) to `0x7E` (tilde). When longer sequences are required, use `quote`.

`quote_char` can not be equal to `sep_char`.

quote

```
my $csv = Text::CSV_PP->new ({ quote => "\N{FULLWIDTH QUOTATION␣
↪MARK}" });
            $csv->quote ("'");
my $quote = $csv->quote;
```

The chars used to quote fields, by default undefined. Limited to 8 bytes.

When set, overrules `quote_char`. If its length is one byte it acts as an alias to `quote_char`.

This method does not support `undef`. Use `quote_char` to disable quotation.

escape_char

```
my $csv = Text::CSV_PP->new ({ escape_char => "\\" });
        $csv->escape_char (":");
my $c = $csv->escape_char;
```

The character to escape certain characters inside quoted fields. This is limited to a single-byte character, usually in the range from `0x20` (space) to `0x7E` (tilde).

The `escape_char` defaults to being the double-quote mark (`"`). In other words the same as the default `quote_char`. This means that doubling the quote mark in a field escapes it:

```
"foo","bar","Escape ""quote mark"" with two ""quote marks""","baz"
```

If you change the quote_char without changing the escape_char, the escape_char will still be the double-quote ("). If instead you want to escape the quote_char by doubling it you will need to also change the escape_char to be the same as what you have changed the quote_char to.

Setting escape_char to undef or "" will completely disable escapes and is greatly discouraged. This will also disable escape_null.

The escape character can not be equal to the separation character.

binary

```
my $csv = Text::CSV_PP->new ({ binary => 1 });
        $csv->binary (0);
my $f = $csv->binary;
```

If this attribute is 1, you may use binary characters in quoted fields, including line feeds, carriage returns and NULL bytes. (The latter could be escaped as "0".) By default this feature is off.

If a string is marked UTF8, binary will be turned on automatically when binary characters other than CR and NL are encountered. Note that a simple string like "\x{00a0}" might still be binary, but not marked UTF8, so setting { binary => 1 } is still a wise option.

strict

```
my $csv = Text::CSV_PP->new ({ strict => 1 });
        $csv->strict (0);
my $f = $csv->strict;
```

If this attribute is set to 1, any row that parses to a different number of fields than the previous row will cause the parser to throw error 2014.

Empty rows or rows that result in no fields (like comment lines) are exempt from these checks.

strict_eol

```
my $csv = Text::CSV_PP->new ({ strict_eol => 1 });
        $csv->strict_eol (0);
my $f = $csv->strict_eol;
```

If this attribute is set to 0, no EOL consistency checks are done.

If this attribute is set to 1, any row that parses with a EOL other than the EOL from the first row will cause a warning. The error will be ignored and parsing continues. This warning is only thrown once. Note that in data with various different line endings, \r\r will still throw an error that cannot be ignored.

If this attribute is set to 2 or higher, any row that parses with a EOL other than the EOL from the first row will cause error 2016 to be thrown. The line being parsed to this error might not be stored in the result.

skip_empty_rows

```
my $csv = Text::CSV_PP->new ({ skip_empty_rows => 1 });
        $csv->skip_empty_rows ("eof");
my $f = $csv->skip_empty_rows;
```

This attribute defines the behavior for empty rows: an “eol” immediately following the start of line. Default behavior is to return one single empty field.

This attribute is only used in parsing. This attribute is ineffective when using “parse” and “fields”.

Possible values for this attribute are

- 0 | undef

  ```
  my $csv = Text::CSV_PP->new ({ skip_empty_rows => 0 });
  $csv->skip_empty_rows (undef);
  ```

  No special action is taken. The result will be one single empty field.

- 1 | “skip”

  ```
  my $csv = Text::CSV_PP->new ({ skip_empty_rows => 1 });
  $csv->skip_empty_rows ("skip");
  ```

  The row will be skipped.

- 2 | “eof” | “stop”

  ```
  my $csv = Text::CSV_PP->new ({ skip_empty_rows => 2 });
  $csv->skip_empty_rows ("eof");
  ```

  The parsing will stop as if an “eof” was detected.

- 3 | “die”

  ```
  my $csv = Text::CSV_PP->new ({ skip_empty_rows => 3 });
  $csv->skip_empty_rows ("die");
  ```

  The parsing will stop. The internal error code will be set to 2015 and the parser will `die`.

- 4 | “croak”

  ```
  my $csv = Text::CSV_PP->new ({ skip_empty_rows => 4 });
  $csv->skip_empty_rows ("croak");
  ```

  The parsing will stop. The internal error code will be set to 2015 and the parser will `croak`.

- 5 | “error”

  ```
  my $csv = Text::CSV_PP->new ({ skip_empty_rows => 5 });
  $csv->skip_empty_rows ("error");
  ```

  The parsing will fail. The internal error code will be set to 2015.

- callback

```
my $csv = Text::CSV_PP->new ({ skip_empty_rows => sub { [] } });
$csv->skip_empty_rows (sub { [ 42, $., undef, "empty" ] });
```

The callback is invoked and its result used instead. If you want the parse to stop after the callback, make sure to return a false value.

The returned value from the callback should be an array-ref. Any other type will cause the parse to stop, so these are equivalent in behavior:

```
csv (in => $fh, skip_empty_rows => "stop");
csv (in => $fh. skip_empty_rows => sub { 0; });
```

Without arguments, the current value is returned: `0`, `1`, `eof`, `die`, `croak` or the callback.

formula_handling

Alias for “formula”

formula

```
my $csv = Text::CSV_PP->new ({ formula => "none" });
        $csv->formula ("none");
my $f = $csv->formula;
```

This defines the behavior of fields containing *formulas*. As formulas are considered dangerous in spreadsheets, this attribute can define an optional action to be taken if a field starts with an equal sign (=).

For purpose of code-readability, this can also be written as

```
my $csv = Text::CSV_PP->new ({ formula_handling => "none" });
        $csv->formula_handling ("none");
my $f = $csv->formula_handling;
```

Possible values for this attribute are

- none

  Take no specific action. This is the default.

  ```
  $csv->formula ("none");
  ```

- die

  Cause the process to `die` whenever a leading = is encountered.

  ```
  $csv->formula ("die");
  ```

- croak

  Cause the process to `croak` whenever a leading = is encountered. (See *Carp*)

```
$csv->formula ("croak");
```

- diag

  Report position and content of the field whenever a leading = is found. The value of the field is unchanged.

```
$csv->formula ("diag");
```

- empty

  Replace the content of fields that start with a = with the empty string.

```
$csv->formula ("empty");
$csv->formula ("");
```

- undef

  Replace the content of fields that start with a = with `undef`.

```
$csv->formula ("undef");
$csv->formula (undef);
```

- a callback

  Modify the content of fields that start with a = with the return-value of the callback. The original content of the field is available inside the callback as `$_`;

```
# Replace all formula's with 42
$csv->formula (sub { 42; });

# same as $csv->formula ("empty") but slower
$csv->formula (sub { "" });

# Allow =4+12
$csv->formula (sub { s/^=(\d+\+\d+)$/$1/eer });

# Allow more complex calculations
$csv->formula (sub { eval { s{^=([-+*/0-9()]+)$}{$1}ee }; $_ });
```

All other values will give a warning and then fallback to `diag`.

decode_utf8

```
my $csv = Text::CSV_PP->new ({ decode_utf8 => 1 });
        $csv->decode_utf8 (0);
my $f = $csv->decode_utf8;
```

This attributes defaults to TRUE.

While *parsing*, fields that are valid UTF-8, are automatically set to be UTF-8, so that

```
$csv->parse ("\xC4\xA8\n");
```

results in

```
PV("\304\250"\0) [UTF8 "\x{128}"]
```

Sometimes it might not be a desired action. To prevent those upgrades, set this attribute to false, and the result will be

```
PV("\304\250"\0)
```

auto_diag

```
my $csv = Text::CSV_PP->new ({ auto_diag => 1 });
        $csv->auto_diag (2);
my $l = $csv->auto_diag;
```

Set this attribute to a number between 1 and 9 causes "error_diag" to be automatically called in void context upon errors.

In case of error `2012 - EOF`, this call will be void.

If `auto_diag` is set to a numeric value greater than 1, it will `die` on errors instead of `warn`. If set to anything unrecognized, it will be silently ignored.

Future extensions to this feature will include more reliable auto-detection of `autodie` being active in the scope of which the error occurred which will increment the value of `auto_diag` with 1 the moment the error is detected.

diag_verbose

```
my $csv = Text::CSV_PP->new ({ diag_verbose => 1 });
        $csv->diag_verbose (2);
my $l = $csv->diag_verbose;
```

Set the verbosity of the output triggered by `auto_diag`. Currently only adds the current input-record-number (if known) to the diagnostic output with an indication of the position of the error.

blank_is_undef

```
my $csv = Text::CSV_PP->new ({ blank_is_undef => 1 });
        $csv->blank_is_undef (0);
my $f = $csv->blank_is_undef;
```

Under normal circumstances, `CSV` data makes no distinction between quoted- and unquoted empty fields. These both end up in an empty string field once read, thus

```
1,"",," ",2
```

is read as

```
("1", "", "", " ", "2")
```

When *writing* CSV files with either always_quote or quote_empty set, the unquoted *empty* field is the result of an undefined value. To enable this distinction when *reading* CSV data, the blank_is_undef attribute will cause unquoted empty fields to be set to undef, causing the above to be parsed as

```
("1", "", undef, " ", "2")
```

Note that this is specifically important when loading CSV fields into a database that allows NULL values, as the perl equivalent for NULL is undef in *DBI* land.

empty_is_undef

```
my $csv = Text::CSV_PP->new ({ empty_is_undef => 1 });
        $csv->empty_is_undef (0);
my $f = $csv->empty_is_undef;
```

Going one step further than blank_is_undef, this attribute converts all empty fields to undef, so

```
1,"",," ",2
```

is read as

```
(1, undef, undef, " ", 2)
```

Note that this affects only fields that are originally empty, not fields that are empty after stripping allowed whitespace. YMMV.

allow_whitespace

```
my $csv = Text::CSV_PP->new ({ allow_whitespace => 1 });
        $csv->allow_whitespace (0);
my $f = $csv->allow_whitespace;
```

When this option is set to true, the whitespace (TAB's and SPACE's) surrounding the separation character is removed when parsing. If either TAB or SPACE is one of the three characters sep_char, quote_char, or escape_char it will not be considered whitespace.

Now lines like:

```
1 , "foo" , bar , 3 , zapp
```

are parsed as valid CSV, even though it violates the CSV specs.

Note that **all** whitespace is stripped from both start and end of each field. That would make it *more* than a *feature* to enable parsing bad CSV lines, as

```
1,   2.0,  3,   ape  , monkey
```

will now be parsed as

```
("1", "2.0", "3", "ape", "monkey")
```

even if the original line was perfectly acceptable CSV.

allow_loose_quotes

```
my $csv = Text::CSV_PP->new ({ allow_loose_quotes => 1 });
        $csv->allow_loose_quotes (0);
my $f = $csv->allow_loose_quotes;
```

By default, parsing unquoted fields containing quote_char characters like

```
1,foo "bar" baz,42
```

would result in parse error 2034. Though it is still bad practice to allow this format, we cannot help the fact that some vendors make their applications spit out lines styled this way.

If there is **really** bad CSV data, like

```
1,"foo "bar" baz",42
```

or

```
1,""foo bar baz"",42
```

there is a way to get this data-line parsed and leave the quotes inside the quoted field as-is. This can be achieved by setting allow_loose_quotes **AND** making sure that the escape_char is *not* equal to quote_char.

allow_loose_escapes

```
my $csv = Text::CSV_PP->new ({ allow_loose_escapes => 1 });
        $csv->allow_loose_escapes (0);
my $f = $csv->allow_loose_escapes;
```

Parsing fields that have escape_char characters that escape characters that do not need to be escaped, like:

```
my $csv = Text::CSV_PP->new ({ escape_char => "\\" });
$csv->parse (qq{1,"my bar\'s",baz,42});
```

would result in parse error 2025. Though it is bad practice to allow this format, this attribute enables you to treat all escape character sequences equal.

allow_unquoted_escape

```
my $csv = Text::CSV_PP->new ({ allow_unquoted_escape => 1 });
        $csv->allow_unquoted_escape (0);
my $f = $csv->allow_unquoted_escape;
```

A backward compatibility issue where `escape_char` differs from `quote_char` prevents `escape_char` to be in the first position of a field. If `quote_char` is equal to the default `"` and `escape_char` is set to `\`, this would be illegal:

```
1,\0,2
```

Setting this attribute to 1 might help to overcome issues with backward compatibility and allow this style.

always_quote

```
my $csv = Text::CSV_PP->new ({ always_quote => 1 });
          $csv->always_quote (0);
my $f = $csv->always_quote;
```

By default the generated fields are quoted only if they *need* to be. For example, if they contain the separator character. If you set this attribute to 1 then *all* defined fields will be quoted. (`undef` fields are not quoted, see "blank_is_undef"). This makes it quite often easier to handle exported data in external applications.

quote_space

```
my $csv = Text::CSV_PP->new ({ quote_space => 1 });
          $csv->quote_space (0);
my $f = $csv->quote_space;
```

By default, a space in a field would trigger quotation. As no rule exists this to be forced in CSV, nor any for the opposite, the default is true for safety. You can exclude the space from this trigger by setting this attribute to 0.

quote_empty

```
my $csv = Text::CSV_PP->new ({ quote_empty => 1 });
          $csv->quote_empty (0);
my $f = $csv->quote_empty;
```

By default the generated fields are quoted only if they *need* to be. An empty (defined) field does not need quotation. If you set this attribute to 1 then *empty* defined fields will be quoted. (`undef` fields are not quoted, see "blank_is_undef"). See also `always_quote`.

quote_binary

```
my $csv = Text::CSV_PP->new ({ quote_binary => 1 });
          $csv->quote_binary (0);
my $f = $csv->quote_binary;
```

By default, all "unsafe" bytes inside a string cause the combined field to be quoted. By setting this attribute to `0`, you can disable that trigger for bytes `>= 0x7F`.

escape_null

```
my $csv = Text::CSV_PP->new ({ escape_null => 1 });
        $csv->escape_null (0);
my $f = $csv->escape_null;
```

By default, a NULL byte in a field would be escaped. This option enables you to treat the NULL byte as a simple binary character in binary mode (the `{ binary => 1 }` is set). The default is true. You can prevent NULL escapes by setting this attribute to 0.

When the escape_char attribute is set to undefined, this attribute will be set to false.

The default setting will encode "=\x00=" as

```
"="0="
```

With escape_null set, this will result in

```
"=\x00="
```

The default when using the csv function is false.

For backward compatibility reasons, the deprecated old name quote_null is still recognized.

keep_meta_info

```
my $csv = Text::CSV_PP->new ({ keep_meta_info => 1 });
        $csv->keep_meta_info (0);
my $f = $csv->keep_meta_info;
```

By default, the parsing of input records is as simple and fast as possible. However, some parsing information - like quotation of the original field - is lost in that process. Setting this flag to true enables retrieving that information after parsing with the methods "meta_info", "is_quoted", and "is_binary" described below. Default is false for performance.

If you set this attribute to a value greater than 9, then you can control output quotation style like it was used in the input of the the last parsed record (unless quotation was added because of other reasons).

```
my $csv = Text::CSV_PP->new ({
   binary         => 1,
   keep_meta_info => 1,
   quote_space    => 0,
   });

my $row = $csv->parse (q{1,,"", ," ",f,"g","h""h",help,"help"});

$csv->print (*STDOUT, \@row);
# 1,,, , ,f,g,"h""h",help,help
$csv->keep_meta_info (11);
```

(continues on next page)

(continued from previous page)

```
$csv->print (*STDOUT, \@row);
# 1,,"", ," ",f,"g","h""h",help,"help"
```

undef_str

```
my $csv = Text::CSV_PP->new ({ undef_str => "\\N" });
        $csv->undef_str (undef);
my $s = $csv->undef_str;
```

This attribute optionally defines the output of undefined fields. The value passed is not changed at all, so if it needs quotation, the quotation needs to be included in the value of the attribute. Use with caution, as passing a value like " , " , , , , """ will for sure mess up your output. The default for this attribute is `undef`, meaning no special treatment.

This attribute is useful when exporting CSV data to be imported in custom loaders, like for MySQL, that recognize special sequences for `NULL` data.

This attribute has no meaning when parsing CSV data.

comment_str

```
my $csv = Text::CSV_PP->new ({ comment_str => "#" });
        $csv->comment_str (undef);
my $s = $csv->comment_str;
```

This attribute optionally defines a string to be recognized as comment. If this attribute is defined, all lines starting with this sequence will not be parsed as CSV but skipped as comment.

This attribute has no meaning when generating CSV.

Comment strings that start with any of the special characters/sequences are not supported (so it cannot start with any of “sep_char”, “quote_char”, “escape_char”, “sep”, “quote”, or “eol”).

For convenience, `comment` is an alias for `comment_str`.

verbatim

```
my $csv = Text::CSV_PP->new ({ verbatim => 1 });
        $csv->verbatim (0);
my $f = $csv->verbatim;
```

This is a quite controversial attribute to set, but makes some hard things possible.

The rationale behind this attribute is to tell the parser that the normally special characters newline (`NL`) and Carriage Return (`CR`) will not be special when this flag is set, and be dealt with as being ordinary binary characters. This will ease working with data with embedded newlines.

When `verbatim` is used with “getline”, “getline” auto-chomp’s every line.

Imagine a file format like

```
M^^Hans^Janssen^Klas 2\n2A^Ja^11-06-2007#\r\n
```

where, the line ending is a very specific "#\r\n", and the sep_char is a ^ (caret). None of the fields is quoted, but embedded binary data is likely to be present. With the specific line ending, this should not be too hard to detect.

By default, Text::CSV_PP' parse function is instructed to only know about "\n" and "\r" to be legal line endings, and so has to deal with the embedded newline as a real end-of-line, so it can scan the next line if binary is true, and the newline is inside a quoted field. With this option, we tell "parse" to parse the line as if "\n" is just nothing more than a binary character.

For "parse" this means that the parser has no more idea about line ending and "getline" chomps line endings on reading.

types

A set of column types; the attribute is immediately passed to the "types" method.

callbacks

See the "Callbacks" section below.

accessors

To sum it up,

```
$csv = Text::CSV_PP->new ();
```

is equivalent to

```
$csv = Text::CSV_PP->new ({
    eol                 => undef, # \r, \n, or \r\n
    sep_char            => ',',
    sep                 => undef,
    quote_char          => '"',
    quote               => undef,
    escape_char         => '"',
    binary              => 0,
    decode_utf8         => 1,
    auto_diag           => 0,
    diag_verbose        => 0,
    blank_is_undef      => 0,
    empty_is_undef      => 0,
    allow_whitespace    => 0,
    allow_loose_quotes  => 0,
    allow_loose_escapes => 0,
    allow_unquoted_escape => 0,
    always_quote        => 0,
    quote_empty         => 0,
```

(continues on next page)

(continued from previous page)

```
    quote_space             => 1,
    escape_null             => 1,
    quote_binary            => 1,
    keep_meta_info          => 0,
    strict                  => 0,
    skip_empty_rows         => 0,
    formula                 => 0,
    verbatim                => 0,
    undef_str               => undef,
    comment_str             => undef,
    types                   => undef,
    callbacks               => undef,
    });
```

For all of the above mentioned flags, an accessor method is available where you can inquire the current value, or change the value

```
my $quote = $csv->quote_char;
$csv->binary (1);
```

It is not wise to change these settings halfway through writing CSV data to a stream. If however you want to create a new stream using the available CSV object, there is no harm in changing them.

If the "new" constructor call fails, it returns undef, and makes the fail reason available through the "error_diag" method.

```
$csv = Text::CSV_PP->new ({ ecs_char => 1 }) or
    die "".Text::CSV_PP->error_diag ();
```

"error_diag" will return a string like

```
"INI - Unknown attribute 'ecs_char'"
```

known_attributes

```
@attr = Text::CSV_PP->known_attributes;
@attr = Text::CSV_PP::known_attributes;
@attr = $csv->known_attributes;
```

This method will return an ordered list of all the supported attributes as described above. This can be useful for knowing what attributes are valid in classes that use or extend Text::CSV_PP.

print

```
$status = $csv->print ($fh, $colref);
```

Similar to "combine" + "string" + "print", but much more efficient. It expects an array ref as input (not an array!) and the resulting string is not really created, but immediately

written to the `$fh` object, typically an IO handle or any other object that offers a "print" method.

For performance reasons `print` does not create a result string, so all "string", "status", "fields", and "error_input" methods will return undefined information after executing this method.

If `$colref` is `undef` (explicit, not through a variable argument) and "bind_columns" was used to specify fields to be printed, it is possible to make performance improvements, as otherwise data would have to be copied as arguments to the method call:

```
$csv->bind_columns (\($foo, $bar));
$status = $csv->print ($fh, undef);
```

A short benchmark

```
my @data = ("aa" .. "zz");
$csv->bind_columns (\(@data));

$csv->print ($fh, [ @data ]);   # 11800 recs/sec
$csv->print ($fh,  \@data  );   # 57600 recs/sec
$csv->print ($fh,   undef  );   # 48500 recs/sec
```

say

```
$status = $csv->say ($fh, $colref);
```

Like `print`, but `eol` defaults to `$\`.

print_hr

```
$csv->print_hr ($fh, $ref);
```

Provides an easy way to print a `$ref` (as fetched with "getline_hr") provided the column names are set with "column_names".

It is just a wrapper method with basic parameter checks over

```
$csv->print ($fh, [ map { $ref->{$_} } $csv->column_names ]);
```

combine

```
$status = $csv->combine (@fields);
```

This method constructs a CSV record from `@fields`, returning success or failure. Failure can result from lack of arguments or an argument that contains an invalid character. Upon success, "string" can be called to retrieve the resultant CSV string. Upon failure, the value returned by "string" is undefined and "error_input" could be called to retrieve the invalid argument.

string

```
$line = $csv->string ();
```

This method returns the input to “parse” or the resultant CSV string of “combine”, whichever was called more recently.

getline

```
$colref = $csv->getline ($fh);
```

This is the counterpart to “print”, as “parse” is the counterpart to “combine”: it parses a row from the `$fh` handle using the “getline” method associated with `$fh` and parses this row into an array ref. This array ref is returned by the function or `undef` for failure. When `$fh` does not support `getline`, you are likely to hit errors.

When fields are bound with “bind_columns” the return value is a reference to an empty list.

The “string”, “fields”, and “status” methods are meaningless again.

getline_all

```
$arrayref = $csv->getline_all ($fh);
$arrayref = $csv->getline_all ($fh, $offset);
$arrayref = $csv->getline_all ($fh, $offset, $length);
```

This will return a reference to a list of getline ($fh) results. In this call, `keep_meta_info` is disabled. If `$offset` is negative, as with `splice`, only the last `abs ($offset)` records of `$fh` are taken into consideration. Parameters `$offset` and `$length` are expected to be integers. Non-integer values are interpreted as integer without check.

Given a CSV file with 10 lines:

```
lines call
----- --------------------------------------------------------
0..9  $csv->getline_all ($fh)         # all
0..9  $csv->getline_all ($fh,  0)     # all
8..9  $csv->getline_all ($fh,  8)     # start at 8
-     $csv->getline_all ($fh,  0,  0) # start at 0 first 0 rows
0..4  $csv->getline_all ($fh,  0,  5) # start at 0 first 5 rows
4..5  $csv->getline_all ($fh,  4,  2) # start at 4 first 2 rows
8..9  $csv->getline_all ($fh, -2)     # last 2 rows
6..7  $csv->getline_all ($fh, -4,  2) # first 2 of last  4 rows
```

getline_hr

The “getline_hr” and “column_names” methods work together to allow you to have rows returned as hashrefs. You must call “column_names” first to declare your column names.

```
$csv->column_names (qw( code name price description ));
$hr = $csv->getline_hr ($fh);
print "Price for $hr->{name} is $hr->{price} EUR\n";
```

"getline_hr" will croak if called before "column_names".

Note that "getline_hr" creates a hashref for every row and will be much slower than the combined use of "bind_columns" and "getline" but still offering the same easy to use hashref inside the loop:

```
my @cols = @{$csv->getline ($fh)};
$csv->column_names (@cols);
while (my $row = $csv->getline_hr ($fh)) {
    print $row->{price};
    }
```

Could easily be rewritten to the much faster:

```
my @cols = @{$csv->getline ($fh)};
my $row = {};
$csv->bind_columns (\@{$row}{@cols});
while ($csv->getline ($fh)) {
    print $row->{price};
    }
```

Your mileage may vary for the size of the data and the number of rows. With perl-5.14.2 the comparison for a 100_000 line file with 14 columns:

```
           Rate hashrefs getlines
hashrefs 1.00/s       --     -76%
getlines 4.15/s     313%       --
```

getline_hr_all

```
$arrayref = $csv->getline_hr_all ($fh);
$arrayref = $csv->getline_hr_all ($fh, $offset);
$arrayref = $csv->getline_hr_all ($fh, $offset, $length);
```

This will return a reference to a list of getline_hr ($fh) results. In this call, `keep_meta_info` is disabled.

parse

```
$status = $csv->parse ($line);
```

This method decomposes a CSV string into fields, returning success or failure. Failure can result from a lack of argument or the given CSV string is improperly formatted. Upon success, "fields" can be called to retrieve the decomposed fields. Upon failure calling "fields" will return undefined data and "error_input" can be called to retrieve the invalid argument.

You may use the "types" method for setting column types. See "types"' description below.

The `$line` argument is supposed to be a simple scalar. Everything else is supposed to croak and set error 1500.

fragment

This function tries to implement RFC7111 (URI Fragment Identifiers for the text/csv Media Type) - https://datatracker.ietf.org/doc/html/rfc7111

```
my $AoA = $csv->fragment ($fh, $spec);
```

In specifications, `*` is used to specify the *last* item, a dash (`-`) to indicate a range. All indices are 1-based: the first row or column has index 1. Selections can be combined with the semi-colon (`;`).

When using this method in combination with "column_names", the returned reference will point to a list of hashes instead of a list of lists. A disjointed cell-based combined selection might return rows with different number of columns making the use of hashes unpredictable.

```
$csv->column_names ("Name", "Age");
my $AoH = $csv->fragment ($fh, "col=3;8");
```

If the "after_parse" callback is active, it is also called on every line parsed and skipped before the fragment.

- row

  ```
  row=4
  row=5-7
  row=6-*
  row=1-2;4;6-*
  ```

- col

  ```
  col=2
  col=1-3
  col=4-*
  col=1-2;4;7-*
  ```

- cell

  In cell-based selection, the comma (`,`) is used to pair row and column

  ```
  cell=4,1
  ```

  The range operator (`-`) using `cell`s can be used to define top-left and bottom-right `cell` location

  ```
  cell=3,1-4,6
  ```

  The `*` is only allowed in the second part of a pair

```
cell=3,2-*,2    # row 3 till end, only column 2
cell=3,2-3,*    # column 2 till end, only row 3
cell=3,2-*,*    # strip row 1 and 2, and column 1
```

Cells and cell ranges may be combined with `;`, possibly resulting in rows with different numbers of columns

```
cell=1,1-2,2;3,3-4,4;1,4;4,1
```

Disjointed selections will only return selected cells. The cells that are not specified will not be included in the returned set, not even as `undef`. As an example given a CSV like

```
11,12,13,...19
21,22,...28,29
:            :
91,...97,98,99
```

with `cell=1,1-2,2;3,3-4,4;1,4;4,1` will return:

```
11,12,14
21,22
33,34
41,43,44
```

Overlapping cell-specs will return those cells only once, So `cell=1,1-3,3;2,2-4,4;2,3;4,2` will return:

```
11,12,13
21,22,23,24
31,32,33,34
42,43,44
```

RFC7111 does **not** allow different types of specs to be combined (either `row` *or* `col` *or* `cell`). Passing an invalid fragment specification will croak and set error 2013.

column_names

Set the "keys" that will be used in the "getline_hr" calls. If no keys (column names) are passed, it will return the current setting as a list.

"column_names" accepts a list of scalars (the column names) or a single array_ref, so you can pass the return value from "getline" too:

```
$csv->column_names ($csv->getline ($fh));
```

"column_names" does **no** checking on duplicates at all, which might lead to unexpected results. Undefined entries will be replaced with the string `"\cAUNDEF\cA"`, so

```
$csv->column_names (undef, "", "name", "name");
$hr = $csv->getline_hr ($fh);
```

will set `$hr->{"\cAUNDEF\cA"}` to the 1st field, `$hr->{""}` to the 2nd field, and `$hr->{name}` to the 4th field, discarding the 3rd field.

"column_names" croaks on invalid arguments.

header

This method does NOT work in perl-5.6.x

Parse the CSV header and set `sep`, column_names and encoding.

```
my @hdr = $csv->header ($fh);
$csv->header ($fh, { sep_set => [ ";", ",", "|", "\t" ] });
$csv->header ($fh, { detect_bom => 1, munge_column_names => "lc" });
```

The first argument should be a file handle.

This method resets some object properties, as it is supposed to be invoked only once per file or stream. It will leave attributes `column_names` and `bound_columns` alone if setting column names is disabled. Reading headers on previously process objects might fail on perl-5.8.0 and older.

Assuming that the file opened for parsing has a header, and the header does not contain problematic characters like embedded newlines, read the first line from the open handle then auto-detect whether the header separates the column names with a character from the allowed separator list.

If any of the allowed separators matches, and none of the *other* allowed separators match, set `sep` to that separator for the current CSV_PP instance and use it to parse the first line, map those to lowercase, and use that to set the instance "column_names":

```
my $csv = Text::CSV_PP->new ({ binary => 1, auto_diag => 1 });
open my $fh, "<", "file.csv";
binmode $fh; # for Windows
$csv->header ($fh);
while (my $row = $csv->getline_hr ($fh)) {
    ...
    }
```

If the header is empty, contains more than one unique separator out of the allowed set, contains empty fields, or contains identical fields (after folding), it will croak with error 1010, 1011, 1012, or 1013 respectively.

If the header contains embedded newlines or is not valid CSV in any other way, this method will croak and leave the parse error untouched.

A successful call to `header` will always set the `sep` of the `$csv` object. This behavior can not be disabled.

return value

On error this method will croak.

In list context, the headers will be returned whether they are used to set "column_names" or not.

In scalar context, the instance itself is returned. **Note**: the values as found in the header will effectively be **lost** if `set_column_names` is false.

Options

- sep_set

```
$csv->header ($fh, { sep_set => [ ";", ",", "|", "\t" ] });
```

The list of legal separators defaults to `[ ";", "," ]` and can be changed by this option. As this is probably the most often used option, it can be passed on its own as an unnamed argument:

```
$csv->header ($fh, [ ";", ",", "|", "\t", "::", "\x{2063}" ]);
```

Multi-byte sequences are allowed, both multi-character and Unicode. See `sep`.

- detect_bom

```
$csv->header ($fh, { detect_bom => 1 });
```

The default behavior is to detect if the header line starts with a BOM. If the header has a BOM, use that to set the encoding of `$fh`. This default behavior can be disabled by passing a false value to `detect_bom`.

Supported encodings from BOM are: UTF-8, UTF-16BE, UTF-16LE, UTF-32BE, and UTF-32LE. BOM also supports UTF-1, UTF-EBCDIC, SCSU, BOCU-1, and GB-18030 but *Encode* does not (yet). UTF-7 is not supported.

If a supported BOM was detected as start of the stream, it is stored in the object attribute `ENCODING`.

```
my $enc = $csv->{ENCODING};
```

The encoding is used with `binmode` on `$fh`.

If the handle was opened in a (correct) encoding, this method will **not** alter the encoding, as it checks the leading **bytes** of the first line. In case the stream starts with a decoded BOM (`U+FEFF`), `{ENCODING}` will be `""` (empty) instead of the default `undef`.

- munge_column_names

This option offers the means to modify the column names into something that is most useful to the application. The default is to map all column names to lower case.

```
$csv->header ($fh, { munge_column_names => "lc" });
```

The following values are available:

```
lc      - lower case
uc      - upper case
db      - valid DB field names
none    - do not change
```

(continues on next page)

(continued from previous page)

```
\%hash - supply a mapping
\&cb   - supply a callback
```

- Lower case

```
$csv->header ($fh, { munge_column_names => "lc" });
```

  The header is changed to all lower-case

```
$_ = lc;
```

- Upper case

```
$csv->header ($fh, { munge_column_names => "uc" });
```

  The header is changed to all upper-case

```
$_ = uc;
```

- Literal

```
$csv->header ($fh, { munge_column_names => "none" });
```

- Hash

```
$csv->header ($fh, { munge_column_names => { foo => "sombrero
 ↪" });
```

  if a value does not exist, the original value is used unchanged

- Database

```
$csv->header ($fh, { munge_column_names => "db" });
```

  * .

    lower-case

  * .

    all sequences of non-word characters are replaced with an underscore

  * .

    all leading underscores are removed

```
$_ = lc (s/\W+/_/gr =~ s/^_+//r);
```

- Callback

```
$csv->header ($fh, { munge_column_names => sub { fc } });
$csv->header ($fh, { munge_column_names => sub { "column_".
 ↪$col++ } });
$csv->header ($fh, { munge_column_names => sub { lc (s/\W+/_/
 ↪gr) } });
```

As this callback is called in a `map`, you can use `$_` directly.

- set_column_names

```
$csv->header ($fh, { set_column_names => 1 });
```

The default is to set the instances column names using "column_names" if the method is successful, so subsequent calls to "getline_hr" can return a hash. Disable setting the header can be forced by using a false value for this option.

As described in "return value" above, content is lost in scalar context.

Validation

When receiving CSV files from external sources, this method can be used to protect against changes in the layout by restricting to known headers (and typos in the header fields).

```
my %known = (
    "record key" => "c_rec",
    "rec id"     => "c_rec",
    "id_rec"     => "c_rec",
    "kode"       => "code",
    "code"       => "code",
    "vaule"      => "value",
    "value"      => "value",
    );
my $csv = Text::CSV_PP->new ({ binary => 1, auto_diag => 1 });
open my $fh, "<", $source or die "$source: $!";
$csv->header ($fh, { munge_column_names => sub {
    s/\s+$//;
    s/^\s+//;
    $known{lc $_} or die "Unknown column '$_' in $source";
    }});
while (my $row = $csv->getline_hr ($fh)) {
    say join "\t", $row->{c_rec}, $row->{code}, $row->{value};
    }
```

bind_columns

Takes a list of scalar references to be used for output with "print" or to store in the fields fetched by "getline". When you do not pass enough references to store the fetched fields in, "getline" will fail with error `3006`. If you pass more than there are fields to return, the content of the remaining references is left untouched. Under `strict` the two should match, otherwise "getline" will fail with error `2014`.

```
$csv->bind_columns (\$code, \$name, \$price, \$description);
while ($csv->getline ($fh)) {
    print "The price of a $name is \x{20ac} $price\n";
    }
```

To reset or clear all column binding, call "bind_columns" with the single argument undef. This will also clear column names.

```
$csv->bind_columns (undef);
```

If no arguments are passed at all, "bind_columns" will return the list of current bindings or undef if no binds are active.

Note that in parsing with `bind_columns`, the fields are set on the fly. That implies that if the third field of a row causes an error (or this row has just two fields where the previous row had more), the first two fields already have been assigned the values of the current row, while the rest of the fields will still hold the values of the previous row. If you want the parser to fail in these cases, use the `strict` attribute.

eof

```
$eof = $csv->eof ();
```

If "parse" or "getline" was used with an IO stream, this method will return true (1) if the last call hit end of file, otherwise it will return false ('). This is useful to see the difference between a failure and end of file.

Note that if the parsing of the last line caused an error, `eof` is still true. That means that if you are *not* using "auto_diag", an idiom like

```
while (my $row = $csv->getline ($fh)) {
    # ...
    }
$csv->eof or $csv->error_diag;
```

will *not* report the error. You would have to change that to

```
while (my $row = $csv->getline ($fh)) {
    # ...
    }
+$csv->error_diag and $csv->error_diag;
```

types

```
$csv->types (\@tref);
```

This method is used to force that (all) columns are of a given type. For example, if you have an integer column, two columns with doubles and a string column, then you might do a

```
$csv->types ([Text::CSV_PP::IV (),
              Text::CSV_PP::NV (),
              Text::CSV_PP::NV (),
              Text::CSV_PP::PV ()]);
```

Column types are used only for *decoding* columns while parsing, in other words by the "parse" and "getline" methods.

You can unset column types by doing a

```
$csv->types (undef);
```

or fetch the current type settings with

```
$types = $csv->types ();
```

- IV
- CSV_TYPE_IV

  Set field type to integer.
- NV
- CSV_TYPE_NV

  Set field type to numeric/float.
- PV
- CSV_TYPE_PV

  Set field type to string.

fields

```
@columns = $csv->fields ();
```

This method returns the input to "combine" or the resultant decomposed fields of a successful "parse", whichever was called more recently.

Note that the return value is undefined after using "getline", which does not fill the data structures returned by "parse".

meta_info

```
@flags = $csv->meta_info ();
```

This method returns the "flags" of the input to "combine" or the flags of the resultant decomposed fields of "parse", whichever was called more recently.

For each field, a meta_info field will hold flags that inform something about the field returned by the "fields" method or passed to the "combine" method. The flags are bit-wise-or'd like:

- 0x0001
- CSV_FLAGS_IS_QUOTED

  The field was quoted.
- 0x0002
- CSV_FLAGS_IS_BINARY

  The field was binary.

- 0x0004
- CSV_FLAGS_ERROR_IN_FIELD

  The field was invalid.

  Currently only used when allow_loose_quotes is active.
- 0x0010
- CSV_FLAGS_IS_MISSING

  The field was missing.

See the is_*** methods below.

is_quoted

```
my $quoted = $csv->is_quoted ($column_idx);
```

where $column_idx is the (zero-based) index of the column in the last result of "parse".

This returns a true value if the data in the indicated column was enclosed in quote_char quotes. This might be important for fields where content ,20070108, is to be treated as a numeric value, and where ,"20070108", is explicitly marked as character string data.

This method is only valid when "keep_meta_info" is set to a true value.

is_binary

```
my $binary = $csv->is_binary ($column_idx);
```

where $column_idx is the (zero-based) index of the column in the last result of "parse".

This returns a true value if the data in the indicated column contained any byte in the range [\x00-\x08,\x10-\x1F,\x7F-\xFF].

This method is only valid when "keep_meta_info" is set to a true value.

is_missing

```
my $missing = $csv->is_missing ($column_idx);
```

where $column_idx is the (zero-based) index of the column in the last result of "getline_hr".

```
$csv->keep_meta_info (1);
while (my $hr = $csv->getline_hr ($fh)) {
    $csv->is_missing (0) and next; # This was an empty line
    }
```

When using "getline_hr", it is impossible to tell if the parsed fields are undef because they where not filled in the CSV stream or because they were not read at all, as **all** the fields defined by "column_names" are set in the hash-ref. If you still need to know if all

fields in each row are provided, you should enable `keep_meta_info` so you can check the flags.

If `keep_meta_info` is `false`, `is_missing` will always return `undef`, regardless of `$column_idx` being valid or not. If this attribute is `true` it will return either `0` (the field is present) or 1 (the field is missing).

A special case is the empty line. If the line is completely empty - after dealing with the flags - this is still a valid CSV line: it is a record of just one single empty field. However, if `keep_meta_info` is set, invoking `is_missing` with index `0` will now return true.

status

```
$status = $csv->status ();
```

This method returns the status of the last invoked "combine" or "parse" call. Status is success (true: 1) or failure (false: `undef` or `0`).

Note that as this only keeps track of the status of above mentioned methods, you are probably looking for `error_diag` instead.

error_input

```
$bad_argument = $csv->error_input ();
```

This method returns the erroneous argument (if it exists) of "combine" or "parse", whichever was called more recently. If the last invocation was successful, `error_input` will return `undef`.

Depending on the type of error, it *might* also hold the data for the last error-input of "getline".

error_diag

```
Text::CSV_PP->error_diag ();
$csv->error_diag ();
$error_code  =  0  + $csv->error_diag ();
$error_str   =  "" . $csv->error_diag ();
($cde, $str, $pos, $rec, $fld, $xs) = $csv->error_diag ();
```

If (and only if) an error occurred, this function returns the diagnostics of that error.

If called in void context, this will print the internal error code and the associated error message to STDERR.

If called in list context, this will return the error code and the error message in that order. If the last error was from parsing, the rest of the values returned are a best guess at the location within the line that was being parsed. Their values are 1-based. The position currently is index of the byte at which the parsing failed in the current record. It might change to be the index of the current character in a later release. The records is the index of the record parsed by the csv instance. The field number is the index of the field the parser thinks it is currently trying to parse. See `examples/csv-check` for how this can be used.

If called in scalar context, it will return the diagnostics in a single scalar, a-la `$!`. It will contain the error code in numeric context, and the diagnostics message in string context.

When called as a class method or a direct function call, the diagnostics are that of the last "new" call.

_cache_diag

Note: This is an internal function only, and output cannot be relied upon. Use at own risk.

If debugging beyond what "error_diag" is able to show, the internal cache can be shown with this function.

```
# Something failed ..
$csv->error_diag;
$csv->_cache_diag ();
```

record_number

```
$recno = $csv->record_number ();
```

Returns the records parsed by this csv instance. This value should be more accurate than `$.` when embedded newlines come in play. Records written by this instance are not counted.

SetDiag

```
$csv->SetDiag (0);
```

Use to reset the diagnostics if you are dealing with errors.

FUNCTIONS

This section is also taken from Text::CSV_XS.

csv

This function is not exported by default and should be explicitly requested:

```
use Text::CSV_PP qw( csv );
```

This is a high-level function that aims at simple (user) interfaces. This can be used to read/parse a `CSV` file or stream (the default behavior) or to produce a file or write to a stream (define the `out` attribute). It returns an array- or hash-reference on parsing (or `undef` on fail) or the numeric value of "error_diag" on writing. When this function fails you can get to the error using the class call to "error_diag"

```
my $aoa = csv (in => "test.csv") or
    die Text::CSV_PP->error_diag;
```

Note that failure here is the inability to start the parser, like when the input does not exist or the arguments are unknown or conflicting. Run-time parsing errors will return a valid reference, which can be empty, but still contains all results up till the error. See "on_error".

This function takes the arguments as key-value pairs. This can be passed as a list or as an anonymous hash:

```
my $aoa = csv (  in => "test.csv", sep_char => ";");
my $aoh = csv ({ in => $fh, headers => "auto" });
```

The arguments passed consist of two parts: the arguments to "csv" itself and the optional attributes to the CSV object used inside the function as enumerated and explained in "new".

If not overridden, the default option used for CSV is

```
auto_diag   => 1
escape_null => 0
strict_eol  => 1
```

The option that is always set and cannot be altered is

```
binary      => 1
```

As this function will likely be used in one-liners, it allows `quote` to be abbreviated as quo, and `escape_char` to be abbreviated as `esc` or `escape`.

Alternative invocations:

```
my $aoa = Text::CSV_PP::csv (in => "file.csv");

my $csv = Text::CSV_PP->new ();
my $aoa = $csv->csv (in => "file.csv");
```

In the latter case, the object attributes are used from the existing object and the attribute arguments in the function call are ignored:

```
my $csv = Text::CSV_PP->new ({ sep_char => ";" });
my $aoh = $csv->csv (in => "file.csv", bom => 1);
```

will parse using `;` as `sep_char`, not `,`.

in

Used to specify the source. `in` can be a file name (e.g. `"file.csv"`), which will be opened for reading and closed when finished, a file handle (e.g. `$fh` or `FH`), a reference to a glob (e.g. `\*ARGV`), the glob itself (e.g. `*STDIN`), or a reference to a scalar (e.g. `\q{1,2,"csv"}`).

When used with "out", `in` should be a reference to a CSV structure (AoA or AoH) or a CODE-ref that returns an array-reference or a hash-reference. The code-ref will be invoked with no arguments.

```
my $aoa = csv (in => "file.csv");

open my $fh, "<", "file.csv";
my $aoa = csv (in => $fh);

my $csv = [ [qw( Foo Bar )], [ 1, 2 ], [ 2, 3 ]];
my $err = csv (in => $csv, out => "file.csv");
```

If called in void context without the "out" attribute, the resulting ref will be used as input to a subsequent call to csv:

```
csv (in => "file.csv", filter => { 2 => sub { length > 2 }})
```

will be a shortcut to

```
csv (in => csv (in => "file.csv", filter => { 2 => sub { length > 2␣
↪}}))
```

where, in the absence of the out attribute, this is a shortcut to

```
csv (in  => csv (in => "file.csv", filter => { 2 => sub { length > 2␣
↪}}),
     out => *STDOUT)
```

out

```
csv (in => $aoa,  out => "file.csv");
csv (in => $aoa,  out => $fh);
csv (in => $aoa,  out =>   STDOUT);
csv (in => $aoa,  out =>  *STDOUT);
csv (in => $aoa,  out => \*STDOUT);
csv (in => $aoa,  out => \my $data);
csv (in => $aoa,  out =>  undef);
csv (in => $aoa,  out => \"skip");

csv (in => $fh,   out => \@aoa);
csv (in => $fh,   out => \@aoh, bom => 1);
csv (in => $fh,   out => \%hsh, key => "key");

csv (in => $file, out => $file);
csv (in => $file, out => $fh);
csv (in => $fh,   out => $file);
csv (in => $fh,   out => $fh);
```

In output mode, the default CSV options when producing CSV are

```
eol       => "\r\n"
```

The "fragment" attribute is ignored in output mode.

out can be a file name (e.g. "file.csv"), which will be opened for writing and closed

when finished, a file handle (e.g. `$fh` or `FH`), a reference to a glob (e.g. `\*STDOUT`), the glob itself (e.g. `*STDOUT`), or a reference to a scalar (e.g. `\my $data`).

```
csv (in => sub { $sth->fetch },            out => "dump.csv");
csv (in => sub { $sth->fetchrow_hashref }, out => "dump.csv",
     headers => $sth->{NAME_lc});
```

When a code-ref is used for `in`, the output is generated per invocation, so no buffering is involved. This implies that there is no size restriction on the number of records. The `csv` function ends when the coderef returns a false value.

If `out` is set to a reference of the literal string `"skip"`, the output will be suppressed completely, which might be useful in combination with a filter for side effects only.

```
my %cache;
csv (in    => "dump.csv",
     out   => \"skip",
     on_in => sub { $cache{$_[1][1]}++ });
```

Currently, setting `out` to any false value (`undef`, `""`, 0) will be equivalent to `\"skip"`.

If the `in` argument point to something to parse, and the `out` is set to a reference to an `ARRAY` or a `HASH`, the output is appended to the data in the existing reference. The result of the parse should match what exists in the reference passed. This might come handy when you have to parse a set of files with similar content (like data stored per period) and you want to collect that into a single data structure:

```
my %hash;
csv (in => $_, out => \%hash, key => "id") for sort glob "foo-[0-
↪9]*.csv";

my @list; # List of arrays
csv (in => $_, out => \@list)              for sort glob "foo-[0-
↪9]*.csv";

my @list; # List of hashes
csv (in => $_, out => \@list, bom => 1)    for sort glob "foo-[0-
↪9]*.csv";
```

Streaming

If **both** `in` and `out` are files, file handles or globs, streaming is enforced by injecting an `after_parse` callback that immediately uses the `say ()` method of the same instance to output the result and then rejects the record.

If a `after_parse` was already passed as attribute, that will be included in the injected call. If `on_in` was passed and `after_parse` was not, it will be used instead. If both were passed, `on_in` is ignored.

The EOL of the first record of the `in` source is consistently used as EOL for all records in the `out` destination.

The `filter` attribute is not available.

All other attributes are shared for `in` and `out`, so you cannot define different encodings for `in` and `out`. You need to pass a `$fh`, where `binmode` was used to apply the encoding layers.

Note that this is work in progress and things might change.

encoding

If passed, it should be an encoding accepted by the `:encoding()` option to open. There is no default value. This attribute does not work in perl 5.6.x. `encoding` can be abbreviated to `enc` for ease of use in command line invocations.

If `encoding` is set to the literal value `"auto"`, the method "header" will be invoked on the opened stream to check if there is a BOM and set the encoding accordingly. This is equal to passing a true value in the option `detect_bom`.

Encodings can be stacked, as supported by `binmode`:

```
# Using PerlIO::via::gzip
csv (in       => \@csv,
     out      => "test.csv:via.gz",
     encoding => ":via(gzip):encoding(utf-8)",
     );
$aoa = csv (in => "test.csv:via.gz",  encoding => ":via(gzip)");

# Using PerlIO::gzip
csv (in       => \@csv,
     out      => "test.csv:via.gz",
     encoding => ":gzip:encoding(utf-8)",
     );
$aoa = csv (in => "test.csv:gzip.gz", encoding => ":gzip");
```

detect_bom

If `detect_bom` is given, the method "header" will be invoked on the opened stream to check if there is a BOM and set the encoding accordingly.

`detect_bom` can be abbreviated to `bom`.

This is the same as setting `encoding` to `"auto"`.

Note that as the method "header" is invoked, its default is to also set the headers.

headers

If this attribute is not given, the default behavior is to produce an array of arrays.

If `headers` is supplied, it should be an anonymous list of column names, an anonymous hashref, a coderef, or a literal flag: `auto`, `lc`, `uc`, or `skip`.

- skip

  When `skip` is used, the header will not be included in the output.

```
my $aoa = csv (in => $fh, headers => "skip");
```

`skip` is invalid/ignored in combinations with `detect_bom`.

- auto

  If `auto` is used, the first line of the CSV source will be read as the list of field headers and used to produce an array of hashes.

```
my $aoh = csv (in => $fh, headers => "auto");
```

- lc

  If `lc` is used, the first line of the CSV source will be read as the list of field headers mapped to lower case and used to produce an array of hashes. This is a variation of `auto`.

```
my $aoh = csv (in => $fh, headers => "lc");
```

- uc

  If `uc` is used, the first line of the CSV source will be read as the list of field headers mapped to upper case and used to produce an array of hashes. This is a variation of `auto`.

```
my $aoh = csv (in => $fh, headers => "uc");
```

- CODE

  If a coderef is used, the first line of the CSV source will be read as the list of mangled field headers in which each field is passed as the only argument to the coderef. This list is used to produce an array of hashes.

```
my $aoh = csv (in      => $fh,
               headers => sub { lc ($_[0]) =~ s/kode/code/gr });
```

  this example is a variation of using `lc` where all occurrences of kode are replaced with code.

- ARRAY

  If `headers` is an anonymous list, the entries in the list will be used as field names. The first line is considered data instead of headers.

```
my $aoh = csv (in => $fh, headers => [qw( Foo Bar )]);
csv (in => $aoa, out => $fh, headers => [qw( code description␣
 ↪price )]);
```

- HASH

  If `headers` is a hash reference, this implies `auto`, but header fields that exist as key in the hashref will be replaced by the value for that key. Given a CSV file like

```
post-kode,city,name,id number,fubble
1234AA,Duckstad,Donald,13,"X313DF"
```

using

```
csv (headers => { "post-kode" => "pc", "id number" => "ID" }, ..
↪.
```

will return an entry like

```
{ pc     => "1234AA",
  city   => "Duckstad",
  name   => "Donald",
  ID     => "13",
  fubble => "X313DF",
  }
```

See also `munge_column_names` and `set_column_names`.

munge_column_names

If `munge_column_names` is set, the method "header" is invoked on the opened stream with all matching arguments to detect and set the headers.

`munge_column_names` can be abbreviated to `munge`.

key

If passed, will default `headers` to `"auto"` and return a hashref instead of an array of hashes. Allowed values are simple scalars or array-references where the first element is the joiner and the rest are the fields to join to combine the key.

```
my $ref = csv (in => "test.csv", key => "code");
my $ref = csv (in => "test.csv", key => [ ":" => "code", "color" ]);
```

with test.csv like

```
code,product,price,color
1,pc,850,gray
2,keyboard,12,white
3,mouse,5,black
```

the first example will return

```
{ 1   => {
      code    => 1,
      color   => 'gray',
      price   => 850,
      product => 'pc'
      },
  2   => {
      code    => 2,
      color   => 'white',
      price   => 12,
      product => 'keyboard'
```

(continues on next page)

(continued from previous page)

```
      },
  3   => {
      code    => 3,
      color   => 'black',
      price   => 5,
      product => 'mouse'
      }
  }
```

the second example will return

```
{ "1:gray"    => {
      code    => 1,
      color   => 'gray',
      price   => 850,
      product => 'pc'
      },
  "2:white"   => {
      code    => 2,
      color   => 'white',
      price   => 12,
      product => 'keyboard'
      },
  "3:black"   => {
      code    => 3,
      color   => 'black',
      price   => 5,
      product => 'mouse'
      }
  }
```

The key attribute can be combined with `headers` for `CSV` date that has no header line, like

```
my $ref = csv (
    in      => "foo.csv",
    headers => [qw( c_foo foo bar description stock )],
    key     =>     "c_foo",
    );
```

value

Used to create key-value hashes.

Only allowed when `key` is valid. A `value` can be either a single column label or an anonymous list of column labels. In the first case, the value will be a simple scalar value, in the latter case, it will be a hashref.

```
my $ref = csv (in => "test.csv", key   => "code",
                                 value => "price");
```

(continues on next page)

(continued from previous page)

```
my $ref = csv (in => "test.csv", key   => "code",
                                 value => [ "product", "price" ]);
my $ref = csv (in => "test.csv", key   => [ ":" => "code", "color"
 ↪],
                                 value => "price");
my $ref = csv (in => "test.csv", key   => [ ":" => "code", "color"
 ↪],
                                 value => [ "product", "price" ]);
```

with test.csv like

```
code,product,price,color
1,pc,850,gray
2,keyboard,12,white
3,mouse,5,black
```

the first example will return

```
{ 1 => 850,
  2 =>  12,
  3 =>   5,
  }
```

the second example will return

```
{ 1   => {
      price   => 850,
      product => 'pc'
      },
  2   => {
      price   => 12,
      product => 'keyboard'
      },
  3   => {
      price   => 5,
      product => 'mouse'
      }
  }
```

the third example will return

```
{ "1:gray"    => 850,
  "2:white"   =>  12,
  "3:black"   =>   5,
  }
```

the fourth example will return

```
{ "1:gray"    => {
      price   => 850,
```

(continues on next page)

(continued from previous page)

```
      product => 'pc'
      },
  "2:white"   => {
      price   => 12,
      product => 'keyboard'
      },
  "3:black"   => {
      price   => 5,
      product => 'mouse'
      }
  }
```

keep_headers

When using hashes, keep the column names into the arrayref passed, so all headers are available after the call in the original order.

```
my $aoh = csv (in => "file.csv", keep_headers => \my @hdr);
```

This attribute can be abbreviated to `kh` or passed as `keep_column_names`.

This attribute implies a default of `auto` for the `headers` attribute.

The headers can also be kept internally to keep stable header order:

```
csv (in      => csv (in => "file.csv", kh => "internal"),
     out     => "new.csv",
     kh      => "internal");
```

where `internal` can also be 1, `yes`, or `true`. This is similar to

```
my @h;
csv (in      => csv (in => "file.csv", kh => \@h),
     out     => "new.csv",
     headers => \@h);
```

fragment

Only output the fragment as defined in the "fragment" method. This option is ignored when *generating* CSV. See "out".

Combining all of them could give something like

```
use Text::CSV_PP qw( csv );
my $aoh = csv (
    in       => "test.txt",
    encoding => "utf-8",
    headers  => "auto",
    sep_char => "|",
    fragment => "row=3;6-9;15-*",
```

(continues on next page)

(continued from previous page)

```
    );
say $aoh->[15]{Foo};
```

sep_set

If `sep_set` is set, the method "header" is invoked on the opened stream to detect and set `sep_char` with the given set.

`sep_set` can be abbreviated to `seps`. If neither `sep_set` not `seps` is given, but `sep` is defined, `sep_set` defaults to `[ sep ]`. This is only supported for perl version 5.10 and up.

Note that as the "header" method is invoked, its default is to also set the headers.

set_column_names

If `set_column_names` is passed, the method "header" is invoked on the opened stream with all arguments meant for "header".

If `set_column_names` is passed as a false value, the content of the first row is only preserved if the output is AoA:

With an input-file like

```
bAr,foo
1,2
3,4,5
```

This call

```
my $aoa = csv (in => $file, set_column_names => 0);
```

will result in

```
[[ "bar", "foo"     ],
 [ "1",   "2"       ],
 [ "3",   "4",  "5" ]]
```

and

```
my $aoa = csv (in => $file, set_column_names => 0, munge => "none");
```

will result in

```
[[ "bAr", "foo"     ],
 [ "1",   "2"       ],
 [ "3",   "4",  "5" ]]
```

csv

The *function* "csv" can also be called as a method or with an existing Text::CSV_PP object. This could help if the function is to be invoked a lot of times and the overhead of creating the object internally over and over again would be prevented by passing an existing instance.

```
my $csv = Text::CSV_PP->new ({ binary => 1, auto_diag => 1 });

my $aoa = $csv->csv (in => $fh);
my $aoa = csv (in => $fh, csv => $csv);
```

both act the same. Running this 20000 times on a 20 lines CSV file, showed a 53% speedup.

Callbacks

Callbacks enable actions triggered from the *inside* of Text::CSV_PP.

While most of what this enables can easily be done in an unrolled loop as described in the "SYNOPSIS" callbacks can be used to meet special demands or enhance the "csv" function.

- error

  ```
  $csv->callbacks (error => sub { $csv->SetDiag (0) });
  ```

  the `error` callback is invoked when an error occurs, but *only* when "auto_diag" is set to a true value. A callback is invoked with the values returned by "error_diag":

  ```
  my ($c, $s);

  sub ignore3006 {
      my ($err, $msg, $pos, $recno, $fldno) = @_;
      if ($err == 3006) {
          # ignore this error
          ($c, $s) = (undef, undef);
          Text::CSV_PP->SetDiag (0);
          }
      # Any other error
      return;
      } # ignore3006

  $csv->callbacks (error => \&ignore3006);
  $csv->bind_columns (\$c, \$s);
  while ($csv->getline ($fh)) {
      # Error 3006 will not stop the loop
      }
  ```

- after_parse

```
$csv->callbacks (after_parse => sub { push @{$_[1]}, "NEW" });
while (my $row = $csv->getline ($fh)) {
    $row->[-1] eq "NEW";
    }
```

This callback is invoked after parsing with "getline" only if no error occurred. The callback is invoked with two arguments: the current CSV parser object and an array reference to the fields parsed.

The return code of the callback is ignored unless it is a reference to the string "skip", in which case the record will be skipped in "getline_all".

```
sub add_from_db {
    my ($csv, $row) = @_;
    $sth->execute ($row->[4]);
    push @$row, $sth->fetchrow_array;
    } # add_from_db

my $aoa = csv (in => "file.csv", callbacks => {
    after_parse => \&add_from_db });
```

This hook can be used for validation:

- FAIL

  Die if any of the records does not validate a rule:

  ```
  after_parse => sub {
      $_[1][4] =~ m/^[0-9]{4}\s?[A-Z]{2}$/ or
          die "5th field does not have a valid Dutch zipcode";
      }
  ```

- DEFAULT

  Replace invalid fields with a default value:

  ```
  after_parse => sub { $_[1][2] =~ m/^\d+$/ or $_[1][2] = 0 }
  ```

- SKIP

  Skip records that have invalid fields (only applies to "getline_all"):

  ```
  after_parse => sub { $_[1][0] =~ m/^\d+$/ or return \"skip";␣
  ↪}
  ```

- before_print

```
my $idx = 1;
$csv->callbacks (before_print => sub { $_[1][0] = $idx++ });
$csv->print (*STDOUT, [ 0, $_ ]) for @members;
```

This callback is invoked before printing with "print" only if no error occurred. The callback is invoked with two arguments: the current CSV parser object and an array reference to the fields passed.

The return code of the callback is ignored.

```
sub max_4_fields {
    my ($csv, $row) = @_;
    @$row > 4 and splice @$row, 4;
    } # max_4_fields

csv (in => csv (in => "file.csv"), out => *STDOUT,
    callbacks => { before_print => \&max_4_fields });
```

This callback is not active for “combine”.

Callbacks for csv ()

```
csv (in        => "file.csv",
     callbacks => {
         filter       => { 6 => sub { $_ > 15 } },    # first
         after_parse  => sub { say "AFTER PARSE";  }, # first
         after_in     => sub { say "AFTER IN";     }, # second
         on_in        => sub { say "ON IN";        }, # third
         },
     );

csv (in        => $aoh,
     out       => "file.csv",
     callbacks => {
         on_in        => sub { say "ON IN";        }, # first
         before_out   => sub { say "BEFORE OUT";   }, # second
         before_print => sub { say "BEFORE PRINT"; }, # third
         },
     );
```

- filter

  This callback can be used to filter records. It is called just after a new record has been scanned. The callback accepts a:

  – hashref

  The keys are the index to the row (the field name or field number, 1-based) and the values are subs to return a true or false value.

  ```
  csv (in => "file.csv", filter => {
             3 => sub { m/a/ },       # third field should␣
  ↪contain an "a"
             5 => sub { length > 4 }, # length of the 5th␣
  ↪field minimal 5
             });

  csv (in => "file.csv", filter => { foo => sub { $_ > 4 }});
  ```

  If the keys to the filter hash contain any character that is not a digit it will also implicitly set “headers” to "auto" unless “headers” was already passed

as argument. When headers are active, returning an array of hashes, the filter is not applicable to the header itself.

All sub results should match, as in AND.

The context of the callback sets $_ localized to the field indicated by the filter. The two arguments are as with all other callbacks, so the other fields in the current row can be seen:

```
filter => { 3 => sub { $_ > 100 ? $_[1][1] =~ m/A/ : $_
↪[1][6] =~ m/B/ }}
```

If the context is set to return a list of hashes ("headers" is defined), the current record will also be available in the localized %_:

```
filter => { 3 => sub { $_ > 100 && $_{foo} =~ m/A/ && $_{bar}
↪ < 1000  }}
```

If the filter is used to *alter* the content by changing $_, make sure that the sub returns true in order not to have that record skipped:

```
filter => { 2 => sub { $_ = uc }}
```

will upper-case the second field, and then skip it if the resulting content evaluates to false. To always accept, end with truth:

```
filter => { 2 => sub { $_ = uc; 1 }}
```

– coderef

```
csv (in => "file.csv", filter => sub { $n++; 0; });
```

If the argument to `filter` is a coderef, it is an alias or shortcut to a filter on column 0:

```
csv (filter => sub { $n++; 0 });
```

is equal to

```
csv (filter => { 0 => sub { $n++; 0 });
```

– filter-name

```
csv (in => "file.csv", filter => "not_blank");
csv (in => "file.csv", filter => "not_empty");
csv (in => "file.csv", filter => "filled");
```

These are predefined filters

Given a file like (line numbers prefixed for doc purpose only):

```
1:1,2,3
2:
3:,
```

(continues on next page)

(continued from previous page)

```
4:""
5:,,
6:, ,
7:"",
8:" "
9:4,5,6
```

* not_blank

  Filter out the blank lines

  This filter is a shortcut for

  ```
  filter => { 0 => sub { @{$_[1]} > 1 or
              defined $_[1][0] && $_[1][0] ne "" } }
  ```

  Due to the implementation, it is currently impossible to also filter lines that consists only of a quoted empty field. These lines are also considered blank lines.

  With the given example, lines 2 and 4 will be skipped.

* not_empty

  Filter out lines where all the fields are empty.

  This filter is a shortcut for

  ```
  filter => { 0 => sub { grep { defined && $_ ne "" } @{$_
  ↪[1]} } }
  ```

  A space is not regarded being empty, so given the example data, lines 2, 3, 4, 5, and 7 are skipped.

* filled

  Filter out lines that have no visible data

  This filter is a shortcut for

  ```
  filter => { 0 => sub { grep { defined && m/\S/ } @{$_[1]}␣
  ↪} }
  ```

  This filter rejects all lines that *not* have at least one field that does not evaluate to the empty string.

  With the given example data, this filter would skip lines 2 through 8.

One could also use modules like Types::Standard:

```
use Types::Standard -types;

my $type   = Tuple[Str, Str, Int, Bool, Optional[Num]];
my $check  = $type->compiled_check;

# filter with compiled check and warnings
```

(continues on next page)

(continued from previous page)

```
my $aoa = csv (
   in     => \$data,
   filter => {
       0 => sub {
           my $ok = $check->($_[1]) or
               warn $type->get_message ($_[1]), "\n";
           return $ok;
           },
       },
   );
```

- after_in

  This callback is invoked for each record after all records have been parsed but before returning the reference to the caller. The hook is invoked with two arguments: the current CSV parser object and a reference to the record. The reference can be a reference to a HASH or a reference to an ARRAY as determined by the arguments.

  This callback can also be passed as an attribute without the `callbacks` wrapper.

- before_out

  This callback is invoked for each record before the record is printed. The hook is invoked with two arguments: the current CSV parser object and a reference to the record. The reference can be a reference to a HASH or a reference to an ARRAY as determined by the arguments.

  This callback can also be passed as an attribute without the `callbacks` wrapper.

  This callback makes the row available in %_ if the row is a hashref. In this case %_ is writable and will change the original row.

- on_in

  This callback acts exactly as the "after_in" or the "before_out" hooks.

  This callback can also be passed as an attribute without the `callbacks` wrapper.

  This callback makes the row available in %_ if the row is a hashref. In this case %_ is writable and will change the original row. So e.g. with

```
my $aoh = csv (
    in      => \"foo\n1\n2\n",
    headers => "auto",
    on_in   => sub { $_{bar} = 2; },
    );
```

  $aoh will be:

```
[ { foo => 1,
    bar => 2,
    }
  { foo => 2,
    bar => 2,
```

(continues on next page)

(continued from previous page)

```
    }
  ]
```

- on_error

  This callback acts exactly as the “error” hook.

```
my @err;
my $aoa = csv (in => $fh, on_error => sub { @err = @_ });
```

  is identical to

```
my $aoa = csv (in => $fh, callbacks => {
    error => sub { @err = @_ },
    });
```

  It can be used for ignoring errors as well as for just keeping the error in case of analysis after the `csv ()` function has returned.

```
my @err;
my $aoa = csv (in => "bad.csv, on_error => sub { @err = @_ });
die Text::CSV_PP->error_diag if @err or !$aoa;
```

DIAGNOSTICS

This section is also taken from Text::CSV_XS.

Still under construction ...

If an error occurs, `$csv->error_diag` can be used to get information on the cause of the failure. Note that for speed reasons the internal value is never cleared on success, so using the value returned by “error_diag” in normal cases - when no error occurred - may cause unexpected results.

If the constructor failed, the cause can be found using “error_diag” as a class method, like `Text::CSV_PP->error_diag`.

The `$csv->error_diag` method is automatically invoked upon error when the contractor was called with `auto_diag` set to 1 or 2, or when *autodie* is in effect. When set to 1, this will cause a `warn` with the error message, when set to 2, it will `die`. `2012 - EOF` is excluded from `auto_diag` reports.

Errors can be (individually) caught using the “error” callback.

The errors as described below are available. I have tried to make the error itself explanatory enough, but more descriptions will be added. For most of these errors, the first three capitals describe the error category:

- INI

  Initialization error or option conflict.

- ECR

  Carriage-Return related parse error.

- EOF

  End-Of-File related parse error.

- EIQ

  Parse error inside quotation.

- EIF

  Parse error inside field.

- ECB

  Combine error.

- EHR

  HashRef parse related error.

And below should be the complete list of error codes that can be returned:

- 1001 “INI - sep_char is equal to quote_char or escape_char”

  The separation character cannot be equal to the quotation character or to the escape character, as this would invalidate all parsing rules.

- 1002 “INI - allow_whitespace with escape_char or quote_char SP or TAB”

  Using the `allow_whitespace` attribute when either `quote_char` or `escape_char` is equal to `SPACE` or `TAB` is too ambiguous to allow.

- 1003 “INI - \r or \n in main attr not allowed”

  Using default `eol` characters in either `sep_char`, `quote_char`, or `escape_char` is not allowed.

- 1004 “INI - callbacks should be undef or a hashref”

  The `callbacks` attribute only allows one to be `undef` or a hash reference.

- 1005 “INI - EOL too long”

  The value passed for EOL is exceeding its maximum length (16).

- 1006 “INI - SEP too long”

  The value passed for SEP is exceeding its maximum length (16).

- 1007 “INI - QUOTE too long”

  The value passed for QUOTE is exceeding its maximum length (16).

- 1008 “INI - SEP undefined”

  The value passed for SEP should be defined and not empty.

- 1010 “INI - the header is empty”

  The header line parsed in the “header” is empty.

- 1011 “INI - the header contains more than one valid separator”

  The header line parsed in the “header” contains more than one (unique) separator character out of the allowed set of separators.

- 1012 “INI - the header contains an empty field”

  The header line parsed in the “header” contains an empty field.

- 1013 “INI - the header contains nun-unique fields”

  The header line parsed in the “header” contains at least two identical fields.

- 1014 “INI - header called on undefined stream”

  The header line cannot be parsed from an undefined source.

- 1500 “PRM - Invalid/unsupported argument(s)”

  Function or method called with invalid argument(s) or parameter(s).

- 1501 “PRM - The key attribute is passed as an unsupported type”

  The `key` attribute is of an unsupported type.

- 1502 “PRM - The value attribute is passed without the key attribute”

  The `value` attribute is only allowed when a valid key is given.

- 1503 “PRM - The value attribute is passed as an unsupported type”

  The `value` attribute is of an unsupported type.

- 2010 “ECR - QUO char inside quotes followed by CR not part of EOL”

  When `eol` has been set to anything but the default, like `"\r\t\n"`, and the `"\r"` is following the **second** (closing) `quote_char`, where the characters following the `"\r"` do not make up the `eol` sequence, this is an error.

- 2011 “ECR - Characters after end of quoted field”

  Sequences like `1,foo,"bar"baz,22,1` are not allowed. `"bar"` is a quoted field and after the closing double-quote, there should be either a new-line sequence or a separation character.

- 2012 “EOF - End of data in parsing input stream”

  Self-explaining. End-of-file while inside parsing a stream. Can happen only when reading from streams with “getline”, as using “parse” is done on strings that are not required to have a trailing `eol`.

- 2013 “INI - Specification error for fragments RFC7111”

  Invalid specification for URI “fragment” specification.

- 2014 “ENF - Inconsistent number of fields”

  Inconsistent number of fields under strict parsing.

- 2015 “ERW - Empty row”

  An empty row was not allowed.

- 2016 “EOL - Inconsistent EOL”

  Inconsistent End-Of-Line detected under strict_eol parsing.

- 2021 “EIQ - NL char inside quotes, binary off”

  Sequences like `1,"foo\nbar",22,1` are allowed only when the binary option has been selected with the constructor.

- 2022 “EIQ - CR char inside quotes, binary off”

  Sequences like `1,"foo\rbar",22,1` are allowed only when the binary option has been selected with the constructor.

- 2023 “EIQ - QUO character not allowed”

  Sequences like `"foo "bar" baz",qu` and `2023,",2008-04-05,"Foo, Bar",\n` will cause this error.

- 2024 “EIQ - EOF cannot be escaped, not even inside quotes”

  The escape character is not allowed as last character in an input stream.

- 2025 “EIQ - Loose unescaped escape”

  An escape character should escape only characters that need escaping.

  Allowing the escape for other characters is possible with the attribute “allow_loose_escapes”.

- 2026 “EIQ - Binary character inside quoted field, binary off”

  Binary characters are not allowed by default. Exceptions are fields that contain valid UTF-8, that will automatically be upgraded if the content is valid UTF-8. Set `binary` to 1 to accept binary data.

- 2027 “EIQ - Quoted field not terminated”

  When parsing a field that started with a quotation character, the field is expected to be closed with a quotation character. When the parsed line is exhausted before the quote is found, that field is not terminated.

- 2030 “EIF - NL char inside unquoted verbatim, binary off”
- 2031 “EIF - CR char is first char of field, not part of EOL”
- 2032 “EIF - CR char inside unquoted, not part of EOL”
- 2034 “EIF - Loose unescaped quote”
- 2035 “EIF - Escaped EOF in unquoted field”
- 2036 “EIF - ESC error”
- 2037 “EIF - Binary character in unquoted field, binary off”
- 2110 “ECB - Binary character in Combine, binary off”
- 2200 “EIO - print to IO failed. See errno”
- 3001 “EHR - Unsupported syntax for column_names ()”
- 3002 “EHR - getline_hr () called before column_names ()”
- 3003 “EHR - bind_columns () and column_names () fields count mismatch”
- 3004 “EHR - bind_columns () only accepts refs to scalars”
- 3006 “EHR - bind_columns () did not pass enough refs for parsed fields”
- 3007 “EHR - bind_columns needs refs to writable scalars”
- 3008 “EHR - unexpected error in bound fields”
- 3009 “EHR - print_hr () called before column_names ()”

- 3010 “EHR - print_hr () called with invalid arguments”

Text::LevenshteinXS

The Levenshtein edit distance of two strings: the fewest insertions, deletions and substitutions that turn one into the other.

`distance($s, $t)` is exported by default. It compares bytes: a character string counts the bytes of its UTF-8 form, and a string ends at its first NUL byte, as the C strings of upstream’s XS do.

This is a native implementation of Text::LevenshteinXS 0.03’s `LevenshteinXS.xs`; its `Text/LevenshteinXS.pm` is used unchanged.

Synopsis

```
use Text::LevenshteinXS;

print distance("foo", "four"), "\n";      # 2
print distance("kitten", "sitting"), "\n";  # 3
```

Differences from upstream

One, where perl 5.44 with LevenshteinXS.xs fails (t/81-xs-native/Text-LevenshteinXS/150-or-better.t): long strings. LevenshteinXS.xs allocates a table of (n+1)(m+1) ints for strings of n and m bytes, does not check the allocation, and indexes the table with an int; when the memory is not there (two strings of 20000 bytes need 1.6 GB), or once n*m passes 2**31, it dumps core. Here the distance is computed in two rows of the shorter string's length.

Functions

Edit distance

distance

`distance($s, $t)`: the Levenshtein distance of the two strings' bytes.

Text::LineFold

Line Folding for Plain Text

SYNOPSIS

```
use Text::LineFold;
$lf = Text::LineFold->new();

# Fold lines
$folded = $lf->fold($string, 'PLAIN');
$indented = $lf->fold(' ' x 8, ' ' x 4, $string);

# Unfold lines
$unfolded = $lf->unfold($string, 'FIXED');
```

DESCRIPTION

Text::LineFold folds or unfolds lines of plain text. As it mainly focuses on plain text e-mail messages, RFC 3676 flowed format is also supported.

Public Interface

- new ([KEY => VALUE, ...])

  Constructor. About KEY => VALUE pairs see config method.

- $self->config (KEY)

- $self->config ([KEY => VAL, ...])

  Instance method. Get or update configuration. Following KEY => VALUE pairs may be specified.

  – Charset => CHARSET

  Character set that is used to encode string. It may be string or *MIME::Charset* object. Default is `"UTF-8"`.

  - Language => LANGUAGE

    Along with Charset option, this may be used to define language/region context. Default is `"XX"`. See also *"Context" in Unicode::LineBreak* option.

  - Newline => STRING

    String to be used for newline sequence. Default is `"\n"`.

  - OutputCharset => CHARSET

    Character set that is used to encode result of fold()/unfold(). It may be string or *MIME::Charset* object. If a special value `"_UNICODE_"` is specified, result will be Unicode string. Default is the value of Charset option.

  - TabSize => NUMBER

    Column width of tab stops. When 0 is specified, tab stops are ignored. Default is 8.

  - BreakIndent
  - CharMax
  - ColMax
  - ColMin
  - ComplexBreaking
  - EAWidth
  - HangulAsAL
  - LBClass
  - LegacyCM
  - Prep
  - Urgent

    See *"Options" in Unicode::LineBreak*.

- $self->fold (STRING, [METHOD])
- $self->fold (INITIAL_TAB, SUBSEQUENT_TAB, STRING, ...)

  Instance method. fold() folds lines of string STRING and returns it. Surplus SPACEs and horizontal tabs at end of line are removed, newline sequences are replaced by that specified by Newline option and newline is appended at end of text if it does not exist. Horizontal tabs are treated as tab stops according to TabSize option.

  By the first style, following options may be specified for METHOD argument.

  - `"FIXED"`

    Lines preceded by `">"` won't be folded. Paragraphs are separated by empty line.

  - `"FLOWED"`

    `"Format=Flowed; DelSp=Yes"` formatting defined by RFC 3676.

- `"PLAIN"`

  Default method. All lines are folded.

Second style is similar to *"wrap()" in Text::Wrap*. All lines are folded. INITIAL_TAB is inserted at beginning of paragraphs and SUBSEQUENT_TAB at beginning of other broken lines.

- $self->unfold (STRING, METHOD)

  Conjunct folded paragraphs of string STRING and returns it.

  Following options may be specified for METHOD argument.

  - `"FIXED"`

    Default method. Lines preceded by `">"` won't be conjuncted. Treat empty line as paragraph separator.

  - `"FLOWED"`

    Unfold `"Format=Flowed; DelSp=Yes"` formatting defined by RFC 3676.

  - `"FLOWEDSP"`

    Unfold `"Format=Flowed; DelSp=No"` formatting defined by RFC 3676.

BUGS

Please report bugs or buggy behaviors to developer.

Text::ParseWords

parse text into an array of tokens or array of arrays

SYNOPSIS

```
use Text::ParseWords;
@lists = nested_quotewords($delim, $keep, @lines);
@words = quotewords($delim, $keep, @lines);
@words = shellwords(@lines);
@words = parse_line($delim, $keep, $line);
@words = old_shellwords(@lines); # DEPRECATED!
```

DESCRIPTION

The `nested_quotewords()` and `quotewords()` functions accept a delimiter (which can be a regular expression) and a list of lines and then breaks those lines up into a list of words ignoring delimiters that appear inside quotes. `quotewords()` returns all of the tokens in a single long list, while `nested_quotewords()` returns a list of token lists corresponding to the elements of `@lines`. `parse_line()` does tokenizing on a single string. The `*quotewords()` functions simply call `parse_line()`, so if you're only splitting one line you can call `parse_line()` directly and save a function call.

The `$keep` controls what happens with delimters and special characters:

- true

  If true, then the tokens are split on the specified delimiter, but all other characters (including quotes and backslashes) are kept in the tokens.

- false

  If $keep is false then the `*quotewords()` functions remove all quotes and backslashes that are not themselves backslash-escaped or inside of single quotes (i.e., `quotewords()` tries to interpret these characters just like the Bourne shell). NB: these semantics are significantly different from the original version of this module shipped with Perl 5.000 through 5.004.

- `"delimiters"`

  As an additional feature, $keep may be the keyword "delimiters" which causes the functions to preserve the delimiters in each string as tokens in the token lists, in addition to preserving quote and backslash characters.

`shellwords()` is written as a special case of `quotewords()`, and it does token parsing with whitespace as a delimiter– similar to most Unix shells.

EXAMPLES

The sample program:

```
use Text::ParseWords;
@words = quotewords('\s+', 0, q{this   is "a test" of\ quotewords \
 ↪"for you});
$i = 0;
foreach (@words) {
    print "$i: <$_>\n";
```

(continues on next page)

(continued from previous page)

```
    $i++;
}
```

produces:

```
0: <this>
1: <is>
2: <a test>
3: <of quotewords>
4: <"for>
5: <you>
```

demonstrating:

- 0

  a simple word

- 1

  multiple spaces are skipped because of our $delim

- 2

  use of quotes to include a space in a word

- 3

  use of a backslash to include a space in a word

- 4

  use of a backslash to remove the special meaning of a double-quote

- 5

  another simple word (note the lack of effect of the backslashed double-quote)

Replacing `quotewords('\s+', 0, q{this is...})` with `shellwords(q{this is...})` is a simpler way to accomplish the same thing.

Text::Tabs

expand and unexpand tabs like unix expand(1) and unexpand(1)

SYNOPSIS

```
use Text::Tabs;

$tabstop = 4;  # default = 8
@lines_without_tabs = expand(@lines_with_tabs);
@lines_with_tabs = unexpand(@lines_without_tabs);
```

DESCRIPTION

Text::Tabs does most of what the unix utilities expand(1) and unexpand(1) do. Given a line with tabs in it, expand replaces those tabs with the appropriate number of spaces. Given a line with or without tabs in it, unexpand adds tabs when it can save bytes by doing so, like the unexpand -a command.

Unlike the old unix utilities, this module correctly accounts for any Unicode combining characters (such as diacriticals) that may occur in each line for both expansion and unexpansion. These are overstrike characters that do not increment the logical position. Make sure you have the appropriate Unicode settings enabled.

EXPORTS

The following are exported:

- expand
- unexpand
- $tabstop

  The `$tabstop` variable controls how many column positions apart each tabstop is. The default is 8.

  Please note that `local($tabstop)` doesn't do the right thing and if you want to use `local` to override `$tabstop`, you need to use `local($Text::Tabs::tabstop)`.

EXAMPLE

```
#!perl
# unexpand -a
use Text::Tabs;

while (<>) {
  print unexpand $_;
}
```

Instead of the shell's expand command, use:

```
perl -MText::Tabs -n -e 'print expand $_'
```

Instead of the shell's unexpand -a command, use:

```
perl -MText::Tabs -n -e 'print unexpand $_'
```

BUGS

Text::Tabs handles only tabs (`"\t"`) and combining characters (`/\pM/`). It doesn't count backwards for backspaces (`"\t"`), omit other non-printing control characters (`/\pC/`), or otherwise deal with any other zero-, half-, and full-width characters.

Text::Wrap

line wrapping to form simple paragraphs

SYNOPSIS

Example 1

```
use Text::Wrap;

$initial_tab = "\t";    # Tab before first line
$subsequent_tab = "";   # All other lines flush left

print wrap($initial_tab, $subsequent_tab, @text);
print fill($initial_tab, $subsequent_tab, @text);

$lines = wrap($initial_tab, $subsequent_tab, @text);

@paragraphs = fill($initial_tab, $subsequent_tab, @text);
```

Example 2

```
use Text::Wrap qw(wrap $columns $huge);

$columns = 132;         # Wrap at 132 characters
$huge = 'die';
$huge = 'wrap';
$huge = 'overflow';
```

Example 3

```
use Text::Wrap;

$Text::Wrap::columns = 72;
print wrap('', '', @text);
```

DESCRIPTION

`Text::Wrap::wrap()` is a very simple paragraph formatter. It formats a single paragraph at a time by breaking lines at word boundaries. Indentation is controlled for the first line (`$initial_tab`) and all subsequent lines (`$subsequent_tab`) independently. Please note: `$initial_tab` and `$subsequent_tab` are the literal strings that will be used: it is unlikely you would want to pass in a number.

`Text::Wrap::fill()` is a simple multi-paragraph formatter. It formats each paragraph separately and then joins them together when it's done. It will destroy any whitespace in the original text. It breaks text into paragraphs by looking for whitespace after a newline. In other respects, it acts like wrap().

`wrap()` compresses trailing whitespace into one newline, and `fill()` deletes all trailing whitespace.

Both `wrap()` and `fill()` return a single string.

Unlike the old Unix fmt(1) utility, this module correctly accounts for any Unicode combining characters (such as diacriticals) that may occur in each line for both expansion and unexpansion. These are overstrike characters that do not increment the logical position. Make sure you have the appropriate Unicode settings enabled.

OVERRIDES

`Text::Wrap::wrap()` has a number of variables that control its behavior. Because other modules might be using `Text::Wrap::wrap()` it is suggested that you leave these variables alone! If you can't do that, then use `local($Text::Wrap::VARIABLE) = YOURVALUE` when you change the values so that the original value is restored. This `local()` trick will not work if you import the variable into your own namespace.

Lines are wrapped at `$Text::Wrap::columns` columns (default value: 76). `$Text::Wrap::columns` should be set to the full width of your output device. In fact, every resulting line will have length of no more than `$columns - 1`.

It is possible to control which characters terminate words by modifying `$Text::Wrap::break`. Set this to a string such as `'[\s:]'` (to break before spaces or colons) or a pre-compiled regexp such as `qr/[\s']/` (to break before spaces or

apostrophes). The default is simply `'\s'`; that is, words are terminated by spaces. (This means, among other things, that trailing punctuation such as full stops or commas stay with the word they are "attached" to.) Setting `$Text::Wrap::break` to a regular expression that doesn't eat any characters (perhaps just a forward look-ahead assertion) will cause warnings.

Beginner note: In example 2, above `$columns` is imported into the local namespace, and set locally. In example 3, `$Text::Wrap::columns` is set in its own namespace without importing it.

`Text::Wrap::wrap()` starts its work by expanding all the tabs in its input into spaces. The last thing it does it to turn spaces back into tabs. If you do not want tabs in your results, set `$Text::Wrap::unexpand` to a false value. Likewise if you do not want to use 8-character tabstops, set `$Text::Wrap::tabstop` to the number of characters you do want for your tabstops.

If you want to separate your lines with something other than `\n` then set `$Text::Wrap::separator` to your preference. This replaces all newlines with `$Text::Wrap::separator`. If you just want to preserve existing newlines but add new breaks with something else, set `$Text::Wrap::separator2` instead.

When words that are longer than `$columns` are encountered, they are broken up. `wrap()` adds a `"\n"` at column `$columns`. This behavior can be overridden by setting `$huge` to 'die' or to 'overflow'. When set to 'die', large words will cause `die()` to be called. When set to 'overflow', large words will be left intact.

Historical notes: 'die' used to be the default value of `$huge`. Now, 'wrap' is the default value.

EXAMPLES

Code:

```
print wrap("\t","",<<END);
This is a bit of text that forms
a normal book-style indented paragraph
END
```

Result:

```
"     This is a bit of text that forms
a normal book-style indented paragraph
"
```

Code:

```
$Text::Wrap::columns=20;
$Text::Wrap::separator="|";
print wrap("","","This is a bit of text that forms a normal book-
 ↪style paragraph");
```

Result:

```
"This is a bit of|text that forms a|normal book-style|paragraph"
```

SEE ALSO

For correct handling of East Asian half- and full-width characters, see Text::WrapI18N. For more detailed controls: Text::Format.

5.2.104 Thread

Manipulate threads in Perl (for old code only)

DEPRECATED

The `Thread` module served as the frontend to the old-style thread model, called *5005threads*, that was introduced in release 5.005. That model was deprecated, and has been removed in version 5.10.

For old code and interim backwards compatibility, the `Thread` module has been reworked to function as a frontend for the new interpreter threads (*ithreads*) model. However, some previous functionality is not available. Further, the data sharing models between the two thread models are completely different, and anything to do with data sharing has to be thought differently. With *ithreads*, you must explicitly `share()` variables between the threads.

You are strongly encouraged to migrate any existing threaded code to the new model (i.e., use the `threads` and `threads::shared` modules) as soon as possible.

HISTORY

In Perl 5.005, the thread model was that all data is implicitly shared, and shared access to data has to be explicitly synchronized. This model is called *5005threads*.

In Perl 5.6, a new model was introduced in which all data is thread local and shared access to data has to be explicitly declared. This model is called *ithreads*, for “interpreter threads”.

In Perl 5.6, the *ithreads* model was not available as a public API; only as an internal API that was available for extension writers, and to implement fork() emulation on Win32 platforms.

In Perl 5.8, the *ithreads* model became available through the `threads` module, and the *5005threads* model was deprecated.

In Perl 5.10, the *5005threads* model was removed from the Perl interpreter.

SYNOPSIS

```
use Thread qw(:DEFAULT async yield);

my $t = Thread->new(\&start_sub, @start_args);

$result = $t->join;
$t->detach;

if ($t->done) {
    $t->join;
}

if($t->equal($another_thread)) {
    # ...
}

yield();

my $tid = Thread->self->tid;

lock($scalar);
lock(@array);
lock(%hash);

my @list = Thread->list;
```

DESCRIPTION

The `Thread` module provides multithreading support for Perl.

FUNCTIONS

- $thread = Thread->new(\&start_sub)
- $thread = Thread->new(\&start_sub, LIST)

  `new` starts a new thread of execution in the referenced subroutine. The optional list is passed as parameters to the subroutine. Execution continues in both the subroutine and the code after the `new` call.

  `Thread->new` returns a thread object representing the newly created thread.

- lock VARIABLE

  `lock` places a lock on a variable until the lock goes out of scope.

  If the variable is locked by another thread, the `lock` call will block until it's available. `lock` is recursive, so multiple calls to `lock` are safe–the variable will remain

locked until the outermost lock on the variable goes out of scope.

Locks on variables only affect `lock` calls–they do *not* affect normal access to a variable. (Locks on subs are different, and covered in a bit.) If you really, *really* want locks to block access, then go ahead and tie them to something and manage this yourself. This is done on purpose. While managing access to variables is a good thing, Perl doesn't force you out of its living room...

If a container object, such as a hash or array, is locked, all the elements of that container are not locked. For example, if a thread does a `lock @a`, any other thread doing a `lock($a[12])` won't block.

Finally, `lock` will traverse up references exactly *one* level. `lock(\$a)` is equivalent to `lock($a)`, while `lock(\\$a)` is not.

- async BLOCK;

  `async` creates a thread to execute the block immediately following it. This block is treated as an anonymous sub, and so must have a semi-colon after the closing brace. Like `Thread->new`, `async` returns a thread object.

- Thread->self

  The `Thread->self` function returns a thread object that represents the thread making the `Thread->self` call.

- Thread->list

  Returns a list of all non-joined, non-detached Thread objects.

- cond_wait VARIABLE

  The `cond_wait` function takes a **locked** variable as a parameter, unlocks the variable, and blocks until another thread does a `cond_signal` or `cond_broadcast` for that same locked variable. The variable that `cond_wait` blocked on is relocked after the `cond_wait` is satisfied. If there are multiple threads `cond_waiting` on the same variable, all but one will reblock waiting to re-acquire the lock on the variable. (So if you're only using `cond_wait` for synchronization, give up the lock as soon as possible.)

- cond_signal VARIABLE

  The `cond_signal` function takes a locked variable as a parameter and unblocks one thread that's `cond_waiting` on that variable. If more than one thread is blocked in a `cond_wait` on that variable, only one (and which one is indeterminate) will be unblocked.

  If there are no threads blocked in a `cond_wait` on the variable, the signal is discarded.

- cond_broadcast VARIABLE

  The `cond_broadcast` function works similarly to `cond_signal`. `cond_broadcast`, though, will unblock **all** the threads that are blocked in a `cond_wait` on the locked variable, rather than only one.

- yield

  The `yield` function allows another thread to take control of the CPU. The exact results are implementation-dependent.

METHODS

- join

  `join` waits for a thread to end and returns any values the thread exited with. `join` will block until the thread has ended, though it won't block if the thread has already terminated.

  If the thread being `joined` `died`, the error it died with will be returned at this time. If you don't want the thread performing the `join` to die as well, you should either wrap the `join` in an `eval` or use the `eval` thread method instead of `join`.

- detach

  `detach` tells a thread that it is never going to be joined i.e. that all traces of its existence can be removed once it stops running. Errors in detached threads will not be visible anywhere - if you want to catch them, you should use $SIG{__DIE__} or something like that.

- equal

  `equal` tests whether two thread objects represent the same thread and returns true if they do.

- tid

  The `tid` method returns the tid of a thread. The tid is a monotonically increasing integer assigned when a thread is created. The main thread of a program will have a tid of zero, while subsequent threads will have tids assigned starting with one.

- done

  The done method returns true if the thread you're checking has finished, and false otherwise.

DEFUNCT

The following were implemented with *5005threads*, but are no longer available with *ithreads*.

- lock(\&sub)

  With 5005threads, you could also `lock` a sub such that any calls to that sub from another thread would block until the lock was released.

  Also, subroutines could be declared with the `:locked` attribute which would serialize access to the subroutine, but allowed different threads non-simultaneous access.

- eval

  The `eval` method wrapped an `eval` around a `join`, and so waited for a thread to exit, passing along any values the thread might have returned and placing any errors into `$@`.

- flags

  The `flags` method returned the flags for the thread - an integer value corresponding to the internal flags for the thread.

Thread::Queue

Thread-safe queues

VERSION

This document describes Thread::Queue version 3.14

SYNOPSIS

```
use strict;
use warnings;

use threads;
use Thread::Queue;

my $q = Thread::Queue->new();    # A new empty queue

# Worker thread
my $thr = threads->create(
    sub {
        # Thread will loop until no more work
        while (defined(my $item = $q->dequeue())) {
            # Do work on $item
            ...
        }
    }
);

# Send work to the thread
$q->enqueue($item1, ...);
# Signal that there is no more work to be sent
$q->end();
# Join up with the thread when it finishes
$thr->join();

...

# Count of items in the queue
my $left = $q->pending();
```

(continues on next page)

(continued from previous page)

```
# Non-blocking dequeue
if (defined(my $item = $q->dequeue_nb())) {
    # Work on $item
}

# Blocking dequeue with 5-second timeout
if (defined(my $item = $q->dequeue_timed(5))) {
    # Work on $item
}

# Set a size for a queue
$q->limit = 5;

# Get the second item in the queue without dequeuing anything
my $item = $q->peek(1);

# Insert two items into the queue just behind the head
$q->insert(1, $item1, $item2);

# Extract the last two items on the queue
my ($item1, $item2) = $q->extract(-2, 2);
```

DESCRIPTION

This module provides thread-safe FIFO queues that can be accessed safely by any number of threads.

Any data types supported by *threads::shared* can be passed via queues:

- Ordinary scalars
- Array refs
- Hash refs
- Scalar refs
- Objects based on the above

Ordinary scalars are added to queues as they are.

If not already thread-shared, the other complex data types will be cloned (recursively, if needed, and including any `bless`ings and read-only settings) into thread-shared structures before being placed onto a queue.

For example, the following would cause *Thread::Queue* to create a empty, shared array reference via `&shared([])`, copy the elements 'foo', 'bar' and 'baz' from `@ary` into it, and then place that shared reference onto the queue:

```
my @ary = qw/foo bar baz/;
$q->enqueue(\@ary);
```

However, for the following, the items are already shared, so their references are added directly to the queue, and no cloning takes place:

```
my @ary :shared = qw/foo bar baz/;
$q->enqueue(\@ary);

my $obj = &shared({});
$$obj{'foo'} = 'bar';
$$obj{'qux'} = 99;
bless($obj, 'My::Class');
$q->enqueue($obj);
```

See “LIMITATIONS” for caveats related to passing objects via queues.

QUEUE CREATION

- ->new()

  Creates a new empty queue.

- ->new(LIST)

  Creates a new queue pre-populated with the provided list of items.

BASIC METHODS

The following methods deal with queues on a FIFO basis.

- ->enqueue(LIST)

  Adds a list of items onto the end of the queue.

- ->dequeue()

- ->dequeue(COUNT)

  Removes the requested number of items (default is 1) from the head of the queue, and returns them. If the queue contains fewer than the requested number of items, then the thread will be blocked until the requisite number of items are available (i.e., until other threads enqueue more items).

- ->dequeue_nb()

- ->dequeue_nb(COUNT)

  Removes the requested number of items (default is 1) from the head of the queue, and returns them. If the queue contains fewer than the requested number of items, then it immediately (i.e., non-blocking) returns whatever items there are on the queue. If the queue is empty, then `undef` is returned.

- ->dequeue_timed(TIMEOUT)

- ->dequeue_timed(TIMEOUT, COUNT)

  Removes the requested number of items (default is 1) from the head of the queue, and returns them. If the queue contains fewer than the requested number of items, then the thread will be blocked until the requisite number of items are available,

or until the timeout is reached. If the timeout is reached, it returns whatever items there are on the queue, or undef if the queue is empty.

The timeout may be a number of seconds relative to the current time (e.g., 5 seconds from when the call is made), or may be an absolute timeout in *epoch* seconds the same as would be used with *cond_timedwait()*. Fractional seconds (e.g., 2.5 seconds) are also supported (to the extent of the underlying implementation).

If TIMEOUT is missing, undef, or less than or equal to 0, then this call behaves the same as dequeue_nb.

- ->pending()

  Returns the number of items still in the queue. Returns undef if the queue has been ended (see below), and there are no more items in the queue.

- ->limit

  Sets the size of the queue. If set, calls to enqueue() will block until the number of pending items in the queue drops below the limit. The limit does not prevent enqueuing items beyond that count:

```
my $q = Thread::Queue->new(1, 2);
$q->limit = 4;
$q->enqueue(3, 4, 5);   # Does not block
$q->enqueue(6);         # Blocks until at least 2 items are
                        # dequeued
my $size = $q->limit;   # Returns the current limit (may return
                        # 'undef')
$q->limit = 0;          # Queue size is now unlimited
```

  Calling any of the dequeue methods with COUNT greater than a queue's limit will generate an error.

- ->end()

  Declares that no more items will be added to the queue.

  All threads blocking on dequeue() calls will be unblocked with any remaining items in the queue and/or undef being returned. Any subsequent calls to dequeue() will behave like dequeue_nb().

  Once ended, no more items may be placed in the queue.

ADVANCED METHODS

The following methods can be used to manipulate items anywhere in a queue.

To prevent the contents of a queue from being modified by another thread while it is being examined and/or changed, *lock* the queue inside a local block:

```
{
    lock($q);   # Keep other threads from changing the queue's␣
↪contents
    my $item = $q->peek();
    if ($item ...) {
```

(continues on next page)

(continued from previous page)

```
        ...
    }
}
# Queue is now unlocked
```

- ->peek()
- ->peek(INDEX)

  Returns an item from the queue without dequeuing anything. Defaults to the head of queue (at index position 0) if no index is specified. Negative index values are supported as with *arrays* (i.e., -1 is the end of the queue, -2 is next to last, and so on).

  If no items exists at the specified index (i.e., the queue is empty, or the index is beyond the number of items on the queue), then `undef` is returned.

  Remember, the returned item is not removed from the queue, so manipulating a peeked at reference affects the item on the queue.

- ->insert(INDEX, LIST)

  Adds the list of items to the queue at the specified index position (0 is the head of the list). Any existing items at and beyond that position are pushed back past the newly added items:

  ```
  $q->enqueue(1, 2, 3, 4);
  $q->insert(1, qw/foo bar/);
  # Queue now contains:  1, foo, bar, 2, 3, 4
  ```

  Specifying an index position greater than the number of items in the queue just adds the list to the end.

  Negative index positions are supported:

  ```
  $q->enqueue(1, 2, 3, 4);
  $q->insert(-2, qw/foo bar/);
  # Queue now contains:  1, 2, foo, bar, 3, 4
  ```

  Specifying a negative index position greater than the number of items in the queue adds the list to the head of the queue.

- ->extract()
- ->extract(INDEX)
- ->extract(INDEX, COUNT)

  Removes and returns the specified number of items (defaults to 1) from the specified index position in the queue (0 is the head of the queue). When called with no arguments, `extract` operates the same as dequeue_nb.

  This method is non-blocking, and will return only as many items as are available to fulfill the request:

```
$q->enqueue(1, 2, 3, 4);
my $item  = $q->extract(2)     # Returns 3
                               # Queue now contains:  1, 2, 4
my @items = $q->extract(1, 3)  # Returns (2, 4)
                               # Queue now contains:  1
```

Specifying an index position greater than the number of items in the queue results in undef or an empty list being returned.

```
$q->enqueue('foo');
my $nada = $q->extract(3)      # Returns undef
my @nada = $q->extract(1, 3)   # Returns ()
```

Negative index positions are supported. Specifying a negative index position greater than the number of items in the queue may return items from the head of the queue (similar to dequeue_nb) if the count overlaps the head of the queue from the specified position (i.e. if queue size + index + count is greater than zero):

```
$q->enqueue(qw/foo bar baz/);
my @nada = $q->extract(-6, 2);  # Returns ()      - (3+(-6)+2)
 ↪<= 0
my @some = $q->extract(-6, 4);  # Returns (foo)   - (3+(-6)+4) >
 ↪ 0
                                # Queue now contains:  bar, baz
my @rest = $q->extract(-3, 4);  # Returns (bar, baz) -
                                #                  (2+(-3)+4) >
 ↪ 0
```

NOTES

Queues created by *Thread::Queue* can be used in both threaded and non-threaded applications.

LIMITATIONS

Passing objects on queues may not work if the objects' classes do not support sharing. See *"BUGS AND LIMITATIONS" in threads::shared* for more.

Passing array/hash refs that contain objects may not work for Perl prior to 5.10.0.

Thread::Semaphore

Thread-safe semaphores

VERSION

This document describes Thread::Semaphore version 2.13

SYNOPSIS

```
use Thread::Semaphore;
my $s = Thread::Semaphore->new();
$s->down();   # Also known as the semaphore P operation.
# The guarded section is here
$s->up();     # Also known as the semaphore V operation.

# Decrement the semaphore only if it would immediately succeed.
if ($s->down_nb()) {
    # The guarded section is here
    $s->up();
}

# Forcefully decrement the semaphore even if its count goes below 0.
$s->down_force();

# The default value for semaphore operations is 1
my $s = Thread::Semaphore->new($initial_value);
$s->down($down_value);
$s->up($up_value);
if ($s->down_nb($down_value)) {
    ...
    $s->up($up_value);
}
$s->down_force($down_value);
```

DESCRIPTION

Semaphores provide a mechanism to regulate access to resources. Unlike locks, semaphores aren't tied to particular scalars, and so may be used to control access to anything you care to use them for.

Semaphores don't limit their values to zero and one, so they can be used to control access to some resource that there may be more than one of (e.g., filehandles). Increment and decrement amounts aren't fixed at one either, so threads can reserve or return multiple resources at once.

METHODS

- ->new()
- ->new(NUMBER)

  new creates a new semaphore, and initializes its count to the specified number (which must be an integer). If no number is specified, the semaphore's count defaults to 1.

- ->down()
- ->down(NUMBER)

  The down method decreases the semaphore's count by the specified number (which must be an integer >= 1), or by one if no number is specified.

  If the semaphore's count would drop below zero, this method will block until such time as the semaphore's count is greater than or equal to the amount you're downing the semaphore's count by.

  This is the semaphore "P operation" (the name derives from the Dutch word "pak", which means "capture" – the semaphore operations were named by the late Dijkstra, who was Dutch).

- ->down_nb()
- ->down_nb(NUMBER)

  The down_nb method attempts to decrease the semaphore's count by the specified number (which must be an integer >= 1), or by one if no number is specified.

  If the semaphore's count would drop below zero, this method will return *false*, and the semaphore's count remains unchanged. Otherwise, the semaphore's count is decremented and this method returns *true*.

- ->down_force()
- ->down_force(NUMBER)

  The down_force method decreases the semaphore's count by the specified number (which must be an integer >= 1), or by one if no number is specified. This method does not block, and may cause the semaphore's count to drop below zero.

- ->down_timed(TIMEOUT)
- ->down_timed(TIMEOUT, NUMBER)

  The down_timed method attempts to decrease the semaphore's count by 1 or by the specified number within the specified timeout period given in seconds (which must be an integer >= 0).

  If the semaphore's count would drop below zero, this method will block until either the semaphore's count is greater than or equal to the amount you're downing the semaphore's count by, or until the timeout is reached.

If the timeout is reached, this method will return *false*, and the semaphore's count remains unchanged. Otherwise, the semaphore's count is decremented and this method returns *true*.

- ->up()
- ->up(NUMBER)

  The up method increases the semaphore's count by the number specified (which must be an integer >= 1), or by one if no number is specified.

  This will unblock any thread that is blocked trying to down the semaphore if the up raises the semaphore's count above the amount that the down is trying to decrement it by. For example, if three threads are blocked trying to down a semaphore by one, and another thread ups the semaphore by two, then two of the blocked threads (which two is indeterminate) will become unblocked.

  This is the semaphore "V operation" (the name derives from the Dutch word "vrij", which means "release").

NOTES

Semaphores created by *Thread::Semaphore* can be used in both threaded and non-threaded applications. This allows you to write modules and packages that potentially make use of semaphores, and that will function in either environment.

5.2.105 Tie

Namespace containing the following modules:

- `Tie::Array` - base class for tied arrays
- `Tie::File` - Access the lines of a disk file via a Perl array
- `Tie::Handle` - base class definitions for tied handles
- `Tie::Hash` - base class definitions for tied hashes

- `Tie::Memoize` - add data to hash when needed
- `Tie::RefHash` - Use references as hash keys
- `Tie::Scalar` - base class definitions for tied scalars
- `Tie::StdHandle` - base class definitions for tied handles
- `Tie::SubstrHash` - Fixed-table-size, fixed-key-length hashing

Tie::Array

base class for tied arrays

SYNOPSIS

```
package Tie::NewArray;
use Tie::Array;
@ISA = ('Tie::Array');

# mandatory methods
sub TIEARRAY { ... }
sub FETCH { ... }
sub FETCHSIZE { ... }

sub STORE { ... }       # mandatory if elements writeable
sub STORESIZE { ... }   # mandatory if elements can be added/deleted
sub EXISTS { ... }      # mandatory if exists() expected to work
sub DELETE { ... }      # mandatory if delete() expected to work

# optional methods - for efficiency
sub CLEAR { ... }
sub PUSH { ... }
sub POP { ... }
sub SHIFT { ... }
sub UNSHIFT { ... }
sub SPLICE { ... }
sub EXTEND { ... }
sub DESTROY { ... }

package Tie::NewStdArray;
use Tie::Array;

@ISA = ('Tie::StdArray');

# all methods provided by default

package main;

$object = tie @somearray,'Tie::NewArray';
$object = tie @somearray,'Tie::StdArray';
$object = tie @somearray,'Tie::NewStdArray';
```

DESCRIPTION

This module provides methods for array-tying classes. See perltie for a list of the functions required in order to tie an array to a package. The basic **Tie::Array** package provides stub `DESTROY`, and `EXTEND` methods that do nothing, stub `DELETE` and `EXISTS` methods that croak() if the delete() or exists() builtins are ever called on the tied array, and implementations of `PUSH`, `POP`, `SHIFT`, `UNSHIFT`, `SPLICE` and `CLEAR` in terms of basic `FETCH`, `STORE`, `FETCHSIZE`, `STORESIZE`.

The **Tie::StdArray** package provides efficient methods required for tied arrays which are implemented as blessed references to an "inner" perl array. It inherits from **Tie::Array**, and should cause tied arrays to behave exactly like standard arrays, allowing for selective overloading of methods.

For developers wishing to write their own tied arrays, the required methods are briefly defined below. See the perltie section for more detailed descriptive, as well as example code:

- TIEARRAY classname, LIST

  The class method is invoked by the command `tie @array, classname`. Associates an array instance with the specified class. `LIST` would represent additional arguments (along the lines of *AnyDBM_File* and compatriots) needed to complete the association. The method should return an object of a class which provides the methods below.

- STORE this, index, value

  Store datum *value* into *index* for the tied array associated with object *this*. If this makes the array larger then class's mapping of `undef` should be returned for new positions.

- FETCH this, index

  Retrieve the datum in *index* for the tied array associated with object *this*.

- FETCHSIZE this

  Returns the total number of items in the tied array associated with object *this*. (Equivalent to `scalar(@array)`).

- STORESIZE this, count

  Sets the total number of items in the tied array associated with object *this* to be *count*. If this makes the array larger then class's mapping of `undef` should be returned for new positions. If the array becomes smaller then entries beyond count should be deleted.

- EXTEND this, count

  Informative call that array is likely to grow to have *count* entries. Can be used to optimize allocation. This method need do nothing.

- EXISTS this, key

  Verify that the element at index *key* exists in the tied array *this*.

  The **Tie::Array** implementation is a stub that simply croaks.

- DELETE this, key

Delete the element at index *key* from the tied array *this*.

The **Tie::Array** implementation is a stub that simply croaks.

- CLEAR this

  Clear (remove, delete, ...) all values from the tied array associated with object *this*.

- DESTROY this

  Normal object destructor method.

- PUSH this, LIST

  Append elements of LIST to the array.

- POP this

  Remove last element of the array and return it.

- SHIFT this

  Remove the first element of the array (shifting other elements down) and return it.

- UNSHIFT this, LIST

  Insert LIST elements at the beginning of the array, moving existing elements up to make room.

- SPLICE this, offset, length, LIST

  Perform the equivalent of `splice` on the array.

  offset is optional and defaults to zero, negative values count back from the end of the array.

  length is optional and defaults to rest of the array.

  LIST may be empty.

  Returns a list of the original *length* elements at *offset*.

CAVEATS

There is no support at present for tied @ISA. There is a potential conflict between magic entries needed to notice setting of @ISA, and those needed to implement 'tie'.

Tie::File

Access the lines of a disk file via a Perl array

SYNOPSIS

```
use Tie::File;

tie @array, 'Tie::File', filename or die ...;

$array[0] = 'blah';      # first line of the file is now 'blah'
                           # (line numbering starts at 0)
print $array[42];        # display line 43 of the file

$n_recs = @array;        # how many records are in the file?
$#array -= 2;            # chop two records off the end

for (@array) {
  s/PERL/Perl/g;        # Replace PERL with Perl everywhere in the
 ↪file
}

# These are just like regular push, pop, unshift, shift, and splice
# Except that they modify the file in the way you would expect

push @array, new recs...;
my $r1 = pop @array;
unshift @array, new recs...;
my $r2 = shift @array;
@old_recs = splice @array, 3, 7, new recs...;

untie @array;            # all finished
```

DESCRIPTION

`Tie::File` represents a regular text file as a Perl array. Each element in the array corresponds to a record in the file. The first line of the file is element 0 of the array; the second line is element 1, and so on.

The file is *not* loaded into memory, so this will work even for gigantic files.

Changes to the array are reflected in the file immediately.

Lazy people and beginners may now stop reading the manual.

unicode

You can read a unicode (UTF-8) file by providing a file handle opened with the desired encoding. It is not safe to write to one because the length in bytes and in characters is often different, Tie::File will miscalculate the length of writes, overwriting parts of other records.

recsep

What is a 'record'? By default, the meaning is the same as for the `<...>` operator: It's a string terminated by `$/`, which is probably `"\n"`. (Minor exception: on DOS and Win32 systems, a 'record' is a string terminated by `"\r\n"`.) You may change the definition of "record" by supplying the `recsep` option in the `tie` call:

```
tie @array, 'Tie::File', $file, recsep => 'es';
```

This says that records are delimited by the string `es`. If the file contained the following data:

```
Curse these pesky flies!\n
```

then the `@array` would appear to have four elements:

```
"Curse th"
"e p"
"ky fli"
"!\n"
```

An undefined value is not permitted as a record separator. Perl's special "paragraph mode" semantics (à la `$/ = ""`) are not emulated.

Records read from the tied array do not have the record separator string on the end; this is to allow

```
$array[17] .= "extra";
```

to work as expected.

(See "autochomp", below.) Records stored into the array will have the record separator string appended before they are written to the file, if they don't have one already. For example, if the record separator string is `"\n"`, then the following two lines do exactly the same thing:

```
$array[17] = "Cherry pie";
$array[17] = "Cherry pie\n";
```

The result is that the contents of line 17 of the file will be replaced with "Cherry pie"; a newline character will separate line 17 from line 18. This means that this code will do nothing:

```
chomp $array[17];
```

Because the `chomp`ed value will have the separator reattached when it is written back to the file. There is no way to create a file whose trailing record separator string is missing.

Inserting records that *contain* the record separator string is not supported by this module. It will probably produce a reasonable result, but what this result will be may change in a future version. Use 'splice' to insert records or to replace one record with several.

autochomp

Normally, array elements have the record separator removed, so that if the file contains the text

```
Gold
Frankincense
Myrrh
```

the tied array will appear to contain `("Gold", "Frankincense", "Myrrh")`. If you set `autochomp` to a false value, the record separator will not be removed. If the file above was tied with

```
tie @gifts, "Tie::File", $gifts, autochomp => 0;
```

then the array `@gifts` would appear to contain `("Gold\n", "Frankincense\n", "Myrrh\n")`, or (on Win32 systems) `("Gold\r\n", "Frankincense\r\n", "Myrrh\r\n")`.

mode

Normally, the specified file will be opened for read and write access, and will be created if it does not exist. (That is, the flags `O_RDWR | O_CREAT` are supplied in the open call.) If you want to change this, you may supply alternative flags in the `mode` option. See *Fcntl* for a listing of available flags. For example:

```
# open the file if it exists, but fail if it does not exist
use Fcntl 'O_RDWR';
tie @array, 'Tie::File', $file, mode => O_RDWR;

# create the file if it does not exist
use Fcntl 'O_RDWR', 'O_CREAT';
tie @array, 'Tie::File', $file, mode => O_RDWR | O_CREAT;

# open an existing file in read-only mode
use Fcntl 'O_RDONLY';
tie @array, 'Tie::File', $file, mode => O_RDONLY;
```

Opening the data file in write-only or append mode is not supported.

memory

This is an upper limit on the amount of memory that `Tie::File` will consume at any time while managing the file. This is used for two things: managing the *read cache* and managing the *deferred write buffer*.

Records read in from the file are cached, to avoid having to re-read them repeatedly. If you read the same record twice, the first time it will be stored in memory, and the second time it will be fetched from the *read cache*. The amount of data in the read cache will not exceed the value you specified for `memory`. If `Tie::File` wants to cache a new record, but the read cache is full, it will make room by expiring the least-recently visited records from the read cache.

The default memory limit is 2Mib. You can adjust the maximum read cache size by supplying the `memory` option. The argument is the desired cache size, in bytes.

```
# I have a lot of memory, so use a large cache to speed up access
tie @array, 'Tie::File', $file, memory => 20_000_000;
```

Setting the memory limit to 0 will inhibit caching; records will be fetched from disk every time you examine them.

The `memory` value is not an absolute or exact limit on the memory used. `Tie::File` objects contains some structures besides the read cache and the deferred write buffer, whose sizes are not charged against `memory`.

The cache itself consumes about 310 bytes per cached record, so if your file has many short records, you may want to decrease the cache memory limit, or else the cache overhead may exceed the size of the cached data.

dw_size

(This is an advanced feature. Skip this section on first reading.)

If you use deferred writing (See "Deferred Writing", below) then data you write into the array will not be written directly to the file; instead, it will be saved in the *deferred write buffer* to be written out later. Data in the deferred write buffer is also charged against the memory limit you set with the `memory` option.

You may set the `dw_size` option to limit the amount of data that can be saved in the deferred write buffer. This limit may not exceed the total memory limit. For example, if you set `dw_size` to 1000 and `memory` to 2500, that means that no more than 1000 bytes of deferred writes will be saved up. The space available for the read cache will vary, but it will always be at least 1500 bytes (if the deferred write buffer is full) and it could grow as large as 2500 bytes (if the deferred write buffer is empty.)

If you don't specify a `dw_size`, it defaults to the entire memory limit.

Option Format

`-mode` is a synonym for `mode`. `-recsep` is a synonym for `recsep`. `-memory` is a synonym for `memory`. You get the idea.

Public Methods

The `tie` call returns an object, say `$o`. You may call

```
$rec = $o->FETCH($n);
$o->STORE($n, $rec);
```

to fetch or store the record at line `$n`, respectively; similarly the other tied array methods. (See perltie for details.) You may also call the following methods on this object:

flock

```
$o->flock(MODE)
```

will lock the tied file. `MODE` has the same meaning as the second argument to the Perl built-in `flock` function; for example `LOCK_SH` or `LOCK_EX | LOCK_NB`. (These constants are provided by the `use Fcntl ':flock'` declaration.)

`MODE` is optional; the default is `LOCK_EX`.

`Tie::File` maintains an internal table of the byte offset of each record it has seen in the file.

When you use `flock` to lock the file, `Tie::File` assumes that the read cache is no longer trustworthy, because another process might have modified the file since the last time it was read. Therefore, a successful call to `flock` discards the contents of the read cache and the internal record offset table.

`Tie::File` promises that the following sequence of operations will be safe:

```
my $o = tie @array, "Tie::File", $filename;
$o->flock;
```

In particular, `Tie::File` will *not* read or write the file during the `tie` call. (Exception: Using `mode => O_TRUNC` will, of course, erase the file during the `tie` call. If you want to do this safely, then open the file without `O_TRUNC`, lock the file, and use `@array = ()`.)

The best way to unlock a file is to discard the object and untie the array. It is probably unsafe to unlock the file without also untying it, because if you do, changes may remain unwritten inside the object. That is why there is no shortcut for unlocking. If you really want to unlock the file prematurely, you know what to do; if you don't know what to do, then don't do it.

All the usual warnings about file locking apply here. In particular, note that file locking in Perl is **advisory**, which means that holding a lock will not prevent anyone else from reading, writing, or erasing the file; it only prevents them from getting another lock at the same time. Locks are analogous to green traffic lights: If you have a green light, that does not prevent the idiot coming the other way from plowing into you sideways; it merely guarantees to you that the idiot does not also have a green light at the same time.

autochomp

```
my $old_value = $o->autochomp(0);    # disable autochomp option
my $old_value = $o->autochomp(1);    #  enable autochomp option

my $ac = $o->autochomp();   # recover current value
```

See "autochomp", above.

defer, flush, discard, and autodefer

See “Deferred Writing”, below.

offset

```
$off = $o->offset($n);
```

This method returns the byte offset of the start of the $nth record in the file. If there is no such record, it returns an undefined value.

Tying to an already-opened filehandle

If $fh is a filehandle, such as is returned by IO::File or one of the other IO modules, you may use:

```
tie @array, 'Tie::File', $fh, ...;
```

Similarly if you opened that handle FH with regular open or sysopen, you may use:

```
tie @array, 'Tie::File', \*FH, ...;
```

Handles that were opened write-only won’t work. Handles that were opened read-only will work as long as you don’t try to modify the array. Handles must be attached to seekable sources of data—that means no pipes or sockets. If Tie::File can detect that you supplied a non-seekable handle, the tie call will throw an exception. (On Unix systems, it can detect this.)

Note that Tie::File will only close any filehandles that it opened internally. If you passed it a filehandle as above, you “own” the filehandle, and are responsible for closing it after you have untied the @array.

Tie::File calls binmode on filehandles that it opens internally, but not on filehandles passed in by the user. For consistency, especially if using the tied files cross-platform, you may wish to call binmode on the filehandle prior to tying the file.

Deferred Writing

(This is an advanced feature. Skip this section on first reading.)

Normally, modifying a Tie::File array writes to the underlying file immediately. Every assignment like $a[3] = ... rewrites as much of the file as is necessary; typically, everything from line 3 through the end will need to be rewritten. This is the simplest and most transparent behavior. Performance even for large files is reasonably good.

However, under some circumstances, this behavior may be excessively slow. For example, suppose you have a million-record file, and you want to do:

```
for (@FILE) {
  $_ = "> $_";
}
```

The first time through the loop, you will rewrite the entire file, from line 0 through the end. The second time through the loop, you will rewrite the entire file from line 1 through the end. The third time through the loop, you will rewrite the entire file from line 2 to the end. And so on.

If the performance in such cases is unacceptable, you may defer the actual writing, and then have it done all at once. The following loop will perform much better for large files:

```
(tied @a)->defer;
for (@a) {
  $_ = "> $_";
}
(tied @a)->flush;
```

If `Tie::File`'s memory limit is large enough, all the writing will done in memory. Then, when you call `->flush`, the entire file will be rewritten in a single pass.

(Actually, the preceding discussion is something of a fib. You don't need to enable deferred writing to get good performance for this common case, because `Tie::File` will do it for you automatically unless you specifically tell it not to. See "Autodeferring", below.)

Calling `->flush` returns the array to immediate-write mode. If you wish to discard the deferred writes, you may call `->discard` instead of `->flush`. Note that in some cases, some of the data will have been written already, and it will be too late for `->discard` to discard all the changes. Support for `->discard` may be withdrawn in a future version of `Tie::File`.

Deferred writes are cached in memory up to the limit specified by the `dw_size` option (see above). If the deferred-write buffer is full and you try to write still more deferred data, the buffer will be flushed. All buffered data will be written immediately, the buffer will be emptied, and the now-empty space will be used for future deferred writes.

If the deferred-write buffer isn't yet full, but the total size of the buffer and the read cache would exceed the `memory` limit, the oldest records will be expired from the read cache until the total size is under the limit.

`push`, `pop`, `shift`, `unshift`, and `splice` cannot be deferred. When you perform one of these operations, any deferred data is written to the file and the operation is performed immediately. This may change in a future version.

If you resize the array with deferred writing enabled, the file will be resized immediately, but deferred records will not be written. This has a surprising consequence: `@a = (...)` erases the file immediately, but the writing of the actual data is deferred. This might be a bug. If it is a bug, it will be fixed in a future version.

Autodeferring

`Tie::File` tries to guess when deferred writing might be helpful, and to turn it on and off automatically.

```
for (@a) {
  $_ = "> $_";
}
```

In this example, only the first two assignments will be done immediately; after this, all the changes to the file will be deferred up to the user-specified memory limit.

You should usually be able to ignore this and just use the module without thinking about deferring. However, special applications may require fine control over which writes are deferred, or may require that all writes be immediate. To disable the autodeferment feature, use

```
(tied @o)->autodefer(0);
```

or

```
tie @array, 'Tie::File', $file, autodefer => 0;
```

Similarly, `->autodefer(1)` re-enables autodeferment, and `->autodefer()` recovers the current value of the autodefer setting.

CONCURRENT ACCESS TO FILES

Caching and deferred writing are inappropriate if you want the same file to be accessed simultaneously from more than one process. Other optimizations performed internally by this module are also incompatible with concurrent access. A future version of this module will support a `concurrent => 1` option that enables safe concurrent access.

Previous versions of this documentation suggested using `memory => 0` for safe concurrent access. This was mistaken. Tie::File will not support safe concurrent access before version 0.96.

CAVEATS

(That's Latin for 'warnings'.)

- Reasonable effort was made to make this module efficient. Nevertheless, changing the size of a record in the middle of a large file will always be fairly slow, because everything after the new record must be moved.
- The behavior of tied arrays is not precisely the same as for regular arrays. For example:

  ```
  # This DOES print "How unusual!"
  undef $a[10];  print "How unusual!\n" if defined $a[10];
  ```

  `undef`-ing a `Tie::File` array element just blanks out the corresponding record in the file. When you read it back again, you'll get the empty string, so the supposedly-`undef`'ed value will be defined. Similarly, if you have `autochomp` disabled, then

  ```
  # This DOES print "How unusual!" if 'autochomp' is disabled
  undef $a[10];
  print "How unusual!\n" if $a[10];
  ```

  Because when `autochomp` is disabled, `$a[10]` will read back as `"\n"` (or whatever the record separator string is.)

There are other minor differences, particularly regarding `exists` and `delete`, but in general, the correspondence is extremely close.

- I have supposed that since this module is concerned with file I/O, almost all normal use of it will be heavily I/O bound. This means that the time to maintain complicated data structures inside the module will be dominated by the time to actually perform the I/O. When there was an opportunity to spend CPU time to avoid doing I/O, I usually tried to take it.
- You might be tempted to think that deferred writing is like transactions, with `flush` as `commit` and `discard` as `rollback`, but it isn't, so don't.
- There is a large memory overhead for each record offset and for each cache entry: about 310 bytes per cached data record, and about 21 bytes per offset table entry.

  The per-record overhead will limit the maximum number of records you can access per file. Note that *accessing* the length of the array via `$x = scalar @tied_file` accesses **all** records and stores their offsets. The same for `foreach (@tied_file)`, even if you exit the loop early.

SUBCLASSING

This version promises absolutely nothing about the internals, which may change without notice. A future version of the module will have a well-defined and stable subclassing API.

WHAT ABOUT DB_File?

People sometimes point out that *DB_File* will do something similar, and ask why `Tie::File` module is necessary.

There are a number of reasons that you might prefer `Tie::File`. A list is available at `http://perl.plover.com/TieFile/why-not-DB_File`.

THANKS

Gigantic thanks to Jarkko Hietaniemi, for agreeing to put this in the core when I hadn't written it yet, and for generally being helpful, supportive, and competent. (Usually the rule is "choose any one.") Also big thanks to Abhijit Menon-Sen for all of the same things.

Special thanks to Craig Berry and Peter Prymmer (for VMS portability help), Randy Kobes (for Win32 portability help), Clinton Pierce and Autrijus Tang (for heroic eleventh-hour Win32 testing above and beyond the call of duty), Michael G Schwern (for testing advice), and the rest of the CPAN testers (for testing generally).

Special thanks to Tels for suggesting several speed and memory optimizations.

Additional thanks to: Edward Avis / Mattia Barbon / Tom Christiansen / Gerrit Haase / Gurusamy Sarathy / Jarkko Hietaniemi (again) / Nikola Knezevic / John Kominetz / Nick Ing-Simmons / Tassilo von Parseval / H. Dieter Pearcey / Slaven Rezic / Eric Roode / Peter Scott / Peter Somu / Autrijus Tang (again) / Tels (again) / Juerd Waalboer / Todd Rinaldo

TODO

More tests. (Stuff I didn't think of yet.)

Paragraph mode?

Fixed-length mode. Leave-blanks mode.

Maybe an autolocking mode?

For many common uses of the module, the read cache is a liability. For example, a program that inserts a single record, or that scans the file once, will have a cache hit rate of zero. This suggests a major optimization: The cache should be initially disabled. Here's a hybrid approach: Initially, the cache is disabled, but the cache code maintains statistics about how high the hit rate would be *if* it were enabled. When it sees the hit rate

get high enough, it enables itself. The STAT comments in this code are the beginning of an implementation of this.

Record locking with fcntl()? Then the module might support an undo log and get real transactions. What a tour de force that would be.

Keeping track of the highest cached record. This would allow reads-in-a-row to skip the cache lookup faster (if reading from 1..N with empty cache at start, the last cached value will be always N-1).

More tests.

Tie::Handle

base class definitions for tied handles

SYNOPSIS

```
package NewHandle;
require Tie::Handle;

@ISA = qw(Tie::Handle);

sub READ { ... }            # Provide a needed method
sub TIEHANDLE { ... }       # Overrides inherited method

package main;

tie *FH, 'NewHandle';
```

DESCRIPTION

This module provides some skeletal methods for handle-tying classes. See perltie for a list of the functions required in tying a handle to a package. The basic **Tie::Handle** package provides a new method, as well as methods `TIEHANDLE`, `PRINT`, `PRINTF` and `GETC`.

For developers wishing to write their own tied-handle classes, the methods are summarized below. The perltie section not only documents these, but has sample code as well:

- TIEHANDLE classname, LIST

  The method invoked by the command `tie *glob, classname`. Associates a new glob instance with the specified class. `LIST` would represent additional arguments (along the lines of *AnyDBM_File* and compatriots) needed to complete the association.

- WRITE this, scalar, length, offset

  Write *length* bytes of data from *scalar* starting at *offset*.

- PRINT this, LIST

Print the values in *LIST*

- PRINTF this, format, LIST

  Print the values in *LIST* using *format*

- READ this, scalar, length, offset

  Read *length* bytes of data into *scalar* starting at *offset*.

- READLINE this

  Read a single line

- GETC this

  Get a single character

- CLOSE this

  Close the handle

- OPEN this, filename

  (Re-)open the handle

- BINMODE this

  Specify content is binary

- EOF this

  Test for end of file.

- TELL this

  Return position in the file.

- SEEK this, offset, whence

  Position the file.

  Test for end of file.

- DESTROY this

  Free the storage associated with the tied handle referenced by *this*. This is rarely needed, as Perl manages its memory quite well. But the option exists, should a class wish to perform specific actions upon the destruction of an instance.

MORE INFORMATION

The perltie section contains an example of tying handles.

COMPATIBILITY

This version of Tie::Handle is neither related to nor compatible with the Tie::Handle (3.0) module available on CPAN. It was due to an accident that two modules with the same name appeared. The namespace clash has been cleared in favor of this module that comes with the perl core in September 2000 and accordingly the version number has been bumped up to 4.0.

Tie::Hash

base class definitions for tied hashes

SYNOPSIS

```
package NewHash;
require Tie::Hash;

@ISA = qw(Tie::Hash);

sub DELETE { ... }          # Provides needed method
sub CLEAR { ... }           # Overrides inherited method

package NewStdHash;
require Tie::Hash;

@ISA = qw(Tie::StdHash);

# All methods provided by default, define
# only those needing overrides
# Accessors access the storage in %{$_[0]};
# TIEHASH should return a reference to the actual storage
sub DELETE { ... }

package NewExtraHash;
require Tie::Hash;

@ISA = qw(Tie::ExtraHash);

# All methods provided by default, define
# only those needing overrides
# Accessors access the storage in %{$_[0][0]};
# TIEHASH should return an array reference with the first element
# being the reference to the actual storage
sub DELETE {
  $_[0][1]->('del', $_[0][0], $_[1]); # Call the report writer
  delete $_[0][0]->{$_[1]};           #  $_[0]->SUPER::DELETE($_[1])
}

package main;

tie %new_hash, 'NewHash';
tie %new_std_hash, 'NewStdHash';
tie %new_extra_hash, 'NewExtraHash',
    sub {warn "Doing \U$_[1]\E of $_[2].\n"};
```

DESCRIPTION

This module provides some skeletal methods for hash-tying classes. See perltie for a list of the functions required in order to tie a hash to a package. The basic **Tie::Hash** package provides a new method, as well as methods TIEHASH, EXISTS and CLEAR. The **Tie::StdHash** and **Tie::ExtraHash** packages provide most methods for hashes described in perltie (the exceptions are UNTIE and DESTROY). They cause tied hashes to behave exactly like standard hashes, and allow for selective overwriting of methods. **Tie::Hash** has legacy support for the new method: it is used if TIEHASH is not defined in the case a class forgets to include a TIEHASH method.

For developers wishing to write their own tied hashes, the required methods are briefly defined below. See the perltie section for more detailed descriptive, as well as example code:

- TIEHASH classname, LIST

  The method invoked by the command `tie %hash, classname`. Associates a new hash instance with the specified class. LIST would represent additional arguments (along the lines of *AnyDBM_File* and compatriots) needed to complete the association.

- STORE this, key, value

  Store datum *value* into *key* for the tied hash *this*.

- FETCH this, key

  Retrieve the datum in *key* for the tied hash *this*.

- FIRSTKEY this

  Return the first key in the hash.

- NEXTKEY this, lastkey

  Return the next key in the hash.

- EXISTS this, key

  Verify that *key* exists with the tied hash *this*.

  The **Tie::Hash** implementation is a stub that simply croaks.

- DELETE this, key

  Delete the key *key* from the tied hash *this*.

- CLEAR this

  Clear all values from the tied hash *this*.

- SCALAR this

  Returns what evaluating the hash in scalar context yields.

  Tie::Hash does not implement this method (but **Tie::StdHash** and **Tie::ExtraHash** do).

Inheriting from Tie::StdHash

The accessor methods assume that the actual storage for the data in the tied hash is in the hash referenced by `tied(%tiedhash)`. Thus overwritten `TIEHASH` method should return a hash reference, and the remaining methods should operate on the hash referenced by the first argument:

```
package ReportHash;
our @ISA = 'Tie::StdHash';

sub TIEHASH  {
  my $storage = bless {}, shift;
  warn "New ReportHash created, stored in $storage.\n";
  $storage
}
sub STORE    {
  warn "Storing data with key $_[1] at $_[0].\n";
  $_[0]{$_[1]} = $_[2]
}
```

Inheriting from Tie::ExtraHash

The accessor methods assume that the actual storage for the data in the tied hash is in the hash referenced by `(tied(%tiedhash))->[0]`. Thus overwritten `TIEHASH` method should return an array reference with the first element being a hash reference, and the remaining methods should operate on the hash `%{ $_[0]->[0] }`:

```
package ReportHash;
our @ISA = 'Tie::ExtraHash';

sub TIEHASH  {
  my $class = shift;
  my $storage = bless [{}, @_], $class;
  warn "New ReportHash created, stored in $storage.\n";
  $storage;
}
sub STORE    {
  warn "Storing data with key $_[1] at $_[0].\n";
  $_[0][0]{$_[1]} = $_[2]
}
```

The default `TIEHASH` method stores "extra" arguments to tie() starting from offset 1 in the array referenced by `tied(%tiedhash)`; this is the same storage algorithm as in TIEHASH subroutine above. Hence, a typical package inheriting from **Tie::ExtraHash** does not need to overwrite this method.

SCALAR, UNTIE and DESTROY

The methods `UNTIE` and `DESTROY` are not defined in **Tie::Hash**, **Tie::StdHash**, or **Tie::ExtraHash**. Tied hashes do not require presence of these methods, but if defined, the methods will be called in proper time, see perltie.

SCALAR is only defined in **Tie::StdHash** and **Tie::ExtraHash**.

If needed, these methods should be defined by the package inheriting from **Tie::Hash**, **Tie::StdHash**, or **Tie::ExtraHash**. See "SCALAR" in perltie to find out what happens when SCALAR does not exist.

MORE INFORMATION

The packages relating to various DBM-related implementations (DB_File, NDBM_File, etc.) show examples of general tied hashes, as does the *Config* module. While these do not utilize **Tie::Hash**, they serve as good working examples.

Modules

- Tie::Hash::Indexed - a hash that keeps its keys in insertion order
- Tie::Hash::NamedCapture - Named regexp capture buffers

Tie::Hash::Indexed

Tie::Hash::Indexed - a hash that keeps its keys in insertion order.

```
use Tie::Hash::Indexed;

tie my %h, 'Tie::Hash::Indexed';
%h = (one => 1, two => 2, three => 3);
print join(' ', keys %h), "\n";           # one two three

my $h = Tie::Hash::Indexed->new(a => 1, b => 2);
$h->push(c => 3);
$h->unshift(z => 0);
print join(' ', $h->keys), "\n";          # z a b c
my ($key, $value) = $h->pop;              # c 3
```

The module works as a tied hash and as an object. The object interface is the faster of the two: it has get, set, exists, delete and clear; keys, values and items (all of them, or those of the keys given); push, unshift, pop and shift for the two ends; merge and assign; and the in-place operators preinc, postinc, predec, postdec, add, subtract, multiply, divide, modulo, concat, or_assign and dor_assign.

Storing to a key that exists keeps its position; push and unshift move it to that end. Deleting a key takes the same time whatever the size of the hash.

iterator and reverse_iterator return an iterator object with next, prev, valid, key and value. An iterator dies with "invalid iterator access" once the hash was changed after it was made.

Objects can be frozen, thawed and cloned with Storable.

This is a native implementation of the CPAN module Tie::Hash::Indexed 0.08; its Indexed.pm is used unchanged.

Differences from upstream

Three, each where perl 5.44 with the XS module reads memory it has freed or a null pointer:

- pop or `shift` of the entry an `each` loop stands on: the loop continues with the next entry, as it does after `delete`.
- `clear`, `assign` or `%h = ()` in the middle of an `each` loop called through `NEXTKEY` directly: the loop ends.
- `NEXTKEY` on an object `FIRSTKEY` was never called on returns the first key.

Modules

- `Tie::Hash::Indexed::Iterator`

Functions

Other Functions

new

`TIEHASH`, `new`: a new hash holding the key/value pairs given.

get

`FETCH`, `get`: the value of a key, undef if there is none.

set

`STORE`, `set`: store a value. A new key goes to the end, an existing one keeps its place. `set` returns the value.

exists

`EXISTS`, `exists`, `has`: whether the hash has the key.

Also available as `Tie::Hash::Indexed::has`.

delete

`DELETE`, `delete`: remove a key and return its value, undef if there was none.

clear

`CLEAR`, `clear`: remove everything. `clear` returns the object.

items

`items`, `as_list`, `keys`, `values`: all entries in order, or those of the keys given (undef for a value that is not there). In scalar context the number of elements the list would have.

Also available as `Tie::Hash::Indexed::as_list`, `Tie::Hash::Indexed::keys`, `Tie::Hash::Indexed::values`.

merge

`merge`, `assign`, `push`, `unshift`: store key/value pairs. `merge` leaves an existing key in place; `assign` clears the hash first; `push` and `unshift` put every pair at that end, moving a key that exists. Returns the number of keys.

Also available as `Tie::Hash::Indexed::assign`, `Tie::Hash::Indexed::push`, `Tie::Hash::Indexed::unshift`.

pop

`pop`, `shift`: remove the last or the first entry. Returns its key and value in list context, its value otherwise, nothing when the hash is empty.

Also available as `Tie::Hash::Indexed::shift`.

iterator

`iterator`, `reverse_iterator`: an iterator standing on the first, or the last, entry.

Also available as `Tie::Hash::Indexed::reverse_iterator`.

preinc

`preinc`, `predec`, `postinc`, `postdec`: `++` and `--` on the value of a key, which starts at 0 if the key is new.

Also available as `Tie::Hash::Indexed::predec`, `Tie::Hash::Indexed::postinc`, `Tie::Hash::Indexed::postdec`.

add

`add`, `subtract`, `multiply`, `divide`, `modulo`, `concat`, `dor_assign`, `or_assign` (and `dor_equals`, `or_equals`): the assignment operator `+=`, `-=`, `*=`, `/=`, `%=`, `.=`, `//=`, `||=` on the value of a key, which starts undefined if the key is new. Returns the new value.

Also available as `Tie::Hash::Indexed::subtract`, `Tie::Hash::Indexed::multiply`, `Tie::Hash::Indexed::divide`, `Tie::Hash::Indexed::modulo`, `Tie::Hash::Indexed::concat`, `Tie::Hash::Indexed::dor_assign`, `Tie::Hash::Indexed::dor_equals`, `Tie::Hash::Indexed::or_assign`, `Tie::Hash::Indexed::or_equals`.

STORABLE_freeze

STORABLE_freeze: Storable's hook. The frozen form is a six-byte header and a reference to every key and value, in order.

STORABLE_thaw

STORABLE_thaw: Storable's hook, the inverse of STORABLE_freeze.

Tie::Hash::Indexed::Iterator

Functions

Other Functions

next

next, prev: in list context the key and value the iterator stands on (nothing at the end); then it moves one entry on, or back.

Also available as Tie::Hash::Indexed::Iterator::prev.

valid

valid: true while the hash is unchanged and the iterator is not at the end.

key

key, value: of the entry the iterator stands on; undef at the end.

Also available as Tie::Hash::Indexed::Iterator::value.

Tie::Hash::NamedCapture

Named regexp capture buffers

SYNOPSIS

```
tie my %hash, "Tie::Hash::NamedCapture";
# %hash now behaves like %+

tie my %hash, "Tie::Hash::NamedCapture", all => 1;
# %hash now access buffers from regexp in $qr like %-
```

DESCRIPTION

This module is used to implement the special hashes %+ and %-, but it can be used to tie other variables as you choose.

When the all parameter is provided, then the tied hash elements will be array refs listing the contents of each capture buffer whose name is the same as the associated

hash key. If none of these buffers were involved in the match, the contents of that array ref will be as many `undef` values as there are capture buffers with that name. In other words, the tied hash will behave as `%-`.

When the `all` parameter is omitted or false, then the tied hash elements will be the contents of the leftmost defined buffer with the name of the associated hash key. In other words, the tied hash will behave as `%+`.

The keys of `%-`-like hashes correspond to all buffer names found in the regular expression; the keys of `%+`-like hashes list only the names of buffers that have captured (and that are thus associated to defined values).

This implementation has been moved into the core executable, but you can still load this module for backward compatibility.

Tie::Memoize

add data to hash when needed

SYNOPSIS

```
require Tie::Memoize;
tie %hash, 'Tie::Memoize',
    \&fetch,                  # The rest is optional
    $DATA, \&exists,
    {%ini_value}, {%ini_existence};
```

DESCRIPTION

This package allows a tied hash to autoload its values on the first access, and to use the cached value on the following accesses.

Only read-accesses (via fetching the value or `exists`) result in calls to the functions; the modify-accesses are performed as on a normal hash.

The required arguments during `tie` are the hash, the package, and the reference to the `FETCH`ing function. The optional arguments are an arbitrary scalar `$data`, the reference to the `EXISTS` function, and initial values of the hash and of the existence cache.

Both the `FETCH`ing function and the `EXISTS` functions have the same signature: the arguments are `$key, $data`; `$data` is the same value as given as argument during tie()ing. Both functions should return an empty list if the value does not exist. If `EXISTS` function is different from the `FETCH`ing function, it should return a TRUE value on success. The `FETCH`ing function should return the intended value if the key is valid.

Inheriting from Tie::Memoize

The structure of the tied() data is an array reference with elements

```
0:  cache of known values
1:  cache of known existence of keys
2:  FETCH  function
3:  EXISTS function
4:  $data
```

The rest is for internal usage of this package. In particular, if TIEHASH is overwritten, it should call SUPER::TIEHASH.

EXAMPLE

```
sub slurp {
  my ($key, $dir) = @_;
  open my $h, '<', "$dir/$key" or return;
  local $/; <$h>                        # slurp it all
}
sub exists { my ($key, $dir) = @_; return -f "$dir/$key" ? 1 : () }

tie %hash, 'Tie::Memoize', \&slurp, $directory, \&exists,
    { fake_file1 => $content1, fake_file2 => $content2 },
    { pretend_does_not_exists => 0, known_to_exist => 1 };
```

This example treats the slightly modified contents of $directory as a hash. The modifications are that the keys `fake_file1` and `fake_file2` fetch values $content1 and $content2, and `pretend_does_not_exists` will never be accessed. Additionally, the existence of `known_to_exist` is never checked (so if it does not exists when its content is needed, the user of %hash may be confused).

BUGS

FIRSTKEY and NEXTKEY methods go through the keys which were already read, not all the possible keys of the hash.

Tie::RefHash

Use references as hash keys

VERSION

version 1.41

SYNOPSIS

```
require 5.004;
use Tie::RefHash;
tie HASHVARIABLE, 'Tie::RefHash', LIST;
tie HASHVARIABLE, 'Tie::RefHash::Nestable', LIST;

untie HASHVARIABLE;
```

DESCRIPTION

This module provides the ability to use references as hash keys if you first `tie` the hash variable to this module. Normally, only the keys of the tied hash itself are preserved as references; to use references as keys in hashes-of-hashes, use Tie::RefHash::Nestable, included as part of Tie::RefHash.

It is implemented using the standard perl TIEHASH interface. Please see the `tie` entry in perlfunc(1) and perltie(1) for more information.

The Nestable version works by looking for hash references being stored and converting them to tied hashes so that they too can have references as keys. This will happen without warning whenever you store a reference to one of your own hashes in the tied hash.

EXAMPLE

```
use Tie::RefHash;
tie %h, 'Tie::RefHash';
$a = [];
$b = {};
$c = \*main;
$d = \"gunk";
$e = sub { 'foo' };
%h = ($a => 1, $b => 2, $c => 3, $d => 4, $e => 5);
$a->[0] = 'foo';
$b->{foo} = 'bar';
for (keys %h) {
   print ref($_), "\n";
}

tie %h, 'Tie::RefHash::Nestable';
$h{$a}->{$b} = 1;
for (keys %h, keys %{$h{$a}}) {
   print ref($_), "\n";
}
```

THREAD SUPPORT

Tie::RefHash fully supports threading using the `CLONE` method.

STORABLE SUPPORT

Storable hooks are provided for semantically correct serialization and cloning of tied refhashes.

SEE ALSO

Tie::Scalar

base class definitions for tied scalars

SYNOPSIS

```
package NewScalar;
require Tie::Scalar;

@ISA = qw(Tie::Scalar);

sub FETCH { ... }           # Provide a needed method
sub TIESCALAR { ... }       # Overrides inherited method

package NewStdScalar;
require Tie::Scalar;

@ISA = qw(Tie::StdScalar);

# All methods provided by default, so define
# only what needs be overridden
sub FETCH { ... }

package main;

tie $new_scalar, 'NewScalar';
tie $new_std_scalar, 'NewStdScalar';
```

DESCRIPTION

This module provides some skeletal methods for scalar-tying classes. See perltie for a list of the functions required in tying a scalar to a package. The basic **Tie::Scalar** package provides a new method, as well as methods TIESCALAR, FETCH and STORE. The **Tie::StdScalar** package provides all the methods specified in perltie. It inherits from **Tie::Scalar** and causes scalars tied to it to behave exactly like the built-in scalars, allowing for selective overloading of methods. The new method is provided as a means of legacy support for classes that forget to provide their own TIESCALAR method.

For developers wishing to write their own tied-scalar classes, the methods are summarized below. The perltie section not only documents these, but has sample code as well:

- TIESCALAR classname, LIST

  The method invoked by the command `tie $scalar, classname`. Associates a new scalar instance with the specified class. LIST would represent additional arguments (along the lines of *AnyDBM_File* and compatriots) needed to complete the association.

- FETCH this

  Retrieve the value of the tied scalar referenced by *this*.

- STORE this, value

  Store data *value* in the tied scalar referenced by *this*.

- DESTROY this

Free the storage associated with the tied scalar referenced by *this*. This is rarely needed, as Perl manages its memory quite well. But the option exists, should a class wish to perform specific actions upon the destruction of an instance.

Tie::Scalar vs Tie::StdScalar

`Tie::Scalar` provides all the necessary methods, but one should realize they do not do anything useful. Calling `Tie::Scalar::FETCH` or `Tie::Scalar::STORE` results in a (trappable) croak. And if you inherit from `Tie::Scalar`, you *must* provide either a `new` or a `TIESCALAR` method.

If you are looking for a class that does everything for you that you don't define yourself, use the `Tie::StdScalar` class, not the `Tie::Scalar` one.

MORE INFORMATION

The perltie section uses a good example of tying scalars by associating process IDs with priority.

Tie::StdHandle

base class definitions for tied handles

SYNOPSIS

```
package NewHandle;
require Tie::Handle;

@ISA = qw(Tie::Handle);

sub READ { ... }             # Provide a needed method
sub TIEHANDLE { ... }        # Overrides inherited method

package main;

tie *FH, 'NewHandle';
```

DESCRIPTION

The **Tie::StdHandle** package provide most methods for file handles described in perltie (the exceptions are `UNTIE` and `DESTROY`). It causes tied file handles to behave exactly like standard file handles and allow for selective overwriting of methods.

Tie::SubstrHash

Fixed-table-size, fixed-key-length hashing

SYNOPSIS

```
require Tie::SubstrHash;

tie %myhash, 'Tie::SubstrHash', $key_len, $value_len, $table_size;
```

DESCRIPTION

The **Tie::SubstrHash** package provides a hash-table-like interface to an array of determinate size, with constant key size and record size.

Upon tying a new hash to this package, the developer must specify the size of the keys that will be used, the size of the value fields that the keys will index, and the size of the overall table (in terms of key-value pairs, not size in hard memory). *These values will not change for the duration of the tied hash.* The newly-allocated hash table may now have data stored and retrieved. Efforts to store more than `$table_size` elements will result in a fatal error, as will efforts to store a value not exactly `$value_len` characters in length, or reference through a key not exactly `$key_len` characters in length. While these constraints may seem excessive, the result is a hash table using much less internal memory than an equivalent freely-allocated hash table.

CAVEATS

Because the current implementation uses the table and key sizes for the hashing algorithm, there is no means by which to dynamically change the value of any of the initialization parameters.

The hash does not support exists().

5.2.106 Time

Namespace containing the following modules:

- `Time::HiRes` - High-resolution timers and sleeps: microsecond `gettimeofday`, sub-second `sleep`, `alarm`, and POSIX clocks.
- `Time::Local` - Efficiently compute time from local and GMT time
- `Time::Piece` - Date and time objects: `use Time::Piece` makes `localtime` and `gmtime` return an object with accessors for every field, formatting and parsing, comparison, and arithmetic with the durations of `Time::Seconds`.
- `Time::Seconds` - a simple API to convert seconds to other date values
- `Time::gmtime` - by-name interface to Perl's built-in gmtime() function
- `Time::localtime` - by-name interface to Perl's built-in localtime() function
- `Time::tm` - internal object used by Time::gmtime and Time::localtime

Time::HiRes

High-resolution timers and sleeps: microsecond `gettimeofday`, sub-second `sleep`, `alarm`, and POSIX clocks.

Where the built-in `time`, `sleep` and `alarm` work in whole seconds, these take and return fractional ones. Use `clock_gettime` with `CLOCK_MONOTONIC` to measure an elapsed interval: it cannot jump backwards the way wall-clock time can.

This is Time::HiRes 1.978; `Time/HiRes.pm` is upstream's. Nothing is exported by default; `use Time::HiRes qw(time sleep alarm)` replaces the built-ins in the importing package.

Synopsis

```
use Time::HiRes qw(time sleep gettimeofday tv_interval clock_gettime␣
↪CLOCK_MONOTONIC);

my $t0 = time;                          # e.g. 1700000000.123456
sleep 0.25;                             # a quarter of a second
printf "%.2f\n", time - $t0;            # about 0.25

my @start = gettimeofday;               # (seconds, microseconds)
my $elapsed = tv_interval(\@start);     # seconds since then, as a␣
↪float

my $m0 = clock_gettime(CLOCK_MONOTONIC);    # for intervals: never␣
↪jumps back
my $dt = clock_gettime(CLOCK_MONOTONIC) - $m0;
```

`tv_interval($start, $end)` (written in Perl) is the time between two `gettimeofday` pairs, `$end` defaulting to now. The clock constants (`CLOCK_REALTIME`, `CLOCK_MONOTONIC`, `CLOCK_PROCESS_CPUTIME_ID`, ...) and `ITIMER_REAL`/`ITIMER_VIRTUAL`/`ITIMER_PROF` for `setitimer` are exported on request.

Differences from upstream

None: upstream's tests pass unchanged (t/81-xs-native/Time-HiRes, the `upstream` files), and the rest there checks against perl 5.44.

Functions

Other Functions

time

Return the current epoch time as a float, with sub-second precision.

gettimeofday

Return the current time as `($seconds, $microseconds)`.

usleep

Sleep for the given number of MICROseconds.

nanosleep

Sleep for the given number of NANOseconds.

sleep

Sleep for a possibly fractional number of seconds.

alarm

Schedule a `SIGALRM` after a possibly fractional delay.

ualarm

Schedule a `SIGALRM` after a delay given in MICROseconds.

setitimer

Arm one of the interval timers (`ITIMER_REAL` and friends).

getitimer

Return an interval timer's current `($value, $interval)` without changing it.

clock_gettime

Read the named POSIX clock, returning the time as a float.

clock_getres

Return the resolution of the named POSIX clock, in seconds.

clock

Return processor time consumed by this process, in seconds.

clock_nanosleep

Sleep against a named POSIX clock, in nanoseconds.

utime

Set access and modification times on files, with sub-second precision.

stat

The built-in `stat`, with the access, modification and change times (elements 8, 9 and 10) in fractional seconds, as precise as the file system keeps them. Takes a file name or a filehandle, `$_` when omitted; returns the empty list for a file that cannot be stat'ed, with `$!` set.

lstat

`stat` for a symbolic link itself rather than what it points to, as the built-in `lstat`, with fractional times.

tv_interval

`tv_interval(\@t0, \@t1?)` - pure Perl in `HiRes.pm`

Time::Local

Efficiently compute time from local and GMT time

VERSION

version 1.35

SYNOPSIS

```
use Time::Local qw( timelocal_posix timegm_posix );

my $time = timelocal_posix( $sec, $min, $hour, $mday, $mon, $year );
my $time = timegm_posix( $sec, $min, $hour, $mday, $mon, $year );
```

DESCRIPTION

This module provides functions that are the inverse of built-in perl functions `localtime()` and `gmtime()`. They accept a date as a six-element array, and return the corresponding `time(2)` value in seconds since the system epoch (Midnight, January 1, 1970 GMT on Unix, for example). This value can be positive or negative, though POSIX only requires support for positive values, so dates before the system's epoch may not work on all operating systems.

It is worth drawing particular attention to the expected ranges for the values provided. The value for the day of the month is the actual day (i.e. 1..31), while the month is the number of months since January (0..11). This is consistent with the values returned from `localtime()` and `gmtime()`.

FUNCTIONS

`timelocal_posix()` and `timegm_posix()`

Since version 1.30.

These functions are the exact inverse of Perl's built-in `localtime` and `gmtime` functions. That means that calling `timelocal_posix( localtime($value) )` will always give you the same `$value` you started with. The same applies to `timegm_posix( gmtime($value) )`.

The one exception is when the value returned from `localtime()` represents an ambiguous local time because of a DST change. See the documentation below for more details.

These functions expect the year value to be the number of years since 1900, which is what the `localtime()` and `gmtime()` built-ins returns.

They perform range checking by default on the input `$sec`, `$min`, `$hour`, `$mday`, and `$mon` values and will croak (using `Carp::croak()`) if given a value outside the allowed ranges.

While it would be nice to make this the default behavior, that would almost certainly break a lot of code, so you must explicitly import these functions and use them instead of the default `timelocal()` and `timegm()`.

You are **strongly** encouraged to use these functions in any new code which uses this module. It will almost certainly make your code's behavior less surprising.

`timelocal_modern()` and `timegm_modern()`

Since version 1.27.

When `Time::Local` was first written, it was a common practice to represent years as a two-digit value like `99` for `1999` or `1` for `2001`. This caused all sorts of problems (google "Y2K problem" if you're very young) and developers eventually realized that this was a terrible idea.

The default exports of `timelocal()` and `timegm()` do a complicated calculation when given a year value less than 1000. This leads to surprising results in many cases. See "Year Value Interpretation" for details.

The `time*_modern()` functions do not do this year munging and simply take the year value as provided.

They perform range checking by default on the input `$sec`, `$min`, `$hour`, `$mday`, and `$mon` values and will croak (using `Carp::croak()`) if given a value outside the allowed ranges.

`timelocal()` and `timegm()`

This module exports two functions by default, `timelocal()` and `timegm()`.

They perform range checking by default on the input `$sec`, `$min`, `$hour`, `$mday`, and `$mon` values and will croak (using `Carp::croak()`) if given a value outside the allowed ranges.

Warning: The year value interpretation that these functions and their nocheck variants use will almost certainly lead to bugs in your code, if not now, then in the future. You are strongly discouraged from using these in new code, and you should convert old code to using either the `*_posix` or `*_modern` functions if possible.

`timelocal_nocheck()` and `timegm_nocheck()`

If you are working with data you know to be valid, you can use the "nocheck" variants, `timelocal_nocheck()` and `timegm_nocheck()`. These variants must be explicitly imported.

If you supply data which is not valid (month 27, second 1,000) the results will be unpredictable (so don't do that).

Note that my benchmarks show that this is just a 3% speed increase over the checked versions, so unless calling `Time::Local` is the hottest spot in your application, using these nocheck variants is unlikely to have much impact on your application.

Year Value Interpretation

This does not apply to the `*_posix` or `*_modern` functions. Use those exports if you want to ensure consistent behavior as your code ages.

Strictly speaking, the year should be specified in a form consistent with `localtime()`, i.e. the offset from 1900. In order to make the interpretation of the year easier for humans, however, who are more accustomed to seeing years as two-digit or four-digit values, the following conventions are followed:

- Years greater than 999 are interpreted as being the actual year, rather than the offset from 1900. Thus, 1964 would indicate the year Martin Luther King won the Nobel prize, not the year 3864.
- Years in the range 100..999 are interpreted as offset from 1900, so that 112 indicates 2012. This rule also applies to years less than zero (but see note below regarding date range).
- Years in the range 0..99 are interpreted as shorthand for years in the rolling "current century," defined as 50 years on either side of the current year. Thus, today, in 1999, 0 would refer to 2000, and 45 to 2045, but 55 would refer to 1955. Twenty years from now, 55 would instead refer to 2055. This is messy, but matches the way people currently think about two digit dates. Whenever possible, use an absolute four digit year instead.

The scheme above allows interpretation of a wide range of dates, particularly if 4-digit years are used. But it also means that the behavior of your code changes as time passes, because the rolling "current century" changes each year.

Limits of time_t

On perl versions older than 5.12.0, the range of dates that can be actually be handled depends on the size of `time_t` (usually a signed integer) on the given platform. Currently, this is 32 bits for most systems, yielding an approximate range from Dec 1901 to Jan 2038.

Both `timelocal()` and `timegm()` croak if given dates outside the supported range.

As of version 5.12.0, perl has stopped using the time implementation of the operating system it's running on. Instead, it has its own implementation of those routines with a safe range of at least +/- 2**52 (about 142 million years)

Ambiguous Local Times (DST)

Because of DST changes, there are many time zones where the same local time occurs for two different GMT times on the same day. For example, in the "Europe/Paris" time zone, the local time of 2001-10-28 02:30:00 can represent either 2001-10-28 00:30:00 GMT, **or** 2001-10-28 01:30:00 GMT.

When given an ambiguous local time, the timelocal() function will always return the epoch for the *earlier* of the two possible GMT times.

Non-Existent Local Times (DST)

When a DST change causes a locale clock to skip one hour forward, there will be an hour's worth of local times that don't exist. Again, for the "Europe/Paris" time zone, the local clock jumped from 2001-03-25 01:59:59 to 2001-03-25 03:00:00.

If the `timelocal()` function is given a non-existent local time, it will simply return an epoch value for the time one hour later.

Negative Epoch Values

On perl version 5.12.0 and newer, negative epoch values are fully supported.

On older versions of perl, negative epoch (`time_t`) values, which are not officially supported by the POSIX standards, are known not to work on some systems. These include MacOS (pre-OSX) and Win32.

On systems which do support negative epoch values, this module should be able to cope with dates before the start of the epoch, down the minimum value of time_t for the system.

IMPLEMENTATION

These routines are quite efficient and yet are always guaranteed to agree with `localtime()` and `gmtime()`. We manage this by caching the start times of any months we've seen before. If we know the start time of the month, we can always calculate any time within the month. The start times are calculated using a mathematical formula. Unlike other algorithms that do multiple calls to `gmtime()`.

The `timelocal()` function is implemented using the same cache. We just assume that we're translating a GMT time, and then fudge it when we're done for the timezone and daylight savings arguments. Note that the timezone is evaluated for each date because countries occasionally change their official timezones. Assuming that `localtime()` corrects for these changes, this routine will also be correct.

AUTHORS EMERITUS

This module is based on a Perl 4 library, timelocal.pl, that was included with Perl 4.036, and was most likely written by Tom Christiansen.

The current version was written by Graham Barr.

BUGS

The whole scheme for interpreting two-digit years can be considered a bug.

Bugs may be submitted at https://github.com/houseabsolute/Time-Local/issues.

There is a mailing list available for users of this distribution, mailto:datetime@perl.org.

SOURCE

The source code repository for Time-Local can be found at https://github.com/houseabsolute/Time-Local.

Time::Piece

Date and time objects: `use Time::Piece` makes `localtime` and `gmtime` return an object with accessors for every field, formatting and parsing, comparison, and arithmetic with the durations of `Time::Seconds`. In string context the object is still the familiar `scalar localtime` text (`Tue Nov 14 22:13:20 2023`).

This is Time::Piece 1.41; `Time/Piece.pm` and `Time/Seconds.pm` are upstream's. Formatting, parsing and the breaking down of an epoch run natively; parsing (`strptime`) does not depend on the system's library, so a format parses the same way everywhere.

Synopsis

```
use Time::Piece;
use Time::Seconds;

my $t = gmtime(1_700_000_000);
print $t->ymd, ' ', $t->hms, "\n";              # 2023-11-14␣
↪22:13:20
print $t->year, ' ', $t->mon, ' ', $t->monname, "\n";   # 2023 11␣
↪Nov
print $t->strftime('%A, %d %B %Y'), "\n";       # Tuesday, 14␣
↪November 2023
print $t->epoch, "\n";                          # 1700000000

my $later = $t + ONE_DAY * 3;
print $later->ymd, "\n";                        # 2023-11-17
print +($later - $t)->days, " days\n";          # 3 days
print $t->add_months(3)->ymd, "\n";             # 2024-02-14

my $p = Time::Piece->strptime('2024-02-29 12:00', '%Y-%m-%d %H:%M');
print $p->is_leap_year ? "leap\n" : "common\n"; # leap
print $p > $t ? "later\n" : "earlier\n";        # later
```

The interface

- **Making one** - `localtime($epoch)`, `gmtime($epoch)` (now without an argument), `Time::Piece->strptime($string, $format)`, and `Time::Piece->new($epoch)`.
- **Fields** - `sec`, `min`, `hour`, `mday` (`day_of_month`), `mon` (1-12), `_mon` (0-11), `monname`/`month`, `fullmonth`, `year`, `yy`, `wday` (1 = Sunday), `_wday` (0 = Sunday), `day_of_week`, `wdayname`, `fullday`, `yday` (`day_of_year`), `isdst`, `tzoffset`, `epoch`, `week` (ISO 8601), `julian_day`, `mjd`, `is_leap_year`, `month_last_day`.
- **Text** - `ymd`, `mdy`, `dmy`, `hms` (each with an optional separator), `datetime` (ISO 8601), `cdate`, `strftime($format)`.
- **Arithmetic** - `+` and `-` with seconds or a `Time::Seconds` (`ONE_DAY`, `ONE_WEEK`, `ONE_HOUR`, ...); two objects subtract to a `Time::Seconds` (`->days`, `->hours`, `->minutes`); `add_months`, `add_years`; `<`, `==`, `<=>` and `cmp` compare.
- **Locale** - `day_list`, `mon_list` and their `full` forms set or read the names `strftime` and `strptime` use; `Time::Piece::use_locale()` takes them from the current locale.

Differences from upstream

None: upstream's tests pass unchanged (t/81-xs-native/Time-Piece, the `upstream` files), and 010-050 there check formatting, parsing and the field breakdown against perl 5.44.

Time::Seconds

a simple API to convert seconds to other date values

SYNOPSIS

```
use Time::Piece;
use Time::Seconds;

my $t = localtime;
$t += ONE_DAY;

my $t2 = localtime;
my $s = $t - $t2;

print "Difference is: ", $s->days, "\n";
```

DESCRIPTION

This module is part of the Time::Piece distribution. It allows the user to find out the number of minutes, hours, days, weeks or years in a given number of seconds. It is returned by Time::Piece when you delta two Time::Piece objects.

Time::Seconds also exports the following constants:

```
ONE_DAY
ONE_WEEK
ONE_HOUR
ONE_MINUTE
ONE_MONTH
ONE_YEAR
ONE_FINANCIAL_MONTH
LEAP_YEAR
NON_LEAP_YEAR
```

Since perl does not (yet?) support constant objects, these constants are in seconds only, so you cannot, for example, do this: `print ONE_WEEK->minutes;`

METHODS

The following methods are available:

```
my $val = Time::Seconds->new(SECONDS);
$val->seconds;
$val->minutes;
$val->hours;
$val->days;
$val->weeks;
$val->months;
$val->financial_months; # 30 days
```

(continues on next page)

(continued from previous page)

```
$val->years;
$val->pretty; # gives English representation of the delta
```

The usual arithmetic (+,-,+=,-=) is also available on the objects.

The methods make the assumption that there are 24 hours in a day, 7 days in a week, 365.24225 days in a year and 12 months in a year. (from The Calendar FAQ at http://www.tondering.dk/claus/calendar.html)

This module is free software, you may distribute it under the same terms as Perl.

Bugs

Currently the methods aren't as efficient as they could be, for reasons of clarity. This is probably a bad idea.

Time::gmtime

by-name interface to Perl's built-in gmtime() function

SYNOPSIS

```
use Time::gmtime;
$gm = gmtime();
printf "The day in Greenwich is %s\n",
   (qw(Sun Mon Tue Wed Thu Fri Sat Sun))[ $gm->wday() ];

use Time::gmtime qw(:FIELDS);
gmtime();
printf "The day in Greenwich is %s\n",
   (qw(Sun Mon Tue Wed Thu Fri Sat Sun))[ $tm_wday ];

$now = gmctime();

use Time::gmtime;
use File::stat;
$date_string = gmctime(stat($file)->mtime);
```

DESCRIPTION

This module's default exports override the core gmtime() function, replacing it with a version that returns "Time::tm" objects. This object has methods that return the similarly named structure field name from the C's tm structure from `time.h`; namely sec, min, hour, mday, mon, year, wday, yday, and isdst.

You may also import all the structure fields directly into your namespace as regular variables using the :FIELDS import tag. (Note that this still overrides your core functions.) Access these fields as variables named with a preceding `tm_` in front their method names. Thus, `$tm_obj->mday()` corresponds to $tm_mday if you import the fields.

The gmctime() function provides a way of getting at the scalar sense of the original CORE::gmtime() function.

To access this functionality without the core overrides, pass the `use` an empty import list, and then access function functions with their full qualified names. On the other hand, the built-ins are still available via the `CORE::` pseudo-package.

NOTE

While this class is currently implemented using the Class::Struct module to build a struct-like class, you shouldn't rely upon this.

AUTHOR

Tom Christiansen

Time::localtime

by-name interface to Perl's built-in localtime() function

SYNOPSIS

```
use Time::localtime;
printf "Year is %d\n", localtime->year() + 1900;

$now = ctime();

use Time::localtime;
use File::stat;
$date_string = ctime(stat($file)->mtime);
```

DESCRIPTION

This module's default exports override the core localtime() function, replacing it with a version that returns "Time::tm" objects. This object has methods that return the similarly named structure field name from the C's tm structure from `time.h`; namely sec, min, hour, mday, mon, year, wday, yday, and isdst.

You may also import all the structure fields directly into your namespace as regular variables using the :FIELDS import tag. (Note that this still overrides your core func-

tions.) Access these fields as variables named with a preceding `tm_` in front their method names. Thus, `$tm_obj->mday()` corresponds to $tm_mday if you import the fields.

The ctime() function provides a way of getting at the scalar sense of the original CORE::localtime() function.

To access this functionality without the core overrides, pass the `use` an empty import list, and then access function functions with their full qualified names. On the other hand, the built-ins are still available via the `CORE::` pseudo-package.

NOTE

While this class is currently implemented using the Class::Struct module to build a struct-like class, you shouldn't rely upon this.

Tom Christiansen

Time::tm

internal object used by Time::gmtime and Time::localtime

SYNOPSIS

Don't use this module directly.

DESCRIPTION

This module is used internally as a base class by Time::localtime And Time::gmtime functions. It creates a Time::tm struct object which is addressable just like's C's tm structure from `time.h`; namely with sec, min, hour, mday, mon, year, wday, yday, and isdst.

This class is an internal interface only.

5.2.107 Types

Namespace containing the following modules:

- `Types::Serialiser` - simple data types for common serialisation formats

Types::Serialiser

simple data types for common serialisation formats

SYNOPSIS

DESCRIPTION

This module provides some extra datatypes that are used by common serialisation formats such as JSON or CBOR. The idea is to have a repository of simple/small constants and containers that can be shared by different implementations so they become interoperable between each other.

SIMPLE SCALAR CONSTANTS

Simple scalar constants are values that are overloaded to act like simple Perl values, but have (class) type to differentiate them from normal Perl scalars. This is necessary because these have different representations in the serialisation formats.

In the following, functions with zero or one arguments have a prototype of `()` and `($)`, respectively, so act as constants and unary operators.

BOOLEANS (Types::Serialiser::Boolean class)

This type has only two instances, true and false. A natural representation for these in Perl is `1` and `0`, but serialisation formats need to be able to differentiate between them and mere numbers.

- $Types::Serialiser::true, Types::Serialiser::true

  This value represents the "true" value. In most contexts is acts like the number `1`. It is up to you whether you use the variable form (`$Types::Serialiser::true`) or the constant form (`Types::Serialiser::true`).

  The constant is represented as a reference to a scalar containing `1` - implementations are allowed to directly test for this.

- $Types::Serialiser::false, Types::Serialiser::false

  This value represents the "false" value. In most contexts is acts like the number `0`. It is up to you whether you use the variable form (`$Types::Serialiser::false`) or the constant form (`Types::Serialiser::false`).

  The constant is represented as a reference to a scalar containing `0` - implementations are allowed to directly test for this.

- Types::Serialiser::as_bool $value

  Converts a Perl scalar into a boolean, which is useful syntactic sugar. Strictly equivalent to:

  ```
  $value ? $Types::Serialiser::true : $Types::Serialiser::false
  ```

- $is_bool = Types::Serialiser::is_bool $value

  Returns true iff the `$value` is either `$Types::Serialiser::true` or `$Types::Serialiser::false`.

  For example, you could differentiate between a perl true value and a `Types::Serialiser::true` by using this:

```
$value && Types::Serialiser::is_bool $value
```

- $is_true = Types::Serialiser::is_true $value

  Returns true iff `$value` is `$Types::Serialiser::true`.

- $is_false = Types::Serialiser::is_false $value

  Returns false iff `$value` is `$Types::Serialiser::false`.

ERROR (Types::Serialiser::Error class)

This class has only a single instance, `error`. It is used to signal an encoding or decoding error. In CBOR for example, and object that couldn't be encoded will be represented by a CBOR undefined value, which is represented by the error value in Perl.

- $Types::Serialiser::error, Types::Serialiser::error

  This value represents the "error" value. Accessing values of this type will throw an exception.

  The constant is represented as a reference to a scalar containing `undef` - implementations are allowed to directly test for this.

- $is_error = Types::Serialiser::is_error $value

  Returns false iff `$value` is `$Types::Serialiser::error`.

A GENERIC OBJECT SERIALIATION PROTOCOL

This section explains the object serialisation protocol used by CBOR::XS. It is meant to be generic enough to support any kind of generic object serialiser.

This protocol is called "the Types::Serialiser object serialisation protocol".

ENCODING

When the encoder encounters an object that it cannot otherwise encode (for example, CBOR::XS can encode a few special types itself, and will first attempt to use the special `TO_CBOR` serialisation protocol), it will look up the `FREEZE` method on the object.

Note that the `FREEZE` method will normally be called *during* encoding, and *MUST NOT* change the data structure that is being encoded in any way, or it might cause memory corruption or worse.

If it exists, it will call it with two arguments: the object to serialise, and a constant string that indicates the name of the data model. For example CBOR::XS uses `CBOR`, and the *JSON* and *JSON::XS* modules (or any other JSON serialiser), would use `JSON` as second argument.

The `FREEZE` method can then return zero or more values to identify the object instance. The serialiser is then supposed to encode the class name and all of these return values (which must be encodable in the format) using the relevant form for Perl objects. In CBOR for example, there is a registered tag number for encoded perl objects.

The values that `FREEZE` returns must be serialisable with the serialiser that calls it. Therefore, it is recommended to use simple types such as strings and numbers, and

maybe array references and hashes (basically, the JSON data model). You can always use a more complex format for a specific data model by checking the second argument, the data model.

The "data model" is not the same as the "data format" - the data model indicates what types and kinds of return values can be returned from FREEZE. For example, in CBOR it is permissible to return tagged CBOR values, while JSON does not support these at all, so JSON would be a valid (but too limited) data model name for CBOR::XS. similarly, a serialising format that supports more or less the same data model as JSON could use JSON as data model without losing anything.

DECODING

When the decoder then encounters such an encoded perl object, it should look up the THAW method on the stored classname, and invoke it with the classname, the constant string to identify the data model/data format, and all the return values returned by FREEZE.

EXAMPLES

See the OBJECT SERIALISATION section in the CBOR::XS manpage for more details, an example implementation, and code examples.

Here is an example FREEZE/THAW method pair:

```
sub My::Object::FREEZE {
   my ($self, $model) = @_;

   ($self->{type}, $self->{id}, $self->{variant})
}

sub My::Object::THAW {
   my ($class, $model, $type, $id, $variant) = @_;

   $class->new (type => $type, id => $id, variant => $variant)
}
```

BUGS

The use of *overload* makes this module much heavier than it should be (on my system, this module: 4kB RSS, overload: 260kB RSS).

SEE ALSO

Currently, *JSON::XS* and CBOR::XS use these types.

5.2.108 UNIVERSAL

base class for ALL classes (blessed references)

SYNOPSIS

```
my $obj_is_io    = $fd->isa("IO::Handle");
my $cls_is_io    = Class->isa("IO::Handle");

my $obj_does_log = $obj->DOES("Logger");
my $cls_does_log = Class->DOES("Logger");

my $obj_sub      = $obj->can("print");
my $cls_sub      = Class->can("print");

my $eval_sub     = eval { $ref->can("fandango") };
my $ver          = $obj->VERSION;

# but never do this!
```

(continues on next page)

(continued from previous page)

```
my $is_io          = UNIVERSAL::isa($fd, "IO::Handle");
my $sub            = UNIVERSAL::can($obj, "print");
```

DESCRIPTION

UNIVERSAL is the base class from which all blessed references inherit. See perlobj.

UNIVERSAL provides the following methods:

- `$obj->isa( TYPE )`
- `CLASS->isa( TYPE )`
- `eval { VAL->isa( TYPE ) }`

  Where

  - `TYPE`

    is a package name

  - `$obj`

    is a blessed reference or a package name

  - `CLASS`

    is a package name

  - `VAL`

    is any of the above or an unblessed reference

  When used as an instance or class method (`$obj->isa( TYPE )`), `isa` returns *true* if $obj is blessed into package `TYPE` or inherits from package `TYPE`.

  When used as a class method (`CLASS->isa( TYPE )`, sometimes referred to as a static method), `isa` returns *true* if `CLASS` inherits from (or is itself) the name of the package `TYPE` or inherits from package `TYPE`.

  If you're not sure what you have (the `VAL` case), wrap the method call in an `eval` block to catch the exception if `VAL` is undefined or an unblessed reference. The *`isa` operator* is an alternative that simply returns false in this case, so the `eval` is not needed.

  If you want to be sure that you're calling `isa` on an instance, not a class, check the invocant with `blessed` from *Scalar::Util* first:

  ```
  use Scalar::Util 'blessed';

  if ( blessed( $obj ) && $obj->isa("Some::Class") ) {
      ...
  }
  ```

- `$obj->DOES( ROLE )`
- `CLASS->DOES( ROLE )`

DOES checks if the object or class performs the role ROLE. A role is a named group of specific behavior (often methods of particular names and signatures), similar to a class, but not necessarily a complete class by itself. For example, logging or serialization may be roles.

DOES and isa are similar, in that if either is true, you know that the object or class on which you call the method can perform specific behavior. However, DOES is different from isa in that it does not care *how* the invocant performs the operations, merely that it does. (isa of course mandates an inheritance relationship. Other relationships include aggregation, delegation, and mocking.)

By default, classes in Perl only perform the UNIVERSAL role, as well as the role of all classes in their inheritance. In other words, by default DOES responds identically to isa.

There is a relationship between roles and classes, as each class implies the existence of a role of the same name. There is also a relationship between inheritance and roles, in that a subclass that inherits from an ancestor class implicitly performs any roles its parent performs. Thus you can use DOES in place of isa safely, as it will return true in all places where isa will return true (provided that any overridden DOES *and* isa methods behave appropriately).

- `$obj->can( METHOD )`
- `CLASS->can( METHOD )`
- `eval { VAL->can( METHOD ) }`

  can checks if the object or class has a method called METHOD. If it does, then it returns a reference to the sub. If it does not, then it returns *undef*. This includes methods inherited or imported by $obj, CLASS, or VAL.

  can cannot know whether an object will be able to provide a method through AUTOLOAD (unless the object's class has overridden can appropriately), so a return value of *undef* does not necessarily mean the object will not be able to handle the method call. To get around this some module authors use a forward declaration (see *perlsub*) for methods they will handle via AUTOLOAD. For such 'dummy' subs, can will still return a code reference, which, when called, will fall through to the AUTOLOAD. If no suitable AUTOLOAD is provided, calling the coderef will cause an error.

  You may call can as a class (static) method or an object method.

  Again, the same rule about having a valid invocant applies – use an eval block or blessed if you need to be extra paranoid.

- `VERSION ( [ REQUIRE ] )`

  VERSION will return the value of the variable $VERSION in the package the object is blessed into. If REQUIRE is given then it will do a comparison and die if the package version is not greater than or equal to REQUIRE, or if either $VERSION or REQUIRE is not a "lax" version number (as defined by the *version* module).

  The return from VERSION will actually be the stringified version object using the package $VERSION scalar, which is guaranteed to be equivalent but may not be precisely the contents of the $VERSION scalar. If you want the actual contents of $VERSION, use $CLASS::VERSION instead.

`VERSION` can be called as either a class (static) method or an object method.

WARNINGS

NOTE: `can` directly uses Perl's internal code for method lookup, and `isa` uses a very similar method and cache-ing strategy. This may cause strange effects if the Perl code dynamically changes @ISA in any package.

You may add other methods to the UNIVERSAL class via Perl code. You do not need to `use UNIVERSAL` to make these methods available to your program (and you should not do so).

EXPORTS

None.

Previous versions of this documentation suggested using `isa` as a function to determine the type of a reference:

```
$yes = UNIVERSAL::isa($h, "HASH");
$yes = UNIVERSAL::isa("Foo", "Bar");
```

The problem is that this code would *never* call an overridden `isa` method in any class. Instead, use `reftype` from *Scalar::Util* for the first case:

```
use Scalar::Util 'reftype';

$yes = reftype( $h ) eq "HASH";
```

and the method form of `isa` for the second:

```
$yes = Foo->isa("Bar");
```

5.2.109 URL

Namespace containing the following modules:

- `URL::Encode` - Encoding and decoding of `application/x-www-form-urlencoded` encoding.

URL::Encode

Encoding and decoding of `application/x-www-form-urlencoded` encoding.

SYNOPSIS

```
$octets = url_decode($octets);
$string = url_decode_utf8($octets);

$octets = url_encode($octets);
$octets = url_encode_utf8($string);
```

(continues on next page)

(continued from previous page)

```
$params = url_params_flat($octets [, $utf8 = false]);
$params = url_params_mixed($octets [, $utf8 = false]);
$params = url_params_multi($octets [, $utf8 = false]);
          url_params_each($octets, $callback [, $utf8 = false]);
```

DESCRIPTION

This module provides functions to encode and decode strings into and from the `application/x-www-form-urlencoded` encoding.

The `application/x-www-form-urlencoded` format encodes a ordered data sets of pairs consisting of a name and a value, with pairs seperated by ampersand or semicolon and names and values seperated by the equal sign. Space characters are replaced with plus sign and any characters not in the unreserved character set is encoded using the percent-encoding scheme also used for resource identifiers. A percent-encoded octet is encoded as a character triplet, consisting of the percent character "%" followed by the two hexadecimal digits representing that octet's numeric value.

The unreserved character set includes the uppercase and lowercase letters, decimal digits, hyphen, period, underscore, and tilde.

```
ABCDEFGHIJKLMNOPQRSTUVWXYZ
abcdefghijklmnopqrstuvwxyz
0123456789
- . _ ~
```

FUNCTIONS

url_decode

```
$octets = url_decode($octets);
```

Returns a decoded representation of the given URL-encoded `$octets` as an octet string.

url_decode_utf8

```
$string = url_decode_utf8($octets);
```

Returns a decoded representation of the given URL-encoded `$octets` in UTF-8 encoding as a character string.

url_encode

```
$octets = url_encode($octets);
```

Returns a URL-encoded representation of the given `$octets` as an octet string.

url_encode_utf8

```
$octets = url_encode_utf8($string);
```

Returns a URL-encoded representation of `$string` in UTF-8 encoding as an octet string.

url_params_flat

```
$params = url_params_flat($octets);
$params = url_params_flat($octets, $utf8);
```

Parses a URL-encoded data set of name/value pairs from the given octets. Returns an ARRAY reference containing the URL-decoded name/value pairs in order.

```
$params = url_params_flat('foo=A&foo=B&bar=C');
$params; # [ foo => 'A', foo => 'B', bar => 'C' ]
```

url_params_mixed

```
$params = url_params_mixed($octets);
$params = url_params_mixed($octets, $utf8);
```

Parses a URL-encoded data set of name/value pairs from the given octets. Returns a HASH reference containing the URL-decoded name/value pairs. Multiple occurrences of a parameter will result in an ARRAY reference holding all the values for that parameter in order.

```
$params = url_params_mixed('foo=A&foo=B&bar=C');
$params; # { foo => [ 'A', 'B' ], bar => 'C' }
```

url_params_multi

```
$params = url_params_multi($octets);
$params = url_params_multi($octets, $utf8);
```

Parses a URL-encoded data set of name/value pairs from the given octets. Returns a HASH reference containing the URL-decoded name/value pairs. Values are stored in an ARRAY reference.

```
$params = url_params_multi('foo=A&foo=B&bar=C');
$params; # { foo => [ 'A', 'B' ], bar => [ 'C' ] }
```

url_params_each

```
url_params_each($octets, $callback);
url_params_each($octets, $callback, $utf8);
```

Parses a URL-encoded data set of name/value pairs from the given octets. Invokes the given callback for each URL-decoded name/value pair.

```
$callback = sub {
    my ($name, $value) = @_;
};

url_params_each($octets, $callback);
```

EXPORTS

None by default. All functions can be exported using the `:all` tag or individually.

DIAGNOSTICS

- **(F)** Usage: %s

  Subroutine called with wrong number of arguments.
- **(F)** Wide character in octet string
- **(F)** Malformed UTF-8 in URL-decoded octets

PERFORMANCE

This module will automatically use *URL::Encode::XS* if it's installed.

Modules

- URL::Encode::XS - Encode and decode the application/x-www-form-urlencoded form of strings, and split a query string into its parameters.

URL::Encode::XS

Encode and decode the application/x-www-form-urlencoded form of strings, and split a query string into its parameters.

This is the fast half of URL::Encode: URL::Encode loads it when it is there, and falls back to its pure-Perl URL::Encode::PP, which gives the same results, otherwise (or when URL_ENCODE_PP is set in the environment). Use URL::Encode; nothing is exported by default.

url_encode escapes every byte except A-Z a-z 0-9 - . _ ~ as %XX, a space as +; url_decode reverses it, and leaves a % that is not followed by two hex digits as it is. The _utf8 variants take and return character strings, the others octets: an octet argument with a character above 255 croaks "Wide character in octet string".

The url_params_* functions split on & and ;, and = separates a name from its value; a pair without = has the value undef. With a true second argument, names and values are decoded as UTF-8. url_params_flat returns an array reference of names and values in order, url_params_mixed a hash reference whose repeated names hold an array reference of their values, url_params_multi a hash reference of array references, and url_params_each calls a code reference with each name and value.

This is a native implementation of URL::Encode::XS 0.03's XS.xs; its URL/Encode/XS.pm is used unchanged.

Synopsis

```
use URL::Encode qw(url_encode_utf8 url_decode_utf8 url_params_
 ↪mixed);

my $q = url_encode_utf8("K\x{f6}ln & more");   # "K%C3%B6ln+%26+more
 ↪"
print url_decode_utf8($q), "\n";               # "Köln & more"

my $p = url_params_mixed("a=1&b=2&a=3");
# { a => [1, 3], b => 2 }
```

Functions

Encoding

url_decode

`url_decode($octets)`: the octets with + and the %XX escapes decoded.

url_decode_utf8

`url_decode_utf8($octets)`: `url_decode`, then the result decoded as UTF-8; croaks "Malformed UTF-8 in URL decoded string" when it is not.

url_encode

`url_encode($octets)`: every byte except `A-Z a-z 0-9 - . _ ~` as %XX, a space as +.

url_encode_utf8

`url_encode_utf8($string)`: the string encoded as UTF-8, then `url_encoded`.

Query strings

url_params_flat

`url_params_flat($octets [, $utf8])`: an array reference of the names and values in order.

url_params_mixed

`url_params_mixed($octets [, $utf8])`: a hash reference; a name given more than once holds an array reference of its values.

url_params_multi

`url_params_multi($octets [, $utf8])`: a hash reference of array references of the values.

url_params_each

`url_params_each($octets, $callback [, $utf8])`: call `$callback` with each name and value; returns nothing.

5.2.110 Unicode

Namespace containing the following modules:

- `Unicode::Collate` - Unicode Collation Algorithm
- `Unicode::GCString`

- `Unicode::LineBreak` - Line breaking for Unicode text, and strings of grapheme clusters.
- `Unicode::Normalize` - the Unicode normalization forms NFD, NFC, NFKD
- `Unicode::UCD` - the Unicode Character Database: what perl knows about

Unicode::Collate

Unicode Collation Algorithm

SYNOPSIS

```
use Unicode::Collate;

#construct
$Collator = Unicode::Collate->new(%tailoring);

#sort
@sorted = $Collator->sort(@not_sorted);

#compare
$result = $Collator->cmp($a, $b); # returns 1, 0, or -1.
```

Note: Strings in `@not_sorted`, `$a` and `$b` are interpreted according to Perl's Unicode support. See perlunicode, perluniintro, perlunitut, perlunifaq, *utf8*. Otherwise you can use `preprocess` or should decode them before.

DESCRIPTION

This module is an implementation of Unicode Technical Standard #10 (a.k.a. UTS #10) - Unicode Collation Algorithm (a.k.a. UCA).

Constructor and Tailoring

The new method returns a collator object. If new() is called with no parameters, the collator should do the default collation.

```
$Collator = Unicode::Collate->new(
   UCA_Version => $UCA_Version,
   alternate => $alternate, # alias for 'variable'
   backwards => $levelNumber, # or \@levelNumbers
   entry => $element,
   hangul_terminator => $term_primary_weight,
   highestFFFF => $bool,
   identical => $bool,
   ignoreName => qr/$ignoreName/,
   ignoreChar => qr/$ignoreChar/,
   ignore_level2 => $bool,
   katakana_before_hiragana => $bool,
   level => $collationLevel,
```

(continues on next page)

(continued from previous page)

```
   long_contraction => $bool,
   minimalFFFE => $bool,
   normalization  => $normalization_form,
   overrideCJK => \&overrideCJK,
   overrideHangul => \&overrideHangul,
   preprocess => \&preprocess,
   rearrange => \@charList,
   rewrite => \&rewrite,
   suppress => \@charList,
   table => $filename,
   undefName => qr/$undefName/,
   undefChar => qr/$undefChar/,
   upper_before_lower => $bool,
   variable => $variable,
);
```

- UCA_Version

  If the revision (previously "tracking version") number of UCA is given, behavior of that revision is emulated on collating. If omitted, the return value of `UCA_Version()` is used.

  The following revisions are supported. The default is 43.

```
  UCA       Unicode Standard          DUCET (@version)
--------------------------------------------------------
   8              3.1                 3.0.1 (3.0.1d9)
   9     3.1 with Corrigendum 3       3.1.1
  11             4.0.0
  14             4.1.0
  16             5.0.0
  18             5.1.0
  20             5.2.0
  22             6.0.0
  24             6.1.0
  26             6.2.0
  28             6.3.0
  30             7.0.0
  32             8.0.0
  34             9.0.0
  36            10.0.0
  38            11.0.0
  40            12.0.0
  41            12.1.0
  43            13.0.0
```

  * See below for `long_contraction` with `UCA_Version` 22 and 24.

  * Noncharacters (e.g. U+FFFF) are not ignored, and can be overridden since `UCA_Version` 22.

  * Out-of-range codepoints (greater than U+10FFFF) are not ignored, and can be

overridden since `UCA_Version` 22.

* Fully ignorable characters were ignored, and would not interrupt contractions with `UCA_Version` 9 and 11.

* Treatment of ignorables after variables and some behaviors were changed at `UCA_Version` 9.

* Characters regarded as CJK unified ideographs (cf. `overrideCJK`) depend on `UCA_Version`.

* Many hangul jamo are assigned at `UCA_Version` 20, that will affect `hangul_terminator`.

- alternate

  – see 3.2.2 Alternate Weighting, version 8 of UTS #10

  For backward compatibility, `alternate` (old name) can be used as an alias for `variable`.

- backwards

  – see 3.4 Backward Accents, UTS #10.

```
backwards => $levelNumber or \@levelNumbers
```

  Weights in reverse order; ex. level 2 (diacritic ordering) in French. If omitted (or `$levelNumber` is `undef` or `\@levelNumbers` is `[]`), forwards at all the levels.

- entry

  – see 5 Tailoring; 9.1 Allkeys File Format, UTS #10.

  If the same character (or a sequence of characters) exists in the collation element table through `table`, mapping to collation elements is overridden. If it does not exist, the mapping is defined additionally.

```
    entry => <<'ENTRY', # for DUCET v4.0.0 (allkeys-4.0.0.txt)
0063 0068 ; [.0E6A.0020.0002.0063] # ch
0043 0068 ; [.0E6A.0020.0007.0043] # Ch
0043 0048 ; [.0E6A.0020.0008.0043] # CH
006C 006C ; [.0F4C.0020.0002.006C] # ll
004C 006C ; [.0F4C.0020.0007.004C] # Ll
004C 004C ; [.0F4C.0020.0008.004C] # LL

00D1      ; [.0F7B.0020.0008.00D1] # N-tilde
004E 0303 ; [.0F7B.0020.0008.00D1] # N-tilde
ENTRY

    entry => <<'ENTRY', # for DUCET v4.0.0 (allkeys-4.0.0.txt)
00E6 ; [.0E33.0020.0002.00E6][.0E8B.0020.0002.00E6] # ae␣
 ↪ligature as <a><e>
00C6 ; [.0E33.0020.0008.00C6][.0E8B.0020.0008.00C6] # AE␣
 ↪ligature as <A><E>
ENTRY
```

NOTE: The code point in the UCA file format (before `';'`) **must** be a Unicode code point (defined as hexadecimal), but not a native code point. So `0063` must always denote `U+0063`, but not a character of `"\x63"`.

Weighting may vary depending on collation element table. So ensure the weights defined in `entry` will be consistent with those in the collation element table loaded via `table`.

In DUCET v4.0.0, primary weight of `C` is `0E60` and that of `D` is `0E6D`. So setting primary weight of `CH` to `0E6A` (as a value between `0E60` and `0E6D`) makes ordering as `C < CH < D`. Exactly speaking DUCET already has some characters between `C` and `D`: `small capital C` (`U+1D04`) with primary weight `0E64`, `c-hook/C-hook` (`U+0188/U+0187`) with `0E65`, and `c-curl` (`U+0255`) with `0E69`. Then primary weight `0E6A` for `CH` makes `CH` ordered between `c-curl` and `D`.

- hangul_terminator

  – see 7.1.4 Trailing Weights, UTS #10.

  If a true value is given (non-zero but should be positive), it will be added as a terminator primary weight to the end of every standard Hangul syllable. Secondary and any higher weights for terminator are set to zero. If the value is false or `hangul_terminator` key does not exist, insertion of terminator weights will not be performed.

  Boundaries of Hangul syllables are determined according to conjoining Jamo behavior in `the Unicode Standard` and `HangulSyllableType.txt`.

  Implementation Note: (1) For expansion mapping (Unicode character mapped to a sequence of collation elements), a terminator will not be added between collation elements, even if Hangul syllable boundary exists there. Addition of terminator is restricted to the next position to the last collation element.

  (2) Non-conjoining Hangul letters (Compatibility Jamo, halfwidth Jamo, and enclosed letters) are not automatically terminated with a terminator primary weight. These characters may need terminator included in a collation element table beforehand.

- highestFFFF

  – see 2.4 Tailored noncharacter weights, UTS #35 (LDML) Part 5: Collation.

  If the parameter is made true, `U+FFFF` has a highest primary weight. When a boolean of `$coll->ge($str, "abc")` and `$coll->le($str, "abc\x{FFFF}")` is true, it is expected that `$str` begins with `"abc"`, or another primary equivalent. `$str` may be `"abcd"`, `"abc012"`, but should not include `U+FFFF` such as `"abc\x{FFFF}xyz"`.

  `$coll->le($str, "abc\x{FFFF}")` works like `$coll->lt($str, "abd")` almost, but the latter has a problem that you should know which letter is next to `c`. For a certain language where `ch` as the next letter, `"abch"` is greater than `"abc\x{FFFF}"`, but less than `"abd"`.

  Note: This is equivalent to `(entry => 'FFFF ; [.FFFE.0020.0005.FFFF]')`. Any other character than `U+FFFF` can be tailored by `entry`.

- identical

  – see A.3 Deterministic Comparison, UTS #10.

By default, strings whose weights are equal should be equal, even though their code points are not equal. Completely ignorable characters are ignored.

If the parameter is made true, a final, tie-breaking level is used. If no difference of weights is found after the comparison through all the level specified by `level`, the comparison with code points will be performed. For the tie-breaking comparison, the sort key has code points of the original string appended. Completely ignorable characters are not ignored.

If `preprocess` and/or `normalization` is applied, the code points of the string after them (in NFD by default) are used.

- ignoreChar
- ignoreName

  – see 3.6 Variable Weighting, UTS #10.

  Makes the entry in the table completely ignorable; i.e. as if the weights were zero at all level.

  Through `ignoreChar`, any character matching `qr/$ignoreChar/` will be ignored. Through `ignoreName`, any character whose name (given in the `table` file as a comment) matches `qr/$ignoreName/` will be ignored.

  E.g. when 'a' and 'e' are ignorable, 'element' is equal to 'lament' (or 'lmnt').

- ignore_level2

  – see 5.1 Parametric Tailoring, UTS #10.

  By default, case-sensitive comparison (that is level 3 difference) won't ignore accents (that is level 2 difference).

  If the parameter is made true, accents (and other primary ignorable characters) are ignored, even though cases are taken into account.

  NOTE: `level` should be 3 or greater.

- katakana_before_hiragana

  – see 7.2 Tertiary Weight Table, UTS #10.

  By default, hiragana is before katakana. If the parameter is made true, this is reversed.

  NOTE: This parameter simplemindedly assumes that any hiragana/katakana distinctions must occur in level 3, and their weights at level 3 must be same as those mentioned in 7.3.1, UTS #10. If you define your collation elements which violate this requirement, this parameter does not work validly.

- level

  – see 4.3 Form Sort Key, UTS #10.

  Set the maximum level. Any higher levels than the specified one are ignored.

```
Level 1: alphabetic ordering
Level 2: diacritic ordering
Level 3: case ordering
Level 4: tie-breaking (e.g. in the case when variable is
```

(continues on next page)

(continued from previous page)

```
↪'shifted')

ex.level => 2,
```

If omitted, the maximum is the 4th.

NOTE: The DUCET includes weights over 0xFFFF at the 4th level. But this module only uses weights within 0xFFFF. When `variable` is 'blanked' or 'non-ignorable' (other than 'shifted' and 'shift-trimmed'), the level 4 may be unreliable.

See also `identical`.

- long_contraction

  – see 3.8.2 Well-Formedness of the DUCET, 4.2 Produce Array, UTS #10.

  If the parameter is made true, for a contraction with three or more characters (here nicknamed "long contraction"), initial substrings will be handled. For example, a contraction ABC, where A is a starter, and B and C are non-starters (character with non-zero combining character class), will be detected even if there is not AB as a contraction.

  Default: Usually false. If `UCA_Version` is 22 or 24, and the value of `long_contraction` is not specified in `new()`, a true value is set implicitly. This is a workaround to pass Conformance Tests for Unicode 6.0.0 and 6.1.0.

  `change()` handles `long_contraction` explicitly only. If `long_contraction` is not specified in `change()`, even though `UCA_Version` is changed, `long_contraction` will not be changed.

  Limitation: Scanning non-starters is one-way (no back tracking). If AB is found but not ABC is not found, other long contraction where the first character is A and the second is not B may not be found.

  Under `(normalization => undef)`, detection step of discontiguous contractions will be skipped.

  Note: The following contractions in DUCET are not considered in steps S2.1.1 to S2.1.3, where they are discontiguous.

```
0FB2 0F71 0F80 (TIBETAN VOWEL SIGN VOCALIC RR)
0FB3 0F71 0F80 (TIBETAN VOWEL SIGN VOCALIC LL)
```

  For example `TIBETAN VOWEL SIGN VOCALIC RR` with `COMBINING TILDE OVERLAY` (`U+0344`) is `0FB2 0344 0F71 0F80` in NFD. In this case `0FB2 0F80` (`TIBETAN VOWEL SIGN VOCALIC R`) is detected, instead of `0FB2 0F71 0F80`. Inserted `0344` makes `0FB2 0F71 0F80` discontiguous and lack of contraction `0FB2 0F71` prohibits `0FB2 0F71 0F80` from being detected.

- minimalFFFE

  – see 1.1.1 U+FFFE, UTS #35 (LDML) Part 5: Collation.

  If the parameter is made true, `U+FFFE` has a minimal primary weight. The comparison between `"$a1\x{FFFE}$a2"` and `"$b1\x{FFFE}$b2"` first compares `$a1` and `$b1` at level 1, and then `$a2` and `$b2` at level 1, as followed.

```
"ab\x{FFFE}a"
"Ab\x{FFFE}a"
"ab\x{FFFE}c"
"Ab\x{FFFE}c"
"ab\x{FFFE}xyz"
"abc\x{FFFE}def"
"abc\x{FFFE}xYz"
"aBc\x{FFFE}xyz"
"abcX\x{FFFE}def"
"abcx\x{FFFE}xyz"
"b\x{FFFE}aaa"
"bbb\x{FFFE}a"
```

Note: This is equivalent to `(entry => 'FFFE ; [.0001.0020.0005.FFFE]')`. Any other character than `U+FFFE` can be tailored by `entry`.

- normalization

  – see 4.1 Normalize, UTS #10.

  If specified, strings are normalized before preparation of sort keys (the normalization is executed after preprocess).

  A form name `Unicode::Normalize::normalize()` accepts will be applied as `$normalization_form`. Acceptable names include `'NFD'`, `'NFC'`, `'NFKD'`, and `'NFKC'`. See `Unicode::Normalize::normalize()` for detail. If omitted, `'NFD'` is used.

  `normalization` is performed after `preprocess` (if defined).

  Furthermore, special values, `undef` and `"prenormalized"`, can be used, though they are not concerned with `Unicode::Normalize::normalize()`.

  If `undef` (not a string `"undef"`) is passed explicitly as the value for this key, any normalization is not carried out (this may make tailoring easier if any normalization is not desired). Under `(normalization => undef)`, only contiguous contractions are resolved; e.g. even if `A-ring` (and `A-ring-cedilla`) is ordered after `Z`, `A-cedilla-ring` would be primary equal to `A`. In this point, `(normalization => undef, preprocess => sub { NFD(shift) })` **is not** equivalent to `(normalization => 'NFD')`.

  In the case of `(normalization => "prenormalized")`, any normalization is not performed, but discontiguous contractions with combining characters are performed. Therefore `(normalization => 'prenormalized', preprocess => sub { NFD(shift) })` **is** equivalent to `(normalization => 'NFD')`. If source strings are finely prenormalized, `(normalization => 'prenormalized')` may save time for normalization.

  Except `(normalization => undef)`, **Unicode::Normalize** is required (see also **CAVEAT**).

- overrideCJK

  – see 7.1 Derived Collation Elements, UTS #10.

  By default, CJK unified ideographs are ordered in Unicode codepoint order, but those in the CJK Unified Ideographs block are less than those in the CJK Unified

Ideographs Extension A etc.

```
In the CJK Unified Ideographs block:
U+4E00..U+9FA5 if UCA_Version is 8, 9 or 11.
U+4E00..U+9FBB if UCA_Version is 14 or 16.
U+4E00..U+9FC3 if UCA_Version is 18.
U+4E00..U+9FCB if UCA_Version is 20 or 22.
U+4E00..U+9FCC if UCA_Version is 24 to 30.
U+4E00..U+9FD5 if UCA_Version is 32 or 34.
U+4E00..U+9FEA if UCA_Version is 36.
U+4E00..U+9FEF if UCA_Version is 38, 40 or 41.
U+4E00..U+9FFC if UCA_Version is 43.

In the CJK Unified Ideographs Extension blocks:
Ext.A (U+3400..U+4DB5)   if UCA_Version is  8 to 41.
Ext.A (U+3400..U+4DBF)   if UCA_Version is 43.
Ext.B (U+20000..U+2A6D6) if UCA_Version is  8 to 41.
Ext.B (U+20000..U+2A6DD) if UCA_Version is 43.
Ext.C (U+2A700..U+2B734) if UCA_Version is 20 or later.
Ext.D (U+2B740..U+2B81D) if UCA_Version is 22 or later.
Ext.E (U+2B820..U+2CEA1) if UCA_Version is 32 or later.
Ext.F (U+2CEB0..U+2EBE0) if UCA_Version is 36 or later.
Ext.G (U+30000..U+3134A) if UCA_Version is 43.
```

Through `overrideCJK`, ordering of CJK unified ideographs (including extensions) can be overridden.

ex. CJK unified ideographs in the JIS code point order.

```
overrideCJK => sub {
    my $u = shift;              # get a Unicode codepoint
    my $b = pack('n', $u);      # to UTF-16BE
    my $s = your_unicode_to_sjis_converter($b); # convert
    my $n = unpack('n', $s);    # convert sjis to short
    [ $n, 0x20, 0x2, $u ];      # return the collation element
},
```

The return value may be an arrayref of 1st to 4th weights as shown above. The return value may be an integer as the primary weight as shown below. If `undef` is returned, the default derived collation element will be used.

```
overrideCJK => sub {
    my $u = shift;              # get a Unicode codepoint
    my $b = pack('n', $u);      # to UTF-16BE
    my $s = your_unicode_to_sjis_converter($b); # convert
    my $n = unpack('n', $s);    # convert sjis to short
    return $n;                  # return the primary weight
},
```

The return value may be a list containing zero or more of an arrayref, an integer, or `undef`.

ex. ignores all CJK unified ideographs.

```
overrideCJK => sub {()}, # CODEREF returning empty list

 # where ->eq("Pe\x{4E00}rl", "Perl") is true
 # as U+4E00 is a CJK unified ideograph and to be ignorable.
```

If a false value (including undef) is passed, overrideCJK has no effect. `$Collator->change(overrideCJK => 0)` resets the old one.

But assignment of weight for CJK unified ideographs in table or entry is still valid. If undef is passed explicitly as the value for this key, weights for CJK unified ideographs are treated as undefined. However when UCA_Version > 8, `(overrideCJK => undef)` has no special meaning.

Note: In addition to them, 12 CJK compatibility ideographs (U+FA0E, U+FA0F, U+FA11, U+FA13, U+FA14, U+FA1F, U+FA21, U+FA23, U+FA24, U+FA27, U+FA28, U+FA29) are also treated as CJK unified ideographs. But they can't be overridden via overrideCJK when you use DUCET, as the table includes weights for them. table or entry has priority over overrideCJK.

- overrideHangul

  – see 7.1 Derived Collation Elements, UTS #10.

  By default, Hangul syllables are decomposed into Hangul Jamo, even if `(normalization => undef)`. But the mapping of Hangul syllables may be overridden.

  This parameter works like overrideCJK, so see there for examples.

  If you want to override the mapping of Hangul syllables, NFD and NFKD are not appropriate, since NFD and NFKD will decompose Hangul syllables before overriding. FCD may decompose Hangul syllables as the case may be.

  If a false value (but not undef) is passed, overrideHangul has no effect. `$Collator->change(overrideHangul => 0)` resets the old one.

  If undef is passed explicitly as the value for this key, weight for Hangul syllables is treated as undefined without decomposition into Hangul Jamo. But definition of weight for Hangul syllables in table or entry is still valid.

- overrideOut

  – see 7.1.1 Handling Ill-Formed Code Unit Sequences, UTS #10.

  Perl seems to allow out-of-range values (greater than 0x10FFFF). By default, out-of-range values are replaced with U+FFFD (REPLACEMENT CHARACTER) when UCA_Version >= 22, or ignored when UCA_Version <= 20.

  When UCA_Version >= 22, the weights of out-of-range values can be overridden. Though table or entry are available for them, out-of-range values are too many.

  overrideOut can perform it algorithmically. This parameter works like overrideCJK, so see there for examples.

  ex. ignores all out-of-range values.

```
overrideOut => sub {()}, # CODEREF returning empty list
```

If a false value (including undef) is passed, overrideOut has no effect. $Collator->change(overrideOut => 0) resets the old one.

NOTE ABOUT U+FFFD:

UCA recommends that out-of-range values should not be ignored for security reasons. Say, "pe\x{110000}rl" should not be equal to "perl". However, U+FFFD is wrongly mapped to a variable collation element in DUCET for Unicode 6.0.0 to 6.2.0, that means out-of-range values will be ignored when variable isn't Non-ignorable.

The mapping of U+FFFD is corrected in Unicode 6.3.0. see http://www.unicode.org/reports/tr10/tr10-28.html#Trailing_Weights (7.1.4 Trailing Weights). Such a correction is reproduced by this.

```
overrideOut => sub { 0xFFFD }, # CODEREF returning a very large␣
↪integer
```

This workaround is unnecessary since Unicode 6.3.0.

- preprocess

  – see 5.4 Preprocessing, UTS #10.

  If specified, the coderef is used to preprocess each string before the formation of sort keys.

  ex. dropping English articles, such as "a" or "the". Then, "the pen" is before "a pencil".

```
preprocess => sub {
      my $str = shift;
      $str =~ s/\b(?:an?|the)\s+//gi;
      return $str;
   },
```

  preprocess is performed before normalization (if defined).

  ex. decoding strings in a legacy encoding such as shift-jis:

```
$sjis_collator = Unicode::Collate->new(
    preprocess => \&your_shiftjis_to_unicode_decoder,
);
@result = $sjis_collator->sort(@shiftjis_strings);
```

  Note: Strings returned from the coderef will be interpreted according to Perl's Unicode support. See perlunicode, perluniintro, perlunitut, perlunifaq, *utf8*.

- rearrange

  – see 3.5 Rearrangement, UTS #10.

  Characters that are not coded in logical order and to be rearranged. If UCA_Version is equal to or less than 11, default is:

```
rearrange => [ 0x0E40..0x0E44, 0x0EC0..0x0EC4 ],
```

If you want to disallow any rearrangement, pass `undef` or `[]` (a reference to empty list) as the value for this key.

If `UCA_Version` is equal to or greater than 14, default is `[]` (i.e. no rearrangement).

According to the version 9 of UCA, this parameter shall not be used; but it is not warned at present.

- rewrite

  If specified, the coderef is used to rewrite lines in `table` or `entry`. The coderef will get each line, and then should return a rewritten line according to the UCA file format. If the coderef returns an empty line, the line will be skipped.

  e.g. any primary ignorable characters into tertiary ignorable:

```
rewrite => sub {
    my $line = shift;
    $line =~ s/\[\.0000\..{4}\..{4}\./[.0000.0000.0000./g;
    return $line;
},
```

  This example shows rewriting weights. `rewrite` is allowed to affect code points, weights, and the name.

  NOTE: `table` is available to use another table file; preparing a modified table once would be more efficient than rewriting lines on reading an unmodified table every time.

- suppress

  – see 3.12 Special-Purpose Commands, UTS #35 (LDML) Part 5: Collation.

  Contractions beginning with the specified characters are suppressed, even if those contractions are defined in `table`.

  An example for Russian and some languages using the Cyrillic script:

```
suppress => [0x0400..0x0417, 0x041A..0x0437, 0x043A..0x045F],
```

  where 0x0400 stands for `U+0400`, CYRILLIC CAPITAL LETTER IE WITH GRAVE.

  NOTE: Contractions via `entry` will not be suppressed.

- table

  – see 3.8 Default Unicode Collation Element Table, UTS #10.

  You can use another collation element table if desired.

  The table file should locate in the `Unicode/Collate` directory on `@INC`. Say, if the filename is `Foo.txt`, the table file is searched as `Unicode/Collate/Foo.txt` in `@INC`.

  By default, `allkeys.txt` (as the filename of DUCET) is used. If you will prepare your own table file, any name other than `allkeys.txt` may be better to avoid namespace conflict.

Explicit saying `(table => 'allkeys.txt')`, or using another table, or using `ignoreChar`, `ignoreName`, `undefChar`, `undefName` or `rewrite` will prevent this module from using the compiled DUCET.

If `undef` is passed explicitly as the value for this key, no file is read (but you can define collation elements via `entry`).

A typical way to define a collation element table without any file of table:

```
   $onlyABC = Unicode::Collate->new(
       table => undef,
       entry => << 'ENTRIES',
0061 ; [.0101.0020.0002.0061] # LATIN SMALL LETTER A
0041 ; [.0101.0020.0008.0041] # LATIN CAPITAL LETTER A
0062 ; [.0102.0020.0002.0062] # LATIN SMALL LETTER B
0042 ; [.0102.0020.0008.0042] # LATIN CAPITAL LETTER B
0063 ; [.0103.0020.0002.0063] # LATIN SMALL LETTER C
0043 ; [.0103.0020.0008.0043] # LATIN CAPITAL LETTER C
ENTRIES
    );
```

If `ignoreName` or `undefName` is used, character names should be specified as a comment (following #) on each line.

- undefChar
- undefName

  – see 6.3.3 Reducing the Repertoire, UTS #10.

  Undefines the collation element as if it were unassigned in the `table`. This reduces the size of the table. If an unassigned character appears in the string to be collated, the sort key is made from its codepoint as a single-character collation element, as it is greater than any other assigned collation elements (in the codepoint order among the unassigned characters). But, it'd be better to ignore characters unfamiliar to you and maybe never used.

  Through `undefChar`, any character matching `qr/$undefChar/` will be undefined. Through `undefName`, any character whose name (given in the `table` file as a comment) matches `qr/$undefName/` will be undefined.

  ex. Collation weights for beyond-BMP characters are not stored in object:

```
undefChar => qr/[^\0-\x{fffd}]/,
```

- upper_before_lower

  – see 6.6 Case Comparisons, UTS #10.

  By default, lowercase is before uppercase. If the parameter is made true, this is reversed.

  NOTE: This parameter simplemindedly assumes that any lowercase/uppercase distinctions must occur in level 3, and their weights at level 3 must be same as those mentioned in 7.3.1, UTS #10. If you define your collation elements which differs from this requirement, this parameter doesn't work validly.

- variable

  – see 3.6 Variable Weighting, UTS #10.

  This key allows for variable weighting of variable collation elements, which are marked with an ASTERISK in the table (NOTE: Many punctuation marks and symbols are variable in `allkeys.txt`).

```
variable => 'blanked', 'non-ignorable', 'shifted', or 'shift-
↪trimmed'.
```

  These names are case-insensitive. By default (if specification is omitted), 'shifted' is adopted.

```
'Blanked'        Variable elements are made ignorable at levels␣
↪1 through 3;
                 considered at the 4th level.

'Non-Ignorable'  Variable elements are not reset to ignorable.

'Shifted'        Variable elements are made ignorable at levels␣
↪1 through 3
                 their level 4 weight is replaced by the old␣
↪level 1 weight.
                 Level 4 weight for Non-Variable elements is␣
↪0xFFFF.

'Shift-Trimmed'  Same as 'shifted', but all FFFF's at the 4th␣
↪level
                 are trimmed.
```

Methods for Collation

- `@sorted = $Collator->sort(@not_sorted)`

  Sorts a list of strings.

- `$result = $Collator->cmp($a, $b)`

  Returns 1 (when `$a` is greater than `$b`) or 0 (when `$a` is equal to `$b`) or -1 (when `$a` is less than `$b`).

- `$result = $Collator->eq($a, $b)`
- `$result = $Collator->ne($a, $b)`
- `$result = $Collator->lt($a, $b)`
- `$result = $Collator->le($a, $b)`
- `$result = $Collator->gt($a, $b)`
- `$result = $Collator->ge($a, $b)`

  They works like the same name operators as theirs.

```
eq : whether $a is equal to $b.
ne : whether $a is not equal to $b.
lt : whether $a is less than $b.
le : whether $a is less than $b or equal to $b.
gt : whether $a is greater than $b.
ge : whether $a is greater than $b or equal to $b.
```

- `$sortKey = $Collator->getSortKey($string)`

  – see 4.3 Form Sort Key, UTS #10.

  Returns a sort key.

  You compare the sort keys using a binary comparison and get the result of the comparison of the strings using UCA.

```
$Collator->getSortKey($a) cmp $Collator->getSortKey($b)

   is equivalent to

$Collator->cmp($a, $b)
```

- `$sortKeyForm = $Collator->viewSortKey($string)`

  Converts a sorting key into its representation form. If `UCA_Version` is 8, the output is slightly different.

```
use Unicode::Collate;
my $c = Unicode::Collate->new();
print $c->viewSortKey("Perl"),"\n";

# output:
# [0B67 0A65 0B7F 0B03 | 0020 0020 0020 0020 | 0008 0002 0002
 ↪0002 | FFFF FFFF FFFF FFFF]
#  Level 1              Level 2              Level 3
 ↪     Level 4
```

Methods for Searching

The `match`, `gmatch`, `subst`, `gsubst` methods work like `m//`, `m//g`, `s///`, `s///g`, respectively, but they are not aware of any pattern, but only a literal substring.

DISCLAIMER: If `preprocess` or `normalization` parameter is true for `$Collator`, calling these methods (`index`, `match`, `gmatch`, `subst`, `gsubst`) is croaked, as the position and the length might differ from those on the specified string.

`rearrange` and `hangul_terminator` parameters are neglected. `katakana_before_hiragana` and `upper_before_lower` don't affect matching and searching, as it doesn't matter whether greater or less.

- `$position = $Collator->index($string, $substring[, $position])`
- `($position, $length) = $Collator->index($string, $substring[, $position])`

If `$substring` matches a part of `$string`, returns the position of the first occurrence of the matching part in scalar context; in list context, returns a two-element list of the position and the length of the matching part.

If `$substring` does not match any part of `$string`, returns `-1` in scalar context and an empty list in list context.

e.g. when the content of `$str` is `"Ich muß studieren Perl."`, you say the following where `$sub` is `"MüSS"`,

```
my $Collator = Unicode::Collate->new( normalization => undef,␣
↪level => 1 );
                                    # (normalization => undef)␣
↪is REQUIRED.
my $match;
if (my($pos,$len) = $Collator->index($str, $sub)) {
    $match = substr($str, $pos, $len);
}
```

and get `"muß"` in `$match`, since `"muß"` is primary equal to `"MüSS"`.

- `$match_ref = $Collator->match($string, $substring)`
- `($match) = $Collator->match($string, $substring)`

If `$substring` matches a part of `$string`, in scalar context, returns **a reference to** the first occurrence of the matching part (`$match_ref` is always true if matches, since every reference is **true**); in list context, returns the first occurrence of the matching part.

If `$substring` does not match any part of `$string`, returns `undef` in scalar context and an empty list in list context.

e.g.

```
if ($match_ref = $Collator->match($str, $sub)) { # scalar␣
↪context
    print "matches [$$match_ref].\n";
} else {
    print "doesn't match.\n";
}

 or

if (($match) = $Collator->match($str, $sub)) { # list context
    print "matches [$match].\n";
} else {
    print "doesn't match.\n";
}
```

- `@match = $Collator->gmatch($string, $substring)`

If `$substring` matches a part of `$string`, returns all the matching parts (or matching count in scalar context).

If `$substring` does not match any part of `$string`, returns an empty list.

- `$count = $Collator->subst($string, $substring, $replacement)`

  If `$substring` matches a part of `$string`, the first occurrence of the matching part is replaced by `$replacement` (`$string` is modified) and `$count` (always equals to 1) is returned.

  `$replacement` can be a CODEREF, taking the matching part as an argument, and returning a string to replace the matching part (a bit similar to `s/(..)/$coderef->($1)/e`).

- `$count = $Collator->gsubst($string, $substring, $replacement)`

  If `$substring` matches a part of `$string`, all the occurrences of the matching part are replaced by `$replacement` (`$string` is modified) and `$count` is returned.

  `$replacement` can be a CODEREF, taking the matching part as an argument, and returning a string to replace the matching part (a bit similar to `s/(..)/$coderef->($1)/eg`).

  e.g.

```
my $Collator = Unicode::Collate->new( normalization => undef,␣
↪level => 1 );
                                    # (normalization => undef)␣
↪is REQUIRED.
my $str = "Camel donkey zebra came\x{301}l CAMEL horse cam\0e\
↪0l...";
$Collator->gsubst($str, "camel", sub { "<b>$_[0]</b>" });

# now $str is "<b>Camel</b> donkey zebra <b>came\x{301}l</b> <b>
↪CAMEL</b> horse <b>cam\0e\0l</b>...";
# i.e., all the camels are made bold-faced.

 Examples: levels and ignore_level2 - what does camel match?
-------------------------------------------------------------
↪-----------
 level  ignore_level2  |  camel  Camel  came\x{301}l  c-a-m-e-l␣
↪ cam\0e\0l
----------------------|--------------------------------------
↪-----------
   1        false      |   yes    yes      yes          yes     ␣
↪   yes
   2        false      |   yes    yes      no           yes     ␣
↪   yes
   3        false      |   yes    no       no           yes     ␣
↪   yes
   4        false      |   yes    no       no           no      ␣
↪   yes
----------------------|--------------------------------------
↪-----------
   1        true       |   yes    yes      yes          yes     ␣
↪   yes
   2        true       |   yes    yes      yes          yes     ␣
↪   yes
```

(continues on next page)

(continued from previous page)

```
   3        true       |   yes    no       yes          yes
↪   yes
   4        true       |   yes    no       yes          no
↪   yes
-------------------------------------------------------------------
↪-----------
 note: if variable => non-ignorable, camel doesn't match c-a-m-
↪e-l
       at any level.
```

Other Methods

- `%old_tailoring = $Collator->change(%new_tailoring)`
- `$modified_collator = $Collator->change(%new_tailoring)`

  Changes the value of specified keys and returns the changed part.

```
$Collator = Unicode::Collate->new(level => 4);

$Collator->eq("perl", "PERL"); # false

%old = $Collator->change(level => 2); # returns (level => 4).

$Collator->eq("perl", "PERL"); # true

$Collator->change(%old); # returns (level => 2).

$Collator->eq("perl", "PERL"); # false
```

  Not all `(key,value)`s are allowed to be changed. See also `@Unicode::Collate::ChangeOK` and `@Unicode::Collate::ChangeNG`.

  In the scalar context, returns the modified collator (but it is **not** a clone from the original).

```
$Collator->change(level => 2)->eq("perl", "PERL"); # true

$Collator->eq("perl", "PERL"); # true; now max level is 2nd.

$Collator->change(level => 4)->eq("perl", "PERL"); # false
```

- `$version = $Collator->version()`

  Returns the version number (a string) of the Unicode Standard which the `table` file used by the collator object is based on. If the table does not include a version line (starting with `@version`), returns `"unknown"`.

- `UCA_Version()`

  Returns the revision number of UTS #10 this module consults, that should correspond with the DUCET incorporated.

- `Base_Unicode_Version()`

  Returns the version number of UTS #10 this module consults, that should correspond with the DUCET incorporated.

EXPORT

No method will be exported.

INSTALL

Though this module can be used without any `table` file, to use this module easily, it is recommended to install a table file in the UCA format, by copying it under the directory <a place in @INC>/Unicode/Collate.

The most preferable one is "The Default Unicode Collation Element Table" (aka DUCET), available from the Unicode Consortium's website:

```
http://www.unicode.org/Public/UCA/

http://www.unicode.org/Public/UCA/latest/allkeys.txt
(latest version)
```

If DUCET is not installed, it is recommended to copy the file from http://www.unicode.org/Public/UCA/latest/allkeys.txt to <a place in @INC>/Unicode/Collate/allkeys.txt manually.

CAVEATS

- Normalization

  Use of the `normalization` parameter requires the **Unicode::Normalize** module (see *Unicode::Normalize*).

  If you need not it (say, in the case when you need not handle any combining characters), assign `(normalization => undef)` explicitly.

  – see 6.5 Avoiding Normalization, UTS #10.

- Conformance Test

  The Conformance Test for the UCA is available under http://www.unicode.org/Public/UCA/.

  For `CollationTest_SHIFTED.txt`, a collator via `Unicode::Collate->new( )` should be used; for `CollationTest_NON_IGNORABLE.txt`, a collator via `Unicode::Collate->new(variable => "non-ignorable", level => 3)`.

  If `UCA_Version` is 26 or later, the `identical` level is preferred; `Unicode::Collate->new(identical => 1)` and `Unicode::Collate->new(identical => 1, variable => "non-ignorable", level => 3)` should be used.

  Unicode::Normalize is required to try The Conformance Test.

  EBCDIC-SUPPORT IS EXPERIMENTAL.

Modules

- `Unicode::Collate::CJK`
- `Unicode::Collate::Locale` - Linguistic tailoring for DUCET via Unicode::Collate

Unicode::Collate::CJK

Namespace containing the following modules:

- `Unicode::Collate::CJK::Big5` - weighting CJK Unified Ideographs for Unicode::Collate
- `Unicode::Collate::CJK::GB2312` - weighting CJK Unified Ideographs for Unicode::Collate
- `Unicode::Collate::CJK::JISX0208` - weighting JIS KANJI for Unicode::Collate

- `Unicode::Collate::CJK::Korean` - weighting CJK Unified Ideographs for Unicode::Collate
- `Unicode::Collate::CJK::Pinyin` - weighting CJK Unified Ideographs for Unicode::Collate
- `Unicode::Collate::CJK::Stroke` - weighting CJK Unified Ideographs for Unicode::Collate
- `Unicode::Collate::CJK::Zhuyin` - weighting CJK Unified Ideographs for Unicode::Collate

Unicode::Collate::CJK::Big5

weighting CJK Unified Ideographs for Unicode::Collate

SYNOPSIS

```
use Unicode::Collate;
use Unicode::Collate::CJK::Big5;

my $collator = Unicode::Collate->new(
    overrideCJK => \&Unicode::Collate::CJK::Big5::weightBig5
);
```

DESCRIPTION

`Unicode::Collate::CJK::Big5` provides `weightBig5()`, that is adequate for `overrideCJK` of `Unicode::Collate` and makes tailoring of CJK Unified Ideographs in the order of CLDR's big5han ordering.

SEE ALSO

- CLDR - Unicode Common Locale Data Repository

Unicode::Collate::CJK::GB2312

weighting CJK Unified Ideographs for Unicode::Collate

SYNOPSIS

```
use Unicode::Collate;
use Unicode::Collate::CJK::GB2312;

my $collator = Unicode::Collate->new(
    overrideCJK => \&Unicode::Collate::CJK::GB2312::weightGB2312
);
```

DESCRIPTION

`Unicode::Collate::CJK::GB2312` provides `weightGB2312()`, that is adequate for `overrideCJK` of `Unicode::Collate` and makes tailoring of CJK Unified Ideographs in the order of CLDR's gb2312han ordering.

CAVEAT

The gb2312han ordering includes 5 code points in private use area (E2D8..E2DC), that can't utilize `weightGB2312()` for collation. For them, use `entry` instead.

Unicode::Collate::CJK::JISX0208

weighting JIS KANJI for Unicode::Collate

SYNOPSIS

```
use Unicode::Collate;
use Unicode::Collate::CJK::JISX0208;

my $collator = Unicode::Collate->new(
    overrideCJK => \&Unicode::Collate::CJK::JISX0208::weightJISX0208
);
```

DESCRIPTION

`Unicode::Collate::CJK::JISX0208` provides `weightJISX0208()`, that is adequate for `overrideCJK` of `Unicode::Collate` and makes tailoring of 6355 kanji (CJK Unified Ideographs) in the JIS X 0208 order.

SEE ALSO

- *Unicode::Collate*
- *Unicode::Collate::Locale*

Unicode::Collate::CJK::Korean

weighting CJK Unified Ideographs for Unicode::Collate

SYNOPSIS

```
use Unicode::Collate;
use Unicode::Collate::CJK::Korean;

my $collator = Unicode::Collate->new(
    overrideCJK => \&Unicode::Collate::CJK::Korean::weightKorean
);
```

DESCRIPTION

`Unicode::Collate::CJK::Korean` provides `weightKorean()`, that is adequate for `overrideCJK` of `Unicode::Collate` and makes tailoring of CJK Unified Ideographs in the order of CLDR's Korean ordering.

SEE ALSO

Unicode::Collate::CJK::Pinyin

weighting CJK Unified Ideographs for Unicode::Collate

SYNOPSIS

```
use Unicode::Collate;
use Unicode::Collate::CJK::Pinyin;

my $collator = Unicode::Collate->new(
    overrideCJK => \&Unicode::Collate::CJK::Pinyin::weightPinyin
);
```

DESCRIPTION

`Unicode::Collate::CJK::Pinyin` provides `weightPinyin()`, that is adequate for `overrideCJK` of `Unicode::Collate` and makes tailoring of CJK Unified Ideographs in the order of CLDR's pinyin ordering.

CAVEAT

The pinyin ordering includes some characters that are not CJK Unified Ideographs and can't utilize `weightPinyin()` for collation. For them, use `entry` instead.

Unicode::Collate::CJK::Stroke

weighting CJK Unified Ideographs for Unicode::Collate

SYNOPSIS

```
use Unicode::Collate;
use Unicode::Collate::CJK::Stroke;

my $collator = Unicode::Collate->new(
    overrideCJK => \&Unicode::Collate::CJK::Stroke::weightStroke
);
```

DESCRIPTION

`Unicode::Collate::CJK::Stroke` provides `weightStroke()`, that is adequate for `overrideCJK` of `Unicode::Collate` and makes tailoring of CJK Unified Ideographs in the order of CLDR's stroke ordering.

CAVEAT

The stroke ordering includes some characters that are not CJK Unified Ideographs and can't utilize `weightStroke()` for collation. For them, use `entry` instead.

Unicode::Collate::CJK::Zhuyin

weighting CJK Unified Ideographs for Unicode::Collate

SYNOPSIS

```
use Unicode::Collate;
use Unicode::Collate::CJK::Zhuyin;

my $collator = Unicode::Collate->new(
    overrideCJK => \&Unicode::Collate::CJK::Zhuyin::weightZhuyin
);
```

DESCRIPTION

`Unicode::Collate::CJK::Zhuyin` provides `weightZhuyin()`, that is adequate for `overrideCJK` of `Unicode::Collate` and makes tailoring of CJK Unified Ideographs in the order of CLDR's zhuyin (bopomofo) ordering.

CAVEAT

The zhuyin ordering includes some characters that are not CJK Unified Ideographs and can't utilize `weightZhuyin()` for collation. For them, use `entry` instead.

Unicode::Collate::Locale

Linguistic tailoring for DUCET via Unicode::Collate

SYNOPSIS

```
use Unicode::Collate::Locale;

#construct
$Collator = Unicode::Collate::Locale->
    new(locale => $locale_name, %tailoring);

#sort
@sorted = $Collator->sort(@not_sorted);

#compare
$result = $Collator->cmp($a, $b); # returns 1, 0, or -1.
```

Note: Strings in `@not_sorted`, `$a` and `$b` are interpreted according to Perl's Unicode support. See perlunicode, perluniintro, perlunitut, perlunifaq, *utf8*. Otherwise you can use `preprocess` (cf. `Unicode::Collate`) or should decode them before.

DESCRIPTION

This module provides linguistic tailoring for it taking advantage of `Unicode::Collate`.

Constructor

The new method returns a collator object.

A parameter list for the constructor is a hash, which can include a special key `locale` and its value (case-insensitive) standing for a Unicode base language code (two or three-letter). For example, `Unicode::Collate::Locale->new(locale => 'ES')` returns a collator tailored for Spanish.

`$locale_name` may be suffixed with a Unicode script code (four-letter), a Unicode region (territory) code, a Unicode language variant code. These codes are case-insensitive, and separated with `'_'` or `'-'`. E.g. `en_US` for English in USA, `az_Cyrl` for Azerbaijani in the Cyrillic script, `es_ES_traditional` for Spanish in Spain (Traditional).

If `$locale_name` is not available, fallback is selected in the following order:

```
1. language with a variant code
2. language with a script code
3. language with a region code
4. language
5. default
```

Tailoring tags provided by `Unicode::Collate` are allowed as long as they are not used for `locale` support. Esp. the `table` tag is always untailorable, since it is reserved for DUCET.

However `entry` is allowed, even if it is used for `locale` support, to add or override mappings.

E.g. a collator for Spanish, which ignores diacritics and case difference (i.e. level 1), with reversed case ordering and no normalization.

```
Unicode::Collate::Locale->new(
    level => 1,
    locale => 'es',
    upper_before_lower => 1,
    normalization => undef
)
```

Overriding a behavior already tailored by `locale` is disallowed if such a tailoring is passed to `new()`.

```
Unicode::Collate::Locale->new(
    locale => 'da',
    upper_before_lower => 0, # causes error as reserved by 'da'
)
```

However `change()` inherited from `Unicode::Collate` allows such a tailoring that is reserved by `locale`. Examples:

```
new(locale => 'fr_ca')->change(backwards => undef)
new(locale => 'da')->change(upper_before_lower => 0)
new(locale => 'ja')->change(overrideCJK => undef)
```

Methods

`Unicode::Collate::Locale` is a subclass of `Unicode::Collate` and methods other than new are inherited from `Unicode::Collate`.

Here is a list of additional methods:

- `$Collator->getlocale`

  Returns a language code accepted and used actually on collation. If linguistic tailoring is not provided for a language code you passed (intensionally for some languages, or due to the incomplete implementation), this method returns a string `'default'` meaning no special tailoring.

- `$Collator->locale_version`

(Since Unicode::Collate::Locale 0.87) Returns the version number (perhaps `/\d\.\d\d/`) of the locale, as that of `Locale/*.pl`.

Note: `Locale/*.pl` that a collator uses should be identified by a combination of return values from `getlocale` and `locale_version`.

A list of tailorable locales

```
  locale name       description
------------------------------------------------------------
  af                Afrikaans
  ar                Arabic

(continued from previous page)

```
------------------------------------------------------------
```

Locales according to the default UCA rules include am (Amharic) without `[reorder Ethi]`, bg (Bulgarian) without `[reorder Cyrl]`, chr (Cherokee) without `[reorder Cher]`, de (German), en (English), fr (French), ga (Irish), id (Indonesian), it (Italian), ka (Georgian) without `[reorder Geor]`, mn (Mongolian) without `[reorder Cyrl Mong]`, ms (Malay), nl (Dutch), pt (Portuguese), ru (Russian) without `[reorder Cyrl]`, sw (Swahili), zu (Zulu).

Note

[1] ja: Ideographs are sorted in JIS X 0208 order. Fullwidth and halfwidth forms are identical to their regular form. The difference between hiragana and katakana is at the 4th level, the comparison also requires `(variable => 'Non-ignorable')`, and then `katakana_before_hiragana` has no effect.

[2] ko: Plenty of ideographs are sorted by their reading. Such an ideograph is primary (level 1) equal to, and secondary (level 2) greater than, the corresponding hangul syllable.

[3] zh__pinyin, zh__stroke and zh__zhuyin: implemented alt='short', where a smaller number of ideographs are tailored.

A list of variant codes and their aliases

```
  variant code       alias
-----------------------------------------
  dictionary         dict
  phonebook          phone     phonebk
  reformed           reform
  traditional        trad
-----------------------------------------
  big5han            big5
  gb2312han          gb2312
  pinyin
  stroke
  zhuyin
-----------------------------------------
```

Note: 'pinyin' is Han in Latin, 'zhuyin' is Han in Bopomofo.

INSTALL

Installation of `Unicode::Collate::Locale` requires `Collate/Locale.pm`, `Collate/Locale/*.pm`, `Collate/CJK/*.pm` and `Collate/allkeys.txt`. On building, `Unicode::Collate::Locale` doesn't require any of `data/*.txt`, `gendata/*`, and `mklocale`. Tests for `Unicode::Collate::Locale` are named `t/loc_*.t`.

CAVEAT

- Tailoring is not maximum

  Even if a certain letter is tailored, its equivalent would not always tailored as well as it. For example, even though W is tailored, fullwidth W (U+FF37), W with acute (U+1E82), etc. are not tailored. The result may depend on whether source strings are normalized or not, and whether decomposed or composed. Thus `(normalization => undef)` is less preferred.

- Collation reordering is not supported

  The order of any groups including scripts is not changed.

Unicode::GCString

Functions

Grapheme cluster strings

as_array

The grapheme clusters as one-cluster `Unicode::GCStrings` - what `@{$gcstring}` gives.

as_string

The string, as a Perl (UTF-8) string - what `"$gcstring"` gives.

chars

The number of characters (code points).

cmp

Compare with another string by code points, as `cmp` does - the overloaded `cmp`.

columns

The number of columns the string occupies (UAX #11).

concat

Join with another string, re-segmenting where they meet - the overloaded `.` and `.=`.

copy

A copy of the string.

eos

True when the iterator position is at the end.

flag

Get, or set, the break flag of cluster `i` (default: the current position).

item

Cluster `i` (default: the current position) as a string.

join

The strings given, joined with this one between them.

length

The number of grapheme clusters.

next

The cluster at the iterator position, advancing it; undef at the end - the overloaded `<>`.

pos

The iterator position, after setting it when an argument is given (negative counts from the end).

substr

`length` clusters from `offset`, as `substr` counts characters; with a replacement, those clusters are replaced in the string.

Overload glue

as_scalarref

A reference to the object's name, "Unicode::GCString(0x...)".

Properties

lbc

The line breaking class of the first grapheme base.

lbcext

The line breaking class of the last grapheme extender, or of its base when the extender has none of its own.

lbclass

Obsolete: the class of cluster `i`'s base; use `lbc`.

lbclass_ext

Obsolete: the class of cluster `i`'s extender; use `lbcext`.

Unicode::LineBreak

Line breaking for Unicode text, and strings of grapheme clusters.

`Unicode::LineBreak` folds text into lines following UAX #14, the Unicode Line Breaking Algorithm: it knows where a line may end in any script, keeps a column budget the way terminals and fixed-width fonts count it (UAX #11 East Asian widths), and lets you tailor classes, widths, line formatting and what happens to a word too long for a line. `Unicode::GCString` is the string type it works in: a sequence of grapheme clusters - what a reader sees as one character - with their columns and line breaking classes. `Text::LineFold` builds on both to fold and unfold plain text.

```
use Unicode::LineBreak;
use Unicode::GCString;

my $lb = Unicode::LineBreak->new(ColMax => 20);
```

(continues on next page)

(continued from previous page)

```
print $lb->break("The quick brown fox jumps over the lazy dog.\n");

my $s = Unicode::GCString->new("e\x{301}\x{65E5}\x{672C}");
print $s->length, " clusters, ", $s->columns, " columns\n";
# The quick brown fox
# jumps over the lazy
# dog.
# 3 clusters, 5 columns
```

Scripts written without spaces between words - Thai, Lao, Khmer, Myanmar - are broken between words with the dictionaries of the system's ICU library when it is installed (`ComplexBreaking`), and kept whole when it is not.

This is a native implementation of the XS half of Unicode-LineBreak 2019.001 (sombok 2.4.0); its `Unicode/LineBreak.pm`, `Unicode/GCString.pm` and `Text/LineFold.pm` are used unchanged.

Differences from upstream

- **Unicode version.** Classes, widths and clusters come from the interpreter's own Unicode tables (`UNICODE_VERSION` is 17.0.0), and the rules are Unicode 17's UAX #14 and UAX #29, the same perl's `\b{lb}` and `\X` follow. Upstream is frozen at Unicode 8.0.0. So emoji are wide, emoji modifier and ZWJ sequences are one cluster, Indic conjuncts join (UAX #29 GB9c), and the Unicode 9-17 classes (EB, EM, ZWJ, HH, AK, AP, AS, VF, VI) exist; their `LB_*` constants follow upstream's 40.
- `ViramaAsJoiner` is accepted and reported but changes nothing: what it did beyond UAX #29 is UAX #29 itself now (GB9c).
- SA text (Thai and its neighbours) is segmented by ICU's dictionaries instead of libthai, so `SouthEastAsian::supported()` names ICU and all four scripts, and Thai words may break differently.
- `LB_CJ` and `LB_XX` are the classes their names say. Upstream's constants swap them: its library numbers CJ 39 and XX 38 while the constants it exports give CJ 38 and XX 39.
- A string that is not valid UTF-8 where a string or GCString is expected (`$gc . "\xE9"`) is read with U+FFFD for each bad sequence; upstream loops forever.
- A `Prep` pattern that matches the empty string keeps the character after the match; upstream drops it.
- `break` breaks a whole text in one pass instead of 1000-character slices; the lines are the same.
- A setting call (`$lb->config(Key => $value)`) returns undef; upstream returns a null pointer to Perl.

Modules

- `Unicode::LineBreak::SouthEastAsian`

Functions

Line breaking

`lbrule`

Obsolete: the breaking action between two classes; use `breakingRule`.

`breakingRule`

The breaking action between the end of one string and the start of another: `MANDATORY`, `DIRECT` (a break may come there), `INDIRECT` (only if spaces come between them) or `PROHIBITED`.

`reset`

Forget a partially broken text, starting afresh.

`strsize`

Obsolete: `len` plus the columns of `spc` and `str`; use `Unicode::GCString::columns`.

`break`

Break a whole text into lines: in list context the lines as `Unicode::GCStrings`, in scalar context the text with line breaks.

`break_partial`

Break text arriving in pieces: each call returns the lines that are complete so far; `undef` ends the text and returns the rest.

Configuration

`copy`

A copy of the object: its settings, tailoring and any partially broken text.

Properties

`EAWidths`

The East_Asian_Width values, in the order of their `EA_*` constants.

LBClasses

The line breaking classes, in the order of their `LB_*` constants.

Overload glue

as_hashref

The object's user hash: what `$lb->{key}` reaches.

as_scalarref

A reference to the object's name, "Unicode::LineBreak(0x...)".

as_string

The object's name, "Unicode::LineBreak(0x...)".

Library info

UNICODE_VERSION

The Unicode version of the character data, "17.0.0".

SOMBOK_VERSION

The version of the sombok library this module reimplements.

Unicode::LineBreak::SouthEastAsian

Functions

Library info

supported

Which scripts written without spaces are broken into words, and by what: "Thai:ICU/78.3 Lao:ICU/78.3 ...", or undef without ICU.

Unicode::Normalize

`Unicode::Normalize` - the Unicode normalization forms NFD, NFC, NFKD and NFKC (UAX #15), and the FCD and FCC forms of UTN #5.

```
use Unicode::Normalize qw(NFD NFC NFKC normalize checkNFC␣
 ↪getCombinClass getCanon);

binmode STDOUT, ':encoding(UTF-8)';
my $s = "Cafe\x{301} \x{FB01}";              # e + combining acute,
 ↪"fi" ligature
printf "NFC  %s (%d chars)\n", NFC($s), length NFC($s);   # Café fi␣
```

(continues on next page)

(continued from previous page)

```
 ↪(6 chars)
printf "NFD  %d chars\n", length NFD("Caf\x{e9}");        # 5 chars
printf "NFKC %s\n", NFKC($s);                             # Café fi
print  "same: ", (normalize('C', $s) eq NFC($s) ? "yes" : "no"), "\n
 ↪";
print  "checkNFC: ", (defined checkNFC($s) ? checkNFC($s) || 'NO' :
 ↪'MAYBE'), "\n";
printf "class of U+0301: %d, U+00E9 = %vX\n", getCombinClass(0x301),␣
 ↪getCanon(0xE9);
# class of U+0301: 230, U+00E9 = 65.301
```

Two strings that look the same can be different sequences of characters: é is one character, U+00E9, or two, e and the combining acute U+0301. Normalizing both to the same form makes them compare equal. NFD and NFKD decompose every character as far as it goes; NFC and NFKC decompose and then compose again, giving the short form. The K forms also replace compatibility characters - ligatures, full-width forms, superscripts - by their plain equivalents, which loses formatting; NFC is the form to store and compare text in.

The data are those of the Unicode version perl itself was built with (17.0.0 for perl 5.44), so normalization agrees with perl's own character properties.

This is a native implementation of `Unicode::Normalize` 1.32; its `Unicode/Normalize.pm` is used unchanged. `use Unicode::Normalize` exports NFC, NFD, NFKC and NFKD; every other function named on this page is exported on request. The `.pm` adds, over these functions:

- `normalize($form, $string)`, where `$form` is C, D, KC, KD (or NFC ...), FCD or FCC, and `check($form, $string)` for the quick checks.
- `FCD($string)`: the string unchanged when it is already in FCD, else a string in FCD.
- `normalize_partial($form, $unprocessed)` and `NFD_partial`, `NFC_partial`, `NFKD_partial`, `NFKC_partial`: normalize what can be normalized now and leave the rest in `$unprocessed`, for text that arrives in pieces (see `splitOnLastStarter`).

A code point argument is converted as an unsigned integer: pass a plain non-negative integer.

Differences from upstream

None.

Functions

Normalization forms

NFD

`NFD($string)`: Normalization Form D, the canonical decomposition with the combining marks in canonical order. `NFKD($string)` is Form KD, the same with compatibility

decomposition. Both exported by default.

Also available as `Unicode::Normalize::NFKD`.

FCC

`NFC($string)`: Normalization Form C, canonical decomposition followed by canonical composition - the composed form, and the usual one for storing and comparing text. `NFKC($string)` is Form KC, from the compatibility decomposition; `FCC($string)` is UTN #5's "Fast C Contiguous" form. `NFC` and `NFKC` are exported by default.

Also available as `Unicode::Normalize::NFC`, `Unicode::Normalize::NFKC`.

Quick checks

checkNFD

`checkNFD($string)`, `checkNFKD($string)`: the quick check of UAX #15, 1 when the string is in NFD (NFKD) and `""` when it is not. For these forms the answer is always definite.

Also available as `Unicode::Normalize::checkNFKD`.

checkNFC

`checkNFC($string)`, `checkNFKC($string)`: the quick check - 1 when the string is in NFC (NFKC), `""` when it is not, and `undef` for "maybe": a combining mark the check cannot decide on alone. `checkNFC("A\x{301}")` and `checkNFC("B\x{301}")` both say maybe, though only the first is not in NFC; for a definite answer compare `$string eq NFC($string)`.

Also available as `Unicode::Normalize::checkNFKC`.

checkFCC

`checkFCD($string)`: 1 when the string is in FCD, `""` when not. `checkFCC($string)`: the same for FCC, with `undef` for "maybe"; a string not in FCD is never in FCC.

Also available as `Unicode::Normalize::checkFCD`.

Building blocks

decompose

`decompose($string [, $compat])`: each character replaced by its canonical decomposition, or by its compatibility decomposition when `$compat` is true. The combining marks are not put in canonical order: `reorder(decompose($s))` is `NFD($s)`, and `reorder(decompose($s, 1))` is `NFKD($s)`.

reorder

`reorder($string)`: every run of combining marks put in canonical order. Joined NFD (or NFKD) strings are NFD again after `reorder`: `reorder(join '', @nfd_strings)`.

compose

`compose($string)`: canonical composition, without decomposing first; `compose($nfd)` is the NFC of an NFD string, `compose($nfkd)` the NFKC of an NFKD one. `composeContiguous($string)` composes only characters that are next to each other, which is how FCC is made.

Also available as `Unicode::Normalize::composeContiguous`.

splitOnLastStarter

`splitOnLastStarter($normalized)`: two strings, the part before the last starter (a character of combining class 0) and the rest. The rest may still change when more text follows, so text normalized in pieces is put together as:

Character data

getCombinClass

`getCombinClass($code_point)`: the canonical combining class, 0 for a starter (230 for U+0301 COMBINING ACUTE ACCENT).

isExclusion

`isExclusion($code_point)`: whether it is a composition exclusion, a character composition never produces.

isSingleton

`isSingleton($code_point)`: whether it decomposes canonically to a single other character.

isNonStDecomp

`isNonStDecomp($code_point)`: whether its decomposition starts with a non-starter (a character of combining class other than 0).

isComp2nd

`isComp2nd($code_point)`: whether it can compose with the character before it (Hangul included, exclusions not). `isNFC_MAYBE` and `isNFKC_MAYBE` are the same property under its quick-check names, `NFC_Quick_Check=Maybe` and `NFKC_Quick_Check=Maybe`.

Also available as `Unicode::Normalize::isNFC_MAYBE`, `Unicode::Normalize::isNFKC_MAYBE`.

isNFD_NO

`isNFD_NO($code_point)`: the derived property `NFD_Quick_Check=No` - whether it decomposes canonically. `isNFKD_NO` is `NFKD_Quick_Check=No`: whether it decomposes at all.

Also available as `Unicode::Normalize::isNFKD_NO`.

isComp_Ex

`isComp_Ex($code_point)`: the derived property Full_Composition_Exclusion - an exclusion, a singleton or a non-starter decomposition. `isNFC_NO` is the same property, as `NFC_Quick_Check=No`; `isNFKC_NO` is `NFKC_Quick_Check=No`, which adds every character whose compatibility decomposition differs from its canonical one (U+FB01, the "fi" ligature).

Also available as `Unicode::Normalize::isNFC_NO`, `Unicode::Normalize::isNFKC_NO`.

getComposite

`getComposite($code_point, $next_code_point)`: the code point the two compose to (Hangul included, exclusions excluded), or `undef`.

getCanon

`getCanon($code_point)`: the full canonical decomposition as a string, or `undef` for a character that does not decompose canonically. `getCompat($code_point)` is the same for the compatibility decomposition. Hangul syllables decompose to their jamo.

Also available as `Unicode::Normalize::getCompat`.

splitOnLastStarter

`splitOnLastStarter($normalized)`: two strings, the part before the last starter (a character of combining class 0) and the rest. The rest may still change when more text follows, so text normalized in pieces is put together as:

```
my ($done, $pending) = splitOnLastStarter($normalized);
my $all = $done . NFC($pending . $more);
```

`$normalized` must already be in the form being built. `normalize_partial` wraps this.

Unicode::UCD

`Unicode::UCD` - the Unicode Character Database: what perl knows about each character, block and script.

```
use Unicode::UCD qw(charblock charinfo);

my $ci = charinfo(0xE9);
printf "Unicode %s | %s | %s, class %s\n",␣
```

(continues on next page)

(continued from previous page)

```
 ↪Unicode::UCD::UnicodeVersion(),
    charblock(0x263A), $ci->{name}, $ci->{category};
# Unicode 17.0.0 | Miscellaneous Symbols | LATIN SMALL LETTER E WITH␣
 ↪ACUTE, class Ll
```

`charinfo`, `charblock`, `charscript`, `charblocks`, `charscripts`, `charprop`, `prop_invlist`, `casefold`, `casespec`, `num` and the rest are `Unicode/UCD.pm` 0.83's own Perl, unchanged, over the data of the Unicode version perl 5.44 was built with (17.0.0) whatever the host has installed.

Upstream reads three of its tables - the Unicode version, the block list and the special casing rules - from files along `@INC` (`unicore/version`, `unicore/Blocks.txt`, `unicore/SpecialCasing.txt`). pperl stores them in the binary when it is built and hands them to `UCD.pm` when it loads, so nothing is read from disk.

Differences from upstream

None in behaviour.

5.2.111 User

Namespace containing the following modules:

- `User::grent` - by-name interface to Perl's built-in getgr*() functions
- `User::pwent` - by-name interface to Perl's built-in getpw*() functions

User::grent

by-name interface to Perl's built-in getgr*() functions

SYNOPSIS

```
use User::grent;
my $gr = getgrgid(0) or die "No group zero";
if ( $gr->name eq 'wheel' && @{$gr->members} > 1 ) {
    print "gid zero name wheel, with other members";
}

use User::grent qw(:FIELDS);
getgrgid(0) or die "No group zero";
if ( $gr_name eq 'wheel' && @gr_members > 1 ) {
    print "gid zero name wheel, with other members";
}

my $gr = getgr($whoever);
```

DESCRIPTION

This module's default exports override the core getgrent(), getgrgid(), and getgrnam() functions, replacing them with versions that return "User::grent" objects. This object has methods that return the similarly named structure field name from the C's passwd structure from `grp.h`; namely name, passwd, gid, and members (not mem). The first three return scalars, the last an array reference.

You may also import all the structure fields directly into your namespace as regular variables using the :FIELDS import tag. (Note that this still overrides your core functions.) Access these fields as variables named with a preceding `gr_`. Thus, `$group_obj->gid()` corresponds to $gr_gid if you import the fields. Array references are available as regular array variables, so `@{ $group_obj->members() }` would be simply @gr_members.

The getgr() function is a simple front-end that forwards a numeric argument to getgrgid() and the rest to getgrnam().

To access this functionality without the core overrides, pass the `use` an empty import list, and then access function functions with their full qualified names. On the other hand, the built-ins are still available via the `CORE::` pseudo-package.

NOTE

While this class is currently implemented using the Class::Struct module to build a struct-like class, you shouldn't rely upon this.

Tom Christiansen

User::pwent

by-name interface to Perl's built-in getpw*() functions

SYNOPSIS

```
use User::pwent;
my $pw = getpwnam('daemon')       || die "No daemon user";
if ( $pw->uid == 1 && $pw->dir =~ m#^/(bin|tmp)?\z#s ) {
    print "gid 1 on root dir";
}

my $real_shell = $pw->shell || '/bin/sh';

for (my ($fullname, $office, $workphone, $homephone) =
       split /\s*,\s*/, $pw->gecos)
{
   s/&/ucfirst(lc($pw->name))/ge;
}

use User::pwent qw(:FIELDS);
```

(continues on next page)

(continued from previous page)

```
getpwnam('daemon')              || die "No daemon user";
if ( $pw_uid == 1 && $pw_dir =~ m#^/(bin|tmp)?\z#s ) {
    print "gid 1 on root dir";
}

my $pw = getpw($whoever);

use User::pwent qw/:DEFAULT pw_has/;
if (pw_has(qw[gecos expire quota])) { .... }
if (pw_has("name uid gid passwd"))  { .... }
print "Your struct pwd has: ", scalar pw_has(), "\n";
```

DESCRIPTION

This module's default exports override the core getpwent(), getpwuid(), and getpwnam() functions, replacing them with versions that return `User::pwent` objects. This object has methods that return the similarly named structure field name from the C's passwd structure from pwd.h, stripped of their leading "pw_" parts, namely `name`, `passwd`, `uid`, `gid`, `change`, `age`, `quota`, `comment`, `class`, `gecos`, `dir`, `shell`, and `expire`. The `passwd`, `gecos`, and `shell` fields are tainted when running in taint mode.

You may also import all the structure fields directly into your namespace as regular variables using the :FIELDS import tag. (Note that this still overrides your core functions.) Access these fields as variables named with a preceding `pw_` in front their method names. Thus, `$passwd_obj->shell` corresponds to $pw_shell if you import the fields.

The getpw() function is a simple front-end that forwards a numeric argument to getpwuid() and the rest to getpwnam().

To access this functionality without the core overrides, pass the `use` an empty import list, and then access function functions with their full qualified names. The built-ins are always still available via the `CORE::` pseudo-package.

System Specifics

Perl believes that no machine ever has more than one of `change`, `age`, or `quota` implemented, nor more than one of either `comment` or `class`. Some machines do not support `expire`, `gecos`, or allegedly, `passwd`. You may call these methods no matter what machine you're on, but they return `undef` if unimplemented.

You may ask whether one of these was implemented on the system Perl was built on by asking the importable `pw_has` function about them. This function returns true if all parameters are supported fields on the build platform, false if one or more were not, and raises an exception if you asked about a field that Perl never knows how to provide. Parameters may be in a space-separated string, or as separate arguments. If you pass no parameters, the function returns the list of `struct pwd` fields supported by your build platform's C library, as a list in list context, or a space-separated string in scalar context. Note that just because your C library had a field doesn't necessarily mean that it's fully implemented on that system.

Interpretation of the `gecos` field varies between systems, but traditionally holds 4 comma-separated fields containing the user's full name, office location, work phone

number, and home phone number. An & in the gecos field should be replaced by the user's properly capitalized login `name`. The `shell` field, if blank, must be assumed to be `/bin/sh`. Perl does not do this for you. The `passwd` is one-way hashed garble, not clear text, and may not be unhashed save by brute-force guessing. Secure systems use more a more secure hashing than DES. On systems supporting shadow password systems, Perl automatically returns the shadow password entry when called by a suitably empowered user, even if your underlying vendor-provided C library was too short-sighted to realize it should do this.

See passwd(5) and getpwent(3) for details.

NOTE

While this class is currently implemented using the Class::Struct module to build a struct-like class, you shouldn't rely upon this.

AUTHOR

Tom Christiansen

HISTORY

- March 18th, 2000

  Reworked internals to support better interface to dodgey fields than normal Perl function provides. Added pw_has() field. Improved documentation.

5.2.112 XML

Namespace containing the following modules:

- `XML::Parser` - A perl module for parsing XML documents

XML::Parser

A perl module for parsing XML documents

SYNOPSIS

```
use XML::Parser;

$p1 = XML::Parser->new(Style => 'Debug');
$p1->parsefile('REC-xml-19980210.xml');
$p1->parse('<foo id="me">Hello World</foo>');

# Alternative
$p2 = XML::Parser->new(Handlers => {Start => \&handle_start,
                                    End   => \&handle_end,
                                    Char  => \&handle_char});
$p2->parse($socket);
```

(continues on next page)

(continued from previous page)

```
# Another alternative
$p3 = XML::Parser->new(ErrorContext => 2);

$p3->setHandlers(Char    => \&text,
                 Default => \&other);

open(my $fh, 'xmlgenerator |');
$p3->parse($fh, ProtocolEncoding => 'ISO-8859-1');
close($fh);

$p3->parsefile('junk.xml', ErrorContext => 3);
```

DESCRIPTION

This module provides ways to parse XML documents. It is built on top of *XML::Parser::Expat*, which is a lower level interface to James Clark's expat library. Each call to one of the parsing methods creates a new instance of XML::Parser::Expat which is then used to parse the document. Expat options may be provided when the XML::Parser object is created. These options are then passed on to the Expat object on each parse call. They can also be given as extra arguments to the parse methods, in which case they override options given at XML::Parser creation time.

The behavior of the parser is controlled either by "`STYLES`" and/or "`HANDLERS`" options, or by "setHandlers" method. These all provide mechanisms for XML::Parser to set the handlers needed by XML::Parser::Expat. If neither `Style` nor `Handlers` are specified, then parsing just checks the document for being well-formed.

When underlying handlers get called, they receive as their first parameter the *Expat* object, not the Parser object.

METHODS

- new

  This is a class method, the constructor for XML::Parser. Options are passed as keyword value pairs. Recognized options are:

  – Style

  This option provides an easy way to create a given style of parser. The built in styles are: "Debug", "Subs", "Tree", "Objects", and "Stream". These are all defined in separate packages under `XML::Parser::Style::*`, and you can find further documentation for each style both below, and in those packages.

  Custom styles can be provided by giving a full package name containing at least one '::'. This package should then have subs defined for each handler it wishes to have installed. See "STYLES" below for a discussion of each built in style.

  – Handlers

  When provided, this option should be an anonymous hash containing as keys the type of handler and as values a sub reference to handle that type of event.

All the handlers get passed as their 1st parameter the instance of expat that is parsing the document. Further details on handlers can be found in "HANDLERS". Any handler set here overrides the corresponding handler set with the Style option.

– Pkg

Some styles will refer to subs defined in this package. If not provided, it defaults to the package which called the constructor.

– ErrorContext

This is an Expat option. When this option is defined, errors are reported in context. The value should be the number of lines to show on either side of the line in which the error occurred.

– ProtocolEncoding

This is an Expat option. This sets the protocol encoding name. It defaults to none. The built-in encodings are: `UTF-8`, `ISO-8859-1`, `UTF-16`, and `US-ASCII`. Other encodings may be used if they have encoding maps in one of the directories in the @Encoding_Path list. Check "ENCODINGS" for more information on encoding maps. Setting the protocol encoding overrides any encoding in the XML declaration.

– Namespaces

This is an Expat option. If this is set to a true value, then namespace processing is done during the parse. See *"Namespaces" in XML::Parser::Expat* for further discussion of namespace processing.

– NoExpand

This is an Expat option. Normally, the parser will try to expand references to entities defined in the internal subset. If this option is set to a true value, and a default handler is also set, then the default handler will be called when an entity reference is seen in text. This has no effect if a default handler has not been registered, and it has no effect on the expansion of entity references inside attribute values.

– Stream_Delimiter

This is an Expat option. It takes a string value. When this string is found alone on a line while parsing from a stream, then the parse is ended as if it saw an end of file. The intended use is with a stream of xml documents in a MIME multipart format. The string should not contain a trailing newline.

– ParseParamEnt

This is an Expat option. Unless standalone is set to "yes" in the XML declaration, setting this to a true value allows the external DTD to be read, and parameter entities to be parsed and expanded.

Implicit vs explicit parameter entity parsing: When `ParseParamEnt` is not set, parameter entity references (e.g. `%foo;`) in the internal DTD subset are passed through to the **Default** handler as literal text. This is the mode that XML::Twig and other DTD round-tripping tools rely on.

When `ParseParamEnt` is set to a true value, or when a declaration handler (**Entity**, **Element**, or **Attlist**) is registered, parameter entity parsing is activated. In this mode, PE references are resolved by expat (via the **ExternEnt** handler) and subsequent declarations are routed to their dedicated declaration handlers instead of the Default handler.

– NoLWP

This option has no effect if the ExternEnt or ExternEntFin handlers are directly set. Otherwise, if true, it forces the use of a file based external entity handler.

– BillionLaughsAttackProtectionMaximumAmplification

Sets the maximum amplification factor for the Billion Laughs attack protection. See “SECURITY” below for details.

This is an Expat option. Requires libexpat >= 2.4.0 built with `XML_DTD` or `XML_GE`.

– BillionLaughsAttackProtectionActivationThreshold

Sets the activation threshold (in bytes) for the Billion Laughs attack protection. See “SECURITY” below for details.

This is an Expat option. Requires libexpat >= 2.4.0 built with `XML_DTD` or `XML_GE`.

– AllocTrackerMaximumAmplification

Sets the maximum amplification factor for the allocation tracker. See “SECURITY” below for details.

This is an Expat option. Requires libexpat >= 2.7.2 built with `XML_DTD` or `XML_GE`.

– AllocTrackerActivationThreshold

Sets the activation threshold (in bytes) for the allocation tracker. See “SECURITY” below for details.

This is an Expat option. Requires libexpat >= 2.7.2 built with `XML_DTD` or `XML_GE`.

– ReparseDeferralEnabled

Enables or disables reparse deferral, a security mechanism that prevents certain token-boundary attacks. See “SECURITY” below for details.

This is an Expat option. Requires libexpat >= 2.6.0.

– Non_Expat_Options

If provided, this should be an anonymous hash whose keys are options that shouldn’t be passed to Expat. This should only be of concern to those subclassing XML::Parser.

- setHandlers(TYPE, HANDLER [, TYPE, HANDLER [...]])

This method registers handlers for various parser events. It overrides any previous handlers registered through the Style or Handler options or through earlier calls to setHandlers. By providing a false or undefined value as the handler, the existing handler can be unset.

This method returns a list of type, handler pairs corresponding to the input. The handlers returned are the ones that were in effect prior to the call.

See a description of the handler types in "HANDLERS".

- parse(SOURCE [, OPT => OPT_VALUE [...]])

  The SOURCE parameter should either be a string containing the whole XML document, or it should be an open IO::Handle. Constructor options to XML::Parser::Expat given as keyword-value pairs may follow the SOURCE parameter. These override, for this call, any options or attributes passed through from the XML::Parser instance.

  A die call is thrown if a parse error occurs. Otherwise it will return 1 or whatever is returned from the **Final** handler, if one is installed. In other words, what parse may return depends on the style.

  See "ERROR HANDLING" below for how to catch and handle parse errors.

- parsestring

  This is just an alias for parse for backwards compatibility.

- parsefile(FILE [, OPT => OPT_VALUE [...]])

  Open FILE for reading, then call parse with the open handle. The file is closed no matter how parse returns. A die call is thrown if the file cannot be opened or if a parse error occurs. Returns what parse returns.

- parse_start([OPT => OPT_VALUE [...]])

  Create and return a new instance of XML::Parser::ExpatNB. Constructor options may be provided. If an init handler has been provided, it is called before returning the ExpatNB object. Documents are parsed by making incremental calls to the parse_more method of this object, which takes a string. A single call to the parse_done method of this object, which takes no arguments, indicates that the document is finished.

  If there is a final handler installed, it is executed by the parse_done method before returning and the parse_done method returns whatever is returned by the final handler.

HANDLERS

Expat is an event based parser. As the parser recognizes parts of the document (say the start or end tag for an XML element), then any handlers registered for that type of an event are called with suitable parameters. All handlers receive an instance of XML::Parser::Expat as their first argument. See *"METHODS" in XML::Parser::Expat* for a discussion of the methods that can be called on this object.

Init (Expat)

This is called just before the parsing of the document starts.

Final (Expat)

This is called just after parsing has finished, but only if no errors occurred during the parse. Parse returns what this returns.

Start (Expat, Element [, Attr, Val [,...]])

This event is generated when an XML start tag is recognized. Element is the name of the XML element type that is opened with the start tag. The Attr & Val pairs are generated for each attribute in the start tag.

End (Expat, Element)

This event is generated when an XML end tag is recognized. Note that an XML empty tag (<foo/>) generates both a start and an end event.

Char (Expat, String)

This event is generated when non-markup is recognized. The non-markup sequence of characters is in String. A single non-markup sequence of characters may generate multiple calls to this handler. Whatever the encoding of the string in the original document, this is given to the handler in UTF-8.

Important: Because the underlying expat library parses in fixed-size chunks, character data that spans a buffer boundary will arrive as two or more consecutive Char events. This typically occurs with files larger than about 32 KiB and is not a bug. To obtain the complete text of an element, accumulate the strings delivered between Start and End events:

```
my $current_text;
sub start_handler { $current_text = ''; }
sub char_handler  { $current_text .= $_[1]; }
sub end_handler   { print "complete text: $current_text\n"; }
```

The Stream style (`XML::Parser::Style::Stream`) already performs this accumulation automatically.

Proc (Expat, Target, Data)

This event is generated when a processing instruction is recognized.

Comment (Expat, Data)

This event is generated when a comment is recognized.

CdataStart (Expat)

This is called at the start of a CDATA section.

CdataEnd (Expat)

This is called at the end of a CDATA section.

Default (Expat, String)

This is called for any characters that don't have a registered handler. This includes both characters that are part of markup for which no events are generated (markup declarations) and characters that could generate events, but for which no handler has been registered.

Whatever the encoding in the original document, the string is returned to the handler in UTF-8.

Unparsed (Expat, Entity, Base, Sysid, Pubid, Notation)

This is called for a declaration of an unparsed entity. Entity is the name of the entity. Base is the base to be used for resolving a relative URI. Sysid is the system id. Pubid is the public id. Notation is the notation name. Base and Pubid may be undefined.

Notation (Expat, Notation, Base, Sysid, Pubid)

This is called for a declaration of notation. Notation is the notation name. Base is the base to be used for resolving a relative URI. Sysid is the system id. Pubid is the public id. Base, Sysid, and Pubid may all be undefined.

ExternEnt (Expat, Base, Sysid, Pubid)

This is called when an external entity is referenced. Base is the base to be used for resolving a relative URI. Sysid is the system id. Pubid is the public id. Base, and Pubid may be undefined.

This handler should either return a string, which represents the contents of the external entity, or return an open filehandle that can be read to obtain the contents of the external entity, or return undef, which indicates the external entity couldn't be found and will generate a parse error.

If an open filehandle is returned, it must be returned as either a glob (*FOO) or as a reference to a glob (e.g. an instance of IO::Handle).

A default handler is installed for this event. The default handler is XML::Parser::lwp_ext_ent_handler unless the NoLWP option was provided with a true value, otherwise XML::Parser::file_ext_ent_handler is the default handler for external entities. Even without the NoLWP option, if the URI or LWP modules are missing, the file based handler ends up being used after giving a warning on the first external entity reference.

The LWP external entity handler will use proxies defined in the environment (http_proxy, ftp_proxy, etc.).

Please note that the LWP external entity handler reads the entire entity into a string and returns it, where as the file handler opens a filehandle.

Also note that the file external entity handler will likely choke on absolute URIs or file names that don't fit the conventions of the local operating system.

The expat base method can be used to set a basename for relative pathnames. If no basename is given, or if the basename is itself a relative name, then it is relative to the current working directory.

ExternEntFin (Expat)

This is called after parsing an external entity. It's not called unless an ExternEnt handler is also set. There is a default handler installed that pairs with the default ExternEnt handler.

If you're going to install your own ExternEnt handler, then you should set (or unset) this handler too.

Entity (Expat, Name, Val, Sysid, Pubid, Ndata, IsParam)

This is called when an entity is declared. For internal entities, the Val parameter will contain the value and the remaining three parameters will be undefined. For external entities, the Val parameter will be undefined, the Sysid parameter will have the system id, the Pubid parameter will have the public id if it was provided (it will be undefined otherwise), the Ndata parameter will contain the notation for unparsed entities. If this is a parameter entity declaration, then the IsParam parameter is true.

Note that this handler and the Unparsed handler above overlap. If both are set, then this handler will not be called for unparsed entities.

Element (Expat, Name, Model)

The element handler is called when an element declaration is found. Name is the element name, and Model is the content model as an XML::Parser::Content object. See *"XML::Parser::ContentModel Methods" in XML::Parser::Expat* for methods available for this class.

Attlist (Expat, Elname, Attname, Type, Default, Fixed)

This handler is called for each attribute in an ATTLIST declaration. So an ATTLIST declaration that has multiple attributes will generate multiple calls to this handler. The Elname parameter is the name of the element with which the attribute is being associated. The Attname parameter is the name of the attribute. Type is the attribute type, given as a string. Default is the default value, which will either be "#REQUIRED", "#IMPLIED" or a quoted string (i.e. the returned string will begin and end with a quote character). If Fixed is true, then this is a fixed attribute.

Doctype (Expat, Name, Sysid, Pubid, Internal)

This handler is called for DOCTYPE declarations. Name is the document type name. Sysid is the system id of the document type, if it was provided, otherwise it's undefined. Pubid is the public id of the document type, which will be undefined if no public id was given. Internal will be true or false, indicating whether or not the doctype declaration contains an internal subset.

* DoctypeFin (Expat)

This handler is called after parsing of the DOCTYPE declaration has finished, including any internal or external DTD declarations.

XMLDecl (Expat, Version, Encoding, Standalone)

This handler is called for xml declarations. Version is a string containing the version. Encoding is either undefined or contains an encoding string. Standalone will be either true, false, or undefined if the standalone attribute is yes, no, or not made respectively.

STYLES

Debug

This just prints out the document in outline form. Nothing special is returned by parse.

Subs

Each time an element starts, a sub by that name in the package specified by the Pkg option is called with the same parameters that the Start handler gets called with.

Each time an element ends, a sub with that name appended with an underscore ("_"), is called with the same parameters that the End handler gets called with.

Nothing special is returned by parse.

Tree

Parse will return a parse tree for the document. Each node in the tree takes the form of a tag, content pair. Text nodes are represented with a pseudo-tag of "0" and the string that is their content. For elements, the content is an array reference. The first item in the array is a (possibly empty) hash reference containing attributes. The remainder of the array is a sequence of tag-content pairs representing the content of the element.

So for example the result of parsing:

```
<foo><head id="a">Hello <em>there</em></head><bar>Howdy<ref/></bar>
 ↪do</foo>
```

would be:

```
           Tag   Content
=============================================================
[foo, [{}, head, [{id => "a"}, 0, "Hello ",  em, [{}, 0, "there"]],
            bar, [         {}, 0, "Howdy",  ref, [{}]],
              0, "do"
      ]
]
```

The root document "foo", has 3 children: a "head" element, a "bar" element and the text "do". After the empty attribute hash, these are represented in it's contents by 3 tag-content pairs.

Objects

This is similar to the Tree style, except that a hash object is created for each element. The corresponding object will be in the class whose name is created by appending "::" and the element name to the package set with the Pkg option. Non-markup text will be in the ::Characters class. The contents of the corresponding object will be in an anonymous array that is the value of the Kids property for that object.

Stream

This style also uses the Pkg package. If none of the subs that this style looks for is there, then the effect of parsing with this style is to print a canonical copy of the document without comments or declarations. All the subs receive as their 1st parameter the Expat instance for the document they're parsing.

It looks for the following routines:

- StartDocument

  Called at the start of the parse .

- StartTag

  Called for every start tag with a second parameter of the element type. The $_ variable will contain a copy of the tag and the %_ variable will contain attribute values supplied for that element.

- EndTag

  Called for every end tag with a second parameter of the element type. The $_ variable will contain a copy of the end tag.

- Text

  Called just before start or end tags with accumulated non-markup text in the $_ variable.

- PI

  Called for processing instructions. The $_ variable will contain a copy of the PI and the target and data are sent as 2nd and 3rd parameters respectively.

- EndDocument

  Called at conclusion of the parse.

ENCODINGS

XML documents may be encoded in character sets other than Unicode as long as they may be mapped into the Unicode character set. Expat has further restrictions on encodings. Read the xmlparse.h header file in the expat distribution to see details on these restrictions.

Expat has built-in encodings for: `UTF-8`, `ISO-8859-1`, `UTF-16`, and `US-ASCII`. Encodings are set either through the XML declaration encoding attribute or through the ProtocolEncoding option to XML::Parser or XML::Parser::Expat.

For encodings other than the built-ins, expat calls the function load_encoding in the Expat package with the encoding name. This function looks for a file in the path list

@XML::Parser::Expat::Encoding_Path, that matches the lower-cased name with a '.enc' extension. The first one it finds, it loads.

If you wish to build your own encoding maps, check out the XML::Encoding module from CPAN.

ERROR HANDLING

XML::Parser throws an exception (dies) when it encounters a parse error. This includes malformed XML, encoding errors, and other problems detected by the underlying expat library.

The `parse`, `parsefile`, and `parse_done` methods may all throw exceptions. To handle parse errors gracefully in your application, wrap the parse call in an `eval` block:

```
my $parser = XML::Parser->new(Style => 'Tree');

my $tree = eval { $parser->parsefile('data.xml') };
if ($@) {
  # Handle the parse error
  warn "Parse failed: $@";
}
```

The error message (in `$@`) will include the line number, column number, and byte position where the error was detected. For additional context around the error location, set the **ErrorContext** option when constructing the parser:

```
my $parser = XML::Parser->new(
  Style        => 'Tree',
  ErrorContext  => 2,
);
```

This will include 2 lines of context on either side of the error in the error message.

SECURITY

XML::Parser relies on the expat C library for parsing. Modern versions of expat include several security mechanisms that can be tuned through constructor options passed to `new()`. These options are forwarded directly to *XML::Parser::Expat* and take effect for every subsequent `parse`, `parsefile`, or `parse_start` call on the parser instance.

All of these options will `croak` at runtime if the underlying libexpat does not support them.

Billion Laughs Attack Protection

The Billion Laughs attack (also known as an XML bomb) uses deeply nested entity definitions to cause exponential expansion, consuming memory and CPU. Expat >= 2.4.0 (built with `XML_DTD` or `XML_GE`) includes built-in protection controlled by two parameters:

- **BillionLaughsAttackProtectionMaximumAmplification**

The maximum ratio between the size of the expanded output and the size of the input. For example, a value of `100.0` means the parser will abort if entity expansion would produce output more than 100 times the size of the input.

- **BillionLaughsAttackProtectionActivationThreshold**

  The number of bytes of expanded output before the amplification limit takes effect. This prevents false positives on small documents that happen to have a high amplification ratio.

Allocation Tracker

Expat >= 2.7.2 (built with `XML_DTD` or `XML_GE`) adds a second layer of amplification tracking through the allocation tracker, which measures memory allocation rather than output size:

- **AllocTrackerMaximumAmplification**

  The maximum ratio of allocated memory to input size.

- **AllocTrackerActivationThreshold**

  The number of bytes of allocation before the limit takes effect.

Reparse Deferral

Expat >= 2.6.0 includes reparse deferral, which prevents attacks that exploit token boundaries. Rather than reparsing incomplete tokens immediately, the parser defers until more input arrives.

- **ReparseDeferralEnabled**

  A boolean. Set to a true value to enable reparse deferral, or `0` to disable it.

For full details on each option, see *"new" in XML::Parser::Expat*.

```
# Example: tighten Billion Laughs limits
my $parser = XML::Parser->new(
  Style => 'Tree',
  BillionLaughsAttackProtectionMaximumAmplification => 50,
  BillionLaughsAttackProtectionActivationThreshold  => 1024,
);
```

AUTHORS

Larry Wall <larry@wall.org> wrote version 1.0.

Clark Cooper <coopercc@netheaven.com> picked up support, changed the API for this version (2.x), provided documentation, and added some standard package features.

Matt Sergeant <matt@sergeant.org> was maintaining XML::Parser from 2003 to 2007.

Alexandr Ciornii <alexchorny@gmail.com> was maintaining XML::Parser from 2007 to 2013.

Todd Rinaldo <toddr@cpan.org> has been maintaining XML::Parser since 2013.

The project started making use of Claude Code <https://claude.ai/code> in January 2026.

Modules

- XML::Parser::Expat - the low-level interface of XML::Parser
- XML::Parser::Style

XML::Parser::Expat

XML::Parser::Expat - the low-level interface of XML::Parser.

```
use XML::Parser;

my $p = XML::Parser->new(Handlers => {
    Start => sub { my ($expat, $elem, %attr) = @_; print "<$elem>\n"
 ↪},
    Char  => sub { my ($expat, $text) = @_; print $text },
});
$p->parse('<doc><item id="1">hello</item></doc>');
```

Most programs use XML::Parser (or a module built on it such as XML::Twig, XML::Simple or XML::Dumper) and never call this module directly. It parses with pperl's XML engine over libxml2, the one XML::LibXML uses too; libxml2 2.15 or newer is required, and the module fails to load with a message saying so when it is older or missing.

This is a native implementation of the CPAN distribution XML-Parser 2.59, which parses with the expat library; its XML/Parser.pm, XML/Parser/Expat.pm and the XML::Parser::Style::* modules are used unchanged. Every handler sees what it sees under expat: the same calls with the same arguments, character data split where expat splits it, and the same text, positions and lengths from recognized_string, original_string, current_byte, current_line, current_column and current_length. Errors carry expat's messages and positions.

Differences from upstream

expat_version reports the expat release whose interface this module provides, expat_2.6.0, since no expat is loaded.

A document with standalone="yes" has the parameter entities of its internal subset expanded, as XML 1.0 requires; expat leaves them unread, and then refuses an entity reference they declare as undefined.

Functions

Other Functions

ParserCreate

`ParserCreate($self, $encoding, $namespaces)`: a new parser for the XML::Parser::Expat object $self, as an integer handle.

ParserRelease

`ParserRelease($parser)`: drop the parser's reference to its object, breaking the cycle so that the object can be freed.

ParserFree

`ParserFree($parser)`: free the parser and every handler it holds.

ParseString

`ParseString($parser, $string)`: parse a whole document.

ParseStream

`ParseStream($parser, $handle, $delim)`: parse from a handle, up to a line holding only `$delim` when it is defined.

ParsePartial

`ParsePartial($parser, $chunk)`: parse one more chunk of a document.

ParseDone

`ParseDone($parser)`: end a document parsed with ParsePartial.

UnsetAllHandlers

`UnsetAllHandlers($parser)`: expat's handlers go, the element ones and the namespace ones included; what is left is the Default handler.

SetBase

`SetBase($parser, $base)`.

GetBase

`GetBase($parser)`: the base, or undef.

PositionContext

`PositionContext($parser, $lines)`: the input around the current position, `$lines` lines either side, and the position's offset in it.

GenerateNSName

`GenerateNSName($name, $namespace, \%table, \@list)`: the name object for `$name` in `$namespace`, as the parser makes them.

DefaultCurrent

`DefaultCurrent($parser)`: pass the current event's text to the Default handler.

RecognizedString

`RecognizedString($parser)`: the text of the current event.

GetErrorCode

`GetErrorCode($parser)`.

GetCurrentLineNumber

`GetCurrentLineNumber($parser)`.

GetCurrentColumnNumber

`GetCurrentColumnNumber($parser)`.

GetCurrentByteIndex

`GetCurrentByteIndex($parser)`.

GetCurrentByteCount

`GetCurrentByteCount($parser)`.

GetSpecifiedAttributeCount

`GetSpecifiedAttributeCount($parser)`.

ErrorString

`ErrorString($code)`: the message for an error code.

ExpatVersion

`ExpatVersion()`: “expat_X.Y.Z”, the interface this module provides.

ExpatVersionInfo

`ExpatVersionInfo()`: `(major => X, minor => Y, micro => Z)`.

LoadEncoding

`LoadEncoding($data, $size)`: register a binary encoding map (an .enc file’s contents) in %Encoding_Table; returns its name, or undef when the data is not a map.

FreeEncoding

`FreeEncoding($encinfo)`: free a map LoadEncoding made.

OriginalString

`OriginalString($parser)`: the input text of the current event.

ElementIndex

`ElementIndex($parser)`: the serial number of the current element.

SkipUntil

`SkipUntil($parser, $index)`: suspend most handlers until the element with serial number `$index` starts.

Do_External_Parse

`Do_External_Parse($parser, $result)`: the ExternEnt handler’s result is read by the loader that called the handler, so outside one there is nothing to parse into.

SetReparseDeferralEnabled

`SetReparseDeferralEnabled($parser, $enabled)`: expat’s deferral of reparsing a token split across buffers (`parse_buffer`); XML_TRUE.

XML::Parser::Style

Namespace containing the following modules:

- `XML::Parser::Style::Debug` - Debug style for XML::Parser
- `XML::Parser::Style::Objects` - Objects styler parser
- `XML::Parser::Style::Stream` - Stream style for XML::Parser
- `XML::Parser::Style::Subs` - glue for handling element callbacks
- `XML::Parser::Style::Tree` - Tree style parser

XML::Parser::Style::Debug

Debug style for XML::Parser

SYNOPSIS

```
use XML::Parser;
my $p = XML::Parser->new(Style => 'Debug');
$p->parsefile('foo.xml');
```

DESCRIPTION

This just prints out the document in outline form to STDERR. Nothing special is returned by parse.

XML::Parser::Style::Objects

Objects styler parser

SYNOPSIS

```
use XML::Parser;
my $p = XML::Parser->new(Style => 'Objects', Pkg => 'MyNode');
my $tree = $p->parsefile('foo.xml');
```

DESCRIPTION

This module implements XML::Parser's Objects style parser.

This is similar to the Tree style, except that a hash object is created for each element. The corresponding object will be in the class whose name is created by appending "::" and the element name to the package set with the Pkg option. Non-markup text will be in the ::Characters class. The contents of the corresponding object will be in an anonymous array that is the value of the Kids property for that object.

SEE ALSO

XML::Parser::Style::Tree

XML::Parser::Style::Stream

Stream style for XML::Parser

SYNOPSIS

```
use XML::Parser;
my $p = XML::Parser->new(Style => 'Stream', Pkg => 'MySubs');
$p->parsefile('foo.xml');
```

(continues on next page)

(continued from previous page)

```
{
  package MySubs;

  sub StartTag {
    my ($e, $name) = @_;
    # do something with start tags
  }

  sub EndTag {
    my ($e, $name) = @_;
    # do something with end tags
  }

  sub Text {
    my ($e) = @_;
    # $_ contains accumulated text
    # do something with text nodes
  }
}
```

DESCRIPTION

This style uses the Pkg option to find subs in a given package to call for each event. If none of the subs that this style looks for is there, then the effect of parsing with this style is to print a canonical copy of the document without comments or declarations. All the subs receive as their 1st parameter the Expat instance for the document they're parsing.

It looks for the following routines:

- StartDocument

  Called at the start of the parse .

- StartTag

  Called for every start tag with a second parameter of the element type. The $_ variable will contain a copy of the tag and the %_ variable will contain attribute values supplied for that element.

- EndTag

  Called for every end tag with a second parameter of the element type. The $_ variable will contain a copy of the end tag.

- Text

  Called just before start or end tags with accumulated non-markup text in the $_ variable.

- PI

  Called for processing instructions. The $_ variable will contain a copy of the PI and the target and data are sent as 2nd and 3rd parameters respectively.

- EndDocument

  Called at conclusion of the parse.

XML::Parser::Style::Subs

glue for handling element callbacks

SYNOPSIS

```
use XML::Parser;
my $p = XML::Parser->new(Style => 'Subs', Pkg => 'MySubs');
$p->parsefile('foo.xml');

{
  package MySubs;

  sub foo {
    # start of foo tag
  }

  sub foo_ {
    # end of foo tag
  }
}
```

DESCRIPTION

Each time an element starts, a sub by that name in the package specified by the Pkg option is called with the same parameters that the Start handler gets called with.

Each time an element ends, a sub with that name appended with an underscore (“_”), is called with the same parameters that the End handler gets called with.

Nothing special is returned by parse.

XML::Parser::Style::Tree

Tree style parser

SYNOPSIS

```
use XML::Parser;
my $p = XML::Parser->new(Style => 'Tree');
my $tree = $p->parsefile('foo.xml');
```

DESCRIPTION

This module implements XML::Parser's Tree style parser.

When parsing a document, `parse()` will return a parse tree for the document. Each node in the tree takes the form of a tag, content pair. Text nodes are represented with a pseudo-tag of "0" and the string that is their content. For elements, the content is an array reference. The first item in the array is a (possibly empty) hash reference containing attributes. The remainder of the array is a sequence of tag-content pairs representing the content of the element.

So for example the result of parsing:

```
<foo><head id="a">Hello <em>there</em></head><bar>Howdy<ref/></bar>
↪do</foo>
```

would be:

```
           Tag   Content
============================================================
[foo, [{}, head, [{id => "a"}, 0, "Hello ",  em, [{}, 0, "there"]],
            bar, [         {}, 0, "Howdy",  ref, [{}]],
              0, "do"
      ]
]
```

The root document "foo", has 3 children: a "head" element, a "bar" element and the text "do". After the empty attribute hash, these are represented in it's contents by 3 tag-content pairs.

Entity Expansion

The underlying Expat parser always expands predefined XML entity references (`<` , `>`, `&`, `"`, `'`) in both text content and attribute values before they reach the Tree style handlers. This is required by the XML specification and cannot be prevented. For example, `<` in the source XML will appear as < in the resulting tree structure.

If you need access to the original unexpanded text, consider using the handler-based API with the `original_string` method on the Expat object instead of the Tree style.

5.2.113 XSLoader

Start the native part of a module

VERSION

Version 0.32, the XSLoader of perl 5.44, unchanged.

SYNOPSIS

```
package YourPackage;
require XSLoader;

XSLoader::load(__PACKAGE__, $VERSION);
```

DESCRIPTION

`XSLoader::load` starts the compiled part of a module. The module's `.pm` calls it, usually right after setting `$VERSION`; without arguments it uses the calling package.

Under pperl, `XSLoader::load` loads no shared object (DynaLoader's `dl_*` functions do, for a library a program asks for). Where pperl implements a module natively, the compiled part is in the pperl binary, and `XSLoader::load` starts it the way perl5 starts an extension linked statically into its binary. That is how the native modules of the module reference load, such as Socket, POSIX, List::Util and Storable: their upstream `.pm` runs unchanged and calls `XSLoader::load`.

For a module pperl has no native part for, `XSLoader::load` dies with perl's own message for a compiled part that is not there:

```
Can't locate loadable object for module Some::Module in @INC (@INC␣
↪contains: ...)
```

That is the message modules with a pure-Perl fallback test for, so a module that calls `XSLoader::load` inside `eval` and falls back when the call fails runs its pure-Perl part under pperl.

5.2.114 XString

The string quoting helpers of `B`, without loading `B`.

`XString::cstring` and `XString::perlstring` return a string quoted and escaped so that it reads back as the same bytes: as a C string literal, or as a Perl double-quoted string. They are `B::cstring` and `B::perlstring`, packaged so that a module can quote strings without pulling in the compiler backend.

Synopsis

```
use XString;
print XString::cstring(qq[a"b\n]), "\n";      # "a\"b\n"
print XString::perlstring('cost: $5 @ 2'), "\n"; # "cost: \$5 \@ 2"
print XString::cstring(undef), "\n";          # 0
```

Nothing is exported; call them by their full names.

This is a native implementation of XString 0.005's `XString.xs`; its `XString.pm` is used unchanged.

Differences from upstream

None.

Functions

Quoting

cstring

Quote a string as a C string literal.

perlstring

Quote a string as a Perl double-quoted string.

cstring

Quote a string as a C string literal.

Synopsis

```
my $c = XString::cstring($str);
```

What you get back

`$str` between double quotes, with `"` and `\` escaped, `\n`, `\r`, `\t`, `\a`, `\b`, `\f` and `\v` in their C spelling, `??` written so that it cannot form a trigraph, and every other unprintable byte as a three-digit octal escape. `undef` gives `0`, unquoted. The same as `B::cstring`.

perlstring

Quote a string as a Perl double-quoted string.

Synopsis

```
my $code = XString::perlstring($str);
my $back = eval $code;        # eq $str
```

What you get back

`$str` between double quotes, escaped so that perl reads it back as the same string: `"`, `\`, `$` and `@` are escaped, control characters take their backslash spelling or an octal escape, and a string of characters is written with `\x{...}` escapes. `undef` gives `0`, unquoted. The same as `B::perlstring`.

5.2.115 YAML

Namespace containing the following modules:

- `YAML::LibYAML` - `YAML-LibYAML` is the CPAN *distribution* name for the `YAML::XS` module.
- `YAML::PP` - YAML 1.2 processor
- `YAML::XS` - use YAML::XS;

YAML::LibYAML

NOTE

`YAML-LibYAML` is the CPAN *distribution* name for the `YAML::XS` module.

See the YAML::XS documentation instead.

YAML::PP

YAML 1.2 processor

SYNOPSIS

WARNING: Most of the inner API is not stable yet.

Here are a few examples of the basic load and dump methods:

```
use YAML::PP;
my $ypp = YAML::PP->new;

my $yaml = <<'EOM';
--- # Document one is a mapping
name: Tina
age: 29
favourite language: Perl

--- # Document two is a sequence
- plain string
- 'in single quotes'
```

(continues on next page)

(continued from previous page)

```
- "in double quotes we have escapes! like \t and \n"
- | # a literal block scalar
  line1
  line2
- > # a folded block scalar
  this is all one
  single line because the
  linebreaks will be folded
EOM

my @documents = $ypp->load_string($yaml);
my @documents = $ypp->load_file($filename);

my $yaml = $ypp->dump_string($data1, $data2);
$ypp->dump_file($filename, $data1, $data2);

# Enable perl data types and objects
my $ypp = YAML::PP->new(schema => [qw/ + Perl /]);
my $yaml = $yp->dump_string($data_with_perl_objects);

# Legacy interface
use YAML::PP qw/ Load Dump LoadFile DumpFile /;
my @documents = Load($yaml);
my @documents = LoadFile($filename);
my @documents = LoadFile($filehandle);
my $yaml = = Dump(@documents);
DumpFile($filename, @documents);
DumpFile($filenhandle @documents);
```

Some utility scripts, mostly useful for debugging:

```
# Load YAML into a data structure and dump with Data::Dumper
yamlpp-load < file.yaml

# Load and Dump
yamlpp-load-dump < file.yaml

# Print the events from the parser in yaml-test-suite format
yamlpp-events < file.yaml

# Parse and emit events directly without loading
yamlpp-parse-emit < file.yaml

# Create ANSI colored YAML. Can also be useful for invalid YAML,
 ↪showing
# you the exact location of the error
yamlpp-highlight < file.yaml
```

DESCRIPTION

YAML::PP is a modular YAML processor.

It aims to support `YAML 1.2` and `YAML 1.1`. See https://yaml.org/. Some (rare) syntax elements are not yet supported and documented below.

YAML is a serialization language. The YAML input is called "YAML Stream". A stream consists of one or more "Documents", separated by a line with a document start marker `---`. A document optionally ends with the document end marker `...`

This allows one to process continuous streams additionally to a fixed input file or string.

The YAML::PP frontend will currently load all documents, and return only the first if called with scalar context.

The YAML backend is implemented in a modular way that allows one to add custom handling of YAML tags, perl objects and data types. The inner API is not yet stable. Suggestions welcome.

You can check out all current parse and load results from the yaml-test-suite here: https://perlpunk.github.io/YAML-PP-p5/test-suite.html

METHODS

new

```
my $ypp = YAML::PP->new;

# use YAML 1.2 Failsafe Schema
my $ypp = YAML::PP->new( schema => ['Failsafe'] );
# use YAML 1.2 JSON Schema
my $ypp = YAML::PP->new( schema => ['JSON'] );
# use YAML 1.2 Core Schema
my $ypp = YAML::PP->new( schema => ['Core'] );

# Die when detecting cyclic references
my $ypp = YAML::PP->new( cyclic_refs => 'fatal' );

my $ypp = YAML::PP->new(
    boolean => 'perl',
    schema => ['Core'],
    cyclic_refs => 'fatal',
    indent => 4,
    header => 1,
    footer => 0,
    version_directive => 0,
    require_footer => 0,
    max_depth => 512,
);
```

Options:

- boolean

Values: `perl` (currently default), `JSON::PP`, `boolean`, `perl_experimental`

This option is for loading and dumping.

In case of perl 5.36 and later, builtin booleans should work out of the box (since YAML::PP >= 0.38.0).

```
print YAML::PP->new->dump_string([ builtin::true, !1 ]);
# ---
# - true
# - false
```

For earlier perl versions, you can use "pseudo" booleans like documented in the following examples.

```
# load/dump booleans via boolean.pm
my $ypp = YAML::PP->new( boolean => 'boolean' );
# load/dump booleans via JSON::PP::true/false
my $ypp = YAML::PP->new( boolean => 'JSON::PP' );
```

You can also specify more than one class, comma separated. This is important for dumping.

```
boolean => 'JSON::PP,boolean'
Booleans will be loaded as JSON::PP::Booleans, but when dumping,
 ↪ also
'boolean' objects will be recognized

boolean => 'JSON::PP,*'
Booleans will be loaded as JSON::PP::Booleans, but when dumping,
 ↪ all
currently supported boolean classes will be recognized

boolean => '*'
Booleans will be loaded as perl booleans, but when dumping, all
currently supported boolean classes will be recognized

boolean => ''
Booleans will be loaded as perl booleans, but when dumping,␣
 ↪nothing
will be recognized as booleans.
This option is for backwards compatibility for perl versions <␣
 ↪5.36,
if you rely on [!!1, !1] being dumped as [1, ''].
```

The option `perl_experimental` was introduced when experimental boolean support was added to perl 5.36. Since it will not be experimental anymore in perl 5.40 \o/ the option is deprecated and the same as `perl`.

- schema

  Default: `['Core']`

  This option is for loading and dumping.

Array reference. Here you can define what schema to use. Supported standard Schemas are: `Failsafe`, `JSON`, `Core`, `YAML1_1`.

To get an overview how the different Schemas behave, see https://perlpunk.github.io/YAML-PP-p5/schemas.html

Additionally you can add further schemas, for example `Merge`.

- cyclic_refs

  Default: `fatal` (since 0.037)

  Before the default was `allow`, but this can lead to memory leaks when loading on untrusted data, so it was changed to `fatal` by default.

  This option is for loading only.

  Defines what to do when a cyclic reference is detected when loading.

```
# fatal  - die
# warn   - Just warn about them and replace with undef
# ignore - replace with undef
# allow  - Default
```

- duplicate_keys

  Default: 0

  Since version 0.027

  This option is for loading.

  The YAML Spec says duplicate mapping keys should be forbidden.

  When set to true, duplicate keys in mappings are allowed (and will overwrite the previous key).

  When set to false, duplicate keys will result in an error when loading.

  This is especially useful when you have a longer mapping and don't see the duplicate key in your editor:

```
---
a: 1
b: 2
# ............
a: 23 # error
```

- indent

  Default: 2

  This option is for dumping.

  Use that many spaces for indenting

- width

  Since version 0.025

  Default: 80

This option is for dumping.

Maximum columns when dumping.

This is only respected when dumping flow collections right now.

in the future it will be used also for wrapping long strings.

- header

  Default: 1

  This option is for dumping.

  Print document header `---`

- footer

  Default: 0

  Since version v0.39

  This option is for dumping.

  Print document footer `...`

- require_footer

  Default: 0

  Will require a `...` at the end of each document. This can be useful in a context where you want to make sure you received the complete content, for example over network.

```
# Good
---
a: 1
...
---
a: 2
...

# Bad
---
a: 1
---
a: 2
```

- max_depth

  Since version v0.40

  default: 512

  Loading deeply nested, but still small YAML documents, like

```
[[[[[[[[[[...]]]]]]]]]]
```

  can be significantly slower than a “normal” document with the same size. By default the depth is limited to 512, which should be more than enough for 99% of the use cases.

- yaml_version

  Since version 0.020

  This option is for loading and dumping.

  Default: `1.2`

  Note that in this case, a directive `%YAML 1.1` will basically be ignored and everything loaded with the `1.2 Core` Schema.

  If you want to support both YAML 1.1 and 1.2, you have to specify that, and the schema (`Core` or `YAML1_1`) will be chosen automatically.

```
my $yp = YAML::PP->new(
    yaml_version => ['1.2', '1.1'],
);
```

  This is the same as

```
my $yp = YAML::PP->new(
    schema => ['+'],
    yaml_version => ['1.2', '1.1'],
);
```

  because the `+` stands for the default schema per version.

  When loading, and there is no `%YAML` directive, `1.2` will be considered as default, and the `Core` schema will be used.

  If there is a `%YAML 1.1` directive, the `YAML1_1` schema will be used.

  Of course, you can also make `1.1` the default:

```
my $yp = YAML::PP->new(
    yaml_version => ['1.1', '1.2'],
);
```

  You can also specify `1.1` only:

```
my $yp = YAML::PP->new(
    yaml_version => ['1.1'],
);
```

  In this case also documents with `%YAML 1.2` will be loaded with the `YAML1_1` schema.

- version_directive

  Since version 0.020

  This option is for dumping.

  Default: 0

  Print Version Directive `%YAML 1.2` (or `%YAML 1.1`) on top of each YAML document. It will use the first version specified in the `yaml_version` option.

- preserve

  Since version 0.021

  Default: false

  This option is for loading and dumping.

  Preserving scalar styles is still experimental.

```
use YAML::PP::Common qw/ :PRESERVE /;

# Preserve the order of hash keys
my $yp = YAML::PP->new( preserve => PRESERVE_ORDER );

# Preserve the quoting style of scalars
my $yp = YAML::PP->new( preserve => PRESERVE_SCALAR_STYLE );

# Preserve block/flow style (since 0.024)
my $yp = YAML::PP->new( preserve => PRESERVE_FLOW_STYLE );

# Preserve alias names (since 0.027)
my $yp = YAML::PP->new( preserve => PRESERVE_ALIAS );

# Combine, e.g. preserve order and scalar style
my $yp = YAML::PP->new( preserve => PRESERVE_ORDER | PRESERVE_
 ↪SCALAR_STYLE );
```

  Do NOT rely on the internal implementation of it.

  If you load the following input:

```
---
z: 1
a: 2
---
- plain
- 'single'
- "double"
- |
  literal
- >
  folded
---
block mapping: &alias
  flow sequence: [a, b]
same mapping: *alias
flow mapping: {a: b}
```

  with this code:

```
my $yp = YAML::PP->new(
    preserve => PRESERVE_ORDER | PRESERVE_SCALAR_STYLE
                | PRESERVE_FLOW_STYLE | PRESERVE_ALIAS
```

(continues on next page)

(continued from previous page)

```
);
my ($hash, $styles, $flow) = $yp->load_file($file);
$yp->dump_file($hash, $styles, $flow);
```

Then dumping it will return the same output.

Note that YAML allows repeated definition of anchors. They cannot be preserved with YAML::PP right now. Example:

```
---
- &seq [a]
- *seq
- &seq [b]
- *seq
```

Because the data could be shuffled before dumping again, the anchor definition could be broken. In this case repeated anchor names will be discarded when loading and dumped with numeric anchors like usual.

Implementation:

When loading, hashes will be tied to an internal class (`YAML::PP::Preserve::Hash`) that keeps the key order.

Scalars will be returned as objects of an internal class (`YAML::PP::Preserve::Scalar`) with overloading. If you assign to such a scalar, the object will be replaced by a simple scalar.

```
# assignment, style gets lost
$styles->[1] .= ' append';
```

You can also pass 1 as a value. In this case all preserving options will be enabled, also if there are new options added in the future.

There are also methods to create preserved nodes from scratch. See the `preserved_(scalar|mapping|sequence)` "METHODS" below.

load_string

```
my $doc = $ypp->load_string("foo: bar");
my @docs = $ypp->load_string("foo: bar\n---\n- a");
```

Input should be Unicode characters.

So if you read from a file, you should decode it, for example with `Encode::decode()`.

Note that in scalar context, `load_string` and `load_file` return the first document (like YAML::Syck), while *YAML* and *YAML::XS* return the last.

load_file

```
my $doc = $ypp->load_file("file.yaml");
my @docs = $ypp->load_file("file.yaml");
```

Strings will be loaded as unicode characters.

dump_string

```
my $yaml = $ypp->dump_string($doc);
my $yaml = $ypp->dump_string($doc1, $doc2);
my $yaml = $ypp->dump_string(@docs);
```

Input strings should be Unicode characters.

Output will return Unicode characters.

So if you want to write that to a file (or pass to YAML::XS, for example), you typically encode it via `Encode::encode()`.

dump_file

```
$ypp->dump_file("file.yaml", $doc);
$ypp->dump_file("file.yaml", $doc1, $doc2);
$ypp->dump_file("file.yaml", @docs);
```

Input data should be Unicode characters.

dump

This will dump to a predefined writer. By default it will just use the *YAML::PP::Writer* and output a string.

```
my $writer = MyWriter->new(\my $output);
my $yp = YAML::PP->new(
    writer => $writer,
);
$yp->dump($data);
```

preserved_scalar

Since version 0.024

Experimental. Please report bugs or let me know this is useful and works.

You can define a certain scalar style when dumping data. Figuring out the best style is a hard task and practically impossible to get it right for all cases. It's also a matter of taste.

```
use YAML::PP::Common qw/ PRESERVE_SCALAR_STYLE YAML_LITERAL_SCALAR_
 ↪STYLE /;
my $yp = YAML::PP->new(
```

(continues on next page)

(continued from previous page)

```
    preserve => PRESERVE_SCALAR_STYLE,
);
# a single linebreak would normally be dumped with double quotes: "\
 ↪n"
my $scalar = $yp->preserved_scalar("\n", style => YAML_LITERAL_
 ↪SCALAR_STYLE );

my $data = { literal => $scalar };
my $dump = $yp->dump_string($data);
# output
---
literal: |+

...
```

preserved_mapping, preserved_sequence

Since version 0.024

Experimental. Please report bugs or let me know this is useful and works.

With this you can define which nodes are dumped with the more compact flow style instead of block style.

If you add PRESERVE_ORDER to the preserve option, it will also keep the order of the keys in a hash.

```
use YAML::PP::Common qw/
    PRESERVE_ORDER PRESERVE_FLOW_STYLE
    YAML_FLOW_MAPPING_STYLE YAML_FLOW_SEQUENCE_STYLE
/;
my $yp = YAML::PP->new(
    preserve => PRESERVE_FLOW_STYLE | PRESERVE_ORDER
);

my $hash = $yp->preserved_mapping({}, style => YAML_FLOW_MAPPING_
 ↪STYLE);
# Add values after initialization to preserve order
%$hash = (z => 1, a => 2, y => 3, b => 4);

my $array = $yp->preserved_sequence([23, 24], style => YAML_FLOW_
 ↪SEQUENCE_STYLE);

my $data = $yp->preserved_mapping({});
%$data = ( map => $hash, seq => $array );

my $dump = $yp->dump_string($data);
# output
---
map: {z: 1, a: 2, y: 3, b: 4}
seq: [23, 24]
```

loader

Returns or sets the loader object, by default YAML::PP::Loader

dumper

Returns or sets the dumper object, by default YAML::PP::Dumper

schema

Returns or sets the schema object

default_schema

Creates and returns the default schema

FUNCTIONS

The functions `Load`, `LoadFile`, `Dump` and `DumpFile` are provided as a drop-in replacement for other existing YAML processors. No function is exported by default.

Note that in scalar context, `Load` and `LoadFile` return the first document (like YAML::Syck), while *YAML* and *YAML::XS* return the last.

- Load

```
use YAML::PP qw/ Load /;
my $doc = Load($yaml);
my @docs = Load($yaml);
```

  Works like `load_string`.

- LoadFile

```
use YAML::PP qw/ LoadFile /;
my $doc = LoadFile($file);
my @docs = LoadFile($file);
my @docs = LoadFile($filehandle);
```

  Works like `load_file`.

- Dump

```
use YAML::PP qw/ Dump /;
my $yaml = Dump($doc);
my $yaml = Dump(@docs);
```

  Works like `dump_string`.

- DumpFile

```
use YAML::PP qw/ DumpFile /;
DumpFile($file, $doc);
```

(continues on next page)

(continued from previous page)

```
DumpFile($file, @docs);
DumpFile($filehandle, @docs);
```

Works like `dump_file`.

PLUGINS

You can alter the behaviour of YAML::PP by using the following schema classes:

- *YAML::PP::Schema::Failsafe*

  One of the three YAML 1.2 official schemas

- *YAML::PP::Schema::JSON*

  One of the three YAML 1.2 official schemas.

- *YAML::PP::Schema::Core*

  One of the three YAML 1.2 official schemas. Default

- *YAML::PP::Schema::YAML1_1*

  Schema implementing the most common YAML 1.1 types

- *YAML::PP::Schema::Perl*

  Serializing Perl objects and types

- *YAML::PP::Schema::Binary*

  Serializing binary data

- *YAML::PP::Schema::Merge*

  YAML 1.1 merge keys for mappings

- *YAML::PP::Schema::Catchall*

  Experimental.

  It was accidentally added in 0.38.1, and unknown tags forbidden. This was reverted in 0.39.0

  By default they will result in an error.

- *YAML::PP::Schema::Include*

  Include other YAML files via `!include` tags

- *YAML::PP::Schema::Tie::IxHash*

  Deprecated. See option `preserve`

To make the parsing process faster, you can plugin the libyaml parser with YAML::PP::LibYAML.

IMPLEMENTATION

The process of loading and dumping is split into the following steps:

```
Load:

YAML Stream        Tokens        Event List        Data Structure
          --------->    --------->        --------->
            lex           parse           construct

Dump:

Data Structure       Event List        YAML Stream
            --------->        --------->
            represent           emit
```

You can dump basic perl types like hashes, arrays, scalars (strings, numbers). For dumping blessed objects and things like coderefs have a look at *YAML::PP::Perl*/*YAML::PP::Schema::Perl*.

- YAML::PP::Lexer

  The Lexer is reading the YAML stream into tokens. This makes it possible to generate syntax highlighted YAML output.

  Note that the API to retrieve the tokens will change.

- YAML::PP::Parser

  The Parser retrieves the tokens from the Lexer. The main YAML content is then parsed with the Grammar.

- *YAML::PP::Grammar*

- *YAML::PP::Constructor*

  The Constructor creates a data structure from the Parser events.

- YAML::PP::Loader

  The Loader combines the constructor and parser.

- YAML::PP::Dumper

  The Dumper will delegate to the Representer

- YAML::PP::Representer

  The Representer will create Emitter events from the given data structure.

- *YAML::PP::Emitter*

  The Emitter creates a YAML stream.

YAML::PP::Parser

Still TODO:

- Implicit collection keys

```
---
[ a, b, c ]: value
```

- Implicit mapping in flow style sequences

  This is supported since 0.029 (except some not relevant cases):

```
---
[ a, b, c: d ]
# equals
[ a, b, { c: d } ]
```

- Plain mapping keys ending with colons

```
---
key ends with two colons::: value
```

  This was implemented in 0.037.

- Supported Characters

  If you have valid YAML that's not parsed, or the other way round, please create an issue.

- Line and Column Numbers

  You will see line and column numbers in the error message. The column numbers might still be wrong in some cases.

- Error Messages

  The error messages need to be improved.

- Unicode Surrogate Pairs

  Currently loaded as single characters without validating

- Possibly more

YAML::PP::Constructor

The Constructor now supports all three YAML 1.2 Schemas, Failsafe, JSON and Core. Additionally you can choose the schema for YAML 1.1 as `YAML1_1`.

Too see what strings are resolved as booleans, numbers, null etc. look at https://perlpunk.github.io/YAML-PP-p5/schema-examples.html.

You can choose the Schema like this:

```
my $ypp = YAML::PP->new(schema => ['JSON']); # default is 'Core'
```

The Tags `!!seq` and `!!map` are still ignored for now.

It supports:

- Handling of Anchors/Aliases

  Like in modules like *YAML*, the Constructor will use references for mappings and sequences, but obviously not for scalars.

  YAML::XS uses real aliases, which allows also aliasing scalars. I might add an option for that since aliasing is now available in pure perl.

- Boolean Handling

  You can choose between `'perl'` (1/”, currently default), `'JSON::PP'` and `'boolean'`.pm for handling boolean types. That allows you to dump the data structure with one of the JSON modules without losing information about booleans.

- Numbers

  Numbers are created as real numbers instead of strings, so that they are dumped correctly by modules like *JSON::PP* or *JSON::XS*, for example.

- Complex Keys

  Mapping Keys in YAML can be more than just scalars. Of course, you can't load that into a native perl structure. The Constructor will stringify those keys with *Data::Dumper* instead of just returning something like `HASH(0x55dc1b5d0178)`.

  Example:

```
use YAML::PP;
use JSON::PP;
my $ypp = YAML::PP->new;
my $coder = JSON::PP->new->ascii->pretty->allow_nonref->
 ↪canonical;
my $yaml = <<'EOM';
complex:
    ?
        ?
            a: 1
            c: 2
        : 23
    : 42
EOM
my $data = $yppl->load_string($yaml);
say $coder->encode($data);
__END__
{
   "complex" : {
      "{'{a => 1,c => 2}' => 23}" : 42
   }
}
```

TODO:

- Parse Tree

  I would like to generate a complete parse tree, that allows you to manipulate the

data structure and also dump it, including all whitespaces and comments. The spec says that this is throwaway content, but I read that many people wish to be able to keep the comments.

YAML::PP::Dumper, YAML::PP::Emitter

The Dumper should be able to dump strings correctly, adding quotes whenever a plain scalar would look like a special string, like `true`, or when it contains or starts with characters that are not allowed.

Most strings will be dumped as plain scalars without quotes. If they contain special characters or have a special meaning, they will be dumped with single quotes. If they contain control characters, including <"\n">, they will be dumped with double quotes.

It will recognize JSON::PP::Boolean and boolean.pm objects and dump them correctly.

Numbers which also have a PV flag will be recognized as numbers and not as strings:

```
my $int = 23;
say "int: $int"; # $int will now also have a PV flag
```

That means that if you accidentally use a string in numeric context, it will also be recognized as a number:

```
my $string = "23";
my $something = $string + 0;
print $yp->dump_string($string);
# will be emitted as an integer without quotes!
```

The layout is like libyaml output:

```
key:
- a
- b
- c
---
- key1: 1
  key2: 2
  key3: 3
---
- - a1
  - a2
- - b1
  - b2
```

FAQ - Frequently Asked Questions

- Are << merge keys supported?

  Yes, this can be enabled optionally, see *YAML::PP::Schema::Merge*

- Is there a linter / formatter for YAML

There is the widely used "yamllint", based on python's PyYAML. It is very configurable and will report errors or warnings. It cannot format.

Now there is also YAML::Tidy, which will format the given file according to your configuration. So far only a few configuration options exist, but they can already be quite helpful.

Which YAML module should I use?

There are many YAML modules on CPAN. For historical reasons some of them aren't handling YAML correctly.

Most of them are not compatible with the YAML spec and with each other, meaning they can interpret the same YAML differently.

The behaviours we are discussing here can be divided into parsing issues (syntax) and loading/constructing issues (for example type resolving which decides what is a number, boolean or null).

See also https://matrix.yaml.info/ (parsing) and https://perlpunk.github.io/YAML-PP-p5/schema-examples.html (loading).

- *"YAML.pm"*

  It was written even before the YAML 1.0 spec was finished and by that enabled perl users to process YAML very early. It might work for you if you have simple data, but it's missing quite some features and can also produce YAML that doesn't roundtrip. Nowadays it might be a good idea to switch.

- *YAML::XS*

  A libyaml binding that is robust and widely used. However, there are two things to consider.

  1. (syntax) libyaml diverged from the spec in several aspects. They are rare though.
  2. The type resolving does not adhere to YAML 1.1 or YAML 1.2, meaning it is incompatible with other YAML libraries in perl or other languages.

- YAML::Tiny

  It implements both a tiny subset of YAML, but also a superset. Meaning it will happily accept some YAML documents that are not officially valid. Type resolving is also not implemented according to the spec.

- YAML::Syck

  A binding to libsyck. It is even less compatible to YAML than libyaml. Also type resolving is not implemented according to the spec.

- *YAML::PP*

  Regarding YAML syntax, it is the second most YAML 1.2 compatible perl module. The cases it cannot (yet) parse are not relevant in perl programming, e.g. hash keys that are not strings. Regarding type resolving, it is compatible with the YAML 1.2 Core schema, so it should be possible to exchange data as YAML with other libraries in other languages. One downside is that it is the slowest perl YAML module.

- YAML::Parser

This is a parser generated by the YAML grammar, and it's passing all official tests. A YAML::PP::Ref frontend exists that you can use just like YAML::PP. It is quite slow (although it might be ok for small files depending on the use case). The error messages it creates on invalid YAML are not helpful currently.

- YAML::PP::LibYAML

  This combines the YAML::LibYAML::API binding for parsing with the YAML::PP frontend for loading and type resolving. It is faster than YAML::PP but slower than YAML::XS. The divergence from the YAML spec regarding syntax is usually not a problem, and at the same time you have the advantage of being compatible to the YAML 1.2 Core Schema.

WHY

Why did I start to write a new YAML module?

All the available parsers and loaders for Perl are behaving differently, and more important, aren't conforming to the spec. *YAML::XS* is doing pretty well, but `libyaml` only handles YAML 1.1 and diverges a bit from the spec. The pure perl loaders lack support for a number of features.

I was going over *YAML*.pm issues end of 2016, integrating old patches from rt.cpan.org and creating some pull requests myself. I realized that it would be difficult to patch YAML.pm to parse YAML 1.1 or even 1.2, and it would also break existing usages relying on the current behaviour.

In 2016 Ingy döt Net initiated two really cool projects:

- "YAML TEST SUITE"
- "YAML EDITOR"

These projects are a big help for any developer. So I got the idea to write my own parser and started on New Year's Day 2017. Without the test suite and the editor I would have never started this.

I also started another YAML Test project which allows one to get a quick overview of which frameworks support which YAML features:

- "YAML TEST MATRIX"

YAML TEST SUITE

https://github.com/yaml/yaml-test-suite

It contains almost 400 test cases and expected parsing events and more. There will be more tests coming. This test suite allows you to write parsers without turning the examples from the Specification into tests yourself. Also the examples aren't completely covering all cases - the test suite aims to do that.

Thanks also to Felix Krause, who is writing a YAML parser in Nim. He turned all the spec examples into test cases.

YAML EDITOR

This is a tool to play around with several YAML parsers and loaders in vim.

https://github.com/yaml/yaml-editor

The project contains the code to build the frameworks (16 as of this writing) and put it into one big Docker image.

It also contains the yaml-editor itself, which will start a vim in the docker container. It uses a lot of funky vimscript that makes playing with it easy and useful. You can choose which frameworks you want to test and see the output in a grid of vim windows.

Especially when writing a parser it is extremely helpful to have all the test cases and be able to play around with your own examples to see how they are handled.

YAML TEST MATRIX

I was curious to see how the different frameworks handle the test cases, so, using the test suite and the docker image, I wrote some code that runs the tests, manipulates the output to compare it with the expected output, and created a matrix view.

https://github.com/perlpunk/yaml-test-matrix

You can find the latest build at https://matrix.yaml.info

CONTRIBUTORS

- Ingy döt Net

  Ingy is one of the creators of YAML. In 2016 he started the YAML Test Suite and the YAML Editor. He also made useful suggestions on the class hierarchy of YAML::PP.

- Felix “flyx” Krause

  Felix answered countless questions about the YAML Specification.

Modules

- `YAML::PP::Common` - Constants and common functions
- `YAML::PP::Constructor` - Constructing data structure from parsing events
- `YAML::PP::Emitter` - Emitting events
- `YAML::PP::Grammar` - YAML grammar
- `YAML::PP::Highlight` - Syntax highlighting utilities
- `YAML::PP::Perl` - Convenience module for loading and dumping Perl objects
- `YAML::PP::Schema` - Schema for YAML::PP
- `YAML::PP::Type`
- `YAML::PP::Writer` - Write YAML output

YAML::PP::Common

Constants and common functions

SYNOPSIS

```
use YAML::PP::Common ':STYLES';
# or
use YAML::PP::Common qw/
    YAML_ANY_SCALAR_STYLE YAML_PLAIN_SCALAR_STYLE
    YAML_SINGLE_QUOTED_SCALAR_STYLE YAML_DOUBLE_QUOTED_SCALAR_STYLE
    YAML_LITERAL_SCALAR_STYLE YAML_FOLDED_SCALAR_STYLE
    YAML_QUOTED_SCALAR_STYLE

    YAML_ANY_SEQUENCE_STYLE
    YAML_BLOCK_SEQUENCE_STYLE YAML_FLOW_SEQUENCE_STYLE

    YAML_ANY_MAPPING_STYLE
    YAML_BLOCK_MAPPING_STYLE YAML_FLOW_MAPPING_STYLE
/;

use YAML::PP::Common ':PRESERVE';
# or
```

(continues on next page)

(continued from previous page)

```
use YAML::PP::Common qw/
    PRESERVE_ALL PRESERVE_ORDER PRESERVE_SCALAR_STYLE PRESERVE_FLOW_
 ↪STYLE
    PRESERVE_ALIAS
/:
```

DESCRIPTION

This module provides common constants and functions for modules working with YAML::PP events.

FUNCTIONS

- event_to_test_suite

  ```
  my $string = YAML::PP::Common::event_to_test_suite($event_prom_
   ↪parser);
  ```

  For examples of the returned format look into this distributions's directory `yaml-test-suite` which is a copy of https://github.com/yaml/yaml-test-suite.

- test_suite_to_event

  ```
  my $event = YAML::PP::Common::test_suite_to_event($str);
  ```

  Turns an event string in test suite format into an event hashref. Not complete yet.

YAML::PP::Constructor

Constructing data structure from parsing events

METHODS

- new

  The Constructor constructor

  ```
  my $constructor = YAML::PP::Constructor->new(
      schema => $schema,
      cyclic_refs => $cyclic_refs,
  );
  ```

- init

  Resets any data being used during construction.

  ```
  $constructor->init;
  ```

- document_start_event, document_end_event, mapping_start_event, mapping_end_event, sequence_start_event, sequence_end_event, scalar_event, alias_event, stream_start_event, stream_end_event

These methods are called from YAML::PP::Parser:

```
$constructor->document_start_event($event);
```

- anchors, set_anchors

  Helper for storing anchors during construction

- docs, set_docs

  Helper for storing resulting documents during construction

- stack, set_stack

  Helper for storing data during construction

- cyclic_refs, set_cyclic_refs

  Option for controlling the behaviour when finding circular references

- schema, set_schema

  Holds a *YAML::PP::Schema* object

- stringify_complex

  When constructing a hash and getting a non-scalar key, this method is used to stringify the key.

  It uses a terse Data::Dumper output. Other modules, like *YAML::XS*, use the default stringification, `ARRAY(0x55617c0c7398)` for example.

YAML::PP::Emitter

Emitting events

SYNOPSIS

```
my $emitter = YAML::PP::Emitter->new(
    indent => 4,
);

$emitter->init;

$emitter->stream_start_event;
$emitter->document_start_event({ implicit => 1 });
$emitter->sequence_start_event;
$emitter->scalar_event({ value => $input, style => $style });
$emitter->sequence_end_event;
$emitter->document_end_event({ implicit => 1 });
$emitter->stream_end_event;

my $yaml = $emitter->writer->output;
$emitter->finish;
```

DESCRIPTION

The emitter emits events to YAML. It provides methods for each event type. The arguments are mostly the same as the events from YAML::PP::Parser.

METHODS

- new

```
my $emitter = YAML::PP::Emitter->new(
    indent => 4,
);
```

  Constructor. Currently takes these options:

  - indent
  - writer

- stream_start_event, stream_end_event, document_start_event, document_end_event, sequence_start_event, sequence_end_event, mapping_start_event, mapping_end_event, scalar_event, alias_event
- indent, set_indent

  Getter/setter for number of indentation spaces.

  TODO: Currently sequences are always zero-indented.

- writer, set_writer

  Getter/setter for the writer object. By default *YAML::PP::Writer*. You can pass your own writer if you want to output the resulting YAML yourself.

- init

  Initialize

- finish

YAML::PP::Grammar

YAML grammar

GRAMMAR

This is the Grammar in YAML

```
# START OF YAML INLINE

# DO NOT CHANGE THIS
# This grammar is automatically generated from etc/grammar.yaml

YAML::PP::Highlight

Syntax highlighting utilities

SYNOPSIS

```
use YAML::PP::Highlight qw/ Dump /;

my $highlighted = Dump $data;
```

FUNCTIONS

- Dump

```
use YAML::PP::Highlight qw/ Dump /;

my $highlighted = Dump $data;
my $highlighted = Dump @docs;
```

It will dump the given data, and then parse it again to create tokens, which are then highlighted with ansi colors.

The return value is ansi colored YAML.

YAML::PP::Perl

Convenience module for loading and dumping Perl objects

SYNOPSIS

```
use YAML::PP::Perl;
my @docs = YAML::PP::Perl->new->load_string($yaml);
my @docs = YAML::PP::Perl::Load($yaml);

# same as
use YAML::PP;
my $yp = YAML::PP->new( schema => [qw/ Core Perl /] );
my @docs = $yp->load_string($yaml);
```

DESCRIPTION

This is just for convenience. It will create a YAML::PP object using the default schema (`Core`) and the *YAML::PP::Schema::Perl* schema.

See *YAML::PP::Schema::Perl* for documentation.

METHODS

- Load, Dump, LoadFile, DumpFile

  These work like the functions in *YAML::PP*, just adding the `Perl` schema.

- new

  Constructor, works like in *YAML::PP*, just adds the `Perl` schema to the list of arguments.

YAML::PP::Schema

Schema for YAML::PP

Modules

- `YAML::PP::Schema::Binary` - Schema for loading and binary data
- `YAML::PP::Schema::Catchall` - YAML 1.2 JSON Schema
- `YAML::PP::Schema::Core` - YAML 1.2 Core Schema
- `YAML::PP::Schema::Failsafe` - YAML 1.2 Failsafe Schema
- `YAML::PP::Schema::Include` - Include YAML files
- `YAML::PP::Schema::JSON` - YAML 1.2 JSON Schema
- `YAML::PP::Schema::Merge` - Enabling YAML merge keys for mappings

YAML::PP::Schema::Binary

Schema for loading and binary data

SYNOPSIS

```
use YAML::PP;
my $yp = YAML::PP->new( schema => [qw/ + Binary /] );
# or

my ($binary, $same_binary) = $yp->load_string(<<'EOM');
--- !!binary "\
  R0lGODlhDAAMAIQAAP//9/X17unp5WZmZgAAAOfn515eXvPz7Y6OjuDg4J+fn5\
  OTk6enp56enmlpaWNjY6Ojo4SEhP/++f/++f/++f/++f/++f/++f/++f/+\
  +f/++f/++f/++f/++f/++SH+Dk1hZGUgd2l0aCBHSU1QACwAAAAADAAMAAAFLC\
  AgjoEwnuNAFOhpEMTRiggcz4BNJHrv/zCFcLiwMWYNG84BwwEeECcgggoBADs="
--- !!binary |
  R0lGODlhDAAMAIQAAP//9/X17unp5WZmZgAAAOfn515eXvPz7Y6OjuDg4J+fn5
  OTk6enp56enmlpaWNjY6Ojo4SEhP/++f/++f/++f/++f/++f/++f/++f/+
  +f/++f/++f/++f/++f/++SH+Dk1hZGUgd2l0aCBHSU1QACwAAAAADAAMAAAFLC
  AgjoEwnuNAFOhpEMTRiggcz4BNJHrv/zCFcLiwMWYNG84BwwEeECcgggoBADs=
# The binary value above is a tiny arrow encoded as a gif image.
EOM
```

DESCRIPTION

See <https://yaml.org/type/binary.html>

By prepending a base64 encoded binary string with the `!!binary` tag, it can be automatically decoded when loading.

Note that the logic for dumping is probably broken, see https://github.com/perlpunk/YAML-PP-p5/issues/28.

Suggestions welcome.

METHODS

- register

  Called by *YAML::PP::Schema*

YAML::PP::Schema::Catchall

YAML 1.2 JSON Schema

SYNOPSIS

```
my $yp = YAML::PP->new( schema => ['JSON'] );
my $yp = YAML::PP->new( schema => [qw/ JSON empty=str /] );
my $yp = YAML::PP->new( schema => [qw/ JSON empty=null /] );
```

DESCRIPTION

YAML::PP::Schema::Core

YAML 1.2 Core Schema

SYNOPSIS

```
my $yp = YAML::PP->new( schema => ['Core'] );
```

DESCRIPTION

This schema is the official recommended Core Schema for YAML 1.2. It loads additional values to the JSON schema as special types, for example `TRUE` and `True` additional to `true`.

Official Schema: https://yaml.org/spec/1.2/spec.html#id2804923

Here you can see all Schemas and examples implemented by YAML::PP: https://perlpunk.github.io/YAML-PP-p5/schemas.html

METHODS

- register

  Called by YAML::PP::Schema

YAML::PP::Schema::Failsafe

YAML 1.2 Failsafe Schema

SYNOPSIS

```
my $yp = YAML::PP->new( schema => ['Failsafe'] );
```

DESCRIPTION

With this schema, everything will be treated as a string. There are no booleans, integers, floats or undefined values.

Here you can see all Schemas and examples implemented by YAML::PP: https://perlpunk.github.io/YAML-PP-p5/schemas.html

Official Schema: https://yaml.org/spec/1.2/spec.html#id2802346

METHODS

- register

  Called by YAML::PP::Schema

YAML::PP::Schema::Include

Include YAML files

SYNOPSIS

```
# /path/to/file.yaml
# ---
# included: !include include/file2.yaml

# /path/to/include/file2.yaml
# ---
# a: b

my $include = YAML::PP::Schema::Include->new;

my $yp = YAML::PP->new( schema => ['+', $include] );
# we need the original YAML::PP object for getting the current␣
 ↪filename
# and for loading another file
$include->yp($yp);

my ($data) = $yp->load_file("/path/to/file.yaml");

# The result will be:
$data = {
    included => { a => 'b' }
};
```

Allow absolute filenames and upwards '..':

```
my $include = YAML::PP::Schema::Include->new(
    allow_absolute => 1, # default: 0
);
```

Specify paths to search for includes:

```
my @include_paths = ("/path/to/include/yaml/1", "/path/to/include/
 ↪yaml/2");
my $include = YAML::PP::Schema::Include->new(
    paths => \@include_paths,
);
my $yp = YAML::PP->new( schema => ['+', $include] );
$include->yp($yp);
```

(continues on next page)

(continued from previous page)

```
# /path/to/include/yaml/1/file1.yaml
# ---
# a: b

my $yaml = <<'EOM';
- included: !include file1.yaml
EOM
my ($data) = $yp->load_string($yaml);
```

DESCRIPTION

This plugin allows you to split a large YAML file into smaller ones. You can then include these files with the `!include` tag.

It will search for the specified filename relative to the currently processed filename.

You can also specify the paths where to search for files to include. It iterates through the paths and returns the first filename that exists.

By default, only relative paths are allowed. Any `../` in the path will be removed. You can change that behaviour by setting the option `allow_absolute` to true.

If the included file contains more than one document, only the first one will be included.

I will probably add a possibility to return all documents as an arrayref.

The included YAML file will be loaded by creating a new *YAML::PP* object with the schema from the existing object. This way you can recursively include files.

You can even reuse the same include via an alias:

```
---
invoice:
    shipping address: &address !include address.yaml
    billing address: *address
```

Circular includes will be detected, and will be fatal.

It's possible to specify what to do with the included file:

```
my $include = YAML::PP::Schema::Include->new(
    loader => sub {
        my ($yp, $filename);
        if ($filename =~ m/\.txt$/) {
            # open file and just return text
        }
        else {
            # default behaviour
            return $yp->load_file($filename);
        }
    },
);
```

For example, RAML defines an `!include` tag which depends on the file content. If it contains a special RAML directive, it will be loaded as YAML, otherwise the content of the file will be included as a string.

So with this plugin you are able to read RAML specifications.

YAML::PP::Schema::JSON

YAML 1.2 JSON Schema

SYNOPSIS

```
my $yp = YAML::PP->new( schema => ['JSON'] );
my $yp = YAML::PP->new( schema => [qw/ JSON empty=str /] );
my $yp = YAML::PP->new( schema => [qw/ JSON empty=null /] );
```

DESCRIPTION

With this schema, the resolution of plain values will work like in JSON. Everything that matches a special value will be loaded as such, other plain scalars will be loaded as strings.

Note that this is different from the official YAML 1.2 JSON Schema, where all strings have to be quoted.

Here you can see all Schemas and examples implemented by YAML::PP: https://perlpunk.github.io/YAML-PP-p5/schemas.html

Official Schema: https://yaml.org/spec/1.2/spec.html#id2803231

CONFIGURATION

The official YAML 1.2 JSON Schema wants all strings to be quoted. YAML::PP currently does not require that (it might do this optionally in the future).

That means, there are no empty nodes allowed in the official schema. Example:

```
---
key:
```

The default behaviour of YAML::PP::Schema::JSON is to return an empty string, so it would be equivalent to:

```
---
key: ''
```

You can configure it to resolve this as `undef`:

```
my $yp = YAML::PP->new( schema => [qw/ JSON empty=null /] );
```

This way it is equivalent to:

```
---
key: null
```

The default is:

```
my $yp = YAML::PP->new( schema => [qw/ JSON empty=str /] );
```

METHODS

- register

  Called by YAML::PP::Schema

- represent_bool, represent_float, represent_int, represent_literal, represent_undef

  Functions to represent the several node types.

  ```
  represent_bool($representer, $node);
  ```

YAML::PP::Schema::Merge

Enabling YAML merge keys for mappings

SYNOPSIS

```
use YAML::PP;
my $yp = YAML::PP->new( schema => [qw/ + Merge /] );

my $yaml = <<'EOM';
---
- &CENTER { x: 1, y: 2 }
- &LEFT { x: 0, y: 2 }
- &BIG { r: 10 }
- &SMALL { r: 1 }

# All the following maps are equal:

- # Explicit keys
  x: 1
  y: 2
  r: 10
  label: center/big

- # Merge one map
  << : *CENTER
  r: 10
  label: center/big

- # Merge multiple maps
  << : [ *CENTER, *BIG ]
```

(continues on next page)

(continued from previous page)

```
  label: center/big

- # Override
  << : [ *BIG, *LEFT, *SMALL ]
  x: 1
  label: center/big
EOM
my $data = $yp->load_string($yaml);
# $data->[4] == $data->[5] == $data->[6] == $data->[7]
```

DESCRIPTION

See https://yaml.org/type/merge.html for the specification.

Quote:

"Specify one or more mappings to be merged with the current one.

The << merge key is used to indicate that all the keys of one or more specified maps should be inserted into the current map. If the value associated with the key is a single mapping node, each of its key/value pairs is inserted into the current mapping, unless the key already exists in it. If the value associated with the merge key is a sequence, then this sequence is expected to contain mapping nodes and each of these nodes is merged in turn according to its order in the sequence. Keys in mapping nodes earlier in the sequence override keys specified in later mapping nodes."

The implementation of this in a generic way is not trivial, because we also have to handle duplicate keys, and YAML::PP allows you to write your own handler for processing mappings.

So the inner API of that is not stable at this point.

Note that if you enable this schema, a plain scalar `<<` will be seen as special anywhere in your document, so if you want a literal `<<`, you have to put it in quotes.

Note that the performed merge is not a "deep merge". Only top-level keys are merged.

METHODS

- register

  Called by YAML::PP::Schema

YAML::PP::Schema::Perl

Schema for serializing perl objects and special types

SYNOPSIS

```
use YAML::PP;
# This can be dangerous when loading untrusted YAML!
my $yp = YAML::PP->new( schema => [qw/ + Perl /] );
```

(continues on next page)

(continued from previous page)

```
# or
my $yp = YAML::PP->new( schema => [qw/ Core Perl /] );
my $yaml = $yp->dump_string(sub { return 23 });

# loading code references
# This is very dangerous when loading untrusted YAML!!
my $yp = YAML::PP->new( schema => [qw/ + Perl +loadcode /] );
my $code = $yp->load_string(<<'EOM');
--- !perl/code |
    {
        use 5.010;
        my ($name) = @_;
        say "Hello $name!";
    }
EOM
$code->("Ingy");
```

DESCRIPTION

This schema allows you to load and dump perl objects and special types.

Please note that loading objects of arbitrary classes can be dangerous in Perl. You have to load the modules yourself, but if an exploitable module is loaded and an object is created, its DESTROY method will be called when the object falls out of scope. *File::Temp* is an example that can be exploitable and might remove arbitrary files.

Dumping code references is on by default, but not loading (because that is easily exploitable since it's using string `eval`).

Tag Styles

You can define the style of tags you want to support:

```
my $yp_perl_two_one = YAML::PP->new(
    schema => [qw/ + Perl tags=!!perl+!perl /],
);
```

- `!perl` (default)

  Only `!perl/type` tags are supported.

- `!!perl`

  Only `!!perl/type` tags are supported.

- `!perl+!!perl`

  Both `!perl/type` and `!!perl/tag` are supported when loading. When dumping, `!perl/type` is used.

- `!!perl+!perl`

  Both `!perl/type` and `!!perl/tag` are supported when loading. When dumping, `!!perl/type` is used.

YAML.pm, YAML::Syck and *YAML::XS* are using `!!perl/type` when dumping.

YAML.pm and YAML::Syck are supporting both `!perl/type` and `!!perl/type` when loading. *YAML::XS* currently only supports the latter.

Allow only certain classes

Since v0.017

Blessing arbitrary objects can be dangerous. Maybe you want to allow blessing only specific classes and ignore others. For this you have to instantiate a Perl Schema object first and use the `classes` option.

Currently it only allows a list of strings:

```
my $perl = YAML::PP::Schema::Perl->new(
    classes => ['Foo', 'Bar'],
);
my $yp = YAML::PP::Perl->new(
    schema => [qw/ + /, $perl],
);
```

Allowed classes will be loaded and dumped as usual. The others will be ignored.

If you want to allow no objects at all, pass an empty array ref.

EXAMPLES

This is a list of the currently supported types and how they are dumped into YAML:

- array

```
# Code
[
    qw/ one two three four /
]

# YAML
---
- one
- two
- three
- four
```

- array_blessed

```
# Code
bless [
    qw/ one two three four /
], "Just::An::Arrayref"
```

(continues on next page)

(continued from previous page)

```
# YAML
--- !perl/array:Just::An::Arrayref
- one
- two
- three
- four
```

- circular

```
# Code
my $circle = bless [ 1, 2 ], 'Circle';
push @$circle, $circle;
$circle;

# YAML
--- &1 !perl/array:Circle
- 1
- 2
- *1
```

- coderef

```
# Code
sub {
    my (%args) = @_;
    return $args{x} + $args{y};
}

# YAML
--- !perl/code |-
  {
      use warnings;
      use strict;
      (my(%args) = @_);
      (return ($args{'x'} + $args{'y'}));
  }
```

- coderef_blessed

```
# Code
bless sub {
    my (%args) = @_;
    return $args{x} - $args{y};
}, "I::Am::Code"

# YAML
--- !perl/code:I::Am::Code |-
```

(continues on next page)

(continued from previous page)

```
  {
      use warnings;
      use strict;
      (my(%args) = @_);
      (return ($args{'x'} - $args{'y'}));
  }
```

- hash

```
# Code
{
    U => 2,
    B => 52,
}

# YAML
---
B: 52
U: 2
```

- hash_blessed

```
# Code
bless {
    U => 2,
    B => 52,
}, 'A::Very::Exclusive::Class'

# YAML
--- !perl/hash:A::Very::Exclusive::Class
B: 52
U: 2
```

- refref

```
# Code
my $ref = { a => 'hash' };
my $refref = \$ref;
$refref;

# YAML
--- !perl/ref
=:
  a: hash
```

- refref_blessed

```
# Code
my $ref = { a => 'hash' };
my $refref = bless \$ref, 'Foo';
$refref;

# YAML
--- !perl/ref:Foo
=:
  a: hash
```

- regexp

```
# Code
my $string = 'unblessed';
qr{$string}

# YAML
--- !perl/regexp unblessed
```

- regexp_blessed

```
# Code
my $string = 'blessed';
bless qr{$string}, "Foo"

# YAML
--- !perl/regexp:Foo blessed
```

- scalarref

```
# Code
my $scalar = "some string";
my $scalarref = \$scalar;
$scalarref;

# YAML
--- !perl/scalar
=: some string
```

- scalarref_blessed

```
# Code
my $scalar = "some other string";
my $scalarref = bless \$scalar, 'Foo';
$scalarref;
```

(continues on next page)

(continued from previous page)

```
# YAML
--- !perl/scalar:Foo
=: some other string
```

METHODS

- new

```
my $perl = YAML::PP::Schema::Perl->new(
    tags => "!perl",
    classes => ['MyClass'],
    loadcode => 1,
    dumpcode => 1,
);
```

The constructor recognizes the following options:

- tags

  Default: '!perl'

  See "Tag Styles"

- classes

  Default: undef

  Since: v0.017

  Accepts an array ref of class names

- loadcode

  Default: 0

- dumpcode

  Default: 1

```
my $yp = YAML::PP->new( schema => [qw/ + Perl -dumpcode /] );
```

- register

  A class method called by *YAML::PP::Schema*

- construct_ref, represent_ref

  Perl variables of the type REF are represented in yaml like this:

```
--- !perl/ref
=:
  a: 1
```

  construct_ref returns the perl data:

```
my $data = YAML::PP::Schema::Perl->construct_ref([ '=', { some
 ↪=> 'data' } ];
my $data = \{ a => 1 };
```

represent_ref turns a REF variable into a YAML mapping:

```
my $data = YAML::PP::Schema::Perl->represent_ref(\{ a => 1 });
my $data = { '=' => { a => 1 } };
```

- construct_scalar, represent_scalar

  Perl variables of the type SCALAR are represented in yaml like this:

```
--- !perl/scalar
=: string
```

  construct_scalar returns the perl data:

```
my $data = YAML::PP::Schema::Perl->construct_ref([ '=', 'string
 ↪' ];
my $data = \'string';
```

  represent_scalar turns a SCALAR variable into a YAML mapping:

```
my $data = YAML::PP::Schema::Perl->represent_scalar(\'string');
my $data = { '=' => 'string' };
```

- construct_regex, represent_regex

  construct_regex returns a qr{} object from the YAML string:

```
my $qr = YAML::PP::Schema::Perl->construct_regex('foo.*');
```

  represent_regex returns a string representing the regex object:

```
my $string = YAML::PP::Schema::Perl->represent_regex(qr{...});
```

- evaluate_code, represent_code

  evaluate_code returns a code reference from a string. The string must start with a { and end with a }.

```
my $code = YAML::PP::Schema::Perl->evaluate_code('{ return 23 }
 ↪');
```

  represent_code returns a string representation of the code reference with the help of B::Deparse:

```
my $string = YAML::PP::Schema::Perl->represent_code(sub {
 ↪return 23 });
```

- construct_glob, represent_glob

  construct_glob returns a glob from a hash.

```
my $glob = YAML::PP::Schema::Perl->construct_glob($hash);
```

represent_glob returns a hash representation of the glob.

```
my $hash = YAML::PP::Schema::Perl->represent_glob($glob);
```

- object

  Does the same as bless:

```
my $object = YAML::PP::Schema::Perl->object($data, $class);
```

YAML::PP::Schema::Tie

Namespace containing the following modules:

- YAML::PP::Schema::Tie::IxHash - (Deprecated) Schema for serializing ordered hashes

YAML::PP::Schema::Tie::IxHash

(Deprecated) Schema for serializing ordered hashes

SYNOPSIS

```
use YAML::PP;
use Tie::IxHash;
my $yp = YAML::PP->new( schema => [qw/ + Tie::IxHash /] );

tie(my %ordered, 'Tie::IxHash');
%ordered = (
    U => 2,
    B => 52,
);

my $yaml = $yp->dump_string(\%ordered);

# Output:
---
U: 2
B: 52
```

DESCRIPTION

This is deprecated. See the new option preserve in *YAML::PP*.

This schema allows you to dump ordered hashes which are tied to Tie::IxHash.

This code is pretty new and experimental.

It is not yet implemented for loading yet, so for now you have to tie the hashes yourself.

Examples:

- order

```
# Code
tie(my %order, 'Tie::IxHash');
%order = (
    U => 2,
    B => 52,
    c => 64,
    19 => 84,
    Disco => 2000,
    Year => 2525,
    days_on_earth => 20_000,
);
\%order;

# YAML
---
U: 2
B: 52
c: 64
19: 84
Disco: 2000
Year: 2525
days_on_earth: 20000
```

- order_blessed

```
# Code
tie(my %order, 'Tie::IxHash');
%order = (
    U => 2,
    B => 52,
    c => 64,
    19 => 84,
    Disco => 2000,
    Year => 2525,
    days_on_earth => 20_000,
);
bless \%order, 'Order';

# YAML
--- !perl/hash:Order
U: 2
B: 52
c: 64
19: 84
Disco: 2000
```

(continues on next page)

(continued from previous page)

```
Year: 2525
days_on_earth: 20000
```

METHODS

- register

  Called by YAML::PP::Schema

YAML::PP::Schema::YAML1_1

YAML 1.1 Schema for YAML::PP

SYNOPSIS

```
use YAML::PP;

my $yp = YAML::PP->new( schema => ['YAML1_1'] );
my $yaml = <<'EOM';
---
booltrue: [ true, True, TRUE, y, Y, yes, Yes, YES, on, On, ON ]
EOM
my $data = $yp->load_string($yaml);
```

DESCRIPTION

This schema allows you to load the common YAML Types from YAML 1.1.

METHODS

- register

  Called by YAML::PP::Schema

SEE ALSO

- https://yaml.org/type/null.html
- https://yaml.org/type/float.html
- https://yaml.org/type/int.html
- https://yaml.org/type/bool.html

YAML::PP::Type

Namespace containing the following modules:

- `YAML::PP::Type::MergeKey` - A special node type for merge keys

YAML::PP::Type::MergeKey

A special node type for merge keys

DESCRIPTION

See *YAML::PP::Schema::Merge*

METHODS

- new

  Constructor

YAML::PP::Writer

Write YAML output

SYNOPSIS

```
my $writer = YAML::PP::Writer->new;
```

DESCRIPTION

The *YAML::PP::Emitter* sends its output to the writer.

You can use your own writer. if you want to send the YAML output to somewhere else. See t/44.writer.t for an example.

METHODS

- new

  ```
  my $writer = YAML::PP::Writer->new;
  ```

  Constructor.

- write

  ```
  $writer->write('- ');
  ```

- init

  ```
  $writer->init;
  ```

  Initialize

- finish

  ```
  $writer->finish;
  ```

  Gets called when the output ends.

- output, set_output

  Getter/setter for the YAML output

Modules

- `YAML::PP::Writer::File` - Write YAML output to file or file handle

YAML::PP::Writer::File

Write YAML output to file or file handle

SYNOPSIS

```
my $writer = YAML::PP::Writer::File->new(output => $file);
```

DESCRIPTION

The *YAML::PP::Emitter* sends its output to the writer.

You can use your own writer. if you want to send the YAML output to somewhere else. See t/44.writer.t for an example.

METHODS

- new

  ```
  my $writer = YAML::PP::Writer::File->new(output => $file);
  my $writer = YAML::PP::Writer::File->new(output => $filehandle);
  ```

  Constructor.

- write

  ```
  $writer->write('- ');
  ```

- init

  ```
  $writer->init;
  ```

  Initialize

- finish

  ```
  $writer->finish;
  ```

  Gets called when the output ends. If The argument was a filename, the filehandle will be closed. If the argument was a filehandle, the caller needs to close it.

- output, set_output

  Getter/setter for the YAML output

YAML::XS

SYNOPSIS

```
use YAML::XS;

# Classic functional interface
my $yaml = Dump [ 1..4 ];
my $array = Load $yaml;

# EXPERIMENTAL: Object Oriented interface for YAML 1.2
# Incompatible to functional interface!
my $xs = YAML::XS->new;
my $yaml = $xs->dump([ 1..4 ]);
my $array = $xs->load($yaml);
```

DESCRIPTION

Under perl this module binds Kirill Simonov's `libyaml`, a C library written to the YAML 1.1 specification. Under pperl its compiled part, *YAML::XS::LibYAML*, reads YAML with *YAML::PP* and writes it as libyaml writes it; that page lists where the two differ.

This module exports the functions `Dump`, `Load`, `DumpFile` and `LoadFile`. These functions are intended to work exactly like `YAML.pm`'s corresponding functions. Only `Load` and `Dump` are exported by default.

CONFIGURATION

The object oriented interface is described below: "OBJECT ORIENTED INTERFACE"

- `$YAML::XS::LoadBlessed` (since v0.69)

  Default: false.

  The default was changed in version 0.81.

  When set to false, it will not bless data into objects, which can be a security problem, when loading YAML from an untrusted source. It will silently ignore the tag and just load the data unblessed.

  In PyYAML, this is called SafeLoad.

  If set to true, it will load the following YAML as objects:

  ```
  ---
  local: !Foo::Bar [a]
  perl: !!perl/hash:Foo::Bar { a: 1 }
  regex: !!perl/regexp:Foo::Bar pattern
  ```

  You can create any kind of object with YAML. The creation itself is not the critical part. If the class has a `DESTROY` method, it will be called once the object is deleted. An example with File::Temp removing files can be found at https://bugs.debian.org/cgi-bin/bugreport.cgi?bug=862373.

- `$YAML::XS::ForbidDuplicateKeys` (since 0.84)

Default: false

When set to true, `Load` will die when encountering a duplicate key in a hash, e.g.

```
key: value
key: another value
```

This can be useful for bigger YAML documents where it is not that obvious, and it is recommended to set it to true. That's also what a YAML loader should do by default according to the YAML specification.

- `$YAML::XS::UseCode`
- `$YAML::XS::DumpCode`
- `$YAML::XS::LoadCode`

  If enabled supports deparsing and evaling of code blocks.

  Note that support for loading code was added in version 0.75, although `$LoadCode` was documented already in earlier versions.

- `$YAML::XS::QuoteNumericStrings`

  When true (the default) strings that look like numbers but have not been numified will be quoted when dumping.

  This ensures leading that things like leading zeros and other formatting are preserved.

- `$YAML::XS::Boolean` (since v0.67)

  Default: undef

  Since YAML::XS 0.89: When used with perl 5.36 or later, builtin booleans will work out of the box. They will be created by `Load` and recognized by `Dump` automatically (since YAML::XS 0.89).

```
say Dump({ truth => builtin::true });
# truth: true
```

  Since YAML::XS v0.902: loaded booleans are not set to readonly anymore.

  For older perl versions you can use the following configuration to serialize data as YAML booleans:

  When set to `"JSON::PP"` or `"boolean"`, the plain (unquoted) strings `true` and `false` will be loaded as `JSON::PP::Boolean` or `boolean.pm` objects. Those objects will be dumped again as plain "true" or "false".

  It will try to load [JSON::PP] or [boolean] and die if it can't be loaded.

  With that it's possible to add new "real" booleans to a data structure:

```
local $YAML::XS::Boolean = "JSON::PP"; # or "boolean"
my $data = Load("booltrue: true");
$data->{boolfalse} = JSON::PP::false;
my $yaml = Dump($data);
# boolfalse: false
# booltrue: true
```

It also lets booleans survive when loading YAML via YAML::XS and encode it in JSON via one of the various JSON encoders, which mostly support JSON::PP booleans.

Please note that JSON::PP::Boolean and boolean.pm behave a bit differently. Ideally you should only use them in boolean context.

If not set, booleans are loaded as special perl variables `PL_sv_yes` and `PL_sv_no`, which have the disadvantage that they are readonly, and you can't add those to an existing data structure with pure perl.

If you simply need to load "perl booleans" that are true or false in boolean context, you will be fine with the default setting.

- `$YAML::XS::Indent` (since v0.76)

  Default is 2.

  Sets the number of spaces for indentation for `Dump`.

USING YAML::XS WITH UNICODE

Handling unicode properly in Perl can be a pain. YAML::XS only deals with streams of utf8 octets. Just remember this:

```
$perl = Load($utf8_octets);
$utf8_octets = Dump($perl);
```

There are many, many places where things can go wrong with unicode. If you are having problems, use Devel::Peek on all the possible data points.

OBJECT ORIENTED INTERFACE

Since version v0.904.0, EXPERIMENTAL

+++NOTE: This is incompatible with the functional interface and will treat YAML values in a different way.+++

This has two MAJOR differences to the old functional interface:

- Object with options

  This provides an interface where you create a YAML::XS object with options (instead of the old interface with global variables).

- YAML 1.2 Core Schema

  It implements the YAML 1.2 Core Schema.

  (Note that the functional interface does not implement YAML 1.1, when it comes to loading numbers, booleans, null etc. It implements its own set of rules.)

  Here is an (incomplete!) example of values that are treated differently than with the functional interface. YAML values that match a certain pattern, are not loaded as strings, but as other types:

```
# Functional interface: special values (not compatible to other
 ↪YAML modules)
- [true, false]                              # booleans
- [null, ~]                                  # undef
- [inf, INF, iNf, iNF, InF, INf, -inf, ...] # Inf
- [100_000]                                  # 100000
- # anything that looks_like_number()        # number

# OOP YAML 1.2 special values
- [true, True, TRUE, false, False, FALSE]   # booleans
- [null, Null, NULL, ~]                     # undef
- [.inf, .Inf, .INF, -.inf, -.Inf, -.INF]   # Inf
- [.nan, .NAN, .NaN]                        # nan
- [42, 0x10, 0o10]                          # dec 42, hex 16,
 ↪oct 8
```

For more subtle differences regarding numbers checkout the comprehensive data here:

- YAML 1.1 / 1.2 definitions: https://perlpunk.github.io/yaml-test-schema/schemas.html
- Test data: https://perlpunk.github.io/yaml-test-schema/data.html

This way the OOP interface is compatible to YAML::PP and YAML processors in other languages supporting YAML 1.2.

- `load` will return the first document in scalar context

  The functional interface returns the last.

- Numbers don't have string flags
- Booleans currently are only preserved for the new builtin booleans

  Adding a JSON::PP boolean option for older perls is planned

- References, objects, globs, regexes and coderefs cannot be loaded or dumped

  This is planned.

Usage

```
use YAML::XS ();
my $xs = YAML::XS->new;
my $yaml = "foo: bar";

# Load single (first) document:
my $data = $xs->load($yaml);
$yaml = $xs->dump($data);

# Or to load all documents:
my @data = $xs->load($yaml);
$yaml = $xs->dump(@data);
```

METHODS

new

```
use YAML::XS;
my $xs = YAML::XS->new(
    # load options
    # require_footer => 0,

    # dump options
    # indent => 2,
    # header => 1,
    # footer => 0,
    # width => 80,
    # anchor_prefix => '',
    # cyclic_refs => 0,

    # load and dump options
    # utf8 => 0,
    # boolean => 0,
);
```

Options:

- indent

  Default: 2

  Sets the number of spaces for indentation for dumping.

- utf8

  Default: false

  When false, the loader will accept unencoded character strings, and the dumper returns unencoded character strings.

  When true, the loader accepts a UTF-8 encoded string of bytes, and the dumper returns a UTF-8 encoded string of bytes. This typically makes sense when you read from / write to a file directly.

- header

  Default: 1

  Writes a `---` before every document

- footer

  Default: 0

  Writes a `...` at the end of every document.

- width

  Set the maximum number of colums for dumping. If a value has too many characters, it will be split into multiple lines.

- require_footer

Default: 0

Can be useful in a use case where you want to make sure you received the complete document from the sender.

- anchor_prefix

  Default: ''

  If set to a string like ANCHOR, anchors and aliases will be prefixed with this instead of just being numbers:

```
# my $xs = YAML::XS->new( anchor_prefix => 'ANCHOR' );
# my $hash = { some => "mapping" };
# say $xs->dump([$hash, $hash]);
- &ANCHOR1
  some: mapping
- *ANCHOR1
```

- cyclic_refs

  Since version v0.907

  Default: 0

  YAML can contain data structures where an alias points to a node containing the current node, creating a cyclic (circular) data structure. If you load untrusted YAML documents, that can lead to memory leaks. Since it's not a very common use case, YAML::XS defaults to not allowing it. It will just behave as if the anchor was never created in this case. You an set it to 1 to allow it.

- boolean

  Since version v0.909

  Default: 0

  Booleans will be loaded as real booleans since perl 5.36.0, and as 1|'' before.

  You can set the value to *JSON::PP* or boolean to load and dump booleans as instances of those classes. Mainly useful for older perl versions where booleans could not roundtrip.

load

```
my $yaml = <<'EOM';
---
- 23
---
some: mapping
EOM
my $array = $xs->load($yaml);
# [23]
my @documents = $xs->load($yaml);
# (
#   [23],
```

(continues on next page)

(continued from previous page)

```
#   { some => "mapping" }
# )
```

In scalar context, if the YAML string contains more than one document, it will return the first document.

dump

```
$yaml = $xs->dump($data);
$yaml = $xs->dump($data1, $data2, $data3);
$yaml = $xs->dump(@data);
```

LIBYAML

`libyaml_version` (since v0.79) answers the libyaml version the module was built with. Under pperl it answers 0.2.4, the libyaml release whose behaviour pperl's engine follows:

```
my $libyaml_version = YAML::XS::LibYAML::libyaml_version();
```

Modules

- `YAML::XS::LibYAML` - the YAML engine behind pperl's YAML::XS

YAML::XS::LibYAML

the YAML engine behind pperl's YAML::XS

SYNOPSIS

```
use YAML::XS qw(Load Dump);

my $data = Load("---\nname: pperl\nlist: [1, 2]\n");
print Dump($data);

my $yaml = YAML::XS->new(indent => 4, footer => 1);
print $yaml->dump($data);
```

DESCRIPTION

`YAML::XS` is YAML-LibYAML 0.910.0's own module. Its compiled part, `YAML::XS::LibYAML`, which under perl wraps the libyaml `C` library, is this module: it reads YAML with *YAML::PP*, pperl's YAML engine, and writes it as libyaml writes it. `Load`, `Dump`, `LoadFile`, `DumpFile`, the object interface (`new`, `load`, `dump`) and the `$YAML::XS::...` settings work as they do under perl, and `Dump` writes the same text: the same quoting, escapes, line folding and indentation. `libyaml_version` answers 0.2.4, the libyaml release whose behaviour this follows.

DIFFERENCES FROM PERL

- Error messages

  A document that does not parse dies with YAML::PP's account of the problem, in libyaml's layout (the problem, the document, the line and the column). The document is nearly always the one libyaml names and the line usually the same, but the words differ and the place can differ by a few columns, since the two parsers notice an error at different points.

- YAML 1.2

  YAML is read as the YAML 1.2 specification reads it, where libyaml, a YAML 1.1 parser, reads it otherwise: `{?foo: bar}` has the key `?foo`, `[?x]` is a list of `?x`, an anchor name may contain `:`, and `{x: :x}` or a tab after an indicator load where libyaml dies. Documents the specification rejects, which libyaml loads (`[-]`, a comment touching a quoted string), die.

- LS and PS

  `Dump` writes the characters U+2028 and U+2029 as `\L` and `\P`. libyaml writes them unescaped, as YAML 1.1 line breaks, and a YAML 1.2 reader then loads a different string back.

- Not yet read

  A flow collection used as a mapping key (`[flow]: block`, `{ [a]: b }`, `[ [a]: b ]`) and the key `: ` do not load yet: YAML::PP does not read them, where libyaml does.

- Where perl fails

  The object interface loads a flow mapping inside a flow sequence (`{ a: [b, { c: d }] }`), on which perl aborts, and dumps strings of latin-1 bytes, which perl refuses ("Could not initialize scalar event").

SEE ALSO

YAML::XS, *YAML::PP*

5.2.116 _charnames

`_charnames` - the Unicode character name table behind `\N{NAME}`, `charnames::viacode`, `charnames::vianame` and `\p{name=...}`.

```
use charnames ();
printf "%s | U+%04X | %s\n", charnames::viacode(0x263A),
    charnames::vianame("GREEK SMALL LETTER ALPHA"),
    "\N{LATIN SMALL LETTER E WITH ACUTE}" eq "\x{e9}" ? "same" :
 ↪"differs";
# WHITE SMILING FACE | U+03B1 | same
```

Nothing uses `_charnames` directly: it is the internal half of `charnames`, loaded by the first `\N{...}` or `charnames` call. The names are those of Unicode 17.0.0, as in perl 5.44.

`_charnames.pm` 1.51 is upstream's. Its one large input, `unicore/Name.pl`, is stored in the binary when pperl is built rather than read from disk at the first lookup, so it costs no parsing or file access.

Differences from upstream

None in behaviour.

5.2.117 attributes

The machinery behind `sub name :attr` and `my $x :attr`: applying the built-in attributes, handing the others to the package that defines them, and reading attributes back.

Perl loads it by itself when it compiles an attribute; `use attributes` is needed only to call its functions. The built-in attributes are `lvalue`, `method`, `const` and `prototype(...)` on a sub, and `shared` on a variable. Any other attribute goes to the package's `MODIFY_CODE_ATTRIBUTES` (or `_SCALAR_`, `_ARRAY_`, `_HASH_`), called as `($package, $ref, @attributes)`; what it returns is the list it did not accept, and those die "Invalid CODE attribute". `FETCH_CODE_ATTRIBUTES` (and the others) add a package's own attributes to what `attributes::get` returns.

This is attributes 0.37; `attributes.pm` is upstream's, and its XS half is native.

Synopsis

```
use attributes;

our $count;
sub counter :lvalue { $count }
counter() = 5;                                  # $count is now 5

sub method_sub :method { 1 }
print join(',', attributes::get(\&counter)), "\n";    # lvalue
print attributes::reftype(\&counter), "\n";           # CODE

package My::Attrs;
my @seen;
sub MODIFY_CODE_ATTRIBUTES { my ($pkg, $ref, @attrs) = @_; push␣
↪@seen, @attrs; return }
sub handler :Cached :Log { 1 }                  # @seen is (Cached,␣
↪Log)
```

Functions

- `attributes::get($ref)` - the attributes of what `$ref` points to: the built-in ones, then those of the package's `FETCH_*_ATTRIBUTES`.
- `attributes::reftype($ref)` - the type `$ref` points to (`CODE`, `HASH`, ...), ignoring blessing, like `Scalar::Util::reftype`.
- `use attributes PACKAGE, \&sub, ATTRIBUTES` - apply attributes at run time, as `sub name :ATTRIBUTES` does at compile time.

Differences from upstream

None: upstream's tests pass unchanged (t/81-xs-native/attributes/100-upstream-op-attrs.t, 110-upstream-uni-attrs.t), and the rest of t/81-xs-native/attributes checks against perl 5.44.

5.2.118 autodie

Replace functions with ones that succeed or die with lexical scope

SYNOPSIS

```
use autodie;            # Recommended: implies 'use autodie␣
↪qw(:default)'

use autodie qw(:all);   # Recommended more: defaults and system/
↪exec.

use autodie qw(open close);   # open/close succeed or die

open(my $fh, "<", $filename); # No need to check!
```

(continues on next page)

(continued from previous page)

```
{
    no autodie qw(open);          # open failures won't die
    open(my $fh, "<", $filename); # Could fail silently!
    no autodie;                   # disable all autodies
}

print "Hello World" or die $!;    # autodie DOESN'T check print!
```

DESCRIPTION

```
bIlujDI' yIchegh()Qo'; yIHegh()!

It is better to die() than to return() in failure.

        -- Klingon programming proverb.
```

The `autodie` pragma provides a convenient way to replace functions that normally return false on failure with equivalents that throw an exception on failure.

The `autodie` pragma has *lexical scope*, meaning that functions and subroutines altered with `autodie` will only change their behaviour until the end of the enclosing block, file, or `eval`.

If `system` is specified as an argument to `autodie`, then it uses IPC::System::Simple to do the heavy lifting. See the description of that module for more information.

EXCEPTIONS

Exceptions produced by the `autodie` pragma are members of the *autodie::exception* class. The preferred way to work with these exceptions under Perl 5.10 is as follows:

```
eval {
    use autodie;

    open(my $fh, '<', $some_file);

    my @records = <$fh>;

    # Do things with @records...

    close($fh);
};

if ($@ and $@->isa('autodie::exception')) {
    if ($@->matches('open')) { print "Error from open\n";   }
    if ($@->matches(':io' )) { print "Non-open, IO error."; }
} elsif ($@) {
    # A non-autodie exception.
}
```

See *autodie::exception* for further information on interrogating exceptions.

CATEGORIES

Autodie uses a simple set of categories to group together similar built-ins. Requesting a category type (starting with a colon) will enable autodie for all built-ins beneath that category. For example, requesting `:file` will enable autodie for `close`, `fcntl`, `open` and `sysopen`.

The categories are currently:

```
:all
    :default
        :io
            read
            seek
            sysread
            sysseek
            syswrite
            :dbm
                dbmclose
                dbmopen
            :file
                binmode
                close
                chmod
                chown
                fcntl
                flock
                ioctl
                open
                sysopen
                truncate
            :filesys
                chdir
                closedir
                opendir
                link
                mkdir
                readlink
                rename
                rmdir
                symlink
                unlink
            :ipc
                kill
                pipe
                :msg
                    msgctl
                    msgget
                    msgrcv
```

(continues on next page)

(continued from previous page)

```
                msgsnd
            :semaphore
                semctl
                semget
                semop
            :shm
                shmctl
                shmget
                shmread
        :socket
            accept
            bind
            connect
            getsockopt
            listen
            recv
            send
            setsockopt
            shutdown
            socketpair
    :threads
        fork
:system
    system
    exec
```

Note that while the above category system is presently a strict hierarchy, this should not be assumed.

A plain `use autodie` implies `use autodie qw(:default)`. Note that `system` and `exec` are not enabled by default. `system` requires the optional IPC::System::Simple module to be installed, and enabling `system` or `exec` will invalidate their exotic forms. See "BUGS" below for more details.

The syntax:

```
use autodie qw(:1.994);
```

allows the `:default` list from a particular version to be used. This provides the convenience of using the default methods, but the surety that no behavioral changes will occur if the `autodie` module is upgraded.

`autodie` can be enabled for all of Perl's built-ins, including `system` and `exec` with:

```
use autodie qw(:all);
```

FUNCTION SPECIFIC NOTES

print

The autodie pragma **does not check calls to `print`**.

flock

It is not considered an error for `flock` to return false if it fails due to an `EWOULDBLOCK` (or equivalent) condition. This means one can still use the common convention of testing the return value of `flock` when called with the `LOCK_NB` option:

```
use autodie;

if ( flock($fh, LOCK_EX | LOCK_NB) ) {
    # We have a lock
}
```

Autodying `flock` will generate an exception if `flock` returns false with any other error.

system/exec

The `system` built-in is considered to have failed in the following circumstances:

- The command does not start.
- The command is killed by a signal.
- The command returns a non-zero exit value (but see below).

On success, the autodying form of `system` returns the *exit value* rather than the contents of `$?`.

Additional allowable exit values can be supplied as an optional first argument to autodying `system`:

```
system( [ 0, 1, 2 ], $cmd, @args);  # 0,1,2 are good exit values
```

`autodie` uses the IPC::System::Simple module to change `system`. See its documentation for further information.

Applying `autodie` to `system` or `exec` causes the exotic forms `system { $cmd } @args` or `exec { $cmd } @args` to be considered a syntax error until the end of the lexical scope. If you really need to use the exotic form, you can call `CORE::system` or `CORE::exec` instead, or use `no autodie qw(system exec)` before calling the exotic form.

GOTCHAS

Functions called in list context are assumed to have failed if they return an empty list, or a list consisting only of a single undef element.

Some builtins (e.g. `chdir` or `truncate`) has a call signature that cannot completely be represented with a Perl prototype. This means that some valid Perl code will be invalid under autodie. As an example:

```
chdir(BAREWORD);
```

Without autodie (and assuming BAREWORD is an open filehandle/dirhandle) this is a valid call to chdir. But under autodie, `chdir` will behave like it had the prototype ";$" and thus BAREWORD will be a syntax error (under "use strict". Without strict, it will interpreted as a filename).

DIAGNOSTICS

- :void cannot be used with lexical scope

  The `:void` option is supported in *Fatal*, but not `autodie`. To workaround this, `autodie` may be explicitly disabled until the end of the current block with `no autodie`. To disable autodie for only a single function (eg, open) use `no autodie qw(open)`.

  `autodie` performs no checking of called context to determine whether to throw an exception; the explicitness of error handling with `autodie` is a deliberate feature.

- No user hints defined for %s

  You've insisted on hints for user-subroutines, either by pre-pending a `!` to the subroutine name itself, or earlier in the list of arguments to `autodie`. However the subroutine in question does not have any hints available.

See also *"DIAGNOSTICS" in Fatal*.

Tips and Tricks

Importing autodie into another namespace than "caller"

It is possible to import autodie into a different namespace by using Import::Into. However, you have to pass a "caller depth" (rather than a package name) for this to work correctly.

BUGS

"Used only once" warnings can be generated when `autodie` or `Fatal` is used with package filehandles (eg, `FILE`). Scalar filehandles are strongly recommended instead.

When using `autodie` or `Fatal` with user subroutines, the declaration of those subroutines must appear before the first use of `Fatal` or `autodie`, or have been exported from a module. Attempting to use `Fatal` or `autodie` on other user subroutines will result in a compile-time error.

Due to a bug in Perl, `autodie` may "lose" any format which has the same name as an autodying built-in or function.

`autodie` may not work correctly if used inside a file with a name that looks like a string eval, such as `eval (3)`.

autodie and string eval

Due to the current implementation of `autodie`, unexpected results may be seen when used near or with the string version of eval. *None of these bugs exist when using block eval.*

Under Perl 5.8 only, `autodie` *does not* propagate into string `eval` statements, although it can be explicitly enabled inside a string `eval`.

Under Perl 5.10 only, using a string eval when `autodie` is in effect can cause the autodie behaviour to leak into the surrounding scope. This can be worked around by using a `no autodie` at the end of the scope to explicitly remove autodie's effects, or by avoiding the use of string eval.

None of these bugs exist when using block eval. The use of `autodie` with block eval is considered good practice.

REPORTING BUGS

Please report bugs via the GitHub Issue Tracker at https://github.com/pjf/autodie/issues.

FEEDBACK

If you find this module useful, please consider rating it on metacpan at https://metacpan.org/pod/autodie .

The module author loves to hear how `autodie` has made your life better (or worse). Feedback can be sent to pjf@perltraining.com.au.

- `autodie::skip` - Skip a package when throwing autodie exceptions

autodie::Scope

Namespace containing the following modules:

- `autodie::Scope::Guard` - Wrapper class for calling subs at end of scope
- `autodie::Scope::GuardStack` - Hook stack for managing scopes via %^H

autodie::Scope::Guard

Wrapper class for calling subs at end of scope

SYNOPSIS

```
use autodie::Scope::Guard;
$^H{'my-key'} = autodie::Scope::Guard->new(sub {
    print "Hallo world\n";
});
```

DESCRIPTION

This class is used to bless perl subs so that they are invoked when they are destroyed. This is mostly useful for ensuring the code is invoked at end of scope. This module is not a part of autodie's public API.

This module is directly inspired by chocolateboy's excellent Scope::Guard module.

Methods

new

```
my $hook = autodie::Scope::Guard->new(sub {});
```

Creates a new `autodie::Scope::Guard`, which will invoke the given sub once it goes out of scope (i.e. its DESTROY handler is called).

autodie::Scope::GuardStack

Hook stack for managing scopes via %^H

SYNOPSIS

```
use autodie::Scope::GuardStack;
my $stack = autodie::Scope::GuardStack->new
$^H{'my-key'} = $stack;

$stack->push_hook(sub {});
```

DESCRIPTION

This class is a stack of hooks to be called in the right order as scopes go away. The stack is only useful when inserted into %^H and will pop hooks as their "scope" is popped. This is useful for uninstalling or reinstalling subs in a namespace as a pragma goes out of scope.

Due to how %^H works, this class is only useful during the compilation phase of a perl module and relies on the internals of how perl handles references in %^H. This module is not a part of autodie's public API.

Methods

new

```
my $stack = autodie::Scope::GuardStack->new;
```

Creates a new `autodie::Scope::GuardStack`. The stack is initially empty and must be inserted into %^H by the creator.

push_hook

```
$stack->push_hook(sub {});
```

Add a sub to the stack. The sub will be called once the current compile-time "scope" is left. Multiple hooks can be added per scope

autodie::Util

Internal Utility subroutines for autodie and Fatal

SYNOPSIS

```
# INTERNAL API for autodie and Fatal only!

use autodie::Util qw(on_end_of_compile_scope);
on_end_of_compile_scope(sub { print "Hallo world\n"; });
```

DESCRIPTION

Internal Utilities for autodie and Fatal! This module is not a part of autodie's public API.

This module contains utility subroutines for abstracting away the underlying magic of autodie and (ab)uses of %^H to call subs at the end of a (compile-time) scopes.

Note that due to how %^H works, some of these utilities are only useful during the compilation phase of a perl module and relies on the internals of how perl handles references in %^H.

Methods

on_end_of_compile_scope

```
on_end_of_compile_scope(sub { print "Hallo world\n"; });
```

Will invoke a sub at the end of a (compile-time) scope. The sub is called once with no arguments. Can be called multiple times (even in the same "compile-time" scope) to install multiple subs. Subs are called in a "first-in-last-out"-order (FILO or "stack"-order).

fill_protos

```
fill_protos('*$$;$@')
```

Given a Perl subroutine prototype, return a list of invocation specifications. Each specification is a listref, where the first member is the (minimum) number of arguments for this invocation specification. The remaining arguments are a string representation of how to pass the arguments correctly to a sub with the given prototype, when called with the given number of arguments.

The specifications are returned in increasing order of arguments starting at 0 (e.g. ';$') or 1 (e.g. '$@'). Note that if the prototype is "slurpy" (e.g. ends with a "@"), the number of arguments for the last specification is a "minimum" number rather than an exact number. This can be detected by the last member of the last specification matching m/[@#]_/.

make_core_trampoline

```
make_core_trampoline('CORE::open', 'main', prototype('CORE::open'))
```

Creates a trampoline for calling a core sub. Essentially, a tiny sub that figures out how we should be calling our core sub, puts in the arguments in the right way, and bounces our control over to it.

If we could reliably use `goto &` on core builtins, we wouldn't need this subroutine.

install_subs

```
install_subs('My::Module', { 'read' => sub { die("Hallo\n"), ... }})
```

Given a package name and a hashref mapping names to a subroutine reference (or undef), this subroutine will install said subroutines on their given name in that module.

If a name mapes to undef, any subroutine with that name in the target module will be removed (possibly "unshadowing" a CORE sub of same name).

autodie::exception

Exceptions from autodying functions.

SYNOPSIS

```
eval {
    use autodie;

    open(my $fh, '<', 'some_file.txt');

    ...
};

if (my $E = $@) {
    say "Ooops!  ",$E->caller," had problems: $@";
}
```

DESCRIPTION

When an *autodie* enabled function fails, it generates an autodie::exception object. This can be interrogated to determine further information about the error that occurred.

This document is broken into two sections; those methods that are most useful to the end-developer, and those methods for anyone wishing to subclass or get very familiar with autodie::exception.

Common Methods

These methods are intended to be used in the everyday dealing of exceptions.

The following assume that the error has been copied into a separate scalar:

```
if ($E = $@) {
    ...
}
```

This is not required, but is recommended in case any code is called which may reset or alter $@.

args

```
my $array_ref = $E->args;
```

Provides a reference to the arguments passed to the subroutine that died.

function

```
my $sub = $E->function;
```

The subroutine (including package) that threw the exception.

file

```
my $file = $E->file;
```

The file in which the error occurred (eg, `myscript.pl` or `MyTest.pm`).

package

```
my $package = $E->package;
```

The package from which the exceptional subroutine was called.

caller

```
my $caller = $E->caller;
```

The subroutine that *called* the exceptional code.

line

```
my $line = $E->line;
```

The line in `$E->file` where the exceptional code was called.

context

```
my $context = $E->context;
```

The context in which the subroutine was called by autodie; usually the same as the context in which you called the autodying subroutine. This can be 'list', 'scalar', or undefined (unknown). It will never be 'void', as `autodie` always captures the return value in one way or another.

For some core functions that always return a scalar value regardless of their context (eg, `chown`), this may be 'scalar', even if you used a list context.

return

```
my $return_value = $E->return;
```

The value(s) returned by the failed subroutine. When the subroutine was called in a list context, this will always be a reference to an array containing the results. When the subroutine was called in a scalar context, this will be the actual scalar returned.

errno

```
my $errno = $E->errno;
```

The value of `$!` at the time when the exception occurred.

NOTE: This method will leave the main `autodie::exception` class and become part of a role in the future. You should only call `errno` for exceptions where `$!` would reasonably have been set on failure.

eval_error

```
my $old_eval_error = $E->eval_error;
```

The contents of `$@` immediately after autodie triggered an exception. This may be useful when dealing with modules such as *Text::Balanced* that set (but do not throw) `$@` on error.

matches

```
if ( $e->matches('open') ) { ... }

if ( 'open' ~~ $e ) { ... }
```

`matches` is used to determine whether a given exception matches a particular role.

An exception is considered to match a string if:

- For a string not starting with a colon, the string exactly matches the package and subroutine that threw the exception. For example, `MyModule::log`. If the string does not contain a package name, `CORE::` is assumed.
- For a string that does start with a colon, if the subroutine throwing the exception *does* that behaviour. For example, the `CORE::open` subroutine does `:file`, `:io` and `:all`.

  See *"CATEGORIES" in autodie* for further information.

  On Perl 5.10 and above, using smart-match (~~) with an `autodie::exception` object will use `matches` underneath. This module used to recommend using smart-match with the exception object on the left hand side, but in future Perls that is likely to stop working. The smart-match facility of this class should only be used with the exception object on the right hand side. Having the exception object on the right is both future-proof and portable to older Perls, back to 5.10. Beware that this facility can only be relied upon when it is certain that the exception object

actually is an `autodie::exception` object; it is no more capable than an explicit call to the `matches` method.

Advanced methods

The following methods, while usable from anywhere, are primarily intended for developers wishing to subclass `autodie::exception`, write code that registers custom error messages, or otherwise work closely with the `autodie::exception` model.

register

```
autodie::exception->register( 'CORE::open' => \&mysub );
```

The `register` method allows for the registration of a message handler for a given subroutine. The full subroutine name including the package should be used.

Registered message handlers will receive the `autodie::exception` object as the first parameter.

add_file_and_line

```
say "Problem occurred",$@->add_file_and_line;
```

Returns the string `at %s line %d`, where `%s` is replaced with the filename, and `%d` is replaced with the line number.

Primarily intended for use by format handlers.

stringify

```
say "The error was: ",$@->stringify;
```

Formats the error as a human readable string. Usually there's no reason to call this directly, as it is used automatically if an `autodie::exception` object is ever used as a string.

Child classes can override this method to change how they're stringified.

format_default

```
my $error_string = $E->format_default;
```

This produces the default error string for the given exception, *without using any registered message handlers*. It is primarily intended to be called from a message handler when they have been passed an exception they don't want to format.

Child classes can override this method to change how default messages are formatted.

new

```
my $error = autodie::exception->new(
    args => \@_,
    function => "CORE::open",
    errno => $!,
    context => 'scalar',
    return => undef,
);
```

Creates a new `autodie::exception` object. Normally called directly from an autodying function. The `function` argument is required, its the function we were trying to call that generated the exception. The `args` parameter is optional.

The `errno` value is optional. In versions of `autodie::exception` 1.99 and earlier the code would try to automatically use the current value of `$!`, but this was unreliable and is no longer supported.

Atrributes such as package, file, and caller are determined automatically, and cannot be specified.

Modules

- `autodie::exception::system` - Exceptions from autodying system().

autodie::exception::system

Exceptions from autodying system().

SYNOPSIS

```
eval {
    use autodie qw(system);

    system($cmd, @args);
```

(continues on next page)

(continued from previous page)

```
};

if (my $E = $@) {
    say "Ooops!  ",$E->caller," had problems: $@";
}
```

DESCRIPTION

This is a *autodie::exception* class for failures from the `system` command.

Presently there is no way to interrogate an `autodie::exception::system` object for the command, exit status, and other information you'd expect such an object to hold. The interface will be expanded to accommodate this in the future.

stringify

When stringified, `autodie::exception::system` objects currently use the message generated by IPC::System::Simple.

autodie::hints

Provide hints about user subroutines to autodie

SYNOPSIS

```
package Your::Module;

our %DOES = ( 'autodie::hints::provider' => 1 );

sub AUTODIE_HINTS {
    return {
        foo => { scalar => HINTS, list => SOME_HINTS },
        bar => { scalar => HINTS, list => MORE_HINTS },
    }
}
```

(continues on next page)

(continued from previous page)

```
# Later, in your main program...

use Your::Module qw(foo bar);
use autodie      qw(:default foo bar);

foo();         # succeeds or dies based on scalar hints

# Alternatively, hints can be set on subroutines we've
# imported.

use autodie::hints;
use Some::Module qw(think_positive);

BEGIN {
    autodie::hints->set_hints_for(
        \&think_positive,
        {
            fail => sub { $_[0] <= 0 }
        }
    )
}
use autodie qw(think_positive);

think_positive(...);    # Returns positive or dies.
```

DESCRIPTION

Introduction

The *autodie* pragma is very smart when it comes to working with Perl's built-in functions. The behaviour for these functions are fixed, and `autodie` knows exactly how they try to signal failure.

But what about user-defined subroutines from modules? If you use `autodie` on a user-defined subroutine then it assumes the following behaviour to demonstrate failure:

- A false value, in scalar context
- An empty list, in list context
- A list containing a single undef, in list context

All other return values (including the list of the single zero, and the list containing a single empty string) are considered successful. However, real-world code isn't always that easy. Perhaps the code you're working with returns a string containing the word "FAIL" upon failure, or a two element list containing `(undef, "human error message")`. To make autodie work with these sorts of subroutines, we have the *hinting interface*.

The hinting interface allows *hints* to be provided to `autodie` on how it should detect failure from user-defined subroutines. While these *can* be provided by the end-user of `autodie`, they are ideally written into the module itself, or into a helper module or sub-class of `autodie` itself.

What are hints?

A *hint* is a subroutine or value that is checked against the return value of an autodying subroutine. If the match returns true, `autodie` considers the subroutine to have failed.

If the hint provided is a subroutine, then `autodie` will pass the complete return value to that subroutine. If the hint is a regexp object, then `autodie` will match it against the return value. If the hint is undef, the return value must be undef. On Perl versions 5.10 and newer, any other value can be provided and it will be smart matched against the value provided. However, smart matched values like this are deprecated.

Hints can be provided for both scalar and list contexts. Note that an autodying subroutine will never see a void context, as `autodie` always needs to capture the return value for examination. Autodying subroutines called in void context act as if they're called in a scalar context, but their return value is discarded after it has been checked.

Example hints

Hints may consist of subroutine references, objects overloading smart-match, regular expressions, and depending on Perl version possibly other things. You can specify different hints for how failure should be identified in scalar and list contexts.

These examples apply for use in the `AUTODIE_HINTS` subroutine and when calling `autodie::hints->set_hints_for()`.

The most common context-specific hints are:

```
# Scalar failures always return undef:
    {  scalar => sub { !defined($_[0]) }  }

# Scalar failures return any false value [default expectation]:
    {  scalar => sub { ! $_[0] }  }

# Scalar failures always return zero explicitly:
    {  scalar => sub { defined($_[0]) && $_[0] eq '0' }  }

# List failures always return an empty list:
    {  list => sub { !@_ }  }

# List failures return () or (undef) [default expectation]:
    {  list => sub { ! @_ || @_ == 1 && !defined $_[0] }  }

# List failures return () or a single false value:
    {  list => sub { ! @_ || @_ == 1 && !$_[0] }  }

# List failures return (undef, "some string")
    {  list => sub { @_ == 2 && !defined $_[0] }  }

# Unsuccessful foo() returns 'FAIL' or '_FAIL' in scalar context,
#                   returns (-1) in list context...
autodie::hints->set_hints_for(
    \&foo,
    {
```

(continues on next page)

(continued from previous page)

```
        scalar => qr/^ _? FAIL $/xms,
        list   => sub { @_ == 1 && $_[0] eq -1 },
    }
);

# Unsuccessful foo() returns 0 in all contexts...
autodie::hints->set_hints_for(
    \&foo,
    {
        scalar => sub { defined($_[0]) && $_[0] == 0 },
        list   => sub { @_ == 1 && defined($_[0]) && $_[0] == 0 },
    }
);
```

This “in all contexts” construction is very common, and can be abbreviated, using the ‘fail’ key. This sets both the `scalar` and `list` hints to the same value:

```
# Unsuccessful foo() returns 0 in all contexts...
autodie::hints->set_hints_for(
    \&foo,
    {
        fail => sub { @_ == 1 and defined $_[0] and $_[0] == 0 }
    }
);

# Unsuccessful think_positive() returns negative number on failure..
 ↪.
autodie::hints->set_hints_for(
    \&think_positive,
    {
        fail => sub { $_[0] < 0 }
    }
);

# Unsuccessful my_system() returns non-zero on failure...
autodie::hints->set_hints_for(
    \&my_system,
    {
        fail => sub { $_[0] != 0 }
    }
);
```

Manually setting hints from within your program

If you are using a module which returns something special on failure, then you can manually create hints for each of the desired subroutines. Once the hints are specified, they are available for all files and modules loaded thereafter, thus you can move this work into a module and it will still work.

```
use Some::Module qw(foo bar);
use autodie::hints;

autodie::hints->set_hints_for(
        \&foo,
        {
                scalar => SCALAR_HINT,
                list   => LIST_HINT,
        }
);
autodie::hints->set_hints_for(
        \&bar,
        { fail => SOME_HINT, }
);
```

It is possible to pass either a subroutine reference (recommended) or a fully qualified subroutine name as the first argument. This means you can set hints on modules that *might* get loaded:

```
use autodie::hints;
autodie::hints->set_hints_for(
        'Some::Module:bar', { fail => SCALAR_HINT, }
);
```

This technique is most useful when you have a project that uses a lot of third-party modules. You can define all your possible hints in one-place. This can even be in a sub-class of autodie. For example:

```
package my::autodie;

use parent qw(autodie);
use autodie::hints;

autodie::hints->set_hints_for(...);

1;
```

You can now `use my::autodie`, which will work just like the standard `autodie`, but is now aware of any hints that you've set.

Adding hints to your module

`autodie` provides a passive interface to allow you to declare hints for your module. These hints will be found and used by `autodie` if it is loaded, but otherwise have no effect (or dependencies) without autodie. To set these, your module needs to declare that it *does* the `autodie::hints::provider` role. This can be done by writing your own `DOES` method, using a system such as `Class::DOES` to handle the heavy-lifting for you, or declaring a `%DOES` package variable with a `autodie::hints::provider` key and a corresponding true value.

Note that checking for a `%DOES` hash is an `autodie`-only short-cut. Other modules do not use this mechanism for checking roles, although you can use the `Class::DOES` module

from the CPAN to allow it.

In addition, you must define a `AUTODIE_HINTS` subroutine that returns a hash-reference containing the hints for your subroutines:

```
package Your::Module;

# We can use the Class::DOES from the CPAN to declare adherence
# to a role.

use Class::DOES 'autodie::hints::provider' => 1;

# Alternatively, we can declare the role in %DOES.  Note that
# this is an autodie specific optimisation, although Class::DOES
# can be used to promote this to a true role declaration.

our %DOES = ( 'autodie::hints::provider' => 1 );

# Finally, we must define the hints themselves.

sub AUTODIE_HINTS {
    return {
        foo => { scalar => HINTS, list => SOME_HINTS },
        bar => { scalar => HINTS, list => MORE_HINTS },
        baz => { fail => HINTS },
    }
}
```

This allows your code to set hints without relying on `autodie` and `autodie::hints` being loaded, or even installed. In this way your code can do the right thing when `autodie` is installed, but does not need to depend upon it to function.

Insisting on hints

When a user-defined subroutine is wrapped by `autodie`, it will use hints if they are available, and otherwise reverts to the *default behaviour* described in the introduction of this document. This can be problematic if we expect a hint to exist, but (for whatever reason) it has not been loaded.

We can ask autodie to *insist* that a hint be used by prefixing an exclamation mark to the start of the subroutine name. A lone exclamation mark indicates that *all* subroutines after it must have hints declared.

```
# foo() and bar() must have their hints defined
use autodie qw( !foo !bar baz );

# Everything must have hints (recommended).
use autodie qw( ! foo bar baz );

# bar() and baz() must have their hints defined
use autodie qw( foo ! bar baz );
```

(continues on next page)

(continued from previous page)

```
# Enable autodie for all of Perl's supported built-ins,
# as well as for foo(), bar() and baz().  Everything must
# have hints.
use autodie qw( ! :all foo bar baz );
```

If hints are not available for the specified subroutines, this will cause a compile-time error. Insisting on hints for Perl's built-in functions (eg, open and `close`) is always successful.

Insisting on hints is *strongly* recommended.

Diagnostics

- Attempts to set_hints_for unidentifiable subroutine

  You've called `autodie::hints->set_hints_for()` using a subroutine reference, but that reference could not be resolved back to a subroutine name. It may be an anonymous subroutine (which can't be made autodying), or may lack a name for other reasons.

  If you receive this error with a subroutine that has a real name, then you may have found a bug in autodie. See *"BUGS" in autodie* for how to report this.

- fail hints cannot be provided with either scalar or list hints for %s

  When defining hints, you can either supply both `list` and `scalar` keywords, *or* you can provide a single `fail` keyword. You can't mix and match them.

- You've provided either a `scalar` hint without supplying a `list` hint, or vice-versa. You *must* supply both `scalar` and `list` hints, *or* a single `fail` hint.

ACKNOWLEDGEMENTS

- Dr Damian Conway for suggesting the hinting interface and providing the example usage.
- Jacinta Richardson for translating much of my ideas into this documentation.

autodie::skip

Skip a package when throwing autodie exceptions

SYNPOSIS

```
use parent qw(autodie::skip);
```

DESCRIPTION

This dummy class exists to signal that the class inheriting it should be skipped when reporting exceptions from autodie. This is useful for utility classes like Path::Tiny that wish to report the location of where they were called on failure.

If your class has a better way of doing roles, then you should not load this class and instead simply say that your class *DOES* `autodie::skip` instead.

5.2.119 autouse

postpone load of modules until a function is used

SYNOPSIS

```
use autouse 'Carp' => qw(carp croak);
carp "this carp was predeclared and autoused ";
```

DESCRIPTION

If the module `Module` is already loaded, then the declaration

```
use autouse 'Module' => qw(func1 func2($;$));
```

is equivalent to

```
use Module qw(func1 func2);
```

if `Module` defines func2() with prototype `($;$)`, and func1() has no prototypes. (At least if `Module` uses `Exporter`'s `import`, otherwise it is a fatal error.)

If the module `Module` is not loaded yet, then the above declaration declares functions func1() and func2() in the current package. When these functions are called, they load the package `Module` if needed, and substitute themselves with the correct definitions.

WARNING

Using `autouse` will move important steps of your program's execution from compile time to runtime. This can

- Break the execution of your program if the module you `autoused` has some initialization which it expects to be done early.
- hide bugs in your code since important checks (like correctness of prototypes) is moved from compile time to runtime. In particular, if the prototype you specified on `autouse` line is wrong, you will not find it out until the corresponding function is executed. This will be very unfortunate for functions which are not always called (note that for such functions `autouse`ing gives biggest win, for a workaround see below).

To alleviate the second problem (partially) it is advised to write your scripts like this:

```
use Module;
use autouse Module => qw(carp($) croak(&$));
carp "this carp was predeclared and autoused ";
```

The first line ensures that the errors in your argument specification are found early. When you ship your application you should comment out the first line, since it makes the second one useless.

5.2.120 base

Establish an ISA relationship with base classes at compile time

SYNOPSIS

```
package Baz;
use base qw(Foo Bar);
```

DESCRIPTION

Unless you are using the `fields` pragma, consider this module discouraged in favor of the lighter-weight `parent`.

Allows you to both load one or more modules, while setting up inheritance from those modules at the same time. Roughly similar in effect to

```
package Baz;
BEGIN {
    require Foo;
    require Bar;
    push @ISA, qw(Foo Bar);
}
```

When `base` tries to `require` a module, it will not die if it cannot find the module's file, but will die on any other error. After all this, should your base class be empty, containing no symbols, `base` will die. This is useful for inheriting from classes in the same file as yourself but where the filename does not match the base module name, like so:

```
# in Bar.pm
package Foo;
sub exclaim { "I can have such a thing?!" }

package Bar;
use base "Foo";
```

There is no `Foo.pm`, but because `Foo` defines a symbol (the `exclaim` subroutine), `base` will not die when the `require` fails to load `Foo.pm`.

`base` will also initialize the fields if one of the base classes has it. Multiple inheritance of fields is **NOT** supported, if two or more base classes each have inheritable fields the 'base' pragma will croak. See *fields* for a description of this feature.

The base class' `import` method is **not** called.

DIAGNOSTICS

- Base class package "%s" is empty.

  base.pm was unable to require the base package, because it was not found in your path.

- Class 'Foo' tried to inherit from itself

  Attempting to inherit from yourself generates a warning.

  ```
  package Foo;
  use base 'Foo';
  ```

HISTORY

This module was introduced with Perl 5.004_04.

CAVEATS

Due to the limitations of the implementation, you must use base *before* you declare any of your own fields.

5.2.121 bigfloat

transparent big floating point number support for Perl

SYNOPSIS

```
use bigfloat;

$x = 2 + 4.5;                       # Math::BigFloat 6.5
print 2 ** 512 * 0.1;               # Math::BigFloat 134...09.6
print inf + 42;                     # Math::BigFloat inf
print NaN * 7;                      # Math::BigFloat NaN
print hex("0x1234567890123490");    # Perl v5.10.0 or later

{
    no bigfloat;
    print 2 ** 256;                 # a normal Perl scalar now
}

# for older Perls, import into current package:
use bigfloat qw/hex oct/;
print hex("0x1234567890123490");
print oct("01234567890123490");
```

DESCRIPTION

All numeric literals in the given scope are converted to Math::BigFloat objects.

All operators (including basic math operations) except the range operator `..` are overloaded.

So, the following:

```
use bigfloat;
$x = 1234;
```

creates a Math::BigFloat and stores a reference to in $x. This happens transparently and behind your back, so to speak.

You can see this with the following:

```
perl -Mbigfloat -le 'print ref(1234)'
```

Since numbers are actually objects, you can call all the usual methods from Math::BigFloat on them. This even works to some extent on expressions:

```
perl -Mbigfloat -le '$x = 1234; print $x->bdec()'
perl -Mbigfloat -le 'print 1234->copy()->binc();'
perl -Mbigfloat -le 'print 1234->copy()->binc->badd(6);'
perl -Mbigfloat -le 'print +(1234)->copy()->binc()'
```

(Note that print doesn't do what you expect if the expression starts with '(' hence the +)

You can even chain the operations together as usual:

```
perl -Mbigfloat -le 'print 1234->copy()->binc->badd(6);'
1241
```

Please note the following does not work as expected (prints nothing), since overloading of '..' is not yet possible in Perl (as of v5.8.0):

```
perl -Mbigfloat -le 'for (1..2) { print ref($_); }'
```

Options

`bigfloat` recognizes some options that can be passed while loading it via via `use`. The following options exist:

- a or accuracy

  This sets the accuracy for all math operations. The argument must be greater than or equal to zero. See Math::BigInt's bround() method for details.

  ```
  perl -Mbigfloat=a,50 -le 'print sqrt(20)'
  ```

  Note that setting precision and accuracy at the same time is not possible.

- p or precision

  This sets the precision for all math operations. The argument can be any integer. Negative values mean a fixed number of digits after the dot, while a positive value rounds to this digit left from the dot. 0 means round to integer. See Math::BigInt's bfround() method for details.

  ```
  perl -Mbigfloat=p,-50 -le 'print sqrt(20)'
  ```

  Note that setting precision and accuracy at the same time is not possible.

- t or trace

  This enables a trace mode and is primarily for debugging.

- l, lib, try, or only

  Load a different math lib, see "Math Library".

```
perl -Mbigfloat=l,GMP -e 'print 2 ** 512'
perl -Mbigfloat=lib,GMP -e 'print 2 ** 512'
perl -Mbigfloat=try,GMP -e 'print 2 ** 512'
perl -Mbigfloat=only,GMP -e 'print 2 ** 512'
```

- hex

  Override the built-in hex() method with a version that can handle big numbers. This overrides it by exporting it to the current package. Under Perl v5.10.0 and higher, this is not so necessary, as hex() is lexically overridden in the current scope whenever the `bigfloat` pragma is active.

- oct

  Override the built-in oct() method with a version that can handle big numbers. This overrides it by exporting it to the current package. Under Perl v5.10.0 and higher, this is not so necessary, as oct() is lexically overridden in the current scope whenever the `bigfloat` pragma is active.

- v or version

  this prints out the name and version of the modules and then exits.

  ```
  perl -Mbigfloat=v
  ```

Math Library

Math with the numbers is done (by default) by a backend library module called Math::BigInt::Calc. The default is equivalent to saying:

```
use bigfloat lib => 'Calc';
```

you can change this by using:

```
use bigfloat lib => 'GMP';
```

The following would first try to find Math::BigInt::Foo, then Math::BigInt::Bar, and if this also fails, revert to Math::BigInt::Calc:

```
use bigfloat lib => 'Foo,Math::BigInt::Bar';
```

Using c<lib> warns if none of the specified libraries can be found and *Math::BigInt* fell back to one of the default libraries. To suppress this warning, use c<try> instead:

```
use bigfloat try => 'GMP';
```

If you want the code to die instead of falling back, use `only` instead:

```
use bigfloat only => 'GMP';
```

Please see respective module documentation for further details.

Method calls

Since all numbers are now objects, you can use all methods that are part of the Math::BigFloat API.

But a warning is in order. When using the following to make a copy of a number, only a shallow copy will be made.

```
$x = 9; $y = $x;
$x = $y = 7;
```

Using the copy or the original with overloaded math is okay, e.g., the following work:

```
$x = 9; $y = $x;
print $x + 1, " ", $y,"\n";     # prints 10 9
```

but calling any method that modifies the number directly will result in **both** the original and the copy being destroyed:

```
$x = 9; $y = $x;
print $x->badd(1), " ", $y,"\n";        # prints 10 10

$x = 9; $y = $x;
print $x->binc(1), " ", $y,"\n";        # prints 10 10

$x = 9; $y = $x;
print $x->bmul(2), " ", $y,"\n";        # prints 18 18
```

Using methods that do not modify, but test that the contents works:

```
$x = 9; $y = $x;
$z = 9 if $x->is_zero();                # works fine
```

See the documentation about the copy constructor and = in overload, as well as the documentation in Math::BigFloat for further details.

Methods

- inf()

  A shortcut to return Math::BigFloat->binf(). Useful because Perl does not always handle bareword `inf` properly.

- NaN()

  A shortcut to return Math::BigFloat->bnan(). Useful because Perl does not always handle bareword `NaN` properly.

- e

  ```
  # perl -Mbigfloat=e -wle 'print e'
  ```

  Returns Euler's number e, aka exp(1)

- PI

```
# perl -Mbigfloat=PI -wle 'print PI'
```

Returns PI.

- bexp()

```
bexp($power, $accuracy);
```

Returns Euler's number `e` raised to the appropriate power, to the wanted accuracy.

Example:

```
# perl -Mbigfloat=bexp -wle 'print bexp(1,80)'
```

- bpi()

```
bpi($accuracy);
```

Returns PI to the wanted accuracy.

Example:

```
# perl -Mbigfloat=bpi -wle 'print bpi(80)'
```

- accuracy()

  Set or get the accuracy.

- precision()

  Set or get the precision.

- round_mode()

  Set or get the rounding mode.

- div_scale()

  Set or get the division scale.

- upgrade()

  Set or get the class that the downgrade class upgrades to, if any. Set the upgrade class to `undef` to disable upgrading.

  Upgrading is disabled by default.

- downgrade()

  Set or get the class that the upgrade class downgrades to, if any. Set the downgrade class to `undef` to disable upgrading.

  Downgrading is disabled by default.

- in_effect()

```
use bigfloat;

print "in effect\n" if bigfloat::in_effect;       # true
```

(continues on next page)

(continued from previous page)

```
{
    no bigfloat;
    print "in effect\n" if bigfloat::in_effect;   # false
}
```

Returns true or false if `bigfloat` is in effect in the current scope.

This method only works on Perl v5.9.4 or later.

CAVEATS

- Hexadecimal, octal, and binary floating point literals

  Perl (and this module) accepts hexadecimal, octal, and binary floating point literals, but use them with care with Perl versions before v5.32.0, because some versions of Perl silently give the wrong result.

- Operator vs literal overloading

  `bigrat` works by overloading handling of integer and floating point literals, converting them to *Math::BigRat* objects.

  This means that arithmetic involving only string values or string literals are performed using Perl's built-in operators.

  For example:

```
use bigrat;
my $x = "900000000000000009";
my $y = "900000000000000007";
print $x - $y;
```

  outputs `0` on default 32-bit builds, since `bigfloat` never sees the string literals. To ensure the expression is all treated as `Math::BigFloat` objects, use a literal number in the expression:

```
print +(0+$x) - $y;
```

- Ranges

  Perl does not allow overloading of ranges, so you can neither safely use ranges with `bigfloat` endpoints, nor is the iterator variable a `Math::BigFloat`.

```
use 5.010;
for my $i (12..13) {
  for my $j (20..21) {
    say $i ** $j;  # produces a floating-point number,
                   # not an object
  }
}
```

- in_effect()

  This method only works on Perl v5.9.4 or later.

- hex()/oct()

  `bigfloat` overrides these routines with versions that can also handle big integer values. Under Perl prior to version v5.9.4, however, this will not happen unless you specifically ask for it with the two import tags "hex" and "oct" - and then it will be global and cannot be disabled inside a scope with `no bigfloat`:

```
use bigfloat qw/hex oct/;

print hex("0x1234567890123456");
{
    no bigfloat;
    print hex("0x1234567890123456");
}
```

  The second call to hex() will warn about a non-portable constant.

  Compare this to:

```
use bigfloat;

# will warn only under Perl older than v5.9.4
print hex("0x1234567890123456");
```

EXAMPLES

Some cool command line examples to impress the Python crowd ;)

```
perl -Mbigfloat -le 'print sqrt(33)'
perl -Mbigfloat -le 'print 2**255'
perl -Mbigfloat -le 'print 4.5+2**255'
perl -Mbigfloat -le 'print 3/7 + 5/7 + 8/3'
perl -Mbigfloat -le 'print 123->is_odd()'
perl -Mbigfloat -le 'print log(2)'
perl -Mbigfloat -le 'print exp(1)'
perl -Mbigfloat -le 'print 2 ** 0.5'
perl -Mbigfloat=a,65 -le 'print 2 ** 0.2'
perl -Mbigfloat=l,GMP -le 'print 7 ** 7777'
```

BUGS

Please report any bugs or feature requests to `bug-bignum at rt.cpan.org`, or through the web interface at https://rt.cpan.org/Ticket/Create.html?Queue=bignum (requires login). We will be notified, and then you'll automatically be notified of progress on your bug as I make changes.

5.2.122 bigint

transparent big integer support for Perl

SYNOPSIS

```
use bigint;

$x = 2 + 4.5;                       # Math::BigInt 6
print 2 ** 512;                     # Math::BigInt 134...096
print inf + 42;                     # Math::BigInt inf
print NaN * 7;                      # Math::BigInt NaN
print hex("0x1234567890123490");    # Perl v5.10.0 or later

{
    no bigint;
    print 2 ** 256;                 # a normal Perl scalar now
}
```

(continues on next page)

(continued from previous page)

```
# for older Perls, import into current package:
use bigint qw/hex oct/;
print hex("0x1234567890123490");
print oct("01234567890123490");
```

DESCRIPTION

All numeric literal in the given scope are converted to Math::BigInt objects. Numeric literal that represent non-integers are truncated to an integer. All results of expressions are also truncated to integer.

All operators (including basic math operations) except the range operator `..` are overloaded.

Unlike the *integer* pragma, the `bigint` pragma creates integers that are only limited in their size by the available memory.

So, the following:

```
use bigint;
$x = 1234;
```

creates a Math::BigInt and stores a reference to in $x. This happens transparently and behind your back, so to speak.

You can see this with the following:

```
perl -Mbigint -le 'print ref(1234)'
```

Since numbers are actually objects, you can call all the usual methods from Math::BigFloat on them. This even works to some extent on expressions:

```
perl -Mbigint -le '$x = 1234; print $x->bdec()'
perl -Mbigint -le 'print 1234->copy()->binc();'
perl -Mbigint -le 'print 1234->copy()->binc->badd(6);'
perl -Mbigint -le 'print +(1234)->copy()->binc()'
```

(Note that print doesn't do what you expect if the expression starts with '(' hence the +)

You can even chain the operations together as usual:

```
perl -Mbigint -le 'print 1234->copy()->binc->badd(6);'
1241
```

Please note the following does not work as expected (prints nothing), since overloading of '..' is not yet possible in Perl (as of v5.8.0):

```
perl -Mbigint -le 'for (1..2) { print ref($_); }'
```

use integer vs. use bigint

There are some difference between `use integer` and `use bigint`.

Whereas `use integer` is limited to what can be handled as a Perl scalar, `use bigint` can handle arbitrarily large integers.

Also, `use integer` does affect assignments to variables and the return value of some functions. `use bigint` truncates these results to integer:

```
# perl -Minteger -wle 'print 3.2'
3.2
# perl -Minteger -wle 'print 3.2 + 0'
3
# perl -Mbigint -wle 'print 3.2'
3
# perl -Mbigint -wle 'print 3.2 + 0'
3

# perl -Mbigint -wle 'print exp(1) + 0'
2
# perl -Mbigint -wle 'print exp(1)'
2
# perl -Minteger -wle 'print exp(1)'
2.71828182845905
# perl -Minteger -wle 'print exp(1) + 0'
2
```

In practice this seldom makes a difference for small integers as **parts and results** of expressions are truncated anyway, but this can, for instance, affect the return value of subroutines:

```
sub three_integer { use integer; return 3.2; }
sub three_bigint { use bigint; return 3.2; }

print three_integer(), " ", three_bigint(),"\n";    # prints "3.2 3"
```

Options

`bigint` recognizes some options that can be passed while loading it via `use`. The following options exist:

- a or accuracy

  This sets the accuracy for all math operations. The argument must be greater than or equal to zero. See Math::BigInt's bround() method for details.

  ```
  perl -Mbigint=a,2 -le 'print 12345+1'
  ```

  Note that setting precision and accuracy at the same time is not possible.

- p or precision

  This sets the precision for all math operations. The argument can be any integer. Negative values mean a fixed number of digits after the dot, and are ignored since

all operations happen in integer space. A positive value rounds to this digit left from the dot. 0 means round to integer. See Math::BigInt's bfround() method for details.

```
perl -mbigint=p,5 -le 'print 123456789+123'
```

Note that setting precision and accuracy at the same time is not possible.

- t or trace

  This enables a trace mode and is primarily for debugging.

- l, lib, try, or only

  Load a different math lib, see "Math Library".

```
perl -Mbigint=l,GMP -e 'print 2 ** 512'
perl -Mbigint=lib,GMP -e 'print 2 ** 512'
perl -Mbigint=try,GMP -e 'print 2 ** 512'
perl -Mbigint=only,GMP -e 'print 2 ** 512'
```

- hex

  Override the built-in hex() method with a version that can handle big numbers. This overrides it by exporting it to the current package. Under Perl v5.10.0 and higher, this is not necessary, as hex() is lexically overridden in the current scope whenever the `bigint` pragma is active.

- oct

  Override the built-in oct() method with a version that can handle big numbers. This overrides it by exporting it to the current package. Under Perl v5.10.0 and higher, this is not so necessary, as oct() is lexically overridden in the current scope whenever the `bigint` pragma is active.

- v or version

  this prints out the name and version of the modules and then exits.

```
perl -Mbigint=v
```

Math Library

Math with the numbers is done (by default) by a backend library module called Math::BigInt::Calc. The default is equivalent to saying:

```
use bigint lib => 'Calc';
```

you can change this by using:

```
use bigint lib => 'GMP';
```

The following would first try to find Math::BigInt::Foo, then Math::BigInt::Bar, and if this also fails, revert to Math::BigInt::Calc:

```
use bigint lib => 'Foo,Math::BigInt::Bar';
```

Using c<lib> warns if none of the specified libraries can be found and *Math::BigInt* fell back to one of the default libraries. To suppress this warning, use c<try> instead:

```
use bigint try => 'GMP';
```

If you want the code to die instead of falling back, use only instead:

```
use bigint only => 'GMP';
```

Please see the respective module documentation for further details.

Method calls

Since all numbers are now objects, you can use all methods that are part of the Math::BigInt API.

But a warning is in order. When using the following to make a copy of a number, only a shallow copy will be made.

```
$x = 9; $y = $x;
$x = $y = 7;
```

Using the copy or the original with overloaded math is okay, e.g., the following work:

```
$x = 9; $y = $x;
print $x + 1, " ", $y,"\n";     # prints 10 9
```

but calling any method that modifies the number directly will result in **both** the original and the copy being destroyed:

```
$x = 9; $y = $x;
print $x->badd(1), " ", $y,"\n";        # prints 10 10

$x = 9; $y = $x;
print $x->binc(1), " ", $y,"\n";        # prints 10 10

$x = 9; $y = $x;
print $x->bmul(2), " ", $y,"\n";        # prints 18 18
```

Using methods that do not modify, but test that the contents works:

```
$x = 9; $y = $x;
$z = 9 if $x->is_zero();                # works fine
```

See the documentation about the copy constructor and = in overload, as well as the documentation in Math::BigInt for further details.

Methods

- inf()

  A shortcut to return Math::BigInt->binf(). Useful because Perl does not always handle bareword `inf` properly.

- NaN()

  A shortcut to return Math::BigInt->bnan(). Useful because Perl does not always handle bareword `NaN` properly.

- e

```
# perl -Mbigint=e -wle 'print e'
```

  Returns Euler's number `e`, aka exp(1). Note that under `bigint`, this is truncated to an integer, i.e., 2.

- PI

```
# perl -Mbigint=PI -wle 'print PI'
```

  Returns PI. Note that under `bigint`, this is truncated to an integer, i.e., 3.

- bexp()

```
bexp($power, $accuracy);
```

  Returns Euler's number `e` raised to the appropriate power, to the wanted accuracy.

  Note that under `bigint`, the result is truncated to an integer.

  Example:

```
# perl -Mbigint=bexp -wle 'print bexp(1,80)'
```

- bpi()

```
bpi($accuracy);
```

  Returns PI to the wanted accuracy. Note that under `bigint`, this is truncated to an integer, i.e., 3.

  Example:

```
# perl -Mbigint=bpi -wle 'print bpi(80)'
```

- accuracy()

  Set or get the accuracy.

- precision()

  Set or get the precision.

- round_mode()

  Set or get the rounding mode.

- div_scale()

  Set or get the division scale.

- in_effect()

```
use bigint;

print "in effect\n" if bigint::in_effect;       # true
{
    no bigint;
    print "in effect\n" if bigint::in_effect;   # false
}
```

  Returns true or false if `bigint` is in effect in the current scope.

  This method only works on Perl v5.9.4 or later.

CAVEATS

- Hexadecimal, octal, and binary floating point literals

  Perl (and this module) accepts hexadecimal, octal, and binary floating point literals, but use them with care with Perl versions before v5.32.0, because some versions of Perl silently give the wrong result.

- Operator vs literal overloading

  `bigint` works by overloading handling of integer and floating point literals, converting them to *Math::BigInt* objects.

  This means that arithmetic involving only string values or string literals are performed using Perl's built-in operators.

  For example:

```
use bigint;
my $x = "900000000000000009";
my $y = "900000000000000007";
print $x - $y;
```

  outputs `0` on default 32-bit builds, since `bigint` never sees the string literals. To ensure the expression is all treated as `Math::BigInt` objects, use a literal number in the expression:

```
print +(0+$x) - $y;
```

- Ranges

  Perl does not allow overloading of ranges, so you can neither safely use ranges with `bigint` endpoints, nor is the iterator variable a `Math::BigInt`.

```
use 5.010;
for my $i (12..13) {
  for my $j (20..21) {
    say $i ** $j;  # produces a floating-point number,
```

(continues on next page)

(continued from previous page)

```
                    # not an object
  }
}
```

- in_effect()

  This method only works on Perl v5.9.4 or later.

- hex()/oct()

  `bigint` overrides these routines with versions that can also handle big integer values. Under Perl prior to version v5.9.4, however, this will not happen unless you specifically ask for it with the two import tags "hex" and "oct" - and then it will be global and cannot be disabled inside a scope with `no bigint`:

```
use bigint qw/hex oct/;

print hex("0x1234567890123456");
{
    no bigint;
    print hex("0x1234567890123456");
}
```

  The second call to hex() will warn about a non-portable constant.

  Compare this to:

```
use bigint;

# will warn only under Perl older than v5.9.4
print hex("0x1234567890123456");
```

EXAMPLES

Some cool command line examples to impress the Python crowd ;) You might want to compare them to the results under -Mbigfloat or -Mbigrat:

```
perl -Mbigint -le 'print sqrt(33)'
perl -Mbigint -le 'print 2**255'
perl -Mbigint -le 'print 4.5+2**255'
perl -Mbigint -le 'print 123->is_odd()'
perl -Mbigint=l,GMP -le 'print 7 ** 7777'
```

BUGS

Please report any bugs or feature requests to `bug-bignum at rt.cpan.org`, or through the web interface at https://rt.cpan.org/Ticket/Create.html?Queue=bignum (requires login). We will be notified, and then you'll automatically be notified of progress on your bug as I make changes.

SUPPORT

You can find documentation for this module with the perldoc command.

```
perldoc bigint
```

5.2.123 bignum

transparent big number support for Perl

SYNOPSIS

```
use bignum;

$x = 2 + 4.5;                       # Math::BigFloat 6.5
print 2 ** 512 * 0.1;               # Math::BigFloat 134...09.6
print 2 ** 512;                     # Math::BigInt 134...096
print inf + 42;                     # Math::BigInt inf
print NaN * 7;                      # Math::BigInt NaN
```

(continues on next page)

(continued from previous page)

```
print hex("0x1234567890123490");    # Perl v5.10.0 or later

{
    no bignum;
    print 2 ** 256;                 # a normal Perl scalar now
}

# for older Perls, import into current package:
use bignum qw/hex oct/;
print hex("0x1234567890123490");
print oct("01234567890123490");
```

DESCRIPTION

Literal numeric constants

By default, every literal integer becomes a Math::BigInt object, and literal non-integer becomes a Math::BigFloat object. Whether a numeric literal is considered an integer or non-integers depends only on the value of the constant, not on how it is represented. For instance, the constants 3.14e2 and 0x1.3ap8 become Math::BigInt objects, because they both represent the integer value decimal 314.

The default `use bignum;` is equivalent to

```
use bignum downgrade => "Math::BigInt", upgrade => "Math::BigFloat";
```

The classes used for integers and non-integers can be set at compile time with the `downgrade` and `upgrade` options, for example

```
# use Math::BigInt for integers and Math::BigRat for non-integers
use bignum upgrade => "Math::BigRat";
```

Note that disabling downgrading and upgrading does not affect how numeric literals are converted to objects

```
# disable both downgrading and upgrading
use bignum downgrade => undef, upgrade => undef;
$x = 2.4;       # becomes 2.4 as a Math::BigFloat
$y = 2;         # becomes 2 as a Math::BigInt
```

Upgrading and downgrading

By default, when the result of a computation is an integer, an Inf, or a NaN, the result is downgraded even when all the operands are instances of the upgrade class.

```
use bignum;
$x = 2.4;       # becomes 2.4 as a Math::BigFloat
$y = 1.2;       # becomes 1.2 as a Math::BigFloat
$z = $x / $y;   # becomes 2 as a Math::BigInt due to downgrading
```

Equivalently, by default, when the result of a computation is a finite non-integer, the result is upgraded even when all the operands are instances of the downgrade class.

```
use bignum;
$x = 7;          # becomes 7 as a Math::BigInt
$y = 2;          # becomes 2 as a Math::BigInt
$z = $x / $y;    # becomes 3.5 as a Math::BigFloat due to upgrading
```

The classes used for downgrading and upgrading can be set at runtime with the "downgrade()" and "upgrade()" methods, but see "CAVEATS" below.

The upgrade and downgrade classes don't have to be Math::BigInt and Math::BigFloat. For example, to use Math::BigRat as the upgrade class, use

```
use bignum upgrade => "Math::BigRat";
$x = 2;          # becomes 2 as a Math::BigInt
$y = 3.6;        # becomes 18/5 as a Math::BigRat
```

The upgrade and downgrade classes can be modified at runtime

```
use bignum;
$x = 3;          # becomes 3 as a Math::BigInt
$y = 2;          # becomes 2 as a Math::BigInt
$z = $x / $y;    # becomes 1.5 as a Math::BigFlaot

bignum -> upgrade("Math::BigRat");
$w = $x / $y;    # becomes 3/2 as a Math::BigRat
```

Disabling downgrading doesn't change the fact that literal constant integers are converted to the downgrade class, it only prevents downgrading as a result of a computation. E.g.,

```
use bignum downgrade => undef;
$x = 2;          # becomes 2 as a Math::BigInt
$y = 2.4;        # becomes 2.4 as a Math::BigFloat
$z = 1.2;        # becomes 1.2 as a Math::BigFloat
$w = $x / $y;    # becomes 2 as a Math::BigFloat due to no␣
↪downgrading
```

If you want all numeric literals, both integers and non-integers, to become Math::BigFloat objects, use the *bigfloat* pragma.

Equivalently, disabling upgrading doesn't change the fact that literal constant non-integers are converted to the upgrade class, it only prevents upgrading as a result of a computation. E.g.,

```
use bignum upgrade => undef;
$x = 2.5;        # becomes 2.5 as a Math::BigFloat
$y = 7;          # becomes 7 as a Math::BigInt
$z = 2;          # becomes 2 as a Math::BigInt
$w = $x / $y;    # becomes 3 as a Math::BigInt due to no upgrading
```

If you want all numeric literals, both integers and non-integers, to become Math::BigInt objects, use the *bigint* pragma.

You can even do

```
use bignum upgrade => "Math::BigRat", upgrade => undef;
```

which converts all integer literals to Math::BigInt objects and all non-integer literals to Math::BigRat objects. However, when the result of a computation involving two Math::BigInt objects results in a non-integer (e.g., 7/2), the result will be truncted to a Math::BigInt rather than being upgraded to a Math::BigRat, since upgrading is disabled.

Overloading

Since all numeric literals become objects, you can call all the usual methods from Math::BigInt and Math::BigFloat on them. This even works to some extent on expressions:

```
perl -Mbignum -le '$x = 1234; print $x->bdec()'
perl -Mbignum -le 'print 1234->copy()->binc();'
perl -Mbignum -le 'print 1234->copy()->binc()->badd(6);'
```

Options

`bignum` recognizes some options that can be passed while loading it via via `use`. The following options exist:

- a or accuracy

  This sets the accuracy for all math operations. The argument must be greater than or equal to zero. See Math::BigInt's bround() method for details.

  ```
  perl -Mbignum=a,50 -le 'print sqrt(20)'
  ```

  Note that setting precision and accuracy at the same time is not possible.

- p or precision

  This sets the precision for all math operations. The argument can be any integer. Negative values mean a fixed number of digits after the dot, while a positive value rounds to this digit left from the dot. 0 means round to integer. See Math::BigInt's bfround() method for details.

  ```
  perl -Mbignum=p,-50 -le 'print sqrt(20)'
  ```

  Note that setting precision and accuracy at the same time is not possible.

- l, lib, try, or only

  Load a different math lib, see "Math Library".

  ```
  perl -Mbignum=l,GMP -e 'print 2 ** 512'
  perl -Mbignum=lib,GMP -e 'print 2 ** 512'
  perl -Mbignum=try,GMP -e 'print 2 ** 512'
  perl -Mbignum=only,GMP -e 'print 2 ** 512'
  ```

- hex

Override the built-in hex() method with a version that can handle big numbers. This overrides it by exporting it to the current package. Under Perl v5.10.0 and higher, this is not so necessary, as hex() is lexically overridden in the current scope whenever the `bignum` pragma is active.

- oct

  Override the built-in oct() method with a version that can handle big numbers. This overrides it by exporting it to the current package. Under Perl v5.10.0 and higher, this is not so necessary, as oct() is lexically overridden in the current scope whenever the `bignum` pragma is active.

- v or version

  this prints out the name and version of the modules and then exits.

```
perl -Mbignum=v
```

Math Library

Math with the numbers is done (by default) by a backend library module called Math::BigInt::Calc. The default is equivalent to saying:

```
use bignum lib => 'Calc';
```

you can change this by using:

```
use bignum lib => 'GMP';
```

The following would first try to find Math::BigInt::Foo, then Math::BigInt::Bar, and if this also fails, revert to Math::BigInt::Calc:

```
use bignum lib => 'Foo,Math::BigInt::Bar';
```

Using c<lib> warns if none of the specified libraries can be found and *Math::BigInt* and *Math::BigFloat* fell back to one of the default libraries. To suppress this warning, use `try` instead:

```
use bignum try => 'GMP';
```

If you want the code to die instead of falling back, use `only` instead:

```
use bignum only => 'GMP';
```

Please see respective module documentation for further details.

Method calls

Since all numbers are now objects, you can use the methods that are part of the Math::BigInt and Math::BigFloat API.

But a warning is in order. When using the following to make a copy of a number, only a shallow copy will be made.

```
$x = 9; $y = $x;
$x = $y = 7;
```

Using the copy or the original with overloaded math is okay, e.g., the following work:

```
$x = 9; $y = $x;
print $x + 1, " ", $y,"\n";     # prints 10 9
```

but calling any method that modifies the number directly will result in **both** the original and the copy being destroyed:

```
$x = 9; $y = $x;
print $x->badd(1), " ", $y,"\n";        # prints 10 10

$x = 9; $y = $x;
print $x->binc(1), " ", $y,"\n";        # prints 10 10

$x = 9; $y = $x;
print $x->bmul(2), " ", $y,"\n";        # prints 18 18
```

Using methods that do not modify, but test that the contents works:

```
$x = 9; $y = $x;
$z = 9 if $x->is_zero();                # works fine
```

See the documentation about the copy constructor and = in overload, as well as the documentation in Math::BigFloat for further details.

Methods

- inf()

  A shortcut to return `inf` as an object. Useful because Perl does not always handle bareword `inf` properly.

- NaN()

  A shortcut to return `NaN` as an object. Useful because Perl does not always handle bareword `NaN` properly.

- e

  ```
  # perl -Mbignum=e -wle 'print e'
  ```

  Returns Euler's number e, aka exp(1) (= 2.7182818284...).

- PI

  ```
  # perl -Mbignum=PI -wle 'print PI'
  ```

  Returns PI (= 3.1415926532..).

- bexp()

```
bexp($power, $accuracy);
```

Returns Euler's number e raised to the appropriate power, to the wanted accuracy.

Example:

```
# perl -Mbignum=bexp -wle 'print bexp(1,80)'
```

- bpi()

```
bpi($accuracy);
```

Returns PI to the wanted accuracy.

Example:

```
# perl -Mbignum=bpi -wle 'print bpi(80)'
```

- accuracy()

  Set or get the accuracy.

- precision()

  Set or get the precision.

- round_mode()

  Set or get the rounding mode.

- div_scale()

  Set or get the division scale.

- upgrade()

  Set or get the class that the downgrade class upgrades to, if any. Set the upgrade class to undef to disable upgrading. See /CAVEATS below.

- downgrade()

  Set or get the class that the upgrade class downgrades to, if any. Set the downgrade class to undef to disable upgrading. See "CAVEATS" below.

- in_effect()

```
use bignum;

print "in effect\n" if bignum::in_effect;       # true
{
    no bignum;
    print "in effect\n" if bignum::in_effect;   # false
}
```

Returns true or false if bignum is in effect in the current scope.

This method only works on Perl v5.9.4 or later.

CAVEATS

- The upgrade() and downgrade() methods

  Note that setting both the upgrade and downgrade classes at runtime with the "upgrade()" and "downgrade()" methods, might not do what you expect:

```
# Assuming that downgrading and upgrading hasn't been modified␣
 ↪so far, so
# the downgrade and upgrade classes are Math::BigInt and␣
 ↪Math::BigFloat,
# respectively, the following sets the upgrade class to␣
 ↪Math::BigRat, i.e.,
# makes Math::BigInt upgrade to Math::BigRat:

bignum -> upgrade("Math::BigRat");

# The following sets the downgrade class to Math::BigInt::Lite,␣
 ↪i.e., makes
# the new upgrade class Math::BigRat downgrade to␣
 ↪Math::BigInt::Lite

bignum -> downgrade("Math::BigInt::Lite");

# Note that at this point, it is still Math::BigInt, not␣
 ↪Math::BigInt::Lite,
# that upgrades to Math::BigRat, so to get Math::BigInt::Lite␣
 ↪to upgrade to
# Math::BigRat, we need to do the following (again):

bignum -> upgrade("Math::BigRat");
```

  A simpler way to do this at runtime is to use import(),

```
bignum -> import(upgrade => "Math::BigRat",
                 downgrade => "Math::BigInt::Lite");
```

- Hexadecimal, octal, and binary floating point literals

  Perl (and this module) accepts hexadecimal, octal, and binary floating point literals, but use them with care with Perl versions before v5.32.0, because some versions of Perl silently give the wrong result.

- Operator vs literal overloading

  `bigrat` works by overloading handling of integer and floating point literals, converting them to *Math::BigRat* objects.

  This means that arithmetic involving only string values or string literals are performed using Perl's built-in operators.

  For example:

```
use bigrat;
my $x = "900000000000000009";
```

(continues on next page)

(continued from previous page)

```
my $y = "900000000000000007";
print $x - $y;
```

outputs `0` on default 32-bit builds, since `bignum` never sees the string literals. To ensure the expression is all treated as `Math::BigFloat` objects, use a literal number in the expression:

```
print +(0+$x) - $y;
```

- Ranges

  Perl does not allow overloading of ranges, so you can neither safely use ranges with `bignum` endpoints, nor is the iterator variable a `Math::BigFloat`.

```
use 5.010;
for my $i (12..13) {
  for my $j (20..21) {
    say $i ** $j;  # produces a floating-point number,
                   # not an object
  }
}
```

- in_effect()

  This method only works on Perl v5.9.4 or later.

- hex()/oct()

  `bignum` overrides these routines with versions that can also handle big integer values. Under Perl prior to version v5.9.4, however, this will not happen unless you specifically ask for it with the two import tags “hex” and “oct” - and then it will be global and cannot be disabled inside a scope with `no bignum`:

```
use bignum qw/hex oct/;

print hex("0x1234567890123456");
{
    no bignum;
    print hex("0x1234567890123456");
}
```

  The second call to hex() will warn about a non-portable constant.

  Compare this to:

```
use bignum;

# will warn only under Perl older than v5.9.4
print hex("0x1234567890123456");
```

EXAMPLES

Some cool command line examples to impress the Python crowd ;)

```
perl -Mbignum -le 'print sqrt(33)'
perl -Mbignum -le 'print 2**255'
perl -Mbignum -le 'print 4.5+2**255'
perl -Mbignum -le 'print 3/7 + 5/7 + 8/3'
perl -Mbignum -le 'print 123->is_odd()'
perl -Mbignum -le 'print log(2)'
perl -Mbignum -le 'print exp(1)'
perl -Mbignum -le 'print 2 ** 0.5'
perl -Mbignum=a,65 -le 'print 2 ** 0.2'
perl -Mbignum=l,GMP -le 'print 7 ** 7777'
```

BUGS

Please report any bugs or feature requests to `bug-bignum at rt.cpan.org`, or through the web interface at https://rt.cpan.org/Ticket/Create.html?Queue=bignum (requires login). We will be notified, and then you'll automatically be notified of progress on your bug as I make changes.

SUPPORT

You can find documentation for this module with the perldoc command.

```
perldoc bignum

5.2.124 bigrat

transparent big rational number support for Perl

SYNOPSIS

```
use bigrat;

print 2 + 4.5;                      # Math::BigRat 13/2
print 1/3 + 1/4;                    # Math::BigRat 7/12
print inf + 42;                     # Math::BigRat inf
print NaN * 7;                      # Math::BigRat NaN
print hex("0x1234567890123490");    # Perl v5.10.0 or later

{
    no bigrat;
    print 1/3;                      # 0.33333...
}

# for older Perls, import into current package:
use bigrat qw/hex oct/;
print hex("0x1234567890123490");
print oct("01234567890123490");
```

DESCRIPTION

All numeric literal in the given scope are converted to Math::BigRat objects.

All operators (including basic math operations) except the range operator `..` are overloaded.

So, the following:

```
use bigrat;
$x = 1234;
```

creates a Math::BigRat and stores a reference to in $x. This happens transparently and behind your back, so to speak.

You can see this with the following:

```
perl -Mbigrat -le 'print ref(1234)'
```

Since numbers are actually objects, you can call all the usual methods from Math::BigRat on them. This even works to some extent on expressions:

```
perl -Mbigrat -le '$x = 1234; print $x->bdec()'
perl -Mbigrat -le 'print 1234->copy()->binc();'
perl -Mbigrat -le 'print 1234->copy()->binc->badd(6);'
perl -Mbigrat -le 'print +(1234)->copy()->binc()'
```

(Note that print doesn't do what you expect if the expression starts with '(' hence the +)

You can even chain the operations together as usual:

```
perl -Mbigrat -le 'print 1234->copy()->binc->badd(6);'
1241
```

Please note the following does not work as expected (prints nothing), since overloading of '..' is not yet possible in Perl (as of v5.8.0):

```
perl -Mbigrat -le 'for (1..2) { print ref($_); }'
```

Options

`bigrat` recognizes some options that can be passed while loading it via `use`. The following options exist:

- a or accuracy

  This sets the accuracy for all math operations. The argument must be greater than or equal to zero. See Math::BigInt's bround() method for details.

  ```
  perl -Mbigrat=a,50 -le 'print sqrt(20)'
  ```

  Note that setting precision and accuracy at the same time is not possible.

- p or precision

  This sets the precision for all math operations. The argument can be any integer. Negative values mean a fixed number of digits after the dot, while a positive value rounds to this digit left from the dot. 0 means round to integer. See Math::BigInt's bfround() method for details.

  ```
  perl -Mbigrat=p,-50 -le 'print sqrt(20)'
  ```

  Note that setting precision and accuracy at the same time is not possible.

- t or trace

  This enables a trace mode and is primarily for debugging.

- l, lib, try, or only

  Load a different math lib, see "Math Library".

```
perl -Mbigrat=l,GMP -e 'print 2 ** 512'
perl -Mbigrat=lib,GMP -e 'print 2 ** 512'
perl -Mbigrat=try,GMP -e 'print 2 ** 512'
perl -Mbigrat=only,GMP -e 'print 2 ** 512'
```

- hex

  Override the built-in hex() method with a version that can handle big numbers. This overrides it by exporting it to the current package. Under Perl v5.10.0 and higher, this is not so necessary, as hex() is lexically overridden in the current scope whenever the `bigrat` pragma is active.

- oct

  Override the built-in oct() method with a version that can handle big numbers. This overrides it by exporting it to the current package. Under Perl v5.10.0 and higher, this is not so necessary, as oct() is lexically overridden in the current scope whenever the `bigrat` pragma is active.

- v or version

  this prints out the name and version of the modules and then exits.

```
perl -Mbigrat=v
```

Math Library

Math with the numbers is done (by default) by a backend library module called Math::BigInt::Calc. The default is equivalent to saying:

```
use bigrat lib => 'Calc';
```

you can change this by using:

```
use bigrat lib => 'GMP';
```

The following would first try to find Math::BigInt::Foo, then Math::BigInt::Bar, and if this also fails, revert to Math::BigInt::Calc:

```
use bigrat lib => 'Foo,Math::BigInt::Bar';
```

Using c<lib> warns if none of the specified libraries can be found and *Math::BigInt* fell back to one of the default libraries. To suppress this warning, use c<try> instead:

```
use bigrat try => 'GMP';
```

If you want the code to die instead of falling back, use `only` instead:

```
use bigrat only => 'GMP';
```

Please see the respective module documentation for further details.

Method calls

Since all numbers are now objects, you can use all methods that are part of the Math::BigRat API.

But a warning is in order. When using the following to make a copy of a number, only a shallow copy will be made.

```
$x = 9; $y = $x;
$x = $y = 7;
```

Using the copy or the original with overloaded math is okay, e.g., the following work:

```
$x = 9; $y = $x;
print $x + 1, " ", $y,"\n";     # prints 10 9
```

but calling any method that modifies the number directly will result in **both** the original and the copy being destroyed:

```
$x = 9; $y = $x;
print $x->badd(1), " ", $y,"\n";        # prints 10 10

$x = 9; $y = $x;
print $x->binc(1), " ", $y,"\n";        # prints 10 10

$x = 9; $y = $x;
print $x->bmul(2), " ", $y,"\n";        # prints 18 18
```

Using methods that do not modify, but test that the contents works:

```
$x = 9; $y = $x;
$z = 9 if $x->is_zero();                # works fine
```

See the documentation about the copy constructor and = in overload, as well as the documentation in Math::BigFloat for further details.

Methods

- inf()

  A shortcut to return Math::BigRat->binf(). Useful because Perl does not always handle bareword `inf` properly.

- NaN()

  A shortcut to return Math::BigRat->bnan(). Useful because Perl does not always handle bareword `NaN` properly.

- e

  ```
  # perl -Mbigrat=e -wle 'print e'
  ```

  Returns Euler's number e, aka exp(1).

- PI

```
# perl -Mbigrat=PI -wle 'print PI'
```

Returns PI.

- bexp()

```
bexp($power, $accuracy);
```

Returns Euler's number e raised to the appropriate power, to the wanted accuracy.

Example:

```
# perl -Mbigrat=bexp -wle 'print bexp(1,80)'
```

- bpi()

```
bpi($accuracy);
```

Returns PI to the wanted accuracy.

Example:

```
# perl -Mbigrat=bpi -wle 'print bpi(80)'
```

- accuracy()

  Set or get the accuracy.

- precision()

  Set or get the precision.

- round_mode()

  Set or get the rounding mode.

- div_scale()

  Set or get the division scale.

- in_effect()

```
use bigrat;

print "in effect\n" if bigrat::in_effect;       # true
{
    no bigrat;
    print "in effect\n" if bigrat::in_effect;   # false
}
```

Returns true or false if `bigrat` is in effect in the current scope.

This method only works on Perl v5.9.4 or later.

CAVEATS

- Hexadecimal, octal, and binary floating point literals

  Perl (and this module) accepts hexadecimal, octal, and binary floating point literals, but use them with care with Perl versions before v5.32.0, because some versions of Perl silently give the wrong result.

- Operator vs literal overloading

  `bigrat` works by overloading handling of integer and floating point literals, converting them to *Math::BigRat* objects.

  This means that arithmetic involving only string values or string literals are performed using Perl's built-in operators.

  For example:

```
use bigrat;
my $x = "900000000000000009";
my $y = "900000000000000007";
print $x - $y;
```

  outputs `0` on default 32-bit builds, since `bigrat` never sees the string literals. To ensure the expression is all treated as `Math::BigRat` objects, use a literal number in the expression:

```
print +(0+$x) - $y;
```

- Ranges

  Perl does not allow overloading of ranges, so you can neither safely use ranges with `bigrat` endpoints, nor is the iterator variable a `Math::BigRat`.

```
use 5.010;
for my $i (12..13) {
  for my $j (20..21) {
    say $i ** $j;  # produces a floating-point number,
                   # not an object
  }
}
```

- in_effect()

  This method only works on Perl v5.9.4 or later.

- hex()/oct()

  `bigrat` overrides these routines with versions that can also handle big integer values. Under Perl prior to version v5.9.4, however, this will not happen unless you specifically ask for it with the two import tags "hex" and "oct" - and then it will be global and cannot be disabled inside a scope with `no bigrat`:

```
use bigrat qw/hex oct/;

print hex("0x1234567890123456");
```

(continues on next page)

(continued from previous page)

```
{
    no bigrat;
    print hex("0x1234567890123456");
}
```

The second call to hex() will warn about a non-portable constant.

Compare this to:

```
use bigrat;

# will warn only under Perl older than v5.9.4
print hex("0x1234567890123456");
```

EXAMPLES

```
perl -Mbigrat -le 'print sqrt(33)'
perl -Mbigrat -le 'print 2**255'
perl -Mbigrat -le 'print 4.5+2**255'
perl -Mbigrat -le 'print 3/7 + 5/7 + 8/3'
perl -Mbigrat -le 'print 12->is_odd()';
perl -Mbigrat=l,GMP -le 'print 7 ** 7777'
```

BUGS

Please report any bugs or feature requests to `bug-bignum at rt.cpan.org`, or through the web interface at https://rt.cpan.org/Ticket/Create.html?Queue=bignum (requires login). We will be notified, and then you'll automatically be notified of progress on your bug as I make changes.

SUPPORT

You can find documentation for this module with the perldoc command.

```
perldoc bigrat
```

5.2.125 blib

Use MakeMaker's uninstalled version of a package

SYNOPSIS

```
perl -Mblib script [args...]

perl -Mblib=dir script [args...]
```

DESCRIPTION

Looks for MakeMaker-like *'blib'* directory structure starting in *dir* (or current directory) and working back up to five levels of '..'.

Intended for use on command line with **-M** option as a way of testing arbitrary scripts against an uninstalled version of a package.

However it is possible to :

```
use blib;
or
use blib '..';
```

etc. if you really must.

BUGS

Pollutes global name space for development only task.

5.2.126 builtin

Perl pragma to import built-in utility functions

SYNOPSIS

```
use builtin qw(
    true false is_bool
    inf nan
    weaken unweaken is_weak
    blessed refaddr reftype
    created_as_string created_as_number
    stringify
    ceil floor
    indexed
    trim
    is_tainted
    export_lexically
    load_module
);

use builtin ':5.40';  # most of the above
```

DESCRIPTION

Perl provides several utility functions in the `builtin` package. These are plain functions, and look and behave just like regular user-defined functions do. They do not provide new syntax or require special parsing. These functions are always present in the interpreter and can be called at any time by their fully-qualified names. By default they are not available as short names, but can be requested for convenience.

Individual named functions can be imported by listing them as import parameters on the `use` statement for this pragma.

The builtin::compat module from CPAN provides versions of many of these functions that can be used on Perl versions where `builtin` or specific functions are not yet available.

Warning: At present, many of the functions in the `builtin` namespace are experimental. Calling them will trigger warnings of the `experimental::builtin` category.

Lexical Import

This pragma module creates *lexical* aliases in the currently-compiling scope to these builtin functions. This is similar to the lexical effect of other pragmas such as *strict* and *feature*.

```
sub classify
{
    my $val = shift;

    use builtin 'is_bool';
    return is_bool($val) ? "boolean" : "not a boolean";
}

# the is_bool() function is no longer visible here
# but may still be called by builtin::is_bool()
```

Because these functions are imported lexically, rather than by package symbols, the user does not need to take any special measures to ensure they don't accidentally appear as object methods from a class.

```
package An::Object::Class {
    use builtin 'true', 'false';
    ...
}

# does not appear as a method
An::Object::Class->true;

# Can't locate object method "true" via package "An::Object::Class"
#   at ...
```

Once imported, a lexical function is much like any other lexical symbol (such as a variable) in that it cannot be removed again. If you wish to limit the visiblity of an imported `builtin` function, put it inside its own scope:

```
{
  use builtin 'refaddr';
  ...
}
```

Version Bundles

The entire set of builtin functions that were considered non-experimental by a version of perl can be imported all at once, by requesting a version bundle. This is done by giving the perl release version (without its subversion suffix) after a colon character:

```
use builtin ':5.40';
```

The following bundles currently exist:

```
Version    Includes
-------    --------

:5.40      true false weaken unweaken is_weak blessed refaddr
 ↪reftype
           ceil floor is_tainted trim indexed
```

Function Optimisations

There are a number of optimisations that apply to functions in the *builtin* package. If you replace or override these functions (such as by assignment into glob references) the optimisations may not take effect. Do so with caution.

FUNCTIONS

true

```
$val = true;
```

Returns the boolean truth value. While any scalar value can be tested for truth and most defined, non-empty and non-zero values are considered "true" by perl, this one is special in that "is_bool" considers it to be a distinguished boolean value.

This gives an equivalent value to expressions like `!!1` or `!0`.

Available starting with Perl 5.36. Since Perl 5.40, it is no longer experimental and it is included in the 5.40 and higher builtin version bundles.

false

```
$val = false;
```

Returns the boolean false value. While any non-true scalar value is considered "false" by perl, this one is special in that "is_bool" considers it to be a distinguished boolean value.

This gives an equivalent value to expressions like `!!0` or `!1`.

Available starting with Perl 5.36. Since Perl 5.40, it is no longer experimental and it is included in the 5.40 and higher builtin version bundles.

is_bool

```
$bool = is_bool($val);
```

This function is currently **experimental**.

Returns true when given a distinguished boolean value, or false if not. A distinguished boolean value is the result of any boolean-returning builtin function (such as `true` or `is_bool` itself), boolean-returning operator (such as the `eq` or `==` comparison tests or the `!` negation operator), or any variable containing one of these results.

This function used to be named `isbool`. A compatibility alias is provided currently but will be removed in a later version.

Available starting with Perl 5.36.

inf

```
$num = inf;
```

This function is currently **experimental**.

Returns the floating-point infinity value. If the underlying numeric C type does not support such a value, it throws a runtime error instead.

Available starting with Perl 5.40.

nan

```
$num = nan;
```

This function is currently **experimental**.

Returns the floating-point "Not-a-Number" value. If the underlying numeric C type does not support such a value, it throws a runtime error instead.

Available starting with Perl 5.40.

weaken

```
weaken($ref);
```

Weakens a reference. A weakened reference does not contribute to the reference count of its referent. If only weakened references to a referent remain, it will be disposed of, and all remaining weak references to it will have their value set to `undef`.

Available starting with Perl 5.36. Since Perl 5.40, it is no longer experimental and it is included in the 5.40 and higher builtin version bundles.

unweaken

```
unweaken($ref);
```

Strengthens a reference, undoing the effects of a previous call to "weaken".

Available starting with Perl 5.36. Since Perl 5.40, it is no longer experimental and it is included in the 5.40 and higher builtin version bundles.

is_weak

```
$bool = is_weak($ref);
```

Returns true when given a weakened reference, or false if not a reference or not weak.

This function used to be named `isweak`. A compatibility alias is provided currently but will be removed in a later version.

Available starting with Perl 5.36. Since Perl 5.40, it is no longer experimental and it is included in the 5.40 and higher builtin version bundles.

blessed

```
$str = blessed($ref);
```

Returns the package name for an object reference, or `undef` for a non-reference or reference that is not an object.

Available starting with Perl 5.36. Since Perl 5.40, it is no longer experimental and it is included in the 5.40 and higher builtin version bundles.

refaddr

```
$num = refaddr($ref);
```

Returns the memory address for a reference, or `undef` for a non-reference. This value is not likely to be very useful for pure Perl code, but is handy as a means to test for referential identity or uniqueness.

Available starting with Perl 5.36. Since Perl 5.40, it is no longer experimental and it is included in the 5.40 and higher builtin version bundles.

reftype

```
$str = reftype($ref);
```

Returns the basic container type of the referent of a reference, or `undef` for a non-reference. This is returned as a string in all-capitals, such as `ARRAY` for array references, or `HASH` for hash references.

Available starting with Perl 5.36. Since Perl 5.40, it is no longer experimental and it is included in the 5.40 and higher builtin version bundles.

created_as_string

```
$bool = created_as_string($val);
```

This function is currently **experimental**.

Returns a boolean representing if the argument value was originally created as a string. It will return true for any scalar expression whose most recent assignment or modification was of a string-like nature - such as assignment from a string literal, or the result of a string operation such as concatenation or regexp. It will return false for references (including any object), numbers, booleans and undef.

It is unlikely that you will want to use this for regular data validation within Perl, as it will not return true for regular numbers that are still perfectly usable as strings, nor for any object reference - especially objects that overload the stringification operator in an attempt to behave more like strings. For example

```
my $val = URI->new( "https://metacpan.org/" );

if( created_as_string $val ) { ... }    # this will not execute
```

Available starting with Perl 5.36.

created_as_number

```
$bool = created_as_number($val);
```

This function is currently **experimental**.

Returns a boolean representing if the argument value was originally created as a number. It will return true for any scalar expression whose most recent assignment or modification was of a numerical nature - such as assignment from a number literal, or the result of a numerical operation such as addition. It will return false for references (including any object), strings, booleans and undef.

It is unlikely that you will want to use this for regular data validation within Perl, as it will not return true for regular strings of decimal digits that are still perfectly usable as numbers, nor for any object reference - especially objects that overload the numification operator in an attempt to behave more like numbers. For example

```
my $val = Math::BigInt->new( 123 );

if( created_as_number $val ) { ... }    # this will not execute
```

While most Perl code should operate on scalar values without needing to know their creation history, these two functions are intended to be used by data serialisation modules such as JSON encoders or similar situations, where language interoperability concerns require making a distinction between values that are fundamentally stringlike versus numberlike in nature.

Available starting with Perl 5.36.

stringify

```
$str = stringify($val);
```

This function is currently **experimental**.

Returns a new plain perl string that represents the given argument.

When given a value that is already a string, a copy of this value is returned unchanged. False booleans are treated like the empty string.

Numbers are turned into a decimal representation. True booleans are treated like the number 1.

References to objects in classes that have *overload* and define the "" overload entry will use the delegated method to provide a value here.

Non-object references, or references to objects in classes without a "" overload will return a string that names the underlying container type of the reference, its memory address, and possibly its class name if it is an object.

Available starting with Perl 5.40.

ceil

```
$num = ceil($num);
```

Returns the smallest integer value greater than or equal to the given numerical argument.

Available starting with Perl 5.36. Since Perl 5.40, it is no longer experimental and it is included in the 5.40 and higher builtin version bundles.

floor

```
$num = floor($num);
```

Returns the largest integer value less than or equal to the given numerical argument.

Available starting with Perl 5.36. Since Perl 5.40, it is no longer experimental and it is included in the 5.40 and higher builtin version bundles.

indexed

```
@ivpairs = indexed(@items)
```

Returns an even-sized list of number/value pairs, where each pair is formed of a number giving an index in the original list followed by the value at that position in it. I.e. returns a list twice the size of the original, being equal to

```
(0, $items[0], 1, $items[1], 2, $items[2], ...)
```

Note that unlike the core `values` function, this function returns copies of its original arguments, not aliases to them. Any modifications of these copies are *not* reflected in modifications to the original.

```
my @x = ...;
$_++ for indexed @x;  # The @x array remains unaffected
```

This function is primarily intended to be useful combined with multi-variable `foreach` loop syntax; as

```
foreach my ($index, $value) (indexed LIST) {
    ...
}
```

In scalar context this function returns the size of the list that it would otherwise have returned, and provokes a warning in the `scalar` category.

Available starting with Perl 5.36. Since Perl 5.40, it is no longer experimental and it is included in the 5.40 and higher builtin version bundles.

trim

```
$stripped = trim($string);
```

Returns the input string with whitespace stripped from the beginning and end. trim() will remove these characters:

" ", an ordinary space.

"\t", a tab.

"\n", a new line (line feed).

"\r", a carriage return.

and all other Unicode characters that are flagged as whitespace. A complete list is in "Whitespace" in perlrecharclass.

```
$var = "  Hello world   ";            # "Hello world"
$var = "\t\t\tHello world";           # "Hello world"
$var = "Hello world\n";               # "Hello world"
$var = "\x{2028}Hello world\x{3000}"; # "Hello world"
```

`trim` is equivalent to:

```
my $trimmed = $str =~ s/\A\s+//ur =~ s/\s+\z//ur;
```

Available starting with Perl 5.36. Since Perl 5.40, it is no longer experimental and it is included in the 5.40 and higher builtin version bundles.

is_tainted

```
$bool = is_tainted($var);
```

Returns true when given a tainted variable.

Available starting with Perl 5.38.

export_lexically

```
export_lexically($name1, $ref1, $name2, $ref2, ...)
```

This function is currently **experimental**.

Exports new lexical names into the scope currently being compiled. Names given by the first of each pair of values will refer to the corresponding item whose reference is given by the second. Types of item that are permitted are subroutines, and scalar, array, and hash variables. If the item is a subroutine, the name may optionally be prefixed with the & sigil, but for convenience it doesn't have to. For items that are variables the sigil is required, and must match the type of the variable.

```
export_lexically func    => \&func,
                 '&func' => \&func;  # same as above
```

(continues on next page)

(continued from previous page)

```
export_lexically '$scalar' => \my $var;
```

```
# The following are not permitted
export_lexically '$var' => \@arr;   # sigil does not match
export_lexically name => \$scalar;  # implied '&' sigil does not
↪match

export_lexically '*name' => \*globref;  # globrefs are not supported
```

This must be called at compile time; which typically means during a `BEGIN` block. Usually this would be used as part of an `import` method of a module, when invoked as part of a `use ...` statement.

Available starting with Perl 5.38.

load_module

```
load_module($module_name);
```

This function is currently **experimental**.

Loads a named module from the inclusion paths (`@INC`). `$module_name` must be a string that provides a module name. It cannot be omitted, and providing an invalid module name will result in an exception. Not providing any argument results in a compilation error. Returns the loaded module's name on success.

The effect of `load_module`-ing a module is mostly the same as `require`-ing, down to the same error conditions when the module does not exist, does not compile, or does not evaluate to a true value. See also *the* `module_true` *feature*.

`load_module` can't be used to require a particular version of Perl, nor can it be given a bareword module name as an argument.

Available starting with Perl 5.40.

5.2.127 bytes

Perl pragma to expose the individual bytes of characters

NOTICE

Because the bytes pragma breaks encapsulation (i.e. it exposes the innards of how the perl executable currently happens to store a string), the byte values that result are in an unspecified encoding.

Use of this module for anything other than debugging purposes is strongly discouraged. If you feel that the functions here within might be useful for your application, this

possibly indicates a mismatch between your mental model of Perl Unicode and the current reality. In that case, you may wish to read some of the perl Unicode documentation: perluniintro, perlunitut, perlunifaq and perlunicode.

SYNOPSIS

```
use bytes;
... chr(...);       # or bytes::chr
... index(...);     # or bytes::index
... length(...);    # or bytes::length
... ord(...);       # or bytes::ord
... rindex(...);    # or bytes::rindex
... substr(...);    # or bytes::substr
no bytes;
```

DESCRIPTION

Perl's characters are stored internally as sequences of one or more bytes. This pragma allows for the examination of the individual bytes that together comprise a character.

Originally the pragma was designed for the loftier goal of helping incorporate Unicode into Perl, but the approach that used it was found to be defective, and the one remaining legitimate use is for debugging when you need to non-destructively examine characters' individual bytes. Just insert this pragma temporarily, and remove it after the debugging is finished.

The original usage can be accomplished by explicit (rather than this pragma's implicit) encoding using the *Encode* module:

```
use Encode qw/encode/;

my $utf8_byte_string   = encode "UTF8",   $string;
my $latin1_byte_string = encode "Latin1", $string;
```

Or, if performance is needed and you are only interested in the UTF-8 representation:

```
utf8::encode(my $utf8_byte_string = $string);
```

`no bytes` can be used to reverse the effect of `use bytes` within the current lexical scope.

As an example, when Perl sees `$x = chr(400)`, it encodes the character in UTF-8 and stores it in `$x`. Then it is marked as character data, so, for instance, `length $x` returns 1. However, in the scope of the `bytes` pragma, `$x` is treated as a series of bytes - the bytes that make up the UTF8 encoding - and `length $x` returns 2:

```
$x = chr(400);
print "Length is ", length $x, "\n";     # "Length is 1"
printf "Contents are %vd\n", $x;         # "Contents are 400"
{
    use bytes; # or "require bytes; bytes::length()"
    print "Length is ", length $x, "\n"; # "Length is 2"
```

(continues on next page)

(continued from previous page)

```
    printf "Contents are %vd\n", $x;     # "Contents are 198.144 (on
                                         # ASCII platforms)"
}
```

`chr()`, `ord()`, `substr()`, `index()` and `rindex()` behave similarly.

For more on the implications, see perluniintro and perlunicode.

`bytes::length()` is admittedly handy if you need to know the **byte length** of a Perl scalar. But a more modern way is:

```
use Encode 'encode';
length(encode('UTF-8', $scalar))
```

LIMITATIONS

`bytes::substr()` does not work as an *lvalue()*.

SEE ALSO

perluniintro, perlunicode, *utf8*, *Encode*

5.2.128 charnames

access to Unicode character names and named character sequences; also define character names

SYNOPSIS

```
use charnames ':full';
print "\N{GREEK SMALL LETTER SIGMA} is called sigma.\n";
print "\N{LATIN CAPITAL LETTER E WITH VERTICAL LINE BELOW}",
      " is an officially named sequence of two Unicode characters\n
 ↪";

use charnames ':loose';
print "\N{Greek small-letter  sigma}",
       "can be used to ignore case, underscores, most blanks,"
       "and when you aren't sure if the official name has hyphens\n
 ↪";

use charnames ':short';
print "\N{greek:Sigma} is an upper-case sigma.\n";

use charnames qw(cyrillic greek);
print "\N{sigma} is Greek sigma, and \N{be} is Cyrillic b.\n";

use utf8;
use charnames ":full", ":alias" => {
```

(continues on next page)

(continued from previous page)

```
  e_ACUTE => "LATIN SMALL LETTER E WITH ACUTE",
  mychar => 0xE8000,  # Private use area
  "自転車に乗る人" => "BICYCLIST"
};
print "\N{e_ACUTE} is a small letter e with an acute.\n";
print "\N{mychar} allows me to name private use characters.\n";
print "And I can create synonyms in other languages,",
      " such as \N{自転車に乗る人} for "BICYCLIST (U+1F6B4)\n";

use charnames ();
print charnames::viacode(0x1234); # prints "ETHIOPIC SYLLABLE SEE"
printf "%04X", charnames::vianame("GOTHIC LETTER AHSA"); # prints
                                                         # "10330"
print charnames::vianame("LATIN CAPITAL LETTER A"); # prints 65 on
                                                    # ASCII␣
 ↪platforms;
                                                    # 193 on EBCDIC
print charnames::string_vianame("LATIN CAPITAL LETTER A"); # prints
 ↪"A"
```

DESCRIPTION

Pragma `use charnames` is used to gain access to the names of the Unicode characters and named character sequences, and to allow you to define your own character and character sequence names.

All forms of the pragma enable use of the following 3 functions:

- "charnames::string_vianame(*name*)" for run-time lookup of a either a character name or a named character sequence, returning its string representation
- "charnames::vianame(*name*)" for run-time lookup of a character name (but not a named character sequence) to get its ordinal value (code point)
- "charnames::viacode(*code*)" for run-time lookup of a code point to get its Unicode name.

Starting in Perl v5.16, any occurrence of `\N{_CHARNAME_}` sequences in a double-quotish string automatically loads this module with arguments `:full` and `:short` (described below) if it hasn't already been loaded with different arguments, in order to compile the named Unicode character into position in the string. Prior to v5.16, an explicit `use charnames` was required to enable this usage. (However, prior to v5.16, the form `"use charnames ();"` did not enable `\N{_CHARNAME_}`.)

Note that `\N{U+_..._}`, where the ... is a hexadecimal number, also inserts a character into a string. The character it inserts is the one whose Unicode code point (ordinal value) is equal to the number. For example, `"\N{U+263a}"` is the Unicode (white background, black foreground) smiley face equivalent to `"\N{WHITE SMILING FACE}"`. Also note, `\N{_..._}` can mean a regex quantifier instead of a character name, when the ... is a number (or comma separated pair of numbers (see "QUANTIFIERS" in perlreref), and is not related to this pragma.

The charnames pragma supports arguments :full, :loose, :short, script names and customized aliases.

If :full is present, for expansion of \N{_CHARNAME_}, the string *CHARNAME* is first looked up in the list of standard Unicode character names.

:loose is a variant of :full which allows *CHARNAME* to be less precisely specified. Details are in "LOOSE MATCHES".

If :short is present, and *CHARNAME* has the form _SCRIPT_:_CNAME_, then *CNAME* is looked up as a letter in script *SCRIPT*, as described in the next paragraph. Or, if use charnames is used with script name arguments, then for \N{_CHARNAME_} the name *CHARNAME* is looked up as a letter in the given scripts (in the specified order). Customized aliases can override these, and are explained in "CUSTOM ALIASES".

For lookup of *CHARNAME* inside a given script *SCRIPTNAME*, this pragma looks in the table of standard Unicode names for the names

```
SCRIPTNAME CAPITAL LETTER CHARNAME
SCRIPTNAME SMALL LETTER CHARNAME
SCRIPTNAME LETTER CHARNAME
```

If *CHARNAME* is all lowercase, then the CAPITAL variant is ignored, otherwise the SMALL variant is ignored, and both *CHARNAME* and *SCRIPTNAME* are converted to all uppercase for look-up. Other than that, both of them follow loose rules if :loose is also specified; strict otherwise.

Note that \N{...} is compile-time; it's a special form of string constant used inside double-quotish strings; this means that you cannot use variables inside the \N{...}. If you want similar run-time functionality, use charnames::string_vianame().

Note, starting in Perl 5.18, the name BELL refers to the Unicode character U+1F514, instead of the traditional U+0007. For the latter, use ALERT or BEL.

It is a syntax error to use \N{NAME} where NAME is unknown.

For \N{NAME}, it is a fatal error if use bytes is in effect and the input name is that of a character that won't fit into a byte (i.e., whose ordinal is above 255).

Otherwise, any string that includes a \N{_charname_} or \N{U+_code point_} will automatically have Unicode rules (see "Byte and Character Semantics" in perlunicode).

LOOSE MATCHES

By specifying :loose, Unicode's loose character name matching rules are selected instead of the strict exact match used otherwise. That means that *CHARNAME* doesn't have to be so precisely specified. Upper/lower case doesn't matter (except with scripts as mentioned above), nor do any underscores, and the only hyphens that matter are those at the beginning or end of a word in the name (with one exception: the hyphen in U+1180 HANGUL JUNGSEONG O-E does matter). Also, blanks not adjacent to hyphens don't matter. The official Unicode names are quite variable as to where they use hyphens versus spaces to separate word-like units, and this option allows you to not have to care as much. The reason non-medial hyphens matter is because of cases like U+0F60 TIBETAN LETTER -A versus U+0F68 TIBETAN LETTER A. The hyphen here is significant, as is the space before it, and so both must be included.

`:loose` slows down look-ups by a factor of 2 to 3 versus `:full`, but the trade-off may be worth it to you. Each individual look-up takes very little time, and the results are cached, so the speed difference would become a factor only in programs that do look-ups of many different spellings, and probably only when those look-ups are through `vianame()` and `string_vianame()`, since `\N{...}` look-ups are done at compile time.

ALIASES

Starting in Unicode 6.1 and Perl v5.16, Unicode defines many abbreviations and names that were formerly Perl extensions, and some additional ones that Perl did not previously accept. The list is getting too long to reproduce here, but you can get the complete list from the Unicode web site: http://www.unicode.org/Public/UNIDATA/NameAliases.txt.

Earlier versions of Perl accepted almost all the 6.1 names. These were most extensively documented in the v5.14 version of this pod: http://perldoc.perl.org/5.14.0/charnames.html#ALIASES.

CUSTOM ALIASES

You can add customized aliases to standard (`:full`) Unicode naming conventions. The aliases override any standard definitions, so, if you're twisted enough, you can change `"\N{LATIN CAPITAL LETTER A}"` to mean `"B"`, etc.

Aliases must begin with a character that is alphabetic. After that, each may contain any combination of word (`\w`) characters, SPACE (U+0020), HYPHEN-MINUS (U+002D), LEFT PARENTHESIS (U+0028), and RIGHT PARENTHESIS (U+0029). These last two should never have been allowed in names, and are retained for backwards compatibility only, and may be deprecated and removed in future releases of Perl, so don't use them for new names. (More precisely, the first character of a name you specify must be something that matches all of `\p{ID_Start}`, `\p{Alphabetic}`, and `\p{Gc=Letter}`. This makes sure it is what any reasonable person would view as an alphabetic character. And, the continuation characters that match `\w` must also match `\p{ID_Continue}`.) Starting with Perl v5.18, any Unicode characters meeting the above criteria may be used; prior to that only Latin1-range characters were acceptable.

An alias can map to either an official Unicode character name (not a loose matched name) or to a numeric code point (ordinal). The latter is useful for assigning names to code points in Unicode private use areas such as U+E800 through U+F8FF. A numeric code point must be a non-negative integer, or a string beginning with `"U+"` or `"0x"` with the remainder considered to be a hexadecimal integer. A literal numeric constant must be unsigned; it will be interpreted as hex if it has a leading zero or contains non-decimal hex digits; otherwise it will be interpreted as decimal. If it begins with `"U+"`, it is interpreted as the Unicode code point; otherwise it is interpreted as native. (Only code points below 256 can differ between Unicode and native.) Thus `U+41` is always the Latin letter "A"; but `0x41` can be "NO-BREAK SPACE" on EBCDIC platforms.

Aliases are added either by the use of anonymous hashes:

```
use charnames ":alias" => {
    e_ACUTE => "LATIN SMALL LETTER E WITH ACUTE",
    mychar1 => 0xE8000,
```

(continues on next page)

(continued from previous page)

```
    };
my $str = "\N{e_ACUTE}";
```

or by using a file containing aliases:

```
use charnames ":alias" => "pro";
```

This will try to read "unicore/pro_alias.pl" from the @INC path. This file should return a list in plain perl:

```
(
A_GRAVE         => "LATIN CAPITAL LETTER A WITH GRAVE",
A_CIRCUM        => "LATIN CAPITAL LETTER A WITH CIRCUMFLEX",
A_DIAERES       => "LATIN CAPITAL LETTER A WITH DIAERESIS",
A_TILDE         => "LATIN CAPITAL LETTER A WITH TILDE",
A_BREVE         => "LATIN CAPITAL LETTER A WITH BREVE",
A_RING          => "LATIN CAPITAL LETTER A WITH RING ABOVE",
A_MACRON        => "LATIN CAPITAL LETTER A WITH MACRON",
mychar2         => "U+E8001",
);
```

Both these methods insert ":full" automatically as the first argument (if no other argument is given), and you can give the ":full" explicitly as well, like

```
use charnames ":full", ":alias" => "pro";
```

":loose" has no effect with these. Input names must match exactly, using ":full" rules.

Also, both these methods currently allow only single characters to be named. To name a sequence of characters, use a custom translator (described below).

charnames::string_vianame(*name*)

This is a runtime equivalent to \N{...}. *name* can be any expression that evaluates to a name accepted by \N{...} under the :full option to charnames. In addition, any other options for the controlling "use charnames" in the same scope apply, like :loose or any script list, :short option, or custom aliases you may have defined.

The only differences are due to the fact that string_vianame is run-time and \N{} is compile time. You can't interpolate inside a \N{}, (so \N{$variable} doesn't work); and if the input name is unknown, string_vianame returns undef instead of it being a syntax error.

charnames::vianame(*name*)

This is similar to string_vianame. The main difference is that under most circumstances, vianame returns an ordinal code point, whereas string_vianame returns a string. For example,

```
printf "U+%04X", charnames::vianame("FOUR TEARDROP-SPOKED ASTERISK
↪");
```

prints “U+2722”.

This leads to the other two differences. Since a single code point is returned, the function can’t handle named character sequences, as these are composed of multiple characters (it returns `undef` for these. And, the code point can be that of any character, even ones that aren’t legal under the `use bytes` pragma,

See “BUGS” for the circumstances in which the behavior differs from that described above.

charnames::viacode(*code*)

Returns the full name of the character indicated by the numeric code. For example,

```
print charnames::viacode(0x2722);
```

prints “FOUR TEARDROP-SPOKED ASTERISK”.

The name returned is the “best” (defined below) official name or alias for the code point, if available; otherwise your custom alias for it, if defined; otherwise `undef`. This means that your alias will only be returned for code points that don’t have an official Unicode name (nor alias) such as private use code points.

If you define more than one name for the code point, it is indeterminate which one will be returned.

As mentioned, the function returns `undef` if no name is known for the code point. In Unicode the proper name for these is the empty string, which `undef` stringifies to. (If you ask for a code point past the legal Unicode maximum of U+10FFFF that you haven’t assigned an alias to, you get `undef` plus a warning.)

The input number must be a non-negative integer, or a string beginning with `"U+"` or `"0x"` with the remainder considered to be a hexadecimal integer. A literal numeric constant must be unsigned; it will be interpreted as hex if it has a leading zero or contains non-decimal hex digits; otherwise it will be interpreted as decimal. If it begins with `"U+"`, it is interpreted as the Unicode code point; otherwise it is interpreted as native. (Only code points below 256 can differ between Unicode and native.) Thus `U+41` is always the Latin letter “A”; but `0x41` can be “NO-BREAK SPACE” on EBCDIC platforms.

As mentioned above under “ALIASES”, Unicode 6.1 defines extra names (synonyms or aliases) for some code points, most of which were already available as Perl extensions. All these are accepted by `\N{...}` and the other functions in this module, but `viacode` has to choose which one name to return for a given input code point, so it returns the “best” name. To understand how this works, it is helpful to know more about the Unicode name properties. All code points actually have only a single name, which (starting in Unicode 2.0) can never change once a character has been assigned to the code point. But mistakes have been made in assigning names, for example sometimes a clerical error was made during the publishing of the Standard which caused words to be misspelled, and there was no way to correct those. The Name_Alias property was eventually created to handle these situations. If a name was wrong, a corrected synonym would be published for it, using Name_Alias. `viacode` will return that corrected synonym as the “best” name for a code point. (It is even possible, though it hasn’t happened yet, that the correction itself will need to be corrected, and so another Name_Alias can be created for that code point; `viacode` will return the most recent correction.)

The Unicode name for each of the control characters (such as LINE FEED) is the empty string. However almost all had names assigned by other standards, such as the ASCII Standard, or were in common use. `viacode` returns these names as the "best" ones available. Unicode 6.1 has created Name_Aliases for each of them, including alternate names, like NEW LINE. `viacode` uses the original name, "LINE FEED" in preference to the alternate. Similarly the name returned for U+FEFF is "ZERO WIDTH NO-BREAK SPACE", not "BYTE ORDER MARK".

Until Unicode 6.1, the 4 control characters U+0080, U+0081, U+0084, and U+0099 did not have names nor aliases. To preserve backwards compatibility, any alias you define for these code points will be returned by this function, in preference to the official name.

Some code points also have abbreviated names, such as "LF" or "NL". `viacode` never returns these.

Because a name correction may be added in future Unicode releases, the name that `viacode` returns may change as a result. This is a rare event, but it does happen.

CUSTOM TRANSLATORS

The mechanism of translation of `\N{...}` escapes is general and not hardwired into `charnames.pm`. A module can install custom translations (inside the scope which `uses` the module) with the following magic incantation:

```
sub import {
    shift;
    $^H{charnames} = \&translator;
}
```

Here translator() is a subroutine which takes *CHARNAME* as an argument, and returns text to insert into the string instead of the `\N{_CHARNAME_}` escape.

This is the only way you can create a custom named sequence of code points.

Since the text to insert should be different in `bytes` mode and out of it, the function should check the current state of `bytes`-flag as in:

```
use bytes ();                       # for $bytes::hint_bits
sub translator {
    if ($^H & $bytes::hint_bits) {
        return bytes_translator(@_);
    }
    else {
        return utf8_translator(@_);
    }
}
```

See "CUSTOM ALIASES" above for restrictions on *CHARNAME*.

Of course, `vianame`, `viacode`, and `string_vianame` would need to be overridden as well.

BUGS

vianame() normally returns an ordinal code point, but when the input name is of the form `U+...`, it returns a chr instead. In this case, if `use bytes` is in effect and the character won't fit into a byte, it returns `undef` and raises a warning.

Since evaluation of the translation function (see "CUSTOM TRANSLATORS") happens in the middle of compilation (of a string literal), the translation function should not do any `evals` or `requires`. This restriction should be lifted (but is low priority) in a future version of Perl.

5.2.129 constant

Perl pragma to declare constants

SYNOPSIS

```
use constant PI    => 4 * atan2(1, 1);
use constant DEBUG => 0;

print "Pi equals ", PI, "...\n" if DEBUG;

use constant {
    SEC   => 0,
    MIN   => 1,
    HOUR  => 2,
    MDAY  => 3,
    MON   => 4,
    YEAR  => 5,
    WDAY  => 6,
    YDAY  => 7,
    ISDST => 8,
};

use constant WEEKDAYS => qw(
    Sunday Monday Tuesday Wednesday Thursday Friday Saturday
);

print "Today is ", (WEEKDAYS)[ (localtime)[WDAY] ], ".\n";
```

DESCRIPTION

This pragma allows you to declare constants at compile-time.

When you declare a constant such as `PI` using the method shown above, each machine your script runs upon can have as many digits of accuracy as it can use. Also, your program will be easier to read, more likely to be maintained (and maintained correctly), and far less likely to send a space probe to the wrong planet because nobody noticed the one equation in which you wrote `3.14195`.

When a constant is used in an expression, Perl replaces it with its value at compile time,

and may then optimize the expression further. In particular, any code in an `if (CONSTANT)` block will be optimized away if the constant is false.

NOTES

As with all `use` directives, defining a constant happens at compile time. Thus, it's probably not correct to put a constant declaration inside of a conditional statement (like `if ($foo) { use constant ... }`).

Constants defined using this module cannot be interpolated into strings like variables. However, concatenation works just fine:

```
print "Pi equals PI...\n";        # WRONG: does not expand "PI"
print "Pi equals ".PI."...\n";    # right
```

Even though a reference may be declared as a constant, the reference may point to data which may be changed, as this code shows.

```
use constant ARRAY => [ 1,2,3,4 ];
print ARRAY->[1];
ARRAY->[1] = " be changed";
print ARRAY->[1];
```

Constants belong to the package they are defined in. To refer to a constant defined in another package, specify the full package name, as in `Some::Package::CONSTANT`. Constants may be exported by modules, and may also be called as either class or instance methods, that is, as `Some::Package->CONSTANT` or as `$obj->CONSTANT` where `$obj` is an instance of `Some::Package`. Subclasses may define their own constants to override those in their base class.

As of version 1.32 of this module, constants can be defined in packages other than the caller, by including the package name in the name of the constant:

```
use constant "OtherPackage::FWIBBLE" => 7865;
constant->import("Other::FWOBBLE",$value); # dynamically at run time
```

The use of all caps for constant names is merely a convention, although it is recommended in order to make constants stand out and to help avoid collisions with other barewords, keywords, and subroutine names. Constant names must begin with a letter or underscore. Names beginning with a double underscore are reserved. Some poor choices for names will generate warnings, if warnings are enabled at compile time.

List constants

Constants may be lists of more (or less) than one value. A constant with no values evaluates to `undef` in scalar context. Note that constants with more than one value do *not* return their last value in scalar context as one might expect. They currently return the number of values, but **this may change in the future**. Do not use constants with multiple values in scalar context.

NOTE: This implies that the expression defining the value of a constant is evaluated in list context. This may produce surprises:

```
use constant TIMESTAMP => localtime;                # WRONG!
use constant TIMESTAMP => scalar localtime;         # right
```

The first line above defines `TIMESTAMP` as a 9-element list, as returned by `localtime()` in list context. To set it to the string returned by `localtime()` in scalar context, an explicit `scalar` keyword is required.

List constants are lists, not arrays. To index or slice them, they must be placed in parentheses.

```
my @workdays = WEEKDAYS[1 .. 5];            # WRONG!
my @workdays = (WEEKDAYS)[1 .. 5];          # right
```

Defining multiple constants at once

Instead of writing multiple `use constant` statements, you may define multiple constants in a single statement by giving, instead of the constant name, a reference to a hash where the keys are the names of the constants to be defined. Obviously, all constants defined using this method must have a single value.

```
use constant {
    FOO => "A single value",
    BAR => "This", "won't", "work!",        # Error!
};
```

This is a fundamental limitation of the way hashes are constructed in Perl. The error messages produced when this happens will often be quite cryptic – in the worst case there may be none at all, and you'll only later find that something is broken.

When defining multiple constants, you cannot use the values of other constants defined in the same declaration. This is because the calling package doesn't know about any constant within that group until *after* the `use` statement is finished.

```
use constant {
    BITMASK => 0xAFBAEBA8,
    NEGMASK => ~BITMASK,                    # Error!
};
```

Magic constants

Magical values and references can be made into constants at compile time, allowing for way cool stuff like this. (These error numbers aren't totally portable, alas.)

```
use constant E2BIG => ($! = 7);
print   E2BIG, "\n";        # something like "Arg list too long"
print 0+E2BIG, "\n";        # "7"
```

You can't produce a tied constant by giving a tied scalar as the value. References to tied variables, however, can be used as constants without any problems.

TECHNICAL NOTES

In the current implementation, scalar constants are actually inlinable subroutines. As of version 5.004 of Perl, the appropriate scalar constant is inserted directly in place of some subroutine calls, thereby saving the overhead of a subroutine call. See *"Constant Functions" in perlsub* for details about how and when this happens.

In the rare case in which you need to discover at run time whether a particular constant has been declared via this module, you may use this function to examine the hash `%constant::declared`. If the given constant name does not include a package name, the current package is used.

```
sub declared ($) {
    use constant 1.01;              # don't omit this!
    my $name = shift;
    $name =~ s/^::/main::/;
    my $pkg = caller;
    my $full_name = $name =~ /::/ ? $name : "${pkg}::$name";
    $constant::declared{$full_name};
}
```

CAVEATS

List constants are not inlined unless you are using Perl v5.20 or higher. In v5.20 or higher, they are still not read-only, but that may change in future versions.

It is not possible to have a subroutine or a keyword with the same name as a constant in the same package. This is probably a Good Thing.

A constant with a name in the list `STDIN STDOUT STDERR ARGV ARGVOUT ENV INC SIG` is not allowed anywhere but in package `main::`, for technical reasons.

Unlike constants in some languages, these cannot be overridden on the command line or via environment variables.

You can get into trouble if you use constants in a context which automatically quotes barewords (as is true for any subroutine call). For example, you can't say `$hash{CONSTANT}` because `CONSTANT` will be interpreted as a string. Use `$hash{CONSTANT()}` or `$hash{+CONSTANT}` to prevent the bareword quoting mechanism from kicking in. Similarly, since the `=>` operator quotes a bareword immediately to its left, you have to say `CONSTANT() => 'value'` (or simply use a comma in place of the big arrow) instead of `CONSTANT => 'value'`.

5.2.130 deprecate

Perl pragma for deprecating the inclusion of a module in core

SYNOPSIS

```
use deprecate;  # warn about future absence if loaded from core
```

DESCRIPTION

This pragma simplifies the maintenance of dual-life modules that will no longer be included in the Perl core in a future Perl release, but are still included currently.

The purpose of the pragma is to alert users to the status of such a module by issuing a warning that encourages them to install the module from CPAN, so that a future upgrade to a perl which omits the module will not break their code.

This warning will only be issued if the module was loaded from a core library directory, which allows the `use deprecate` line to be included in the CPAN version of the module. Because the pragma remains silent when the module is run from a non-core library directory, the pragma call does not need to be patched into or out of either the core or CPAN version of the module. The exact same code can be shipped for either purpose.

Important Caveat

Note that when a module installs from CPAN to a core library directory rather than the site library directories, the user gains no protection from having installed it.

At the same time, this pragma cannot detect when such a module has installed from CPAN to the core library, and so it would endlessly and uselessly exhort the user to upgrade.

Therefore modules that can install from CPAN to the core library must make sure not to call this pragma when they have done so. Generally this means that the exact logic from the installer must be mirrored inside the module. E.g.:

```
# Makefile.PL
WriteMakefile(
    # ...
    INSTALLDIRS => ( "$]" >= 5.011 ? 'site' : 'perl' ),
);

# lib/Foo/Bar.pm
use if "$]" >= 5.011, 'deprecate';
```

(The above example shows the most important case of this: when the target is a Perl older than 5.12 (where the core library directories take precedence over the site library directories) and the module being installed was included in core in that Perl version. Under those circumstances, an upgrade of the module from CPAN is only possible by installing to the core library.)

EXPORT

None by default. The only method is `import`, called by `use deprecate;`.

SEE ALSO

First example to `use deprecate;` was Switch.

5.2.131 diagnostics

produce verbose warning diagnostics

SYNOPSIS

Using the `diagnostics` pragma:

```
use diagnostics;
use diagnostics -verbose;

diagnostics->enable;
diagnostics->disable;
```

Using the `splain` standalone filter program:

```
perl program 2>diag.out
splain [-v] [-p] diag.out
```

Using diagnostics to get stack traces from a misbehaving script:

```
perl -Mdiagnostics=-traceonly my_script.pl
```

DESCRIPTION

The `diagnostics` Pragma

This module extends the terse diagnostics normally emitted by both the perl compiler and the perl interpreter (from running perl with a -w switch or `use warnings`), augmenting them with the more explicative and endearing descriptions found in *perldiag*. Like the other pragmata, it affects the compilation phase of your program rather than merely the execution phase.

To use in your program as a pragma, merely invoke

```
use diagnostics;
```

at the start (or near the start) of your program. (Note that this *does* enable perl's **-w** flag.) Your whole compilation will then be subject(ed :-) to the enhanced diagnostics. These still go out **STDERR**.

Due to the interaction between runtime and compiletime issues, and because it's probably not a very good idea anyway, you may not use `no diagnostics` to turn them off at compiletime. However, you may control their behaviour at runtime using the `disable()` and `enable()` methods to turn them off and on respectively.

The **-verbose** flag first prints out the *perldiag* introduction before any other diagnostics. The $diagnostics::PRETTY variable can generate nicer escape sequences for pagers.

Warnings dispatched from perl itself (or more accurately, those that match descriptions found in *perldiag*) are only displayed once (no duplicate descriptions). User code generated warnings a la warn() are unaffected, allowing duplicate user messages to be displayed.

This module also adds a stack trace to the error message when perl dies. This is useful for pinpointing what caused the death. The **-traceonly** (or just **-t**) flag turns off the explanations of warning messages leaving just the stack traces. So if your script is dieing, run it again with

```
perl -Mdiagnostics=-traceonly my_bad_script
```

to see the call stack at the time of death. By supplying the **-warntrace** (or just **-w**) flag, any warnings emitted will also come with a stack trace.

The *splain* Program

Another program, *splain* is actually nothing more than a link to the (executable) `diagnostics.pm` module, as well as a link to the `diagnostics.pod` documentation. The **-v** flag is like the `use diagnostics -verbose` directive. The **-p** flag is like the $diagnostics::PRETTY variable. Since you're post-processing with *splain*, there's no sense in being able to enable() or disable() processing.

Output from *splain* is directed to **STDOUT**, unlike the pragma.

EXAMPLES

The following file is certain to trigger a few errors at both runtime and compiletime:

```
use diagnostics;
print NOWHERE "nothing\n";
print STDERR "\n\tThis message should be unadorned.\n";
warn "\tThis is a user warning";
print "\nDIAGNOSTIC TESTER: Please enter a <CR> here: ";
my $a, $b = scalar <STDIN>;
print "\n";
print $x/$y;
```

If you prefer to run your program first and look at its problem afterwards, do this:

```
perl -w test.pl 2>test.out
./splain < test.out
```

Note that this is not in general possible in shells of more dubious heritage, as the theoretical

```
(perl -w test.pl >/dev/tty) >& test.out
./splain < test.out
```

Because you just moved the existing **stdout** to somewhere else.

If you don't want to modify your source code, but still have on-the-fly warnings, do this:

```
exec 3>&1; perl -w test.pl 2>&1 1>&3 3>&- | splain 1>&2 3>&-
```

Nifty, eh?

If you want to control warnings on the fly, do something like this. Make sure you do the `use` first, or you won't be able to get at the enable() or disable() methods.

```
use diagnostics; # checks entire compilation phase
    print "\ntime for 1st bogus diags: SQUAWKINGS\n";
    print BOGUS1 'nada';
    print "done with 1st bogus\n";

diagnostics->disable; # only turns off runtime warnings
    print "\ntime for 2nd bogus: (squelched)\n";
    print BOGUS2 'nada';
```

(continues on next page)

(continued from previous page)

```
    print "done with 2nd bogus\n";

diagnostics->enable; # turns back on runtime warnings
    print "\ntime for 3rd bogus: SQUAWKINGS\n";
    print BOGUS3 'nada';
    print "done with 3rd bogus\n";

diagnostics->disable;
    print "\ntime for 4th bogus: (squelched)\n";
    print BOGUS4 'nada';
    print "done with 4th bogus\n";
```

INTERNALS

Diagnostic messages derive from the `perldiag.pod` file when available at runtime. Otherwise, they may be embedded in the file itself when the splain package is built. See the `Makefile` for details.

If an extant $SIG{__WARN__} handler is discovered, it will continue to be honored, but only after the diagnostics::splainthis() function (the module's $SIG{__WARN__} interceptor) has had its way with your warnings.

There is a $diagnostics::DEBUG variable you may set if you're desperately curious what sorts of things are being intercepted.

```
BEGIN { $diagnostics::DEBUG = 1 }
```

BUGS

Not being able to say "no diagnostics" is annoying, but may not be insurmountable.

The `-pretty` directive is called too late to affect matters. You have to do this instead, and *before* you load the module.

```
BEGIN { $diagnostics::PRETTY = 1 }
```

I could start up faster by delaying compilation until it should be needed, but this gets a "panic: top_level" when using the pragma form in Perl 5.001e.

While it's true that this documentation is somewhat subserious, if you use a program named *splain*, you should expect a bit of whimsy.

5.2.132 encoding

allows you to write your script in non-ASCII and non-UTF-8

WARNING

This module has been deprecated since perl v5.18. See “DESCRIPTION” and “BUGS”.

SYNOPSIS

```
use encoding "greek";  # Perl like Greek to you?
use encoding "euc-jp"; # Jperl!

# or you can even do this if your shell supports your native␣
↪encoding

perl -Mencoding=latin2 -e'...' # Feeling centrally European?
perl -Mencoding=euc-kr -e'...' # Or Korean?

# more control

# A simple euc-cn => utf-8 converter
use encoding "euc-cn", STDOUT => "utf8";  while(<>){print};

# "no encoding;" supported
no encoding;

# an alternate way, Filter
use encoding "euc-jp", Filter=>1;
# now you can use kanji identifiers -- in euc-jp!

# encode based on the current locale - specialized purposes only;
# fraught with danger!!
use encoding ':locale';
```

DESCRIPTION

This pragma is used to enable a Perl script to be written in encodings that aren’t strictly ASCII nor UTF-8. It translates all or portions of the Perl program script from a given encoding into UTF-8, and changes the PerlIO layers of `STDIN` and `STDOUT` to the encoding specified.

This pragma dates from the days when UTF-8-enabled editors were uncommon. But that was long ago, and the need for it is greatly diminished. That, coupled with the fact that it doesn’t work with threads, along with other problems, (see “BUGS”) have led to its being deprecated. It is planned to remove this pragma in a future Perl version. New code should be written in UTF-8, and the `use utf8` pragma used instead (see perluniintro and *utf8* for details). Old code should be converted to UTF-8, via something like the recipe in the “SYNOPSIS” (though this simple approach may require manual adjustments afterwards).

If UTF-8 is not an option, it is recommended that one use a simple source filter, such as that provided by Filter::Encoding on CPAN or this pragma’s own `Filter` option (see below).

The only legitimate use of this pragma is almost certainly just one per file, near the top,

with file scope, as the file is likely going to only be written in one encoding. Further restrictions apply in Perls before v5.22 (see "Prior to Perl v5.22").

There are two basic modes of operation (plus turning if off):

- `use encoding ['_ENCNAME_'] ;`

  Please note: This mode of operation is no longer supported as of Perl v5.26.

  This is the normal operation. It translates various literals encountered in the Perl source file from the encoding *ENCNAME* into UTF-8, and similarly converts character code points. This is used when the script is a combination of ASCII (for the variable names and punctuation, *etc*), but the literal data is in the specified encoding.

  ENCNAME is optional. If omitted, the encoding specified in the environment variable `PERL_ENCODING` is used. If this isn't set, or the resolved-to encoding is not known to `Encode`, the error `Unknown encoding '_ENCNAME_'` will be thrown.

  Starting in Perl v5.8.6 (`Encode` version 2.0.1), *ENCNAME* may be the name `:locale`. This is for very specialized applications, and is documented in "The `:locale` sub-pragma" below.

  The literals that are converted are `q//`, `qq//`, `qr//`, `qw///`, `qx//`, and starting in v5.8.1, `tr///`. Operations that do conversions include `chr`, `ord`, `utf8::upgrade` (but not `utf8::downgrade`), and `chomp`.

  Also starting in v5.8.1, the `DATA` pseudo-filehandle is translated from the encoding into UTF-8.

  For example, you can write code in EUC-JP as follows:

```
my $Rakuda = "\xF1\xD1\xF1\xCC"; # Camel in Kanji
             #<-char-><-char->   # 4 octets
s/\bCamel\b/$Rakuda/;
```

  And with `use encoding "euc-jp"` in effect, it is the same thing as that code in UTF-8:

```
my $Rakuda = "\x{99F1}\x{99DD}"; # two Unicode Characters
s/\bCamel\b/$Rakuda/;
```

  See "EXAMPLE" below for a more complete example.

  Unless `${^UNICODE}` (available starting in v5.8.2) exists and is non-zero, the PerlIO layers of `STDIN` and `STDOUT` are set to "`:encoding(_ENCNAME_)`". Therefore,

```
use encoding "euc-jp";
my $message = "Camel is the symbol of perl.\n";
my $Rakuda = "\xF1\xD1\xF1\xCC"; # Camel in Kanji
$message =~ s/\bCamel\b/$Rakuda/;
print $message;
```

  will print

```
"\xF1\xD1\xF1\xCC is the symbol of perl.\n"
```

not

```
"\x{99F1}\x{99DD} is the symbol of perl.\n"
```

You can override this by giving extra arguments; see below.

Note that STDERR WILL NOT be changed, regardless.

Also note that non-STD file handles remain unaffected. Use `use open` or `binmode` to change the layers of those.

- `use encoding _ENCNAME_, Filter=>1;`

  This operates as above, but the `Filter` argument with a non-zero value causes the entire script, and not just literals, to be translated from the encoding into UTF-8. This allows identifiers in the source to be in that encoding as well. (Problems may occur if the encoding is not a superset of ASCII; imagine all your semi-colons being translated into something different.) One can use this form to make

  ```
  ${"\x{4eba}"}++
  ```

  work. (This is equivalent to `$_human_++`, where *human* is a single Han ideograph).

  This effectively means that your source code behaves as if it were written in UTF-8 with `'use utf8'` in effect. So even if your editor only supports Shift_JIS, for example, you can still try examples in Chapter 15 of `Programming Perl, 3rd Ed.`.

  This option is significantly slower than the other one.

- `no encoding;`

  Unsets the script encoding. The layers of `STDIN`, `STDOUT` are reset to "`:raw`" (the default unprocessed raw stream of bytes).

OPTIONS

Setting STDIN and/or STDOUT individually

The encodings of `STDIN` and `STDOUT` are individually settable by parameters to the pragma:

```
use encoding 'euc-tw', STDIN => 'greek'  ...;
```

In this case, you cannot omit the first *ENCNAME*. `STDIN => undef` turns the I/O transcoding completely off for that filehandle.

When `${^UNICODE}` (available starting in v5.8.2) exists and is non-zero, these options will be completely ignored. See "`${^UNICODE}`" *in perlvar* and "`-C`" in perlrun for details.

The `:locale` sub-pragma

Starting in v5.8.6, the encoding name may be `:locale`. This means that the encoding is taken from the current locale, and not hard-coded by the pragma. Since a script really can only be encoded in exactly one encoding, this option is dangerous. It makes sense only if the script itself is written in ASCII, and all the possible locales that will be in

use when the script is executed are supersets of ASCII. That means that the script itself doesn't get changed, but the I/O handles have the specified encoding added, and the operations like `chr` and `ord` use that encoding.

The logic of finding which locale `:locale` uses is as follows:

1. If the platform supports the `langinfo(CODESET)` interface, the codeset returned is used as the default encoding for the open pragma.
2. If 1. didn't work but we are under the locale pragma, the environment variables `LC_ALL` and `LANG` (in that order) are matched for encodings (the part after "`.`", if any), and if any found, that is used as the default encoding for the open pragma.
3. If 1. and 2. didn't work, the environment variables `LC_ALL` and `LANG` (in that order) are matched for anything looking like UTF-8, and if any found, `:utf8` is used as the default encoding for the open pragma.

If your locale environment variables (`LC_ALL`, `LC_CTYPE`, `LANG`) contain the strings 'UTF-8' or 'UTF8' (case-insensitive matching), the default encoding of your `STDIN`, `STDOUT`, and `STDERR`, and of **any subsequent file open**, is UTF-8.

CAVEATS

SIDE EFFECTS

- If the `encoding` pragma is in scope then the lengths returned are calculated from the length of `$/` in Unicode characters, which is not always the same as the length of `$/` in the native encoding.
- Without this pragma, if strings operating under byte semantics and strings with Unicode character data are concatenated, the new string will be created by decoding the byte strings as *ISO 8859-1 (Latin-1)*.

  The **encoding** pragma changes this to use the specified encoding instead. For example:

```
use encoding 'utf8';
my $string = chr(20000); # a Unicode string
utf8::encode($string);   # now it's a UTF-8 encoded byte string
# concatenate with another Unicode string
print length($string . chr(20000));
```

  Will print 2, because `$string` is upgraded as UTF-8. Without `use encoding 'utf8';`, it will print 4 instead, since `$string` is three octets when interpreted as Latin-1.

DO NOT MIX MULTIPLE ENCODINGS

Notice that only literals (string or regular expression) having only legacy code points are affected: if you mix data like this

```
\x{100}\xDF
\xDF\x{100}
```

the data is assumed to be in (Latin 1 and) Unicode, not in your native encoding. In other words, this will match in "greek":

```
"\xDF" =~ /\x{3af}/
```

but this will not

```
"\xDF\x{100}" =~ /\x{3af}\x{100}/
```

since the `\xDF` (ISO 8859-7 GREEK SMALL LETTER IOTA WITH TONOS) on the left will **not** be upgraded to `\x{3af}` (Unicode GREEK SMALL LETTER IOTA WITH TONOS) because of the `\x{100}` on the left. You should not be mixing your legacy data and Unicode in the same string.

This pragma also affects encoding of the 0x80..0xFF code point range: normally characters in that range are left as eight-bit bytes (unless they are combined with characters with code points 0x100 or larger, in which case all characters need to become UTF-8 encoded), but if the `encoding` pragma is present, even the 0x80..0xFF range always gets UTF-8 encoded.

After all, the best thing about this pragma is that you don't have to resort to \x{....} just to spell your name in a native encoding. So feel free to put your strings in your encoding in quotes and regexes.

Prior to Perl v5.22

The pragma was a per script, not a per block lexical. Only the last `use encoding` or `no encoding` mattered, and it affected **the whole script**. However, the `no encoding` pragma was supported and `use encoding` could appear as many times as you want in a given script (though only the last was effective).

Since the scope wasn't lexical, other modules' use of `chr`, `ord`, *etc.* were affected. This leads to spooky, incorrect action at a distance that is hard to debug.

This means you would have to be very careful of the load order:

```
# called module
package Module_IN_BAR;
use encoding "bar";
# stuff in "bar" encoding here
1;

# caller script
use encoding "foo"
use Module_IN_BAR;
# surprise! use encoding "bar" is in effect.
```

The best way to avoid this oddity is to use this pragma RIGHT AFTER other modules are loaded. i.e.

```
use Module_IN_BAR;
use encoding "foo";
```

Prior to Encode version 1.87

- `STDIN` and `STDOUT` were not set under the filter option. And `STDIN=>_ENCODING_` and `STDOUT=>_ENCODING_` didn't work like non-filter version.
- `use utf8` wasn't implicitly declared so you have to `use utf8` to do

```
${"\x{4eba}"}++
```

Prior to Perl v5.8.1

- "NON-EUC" doublebyte encodings

  Because perl needs to parse the script before applying this pragma, such encodings as Shift_JIS and Big-5 that may contain `'\'` (BACKSLASH; `\x5c`) in the second byte fail because the second byte may accidentally escape the quoting character that follows.

- `tr///`

  The **encoding** pragma works by decoding string literals in `q//`, `qq//`, `qr//`, `qw//`, `qx//` and so forth. In perl v5.8.0, this does not apply to `tr///`. Therefore,

```
use encoding 'euc-jp';
#....
$kana =~ tr/\xA4\xA1-\xA4\xF3/\xA5\xA1-\xA5\xF3/;
#           -------- -------- -------- --------
```

  Does not work as

```
$kana =~ tr/\x{3041}-\x{3093}/\x{30a1}-\x{30f3}/;
```

  – Legend of characters above

```
utf8     euc-jp   charnames::viacode()
----------------------------------------
\x{3041} \xA4\xA1 HIRAGANA LETTER SMALL A
\x{3093} \xA4\xF3 HIRAGANA LETTER N
\x{30a1} \xA5\xA1 KATAKANA LETTER SMALL A
\x{30f3} \xA5\xF3 KATAKANA LETTER N
```

  This counterintuitive behavior has been fixed in perl v5.8.1.

  In perl v5.8.0, you can work around this as follows;

```
use encoding 'euc-jp';
#  ....
eval qq{ \$kana =~ tr/\xA4\xA1-\xA4\xF3/\xA5\xA1-\xA5\xF3/ };
```

  Note the `tr//` expression is surrounded by `qq{}`. The idea behind this is the same as the classic idiom that makes `tr///` 'interpolate':

```
tr/$from/$to/;             # wrong!
eval qq{ tr/$from/$to/ }; # workaround.
```

EXAMPLE - Greekperl

```
use encoding "iso 8859-7";

# \xDF in ISO 8859-7 (Greek) is \x{3af} in Unicode.

$a = "\xDF";
$b = "\x{100}";

printf "%#x\n", ord($a); # will print 0x3af, not 0xdf

$c = $a . $b;

# $c will be "\x{3af}\x{100}", not "\x{df}\x{100}".

# chr() is affected, and ...

print "mega\n"  if ord(chr(0xdf)) == 0x3af;

# ... ord() is affected by the encoding pragma ...

print "tera\n" if ord(pack("C", 0xdf)) == 0x3af;

# ... as are eq and cmp ...

print "peta\n" if "\x{3af}" eq  pack("C", 0xdf);
print "exa\n"  if "\x{3af}" cmp pack("C", 0xdf) == 0;

# ... but pack/unpack C are not affected, in case you still
# want to go back to your native encoding

print "zetta\n" if unpack("C", (pack("C", 0xdf))) == 0xdf;
```

BUGS

- Thread safety

  `use encoding ...` is not thread-safe (i.e., do not use in threaded applications).

- Can't be used by more than one module in a single program.

  Only one encoding is allowed. If you combine modules in a program that have different encodings, only one will be actually used.

- Other modules using `STDIN` and `STDOUT` get the encoded stream

  They may be expecting something completely different.

- literals in regex that are longer than 127 bytes

  For native multibyte encodings (either fixed or variable length), the current implementation of the regular expressions may introduce recoding errors for regular expression literals longer than 127 bytes.

- EBCDIC

The encoding pragma is not supported on EBCDIC platforms.

- `format`

  This pragma doesn't work well with `format` because PerlIO does not get along very well with it. When `format` contains non-ASCII characters it prints funny or gets "wide character warnings". To understand it, try the code below.

```
# Save this one in utf8
# replace *non-ascii* with a non-ascii string
my $camel;
format STDOUT =
*non-ascii*@>>>>>>>
$camel
.
$camel = "*non-ascii*";
binmode(STDOUT=>':encoding(utf8)'); # bang!
write;              # funny
print $camel, "\n"; # fine
```

  Without binmode this happens to work but without binmode, print() fails instead of write().

  At any rate, the very use of `format` is questionable when it comes to unicode characters since you have to consider such things as character width (i.e. double-width for ideographs) and directions (i.e. BIDI for Arabic and Hebrew).

- See also "CAVEATS"

HISTORY

This pragma first appeared in Perl v5.8.0. It has been enhanced in later releases as specified above.

Modules

- `encoding::warnings` - Warn on implicit encoding conversions

encoding::warnings

Warn on implicit encoding conversions

VERSION

This document describes version 0.13 of encoding::warnings, released June 20, 2016.

NOTICE

As of Perl 5.26.0, this module has no effect. The internal Perl feature that was used to implement this module has been removed. In recent years, much work has been done on the Perl core to eliminate discrepancies in the treatment of upgraded versus downgraded strings. In addition, the *encoding* pragma, which caused many of the problems, is no longer supported. Thus, the warnings this module produced are no longer necessary.

Hence, if you load this module on Perl 5.26.0, you will get one warning that the module is no longer supported; and the module will do nothing thereafter.

SYNOPSIS

```
use encoding::warnings; # or 'FATAL' to raise fatal exceptions

utf8::encode($a = chr(20000));  # a byte-string (raw bytes)
$b = chr(20000);                # a unicode-string (wide characters)

# "Bytes implicitly upgraded into wide characters as iso-8859-1"
$c = $a . $b;
```

DESCRIPTION

Overview of the problem

By default, there is a fundamental asymmetry in Perl's unicode model: implicit upgrading from byte-strings to unicode-strings assumes that they were encoded in *ISO 8859-1 (Latin-1)*, but unicode-strings are downgraded with UTF-8 encoding. This happens because the first 256 codepoints in Unicode happens to agree with Latin-1.

However, this silent upgrading can easily cause problems, if you happen to mix unicode strings with non-Latin1 data – i.e. byte-strings encoded in UTF-8 or other encodings. The error will not manifest until the combined string is written to output, at which time it would be impossible to see where did the silent upgrading occur.

Detecting the problem

This module simplifies the process of diagnosing such problems. Just put this line on top of your main program:

```
use encoding::warnings;
```

Afterwards, implicit upgrading of high-bit bytes will raise a warning. Ex.: `Bytes implicitly upgraded into wide characters as iso-8859-1 at \- line 7.`

However, strings composed purely of ASCII code points (`0x00..0x7F`) will *not* trigger this warning.

You can also make the warnings fatal by importing this module as:

```
use encoding::warnings 'FATAL';
```

Solving the problem

Most of the time, this warning occurs when a byte-string is concatenated with a unicode-string. There are a number of ways to solve it:

- Upgrade both sides to unicode-strings

  If your program does not need compatibility for Perl 5.6 and earlier, the recommended approach is to apply appropriate IO disciplines, so all data in your program become unicode-strings. See *encoding*, *open* and *"binmode" in perlfunc* for how.

- Downgrade both sides to byte-strings

  The other way works too, especially if you are sure that all your data are under the same encoding, or if compatibility with older versions of Perl is desired.

  You may downgrade strings with `Encode::encode` and `utf8::encode`. See *Encode* and *utf8* for details.

- Specify the encoding for implicit byte-string upgrading

  If you are confident that all byte-strings will be in a specific encoding like UTF-8, *and* need not support older versions of Perl, use the `encoding` pragma:

  ```
  use encoding 'utf8';
  ```

  Similarly, this will silence warnings from this module, and preserve the default behaviour:

  ```
  use encoding 'iso-8859-1';
  ```

  However, note that `use encoding` actually had three distinct effects:

  – PerlIO layers for **STDIN** and **STDOUT**

    This is similar to what *open* pragma does.

  – Literal conversions

    This turns *all* literal string in your program into unicode-strings (equivalent to a `use utf8`), by decoding them using the specified encoding.

  – Implicit upgrading for byte-strings

    This will silence warnings from this module, as shown above.

  Because literal conversions also work on empty strings, it may surprise some people:

  ```
  use encoding 'big5';

  my $byte_string = pack("C*", 0xA4, 0x40);
  print length $a;    # 2 here.
  ```

(continues on next page)

(continued from previous page)

```
$a .= "";           # concatenating with a unicode string...
print length $a;    # 1 here!
```

In other words, do not `use encoding` unless you are certain that the program will not deal with any raw, 8-bit binary data at all.

However, the `Filter => 1` flavor of `use encoding` will *not* affect implicit upgrading for byte-strings, and is thus incapable of silencing warnings from this module. See *encoding* for more details.

CAVEATS

For Perl 5.9.4 or later, this module's effect is lexical.

For Perl versions prior to 5.9.4, this module affects the whole script, instead of inside its lexical block.

5.2.133 experimental

Experimental features made easy

VERSION

version 0.036

SYNOPSIS

```
use experimental 'lexical_subs', 'signatures';
my sub plus_one($value) { $value + 1 }
```

DESCRIPTION

This pragma provides an easy and convenient way to enable or disable experimental features.

Every version of perl has some number of features present but considered "experimental." For much of the life of Perl 5, this was only a designation found in the documentation. Starting in Perl v5.10.0, and more aggressively in v5.18.0, experimental features were placed behind pragmata used to enable the feature and disable associated warnings.

The `experimental` pragma exists to combine the required incantations into a single interface stable across releases of perl. For every experimental feature, this should enable the feature and silence warnings for the enclosing lexical scope:

```
use experimental 'feature-name';
```

To disable the feature and, if applicable, re-enable any warnings, use:

```
no experimental 'feature-name';
```

The supported features, documented further below, are:

- `args_array_with_signatures` - allow `@_` to be used in signatured subs.

  This is supported on perl 5.20.0 and above, but is likely to be removed in the future.

- `array_base` - allow the use of `$[` to change the starting index of `@array`.

  This was removed in perl 5.30.0.

- `autoderef` - allow push, each, keys, and other built-ins on references.

  This was added in perl 5.14.0 and removed in perl 5.24.0.

- `bitwise` - allow the new stringwise bit operators

  This was added in perl 5.22.0.

- `builtin` - allow the use of the functions in the builtin:: namespace

  This was added in perl 5.36.0

- `const_attr` - allow the :const attribute on subs

  This was added in perl 5.22.0.

- `class` - enables the `class`, `field`, and `method` syntax

  This was added in perl 5.38.0.

- `declared_refs` - enables aliasing via assignment to references

  This was added in perl 5.26.0.

- `defer` - enables the use of defer blocks

  This was added in perl 5.36.0

- `extra_paired_delimiters` - enables the use of more paired string delimiters than the traditional four, `< >`, `( )`, `{ }`, and `[ ]`.

  This was added in perl 5.36.

- `for_list` - allows iterating over multiple values at a time with `for`

  This was added in perl 5.36.0

- `isa` - allow the use of the `isa` infix operator

  This was added in perl 5.32.0.

- `keyword_all` - enables the `all` operator

  This was added in perl 5.42.0.

- `keyword_any` - enables the `any` operator

  This was added in perl 5.42.0.

- `lexical_topic` - allow the use of lexical `$_` via `my $_`.

  This was added in perl 5.10.0 and removed in perl 5.24.0.

- `lexical_subs` - allow the use of lexical subroutines.

  This was added in 5.18.0, and became non-experimental (and always enabled) in 5.26.0.

- `postderef` - allow the use of postfix dereferencing expressions

  This was added in perl 5.20.0, and became non-experimental (and always enabled) in 5.24.0.

- `postderef_qq` - allow the use of postfix dereferencing expressions inside interpolating strings

  This was added in perl 5.20.0, and became non-experimental (and always enabled) in 5.24.0.

- `re_strict` - enables strict mode in regular expressions

  This was added in perl 5.22.0.

- `refaliasing` - allow aliasing via `\$x = \$y`

  This was added in perl 5.22.0.

- `regex_sets` - allow extended bracketed character classes in regexps

  This was added in perl 5.18.0, and became non-experimental (and always enabled) in 5.36.0.

  This is documented at "Extended Bracketed Character Classes" in perlrecharclass.

- `signatures` - allow subroutine signatures (for named arguments)

  This was added in perl 5.20.0.

- `smartmatch` - allow the use of ~~

  This was added in perl 5.10.0, but it should be noted there are significant incompatibilities between 5.10.0 and 5.10.1.

  The feature was deprecated in perl 5.38.0, and undeprecated in 5.42.0.

- `switch` - allow the use of ~~, given, and when

  This was added in perl 5.10.0.

The feature was deprecated in perl 5.38.0, and undeprecated in 5.42.0.

- `try` - allow the use of `try` and `catch`

  This was added in perl 5.34.0

- `win32_perlio` - allows the use of the :win32 IO layer.

  This was added on perl 5.22.0.

Ordering matters

Using this pragma to 'enable an experimental feature' is another way of saying that this pragma will disable the warnings which would result from using that feature. Therefore, the order in which pragmas are applied is important. In particular, you probably want to enable experimental features *after* you enable warnings:

```
use warnings;
use experimental 'smartmatch';
```

You also need to take care with modules that enable warnings for you. A common example being Moose. In this example, warnings for the 'smartmatch' feature are first turned on by the warnings pragma, off by the experimental pragma and back on again by the Moose module (fix is to switch the last two lines):

```
use warnings;
use experimental 'smartmatch';
use Moose;
```

Disclaimer

Because of the nature of the features it enables, forward compatibility can not be guaranteed in any way.

5.2.134 feature

Perl pragma to enable new features

SYNOPSIS

```
use feature qw(fc say);

# Without the "use feature" above, this code would not be able to␣
 ↪find
# the built-ins "say" or "fc":
say "The case-folded version of $x is: " . fc $x;

# set features to match the :5.36 bundle, which may turn off or on
# multiple features (see "FEATURE BUNDLES" below)
use feature ':5.36';

# implicitly loads :5.36 feature bundle
use v5.36;
```

DESCRIPTION

It is usually impossible to add new syntax to Perl without breaking some existing programs. This pragma provides a way to minimize that risk. New syntactic constructs, or new semantic meanings to older constructs, can be enabled by `use feature 'foo'`, and will be parsed only when the appropriate feature pragma is in scope. (Nevertheless, the `CORE::` prefix provides access to all Perl keywords, regardless of this pragma.)

Lexical effect

Like other pragmas (`use strict`, for example), features have a lexical effect. `use feature qw(foo)` will only make the feature "foo" available from that point to the end of the enclosing block.

```
{
    use feature 'say';
    say "say is available here";
}
print "But not here.\n";
```

no feature

Features can also be turned off by using `no feature "foo"`. This too has lexical effect.

```
use feature 'say';
say "say is available here";
{
    no feature 'say';
```

(continues on next page)

(continued from previous page)

```
    print "But not here.\n";
}
say "Yet it is here.";
```

`no feature` with no features specified will reset to the default group. To disable *all* features (an unusual request!) use `no feature ':all'`.

AVAILABLE FEATURES

Read "FEATURE BUNDLES" for the feature cheat sheet summary.

The 'apostrophe_as_package_separator' feature

This feature enables use `'` (apostrophe) as an alternative to using `::` as a separate in package and other global names.

This is enabled by default, but disabled from the 5.42 feature bundle onwards. In previous versions it was enabled all the time.

This only disables `'` in symbols in your source code, the internal conversion from `'` to `::`, including for symbolic references, is always enabled.

The 'array_base' feature

This feature supported the legacy `$[` variable. See *"$[" in perlvar*. It was on by default but disabled under `use v5.16` (see "IMPLICIT LOADING", below) and unavailable since perl 5.30.

This feature is available under this name starting with Perl 5.16. In previous versions, it was simply on all the time, and this pragma knew nothing about it.

The 'bareword_filehandles' feature

This feature enables bareword filehandles for builtin functions operations, a generally discouraged practice. It is enabled by default, but can be turned off to disable bareword filehandles, except for the exceptions listed below.

The perl built-in filehandles `STDIN`, `STDOUT`, `STDERR`, `DATA`, `ARGV`, `ARGVOUT` and the special `_` are always enabled.

This feature is available under this name from Perl 5.34 onwards. In previous versions it was simply on all the time. It is disabled from the 5.38 feature bundle onwards.

You can use the bareword::filehandles module on CPAN to disable bareword filehandles for older versions of perl.

The 'bitwise' feature

This makes the four standard bitwise operators (`& | ^ ~`) treat their operands consistently as numbers, and introduces four new dotted operators (`&. |. ^. ~.`) that treat their operands consistently as strings. The same applies to the assignment variants (`&= |= ^= &.= |.= ^.=`).

See *"Bitwise String Operators" in perlop* for details.

This feature is available from Perl 5.22 onwards. Starting in Perl 5.28, `use v5.28` will enable the feature. Before 5.28, it was still experimental and would emit a warning in the "experimental::bitwise" category.

The 'class' feature

WARNING: This feature is still experimental and the implementation may change or be removed in future versions of Perl. For this reason, Perl will warn when you use the feature, unless you have explicitly disabled the warning:

```
no warnings "experimental::class";
```

This feature enables the `class` block syntax and other associated keywords which implement the "new" object system, previously codenamed "Corinna".

This feature is available starting in Perl 5.38.

The 'current_sub' feature

This provides the `__SUB__` token that returns a reference to the current subroutine or `undef` outside of a subroutine.

This feature is available starting with Perl 5.16.

The 'declared_refs' feature

WARNING: This feature is still experimental and the implementation may change or be removed in future versions of Perl. For this reason, Perl will warn when you use the feature, unless you have explicitly disabled the warning:

```
no warnings "experimental::declared_refs";
```

This allows a reference to a variable to be declared with `my`, `state`, or `our`, or localized with `local`. It is intended mainly for use in conjunction with the "refaliasing" feature. See "Declaring a Reference to a Variable" in perlref for examples.

This feature is available from Perl 5.26 onwards.

The 'defer' feature

WARNING: This feature is still experimental and the implementation may change or be removed in future versions of Perl. For this reason, Perl will warn when you use the feature, unless you have explicitly disabled the warning:

```
no warnings "experimental::defer";
```

This feature enables the `defer` block syntax, which allows a block of code to be deferred until when the flow of control leaves the block which contained it. For more details, see "defer" in perlsyn.

This feature is available starting in Perl 5.36.

The 'enhanced_xx' feature

WARNING: This feature is still experimental and the implementation may change or be removed in future versions of Perl. For this reason, Perl will warn when you use the feature, unless you have explicitly disabled the warning:

```
no warnings "experimental::eenhanced_xx";
```

This feature changes the meaning of the `/xx` regular expression pattern modifier to allow bracketed character classes to be split across lines, and to catch cases where a literal # was meant to be matched, but instead that and the rest of the line was taken to be a comment.

This feature is available starting in Perl 5.44.

The 'evalbytes' feature

See "The 'unicode_eval' and 'evalbytes' features"

The 'extra_paired_delimiters' feature

WARNING: This feature is still experimental and the implementation may change or be removed in future versions of Perl. For this reason, Perl will warn when you use the feature, unless you have explicitly disabled the warning:

```
no warnings "experimental::extra_paired_delimiters";
```

This feature enables the use of more paired string delimiters than the traditional four, `< >`, `( )`, `{ }`, and `[ ]`. When this feature is on, for example, you can say `qr«pat»`.

As with any usage of non-ASCII delimiters in a UTF-8-encoded source file, you will want to ensure the parser will decode the source code from UTF-8 bytes with a declaration such as `use utf8`.

This feature is available starting in Perl 5.36.

For a full list of the available characters, see *"List of Extra Paired Delimiters" in perlop*.

The 'fc' feature

`use feature 'fc'` tells the compiler to enable the `fc` function, which implements Unicode casefolding.

See *"fc" in perlfunc* for details.

This feature is available from Perl 5.16 onwards.

The 'indirect' feature

This feature allows the use of indirect object syntax for method calls, e.g. `new Foo 1, 2;`. It is enabled by default, but can be turned off to disallow indirect object syntax.

This feature is available under this name from Perl 5.32 onwards. In previous versions, it was simply on all the time. To disallow (or warn on) indirect object syntax on older Perls, see the indirect CPAN module. It is disabled from the 5.36 feature bundle onwards.

The 'isa' feature

This allows the use of the `isa` infix operator, which tests whether the scalar given by the left operand is an object of the class given by the right operand. See *"Class Instance Operator" in perlop* for more details.

This feature is available from Perl 5.32 onwards. From Perl 5.32 to 5.34, it was classed as experimental, and Perl emitted a warning for its usage, except when explicitly disabled:

```
no warnings "experimental::isa";
```

As of Perl 5.36, use of this feature no longer triggers a warning (though the `experimental::isa` warning category still exists for compatibility with code that disables it). This feature is now considered stable, and is enabled automatically by `use v5.36` (or higher).

The 'keyword_all' feature

WARNING: This feature is still experimental and the implementation may change or be removed in future versions of Perl. For this reason, Perl will warn when you use the feature, unless you have explicitly disabled the warning:

```
no warnings "experimental::keyword_all";
```

This feature enables the `all` operator keyword. This allow testing whether all of the values in a list satisfy a given condition, with short-circuiting behaviour as soon as it finds one that does not.

This feature is available starting in Perl 5.42.

The 'keyword_any' feature

WARNING: This feature is still experimental and the implementation may change or be removed in future versions of Perl. For this reason, Perl will warn when you use the feature, unless you have explicitly disabled the warning:

```
no warnings "experimental::keyword_any";
```

This feature enables the `any` operator keyword. This allow testing whether any of the values in a list satisfy a given condition, with short-circuiting behaviour as soon as it finds one.

This feature is available starting in Perl 5.42.

The 'lexical_subs' feature

In Perl versions prior to 5.26, this feature enabled declaration of subroutines via `my sub foo`, `state sub foo` and `our sub foo` syntax. See *"Lexical Subroutines" in perlsub* for details.

This feature is available from Perl 5.18 onwards. From Perl 5.18 to 5.24, it was classed as experimental, and Perl emitted a warning for its usage, except when explicitly disabled:

```
no warnings "experimental::lexical_subs";
```

As of Perl 5.26, use of this feature no longer triggers a warning, though the `experimental::lexical_subs` warning category still exists (for compatibility with code that disables it). In addition, this syntax is not only no longer experimental, but it is enabled for all Perl code, regardless of what feature declarations are in scope.

The 'module_true' feature

This feature removes the need to return a true value at the end of a module loaded with `require` or `use`. Any errors during compilation will cause failures, but reaching the end of the module when this feature is in effect will prevent `perl` from throwing an exception that the module "did not return a true value".

This feature is available from Perl 5.38 onwards.

The 'multidimensional' feature

This feature enables multidimensional array emulation, a perl 4 (or earlier) feature that was used to emulate multidimensional arrays with hashes. This works by converting code like `$foo{$x, $y}` into `$foo{join($;, $x, $y)}`. It is enabled by default, but can be turned off to disable multidimensional array emulation.

When this feature is disabled the syntax that is normally replaced will report a compilation error.

This feature is available under this name from Perl 5.34 onwards. In previous versions, it was simply on all the time. It is disabled from the 5.36 feature bundle onwards.

You can use the multidimensional module on CPAN to disable multidimensional array emulation for older versions of Perl.

The 'postderef' and 'postderef_qq' features

The 'postderef_qq' feature extends the applicability of postfix dereference syntax so that postfix array dereference, postfix scalar dereference, and postfix array highest index access are available in double-quotish interpolations. For example, it makes the following two statements equivalent:

```
my $s = "[@{ $h->{a} }]";
my $s = "[$h->{a}->@*]";
```

This feature is available from Perl 5.20 onwards. In Perl 5.20 and 5.22, it was classed as experimental, and Perl emitted a warning for its usage, except when explicitly disabled:

```
no warnings "experimental::postderef";
```

As of Perl 5.24, use of this feature no longer triggers a warning, though the `experimental::postderef` warning category still exists (for compatibility with code that disables it).

The 'postderef' feature was used in Perl 5.20 and Perl 5.22 to enable postfix dereference syntax outside double-quotish interpolations. In those versions, using it triggered the

`experimental::postderef` warning in the same way as the 'postderef_qq' feature did. As of Perl 5.24, this syntax is not only no longer experimental, but it is enabled for all Perl code, regardless of what feature declarations are in scope.

The 'refaliasing' feature

WARNING: This feature is still experimental and the implementation may change or be removed in future versions of Perl. For this reason, Perl will warn when you use the feature, unless you have explicitly disabled the warning:

```
no warnings "experimental::refaliasing";
```

This enables aliasing via assignment to references:

```
\$a = \$b; # $a and $b now point to the same scalar
\@a = \@b; #                    to the same array
\%a = \%b;
\&a = \&b;
foreach \%hash (@array_of_hash_refs) {
    ...
}
```

See "Assigning to References" in perlref for details.

This feature is available from Perl 5.22 onwards.

The 'say' feature

`use feature 'say'` tells the compiler to enable the Raku-inspired `say` function.

See *"say" in perlfunc* for details.

This feature is available starting with Perl 5.10.

The 'signatures' feature

This enables syntax for declaring subroutine arguments as lexical variables. For example, for this subroutine:

```
sub foo ($left, $right) {
    return $left + $right;
}
```

Calling `foo(3, 7)` will assign 3 into `$left` and 7 into `$right`.

See *"Signatures" in perlsub* for details.

This feature is available from Perl 5.20 onwards. From Perl 5.20 to 5.34, it was classed as experimental, and Perl emitted a warning for its usage, except when explicitly disabled:

```
no warnings "experimental::signatures";
```

As of Perl 5.36, use of this feature no longer triggers a warning, though the `experimental::signatures` warning category still exists (for compatibility with code that disables it). This feature is now considered stable, and is enabled automatically by `use v5.36` (or higher).

The 'smartmatch' feature

`use feature 'smartmatch'` tells the compiler to enable the smartmatch operator `~~`. It is enabled by default, but can be turned off to disallow the `~~` operator.

This feature is disabled by default in the 5.42 feature bundle onwards:

```
$x ~~ $y; # fine
use v5.42;
$x ~~ $y; # error
```

This has no effect on the implicit smartmatches done by `when`.

See *"Smartmatch Operator" in perlop* for details.

The 'state' feature

`use feature 'state'` tells the compiler to enable `state` variables.

See *"Persistent Private Variables" in perlsub* for details.

This feature is available starting with Perl 5.10.

The 'switch' feature

`use feature 'switch'` tells the compiler to enable the Raku given/when construct.

See "Switch Statements" in perlsyn for details.

This feature is available starting with Perl 5.10. It is enabled by feature bundles 5.10 through 5.34, and disabled from the 5.36 feature bundle onwards.

The 'try' feature

WARNING: This feature is still partly experimental, and the implementation may change or be removed in future versions of Perl.

This feature enables the `try` and `catch` syntax, which allows exception handling, where exceptions thrown from the body of the block introduced with `try` are caught by executing the body of the `catch` block.

This feature is available starting in Perl 5.34. Before Perl 5.40 it was classed as experimental, and Perl emitted a warning for its usage, except when explicitly disabled:

```
no warnings "experimental::try";
```

As of Perl 5.40, use of this feature without a `finally` block no longer triggers a warning. The optional `finally` block is still considered experimental and emits a warning, except when explicitly disabled as above.

For more information, see "Try Catch Exception Handling" in perlsyn.

The 'unicode_eval' and 'evalbytes' features

Together, these two features are intended to replace the legacy string `eval` function, which behaves problematically in some instances. They are available starting with Perl 5.16, and are enabled by default by a `use 5.16` or higher declaration.

`unicode_eval` changes the behavior of plain string `eval` to work more consistently, especially in the Unicode world. Certain (mis)behaviors couldn't be changed without breaking some things that had come to rely on them, so the feature can be enabled and disabled. Details are at *"Under the "unicode_eval" feature" in perlfunc*.

`evalbytes` is like string `eval`, but it treats its argument as a byte string. Details are at *"evalbytes EXPR" in perlfunc*. Without a `use feature 'evalbytes'` nor a `use v5.16` (or higher) declaration in the current scope, you can still access it by instead writing `CORE::evalbytes`.

The 'unicode_strings' feature

`use feature 'unicode_strings'` tells the compiler to use Unicode rules in all string operations executed within its scope (unless they are also within the scope of either `use locale` or `use bytes`). The same applies to all regular expressions compiled within the scope, even if executed outside it. It does not change the internal representation of strings, but only how they are interpreted.

`no feature 'unicode_strings'` tells the compiler to use the traditional Perl rules wherein the native character set rules is used unless it is clear to Perl that Unicode is desired. This can lead to some surprises when the behavior suddenly changes. (See "The "Unicode Bug"" in perlunicode for details.) For this reason, if you are potentially using Unicode in your program, the `use feature 'unicode_strings'` subpragma is **strongly** recommended.

This feature is available starting with Perl 5.12; was almost fully implemented in Perl 5.14; and extended in Perl 5.16 to cover `quotemeta`; was extended further in Perl 5.26 to cover *the range operator*; and was extended again in Perl 5.28 to cover *special-cased whitespace splitting*.

FEATURE BUNDLES

It's possible to load multiple features together, using a *feature bundle*. The name of a feature bundle is prefixed with a colon, to distinguish it from an actual feature.

```
use feature ":5.10";
```

The following feature bundles are available:

```
bundle    features included
--------- -----------------
:default  indirect multidimensional
          bareword_filehandles
          apostrophe_as_package_separator smartmatch

:5.10     apostrophe_as_package_separator
          bareword_filehandles indirect
```

(continues on next page)

(continued from previous page)

```
          multidimensional say smartmatch state switch

:5.12     apostrophe_as_package_separator
          bareword_filehandles indirect

:5.42     bitwise current_sub evalbytes fc isa
          module_true postderef_qq say signatures
          state try unicode_eval unicode_strings

:5.44     bitwise current_sub evalbytes fc isa
          module_true postderef_qq say signatures
          state try unicode_eval unicode_strings
```

The `:default` bundle represents the feature set that is enabled before any `use feature` or `no feature` declaration.

Specifying sub-versions such as the `0` in `5.14.0` in feature bundles has no effect. Feature bundles are guaranteed to be the same for all sub-versions.

```
use feature ":5.14.0";    # same as ":5.14"
```

(continues on next page)

(continued from previous page)

```
use feature ":5.14.1";    # same as ":5.14"
```

You can also do:

```
use feature ":all";
```

or

```
no feature ":all";
```

but the first may enable features in a later version of Perl that change the meaning of your code, and the second may disable mechanisms that are part of Perl's current behavior that have been turned into features, just as `indirect` and `bareword_filehandles` were.

IMPLICIT LOADING

Instead of loading feature bundles by name, it is easier to let Perl do implicit loading of a feature bundle for you.

There are two ways to load the `feature` pragma implicitly:

- By using the `-E` switch on the Perl command-line instead of `-e`. That will enable the feature bundle for that version of Perl in the main compilation unit (that is, the one-liner that follows `-E`).
- By explicitly requiring a minimum Perl version number for your program, with the `use VERSION` construct. That is,

  ```
  use v5.36.0;
  ```

  will do an implicit

  ```
  no feature ':all';
  use feature ':5.36';
  ```

  and so on. Note how the trailing sub-version is automatically stripped from the version.

  But to avoid portability warnings (see *"use" in perlfunc*), you may prefer:

  ```
  use 5.036;
  ```

  with the same effect.

  If the required version is older than Perl 5.10, the ":default" feature bundle is automatically loaded instead.

  Unlike `use feature ":5.12"`, saying `use v5.12` (or any higher version) also does the equivalent of `use strict`; see *"use" in perlfunc* for details.

CHECKING FEATURES

`feature` provides some simple APIs to check which features are enabled.

These functions cannot be imported and must be called by their fully qualified names. If you don't otherwise need to set a feature you will need to ensure `feature` is loaded with:

```
use feature ();
```

- feature_enabled($feature)
- feature_enabled($feature, $depth)

  ```
  package MyStandardEnforcer;
  use feature ();
  use Carp "croak";
  sub import {
    croak "disable indirect!" if feature::feature_enabled(
  ↪"indirect");
  }
  ```

  Test whether a named feature is enabled at a given level in the call stack, returning a true value if it is. `$depth` defaults to 1, which checks the scope that called the scope calling feature::feature_enabled().

  croaks for an unknown feature name.

- features_enabled()
- features_enabled($depth)

  ```
  package ReportEnabledFeatures;
  use feature "say";
  sub import {
    say STDERR join " ", feature::features_enabled();
  }
  ```

  Returns a list of the features enabled at a given level in the call stack. `$depth` defaults to 1, which checks the scope that called the scope calling feature::features_enabled().

- feature_bundle()
- feature_bundle($depth)

  Returns the feature bundle, if any, selected at a given level in the call stack. `$depth` defaults to 1, which checks the scope that called the scope calling feature::feature_bundle().

  Returns an undefined value if no feature bundle is selected in the scope.

  The bundle name returned will be for the earliest bundle matching the selected bundle, so:

```
use feature ();
use v5.12;
BEGIN { print feature::feature_bundle(0); }
```

will print `5.11`.

This returns internal state, at this point `use v5.12;` sets the feature bundle, but `use feature ":5.12";` does not set the feature bundle. This may change in a future release of perl.

5.2.135 fields

compile-time class fields

SYNOPSIS

```
{
    package Foo;
    use fields qw(foo bar _Foo_private);
    sub new {
        my Foo $self = shift;
        unless (ref $self) {
            $self = fields::new($self);
            $self->{_Foo_private} = "this is Foo's secret";
        }
        $self->{foo} = 10;
        $self->{bar} = 20;
        return $self;
    }
}

my $var = Foo->new;
$var->{foo} = 42;

# this will generate a run-time error
$var->{zap} = 42;

# this will generate a compile-time error
my Foo $foo = Foo->new;
$foo->{zap} = 24;

# subclassing
{
    package Bar;
    use base 'Foo';
    use fields qw(baz _Bar_private);        # not shared with Foo
    sub new {
        my $class = shift;
        my $self = fields::new($class);
        $self->SUPER::new();                # init base fields
```

(continues on next page)

(continued from previous page)

```
        $self->{baz} = 10;                  # init own fields
        $self->{_Bar_private} = "this is Bar's secret";
        return $self;
    }
}
```

DESCRIPTION

The `fields` pragma enables compile-time and run-time verified class fields.

NOTE: The current implementation keeps the declared fields in the %FIELDS hash of the calling package, but this may change in future versions. Do **not** update the %FIELDS hash directly, because it must be created at compile-time for it to be fully useful, as is done by this pragma.

If a typed lexical variable (`my Class $var`) holding a reference is used to access a hash element and a package with the same name as the type has declared class fields using this pragma, then the hash key is verified at compile time. If the variables are not typed, access is only checked at run time.

The related `base` pragma will combine fields from base classes and any fields declared using the `fields` pragma. This enables field inheritance to work properly. Inherited fields can be overridden but will generate a warning if warnings are enabled.

Only valid for Perl 5.8.x and earlier: Field names that start with an underscore character are made private to the class and are not visible to subclasses.

Also, **in Perl 5.8.x and earlier**, this pragma uses pseudo-hashes, the effect being that you can have objects with named fields which are as compact and fast as arrays to access, as long as the objects are accessed through properly typed variables.

The following functions are supported:

- new

  fields::new() creates and blesses a hash of the fields declared using the `fields` pragma into the specified class. It is the recommended way to construct a fields-based object.

  This makes it possible to write a constructor like this:

  ```
  package Critter::Sounds;
  use fields qw(cat dog bird);

  sub new {
      my $self = shift;
      $self = fields::new($self) unless ref $self;
      $self->{cat} = 'meow';                    # scalar element
      @$self{'dog','bird'} = ('bark','tweet');  # slice
      return $self;
  }
  ```

- phash

This function only works in Perl 5.8.x and earlier. Pseudo-hashes were removed from Perl as of 5.10. Consider using restricted hashes or fields::new() instead (which itself uses restricted hashes under 5.10+). See *Hash::Util*. Using fields::phash() under 5.10 or higher will cause an error.

fields::phash() can be used to create and initialize a plain (unblessed) pseudo-hash. This function should always be used instead of creating pseudo-hashes directly.

If the first argument is a reference to an array, the pseudo-hash will be created with keys from that array. If a second argument is supplied, it must also be a reference to an array whose elements will be used as the values. If the second array contains fewer elements than the first, the trailing elements of the pseudo-hash will not be initialized. This makes it particularly useful for creating a pseudo-hash from subroutine arguments:

```
sub dogtag {
   my $tag = fields::phash([qw(name rank ser_num)], [@_]);
}
```

fields::phash() also accepts a list of key-value pairs that will be used to construct the pseudo hash. Examples:

```
my $tag = fields::phash(name => "Joe",
                        rank => "captain",
                        ser_num => 42);

my $pseudohash = fields::phash(%args);
```

base, *Hash::Util*

5.2.136 filetest

Perl pragma to control the filetest permission operators

SYNOPSIS

```
$can_perhaps_read = -r "file";       # use the mode bits
{
    use filetest 'access';           # intuit harder
    $can_really_read = -r "file";
}
$can_perhaps_read = -r "file";       # use the mode bits again
```

DESCRIPTION

This pragma tells the compiler to change the behaviour of the filetest permission operators, `-r -w -x -R -W -X` (see *perlfunc*).

The default behaviour of file test operators is to use the simple mode bits as returned by the stat() family of system calls. However, many operating systems have additional

features to define more complex access rights, for example ACLs (Access Control Lists). For such environments, `use filetest` may help the permission operators to return results more consistent with other tools.

The `use filetest` or `no filetest` statements affect file tests defined in their block, up to the end of the closest enclosing block (they are lexically block-scoped).

Currently, only the `access` sub-pragma is implemented. It enables (or disables) the use of access() when available, that is, on most UNIX systems and other POSIX environments. See details below.

Consider this carefully

The stat() mode bits are probably right for most of the files and directories found on your system, because few people want to use the additional features offered by access(). But you may encounter surprises if your program runs on a system that uses ACLs, since the stat() information won't reflect the actual permissions.

There may be a slight performance decrease in the filetest operations when the filetest pragma is in effect, because checking bits is very cheap.

Also, note that using the file tests for security purposes is a lost cause from the start: there is a window open for race conditions (who is to say that the permissions will not change between the test and the real operation?). Therefore if you are serious about security, just try the real operation and test for its success - think in terms of atomic operations. Filetests are more useful for filesystem administrative tasks, when you have no need for the content of the elements on disk.

The "access" sub-pragma

UNIX and POSIX systems provide an abstract access() operating system call, which should be used to query the read, write, and execute rights. This function hides various distinct approaches in additional operating system specific security features, like Access Control Lists (ACLs)

The extended filetest functionality is used by Perl only when the argument of the operators is a filename, not when it is a filehandle.

Limitation with regard to _

Because access() does not invoke stat() (at least not in a way visible to Perl), **the stat result cache "_" is not set**. This means that the outcome of the following two tests is different. The first has the stat bits of `/etc/passwd` in _, and in the second case this still contains the bits of `/etc`.

```
{ -d '/etc';
  -w '/etc/passwd';
  print -f _ ? 'Yes' : 'No';   # Yes
}

{ use filetest 'access';
  -d '/etc';
  -w '/etc/passwd';
```

(continues on next page)

(continued from previous page)

```
  print -f _ ? 'Yes' : 'No';   # No
}
```

Of course, unless your OS does not implement access(), in which case the pragma is simply ignored. Best not to use _ at all in a file where the filetest pragma is active!

As a side effect, as _ doesn't work, stacked filetest operators (`-f -w $file`) won't work either.

This limitation might be removed in a future version of perl.

5.2.137 if

`use` a Perl module if a condition holds

SYNOPSIS

```
use if CONDITION, "MODULE", ARGUMENTS;
no  if CONDITION, "MODULE", ARGUMENTS;
```

DESCRIPTION

use if

The `if` module is used to conditionally load another module. The construct:

```
use if CONDITION, "MODULE", ARGUMENTS;
```

... will load `MODULE` only if `CONDITION` evaluates to true; it has no effect if `CONDITION` evaluates to false. (The module name, assuming it contains at least one `::`, must be quoted when `'use strict "subs";'` is in effect.) If the CONDITION does evaluate to true, then the above line has the same effect as:

```
use MODULE ARGUMENTS;
```

For example, the `Unicode::UCD` module's `charinfo` function will use two functions from `Unicode::Normalize` only if a certain condition is met:

```
use if defined &DynaLoader::boot_DynaLoader,
    "Unicode::Normalize" => qw(getCombinClass NFD);
```

Suppose you wanted `ARGUMENTS` to be an empty list, *i.e.*, to have the effect of:

```
use MODULE ();
```

You can't do this with the `if` pragma; however, you can achieve exactly this effect, at compile time, with:

```
BEGIN { require MODULE if CONDITION }
```

no if

The `no if` construct is mainly used to deactivate categories of warnings when those categories would produce superfluous output under specified versions of `perl`.

For example, the `redundant` category of warnings was introduced in Perl-5.22. This warning flags certain instances of superfluous arguments to `printf` and `sprintf`. But if your code was running warnings-free on earlier versions of `perl` and you don't care about `redundant` warnings in more recent versions, you can call:

```
use warnings;
no if $] >= 5.022, q|warnings|, qw(redundant);

my $test   = { fmt  => "%s", args => [ qw( x y ) ] };
my $result  = sprintf $test->{fmt}, @{$test->{args}};
```

The `no if` construct assumes that a module or pragma has correctly implemented an `unimport()` method – but most modules and pragmata have not. That explains why the `no if` construct is of limited applicability.

BUGS

The current implementation does not allow specification of the required version of the module.

SEE ALSO

Module::Requires can be used to conditionally load one or more modules, with constraints based on the version of the module. Unlike `if` though, Module::Requires is not a core module.

Module::Load::Conditional provides a number of functions you can use to query what modules are available, and then load one or more of them at runtime.

The provide module from CPAN can be used to select one of several possible modules to load based on the version of Perl that is running.

5.2.138 integer

Perl pragma to use integer arithmetic instead of floating point

SYNOPSIS

```
use integer;
$x = 10/3;
# $x is now 3, not 3.33333333333333333
```

DESCRIPTION

This tells the compiler to use integer operations from here to the end of the enclosing BLOCK. On many machines, this doesn't matter a great deal for most computations, but on those without floating point hardware, it can make a big difference in performance.

Note that this only affects how most of the arithmetic and relational **operators** handle their operands and results, and **not** how all numbers everywhere are treated. Specifically, `use integer;` has the effect that before computing the results of the arithmetic operators (+, -, *, /, %, +=, -=, *=, /=, %=, and unary minus), the comparison operators (<, <=, >, >=, ==, !=, <=>), and the bitwise operators (|, &, ^, <<, >>, |=, &=, ^=, <<=, >>=), the operands have their fractional portions truncated (or floored), and the result will have its fractional portion truncated as well. In addition, the range of operands and results is restricted to that of familiar two's complement integers, i.e., -(2**31) .. (2**31-1) on 32-bit architectures, and -(2**63) .. (2**63-1) on 64-bit architectures. For example, this code

```
use integer;
$x = 5.8;
$y = 2.5;
$z = 2.7;
$a = 2**31 - 1;  # Largest positive integer on 32-bit machines
$, = ", ";
print $x, -$x, $x+$y, $x-$y, $x/$y, $x*$y, $y==$z, $a, $a+1;
```

will print: 5.8, -5, 7, 3, 2, 10, 1, 2147483647, -2147483648

Note that $x is still printed as having its true non-integer value of 5.8 since it wasn't operated on. And note too the wrap-around from the largest positive integer to the largest negative one. Also, arguments passed to functions and the values returned by them are **not** affected by `use integer;`. E.g.,

```
srand(1.5);
$, = ", ";
print sin(.5), cos(.5), atan2(1,2), sqrt(2), rand(10);
```

will give the same result with or without `use integer;` The power operator ** is also not affected, so that 2 ** .5 is always the square root of 2. Now, it so happens that the pre- and post- increment and decrement operators, ++ and –, are not affected by `use integer;` either. Some may rightly consider this to be a bug – but at least it's a long-standing one.

Finally, `use integer;` also has an additional affect on the bitwise operators. Normally, the operands and results are treated as **unsigned** integers, but with `use integer;` the operands and results are **signed**. This means, among other things, that ~0 is -1, and -2 & -5 is -6.

Internally, native integer arithmetic (as provided by your C compiler) is used. This means that Perl's own semantics for arithmetic operations may not be preserved. One common source of trouble is the modulus of negative numbers, which Perl does one way, but your hardware may do another.

```
% perl -le 'print (4 % -3)'
-2
% perl -Minteger -le 'print (4 % -3)'
1
```

See "Pragmatic Modules" in perlmodlib, *"Integer Arithmetic" in perlop*

5.2.139 less

perl pragma to request less of something

SYNOPSIS

```
use less 'CPU';
```

DESCRIPTION

This is a user-pragma. If you're very lucky some code you're using will know that you asked for less CPU usage or ram or fat or... we just can't know. Consult your documentation on everything you're currently using.

For general suggestions, try requesting `CPU` or `memory`.

```
use less 'memory';
use less 'CPU';
use less 'fat';
```

If you ask for nothing in particular, you'll be asking for `less 'please'`.

```
use less 'please';
```

FOR MODULE AUTHORS

less has been in the core as a "joke" module for ages now and it hasn't had any real way to communicating any information to anything. Thanks to Nicholas Clark we have user pragmas (see perlpragma) and now `less` can do something.

You can probably expect your users to be able to guess that they can request less CPU or memory or just "less" overall.

If the user didn't specify anything, it's interpreted as having used the `please` tag. It's up to you to make this useful.

```
# equivalent
use less;
use less 'please';
```

BOOLEAN = less->of(FEATURE)

The class method `less->of( NAME )` returns a boolean to tell you whether your user requested less of something.

```
if ( less->of( 'CPU' ) ) {
    ...
}
elsif ( less->of( 'memory' ) ) {

}
```

FEATURES = less->of()

If you don't ask for any feature, you get the list of features that the user requested you to be nice to. This has the nice side effect that if you don't respect anything in particular then you can just ask for it and use it like a boolean.

```
if ( less->of ) {
    ...
}
else {
    ...
}
```

CAVEATS

- This probably does nothing.
- This works only on 5.10+

  At least it's backwards compatible in not doing much.

5.2.140 lib

manipulate @INC at compile time

SYNOPSIS

```
use lib LIST;

no lib LIST;
```

DESCRIPTION

This is a small simple module which simplifies the manipulation of @INC at compile time.

It is typically used to add extra directories to perl's search path so that later `use` or `require` statements will find modules which are not located on perl's default search path.

Adding directories to @INC

The parameters to `use lib` are added to the start of the perl search path. Saying

```
use lib LIST;
```

is *almost* the same as saying

```
BEGIN { unshift(@INC, LIST) }
```

For each directory in LIST (called $dir here) the lib module also checks to see if a directory called $dir/$archname/auto exists. If so the $dir/$archname directory is assumed to be a corresponding architecture specific directory and is added to @INC in front of $dir. lib.pm also checks if directories called $dir/$version and $dir/$version/$archname exist and adds these directories to @INC.

The current value of `$archname` can be found with this command:

```
perl -V:archname
```

The corresponding command to get the current value of `$version` is:

```
perl -V:version
```

To avoid memory leaks, all trailing duplicate entries in @INC are removed.

Deleting directories from @INC

You should normally only add directories to @INC. If you need to delete directories from @INC take care to only delete those which you added yourself or which you are certain are not needed by other modules in your script. Other modules may have added directories which they need for correct operation.

The `no lib` statement deletes all instances of each named directory from @INC.

For each directory in LIST (called $dir here) the lib module also checks to see if a directory called $dir/$archname/auto exists. If so the $dir/$archname directory is assumed to be a corresponding architecture specific directory and is also deleted from @INC. lib.pm also checks if directories called $dir/$version and $dir/$version/$archname exist and deletes these directories from @INC.

Restoring original @INC

When the lib module is first loaded it records the current value of @INC in an array `@lib::ORIG_INC`. To restore @INC to that value you can say

```
@INC = @lib::ORIG_INC;
```

CAVEATS

In order to keep lib.pm small and simple, it only works with Unix filepaths. This doesn't mean it only works on Unix, but non-Unix users must first translate their file paths to Unix conventions.

```
# VMS users wanting to put [.stuff.moo] into
# their @INC would write
use lib 'stuff/moo';
```

NOTES

In the future, this module will likely use File::Spec for determining paths, as it does now for Mac OS (where Unix-style or Mac-style paths work, and Unix-style paths are converted properly to Mac-style paths before being added to @INC).

If you try to add a file to @INC as follows:

```
use lib 'this_is_a_file.txt';
```

`lib` will warn about this. The sole exceptions are files with the `.par` extension which are intended to be used as libraries.

SEE ALSO

FindBin - optional module which deals with paths relative to the source file.

PAR - optional module which can treat `.par` files as Perl libraries.

AUTHOR

Tim Bunce, 2nd June 1995.

`lib` is maintained by the perl5-porters. Please direct any questions to the canonical mailing list. Anything that is applicable to the CPAN release can be sent to its maintainer, though.

5.2.141 locale

Perl pragma to use or avoid POSIX locales for built-in operations

SYNOPSIS

```
my @x1 = sort @y;      # Native-platform/Unicode code point sort␣
↪order
{
    use locale;
```

(continues on next page)

(continued from previous page)

```
    my @x2 = sort @y;  # Locale-defined sort order
}
my @x3 = sort @y;      # Native-platform/Unicode code point sort␣
↪order
                       # again

# Parameters to the pragma are to work around deficiencies in locale
# handling that have since been fixed, and hence these are likely no
# longer useful
use locale qw(:ctype :collate);    # Only use the locale for␣
↪character
                                   # classification (\w, \d, etc.),␣
↪and
                                   # for string comparison␣
↪operations
                                   # like '$a le $b' and sorting.
use locale ':not_characters';      # Use the locale for everything␣
↪but
                                   # character classification and␣
↪string
                                   # comparison operations

use locale ':!numeric';            # Use the locale for everything␣
↪but
                                   # numeric-related operations
use locale ':not_numeric';         # Same

no locale;             # Turn off locale handling for the remainder␣
↪of
                       # the scope.
```

DESCRIPTION

This pragma tells the compiler to enable (or disable) the use of POSIX locales for built-in operations (for example, `LC_CTYPE` for regular expressions, `LC_COLLATE` for string comparison, and `LC_NUMERIC` for number formatting). Each `use locale` or `no locale` affects statements to the end of the enclosing BLOCK.

The pragma is documented as part of *perllocale*.

5.2.142 mro

Method Resolution Order - how Perl decides which parent class's method a call inherits.

When a method is called on an object, Perl walks a list of classes looking for a matching subroutine. That list - the *linearized MRO* - is derived from `@ISA` and from the algorithm currently in effect for the class. The `mro` module lets you pick the algorithm, inspect the resulting class list, query the reverse `@ISA` relation, and manage the method cache.

Two algorithms are available. `dfs` (depth-first search) is the default and matches Perl's historical behaviour. `c3` produces the *C3 linearization* familiar from Python, Dylan, and

Raku, which keeps subclasses ahead of their ancestors even under diamond inheritance. Pick `c3` when multiple inheritance makes the `dfs` order surprising; otherwise leave the default alone.

Loading the module also enables `next::method`, `next::can`, and `maybe::next::method` - the C3-aware cousins of `SUPER::`. They always walk the C3 linearization regardless of which MRO the class itself uses.

Synopsis

```
use mro;                  # enables next::method, next::can,␣
↪maybe::next::method

use mro 'c3';             # set C3 linearization for the current␣
↪package
use mro 'dfs';            # set depth-first (Perl's default)␣
↪explicitly

my $order = mro::get_linear_isa('MyClass');   # arrayref of class␣
↪names
my $algo  = mro::get_mro('MyClass');          # "dfs" or "c3"
mro::set_mro('MyClass', 'c3');                # set per-class at␣
↪runtime
```

next:: dispatch

These are mro.pm's own Perl subs, unchanged:

- `$self->next::method(@args)` - jumps (as `goto &sub`) to the next implementation of the current method in the C3 linearization of `$self`'s class, in the caller's context; dies with `No next::method 'NAME' found for CLASS` when there is none.
- `$self->maybe::next::method(@args)` - the same, but returns empty when there is no next method.
- `$self->next::can` - a code reference to the next method, or undef.

All three must be called from inside a named method; elsewhere they die with `next::method/next::can/maybe::next::method must be used in method context`.

This is a native implementation of the XS half of mro 1.30; its `mro.pm` is used unchanged.

Differences from upstream

None.

Functions

MRO selection

set_mro

Set the method-resolution algorithm for `$class` to either `"dfs"` or `"c3"`.

MRO introspection

get_linear_isa

Return the full ordered list of classes Perl would search for a method call on `$class`, starting with `$class` itself.

get_mro

Report which method-resolution algorithm is currently in effect for `$class`.

get_isarev

List every class that inherits from `$class`, directly or transitively, via `@ISA`.

is_universal

Report whether `$class` is `UNIVERSAL` itself or one of its ancestors via `@ISA`.

get_pkg_gen

Return a counter that increments every time a local method in `$class` changes or its local `@ISA` is modified.

Method cache

invalidate_all_method_caches

Invalidate the method cache for every package in the interpreter.

Other Functions

next::method

Tail-call the next implementation of the currently executing method, passing the original arguments.

next::can

Return a code reference to the next implementation of the currently executing method, or `undef` if there is none.

maybe::next::method

Tail-call the next implementation of the currently executing method if one exists; otherwise return quietly.

get_linear_isa

Return the full ordered list of classes Perl would search for a method call on `$class`, starting with `$class` itself.

Synopsis

```
my $list = mro::get_linear_isa($class);
my $list = mro::get_linear_isa($class, $type);
```

The result is an array reference of package names. By default the list is produced using whichever algorithm is active for the class (`dfs` or `c3`). Pass an explicit `"dfs"` or `"c3"` as `$type` to force one without changing the class's setting.

The list always begins with `$class`, even if `$class` has no stash yet - in that case the result is `[ $class ]`. `UNIVERSAL` and its ancestors are not included; they are searched implicitly after the returned list is exhausted. For a class that exists the array is the cached linearization itself, and it is read-only.

Inconsistent C3 hierarchies (conflicting parent orderings across a diamond) croak with `Inconsistent hierarchy during C3 merge of class '...'`. Recursive `@ISA` chains deeper than 100 levels croak with `Recursive inheritance detected in package '...'`. An unknown `$type` croaks with `Invalid mro name: '...'`.

set_mro

Set the method-resolution algorithm for `$class` to either `"dfs"` or `"c3"`.

Synopsis

```
mro::set_mro($class, 'c3');
mro::set_mro($class, 'dfs');
```

After the call, subsequent method dispatches on `$class` - and subclasses that inherit the setting - walk the chosen linearization. `get_linear_isa($class)` reflects the new choice on the next invocation.

A name that is not a registered algorithm croaks with `Invalid mro name: '...'`. Usage with any argument count other than two croaks with `Usage: mro::set_mro(classname, type)`. The stash for `$class` is created on demand if it does not yet exist, so selecting an MRO before the package is declared works.

get_mro

Report which method-resolution algorithm is currently in effect for `$class`.

Synopsis

```
my $algo = mro::get_mro($class);   # "dfs" or "c3"
```

Returns the string `"dfs"` or `"c3"`. Classes that have never called `set_mro` or `use mro '...'` report `"dfs"` (Perl's default). Calling on a non-existent class also reports `"dfs"`; the call does not force the stash into existence.

get_isarev

List every class that inherits from `$class`, directly or transitively, via `@ISA`.

Synopsis

```
my $subclasses = mro::get_isarev($class);   # arrayref
```

Returns an array reference of package names: each class whose linearized MRO contains `$class`. This is the inverse of `get_linear_isa` - given a parent, find its descendants.

`UNIVERSAL` is treated specially: its `isarev` list is not populated with every class in the program, even though every class implicitly inherits from it. Check with `is_universal` rather than `get_isarev` when you need that relationship.

Classes with no known subclasses produce an empty array reference.

is_universal

Report whether `$class` is `UNIVERSAL` itself or one of its ancestors via `@ISA`.

Synopsis

```
if (mro::is_universal($class)) { ... }
```

Returns a true value exactly when every class in the program can inherit methods from `$class`. That happens in two cases: the class literally *is* `UNIVERSAL`, or something has pushed it into `@UNIVERSAL::ISA` (directly or indirectly). Most programs never see the second case, but frameworks that mix a trait into `UNIVERSAL` rely on it.

A single argument is required; calling with any other arity croaks with `Usage: mro::is_universal(classname)`.

invalidate_all_method_caches

Invalidate the method cache for every package in the interpreter.

Synopsis

```
mro::invalidate_all_method_caches();
```

The next method dispatch after the call walks `@ISA` from scratch instead of reusing a cached resolution. Use this when you have globally disturbed the class graph - rebuilt `@ISA` wholesale across many packages, or hot-patched method tables - and cannot name every affected class individually. For a targeted invalidation, prefer `method_changed_in`.

Takes no arguments. Any non-empty call croaks with `Usage: mro::invalidate_all_method_caches()`.

get_pkg_gen

Return a counter that increments every time a local method in `$class` changes or its local `@ISA` is modified.

Synopsis

```
my $gen = mro::get_pkg_gen($class);
```

Useful to class-introspection code that wants a cheap "has anything I care about changed since last time?" check. Store the value, do your work, compare the next value against the stored one. Equal values mean nothing local changed; unequal values mean *something* did, but you still have to investigate what.

Changes in superclasses do **not** bump this number - only edits inside `$class` itself. A stash instantiated for a normal package starts at `1`; `$class` with no stash at all returns `0`. Wiping a stash (`undef %Pkg::`) can reset the counter to `0` or `1` depending on how thorough the wipe was.

next::method

Tail-call the next implementation of the currently executing method, passing the original arguments.

Synopsis

```
sub greet {
    my $self = shift;
    $self->next::method(@_);   # call the parent implementation
}
```

Resolves the next method via the C3 linearization of `$self` and jumps to it as if with `goto &sub`. Control does not return to the caller of `next::method`; the resolved method's return value is the one the original caller sees.

Croaks with `No next::method 'NAME' found for CLASS` when nothing further in the linearization implements the method. Use `maybe::next::method` or `next::can` if the absence of a further implementation is expected.

next::can

Return a code reference to the next implementation of the currently executing method, or `undef` if there is none.

Synopsis

```
my $cv = $self->next::can;
$cv->($self, @args) if $cv;
```

Looks at the method currently on the call stack, walks the C3 linearization of `$self` past its defining package, and returns the first same-named method found further down the list as a CV reference. Unlike `next::method`, finding no such method is not fatal - it returns `undef` so you can decide how to handle the absence.

Must be called inside a method body. Top-level or non-method callers croak with `next::method/next::can/maybe::next::method must be used in method context`.

maybe::next::method

Tail-call the next implementation of the currently executing method if one exists; otherwise return quietly.

Synopsis

```
sub DESTROY {
    my $self = shift;
    ...                         # cleanup
    $self->maybe::next::method;
}
```

Equivalent to `$self->next::method(@_) if $self->next::can` in the common case. The usual reason to reach for it is a `DESTROY` or hook method where missing parent implementations are normal.

It does not work as the target of `goto &maybe::next::method`: after the `goto` the method that did it is no longer on the call stack, so the lookup starts from its caller instead - at top level that croaks with `next::method/next::can/maybe::next::method must be used in method context`.

5.2.143 ok

Alternative to Test::More::use_ok

SYNOPSIS

```
use ok 'Some::Module';
```

DESCRIPTION

With this module, simply change all `use_ok` in test scripts to `use ok`, and they will be executed at `BEGIN` time.

Please see *Test::use::ok* for the full description.

CC0 1.0 Universal

To the extent possible under law, 唐鳳 has waived all copyright and related or neighboring rights to *Test::use::ok*.

This work is published from Taiwan.

5.2.144 open

perl pragma to set default PerlIO layers for input and output

SYNOPSIS

```
use open IN  => ':crlf', OUT => ':raw';
open my $in, '<', 'foo.txt' or die "open failed: $!";
my $line = <$in>; # CRLF translated
close $in;
open my $out, '>', 'bar.txt' or die "open failed: $!";
print $out $line; # no translation of bytes
close $out;

use open OUT => ':encoding(UTF-8)';
use open IN  => ':encoding(iso-8859-7)';

use open IO  => ':locale';

# IO implicit only for :utf8, :encoding, :locale
use open ':encoding(UTF-8)';
use open ':encoding(iso-8859-7)';
use open ':locale';

# with :std, also affect global standard handles
use open ':std', ':encoding(UTF-8)';
use open ':std', OUT => ':encoding(cp1252)';
use open ':std', IO => ':raw :encoding(UTF-16LE)';
```

DESCRIPTION

Full-fledged support for I/O layers is now implemented provided Perl is configured to use PerlIO as its IO system (which has been the default since 5.8, and the only supported configuration since 5.16).

The open pragma serves as one of the interfaces to declare default “layers” (previously known as “disciplines”) for all I/O. Any open(), readpipe() (aka qx//) and similar opera-

tors found within the lexical scope of this pragma will use the declared defaults via the `${^OPEN}` variable.

Layers are specified with a leading colon by convention. You can specify a stack of multiple layers as a space-separated string. See *PerlIO* for more information on the available layers.

With the `IN` subpragma you can declare the default layers of input streams, and with the `OUT` subpragma you can declare the default layers of output streams. With the `IO` subpragma (may be omitted for `:utf8`, `:locale`, or `:encoding`) you can control both input and output streams simultaneously.

When open() is given an explicit list of layers (with the three-arg syntax), they override the list declared using this pragma. open() can also be given a single colon (:) for a layer name, to override this pragma and use the default as detailed in *"Defaults and how to override them" in PerlIO*.

To translate from and to an arbitrary text encoding, use the `:encoding` layer. The matching of encoding names in `:encoding` is loose: case does not matter, and many encodings have several aliases. See Encode::Supported for details and the list of supported locales.

If you want to set your encoding layers based on your locale environment variables, you can use the `:locale` pseudo-layer. For example:

```
$ENV{LANG} = 'ru_RU.KOI8-R';
# the :locale will probe the locale environment variables like LANG
use open OUT => ':locale';
open(my $out, '>', 'koi8') or die "open failed: $!";
print $out chr(0x430); # CYRILLIC SMALL LETTER A = KOI8-R 0xc1
close $out;
open(my $in, '<', 'koi8') or die "open failed: $!";
printf "%#x\n", ord(<$in>); # this should print 0xc1
close $in;
```

The logic of `:locale` is described in full in *"The `:locale` sub-pragma" in encoding*, but in short it is first trying nl_langinfo(CODESET) and then guessing from the LC_ALL and LANG locale environment variables. `:locale` also implicitly turns on `:std`.

`:std` is not a layer but an additional subpragma. When specified in the import list, it activates an additional functionality of pushing the layers selected for input/output handles to the standard filehandles (STDIN, STDOUT, STDERR). If the new layers and existing layer stack both end with an `:encoding` layer, the existing `:encoding` layer will also be removed.

For example, if both input and out are chosen to be `:encoding(UTF-8)`, a `:std` will mean that STDIN, STDOUT, and STDERR will also have `:encoding(UTF-8)` set. On the other hand, if only output is chosen to be in `:encoding(koi8r)`, a `:std` will cause only the STDOUT and STDERR to be in `koi8r`.

The effect of `:std` is not lexical as it modifies the layer stack of the global handles. If you wish to apply only this global effect and not the effect on handles that are opened in that scope, you can isolate the call to this pragma in its own lexical scope.

```
{ use open ':std', IO => ':encoding(UTF-8)' }
```

Before Perl 5.34, `:std` would only apply the first layer provided that is either `:utf8` or has a layer argument, e.g. `:encoding(UTF-8)`. Since Perl 5.34 it will apply the same layer stack it provides to `${^OPEN}`.

IMPLEMENTATION DETAILS

It is called by `import` to validate the layers:

```
PerlIO::Layer::->find("perlio")
```

The return value (if defined) is a Perl object, of class `PerlIO::Layer` which is created by the C code in `perlio.c`. As yet there is nothing useful you can do with the object at the perl level.

5.2.145 ops

Perl pragma to restrict unsafe operations when compiling

SYNOPSIS

```
perl -Mops=:default ...    # only allow reasonably safe operations

perl -M-ops=system ...     # disable the 'system' opcode
```

DESCRIPTION

Since the ops pragma currently has an irreversible global effect, it is only of significant practical use with the `-M` option on the command line.

See the *Opcode* module for information about opcodes, optags, opmasks and important information about safety.

5.2.146 overload

Package for overloading Perl operations

SYNOPSIS

```
package SomeThing;

use overload
    '+' => \&myadd,
```

(continues on next page)

(continued from previous page)

```
    '-' => \&mysub;
    # etc
...

package main;
$a = SomeThing->new( 57 );
$b = 5 + $a;
...
if (overload::Overloaded $b) {...}
...
$strval = overload::StrVal $b;
```

DESCRIPTION

This pragma allows overloading of Perl's operators for a class. To overload built-in functions, see *"Overriding Built-in Functions" in perlsub* instead.

Fundamentals

Declaration

Arguments of the `use overload` directive are (key, value) pairs. For the full set of legal keys, see "Overloadable Operations" below.

Operator implementations (the values) can be subroutines, references to subroutines, or anonymous subroutines - in other words, anything legal inside a `&{ ... }` call. Values specified as strings are interpreted as method names. Thus

```
package Number;
use overload
    "-" => "minus",
    "*=" => \&muas,
    '""' => sub { ...; };
```

declares that subtraction is to be implemented by method `minus()` in the class `Number` (or one of its base classes), and that the function `Number::muas()` is to be used for the assignment form of multiplication, `*=`. It also defines an anonymous subroutine to implement stringification: this is called whenever an object blessed into the package `Number` is used in a string context (this subroutine might, for example, return the number as a Roman numeral).

Calling Conventions and Magic Autogeneration

The following sample implementation of `minus()` (which assumes that `Number` objects are simply blessed references to scalars) illustrates the calling conventions:

```
package Number;
sub minus {
    my ($self, $other, $swap) = @_;
```

(continues on next page)

(continued from previous page)

```
    my $result = $$self - $other;         # *
    $result = -$result if $swap;
    ref $result ? $result : bless \$result;
}
# * may recurse once - see table below
```

Three arguments are passed to all subroutines specified in the `use overload` directive (with exceptions - see below, particularly "nomethod").

The first of these is the operand providing the overloaded operator implementation - in this case, the object whose `minus()` method is being called.

The second argument is the other operand, or `undef` in the case of a unary operator.

The third argument is set to TRUE if (and only if) the two operands have been swapped. Perl may do this to ensure that the first argument (`$self`) is an object implementing the overloaded operation, in line with general object calling conventions. For example, if `$x` and `$y` are `Numbers`:

```
operation    |   generates a call to
=============|======================
$x - $y      |   minus($x, $y, '')
$x - 7       |   minus($x, 7, '')
7 - $x       |   minus($x, 7, 1)
```

Perl may also use `minus()` to implement other operators which have not been specified in the `use overload` directive, according to the rules for "Magic Autogeneration" described later. For example, the `use overload` above declared no subroutine for any of the operators `--`, neg (the overload key for unary minus), or `-=`. Thus

```
operation    |   generates a call to
=============|======================
-$x          |   minus($x, 0, 1)
$x--         |   minus($x, 1, undef)
$x -= 3      |   minus($x, 3, undef)
```

Note the `undefs`: where autogeneration results in the method for a standard operator which does not change either of its operands, such as `-`, being used to implement an operator which changes the operand ("mutators": here, `--` and `-=`), Perl passes undef as the third argument. This still evaluates as FALSE, consistent with the fact that the operands have not been swapped, but gives the subroutine a chance to alter its behaviour in these cases.

In all the above examples, `minus()` is required only to return the result of the subtraction: Perl takes care of the assignment to $x. In fact, such methods should *not* modify their operands, even if `undef` is passed as the third argument (see "Overloadable Operations").

The same is not true of implementations of `++` and `--`: these are expected to modify their operand. An appropriate implementation of `--` might look like

```
use overload '--' => "decr",
    # ...
sub decr { --${$_[0]}; }
```

If the "bitwise" feature is enabled (see *feature*), a fifth TRUE argument is passed to subroutines handling &, |, ^ and ~. This indicates that the caller is expecting numeric behaviour. The fourth argument will be `undef`, as that position (`$_[3]`) is reserved for use by "nomethod".

Mathemagic, Mutators, and Copy Constructors

The term 'mathemagic' describes the overloaded implementation of mathematical operators. Mathemagical operations raise an issue. Consider the code:

```
$a = $b;
--$a;
```

If `$a` and `$b` are scalars then after these statements

```
$a == $b - 1
```

An object, however, is a reference to blessed data, so if `$a` and `$b` are objects then the assignment `$a = $b` copies only the reference, leaving `$a` and `$b` referring to the same object data. One might therefore expect the operation `--$a` to decrement `$b` as well as `$a`. However, this would not be consistent with how we expect the mathematical operators to work.

Perl resolves this dilemma by transparently calling a copy constructor before calling a method defined to implement a mutator (`--`, `+=`, and so on.). In the above example, when Perl reaches the decrement statement, it makes a copy of the object data in `$a` and assigns to `$a` a reference to the copied data. Only then does it call `decr()`, which alters the copied data, leaving `$b` unchanged. Thus the object metaphor is preserved as far as possible, while mathemagical operations still work according to the arithmetic metaphor.

Note: the preceding paragraph describes what happens when Perl autogenerates the copy constructor for an object based on a scalar. For other cases, see "Copy Constructor".

Overloadable Operations

The complete list of keys that can be specified in the `use overload` directive are given, separated by spaces, in the values of the hash `%overload::ops`:

```
with_assign          => '+ - * / % ** << >> x .',
assign               => '+= -= *= /= %= **= <<= >>= x= .=',
num_comparison       => '< <= > >= == !=',
'3way_comparison'    => '<=> cmp',
str_comparison       => 'lt le gt ge eq ne',
binary               => '& &= | |= ^ ^= &. &.= |. |.= ^. ^.=',
unary                => 'neg ! ~ ~.',
mutators             => '++ --',
```

(continues on next page)

(continued from previous page)

```
func                => 'atan2 cos sin exp abs log sqrt int',
conversion          => 'bool "" 0+ qr',
iterators           => '<>',
filetest            => '-X',
dereferencing       => '${} @{} %{} &{} *{}',
matching            => '~~',
special             => 'nomethod fallback =',
```

Most of the overloadable operators map one-to-one to these keys. Exceptions, including additional overloadable operations not apparent from this hash, are included in the notes which follow. This list is subject to growth over time.

A warning is issued if an attempt is made to register an operator not found above.

- `not`

  The operator `not` is not a valid key for `use overload`. However, if the operator `!` is overloaded then the same implementation will be used for `not` (since the two operators differ only in precedence).

- `neg`

  The key `neg` is used for unary minus to disambiguate it from binary `-`.

- `++`, `--`

  Assuming they are to behave analogously to Perl's `++` and `--`, overloaded implementations of these operators are required to mutate their operands.

  No distinction is made between prefix and postfix forms of the increment and decrement operators: these differ only in the point at which Perl calls the associated subroutine when evaluating an expression.

- *Assignments*

  ```
  +=   -=   *=   /=   %=   **=   <<=   >>=   x=   .=
  &=   |=   ^=   &.=   |.=   ^.=
  ```

  Simple assignment is not overloadable (the `'='` key is used for the "Copy Constructor"). Perl does have a way to make assignments to an object do whatever you want, but this involves using tie(), not overload - see *"tie" in perlfunc* and the "COOKBOOK" examples below.

  The subroutine for the assignment variant of an operator is required only to return the result of the operation. It is permitted to change the value of its operand (this is safe because Perl calls the copy constructor first), but this is optional since Perl assigns the returned value to the left-hand operand anyway.

  An object that overloads an assignment operator does so only in respect of assignments to that object. In other words, Perl never calls the corresponding methods with the third argument (the "swap" argument) set to TRUE. For example, the operation

  ```
  $a *= $b
  ```

cannot lead to $b's implementation of *= being called, even if $a is a scalar. (It can, however, generate a call to $b's method for *).

- *Non-mutators with a mutator variant*

```
+  -  *  /  %  **  <<  >>  x  .
&  |  ^  &.  |.  ^.
```

As described above, Perl may call methods for operators like + and & in the course of implementing missing operations like ++, +=, and &=. While these methods may detect this usage by testing the definedness of the third argument, they should in all cases avoid changing their operands. This is because Perl does not call the copy constructor before invoking these methods.

- `int`

Traditionally, the Perl function `int` rounds to 0 (see *"int" in perlfunc*), and so for floating-point-like types one should follow the same semantic.

- *String, numeric, boolean, and regexp conversions*

```
""  0+  bool
```

These conversions are invoked according to context as necessary. For example, the subroutine for `'""'` (stringify) may be used where the overloaded object is passed as an argument to `print`, and that for `'bool'` where it is tested in the condition of a flow control statement (like `while`) or the ternary `?:` operation.

Of course, in contexts like, for example, `$obj + 1`, Perl will invoke `$obj`'s implementation of + rather than (in this example) converting `$obj` to a number using the numify method `'0+'` (an exception to this is when no method has been provided for `'+'` and "fallback" is set to TRUE).

The subroutines for `'""'`, `'0+'`, and `'bool'` can return any arbitrary Perl value. If the corresponding operation for this value is overloaded too, the operation will be called again with this value.

As a special case if the overload returns the object itself then it will be used directly. An overloaded conversion returning the object is probably a bug, because you're likely to get something that looks like `YourPackage=HASH(0x8172b34)`.

```
qr
```

The subroutine for `'qr'` is used wherever the object is interpolated into or used as a regexp, including when it appears on the RHS of a `=~` or `!~` operator.

`qr` must return a compiled regexp, or a ref to a compiled regexp (such as `qr//` returns), and any further overloading on the return value will be ignored.

- *Iteration*

If `<>` is overloaded then the same implementation is used for both the *read-filehandle* syntax `<$var>` and *globbing* syntax `<${var}>`.

- *File tests*

The key `'-X'` is used to specify a subroutine to handle all the filetest operators (`-f`, `-x`, and so on: see *"-X" in perlfunc* for the full list); it is not possible to overload

any filetest operator individually. To distinguish them, the letter following the '-' is passed as the second argument (that is, in the slot that for binary operators is used to pass the second operand).

Calling an overloaded filetest operator does not affect the stat value associated with the special filehandle _. It still refers to the result of the last `stat`, `lstat` or unoverloaded filetest.

This overload was introduced in Perl 5.12.

- *Matching*

  The key `"~~"` allows you to override the smart matching logic used by the ~~ operator and the switch construct (`given`/`when`). See "Switch Statements" in perlsyn and *feature*.

  Unusually, the overloaded implementation of the smart match operator does not get full control of the smart match behaviour. In particular, in the following code:

```
package Foo;
use overload '~~' => 'match';

my $obj =  Foo->new();
$obj ~~ [ 1,2,3 ];
```

  the smart match does *not* invoke the method call like this:

```
$obj->match([1,2,3],0);
```

  rather, the smart match distributive rule takes precedence, so $obj is smart matched against each array element in turn until a match is found, so you may see between one and three of these calls instead:

```
$obj->match(1,0);
$obj->match(2,0);
$obj->match(3,0);
```

  Consult the match table in *"Smartmatch Operator" in perlop* for details of when overloading is invoked.

- *Dereferencing*

```
${}  @{}  %{}  &{}  *{}
```

  If these operators are not explicitly overloaded then they work in the normal way, yielding the underlying scalar, array, or whatever stores the object data (or the appropriate error message if the dereference operator doesn't match it). Defining a catch-all `'nomethod'` (see below) makes no difference to this as the catch-all function will not be called to implement a missing dereference operator.

  If a dereference operator is overloaded then it must return a *reference* of the appropriate type (for example, the subroutine for key `'${}'` should return a reference to a scalar, not a scalar), or another object which overloads the operator: that is, the subroutine only determines what is dereferenced and the actual dereferencing is left to Perl. As a special case, if the subroutine returns the object itself then it will not be called again - avoiding infinite recursion.

- *Special*

```
nomethod  fallback  =
```

  See “Special Keys for `use overload`”.

Magic Autogeneration

If a method for an operation is not found then Perl tries to autogenerate a substitute implementation from the operations that have been defined.

Note: the behaviour described in this section can be disabled by setting `fallback` to FALSE (see “fallback”).

In the following tables, numbers indicate priority. For example, the table below states that, if no implementation for `'!'` has been defined then Perl will implement it using `'bool'` (that is, by inverting the value returned by the method for `'bool'`); if boolean conversion is also unimplemented then Perl will use `'0+'` or, failing that, `'""'`.

```
operator | can be autogenerated from
         |
         | 0+   ""   bool   .   x
=========|========================
   0+    |       1     2
   ""    |  1          2
   bool  |  1    2
   int   |  1    2     3
   !     |  2    3     1
   qr    |  2    1     3
   .     |  2    1     3
   x     |  2    1     3
   .=    |  3    2     4    1
   x=    |  3    2     4         1
   <>    |  2    1     3
   -X    |  2    1     3
```

Note: The iterator (`'<>'`) and file test (`'-X'`) operators work as normal: if the operand is not a blessed glob or IO reference then it is converted to a string (using the method for `'""'`, `'0+'`, or `'bool'`) to be interpreted as a glob or filename.

```
operator | can be autogenerated from
         |
         |  <   <=>   neg   -=    -
=========|==========================
   neg   |                        1
   -=    |                        1
   --    |                    1   2
   abs   | a1    a2    b1        b2    [*]
   <     |        1
   <=    |        1
   >     |        1
   >=    |        1
```

(continues on next page)

(continued from previous page)

```
   ==     |         1
   !=     |         1

* one from [a1, a2] and one from [b1, b2]
```

Just as numeric comparisons can be autogenerated from the method for `'<=>'`, string comparisons can be autogenerated from that for `'cmp'`:

```
 operators           |  can be autogenerated from
=====================|============================
 lt gt le ge eq ne   |  cmp
```

Similarly, autogeneration for keys `'+='` and `'++'` is analogous to `'-='` and `'--'` above:

```
operator | can be autogenerated from
         |
         |  +=    +
=========|==========================
    +=   |         1
    ++   |   1     2
```

And other assignment variations are analogous to `'+='` and `'-='` (and similar to `'.='` and `'x='` above):

```
          operator ||  *= /= %= **= <<= >>= &= ^= |= &.= ^.= |.=
-------------------||-----------------------------------------
autogenerated from ||  *  /  %  **  <<  >>  &  ^  |  &.  ^.  |.
```

Note also that the copy constructor (key `'='`) may be autogenerated, but only for objects based on scalars. See “Copy Constructor”.

Minimal Set of Overloaded Operations

Since some operations can be automatically generated from others, there is a minimal set of operations that need to be overloaded in order to have the complete set of overloaded operations at one’s disposal. Of course, the autogenerated operations may not do exactly what the user expects. The minimal set is:

```
+ - * / % ** << >> x
<=> cmp
& | ^ ~ &. |. ^. ~.
atan2 cos sin exp log sqrt int
"" 0+ bool
~~
```

Of the conversions, only one of string, boolean or numeric is needed because each can be generated from either of the other two.

Special Keys for `use overload`

`nomethod`

The `'nomethod'` key is used to specify a catch-all function to be called for any operator that is not individually overloaded. The specified function will be passed four parameters. The first three arguments coincide with those that would have been passed to the corresponding method if it had been defined. The fourth argument is the `use overload` key for that missing method. If the "bitwise" feature is enabled (see *feature*), a fifth TRUE argument is passed to subroutines handling `&`, `|`, `^` and `~` to indicate that the caller is expecting numeric behaviour.

For example, if `$a` is an object blessed into a package declaring

```
use overload 'nomethod' => 'catch_all', # ...
```

then the operation

```
3 + $a
```

could (unless a method is specifically declared for the key `'+'`) result in a call

```
catch_all($a, 3, 1, '+')
```

See "How Perl Chooses an Operator Implementation".

`fallback`

The value assigned to the key `'fallback'` tells Perl how hard it should try to find an alternative way to implement a missing operator.

- defined, but FALSE

  ```
  use overload "fallback" => 0, # ... ;
  ```

  This disables "Magic Autogeneration".

- `undef`

  In the default case where no value is explicitly assigned to `fallback`, magic autogeneration is enabled.

- TRUE

  The same as for `undef`, but if a missing operator cannot be autogenerated then, instead of issuing an error message, Perl is allowed to revert to what it would have done for that operator if there had been no `use overload` directive.

  Note: in most cases, particularly the "Copy Constructor", this is unlikely to be appropriate behaviour.

See "How Perl Chooses an Operator Implementation".

Copy Constructor

As mentioned above, this operation is called when a mutator is applied to a reference that shares its object with some other reference. For example, if `$b` is mathemagical, and `'++'` is overloaded with `'incr'`, and `'='` is overloaded with `'clone'`, then the code

```
$a = $b;
# ... (other code which does not modify $a or $b) ...
++$b;
```

would be executed in a manner equivalent to

```
$a = $b;
# ...
$b = $b->clone(undef, "");
$b->incr(undef, "");
```

Note:

- The subroutine for `'='` does not overload the Perl assignment operator: it is used only to allow mutators to work as described here. (See "Assignments" above.)
- As for other operations, the subroutine implementing '=' is passed three arguments, though the last two are always `undef` and `''`.
- The copy constructor is called only before a call to a function declared to implement a mutator, for example, if `++$b;` in the code above is effected via a method declared for key `'++'` (or 'nomethod', passed `'++'` as the fourth argument) or, by autogeneration, `'+='`. It is not called if the increment operation is effected by a call to the method for `'+'` since, in the equivalent code,

  ```
  $a = $b;
  $b = $b + 1;
  ```

  the data referred to by `$a` is unchanged by the assignment to `$b` of a reference to new object data.
- The copy constructor is not called if Perl determines that it is unnecessary because there is no other reference to the data being modified.
- If `'fallback'` is undefined or TRUE then a copy constructor can be autogenerated, but only for objects based on scalars. In other cases it needs to be defined explicitly. Where an object's data is stored as, for example, an array of scalars, the following might be appropriate:

  ```
  use overload '=' => sub { bless [ @{$_[0]} ] },  # ...
  ```

- If `'fallback'` is TRUE and no copy constructor is defined then, for objects not based on scalars, Perl may silently fall back on simple assignment - that is, assignment of the object reference. In effect, this disables the copy constructor mechanism since no new copy of the object data is created. This is almost certainly not what you want. (It is, however, consistent: for example, Perl's fallback for the `++` operator is to increment the reference itself.)

How Perl Chooses an Operator Implementation

Which is checked first, `nomethod` or `fallback`? If the two operands of an operator are of different types and both overload the operator, which implementation is used? The following are the precedence rules:

1. If the first operand has declared a subroutine to overload the operator then use that implementation.
2. Otherwise, if fallback is TRUE or undefined for the first operand then see if the rules for autogeneration allows another of its operators to be used instead.
3. Unless the operator is an assignment (`+=`, `-=`, etc.), repeat step (1) in respect of the second operand.
4. Repeat Step (2) in respect of the second operand.
5. If the first operand has a “nomethod” method then use that.
6. If the second operand has a “nomethod” method then use that.
7. If `fallback` is TRUE for both operands then perform the usual operation for the operator, treating the operands as numbers, strings, or booleans as appropriate for the operator (see note).
8. Nothing worked - die.

Where there is only one operand (or only one operand with overloading) the checks in respect of the other operand above are skipped.

There are exceptions to the above rules for dereference operations (which, if Step 1 fails, always fall back to the normal, built-in implementations - see Dereferencing), and for ~~ (which has its own set of rules - see `Matching` under “Overloadable Operations” above).

Note on Step 7: some operators have a different semantic depending on the type of their operands. As there is no way to instruct Perl to treat the operands as, e.g., numbers instead of strings, the result here may not be what you expect. See “BUGS AND PITFALLS”.

Losing Overloading

The restriction for the comparison operation is that even if, for example, `cmp` should return a blessed reference, the autogenerated `lt` function will produce only a standard logical value based on the numerical value of the result of `cmp`. In particular, a working numeric conversion is needed in this case (possibly expressed in terms of other conversions).

Similarly, `.=` and `x=` operators lose their mathemagical properties if the string conversion substitution is applied.

When you chop() a mathemagical object it is promoted to a string and its mathemagical properties are lost. The same can happen with other operations as well.

Inheritance and Overloading

Overloading respects inheritance via the @ISA hierarchy. Inheritance interacts with overloading in two ways.

- Method names in the `use overload` directive

  If `value` in

  ```
  use overload key => value;
  ```

  is a string, it is interpreted as a method name - which may (in the usual way) be inherited from another class.

- Overloading of an operation is inherited by derived classes

  Any class derived from an overloaded class is also overloaded and inherits its operator implementations. If the same operator is overloaded in more than one ancestor then the implementation is determined by the usual inheritance rules.

  For example, if `A` inherits from `B` and `C` (in that order), `B` overloads `+` with `\&D::plus_sub`, and `C` overloads `+` by `"plus_meth"`, then the subroutine `D::plus_sub` will be called to implement operation `+` for an object in package `A`.

Note that in Perl version prior to 5.18 inheritance of the `fallback` key was not governed by the above rules. The value of `fallback` in the first overloaded ancestor was used. This was fixed in 5.18 to follow the usual rules of inheritance.

Run-time Overloading

Since all `use` directives are executed at compile-time, the only way to change overloading during run-time is to

```
eval 'use overload "+" => \&addmethod';
```

You can also use

```
eval 'no overload "+", "--", "<="';
```

though the use of these constructs during run-time is questionable.

Public Functions

Package `overload.pm` provides the following public functions:

- overload::StrVal(arg)

  Gives the string value of `arg` as in the absence of stringify overloading. If you are using this to get the address of a reference (useful for checking if two references point to the same thing) then you may be better off using `builtin::refaddr()` or `Scalar::Util::refaddr()`, which are faster.

- overload::Overloaded(arg)

  Returns true if `arg` is subject to overloading of some operations.

- overload::Method(obj,op)

  Returns `undef` or a reference to the method that implements op.

Overloading Constants

For some applications, the Perl parser mangles constants too much. It is possible to hook into this process via `overload::constant()` and `overload::remove_constant()` functions.

These functions take a hash as an argument. The recognized keys of this hash are:

- integer

  to overload integer constants,

- float

  to overload floating point constants,

- binary

  to overload octal and hexadecimal constants,

- q

  to overload q-quoted strings, constant pieces of qq- and qx-quoted strings and here-documents,

- qr

  to overload constant pieces of regular expressions.

The corresponding values are references to functions which take three arguments: the first one is the *initial* string form of the constant, the second one is how Perl interprets this constant, the third one is how the constant is used. Note that the initial string form does not contain string delimiters, and has backslashes in backslash-delimiter combinations stripped (thus the value of delimiter is not relevant for processing of this string). The return value of this function is how this constant is going to be interpreted by Perl. The third argument is undefined unless for overloaded `q`- and `qr`- constants, it is `q` in single-quote context (comes from strings, regular expressions, and single-quote HERE documents), it is `tr` for arguments of `tr`/`y` operators, it is `s` for right-hand side of `s`-operator, and it is `qq` otherwise.

Since an expression `"ab$cd,,"` is just a shortcut for `'ab' . $cd . ',,'`, it is expected that overloaded constant strings are equipped with reasonable overloaded catenation operator, otherwise absurd results will result. Similarly, negative numbers are considered as negations of positive constants.

Note that it is probably meaningless to call the functions overload::constant() and overload::remove_constant() from anywhere but import() and unimport() methods. From these methods they may be called as

```
sub import {
    shift;
    return unless @_;
    die "unknown import: @_" unless @_ == 1 and $_[0] eq ':constant
↪';
    overload::constant integer => sub {Math::BigInt->new(shift)};
}
```

IMPLEMENTATION

What follows is subject to change RSN.

The table of methods for all operations is cached in magic for the symbol table hash for the package. The cache is invalidated during processing of `use overload`, `no overload`, new function definitions, and changes in @ISA.

(Every SVish thing has a magic queue, and magic is an entry in that queue. This is how a single variable may participate in multiple forms of magic simultaneously. For instance, environment variables regularly have two forms at once: their %ENV magic and their taint magic. However, the magic which implements overloading is applied to the stashes, which are rarely used directly, thus should not slow down Perl.)

If a package uses overload, it carries a special flag. This flag is also set when new functions are defined or @ISA is modified. There will be a slight speed penalty on the very first operation thereafter that supports overloading, while the overload tables are updated. If there is no overloading present, the flag is turned off. Thus the only speed penalty thereafter is the checking of this flag.

It is expected that arguments to methods that are not explicitly supposed to be changed are constant (but this is not enforced).

COOKBOOK

Please add examples to what follows!

Two-face Scalars

Put this in `two_face.pm` in your Perl library directory:

```
package two_face;               # Scalars with separate string and
                                # numeric values.
sub new { my $p = shift; bless [@_], $p }
use overload '""' => \&str, '0+' => \&num, fallback => 1;
sub num {shift->[1]}
sub str {shift->[0]}
```

Use it as follows:

```
require two_face;
my $seven = two_face->new("vii", 7);
printf "seven=$seven, seven=%d, eight=%d\n", $seven, $seven+1;
print "seven contains 'i'\n" if $seven =~ /i/;
```

(The second line creates a scalar which has both a string value, and a numeric value.) This prints:

```
seven=vii, seven=7, eight=8
seven contains 'i'
```

Two-face References

Suppose you want to create an object which is accessible as both an array reference and a hash reference.

```
package two_refs;
use overload '%{}' => \&gethash, '@{}' => sub { $ {shift()} };
sub new {
    my $p = shift;
    bless \ [@_], $p;
}
sub gethash {
    my %h;
    my $self = shift;
    tie %h, ref $self, $self;
    \%h;
}

sub TIEHASH { my $p = shift; bless \ shift, $p }
my %fields;
my $i = 0;
$fields{$_} = $i++ foreach qw{zero one two three};
sub STORE {
    my $self = ${shift()};
    my $key = $fields{shift()};
    defined $key or die "Out of band access";
    $$self->[$key] = shift;
}
sub FETCH {
    my $self = ${shift()};
    my $key = $fields{shift()};
    defined $key or die "Out of band access";
    $$self->[$key];
}
```

Now one can access an object using both the array and hash syntax:

```
my $bar = two_refs->new(3,4,5,6);
$bar->[2] = 11;
$bar->{two} == 11 or die 'bad hash fetch';
```

Note several important features of this example. First of all, the *actual* type of $bar is a scalar reference, and we do not overload the scalar dereference. Thus we can get the *actual* non-overloaded contents of $bar by just using `$$bar` (what we do in functions which overload dereference). Similarly, the object returned by the TIEHASH() method is a scalar reference.

Second, we create a new tied hash each time the hash syntax is used. This allows us not to worry about a possibility of a reference loop, which would lead to a memory leak.

Both these problems can be cured. Say, if we want to overload hash dereference on a reference to an object which is *implemented* as a hash itself, the only problem one has to circumvent is how to access this *actual* hash (as opposed to the *virtual* hash exhibited

by the overloaded dereference operator). Here is one possible fetching routine:

```
sub access_hash {
    my ($self, $key) = (shift, shift);
    my $class = ref $self;
    bless $self, 'overload::dummy'; # Disable overloading of %{}
    my $out = $self->{$key};
    bless $self, $class;            # Restore overloading
    $out;
}
```

To remove creation of the tied hash on each access, one may an extra level of indirection which allows a non-circular structure of references:

```
package two_refs1;
use overload
    '%{}' => sub { ${shift()}->[1] },
    '@{}' => sub { ${shift()}->[0] };

sub new {
    my $p = shift;
    my $a = [@_];
    my %h;
    tie %h, $p, $a;
    bless \ [$a, \%h], $p;
}
sub gethash {
    my %h;
    my $self = shift;
    tie %h, ref $self, $self;
    \%h;
}

sub TIEHASH { my $p = shift; bless \ shift, $p }
my %fields;
my $i = 0;
$fields{$_} = $i++ foreach qw{zero one two three};
sub STORE {
    my $a = ${shift()};
    my $key = $fields{shift()};
    defined $key or die "Out of band access";
    $a->[$key] = shift;
}
sub FETCH {
    my $a = ${shift()};
    my $key = $fields{shift()};
    defined $key or die "Out of band access";
    $a->[$key];
}
```

Now if $baz is overloaded like this, then `$baz` is a reference to a reference to the intermediate array, which keeps a reference to an actual array, and the access hash. The

tie()ing object for the access hash is a reference to a reference to the actual array, so

- There are no loops of references.
- Both "objects" which are blessed into the class `two_refs1` are references to a reference to an array, thus references to a *scalar*. Thus the accessor expression `$$foo->[$ind]` involves no overloaded operations.

Symbolic Calculator

Put this in `symbolic.pm` in your Perl library directory:

```
package symbolic;            # Primitive symbolic calculator
use overload nomethod => \&wrap;

sub new { shift; bless ['n', @_] }
sub wrap {
    my ($obj, $other, $inv, $meth) = @_;
    ($obj, $other) = ($other, $obj) if $inv;
    bless [$meth, $obj, $other];
}
```

This module is very unusual as overloaded modules go: it does not provide any usual overloaded operators, instead it provides an implementation for `"nomethod"`. In this example the `nomethod` subroutine returns an object which encapsulates operations done over the objects: `symbolic->new(3)` contains `['n', 3]`, `2 + symbolic->new(3)` contains `['+', 2, ['n', 3]]`.

Here is an example of the script which "calculates" the side of circumscribed octagon using the above package:

```
require symbolic;
my $iter = 1;                   # 2**($iter+2) = 8
my $side = symbolic->new(1);
my $cnt = $iter;

while ($cnt--) {
    $side = (sqrt(1 + $side**2) - 1)/$side;
}
print "OK\n";
```

The value of $side is

```
['/', ['-', ['sqrt', ['+', 1, ['**', ['n', 1], 2]],
                     undef], 1], ['n', 1]]
```

Note that while we obtained this value using a nice little script, there is no simple way to *use* this value. In fact this value may be inspected in debugger (see perldebug), but only if `bareStringify` **O**ption is set, and not via p command.

If one attempts to print this value, then the overloaded operator `""` will be called, which will call `nomethod` operator. The result of this operator will be stringified again, but this result is again of type `symbolic`, which will lead to an infinite loop.

Add a pretty-printer method to the module `symbolic.pm`:

```
sub pretty {
    my ($meth, $a, $b) = @{+shift};
    $a = 'u' unless defined $a;
    $b = 'u' unless defined $b;
    $a = $a->pretty if ref $a;
    $b = $b->pretty if ref $b;
    "[$meth $a $b]";
}
```

Now one can finish the script by

```
print "side = ", $side->pretty, "\n";
```

The method `pretty` is doing object-to-string conversion, so it is natural to overload the operator `""` using this method. However, inside such a method it is not necessary to pretty-print the *components* `$a` and `$b` of an object. In the above subroutine `"[$meth $a $b]"` is a catenation of some strings and components `$a` and `$b`. If these components use overloading, the catenation operator will look for an overloaded operator `.`; if not present, it will look for an overloaded operator `""`. Thus it is enough to use

```
use overload nomethod => \&wrap, '""' => \&str;
sub str {
    my ($meth, $a, $b) = @{+shift};
    $a = 'u' unless defined $a;
    $b = 'u' unless defined $b;
    "[$meth $a $b]";
}
```

Now one can change the last line of the script to

```
print "side = $side\n";
```

which outputs

```
side = [/ [- [sqrt [+ 1 [** [n 1 u] 2]] u] 1] [n 1 u]]
```

and one can inspect the value in debugger using all the possible methods.

Something is still amiss: consider the loop variable `$cnt` of the script. It was a number, not an object. We cannot make this value of type `symbolic`, since then the loop will not terminate.

Indeed, to terminate the cycle, the `$cnt` should become false. However, the operator `bool` for checking falsity is overloaded (this time via overloaded `""`), and returns a long string, thus any object of type `symbolic` is true. To overcome this, we need a way to compare an object to 0. In fact, it is easier to write a numeric conversion routine.

Here is the text of `symbolic.pm` with such a routine added (and slightly modified str()):

```
package symbolic;           # Primitive symbolic calculator
use overload
```

(continues on next page)

(continued from previous page)

```
    nomethod => \&wrap, '"' => \&str, '0+' => \&num;

sub new { shift; bless ['n', @_] }
sub wrap {
    my ($obj, $other, $inv, $meth) = @_;
    ($obj, $other) = ($other, $obj) if $inv;
    bless [$meth, $obj, $other];
}
sub str {
    my ($meth, $a, $b) = @{+shift};
    $a = 'u' unless defined $a;
    if (defined $b) {
        "[$meth $a $b]";
    } else {
        "[$meth $a]";
    }
}
my %subr = (
    n => sub {$_[0]},
    sqrt => sub {sqrt $_[0]},
    '-' => sub {shift() - shift()},
    '+' => sub {shift() + shift()},
    '/' => sub {shift() / shift()},
    '*' => sub {shift() * shift()},
    '**' => sub {shift() ** shift()},
);
sub num {
    my ($meth, $a, $b) = @{+shift};
    my $subr = $subr{$meth}
    or die "Do not know how to ($meth) in symbolic";
    $a = $a->num if ref $a eq __PACKAGE__;
    $b = $b->num if ref $b eq __PACKAGE__;
    $subr->($a,$b);
}
```

All the work of numeric conversion is done in %subr and num(). Of course, %subr is not complete, it contains only operators used in the example below. Here is the extra-credit question: why do we need an explicit recursion in num()? (Answer is at the end of this section.)

Use this module like this:

```
require symbolic;
my $iter = symbolic->new(2);        # 16-gon
my $side = symbolic->new(1);
my $cnt = $iter;

while ($cnt) {
    $cnt = $cnt - 1;                # Mutator '--' not implemented
    $side = (sqrt(1 + $side**2) - 1)/$side;
```

(continues on next page)

(continued from previous page)

```
}
printf "%s=%f\n", $side, $side;
printf "pi=%f\n", $side*(2**($iter+2));
```

It prints (without so many line breaks)

```
[/ [- [sqrt [+ 1 [** [/ [- [sqrt [+ 1 [** [n 1] 2]]] 1]
                        [n 1]] 2]]] 1]
[/ [- [sqrt [+ 1 [** [n 1] 2]]] 1] [n 1]]]=0.198912
pi=3.182598
```

The above module is very primitive. It does not implement mutator methods (++, -= and so on), does not do deep copying (not required without mutators!), and implements only those arithmetic operations which are used in the example.

To implement most arithmetic operations is easy; one should just use the tables of operations, and change the code which fills %subr to

```
my %subr = ( 'n' => sub {$_[0]} );
foreach my $op (split " ", $overload::ops{with_assign}) {
    $subr{$op} = $subr{"$op="} = eval "sub {shift() $op shift()}";
}
my @bins = qw(binary 3way_comparison num_comparison str_comparison);
foreach my $op (split " ", "@overload::ops{ @bins }") {
    $subr{$op} = eval "sub {shift() $op shift()}";
}
foreach my $op (split " ", "@overload::ops{qw(unary func)}") {
    print "defining '$op'\n";
    $subr{$op} = eval "sub {$op shift()}";
}
```

Since subroutines implementing assignment operators are not required to modify their operands (see “Overloadable Operations” above), we do not need anything special to make += and friends work, besides adding these operators to %subr and defining a copy constructor (needed since Perl has no way to know that the implementation of '+=' does not mutate the argument - see “Copy Constructor”).

To implement a copy constructor, add '=' => \&cpy to use overload line, and code (this code assumes that mutators change things one level deep only, so recursive copying is not needed):

```
sub cpy {
    my $self = shift;
    bless [@$self], ref $self;
}
```

To make ++ and -- work, we need to implement actual mutators, either directly, or in nomethod. We continue to do things inside nomethod, thus add

```
if ($meth eq '++' or $meth eq '--') {
    @$obj = ($meth, (bless [@$obj]), 1); # Avoid circular reference
```

(continues on next page)

(continued from previous page)

```
    return $obj;
}
```

after the first line of wrap(). This is not a most effective implementation, one may consider

```
sub inc { $_[0] = bless ['++', shift, 1]; }
```

instead.

As a final remark, note that one can fill %subr by

```
my %subr = ( 'n' => sub {$_[0]} );
foreach my $op (split " ", $overload::ops{with_assign}) {
    $subr{$op} = $subr{"$op="} = eval "sub {shift() $op shift()}";
}
my @bins = qw(binary 3way_comparison num_comparison str_comparison);
foreach my $op (split " ", "@overload::ops{ @bins }") {
    $subr{$op} = eval "sub {shift() $op shift()}";
}
foreach my $op (split " ", "@overload::ops{qw(unary func)}") {
    $subr{$op} = eval "sub {$op shift()}";
}
$subr{'++'} = $subr{'+'};
$subr{'--'} = $subr{'-'};
```

This finishes implementation of a primitive symbolic calculator in 50 lines of Perl code. Since the numeric values of subexpressions are not cached, the calculator is very slow.

Here is the answer for the exercise: In the case of str(), we need no explicit recursion since the overloaded `.`-operator will fall back to an existing overloaded operator `""`. Overloaded arithmetic operators *do not* fall back to numeric conversion if `fallback` is not explicitly requested. Thus without an explicit recursion num() would convert `['+', $a, $b]` to `$a + $b`, which would just rebuild the argument of num().

If you wonder why defaults for conversion are different for str() and num(), note how easy it was to write the symbolic calculator. This simplicity is due to an appropriate choice of defaults. One extra note: due to the explicit recursion num() is more fragile than sym(): we need to explicitly check for the type of $a and $b. If components $a and $b happen to be of some related type, this may lead to problems.

Really Symbolic Calculator

One may wonder why we call the above calculator symbolic. The reason is that the actual calculation of the value of expression is postponed until the value is *used*.

To see it in action, add a method

```
sub STORE {
    my $obj = shift;
    $#$obj = 1;
```

(continues on next page)

(continued from previous page)

```
    @$obj->[0,1] = ('=', shift);
}
```

to the package `symbolic`. After this change one can do

```
my $a = symbolic->new(3);
my $b = symbolic->new(4);
my $c = sqrt($a**2 + $b**2);
```

and the numeric value of $c becomes 5. However, after calling

```
$a->STORE(12);  $b->STORE(5);
```

the numeric value of $c becomes 13. There is no doubt now that the module symbolic provides a *symbolic* calculator indeed.

To hide the rough edges under the hood, provide a tie()d interface to the package `symbolic`. Add methods

```
sub TIESCALAR { my $pack = shift; $pack->new(@_) }
sub FETCH { shift }
sub nop {  }                    # Around a bug
```

(the bug, fixed in Perl 5.14, is described in "BUGS"). One can use this new interface as

```
tie $a, 'symbolic', 3;
tie $b, 'symbolic', 4;
$a->nop;  $b->nop;              # Around a bug

my $c = sqrt($a**2 + $b**2);
```

Now numeric value of $c is 5. After `$a = 12; $b = 5` the numeric value of $c becomes 13. To insulate the user of the module add a method

```
sub vars { my $p = shift; tie($_, $p), $_->nop foreach @_; }
```

Now

```
my ($a, $b);
symbolic->vars($a, $b);
my $c = sqrt($a**2 + $b**2);

$a = 3; $b = 4;
printf "c5  %s=%f\n", $c, $c;

$a = 12; $b = 5;
printf "c13  %s=%f\n", $c, $c;
```

shows that the numeric value of $c follows changes to the values of $a and $b.

SEE ALSO

The `overloading` pragma can be used to enable or disable overloaded operations within a lexical scope - see *overloading*.

DIAGNOSTICS

When Perl is run with the **-Do** switch or its equivalent, overloading induces diagnostic messages.

Using the `m` command of Perl debugger (see perldebug) one can deduce which operations are overloaded (and which ancestor triggers this overloading). Say, if `eq` is overloaded, then the method `(eq` is shown by debugger. The method `()` corresponds to the `fallback` key (in fact a presence of this method shows that this package has overloading enabled, and it is what is used by the `Overloaded` function of module `overload`).

The module might issue the following warnings:

- Odd number of arguments for overload::constant

  (W) The call to overload::constant contained an odd number of arguments. The arguments should come in pairs.

- '%s' is not an overloadable type

  (W) You tried to overload a constant type the overload package is unaware of.

- '%s' is not a code reference

  (W) The second (fourth, sixth, ...) argument of overload::constant needs to be a code reference. Either an anonymous subroutine, or a reference to a subroutine.

- overload arg '%s' is invalid

  (W) `use overload` was passed an argument it did not recognize. Did you mistype an operator?

BUGS AND PITFALLS

- A pitfall when fallback is TRUE and Perl resorts to a built-in implementation of an operator is that some operators have more than one semantic, for example `|`:

```
use overload '0+' => sub { $_[0]->{n}; },
    fallback => 1;
my $x = bless { n => 4 }, "main";
my $y = bless { n => 8 }, "main";
print $x | $y, "\n";
```

  You might expect this to output "12". In fact, it prints "<": the ASCII result of treating "|" as a bitwise string operator - that is, the result of treating the operands as the strings "4" and "8" rather than numbers. The fact that numify (`0+`) is implemented but stringify (`""`) isn't makes no difference since the latter is simply autogenerated from the former.

The only way to change this is to provide your own subroutine for `'|'`.

- Magic autogeneration increases the potential for inadvertently creating self-referential structures. Currently Perl will not free self-referential structures until cycles are explicitly broken. For example,

```
use overload '+' => 'add';
sub add { bless [ \$_[0], \$_[1] ] };
```

is asking for trouble, since

```
$obj += $y;
```

will effectively become

```
$obj = add($obj, $y, undef);
```

with the same result as

```
$obj = [\$obj, \$foo];
```

Even if no *explicit* assignment-variants of operators are present in the script, they may be generated by the optimizer. For example,

```
"obj = $obj\n"
```

may be optimized to

```
my $tmp = 'obj = ' . $obj;  $tmp .= "\n";
```

- The symbol table is filled with names looking like line-noise.
- This bug was fixed in Perl 5.18, but may still trip you up if you are using older versions:

  For the purpose of inheritance every overloaded package behaves as if `fallback` is present (possibly undefined). This may create interesting effects if some package is not overloaded, but inherits from two overloaded packages.

- Before Perl 5.14, the relation between overloading and tie()ing was broken. Overloading was triggered or not based on the *previous* class of the tie()d variable.

  This happened because the presence of overloading was checked too early, before any tie()d access was attempted. If the class of the value FETCH()ed from the tied variable does not change, a simple workaround for code that is to run on older Perl versions is to access the value (via `() = $foo` or some such) immediately after tie()ing, so that after this call the *previous* class coincides with the current one.

- Barewords are not covered by overloaded string constants.
- The range operator `..` cannot be overloaded.

5.2.147 overloading

perl pragma to lexically control overloading

SYNOPSIS

```
{
    no overloading;
    my $str = "$object"; # doesn't call stringification overload
}

# it's lexical, so this stringifies:
warn "$object";

# it can be enabled per op
no overloading qw("");
warn "$object";

# and also reenabled
use overloading;
```

DESCRIPTION

This pragma allows you to lexically disable or enable overloading.

- `no overloading`

  Disables overloading entirely in the current lexical scope.

- `no overloading @ops`

  Disables only specific overloads in the current lexical scope.

- `use overloading`

  Reenables overloading in the current lexical scope.

- `use overloading @ops`

  Reenables overloading only for specific ops in the current lexical scope.

5.2.148 parent

Establish an ISA relationship with base classes at compile time

SYNOPSIS

```
package Baz;
use parent qw(Foo Bar);
```

DESCRIPTION

Allows you to both load one or more modules, while setting up inheritance from those modules at the same time. Mostly similar in effect to

```
package Baz;
BEGIN {
    require Foo;
    require Bar;
    push @ISA, qw(Foo Bar);
}
```

By default, every base class needs to live in a file of its own. If you want to have a subclass and its parent class in the same file, you can tell `parent` not to load any modules by using the `-norequire` switch:

```
package Foo;
sub exclaim { "I CAN HAS PERL" }

package DoesNotLoadFooBar;
use parent -norequire, 'Foo', 'Bar';
# will not go looking for Foo.pm or Bar.pm
```

This is equivalent to the following code:

```
package Foo;
sub exclaim { "I CAN HAS PERL" }

package DoesNotLoadFooBar;
push @DoesNotLoadFooBar::ISA, 'Foo', 'Bar';
```

This is also helpful for the case where a package lives within a differently named file:

```
package MyHash;
use Tie::Hash;
use parent -norequire, 'Tie::StdHash';
```

This is equivalent to the following code:

```
package MyHash;
require Tie::Hash;
push @ISA, 'Tie::StdHash';
```

If you want to load a subclass from a file that `require` would not consider an eligible filename (that is, it does not end in either `.pm` or `.pmc`), use the following code:

```
package MySecondPlugin;
require './plugins/custom.plugin'; # contains Plugin::Custom
use parent -norequire, 'Plugin::Custom';
```

HISTORY

This module was forked from *base* to remove the cruft that had accumulated in it.

CAVEATS

SEE ALSO

- *base*
- parent::versioned

  A fork of *parent* that provides version checking in parent class modules.

5.2.149 perlfaq

Frequently asked questions about Perl

VERSION

version 5.20250619

DESCRIPTION

The perlfaq comprises several documents that answer the most commonly asked questions about Perl and Perl programming. It's divided by topic into nine major sections outlined in this document.

Where to find the perlfaq

The perlfaq is an evolving document. Read the latest version at https://perldoc.perl.org/perlfaq. It is also included in the standard Perl distribution.

How to contribute to the perlfaq

Review https://github.com/perl-doc-cats/perlfaq/wiki. If you don't find your suggestion create an issue or pull request against https://github.com/perl-doc-cats/perlfaq.

Once approved, changes will be distributed with the next Perl release and subsequently appear at https://perldoc.perl.org/perlfaq.

What if my question isn't answered in the FAQ?

Try the resources in perlfaq2.

TABLE OF CONTENTS

- perlfaq1 - General Questions About Perl
- perlfaq2 - Obtaining and Learning about Perl
- perlfaq3 - Programming Tools
- perlfaq4 - Data Manipulation
- perlfaq5 - Files and Formats
- perlfaq6 - Regular Expressions
- perlfaq7 - General Perl Language Issues
- perlfaq8 - System Interaction
- perlfaq9 - Web, Email and Networking

THE QUESTIONS

perlfaq1: General Questions About Perl

This section of the FAQ answers very general, high-level questions about Perl.

- What is Perl?
- Who supports Perl? Who develops it? Why is it free?
- Which version of Perl should I use?
- What is Raku (Perl 6)?
- How stable is Perl?
- How often are new versions of Perl released?
- Is Perl difficult to learn?
- How does Perl compare with other languages like Java, Python, REXX, Scheme, or Tcl?
- Can I do [task] in Perl?
- When shouldn't I program in Perl?
- What's the difference between "perl" and "Perl"?
- What is a JAPH?

- How can I convince others to use Perl?

perlfaq2: Obtaining and Learning about Perl

This section of the FAQ answers questions about where to find source and documentation for Perl, support, and related matters.

- What machines support Perl? Where do I get it?
- How can I get a binary version of Perl?
- I don't have a C compiler. How can I build my own Perl interpreter?
- I copied the Perl binary from one machine to another, but scripts don't work.
- I grabbed the sources and tried to compile but gdbm/dynamic loading/malloc/linking/... failed. How do I make it work?
- What modules and extensions are available for Perl? What is CPAN?
- Where can I get information on Perl?
- What is perl.com? Perl Mongers? pm.org? perl.org? cpan.org?
- Where can I post questions?
- Perl Books
- Which magazines have Perl content?
- Which Perl blogs should I read?
- What mailing lists are there for Perl?
- Where can I buy a commercial version of Perl?
- Where do I send bug reports?

perlfaq3: Programming Tools

This section of the FAQ answers questions related to programmer tools and programming support.

- How do I do (anything)?
- How can I use Perl interactively?
- How do I find which modules are installed on my system?
- How do I debug my Perl programs?
- How do I profile my Perl programs?
- How do I cross-reference my Perl programs?
- Is there a pretty-printer (formatter) for Perl?
- Is there an IDE or Windows Perl Editor?
- Where can I get Perl macros for vi?
- Where can I get perl-mode or cperl-mode for emacs?
- How can I use curses with Perl?

- How can I write a GUI (X, Tk, Gtk, etc.) in Perl?
- How can I make my Perl program run faster?
- How can I make my Perl program take less memory?
- Is it safe to return a reference to local or lexical data?
- How can I free an array or hash so my program shrinks?
- How can I make my CGI script more efficient?
- How can I hide the source for my Perl program?
- How can I compile my Perl program into byte code or C?
- How can I get `#!perl` to work on [MS-DOS,NT,...]?
- Can I write useful Perl programs on the command line?
- Why don't Perl one-liners work on my DOS/Mac/VMS system?
- Where can I learn about CGI or Web programming in Perl?
- Where can I learn about object-oriented Perl programming?
- Where can I learn about linking C with Perl?
- I've read perlembed, perlguts, etc., but I can't embed perl in my C program; what am I doing wrong?
- When I tried to run my script, I got this message. What does it mean?
- What's MakeMaker?

perlfaq4: Data Manipulation

This section of the FAQ answers questions related to manipulating numbers, dates, strings, arrays, hashes, and miscellaneous data issues.

- Why am I getting long decimals (eg, 19.9499999999999) instead of the numbers I should be getting (eg, 19.95)? - Why is int() broken? - Why isn't my octal data interpreted correctly? - Does Perl have a round() function? What about ceil() and floor()? Trig functions? - How do I convert between numeric representations/bases/radixes? - Why doesn't & work the way I want it to? - How do I multiply matrices? - How do I perform an operation on a series of integers? - How can I output Roman numerals? - Why aren't my random numbers random? - How do I get a random number between X and Y? - How do I find the day or week of the year? - How do I find the current century or millennium? - How can I compare two dates and find the difference? - How can I take a string and turn it into epoch seconds? - How can I find the Julian Day? - How do I find yesterday's date? - Does Perl have a Year 2000 or 2038 problem? Is Perl Y2K compliant? - How do I validate input? - How do I unescape a string? - How do I remove consecutive pairs of characters? - How do I expand function calls in a string? - How do I find matching/nesting anything? - How do I reverse a string? - How do I expand tabs in a string? - How do I reformat a paragraph? - How can I access or change N characters of a string? - How do I change the Nth occurrence of something? - How can I count the number of occurrences of a substring within a string? - How do I capitalize all the words on one line? - How can I split a [character]-delimited string except when inside [character]? - How do I strip blank space from the beginning/end of a string? -

How do I pad a string with blanks or pad a number with zeroes? - How do I extract selected columns from a string? - How do I find the soundex value of a string? - How can I expand variables in text strings? - Does Perl have anything like Ruby's #{} or Python's f string? - What's wrong with always quoting "$vars"? - Why don't my <<HERE documents work? - What is the difference between a list and an array? - What is the difference between $array[1] and @array[1]? - How can I remove duplicate elements from a list or array? - How can I tell whether a certain element is contained in a list or array? - How do I compute the difference of two arrays? How do I compute the intersection of two arrays? - How do I test whether two arrays or hashes are equal? - How do I find the first array element for which a condition is true? - How do I handle linked lists? - How do I handle circular lists? - How do I shuffle an array randomly? - How do I process/modify each element of an array? - How do I select a random element from an array? - How do I permute N elements of a list? - How do I sort an array by (anything)? - How do I manipulate arrays of bits? - Why does defined() return true on empty arrays and hashes? - How do I process an entire hash? - How do I merge two hashes? - What happens if I add or remove keys from a hash while iterating over it? - How do I look up a hash element by value? - How can I know how many entries are in a hash? - How do I sort a hash (optionally by value instead of key)? - How can I always keep my hash sorted? - What's the difference between "delete" and "undef" with hashes? - Why don't my tied hashes make the defined/exists distinction? - How do I reset an each() operation part-way through? - How can I get the unique keys from two hashes? - How can I store a multidimensional array in a DBM file? - How can I make my hash remember the order I put elements into it? - Why does passing a subroutine an undefined element in a hash create it? - How can I make the Perl equivalent of a C structure/C++ class/hash or array of hashes or arrays? - How can I use a reference as a hash key? - How can I check if a key exists in a multilevel hash? - How can I prevent addition of unwanted keys into a hash? - How do I handle binary data correctly? - How do I determine whether a scalar is a number/whole/integer/float? - How do I keep persistent data across program calls? - How do I print out or copy a recursive data structure? - How do I define methods for every class/object? - How do I verify a credit card checksum?

perlfaq5: Files and Formats

This section deals with I/O and the "f" issues: filehandles, flushing, formats, and footers.

- How do I flush/unbuffer an output filehandle? Why must I do this?
- How do I change, delete, or insert a line in a file, or append to the beginning of a file?
- How do I count the number of lines in a file?
- How do I delete the last N lines from a file?
- How can I use Perl's `-i` option from within a program?
- How can I copy a file?
- How do I make a temporary file name?
- How can I manipulate fixed-record-length files?
- How can I make a filehandle local to a subroutine? How do I pass filehandles between subroutines? How do I make an array of filehandles?

- How can I use a filehandle indirectly?
- How can I open a filehandle to a string?
- How can I set up a footer format to be used with write()?
- How can I write() into a string?
- How can I output my numbers with commas added?
- How can I translate tildes (~) in a filename?
- When I open a file read-write, why does it wipe it out?
- Why do I sometimes get an “Argument list too long” when I use <*>?
- How can I open a file named with a leading “>” or trailing blanks?
- How can I reliably rename a file?
- How can I lock a file?
- Why can’t I just open(FH, “>file.lock”)?
- I still don’t get locking. I just want to increment the number in the file. How can I do this?
- All I want to do is append a small amount of text to the end of a file. Do I still have to use locking?
- How do I randomly update a binary file?
- How do I get a file’s timestamp in perl?
- How do I set a file’s timestamp in perl?
- How do I print to more than one file at once?
- How can I read in an entire file all at once?
- How can I read in a file by paragraphs?
- How can I read a single character from a file? From the keyboard?
- How can I tell whether there’s a character waiting on a filehandle?
- How do I do a `tail -f` in perl?
- How do I dup() a filehandle in Perl?
- How do I close a file descriptor by number?
- Why can’t I use “C:\temp\foo” in DOS paths? Why doesn’t `C:\temp\foo.exe` work?
- Why doesn’t glob(“*.*”) get all the files?
- Why does Perl let me delete read-only files? Why does `-i` clobber protected files? Isn’t this a bug in Perl?
- How do I select a random line from a file?
- Why do I get weird spaces when I print an array of lines?
- How do I traverse a directory tree?
- How do I delete a directory tree?

- How do I copy an entire directory?

perlfaq6: Regular Expressions

This section is surprisingly small because the rest of the FAQ is littered with answers involving regular expressions. For example, decoding a URL and checking whether something is a number can be handled with regular expressions, but those answers are found elsewhere in this document (in perlfaq9 : "How do I decode or create those %-encodings on the web" and perlfaq4 : "How do I determine whether a scalar is a number/whole/integer/float", to be precise).

- How can I hope to use regular expressions without creating illegible and unmaintainable code?
- I'm having trouble matching over more than one line. What's wrong?
- How can I pull out lines between two patterns that are themselves on different lines?
- How do I match XML, HTML, or other nasty, ugly things with a regex?
- I put a regular expression into $/ but it didn't work. What's wrong?
- How do I substitute case-insensitively on the LHS while preserving case on the RHS?
- How can I make `\w` match national character sets?
- How can I match a locale-smart version of `/[a-zA-Z]/` ?
- How can I quote a variable to use in a regex?
- What is `/o` really for?
- How do I use a regular expression to strip C-style comments from a file?
- Can I use Perl regular expressions to match balanced text?
- What does it mean that regexes are greedy? How can I get around it?
- How do I process each word on each line?
- How can I print out a word-frequency or line-frequency summary?
- How can I do approximate matching?
- How do I efficiently match many regular expressions at once?
- Why don't word-boundary searches with `\b` work for me?
- Why does using $&, $`, or $' slow my program down?
- What good is `\G` in a regular expression?
- Are Perl regexes DFAs or NFAs? Are they POSIX compliant?
- What's wrong with using grep in a void context?
- How can I match strings with multibyte characters?
- How do I match a regular expression that's in a variable?

perlfaq7: General Perl Language Issues

This section deals with general Perl language issues that don't clearly fit into any of the other sections.

- Can I get a BNF/yacc/RE for the Perl language? - What are all these $@%&* punctuation signs, and how do I know when to use them? - Do I always/never have to quote my strings or use semicolons and commas? - How do I skip some return values? - How do I temporarily block warnings? - What's an extension? - Why do Perl operators have different precedence than C operators? - How do I declare/create a structure? - How do I create a module? - How do I adopt or take over a module already on CPAN? - How do I create a class? - How can I tell if a variable is tainted? - What's a closure? - What is variable suicide and how can I prevent it? - How can I pass/return a {Function, FileHandle, Array, Hash, Method, Regex}? - How do I create a static variable? - What's the difference between dynamic and lexical (static) scoping? Between local() and my()? - How can I access a dynamic variable while a similarly named lexical is in scope? - What's the difference between deep and shallow binding? - Why doesn't "my($foo) = <$fh>;" work right? - How do I redefine a builtin function, operator, or method? - What's the difference between calling a function as &foo and foo()? - How do I create a switch or case statement? - How can I catch accesses to undefined variables, functions, or methods? - Why can't a method included in this same file be found? - How can I find out my current or calling package? - How can I comment out a large block of Perl code? - How do I clear a package? - How can I use a variable as a variable name? - What does "bad interpreter" mean?

perlfaq8: System Interaction

This section of the Perl FAQ covers questions involving operating system interaction. Topics include interprocess communication (IPC), control over the user-interface (keyboard, screen and pointing devices), and most anything else not related to data manipulation.

- How do I find out which operating system I'm running under?
- Why does exec() not return?
- How do I do fancy stuff with the keyboard/screen/mouse?
- How do I print something out in color?
- How do I read just one key without waiting for a return key?
- How do I check whether input is ready on the keyboard?
- How do I clear the screen?
- How do I get the screen size?
- How do I ask the user for a password?
- How do I read and write the serial port?
- How do I decode encrypted password files?
- How do I start a process in the background?
- How do I trap control characters/signals?

- How do I modify the shadow password file on a Unix system?
- How do I set the time and date?
- How can I sleep() or alarm() for under a second?
- How can I measure time under a second?
- How can I do an atexit() or setjmp()/longjmp()? (Exception handling)
- Why doesn't my sockets program work under System V (Solaris)? What does the error message "Protocol not supported" mean?
- How can I call my system's unique C functions from Perl?
- Where do I get the include files to do ioctl() or syscall()?
- Why do setuid perl scripts complain about kernel problems?
- How can I open a pipe both to and from a command?
- Why can't I get the output of a command with system()?
- How can I capture STDERR from an external command?
- Why doesn't open() return an error when a pipe open fails?
- What's wrong with using backticks in a void context?
- How can I call backticks without shell processing?
- Why can't my script read from STDIN after I gave it EOF (^D on Unix, ^Z on MS-DOS)?
- How can I convert my shell script to perl?
- Can I use perl to run a telnet or ftp session?
- How can I write expect in Perl?
- Is there a way to hide perl's command line from programs such as "ps"?
- I {changed directory, modified my environment} in a perl script. How come the change disappeared when I exited the script? How do I get my changes to be visible?
- How do I close a process's filehandle without waiting for it to complete?
- How do I fork a daemon process?
- How do I find out if I'm running interactively or not?
- How do I timeout a slow event?
- How do I set CPU limits?
- How do I avoid zombies on a Unix system?
- How do I use an SQL database?
- How do I make a system() exit on control-C?
- How do I open a file without blocking?
- How do I tell the difference between errors from the shell and perl?
- How do I install a module from CPAN?

- What's the difference between require and use?
- How do I keep my own module/library directory?
- How do I add the directory my program lives in to the module/library search path?
- How do I add a directory to my include path (@INC) at runtime?
- Where are modules installed?
- What is socket.ph and where do I get it?

perlfaq9: Web, Email and Networking

This section deals with questions related to running web sites, sending and receiving email as well as general networking.

- Should I use a web framework?
- Which web framework should I use?
- What is Plack and PSGI?
- How do I remove HTML from a string?
- How do I extract URLs?
- How do I fetch an HTML file?
- How do I automate an HTML form submission?
- How do I decode or create those %-encodings on the web?
- How do I redirect to another page?
- How do I put a password on my web pages?
- How do I make sure users can't enter values into a form that causes my CGI script to do bad things?
- How do I parse a mail header?
- How do I check a valid mail address?
- How do I decode a MIME/BASE64 string?
- How do I find the user's mail address?
- How do I send email?
- How do I use MIME to make an attachment to a mail message?
- How do I read email?
- How do I find out my hostname, domainname, or IP address?
- How do I fetch/put an (S)FTP file?
- How can I do RPC in Perl?

CREDITS

Tom Christiansen wrote the original perlfaq then expanded it with the help of Nat Torkington. brian d foy substantially edited and expanded the perlfaq. perlfaq-workers and others have also supplied feedback, patches and corrections over the years.

AUTHOR AND COPYRIGHT

Tom Christiansen wrote the original version of this document. brian d foy <briandfoy@pobox.com> wrote this version. See the individual perlfaq documents for additional copyright information.

This document is available under the same terms as Perl itself. Code examples in all the perlfaq documents are in the public domain. Use them as you see fit (and at your own risk with no warranty from anyone).

5.2.150 re

The `re` pragma and regular-expression introspection module.

Two jobs, one module:

- **As a pragma** - `use re` turns on lexically scoped regex behaviour: compile-time and run-time debug output (`use re 'debug'`, `use re 'debugcolor'`, `use re qw(Debug ...)`), permission to run code inside patterns derived from interpolated variables (`use re 'eval'`), taint propagation (`use re 'taint'`), stricter pattern checking (`use re 'strict'`), and default pattern flags (`use re '/ix'`).
- **As an introspection API** - when imported, it exposes a small set of utility functions for inspecting compiled patterns (`qr//` objects) and the named-capture groups of the most recent successful match: `is_regexp`, `regexp_pattern`, `regname`, `regnames`, `regnames_count`, `regmust`, `optimization`.

Synopsis

```
use re 'debug';                         # dump compile + match info
use re qw(Debug PARSE DUMP);            # pick specific debug categories
use re 'eval';                          # allow (?{...}) from variables
use re '/ix';                           # add /i and /x to every regex

use re qw(is_regexp regexp_pattern regnames);
if (is_regexp($qr)) {
    my ($pat, $mods) = regexp_pattern($qr);   # list: pattern,␣
↪modifiers
    my $str          = regexp_pattern($qr);   # scalar: "(?^
↪flags:pattern)"
}
"foobar" =~ /(?<first>foo)(?<rest>bar)/;
my @names = regnames();                        # ('first', 'rest')
my $cap   = regname('first');                  # 'foo'
```

What you can do with it

- Turn on regex debug output during one lexical scope and turn it back off outside - handy when a single pattern misbehaves in a large program.
- Ask whether an arbitrary value is really a compiled regex (even if it's blessed or overloaded) without having it stringify on you.
- Recover the original pattern text and modifier letters from a `qr//`, in either list or scalar form.
- Walk the named-capture groups of the last successful match by name, enumerate all names, or just count them.
- Peek at what the regex optimiser found - the longest anchored and floating substrings, the start class, the start-of-string anchors - to understand why a pattern is fast or slow.

This is a native implementation of the XS half of re 0.48 (`regmust`, `optimization`, and the hook that switches a scope's regex engine); `re.pm` is used unchanged. `is_regexp`, `regexp_pattern`, `regname`, `regnames` and `regnames_count` are built into perl itself.

Differences from upstream

One gap, not a difference in what works: `use re 'debug'` and `use re 'debugcolor'` are accepted but print nothing, because the debugging regex engine they switch to is not built in.

Functions

Pragma behaviour

`install`

Return an integer handle to the regex engine and reset the debug-colour flag.

Pattern introspection

`is_regexp`

Returns true if the argument is a compiled regular expression as returned by `qr//`, false if it is not.

`regexp_pattern`

Returns the pattern of a compiled regular expression, and in list context its modifiers as well.

Named captures

`regname`

Returns the contents of a named capture group of the last successful match.

regnames

Returns the names of the named capture groups of the last successful match.

regnames_count

Returns the number of distinct names defined in the pattern of the last successful match.

Optimiser introspection

regmust

Return the longest anchored and longest floating fixed strings the optimiser extracted from a compiled pattern.

optimization

Return a hashref of the optimiser's compile-time findings for a compiled pattern.

install

Return an integer handle to the regex engine and reset the debug-colour flag.

Not intended for user code. This is the hook `use re` itself calls to wire the debug engine into `%^H{regcomp}`. End users should write `use re 'debug'`, `use re 'eval'`, `use re '/ix'` and friends instead of touching `install` directly.

Synopsis

```
my $handle = re::install();   # pragma plumbing; not for application
↪code
```

What you get back

An integer that, when reinterpreted as a C pointer, resolves to the compile-time regex engine. Any other use of the value produces undefined behaviour.

Differences from upstream

- The returned integer points to the core regex engine, not to the debug engine. The debug engine is not available in this build; `use re 'debug'` therefore cannot produce upstream-style compile-time dumps. Truthiness of the return value - which is all the non-debug subpragmas (`taint`, `eval`) rely on - is preserved.

regmust

Return the longest anchored and longest floating fixed strings the optimiser extracted from a compiled pattern.

A *fixed string* is a substring that must appear in any string that matches. An *anchored* fixed string is one whose offset from the start of the match is known; a *floating* fixed

string can appear anywhere in a range of positions. The optimiser uses whichever it finds - preferring the longer, or the floating one if they are the same length - to skip positions that cannot match.

Synopsis

```
use re 'regmust';
my ($anchored, $floating) = regmust(qr/here .* there/x);
# $anchored = 'here', $floating = 'there'
```

What you get back

A two-element list `($anchored, $floating)`. Each element is either the fixed-string text as an SV or `&PL_sv_no` (the false-but-defined sentinel) when the optimiser has no fixed string of that kind. Returns `undef` if the argument is not a compiled pattern or its engine is unknown.

Examples

```
my ($a, $f) = regmust(qr/foo\s+bar/);    # $a = 'foo', $f = 'bar'
my ($a, $f) = regmust(qr/\d+/);          # no fixed strings - both␣
↪false
my @got     = regmust("not a regex");    # empty list - ref wasn't a␣
↪qr//
```

Edge cases

- Argument is not a `qr//` - returns `undef`.
- Pattern's engine is not the core engine - returns `undef`.
- Pattern has only one kind of fixed string - the other slot is `&PL_sv_no` (false but defined).
- UTF-8 substrings are returned as-is; the optimiser stores the UTF-8 form in a separate slot and this function prefers the byte form when both are present.

Differences from upstream

- The returned fixed strings are the values picked by this build's optimiser; upstream's POD notes that the exact result is optimiser-dependent and may change between Perl versions. The same caveat applies here.

optimization

Return a hashref of the optimiser's compile-time findings for a compiled pattern.

Intended for writing tests that pin optimiser behaviour, not for application logic. The set of keys and the meaning of their values are not a stable API - they change as the optimiser changes, even between minor perl releases.

Synopsis

```
use re 'optimization';
my $info = optimization(qr/^\d+foo/);
print $info->{anchored};            # 'foo'
print $info->{'anchor SBOL'};       # 1
print $info->{minlen};              # minimum match length
```

What you get back

A hashref, or undef if the argument is not a compiled pattern or its engine is unknown. Keys include minlen, minlenret, gofs, anchored, anchored utf8, anchored min offset, anchored max offset, anchored end shift, floating, floating utf8, floating min offset, floating max offset, floating end shift, checking ("anchored", "floating", or "none"), the booleans noscan, isall, anchor SBOL, anchor MBOL, anchor GPOS, skip, implicit, and stclass.

Edge cases

- Argument is not a qr// - returns undef.
- Pattern has no extracted substrings - the substring-related keys are undef or 0 and checking is "none".

Differences from upstream

- stclass is always undef. Upstream returns a textual rendering of the start class produced by my_regprop, which is compiled only with PERL_EXT_RE_DEBUG and is not available in this build.

is_regexp

Returns true if the argument is a compiled regular expression as returned by qr//, false if it is not.

Synopsis

```
use re qw(is_regexp);
is_regexp(qr/x/);               # 1
is_regexp("x");                 # false
is_regexp(bless {}, "Regexp");  # false
```

Overloading and blessing do not fool it: it looks at the compiled regexp inside the value, not at the package the value is blessed into. A hash blessed into Regexp is therefore not a regexp, and a qr// object reblessed into another class still is.

regexp_pattern

Returns the pattern of a compiled regular expression, and in list context its modifiers as well.

Synopsis

```
use re qw(regexp_pattern);
my $qr = qr/(?<y>\d{4})-(?<m>\d\d)/i;
my ($pat, $mods) = regexp_pattern($qr);
# $pat  is '(?<y>\d{4})-(?<m>\d\d)', $mods is 'i'
my $str = regexp_pattern($qr);
# $str  is '(?^i:(?<y>\d{4})-(?<m>\d\d))'
```

In list context it returns two elements: the pattern and the modifiers it was compiled with. In scalar context it returns what perl gives when it stringifies the `qr//`.

For an argument that is not a compiled regexp it returns the empty list in list context and a false but defined value in scalar context, so `regexp_pattern($ref) eq '(?^i:foo)'` never warns, whatever `$ref` holds. Like `is_regexp`, it is not fooled by overloading or blessing.

regname

Returns the contents of a named capture group of the last successful match.

Synopsis

```
use re qw(regname);
if ("2026-10" =~ /(?<y>\d{4})-(?<m>\d\d)/) {
    my $year = regname("y");          # '2026'
}
"a1" =~ /(?<d>a)(?<d>\d)?/;
my $all = regname("d", 1);           # ['a', '1']
```

A name can label more than one group. Without the second argument, or with it false, the result is the first of those groups that matched. With it true, the result is an array reference holding one entry per group of that name, in pattern order, with `undef` for a group that did not take part in the match.

regnames

Returns the names of the named capture groups of the last successful match.

Synopsis

```
use re qw(regnames);
"ab" =~ /(?<a>a)|(?<b>x)/;
my @used = regnames();      # ('a')
my @all  = regnames(1);     # ('a', 'b')
```

Without an argument, or with a false one, only the names of groups that took part in the match are returned. With a true argument, every name the pattern defines is returned, matched or not. The order of the names is not defined; sort them if it matters.

regnames_count

Returns the number of distinct names defined in the pattern of the last successful match.

Synopsis

```
use re qw(regnames_count);
"ab" =~ /(?<a>a)|(?<b>x)/;
my $n = regnames_count();   # 2
```

The count is of the names the pattern defines, whether or not their groups matched, so it can be larger than the number of names `regnames()` returns without its argument.

5.2.151 sigtrap

Perl pragma to enable simple signal handling

SYNOPSIS

```
use sigtrap;
use sigtrap qw(stack-trace old-interface-signals);  # equivalent
use sigtrap qw(BUS SEGV PIPE ABRT);
use sigtrap qw(die INT QUIT);
use sigtrap qw(die normal-signals);
use sigtrap qw(die untrapped normal-signals);
use sigtrap qw(die untrapped normal-signals
               stack-trace any error-signals);
use sigtrap 'handler' => \&my_handler, 'normal-signals';
use sigtrap qw(handler my_handler normal-signals
               stack-trace error-signals);
```

DESCRIPTION

The **sigtrap** pragma is a simple interface to installing signal handlers. You can have it install one of two handlers supplied by **sigtrap** itself (one which provides a Perl stack trace and one which simply `die()`s), or alternately you can supply your own handler for it to install. It can be told only to install a handler for signals which are either untrapped or ignored. It has three lists of signals to trap, plus you can supply your own list of signals.

The arguments passed to the `use` statement which invokes **sigtrap** are processed in order. When a signal name or the name of one of **sigtrap**'s signal lists is encountered a handler is immediately installed, when an option is encountered it affects subsequently installed handlers.

OPTIONS

SIGNAL HANDLERS

These options affect which handler will be used for subsequently installed signals.

- **stack-trace**

  The handler used for subsequently installed signals outputs a Perl stack trace to STDERR and then tries to dump core. This is the default signal handler.

- **die**

  The handler used for subsequently installed signals calls `die` (actually `croak`) with a message indicating which signal was caught.

- **handler** *your-handler*

  your-handler will be used as the handler for subsequently installed signals. *your-handler* can be any value which is valid as an assignment to an element of `%SIG`. See *perlvar* for examples of handler functions.

SIGNAL LISTS

sigtrap has a few built-in lists of signals to trap. They are:

- **normal-signals**

  These are the signals which a program might normally expect to encounter and which by default cause it to terminate. They are HUP, INT, PIPE and TERM.

- **error-signals**

  These signals usually indicate a serious problem with the Perl interpreter or with your script. They are ABRT, BUS, EMT, FPE, ILL, QUIT, SEGV, SYS and TRAP.

- **old-interface-signals**

  These are the signals which were trapped by default by the old **sigtrap** interface, they are ABRT, BUS, EMT, FPE, ILL, PIPE, QUIT, SEGV, SYS, TERM, and TRAP. If no signals or signals lists are passed to **sigtrap**, this list is used.

For each of these three lists, the collection of signals set to be trapped is checked before trapping; if your architecture does not implement a particular signal, it will not be trapped but rather silently ignored.

OTHER

- **untrapped**

  This token tells **sigtrap** to install handlers only for subsequently listed signals which aren't already trapped or ignored.

- **any**

  This token tells **sigtrap** to install handlers for all subsequently listed signals. This is the default behavior.

- *signal*

Any argument which looks like a signal name (that is, `/^[A-Z][A-Z0-9]*$/`) indicates that **sigtrap** should install a handler for that name.

- *number*

  Require that at least version *number* of **sigtrap** is being used.

EXAMPLES

Provide a stack trace for the old-interface-signals:

```
use sigtrap;
```

Ditto:

```
use sigtrap qw(stack-trace old-interface-signals);
```

Provide a stack trace on the 4 listed signals only:

```
use sigtrap qw(BUS SEGV PIPE ABRT);
```

Die on INT or QUIT:

```
use sigtrap qw(die INT QUIT);
```

Die on HUP, INT, PIPE or TERM:

```
use sigtrap qw(die normal-signals);
```

Die on HUP, INT, PIPE or TERM, except don't change the behavior for signals which are already trapped or ignored:

```
use sigtrap qw(die untrapped normal-signals);
```

Die on receipt one of any of the **normal-signals** which is currently **untrapped**, provide a stack trace on receipt of **any** of the **error-signals**:

```
use sigtrap qw(die untrapped normal-signals
               stack-trace any error-signals);
```

Install my_handler() as the handler for the **normal-signals**:

```
use sigtrap 'handler', \&my_handler, 'normal-signals';
```

Install my_handler() as the handler for the normal-signals, provide a Perl stack trace on receipt of one of the error-signals:

```
use sigtrap qw(handler my_handler normal-signals
               stack-trace error-signals);
```

5.2.152 sort

perl pragma to control sort() behaviour

SYNOPSIS

The sort pragma is now a no-op, and its use is discouraged. These three operations are valid, but have no effect:

```
use sort 'stable';          # guarantee stability
use sort 'defaults';        # revert to default behavior
no  sort 'stable';          # stability not important
```

DESCRIPTION

Historically the `sort` pragma you can control the behaviour of the builtin `sort()` function.

Prior to v5.28.0 there were two other options:

```
use sort '_mergesort';
use sort '_qsort';          # or '_quicksort'
```

If you try and specify either of these in v5.28+ it will croak.

The default sort has been stable since v5.8.0, and given this consistent behaviour for almost two decades, everyone has come to assume stability.

Stability will remain the default - hence there is no need for a pragma for code to opt into stability "just in case" this changes - it won't.

We do not foresee going back to offering multiple implementations of general purpose sorting - hence there is no future need to offer a pragma to choose between them.

If you know that you care that much about performance of your sorting, and that for your use case and your data, it was worth investigating alternatives, possible to identify an alternative from our default that was better, and the cost of switching was worth it, then you know more than we do. Likely whatever choices we can give are not as good as implementing your own. (For example, a Radix sort can be faster than O(n log n), but can't be used for all keys and has larger overheads.)

We are not averse to **changing** the sort algorithm, but we don't see the benefit in offering the choice of two general purpose implementations.

CAVEATS

The function `sort::current()` was provided to report the current state of the sort pragmata. This function was not exported, and there is no code to call it on CPAN. It is now deprecated, and will warn by default.

As we no longer store any sort "state", it can no longer return the correct value, so it will always return the string `stable`, as this is consistent with what we actually have implemented.

5.2.153 source

Namespace containing the following modules:

- `source::encoding` - Declare Perl source code encoding

source::encoding

Declare Perl source code encoding

SYNOPSIS

```
use source::encoding 'ascii';
use source::encoding 'utf8';
no source::encoding;
```

DESCRIPTION

These days, Perl code either generally contains only ASCII characters with `\x{}` and similar escapes to represent non-ASCII, or `use utf8` is used to indicate that the source code itself contains characters encoded as UTF-8.

That means that a character in the source code not meeting these criteria is often a typographical error. This pragma is used to tell Perl to raise an error when this happens.

`use source::encoding 'utf8'` is a synonym for `use utf8`. They may be used interchangeably.

`use source::encoding 'ascii'` turns off any UTF-8 expectations, and raises a fatal error if any character within its scope in the input source code is not ASCII.

`no source::encoding` turns off any UTF-8/ASCII expectations for the remainder of its scope. The meaning of non-ASCII characters is then undefined.

`use source::encoding 'ascii'` is automatically enabled within the lexical scope of a `use v5.41.0` or higher.

SEE ALSO

utf8

5.2.154 stable

Experimental features made easy, once we know they're stable

VERSION

version 0.036

SYNOPSIS

```
use stable 'lexical_subs', 'bitwise';
my sub is_odd($value) { $value & 1 }
```

DESCRIPTION

The *experimental* pragma makes it easy to turn on experiments while turning off associated warnings. You should read about it, if you don't already know what it does.

Seeing `use experimental` in code might be scary. In fact, it probably should be! Code that uses experimental features might break in the future if the perl development team decides that the experiment needs to be altered. When experiments become stable, because the developers decide they're a success, the warnings associated with them go away. When that happens, they can generally be turned on with `use feature`.

This is great, if you are using a version of perl where the feature you want is already stable. If you're using an older perl, though, it might be the case that you want to use an experimental feature that still warns, even though there's no risk in using it, because subsequent versions of perl have that feature unchanged and now stable.

Here's an example: The `postderef` feature was added in perl 5.20.0. In perl 5.24.0, it was marked stable. Using it would no longer trigger a warning. The behavior of the feature didn't change between 5.20.0 and 5.24.0. That means that it's perfectly safe to use the feature on 5.20 or 5.22, even though there's a warning.

In that case, you could very justifiably add `use experimental 'postderef'` but the casual reader may still be worried at seeing that. The `stable` pragma exists to turn on experimental features only when it's known that their behavior in the running perl is their stable behavior.

If you try to use an experimental feature that isn't stable or available on the running version of perl, an exception will be thrown. You should also take care that you've required the version of `stable` that you need!

If it's not immediately obvious why, here's a bit of explanation:

- `stable` comes with perl, starting with perl v5.38.
- Imagine that v5.38 adds a feature called "florps". It will stop being experimental in v5.42.
- The version of `stable` that comes with perl v5.38 can't know that the *florps* experiment will succeed, so you can't `use stable 'florps'` on the version of stable ships with v5.38, because it can't see the future!
- You'll need to write `use stable 1.234 'florps'` to say that you need version 1.234 of stable, which is when *florps* became known to stable.

Sure, it's a little weird, but it's worth it! The documentation of this pragma will tell you what version of `stable` you need to require in order to use various features. See below.

At present there are only a few "stable" features:

- `bitwise` - stable as of perl 5.22, available via stable 0.031
- `isa` - stable as of perl 5.32, available via stable 0.031

- `lexical_subs` - stable as of perl 5.22, available via stable 0.031

  Lexical subroutines were actually added in 5.18, and their design did not change, but significant bugs makes them unsafe to use before 5.22.

- `postderef` - stable as of perl 5.20, available via stable 0.031
- `const_attr` - stable as of perl 5.22, available via stable 0.032
- `for_list` - stable as of perl 5.36, available via stable 0.032

SEE ALSO

perlexperiment contains more information about experimental features.

5.2.155 strict

Perl pragma to restrict unsafe constructs

SYNOPSIS

```
use strict;

use strict "vars";
use strict "refs";
use strict "subs";

use strict;
no strict "vars";
```

DESCRIPTION

The `strict` pragma disables certain Perl expressions that could behave unexpectedly or are difficult to debug, turning them into errors. The effect of this pragma is limited to the current file or scope block.

If no import list is supplied, all possible restrictions are assumed. (This is the safest mode to operate in, but is sometimes too strict for casual programming.) Currently, there are three possible things to be strict about: “subs”, “vars”, and “refs”.

- `strict refs`

  This generates a runtime error if you use symbolic references (see perlref).

```
use strict 'refs';
$ref = \$foo;
print $$ref;        # ok
$ref = "foo";
print $$ref;        # runtime error; normally ok
$file = "STDOUT";
print $file "Hi!";  # error; note: no comma after $file
```

There is one exception to this rule:

```
$bar = \&{'foo'};
&$bar;
```

is allowed so that `goto &$AUTOLOAD` would not break under stricture.

- `strict vars`

  This generates a compile-time error if you access a variable that was neither explicitly declared (using any of `my`, `our`, `state`, or `use vars`) nor fully qualified. (Because this is to avoid variable suicide problems and subtle dynamic scoping issues, a merely `local` variable isn't good enough.) See *"my" in perlfunc*, *"our" in perlfunc*, *"state" in perlfunc*, *"local" in perlfunc*, and *vars*.

```
use strict 'vars';
$X::foo = 1;          # ok, fully qualified
my $foo = 10;         # ok, my() var
local $baz = 9;       # blows up, $baz not declared before

package Cinna;
our $bar;                    # Declares $bar in current package
$bar = 'HgS';                # ok, global declared via pragma
```

The local() generated a compile-time error because you just touched a global name without fully qualifying it.

Because of their special use by sort(), the variables $a and $b are exempted from this check.

- `strict subs`

  This disables the poetry optimization, generating a compile-time error if you try to use a bareword identifier that's not a subroutine, unless it is a simple identifier (no colons) and that it appears in curly braces, on the left hand side of the => symbol, or has the unary minus operator applied to it.

```
use strict 'subs';
$SIG{PIPE} = Plumber;   # blows up
$SIG{PIPE} = "Plumber"; # fine: quoted string is always ok
$SIG{PIPE} = \&Plumber; # preferred form
```

See "Pragmatic Modules" in perlmodlib.

HISTORY

`strict 'subs'`, with Perl 5.6.1, erroneously permitted to use an unquoted compound identifier (e.g. `Foo::Bar`) as a hash key (before => or inside curlies), but without forcing it always to a literal string.

Starting with Perl 5.8.1 strict is strict about its restrictions: if unknown restrictions are used, the strict pragma will abort with

```
Unknown 'strict' tag(s) '...'
```

As of version 1.04 (Perl 5.10), strict verifies that it is used as "strict" to avoid the dreaded Strict trap on case insensitive file systems.

Beginning with Perl 5.12, use of "use VERSION" (where VERSION >= 5.11.0) now lexically enables strictures just like "use strict" (in addition to the normal "use VERSION" effects and features.) In other words, "use v5.011" or higher now implies "use strict" automatically, as noted in "Implicit strictures" in perl5120delta and `use VERSION`.

5.2.156 subs

Perl pragma to predeclare subroutine names

SYNOPSIS

```
use subs qw(frob);
frob 3..10;
```

DESCRIPTION

This will predeclare all the subroutines whose names are in the list, allowing you to use them without parentheses (as list operators) even before they're declared.

Unlike pragmas that affect the `$^H` hints variable, the `use vars` and `use subs` declarations are not lexically scoped to the block they appear in: they affect the entire package in which they appear. It is not possible to rescind these declarations with `no vars` or `no subs`.

See "Pragmatic Modules" in perlmodlib and *"strict subs" in strict*.

5.2.157 threads

Perl interpreter-based threads

VERSION

This document describes threads version 2.45

WARNING

The “interpreter-based threads” provided by Perl are not the fast, lightweight system for multitasking that one might expect or hope for. Threads are implemented in a way that makes them easy to misuse. Few people know how to use them correctly or will be able to provide help.

The use of interpreter-based threads in perl is officially discouraged.

SYNOPSIS

```
use threads ('yield',
             'stack_size' => 64*4096,
             'exit' => 'threads_only',
             'stringify');

sub start_thread {
    my @args = @_;
    print('Thread started: ', join(' ', @args), "\n");
}
my $thr = threads->create('start_thread', 'argument');
$thr->join();

threads->create(sub { print("I am a thread\n"); })->join();

my $thr2 = async { foreach (@files) { ... } };
$thr2->join();
if (my $err = $thr2->error()) {
    warn("Thread error: $err\n");
}

# Invoke thread in list context (implicit) so it can return a list
my ($thr) = threads->create(sub { return (qw/a b c/); });
# or specify list context explicitly
my $thr = threads->create({'context' => 'list'},
                          sub { return (qw/a b c/); });
my @results = $thr->join();

$thr->detach();

# Get a thread's object
$thr = threads->self();
$thr = threads->object($tid);

# Get a thread's ID
$tid = threads->tid();
$tid = $thr->tid();
$tid = "$thr";

# Give other threads a chance to run
threads->yield();
```

(continues on next page)

(continued from previous page)

```
yield();

# Lists of non-detached threads
my @threads = threads->list();
my $thread_count = threads->list();

my @running = threads->list(threads::running);
my @joinable = threads->list(threads::joinable);

# Test thread objects
if ($thr1 == $thr2) {
    ...
}

# Manage thread stack size
$stack_size = threads->get_stack_size();
$old_size = threads->set_stack_size(32*4096);

# Create a thread with a specific context and stack size
my $thr = threads->create({ 'context'    => 'list',
                            'stack_size' => 32*4096,
                            'exit'       => 'thread_only' },
                          \&foo);

# Get thread's context
my $wantarray = $thr->wantarray();

# Check thread's state
if ($thr->is_running()) {
    sleep(1);
}
if ($thr->is_joinable()) {
    $thr->join();
}

# Send a signal to a thread
$thr->kill('SIGUSR1');

# Exit a thread
threads->exit();
```

DESCRIPTION

Since Perl 5.8, thread programming has been available using a model called *interpreter threads* which provides a new Perl interpreter for each thread, and, by default, results in no data or state information being shared between threads.

(Prior to Perl 5.8, *5005threads* was available through the `Thread.pm` API. This threading model has been deprecated, and was removed as of Perl 5.10.0.)

As just mentioned, all variables are, by default, thread local. To use shared variables, you need to also load *threads::shared*:

```
use threads;
use threads::shared;
```

When loading *threads::shared*, you must `use threads` before you `use threads::shared`. (`threads` will emit a warning if you do it the other way around.)

It is strongly recommended that you enable threads via `use threads` as early as possible in your script.

If needed, scripts can be written so as to run on both threaded and non-threaded Perls:

```
my $can_use_threads = eval 'use threads; 1';
if ($can_use_threads) {
    # Do processing using threads
    ...
} else {
    # Do it without using threads
    ...
}
```

- $thr = threads->create(FUNCTION, ARGS)

  This will create a new thread that will begin execution with the specified entry point function, and give it the *ARGS* list as parameters. It will return the corresponding threads object, or `undef` if thread creation failed.

  FUNCTION may either be the name of a function, an anonymous subroutine, or a code ref.

  ```
  my $thr = threads->create('func_name', ...);
      # or
  my $thr = threads->create(sub { ... }, ...);
      # or
  my $thr = threads->create(\&func, ...);
  ```

  The `->new()` method is an alias for `->create()`.

- $thr->join()

  This will wait for the corresponding thread to complete its execution. When the thread finishes, `->join()` will return the return value(s) of the entry point function.

  The context (void, scalar or list) for the return value(s) for `->join()` is determined at the time of thread creation.

  ```
  # Create thread in list context (implicit)
  my ($thr1) = threads->create(sub {
                                  my @results = qw(a b c);
                                  return (@results);
                               });
  #   or (explicit)
  ```

(continues on next page)

(continued from previous page)

```
my $thr1 = threads->create({'context' => 'list'},
                           sub {
                                my @results = qw(a b c);
                                return (@results);
                           });
# Retrieve list results from thread
my @res1 = $thr1->join();

# Create thread in scalar context (implicit)
my $thr2 = threads->create(sub {
                                my $result = 42;
                                return ($result);
                             });
# Retrieve scalar result from thread
my $res2 = $thr2->join();

# Create a thread in void context (explicit)
my $thr3 = threads->create({'void' => 1},
                           sub { print("Hello, world\n"); });
# Join the thread in void context (i.e., no return value)
$thr3->join();
```

See “THREAD CONTEXT” for more details.

If the program exits without all threads having either been joined or detached, then a warning will be issued.

Calling `->join()` or `->detach()` on an already joined thread will cause an error to be thrown.

- $thr->detach()

  Makes the thread unjoinable, and causes any eventual return value to be discarded. When the program exits, any detached threads that are still running are silently terminated.

  If the program exits without all threads having either been joined or detached, then a warning will be issued.

  Calling `->join()` or `->detach()` on an already detached thread will cause an error to be thrown.

- threads->detach()

  Class method that allows a thread to detach itself.

- threads->self()

  Class method that allows a thread to obtain its own *threads* object.

- $thr->tid()

  Returns the ID of the thread. Thread IDs are unique integers with the main thread in a program being 0, and incrementing by 1 for every thread created.

- threads->tid()

Class method that allows a thread to obtain its own ID.

- "$thr"

  If you add the `stringify` import option to your `use threads` declaration, then using a threads object in a string or a string context (e.g., as a hash key) will cause its ID to be used as the value:

```
use threads qw(stringify);

my $thr = threads->create(...);
print("Thread $thr started\n");  # Prints: Thread 1 started
```

- threads->object($tid)

  This will return the *threads* object for the *active* thread associated with the specified thread ID. If `$tid` is the value for the current thread, then this call works the same as `->self()`. Otherwise, returns `undef` if there is no thread associated with the TID, if the thread is joined or detached, if no TID is specified or if the specified TID is undef.

- threads->yield()

  This is a suggestion to the OS to let this thread yield CPU time to other threads. What actually happens is highly dependent upon the underlying thread implementation.

  You may do `use threads qw(yield)`, and then just use `yield()` in your code.

- threads->list()
- threads->list(threads::all)
- threads->list(threads::running)
- threads->list(threads::joinable)

  With no arguments (or using `threads::all`) and in a list context, returns a list of all non-joined, non-detached *threads* objects. In a scalar context, returns a count of the same.

  With a *true* argument (using `threads::running`), returns a list of all non-joined, non-detached *threads* objects that are still running.

  With a *false* argument (using `threads::joinable`), returns a list of all non-joined, non-detached *threads* objects that have finished running (i.e., for which `->join()` will not *block*).

- $thr1->equal($thr2)

  Tests if two threads objects are the same thread or not. This is overloaded to the more natural forms:

```
if ($thr1 == $thr2) {
    print("Threads are the same\n");
}
# or
if ($thr1 != $thr2) {
    print("Threads differ\n");
}
```

(Thread comparison is based on thread IDs.)

- async BLOCK;

  `async` creates a thread to execute the block immediately following it. This block is treated as an anonymous subroutine, and so must have a semicolon after the closing brace. Like `threads->create()`, `async` returns a *threads* object.

- $thr->error()

  Threads are executed in an `eval` context. This method will return `undef` if the thread terminates *normally*. Otherwise, it returns the value of `$@` associated with the thread's execution status in its `eval` context.

- $thr->_handle()

  This *private* method returns a pointer (i.e., the memory location expressed as an unsigned integer) to the internal thread structure associated with a threads object. For Win32, this is a pointer to the `HANDLE` value returned by `CreateThread` (i.e., `HANDLE *`); for other platforms, it is a pointer to the `pthread_t` structure used in the `pthread_create` call (i.e., `pthread_t *`).

  This method is of no use for general Perl threads programming.

- threads->_handle()

  Class method that allows a thread to obtain its own *handle*.

EXITING A THREAD

The usual method for terminating a thread is to *return()* from the entry point function with the appropriate return value(s).

- threads->exit()

  If needed, a thread can be exited at any time by calling `threads->exit()`. This will cause the thread to return `undef` in a scalar context, or the empty list in a list context.

  When called from the *main* thread, this behaves the same as `exit(0)`.

- threads->exit(status)

  When called from a thread, this behaves like `threads->exit()` (i.e., the exit status code is ignored).

  When called from the *main* thread, this behaves the same as `exit(status)`.

- die()

  Calling `die()` in a thread indicates an abnormal exit for the thread. Any `$SIG{__DIE__}` handler in the thread will be called first, and then the thread will exit with a warning message that will contain any arguments passed in the `die()` call.

- exit(status)

  Calling *exit()* inside a thread causes the whole application to terminate. Because of this, the use of `exit()` inside threaded code, or in modules that might be used in threaded applications, is strongly discouraged.

If `exit()` really is needed, then consider using the following:

```
threads->exit() if threads->can('exit');   # Thread friendly
exit(status);
```

- use threads 'exit' => 'threads_only'

  This globally overrides the default behavior of calling `exit()` inside a thread, and effectively causes such calls to behave the same as `threads->exit()`. In other words, with this setting, calling `exit()` causes only the thread to terminate.

  Because of its global effect, this setting should not be used inside modules or the like.

  The *main* thread is unaffected by this setting.

- threads->create({'exit' => 'thread_only'}, ...)

  This overrides the default behavior of `exit()` inside the newly created thread only.

- $thr->set_thread_exit_only(boolean)

  This can be used to change the *exit thread only* behavior for a thread after it has been created. With a *true* argument, `exit()` will cause only the thread to exit. With a *false* argument, `exit()` will terminate the application.

  The *main* thread is unaffected by this call.

- threads->set_thread_exit_only(boolean)

  Class method for use inside a thread to change its own behavior for `exit()`.

  The *main* thread is unaffected by this call.

THREAD STATE

The following boolean methods are useful in determining the *state* of a thread.

- $thr->is_running()

  Returns true if a thread is still running (i.e., if its entry point function has not yet finished or exited).

- $thr->is_joinable()

  Returns true if the thread has finished running, is not detached and has not yet been joined. In other words, the thread is ready to be joined, and a call to `$thr->join()` will not *block*.

- $thr->is_detached()

  Returns true if the thread has been detached.

- threads->is_detached()

  Class method that allows a thread to determine whether or not it is detached.

THREAD CONTEXT

As with subroutines, the type of value returned from a thread's entry point function may be determined by the thread's *context*: list, scalar or void. The thread's context is determined at thread creation. This is necessary so that the context is available to the entry point function via *wantarray()*. The thread may then specify a value of the appropriate type to be returned from `->join()`.

Explicit context

Because thread creation and thread joining may occur in different contexts, it may be desirable to state the context explicitly to the thread's entry point function. This may be done by calling `->create()` with a hash reference as the first argument:

```
my $thr = threads->create({'context' => 'list'}, \&foo);
...
my @results = $thr->join();
```

In the above, the threads object is returned to the parent thread in scalar context, and the thread's entry point function `foo` will be called in list (array) context such that the parent thread can receive a list (array) from the `->join()` call. (`'array'` is synonymous with `'list'`.)

Similarly, if you need the threads object, but your thread will not be returning a value (i.e., *void* context), you would do the following:

```
my $thr = threads->create({'context' => 'void'}, \&foo);
...
$thr->join();
```

The context type may also be used as the *key* in the hash reference followed by a *true* value:

```
threads->create({'scalar' => 1}, \&foo);
...
my ($thr) = threads->list();
my $result = $thr->join();
```

Implicit context

If not explicitly stated, the thread's context is implied from the context of the `->create()` call:

```
# Create thread in list context
my ($thr) = threads->create(...);

# Create thread in scalar context
my $thr = threads->create(...);

# Create thread in void context
threads->create(...);
```

$thr->wantarray()

This returns the thread's context in the same manner as *wantarray()*.

threads->wantarray()

Class method to return the current thread's context. This returns the same value as running *wantarray()* inside the current thread's entry point function.

THREAD STACK SIZE

The default per-thread stack size for different platforms varies significantly, and is almost always far more than is needed for most applications. On Win32, Perl's makefile explicitly sets the default stack to 16 MB; on most other platforms, the system default is used, which again may be much larger than is needed.

By tuning the stack size to more accurately reflect your application's needs, you may significantly reduce your application's memory usage, and increase the number of simultaneously running threads.

Note that on Windows, address space allocation granularity is 64 KB, therefore, setting the stack smaller than that on Win32 Perl will not save any more memory.

- threads->get_stack_size();

  Returns the current default per-thread stack size. The default is zero, which means the system default stack size is currently in use.

- $size = $thr->get_stack_size();

  Returns the stack size for a particular thread. A return value of zero indicates the system default stack size was used for the thread.

- $old_size = threads->set_stack_size($new_size);

  Sets a new default per-thread stack size, and returns the previous setting.

  Some platforms have a minimum thread stack size. Trying to set the stack size below this value will result in a warning, and the minimum stack size will be used.

  Some Linux platforms have a maximum stack size. Setting too large of a stack size will cause thread creation to fail.

  If needed, `$new_size` will be rounded up to the next multiple of the memory page size (usually 4096 or 8192).

  Threads created after the stack size is set will then either call `pthread_attr_setstacksize()` *(for pthreads platforms)*, or supply the stack size to `CreateThread()` *(for Win32 Perl)*.

  (Obviously, this call does not affect any currently extant threads.)

- use threads ('stack_size' => VALUE);

  This sets the default per-thread stack size at the start of the application.

- $ENV{'PERL5_ITHREADS_STACK_SIZE'}

  The default per-thread stack size may be set at the start of the application through the use of the environment variable `PERL5_ITHREADS_STACK_SIZE`:

```
PERL5_ITHREADS_STACK_SIZE=1048576
export PERL5_ITHREADS_STACK_SIZE
perl -e'use threads; print(threads->get_stack_size(), "\n")'
```

This value overrides any `stack_size` parameter given to `use threads`. Its primary purpose is to permit setting the per-thread stack size for legacy threaded applications.

- threads->create({'stack_size' => VALUE}, FUNCTION, ARGS)

  To specify a particular stack size for any individual thread, call `->create()` with a hash reference as the first argument:

```
my $thr = threads->create({'stack_size' => 32*4096},
                          \&foo, @args);
```

- $thr2 = $thr1->create(FUNCTION, ARGS)

  This creates a new thread (`$thr2`) that inherits the stack size from an existing thread (`$thr1`). This is shorthand for the following:

```
my $stack_size = $thr1->get_stack_size();
my $thr2 = threads->create({'stack_size' => $stack_size},
                           FUNCTION, ARGS);
```

THREAD SIGNALLING

When safe signals is in effect (the default behavior - see "Unsafe signals" for more details), then signals may be sent and acted upon by individual threads.

- $thr->kill('SIG...');

  Sends the specified signal to the thread. Signal names and (positive) signal numbers are the same as those supported by *kill()*. For example, 'SIGTERM', 'TERM' and (depending on the OS) 15 are all valid arguments to `->kill()`.

  Returns the thread object to allow for method chaining:

```
$thr->kill('SIG...')->join();
```

Signal handlers need to be set up in the threads for the signals they are expected to act upon. Here's an example for *cancelling* a thread:

```
use threads;

sub thr_func
{
    # Thread 'cancellation' signal handler
    $SIG{'KILL'} = sub { threads->exit(); };

    ...
}
```

(continues on next page)

(continued from previous page)

```
# Create a thread
my $thr = threads->create('thr_func');

...

# Signal the thread to terminate, and then detach
# it so that it will get cleaned up automatically
$thr->kill('KILL')->detach();
```

Here's another simplistic example that illustrates the use of thread signalling in conjunction with a semaphore to provide rudimentary *suspend* and *resume* capabilities:

```
use threads;
use Thread::Semaphore;

sub thr_func
{
    my $sema = shift;

    # Thread 'suspend/resume' signal handler
    $SIG{'STOP'} = sub {
        $sema->down();      # Thread suspended
        $sema->up();        # Thread resumes
    };

    ...
}

# Create a semaphore and pass it to a thread
my $sema = Thread::Semaphore->new();
my $thr = threads->create('thr_func', $sema);

# Suspend the thread
$sema->down();
$thr->kill('STOP');

...

# Allow the thread to continue
$sema->up();
```

CAVEAT: The thread signalling capability provided by this module does not actually send signals via the OS. It *emulates* signals at the Perl-level such that signal handlers are called in the appropriate thread. For example, sending `$thr->kill('STOP')` does not actually suspend a thread (or the whole process), but does cause a `$SIG{'STOP'}` handler to be called in that thread (as illustrated above).

As such, signals that would normally not be appropriate to use in the `kill()` command (e.g., `kill('KILL', $$)`) are okay to use with the `->kill()` method (again, as illustrated above).

Correspondingly, sending a signal to a thread does not disrupt the operation the thread is currently working on: The signal will be acted upon after the current operation has completed. For instance, if the thread is *stuck* on an I/O call, sending it a signal will not cause the I/O call to be interrupted such that the signal is acted up immediately.

Sending a signal to a terminated/finished thread is ignored.

WARNINGS

- Perl exited with active threads:

  If the program exits without all threads having either been joined or detached, then this warning will be issued.

  NOTE: If the *main* thread exits, then this warning cannot be suppressed using no `warnings 'threads';` as suggested below.

- Thread creation failed: pthread_create returned #

  See the appropriate *man* page for `pthread_create` to determine the actual cause for the failure.

- Thread # terminated abnormally: ...

  A thread terminated in some manner other than just returning from its entry point function, or by using `threads->exit()`. For example, the thread may have terminated because of an error, or by using `die`.

- Using minimum thread stack size of #

  Some platforms have a minimum thread stack size. Trying to set the stack size below this value will result in the above warning, and the stack size will be set to the minimum.

- Thread creation failed: pthread_attr_setstacksize(*SIZE*) returned 22

  The specified *SIZE* exceeds the system's maximum stack size. Use a smaller value for the stack size.

If needed, thread warnings can be suppressed by using:

```
no warnings 'threads';
```

in the appropriate scope.

ERRORS

- This Perl not built to support threads

  The particular copy of Perl that you're trying to use was not built using the `useithreads` configuration option.

- Cannot change stack size of an existing thread

  The stack size of currently extant threads cannot be changed, therefore, the following results in the above error:

  ```
  $thr->set_stack_size($size);
  ```

- Cannot signal threads without safe signals

  Safe signals must be in effect to use the `->kill()` signalling method. See "Unsafe signals" for more details.

- Unrecognized signal name: ...

  The particular copy of Perl that you're trying to use does not support the specified signal being used in a `->kill()` call.

BUGS AND LIMITATIONS

Before you consider posting a bug report, please consult, and possibly post a message to the discussion forum to see if what you've encountered is a known problem.

- Thread-safe modules
- Using non-thread-safe modules

  Unfortunately, you may encounter Perl modules that are not *thread-safe*. For example, they may crash the Perl interpreter during execution, or may dump core on termination. Depending on the module and the requirements of your application, it may be possible to work around such difficulties.

  If the module will only be used inside a thread, you can try loading the module from inside the thread entry point function using `require` (and `import` if needed):

```
sub thr_func
{
    require Unsafe::Module
    # Unsafe::Module->import(...);

    ....
}
```

  If the module is needed inside the *main* thread, try modifying your application so that the module is loaded (again using `require` and `->import()`) after any threads are started, and in such a way that no other threads are started afterwards.

  If the above does not work, or is not adequate for your application, then file a bug report on https://rt.cpan.org/Public/ against the problematic module.

- Memory consumption

  On most systems, frequent and continual creation and destruction of threads can lead to ever-increasing growth in the memory footprint of the Perl interpreter. While it is simple to just launch threads and then `->join()` or `->detach()` them, for long-lived applications, it is better to maintain a pool of threads, and to reuse them for the work needed, using *queues* to notify threads of pending work. The CPAN distribution of this module contains a simple example (`examples/pool_reuse.pl`) illustrating the creation, use and monitoring of a pool of *reusable* threads.

- Current working directory

  On all platforms except MSWin32, the setting for the current working directory is shared among all threads such that changing it in one thread (e.g., using `chdir()`) will affect all the threads in the application.

On MSWin32, each thread maintains its own the current working directory setting.

- Locales

  Prior to Perl 5.28, locales could not be used with threads, due to various race conditions. Starting in that release, on systems that implement thread-safe locale functions, threads can be used, with some caveats. This includes Windows starting with Visual Studio 2005, and systems compatible with POSIX 2008. See *"Multi-threaded operation" in perllocale*.

  Each thread (except the main thread) is started using the C locale. The main thread is started like all other Perl programs; see *"ENVIRONMENT" in perllocale*. You can switch locales in any thread as often as you like.

  If you want to inherit the parent thread's locale, you can, in the parent, set a variable like so:

```
$foo = POSIX::setlocale(LC_ALL, NULL);
```

  and then pass to threads->create() a sub that closes over `$foo`. Then, in the child, you say

```
POSIX::setlocale(LC_ALL, $foo);
```

  Or you can use the facilities in *threads::shared* to pass `$foo`; or if the environment hasn't changed, in the child, do

```
POSIX::setlocale(LC_ALL, "");
```

- Environment variables

  Currently, on all platforms except MSWin32, all *system* calls (e.g., using `system()` or back-ticks) made from threads use the environment variable settings from the *main* thread. In other words, changes made to `%ENV` in a thread will not be visible in *system* calls made by that thread.

  To work around this, set environment variables as part of the *system* call. For example:

```
my $msg = 'hello';
system("FOO=$msg; echo \$FOO");   # Outputs 'hello' to STDOUT
```

  On MSWin32, each thread maintains its own set of environment variables.

- Catching signals

  Signals are *caught* by the main thread (thread ID = 0) of a script. Therefore, setting up signal handlers in threads for purposes other than "THREAD SIGNALLING" as documented above will not accomplish what is intended.

  This is especially true if trying to catch `SIGALRM` in a thread. To handle alarms in threads, set up a signal handler in the main thread, and then use "THREAD SIGNALLING" to relay the signal to the thread:

```
# Create thread with a task that may time out
my $thr = threads->create(sub {
```

(continues on next page)

(continued from previous page)

```
    threads->yield();
    eval {
        $SIG{ALRM} = sub { die("Timeout\n"); };
        alarm(10);
        ...  # Do work here
        alarm(0);
    };
    if ($@ =~ /Timeout/) {
        warn("Task in thread timed out\n");
    }
};

# Set signal handler to relay SIGALRM to thread
$SIG{ALRM} = sub { $thr->kill('ALRM') };

... # Main thread continues working
```

- Parent-child threads

  On some platforms, it might not be possible to destroy *parent* threads while there are still existing *child* threads.

- Unsafe signals

  Since Perl 5.8.0, signals have been made safer in Perl by postponing their handling until the interpreter is in a *safe* state. See "Safe Signals" in perl58delta and "Deferred Signals (Safe Signals)" in perlipc for more details.

  Safe signals is the default behavior, and the old, immediate, unsafe signalling behavior is only in effect in the following situations:

  – Perl has been built with `PERL_OLD_SIGNALS` (see `perl -V`).

  – The environment variable `PERL_SIGNALS` is set to `unsafe` (see "PERL_SIGNALS" in perlrun).

  – The module Perl::Unsafe::Signals is used.

  If unsafe signals is in effect, then signal handling is not thread-safe, and the `->kill()` signalling method cannot be used.

- Identity of objects returned from threads

  When a value is returned from a thread through a `join` operation, the value and everything that it references is copied across to the joining thread, in much the same way that values are copied upon thread creation. This works fine for most kinds of value, including arrays, hashes, and subroutines. The copying recurses through array elements, reference scalars, variables closed over by subroutines, and other kinds of reference.

  However, everything referenced by the returned value is a fresh copy in the joining thread, even if a returned object had in the child thread been a copy of something that previously existed in the parent thread. After joining, the parent will therefore have a duplicate of each such object. This sometimes matters, especially if the

object gets mutated; this can especially matter for private data to which a returned subroutine provides access.

- Returning blessed objects from threads

  Returning blessed objects from threads does not work. Depending on the classes involved, you may be able to work around this by returning a serialized version of the object (e.g., using *Data::Dumper* or *Storable*), and then reconstituting it in the joining thread. If you're using Perl 5.10.0 or later, and if the class supports *shared objects*, you can pass them via *shared queues*.

- END blocks in threads

  It is possible to add END blocks to threads by using *require* or *eval* with the appropriate code. These `END` blocks will then be executed when the thread's interpreter is destroyed (i.e., either during a `->join()` call, or at program termination).

  However, calling any *threads* methods in such an `END` block will most likely *fail* (e.g., the application may hang, or generate an error) due to mutexes that are needed to control functionality within the *threads* module.

  For this reason, the use of `END` blocks in threads is **strongly** discouraged.

- Open directory handles

  In perl 5.14 and higher, on systems other than Windows that do not support the `fchdir` C function, directory handles (see *opendir*) will not be copied to new threads. You can use the `d_fchdir` variable in *Config.pm* to determine whether your system supports it.

  In prior perl versions, spawning threads with open directory handles would crash the interpreter. [perl #75154]

- Detached threads and global destruction

  If the main thread exits while there are detached threads which are still running, then Perl's global destruction phase is not executed because otherwise certain global structures that control the operation of threads and that are allocated in the main thread's memory may get destroyed before the detached thread is destroyed.

  If you are using any code that requires the execution of the global destruction phase for clean up (e.g., removing temp files), then do not use detached threads, but rather join all threads before exiting the program.

- Perl Bugs and the CPAN Version of *threads*

  Support for threads extends beyond the code in this module (i.e., `threads.pm` and `threads.xs`), and into the Perl interpreter itself. Older versions of Perl contain bugs that may manifest themselves despite using the latest version of *threads* from CPAN. There is no workaround for this other than upgrading to the latest version of Perl.

  Even with the latest version of Perl, it is known that certain constructs with threads may result in warning messages concerning leaked scalars or unreferenced scalars. However, such warnings are harmless, and may safely be ignored.

  You can search for *threads* related bug reports at https://rt.cpan.org/Public/. If needed submit any new bugs, problems, patches, etc. to: https://rt.cpan.org/Public/Dist/Display.html?Name=threads

REQUIREMENTS

Perl 5.8.0 or later

Modules

- `threads::shared` - Perl extension for sharing data structures between threads

threads::shared

Perl extension for sharing data structures between threads

VERSION

This document describes threads::shared version 1.73

SYNOPSIS

```
use threads;
use threads::shared;

my $var :shared;
my %hsh :shared;
my @ary :shared;

my ($scalar, @array, %hash);
share($scalar);
share(@array);
share(%hash);

$var = $scalar_value;
$var = $shared_ref_value;
$var = shared_clone($non_shared_ref_value);
$var = shared_clone({'foo' => [qw/foo bar baz/]});

$hsh{'foo'} = $scalar_value;
$hsh{'bar'} = $shared_ref_value;
$hsh{'baz'} = shared_clone($non_shared_ref_value);
$hsh{'quz'} = shared_clone([1..3]);

$ary[0] = $scalar_value;
$ary[1] = $shared_ref_value;
$ary[2] = shared_clone($non_shared_ref_value);
$ary[3] = shared_clone([ {}, [] ]);

{ lock(%hash); ...  }

cond_wait($scalar);
cond_timedwait($scalar, time() + 30);
cond_broadcast(@array);
cond_signal(%hash);

my $lockvar :shared;
# condition var != lock var
cond_wait($var, $lockvar);
cond_timedwait($var, time()+30, $lockvar);
```

DESCRIPTION

By default, variables are private to each thread, and each newly created thread gets a private copy of each existing variable. This module allows you to share variables across different threads (and pseudo-forks on Win32). It is used together with the *threads* mod-

ule.

This module supports the sharing of the following data types only: scalars and scalar refs, arrays and array refs, and hashes and hash refs.

EXPORT

The following functions are exported by this module: `share`, `shared_clone`, `is_shared`, `cond_wait`, `cond_timedwait`, `cond_signal` and `cond_broadcast`

Note that if this module is imported when *threads* has not yet been loaded, then these functions all become no-ops. This makes it possible to write modules that will work in both threaded and non-threaded environments.

FUNCTIONS

- share VARIABLE

  `share` takes a variable and marks it as shared:

```
my ($scalar, @array, %hash);
share($scalar);
share(@array);
share(%hash);
```

  `share` will return the shared rvalue, but always as a reference.

  Variables can also be marked as shared at compile time by using the `:shared` attribute:

```
my ($var, %hash, @array) :shared;
```

  Shared variables can only store scalars, refs of shared variables, or refs of shared data (discussed in next section):

```
my ($var, %hash, @array) :shared;
my $bork;

# Storing scalars
$var = 1;
$hash{'foo'} = 'bar';
$array[0] = 1.5;

# Storing shared refs
$var = \%hash;
$hash{'ary'} = \@array;
$array[1] = \$var;

# The following are errors:
#   $var = \$bork;                  # ref of non-shared
 ↪variable
#   $hash{'bork'} = [];             # non-shared array ref
#   push(@array, { 'x' => 1 });     # non-shared hash ref
```

- shared_clone REF

  `shared_clone` takes a reference, and returns a shared version of its argument, performing a deep copy on any non-shared elements. Any shared elements in the argument are used as is (i.e., they are not cloned).

```
my $cpy = shared_clone({'foo' => [qw/foo bar baz/]});
```

  Object status (i.e., the class an object is blessed into) is also cloned.

```
my $obj = {'foo' => [qw/foo bar baz/]};
bless($obj, 'Foo');
my $cpy = shared_clone($obj);
print(ref($cpy), "\n");          # Outputs 'Foo'
```

  For cloning empty array or hash refs, the following may also be used:

```
$var = &share([]);   # Same as $var = shared_clone([]);
$var = &share({});   # Same as $var = shared_clone({});
```

  Not all Perl data types can be cloned (e.g., globs, code refs). By default, `shared_clone` will *croak* if it encounters such items. To change this behaviour to a warning, then set the following:

```
$threads::shared::clone_warn = 1;
```

  In this case, `undef` will be substituted for the item to be cloned. If set to zero:

```
$threads::shared::clone_warn = 0;
```

  then the `undef` substitution will be performed silently.

- is_shared VARIABLE

  `is_shared` checks if the specified variable is shared or not. If shared, returns the variable's internal ID (similar to `refaddr()` (see *Scalar::Util*). Otherwise, returns `undef`.

```
if (is_shared($var)) {
    print("\$var is shared\n");
} else {
    print("\$var is not shared\n");
}
```

  When used on an element of an array or hash, `is_shared` checks if the specified element belongs to a shared array or hash. (It does not check the contents of that element.)

```
my %hash :shared;
if (is_shared(%hash)) {
    print("\%hash is shared\n");
}

$hash{'elem'} = 1;
```

(continues on next page)

(continued from previous page)

```
if (is_shared($hash{'elem'})) {
    print("\$hash{'elem'} is in a shared hash\n");
}
```

- lock VARIABLE

  `lock` places a **advisory** lock on a variable until the lock goes out of scope. If the variable is locked by another thread, the `lock` call will block until it's available. Multiple calls to `lock` by the same thread from within dynamically nested scopes are safe – the variable will remain locked until the outermost lock on the variable goes out of scope.

  `lock` follows references exactly *one* level:

```
my %hash :shared;
my $ref = \%hash;
lock($ref);           # This is equivalent to lock(%hash)
```

  Note that you cannot explicitly unlock a variable; you can only wait for the lock to go out of scope. This is most easily accomplished by locking the variable inside a block.

```
my $var :shared;
{
    lock($var);
    # $var is locked from here to the end of the block
    ...
}
# $var is now unlocked
```

  As locks are advisory, they do not prevent data access or modification by another thread that does not itself attempt to obtain a lock on the variable.

  You cannot lock the individual elements of a container variable:

```
my %hash :shared;
$hash{'foo'} = 'bar';
#lock($hash{'foo'});          # Error
lock(%hash);                  # Works
```

  If you need more fine-grained control over shared variable access, see *Thread::Semaphore*.

- cond_wait VARIABLE
- cond_wait CONDVAR, LOCKVAR

  The `cond_wait` function takes a **locked** variable as a parameter, unlocks the variable, and blocks until another thread does a `cond_signal` or `cond_broadcast` for that same locked variable. The variable that `cond_wait` blocked on is re-locked after the `cond_wait` is satisfied. If there are multiple threads `cond_waiting` on the same variable, all but one will re-block waiting to reacquire the lock on the variable. (So if you're only using `cond_wait` for synchronization, give up the lock as soon as possible). The two actions of unlocking the variable and entering the

blocked wait state are atomic, the two actions of exiting from the blocked wait state and re-locking the variable are not.

In its second form, `cond_wait` takes a shared, **unlocked** variable followed by a shared, **locked** variable. The second variable is unlocked and thread execution suspended until another thread signals the first variable.

It is important to note that the variable can be notified even if no thread `cond_signal` or `cond_broadcast` on the variable. It is therefore important to check the value of the variable and go back to waiting if the requirement is not fulfilled. For example, to pause until a shared counter drops to zero:

```
{ lock($counter); cond_wait($counter) until $counter == 0; }
```

- cond_timedwait VARIABLE, ABS_TIMEOUT
- cond_timedwait CONDVAR, ABS_TIMEOUT, LOCKVAR

  In its two-argument form, `cond_timedwait` takes a **locked** variable and an absolute timeout in *epoch* seconds (see *time() in perlfunc* for more) as parameters, unlocks the variable, and blocks until the timeout is reached or another thread signals the variable. A false value is returned if the timeout is reached, and a true value otherwise. In either case, the variable is re-locked upon return.

  Like `cond_wait`, this function may take a shared, **locked** variable as an additional parameter; in this case the first parameter is an **unlocked** condition variable protected by a distinct lock variable.

  Again like `cond_wait`, waking up and reacquiring the lock are not atomic, and you should always check your desired condition after this function returns. Since the timeout is an absolute value, however, it does not have to be recalculated with each pass:

```
lock($var);
my $abs = time() + 15;
until ($ok = desired_condition($var)) {
    last if !cond_timedwait($var, $abs);
}
# we got it if $ok, otherwise we timed out!
```

- cond_signal VARIABLE

  The `cond_signal` function takes a **locked** variable as a parameter and unblocks one thread that's `cond_waiting` on that variable. If more than one thread is blocked in a `cond_wait` on that variable, only one (and which one is indeterminate) will be unblocked.

  If there are no threads blocked in a `cond_wait` on the variable, the signal is discarded. By always locking before signaling, you can (with care), avoid signaling before another thread has entered cond_wait().

  `cond_signal` will normally generate a warning if you attempt to use it on an unlocked variable. On the rare occasions where doing this may be sensible, you can suppress the warning with:

```
{ no warnings 'threads'; cond_signal($foo); }
```

- cond_broadcast VARIABLE

  The `cond_broadcast` function works similarly to `cond_signal`. `cond_broadcast`, though, will unblock **all** the threads that are blocked in a `cond_wait` on the locked variable, rather than only one.

OBJECTS

threads::shared exports a version of *bless()* that works on shared objects such that *blessings* propagate across threads.

```
# Create a shared 'Foo' object
my $foo :shared = shared_clone({});
bless($foo, 'Foo');

# Create a shared 'Bar' object
my $bar :shared = shared_clone({});
bless($bar, 'Bar');

# Put 'bar' inside 'foo'
$foo->{'bar'} = $bar;

# Rebless the objects via a thread
threads->create(sub {
    # Rebless the outer object
    bless($foo, 'Yin');

    # Cannot directly rebless the inner object
    #bless($foo->{'bar'}, 'Yang');

    # Retrieve and rebless the inner object
    my $obj = $foo->{'bar'};
    bless($obj, 'Yang');
    $foo->{'bar'} = $obj;

})->join();

print(ref($foo),          "\n");    # Prints 'Yin'
print(ref($foo->{'bar'}), "\n");    # Prints 'Yang'
print(ref($bar),          "\n");    # Also prints 'Yang'
```

NOTES

threads::shared is designed to disable itself silently if threads are not available. This allows you to write modules and packages that can be used in both threaded and non-threaded applications.

If you want access to threads, you must `use threads` before you `use threads::shared`. *threads* will emit a warning if you use it after *threads::shared*.

WARNINGS

- cond_broadcast() called on unlocked variable
- cond_signal() called on unlocked variable

  See "cond_signal VARIABLE", above.

BUGS AND LIMITATIONS

When `share` is used on arrays, hashes, array refs or hash refs, any data they contain will be lost.

```
my @arr = qw(foo bar baz);
share(@arr);
# @arr is now empty (i.e., == ());

# Create a 'foo' object
my $foo = { 'data' => 99 };
bless($foo, 'foo');

# Share the object
share($foo);        # Contents are now wiped out
print("ERROR: \$foo is empty\n")
    if (! exists($foo->{'data'}));
```

Therefore, populate such variables **after** declaring them as shared. (Scalar and scalar refs are not affected by this problem.)

Blessing a shared item after it has been nested in another shared item does not propagate the blessing to the shared reference:

```
my $foo = &share({});
my $bar = &share({});
$bar->{foo} = $foo;
bless($foo, 'baz');   # $foo is now of class 'baz',
                      # but $bar->{foo} is unblessed.
```

Therefore, you should bless objects before sharing them.

It is often not wise to share an object unless the class itself has been written to support sharing. For example, a shared object's destructor may get called multiple times, once for each thread's scope exit, or may not get called at all if it is embedded inside another shared object. Another issue is that the contents of hash-based objects will be lost due to the above mentioned limitation. See `examples/class.pl` (in the CPAN distribution of this module) for how to create a class that supports object sharing.

Destructors may not be called on objects if those objects still exist at global destruction time. If the destructors must be called, make sure there are no circular references and that nothing is referencing the objects before the program ends.

Does not support `splice` on arrays. Does not support explicitly changing array lengths via $#array – use `push` and pop instead.

Taking references to the elements of shared arrays and hashes does not autovivify the

elements, and neither does slicing a shared array/hash over non-existent indices/keys autovivify the elements.

`share()` allows you to `share($hashref->{key})` and `share($arrayref->[idx])` without giving any error message. But the `$hashref->{key}` or `$arrayref->[idx]` is **not** shared, causing the error "lock can only be used on shared values" to occur when you attempt to `lock($hashref->{key})` or `lock($arrayref->[idx])` in another thread.

Using `refaddr()` is unreliable for testing whether or not two shared references are equivalent (e.g., when testing for circular references). Use is_shared(), instead:

```
use threads;
use threads::shared;
use Scalar::Util qw(refaddr);

# If ref is shared, use threads::shared's internal ID.
# Otherwise, use refaddr().
my $addr1 = is_shared($ref1) || refaddr($ref1);
my $addr2 = is_shared($ref2) || refaddr($ref2);

if ($addr1 == $addr2) {
    # The refs are equivalent
}
```

each() does not work properly on shared references embedded in shared structures. For example:

```
my %foo :shared;
$foo{'bar'} = shared_clone({'a'=>'x', 'b'=>'y', 'c'=>'z'});

while (my ($key, $val) = each(%{$foo{'bar'}})) {
    ...
}
```

Either of the following will work instead:

```
my $ref = $foo{'bar'};
while (my ($key, $val) = each(%{$ref})) {
    ...
}

foreach my $key (keys(%{$foo{'bar'}})) {
    my $val = $foo{'bar'}{$key};
    ...
}
```

This module supports dual-valued variables created using `dualvar()` from *Scalar::Util*. However, while `$!` acts like a dualvar, it is implemented as a tied SV. To propagate its value, use the follow construct, if needed:

```
my $errno :shared = dualvar($!,$!);
```

5.2.158 utf8

Perl pragma to enable/disable UTF-8 (or UTF-EBCDIC) in source code

SYNOPSIS

```
use utf8;
no utf8;

# Convert the internal representation of a Perl scalar to/from UTF-
 ↪8.

$num_octets = utf8::upgrade($string);
$success    = utf8::downgrade($string[, $fail_ok]);

# Change each character of a Perl scalar to/from a series of
# characters that represent the UTF-8 bytes of each original␣
 ↪character.

utf8::encode($string);  # "\x{100}"  becomes "\xc4\x80"
utf8::decode($string);  # "\xc4\x80" becomes "\x{100}"

# Convert a code point from the platform native character set to
# Unicode, and vice-versa.
```

(continues on next page)

(continued from previous page)

```
$unicode = utf8::native_to_unicode(ord('A')); # returns 65 on both
                                              # ASCII and EBCDIC
                                              # platforms
$native = utf8::unicode_to_native(65);        # returns 65 on ASCII
                                              # platforms; 193 on
                                              # EBCDIC

$flag = utf8::is_utf8($string); # since Perl 5.8.1
$flag = utf8::valid($string);
```

DESCRIPTION

The `use utf8` pragma tells the Perl parser to allow UTF-8 in the program text in the current lexical scope. The `no utf8` pragma tells Perl to switch back to treating the source text as literal bytes in the current lexical scope. (On EBCDIC platforms, technically it is allowing UTF-EBCDIC, and not UTF-8, but this distinction is academic, so in this document the term UTF-8 is used to mean both).

Do not use this pragma for anything else than telling Perl that your script is written in UTF-8. The utility functions described below are directly usable without `use utf8;`.

Because it is not possible to reliably tell UTF-8 from native 8 bit encodings, you need either a Byte Order Mark at the beginning of your source code, or `use utf8;`, to instruct perl.

When UTF-8 becomes the standard source format, this pragma will effectively become a no-op.

See also the effects of the `-C` switch and its cousin, the `PERL_UNICODE` environment variable, in perlrun.

Enabling the `utf8` pragma has the following effect:

- Bytes in the source text that are not in the ASCII character set will be treated as being part of a literal UTF-8 sequence. This includes most literals such as identifier names, string constants, and constant regular expression patterns.

Note that if you have non-ASCII, non-UTF-8 bytes in your script (for example embedded Latin-1 in your string literals), `use utf8` will be unhappy. If you want to have such bytes under `use utf8`, you can disable this pragma until the end the block (or file, if at top level) by `no utf8;`.

Utility functions

The following functions are defined in the `utf8::` package by the Perl core. You do not need to say `use utf8` to use these and in fact you should not say that unless you really want to have UTF-8 source code.

- `$num_octets = utf8::upgrade($string)`

  (Since Perl v5.8.0) Converts in-place the internal representation of the string from an octet sequence in the native encoding (Latin-1 or EBCDIC) to UTF-8. The logical character sequence itself is unchanged. If *$string* is already upgraded, then this is a no-op. Returns the number of octets necessary to represent the string as UTF-8.

Since Perl v5.38, if `$string` is `undef` no action is taken; prior to that, it would be converted to be defined and zero-length.

If your code needs to be compatible with versions of perl without `use feature 'unicode_strings';`, you can force Unicode semantics on a given string:

```
# force unicode semantics for $string without the
# "unicode_strings" feature
utf8::upgrade($string);
```

For example:

```
# without explicit or implicit use feature 'unicode_strings'
my $x = "\xDF";    # LATIN SMALL LETTER SHARP S
$x =~ /ss/i;       # won't match
my $y = uc($x);    # won't convert
utf8::upgrade($x);
$x =~ /ss/i;       # matches
my $z = uc($x);    # converts to "SS"
```

Note that this function does not handle arbitrary encodings; use *Encode* instead.

- `$success = utf8::downgrade($string[, $fail_ok])`

  (Since Perl v5.8.0) Converts in-place the internal representation of the string from UTF-8 to the equivalent octet sequence in the native encoding (Latin-1 or EBCDIC). The logical character sequence itself is unchanged. If *$string* is already stored as native 8 bit, then this is a no-op. Can be used to make sure that the UTF-8 flag is off, e.g. when you want to make sure that the substr() or length() function works with the usually faster byte algorithm.

  Fails if the original UTF-8 sequence cannot be represented in the native 8 bit encoding. On failure dies or, if the value of *$fail_ok* is true, returns false.

  Returns true on success.

  If your code expects an octet sequence this can be used to validate that you've received one:

```
# throw an exception if not representable as octets
utf8::downgrade($string)

# or do your own error handling
utf8::downgrade($string, 1) or die "string must be octets";
```

  Note that this function does not handle arbitrary encodings; use *Encode* instead.

- `utf8::encode($string)`

  (Since Perl v5.8.0) Converts in-place the character sequence to the corresponding octet sequence in Perl's extended UTF-8. That is, every (possibly wide) character gets replaced with a sequence of one or more characters that represent the individual UTF-8 bytes of the character. The UTF8 flag is turned off. Returns nothing.

```
my $x = "\x{100}"; # $x contains one character, with ord 0x100
utf8::encode($x);  # $x contains two characters, with ords (on
                   # ASCII platforms) 0xc4 and 0x80.  On EBCDIC
                   # 1047, this would instead be 0x8C and 0x41.
```

Similar to:

```
use Encode;
$x = Encode::encode("utf8", $x);
```

Note that this function does not handle arbitrary encodings; use *Encode* instead.

- `$success = utf8::decode($string)`

  (Since Perl v5.8.0) Attempts to convert in-place the octet sequence encoded in Perl's extended UTF-8 to the corresponding character sequence. That is, it replaces each sequence of characters in the string whose ords represent a valid (extended) UTF-8 byte sequence, with the corresponding single character. The UTF-8 flag is turned on only if the source string contains multiple-byte UTF-8 characters. If *$string* is invalid as extended UTF-8, returns false; otherwise returns true.

```
my $x = "\xc4\x80"; # $x contains two characters, with ords
                    # 0xc4 and 0x80
utf8::decode($x);   # On ASCII platforms, $x contains one char,
                    # with ord 0x100.   Since these bytes aren't
                    # legal UTF-EBCDIC, on EBCDIC platforms, $x
 ↪is
                    # unchanged and the function returns FALSE.
my $y = "\xc3\x83\xc2\xab"; This has been encoded twice; this
                    # example is only for ASCII platforms
utf8::decode($y);   # Converts $y to \xc3\xab, returns TRUE;
utf8::decode($y);   # Further converts to \xeb, returns TRUE;
utf8::decode($y);   # Returns FALSE, leaves $y unchanged
```

Note that this function does not handle arbitrary encodings; use *Encode* instead.

- `$unicode = utf8::native_to_unicode($code_point)`

  (Since Perl v5.8.0) This takes an unsigned integer (which represents the ordinal number of a character (or a code point) on the platform the program is being run on) and returns its Unicode equivalent value. Since ASCII platforms natively use the Unicode code points, this function returns its input on them. On EBCDIC platforms it converts from EBCDIC to Unicode.

  A meaningless value will currently be returned if the input is not an unsigned integer.

  Since Perl v5.22.0, calls to this function are optimized out on ASCII platforms, so there is no performance hit in using it there.

- `$native = utf8::unicode_to_native($code_point)`

  (Since Perl v5.8.0) This is the inverse of `utf8::native_to_unicode()`, converting

the other direction. Again, on ASCII platforms, this returns its input, but on EBCDIC platforms it will find the native platform code point, given any Unicode one.

A meaningless value will currently be returned if the input is not an unsigned integer.

Since Perl v5.22.0, calls to this function are optimized out on ASCII platforms, so there is no performance hit in using it there.

- `$flag = utf8::is_utf8($string)`

  (Since Perl 5.8.1) Test whether *$string* is marked internally as encoded in UTF-8. Functionally the same as `Encode::is_utf8($string)`.

  Typically only necessary for debugging and testing, if you need to dump the internals of an SV, *Devel::Peek's* Dump() provides more detail in a compact form.

  If you still think you need this outside of debugging, testing or dealing with filenames, you should probably read perlunitut and "What is "the UTF8 flag"?" in perlunifaq.

  Don't use this flag as a marker to distinguish character and binary data: that should be decided for each variable when you write your code.

  To force unicode semantics in code portable to perl 5.8 and 5.10, call `utf8::upgrade($string)` unconditionally.

- `$flag = utf8::valid($string)`

  [INTERNAL] Test whether *$string* is in a consistent state regarding UTF-8. Will return true if it is well-formed Perl extended UTF-8 and has the UTF-8 flag on **or** if *$string* is held as bytes (both these states are 'consistent'). The main reason for this routine is to allow Perl's test suite to check that operations have left strings in a consistent state.

`utf8::encode` is like `utf8::upgrade`, but the UTF8 flag is cleared. See perlunicode, and the C API functions `sv_utf8_upgrade`, `"sv_utf8_downgrade" in perlapi`, `"sv_utf8_encode" in perlapi`, and `"sv_utf8_decode" in perlapi`, which are wrapped by the Perl functions `utf8::upgrade`, `utf8::downgrade`, `utf8::encode` and `utf8::decode`. Also, the functions `utf8::is_utf8`, `utf8::valid`, `utf8::encode`, `utf8::decode`, `utf8::upgrade`, and `utf8::downgrade` are actually internal, and thus always available, without a `require utf8` statement.

BUGS

Some filesystems may not support UTF-8 file names, or they may be supported incompatibly with Perl. Therefore UTF-8 names that are visible to the filesystem, such as module names may not work.

5.2.159 vars

Perl pragma to predeclare global variable names

SYNOPSIS

```
use vars qw($frob @mung %seen);
```

DESCRIPTION

NOTE: For use with variables in the current package for a single scope, the functionality provided by this pragma has been superseded by `our` declarations, available in Perl v5.6.0 or later, and use of this pragma is discouraged. See *"our" in perlfunc*.

This pragma will predeclare all the variables whose names are in the list, allowing you to use them under `use strict`, and disabling any typo warnings for them.

Unlike pragmas that affect the `$^H` hints variable, the `use vars` and `use subs` declarations are not lexically scoped to the block they appear in: they affect the entire package in which they appear. It is not possible to rescind these declarations with `no vars` or `no subs`.

Packages such as the **AutoLoader** and **SelfLoader** that delay loading of subroutines within packages can create problems with package lexicals defined using `my()`. While the **vars** pragma cannot duplicate the effect of package lexicals (total transparency outside of the package), it can act as an acceptable substitute by pre-declaring global symbols, ensuring their availability to the later-loaded routines.

See "Pragmatic Modules" in perlmodlib.

5.2.160 version

Turn a version string into an object you can compare, print, and introspect.

Perl has three spellings for a version, and mixing them in one program is normal. `version` gives you a single object type that handles all three so `$a <=> $b` always does the right thing.

- **Decimal** - a plain number like `1.023` or `"1.02_03"`. One integer part, then three-digit chunks after the dot. An underscore marks an alpha release.
- **Dotted-integer** - two or more integers separated by dots, e.g. `1.2.3`. No `v` prefix required, but three or more components are treated as dotted-integer regardless.
- **v-string** - an explicit v prefix, e.g. `v1.23.45`. This form is recommended for `$VERSION` declarations and is required to pass `is_strict`.

Synopsis

```
use version 0.77;
our $VERSION = version->declare("v1.2.3");
my $v = version->parse("1.0203");
if ($v1 == $v2)  { ... }                # numeric equality
@sorted = sort { $a <=> $b } @versions; # ordering
```

`use version` imports qv into the caller's package and installs `version::_VERSION` as `UNIVERSAL::VERSION`, so `$module->VERSION($min)` compares with version-object semantics; `$module->VERSION` itself still returns a plain string.

Operators

version objects are overloaded so you can use the normal Perl comparison operators directly:

- ==, != - numeric equality
- <, <=, >, >=, <=> - numeric ordering
- eq, ne, cmp - same thing, stringwise spelling
- "" - stringifies to original form (dotted) or decimal, whichever the object was created with
- 0+ - numifies to a decimal

The overload fallback is on, so any relational operator not listed above works by auto-generation from <=>.

Functions

Introspection

is_lax

Test whether a string is acceptable to `parse` / `new` as a version.

is_strict

Test whether a string is a strict version suitable for CPAN indexing.

is_lax

Test whether a string is acceptable to `parse` / `new` as a version.

Synopsis

```
version::is_lax($str);
is_lax($str);            # after use version qw(is_lax)
```

Accepts anything the constructor would accept: decimal, dotted-integer, v-string, with or without an underscore for alpha. Use it to validate user input before feeding it to `parse`.

What you get back

A boolean: 1 if the string parses as any valid version, the empty string otherwise.

Examples

```
version::is_lax("1.0203");      # 1
version::is_lax("v1.2.3");      # 1
version::is_lax("1.02_03");     # 1
version::is_lax("");            # ""
version::is_lax("abc");         # ""
```

Differences from upstream

Fully compatible with upstream version 0.9934.

See also

- `is_strict` - the tighter validator, used for CPAN-indexable versions
- new - accepts the same set of strings

is_strict

Test whether a string is a strict version suitable for CPAN indexing.

Synopsis

```
version::is_strict($str);
is_strict($str);         # after use version qw(is_strict)
```

Strict versions rule out alpha underscores and unusual shapes. A decimal version is an integer without leading zeros, optionally followed by one dot and a digit run; a dotted-integer version must start with v and have at least three components. This is the form PAUSE expects for permanent releases.

What you get back

A boolean: 1 if the string matches the strict grammar, the empty string otherwise.

Examples

```
version::is_strict("1.02");         # 1
version::is_strict("v1.2.3");       # 1
version::is_strict("1.2.3");        # ""  - needs the v prefix
version::is_strict("1.02_03");      # ""  - underscores disallowed
version::is_strict("v1.2");         # ""  - needs 3+ components
```

Differences from upstream

Fully compatible with upstream version 0.9934.

5.2.161 warnings

Perl pragma to control optional warnings

SYNOPSIS

```
use warnings;
no warnings;

# Standard warnings are enabled by use v5.35 or above
use v5.35;

use warnings "all";
no warnings "uninitialized";

# or equivalent to those last two ...
use warnings qw(all -uninitialized);

use warnings::register;
if (warnings::enabled()) {
    warnings::warn("some warning");
}

if (warnings::enabled("void")) {
    warnings::warn("void", "some warning");
}

if (warnings::enabled($object)) {
    warnings::warn($object, "some warning");
}

warnings::warnif("some warning");
warnings::warnif("void", "some warning");
warnings::warnif($object, "some warning");
```

DESCRIPTION

The `warnings` pragma gives control over which warnings are enabled in which parts of a Perl program. It's a more flexible alternative for both the command line flag **-w** and the equivalent Perl variable, `$^W`.

This pragma works just like the `strict` pragma. This means that the scope of the warning pragma is limited to the enclosing block. It also means that the pragma setting will not leak across files (via `use`, `require` or do). This allows authors to independently define the degree of warning checks that will be applied to their module.

By default, optional warnings are disabled, so any legacy code that doesn't attempt to control the warnings will work unchanged.

All warnings are enabled in a block by either of these:

```
use warnings;
use warnings 'all';
```

Similarly all warnings are disabled in a block by either of these:

```
no warnings;
no warnings 'all';
```

For example, consider the code below:

```
use warnings;
my @x;
{
    no warnings;
    my $y = @x[0];
}
my $z = @x[0];
```

The code in the enclosing block has warnings enabled, but the inner block has them disabled. In this case that means the assignment to the scalar `$z` will trip the `"Scalar value @x[0] better written as $x[0]"` warning, but the assignment to the scalar `$y` will not.

All warnings are enabled automatically within the scope of a `use v5.35` (or higher) declaration.

Default Warnings and Optional Warnings

Before the introduction of lexical warnings, Perl had two classes of warnings: mandatory and optional.

As its name suggests, if your code tripped a mandatory warning, you would get a warning whether you wanted it or not. For example, the code below would always produce an `"isn't numeric"` warning about the "2:".

```
my $x = "2:" + 3;
```

With the introduction of lexical warnings, mandatory warnings now become *default* warnings. The difference is that although the previously mandatory warnings are still enabled by default, they can then be subsequently enabled or disabled with the lexical warning pragma. For example, in the code below, an `"isn't numeric"` warning will only be reported for the `$x` variable.

```
my $x = "2:" + 3;
no warnings;
my $y = "2:" + 3;
```

Note that neither the **-w** flag or the `$^W` can be used to disable/enable default warnings. They are still mandatory in this case.

"Negative warnings"

As a convenience, you can (as of Perl 5.34) pass arguments to the `import()` method both positively and negatively. Negative warnings are those with a `-` sign prepended to their names; positive warnings are anything else. This lets you turn on some warnings and turn off others in one command. So, assuming that you've already turned on a bunch of warnings but want to tweak them a bit in some block, you can do this:

```
{
    use warnings qw(uninitialized -redefine);
    ...
}
```

which is equivalent to:

```
{
    use warnings qw(uninitialized);
    no warnings qw(redefine);
    ...
}
```

The argument list is processed in the order you specify. So, for example, if you don't want to be warned about use of experimental features, except for `somefeature` that you really dislike, you can say this:

```
use warnings qw(all -experimental experimental::somefeature);
```

which is equivalent to:

```
use warnings 'all';
no warnings  'experimental';
use warnings 'experimental::somefeature';
```

As experimental features become regular features of Perl, the corresponding warnings are not printed anymore. They also stop being listed in the "Category Hierarchy" below.

It is still possible to request turning on or off these warnings, but doing so has no effect.

What's wrong with -w and $^W

Although very useful, the big problem with using **-w** on the command line to enable warnings is that it is all or nothing. Take the typical scenario when you are writing a Perl program. Parts of the code you will write yourself, but it's very likely that you will make use of pre-written Perl modules. If you use the **-w** flag in this case, you end up enabling warnings in pieces of code that you haven't written.

Similarly, using `$^W` to either disable or enable blocks of code is fundamentally flawed. For a start, say you want to disable warnings in a block of code. You might expect this to be enough to do the trick:

```
{
    local ($^W) = 0;
    my $x =+ 2;
```

(continues on next page)

(continued from previous page)

```
    my $y; chop $y;
}
```

When this code is run with the **-w** flag, a warning will be produced for the `$x` line: `"Reversed += operator"`.

The problem is that Perl has both compile-time and run-time warnings. To disable compile-time warnings you need to rewrite the code like this:

```
{
    BEGIN { $^W = 0 }
    my $x =+ 2;
    my $y; chop $y;
}
```

And note that unlike the first example, this will permanently set `$^W` since it cannot both run during compile-time and be localized to a run-time block.

The other big problem with `$^W` is the way you can inadvertently change the warning setting in unexpected places in your code. For example, when the code below is run (without the **-w** flag), the second call to `doit` will trip a `"Use of uninitialized value"` warning, whereas the first will not.

```
sub doit
{
    my $y; chop $y;
}

doit();

{
    local ($^W) = 1;
    doit()
}
```

This is a side-effect of `$^W` being dynamically scoped.

Lexical warnings get around these limitations by allowing finer control over where warnings can or can't be tripped.

Controlling Warnings from the Command Line

There are three Command Line flags that can be used to control when warnings are (or aren't) produced:

- **-w**

  This is the existing flag. If the lexical warnings pragma is **not** used in any of your code, or any of the modules that you use, this flag will enable warnings everywhere. See "Backward Compatibility" for details of how this flag interacts with lexical warnings.

- **-W**

If the **-W** flag is used on the command line, it will enable all warnings throughout the program regardless of whether warnings were disabled locally using `no warnings` or `$^W =0`. This includes all files that get included via `use`, `require` or do. Think of it as the Perl equivalent of the "lint" command.

- **-X**

  Does the exact opposite to the **-W** flag, i.e. it disables all warnings.

Backward Compatibility

If you are used to working with a version of Perl prior to the introduction of lexically scoped warnings, or have code that uses both lexical warnings and `$^W`, this section will describe how they interact.

How Lexical Warnings interact with **-w**/`$^W`:

1. If none of the three command line flags (**-w**, **-W** or **-X**) that control warnings is used and neither `$^W` nor the `warnings` pragma are used, then default warnings will be enabled and optional warnings disabled. This means that legacy code that doesn't attempt to control the warnings will work unchanged.
2. The **-w** flag just sets the global `$^W` variable as in 5.005. This means that any legacy code that currently relies on manipulating `$^W` to control warning behavior will still work as is.
3. Apart from now being a boolean, the `$^W` variable operates in exactly the same horrible uncontrolled global way, except that it cannot disable/enable default warnings.
4. If a piece of code is under the control of the `warnings` pragma, both the `$^W` variable and the **-w** flag will be ignored for the scope of the lexical warning.
5. The only way to override a lexical warnings setting is with the **-W** or **-X** command line flags.

The combined effect of 3 & 4 is that it will allow code which uses the `warnings` pragma to control the warning behavior of `$^W`-type code (using a `local $^W=0`) if it really wants to, but not vice-versa.

Category Hierarchy

A hierarchy of "categories" have been defined to allow groups of warnings to be enabled/disabled in isolation.

The current hierarchy is:

```
all -+
     |
     +- closure
     |
     +- deprecated -----+
     |                  |
     |                  +- deprecated::delimiter_will_be_paired
     |                  |
```

(continues on next page)

(continued from previous page)

```
    |                   +- deprecated::dot_in_inc
    |                   |
    |                   +- deprecated::subsequent_use_version
    |                   |
    |                   +- deprecated::unicode_property_name
    |                   |
    |                   +- deprecated::version_downgrade
    |
    +- exiting
    |
    +- experimental ---+
    |                   |
    |                   +- experimental::args_array_with_signatures
    |                   |
    |                   +- experimental::builtin
    |                   |
    |                   +- experimental::class
    |                   |
    |                   +- experimental::declared_refs
    |                   |
    |                   +- experimental::defer
    |                   |
    |                   +- experimental::enhanced_xx
    |                   |
    |                   +- experimental::extra_paired_delimiters
    |                   |
    |                   +- experimental::keyword_all
    |                   |
    |                   +- experimental::keyword_any
    |                   |
    |                   +- experimental::private_use
    |                   |
    |                   +- experimental::re_strict
    |                   |
    |                   +- experimental::refaliasing
    |                   |
    |                   +- experimental::regex_sets
    |                   |
    |                   +- experimental::signature_named_parameters
    |                   |
    |                   +- experimental::try
    |                   |

    |                   +- parenthesis
    |                   |
    |                   +- precedence
    |                   |
    |                   +- printf
    |                   |
    |                   +- prototype
    |                   |
    |                   +- qw
    |                   |
    |                   +- reserved
    |                   |
    |                   +- semicolon
    |
    +- taint
    |
    +- threads
    |
    +- uninitialized
    |
    +- unpack
    |
    +- untie
    |
    +- utf8 -----------+
    |                   |
    |                   +- non_unicode
```

(continues on next page)

(continued from previous page)

```
    |                   |
    |                   +- nonchar
    |                   |
    |                   +- surrogate
    |
    +- void
```

Just like the "strict" pragma any of these categories can be combined

```
use warnings qw(void redefine);
no warnings qw(io syntax untie);
```

Also like the "strict" pragma, if there is more than one instance of the `warnings` pragma in a given scope the cumulative effect is additive.

```
use warnings qw(void); # only "void" warnings enabled
...
use warnings qw(io);   # only "void" & "io" warnings enabled
...
no warnings qw(void);  # only "io" warnings enabled
```

To determine which category a specific warning has been assigned to see *perldiag*.

Note: Before Perl 5.8.0, the lexical warnings category "deprecated" was a sub-category of the "syntax" category. It is now a top-level category in its own right.

Note: Before 5.21.0, the "missing" lexical warnings category was internally defined to be the same as the "uninitialized" category. It is now a top-level category in its own right.

Fatal Warnings

The presence of the word "FATAL" in the category list will escalate warnings in those categories into fatal errors in that lexical scope.

NOTE: FATAL warnings should be used with care, particularly `FATAL => 'all'`.

Libraries using warnings::warn for custom warning categories generally don't expect warnings::warn to be fatal and can wind up in an unexpected state as a result.

Moreover, the Perl interpreter itself has had serious bugs involving fatalized warnings. For a summary of resolved and unresolved problems as of January 2015, please see this perl5-porters post.

While some developers find fatalizing some warnings to be a useful defensive programming technique, using `FATAL => 'all'` to fatalize all possible warning categories – including custom ones – is particularly risky. Therefore, the use of `FATAL => 'all'` is discouraged.

The strictures module on CPAN offers one example of a warnings subset that the module's authors believe is relatively safe to fatalize.

NOTE: Users of FATAL warnings, especially those using `FATAL => 'all'`, should be fully aware that they are risking future portability of their programs by doing so. Perl

makes absolutely no commitments to not introduce new warnings or warnings categories in the future; indeed, we explicitly reserve the right to do so. Code that may not warn now may warn in a future release of Perl if the Perl5 development team deems it in the best interests of the community to do so. Should code using FATAL warnings break due to the introduction of a new warning we will NOT consider it an incompatible change. Users of FATAL warnings should take special caution during upgrades to check to see if their code triggers any new warnings and should pay particular attention to the fine print of the documentation of the features they use to ensure they do not exploit features that are documented as risky, deprecated, or unspecified, or where the documentation says "so don't do that", or anything with the same sense and spirit. Use of such features in combination with FATAL warnings is ENTIRELY AT THE USER'S RISK.

The following documentation describes how to use FATAL warnings but the perl5 porters strongly recommend that you understand the risks before doing so, especially for library code intended for use by others, as there is no way for downstream users to change the choice of fatal categories.

In the code below, the use of `time`, `length` and `join` can all produce a `"Useless use of xxx in void context"` warning.

```
use warnings;

time;

{
    use warnings FATAL => qw(void);
    length "abc";
}

join "", 1,2,3;

print "done\n";
```

When run it produces this output

```
Useless use of time in void context at fatal line 3.
Useless use of length in void context at fatal line 7.
```

The scope where `length` is used has escalated the `void` warnings category into a fatal error, so the program terminates immediately when it encounters the warning.

To explicitly turn off a "FATAL" warning you just disable the warning it is associated with. So, for example, to disable the "void" warning in the example above, either of these will do the trick:

```
no warnings qw(void);
no warnings FATAL => qw(void);
```

If you want to downgrade a warning that has been escalated into a fatal error back to a normal warning, you can use the "NONFATAL" keyword. For example, the code below will promote all warnings into fatal errors, except for those in the "syntax" category.

```
use warnings FATAL => 'all', NONFATAL => 'syntax';
```

As of Perl 5.20, instead of `use warnings FATAL => 'all';` you can use:

```
use v5.20;       # Perl 5.20 or greater is required for the␣
 ↪following
use warnings 'FATAL';  # short form of "use warnings FATAL => 'all';
 ↪"
```

However, you should still heed the guidance earlier in this section against using `use warnings FATAL => 'all';`.

If you want your program to be compatible with versions of Perl before 5.20, you must use `use warnings FATAL => 'all';` instead. (In previous versions of Perl, the behavior of the statements `use warnings 'FATAL';`, `use warnings 'NONFATAL';` and `no warnings 'FATAL';` was unspecified; they did not behave as if they included the `=> 'all'` portion. As of 5.20, they do.)

Reporting Warnings from a Module

The `warnings` pragma provides a number of functions that are useful for module authors. These are used when you want to report a module-specific warning to a calling module that has enabled warnings via the `warnings` pragma.

Consider the module `MyMod::Abc` below.

```
package MyMod::Abc;

use warnings::register;

sub open {
    my $path = shift;
    if ($path !~ m#^/#) {
        warnings::warn("changing relative path to /var/abc")
            if warnings::enabled();
        $path = "/var/abc/$path";
    }
}

1;
```

The call to `warnings::register` will create a new warnings category called "MyMod::Abc", i.e. the new category name matches the current package name. The open function in the module will display a warning message if it gets given a relative path as a parameter. This warning will only be displayed if the code that uses `MyMod::Abc` has actually enabled them with the `warnings` pragma as below - note that a plain `use warnings` enables even warnings that have not yet been registered.

```
use warnings;
use MyMod::Abc;
...
abc::open("../fred.txt");
```

The specific warning can be enabled or disabled, but only after the module has been imported:

```
# no warnings 'MyMod::Abc';     # error, unknown category before
                                # the module is loaded
use MyMod::Abc;
no warnings 'MyMod::Abc';       # ok after the module is loaded
...
abc::open("../fred.txt");
```

It is also possible to test whether the pre-defined warnings categories are set in the calling module with the `warnings::enabled` function. Consider this snippet of code:

```
package MyMod::Abc;

sub open2 {
    if (warnings::enabled("deprecated")) {
        warnings::warn("deprecated",
                       "open2 is deprecated, use open instead");
    }
    open(@_);
}

sub open
...
1;
```

The function open2 has been deprecated, so code has been included to display a warning message whenever the calling module has (at least) the "deprecated" warnings category enabled. Something like this, say.

```
use warnings 'deprecated';
use MyMod::Abc;
...
MyMod::Abc::open2($filename);
```

Either the `warnings::warn` or `warnings::warnif` function should be used to actually display the warnings message. This is because they can make use of the feature that allows warnings to be escalated into fatal errors. So in this case

```
use MyMod::Abc;
use warnings FATAL => 'MyMod::Abc';
...
MyMod::Abc::open('../fred.txt');
```

the `warnings::warnif` function will detect this and die after displaying the warning message.

The three warnings functions, `warnings::warn`, `warnings::warnif` and `warnings::enabled` can optionally take an object reference in place of a category name. In this case the functions will use the class name of the object as the warnings category.

Consider this example:

```
package Original;

no warnings;
use warnings::register;

sub new
{
    my $class = shift;
    bless [], $class;
}

sub check
{
    my $self = shift;
    my $value = shift;

    if ($value % 2 && warnings::enabled($self))
      { warnings::warn($self, "Odd numbers are unsafe") }
}

sub doit
{
    my $self = shift;
    my $value = shift;
    $self->check($value);
    # ...
}

1;

package Derived;

use warnings::register;
use Original;
our @ISA = qw( Original );
sub new
{
    my $class = shift;
    bless [], $class;
}

1;
```

The code below makes use of both modules, but it only enables warnings from `Derived`.

```
use Original;
use Derived;
use warnings 'Derived';
my $x = Original->new();
```

(continues on next page)

(continued from previous page)

```
$x->doit(1);
my $y = Derived->new();
$x->doit(1);
```

When this code is run only the `Derived` object, `$y`, will generate a warning.

```
Odd numbers are unsafe at main.pl line 7
```

Notice also that the warning is reported at the line where the object is first used.

When registering new categories of warning, you can supply more names to warnings::register like this:

```
package MyModule;
use warnings::register qw(format precision);

...

warnings::warnif('MyModule::format', '...');
```

FUNCTIONS

Note: The functions with names ending in `_at_level` were added in Perl 5.28.

- use warnings::register

  Creates a new warnings category with the same name as the package where the call to the pragma is used.

- warnings::enabled()

  Use the warnings category with the same name as the current package.

  Return TRUE if that warnings category is enabled in the calling module. Otherwise returns FALSE.

- warnings::enabled($category)

  Return TRUE if the warnings category, `$category`, is enabled in the calling module. Otherwise returns FALSE.

- warnings::enabled($object)

  Use the name of the class for the object reference, `$object`, as the warnings category.

  Return TRUE if that warnings category is enabled in the first scope where the object is used. Otherwise returns FALSE.

- warnings::enabled_at_level($category, $level)

  Like `warnings::enabled`, but $level specifies the exact call frame, 0 being the immediate caller.

- warnings::fatal_enabled()

  Return TRUE if the warnings category with the same name as the current package has been set to FATAL in the calling module. Otherwise returns FALSE.

- warnings::fatal_enabled($category)

  Return TRUE if the warnings category `$category` has been set to FATAL in the calling module. Otherwise returns FALSE.

- warnings::fatal_enabled($object)

  Use the name of the class for the object reference, `$object`, as the warnings category.

  Return TRUE if that warnings category has been set to FATAL in the first scope where the object is used. Otherwise returns FALSE.

- warnings::fatal_enabled_at_level($category, $level)

  Like `warnings::fatal_enabled`, but $level specifies the exact call frame, 0 being the immediate caller.

- warnings::warn($message)

  Print `$message` to STDERR.

  Use the warnings category with the same name as the current package.

  If that warnings category has been set to "FATAL" in the calling module then die. Otherwise return.

- warnings::warn($category, $message)

  Print `$message` to STDERR.

  If the warnings category, `$category`, has been set to "FATAL" in the calling module then die. Otherwise return.

- warnings::warn($object, $message)

  Print `$message` to STDERR.

  Use the name of the class for the object reference, `$object`, as the warnings category.

  If that warnings category has been set to "FATAL" in the scope where `$object` is first used then die. Otherwise return.

- warnings::warn_at_level($category, $level, $message)

  Like `warnings::warn`, but $level specifies the exact call frame, 0 being the immediate caller.

- warnings::warnif($message)

  Equivalent to:

```
if (warnings::enabled())
  { warnings::warn($message) }
```

- warnings::warnif($category, $message)

  Equivalent to:

```
if (warnings::enabled($category))
  { warnings::warn($category, $message) }
```

- warnings::warnif($object, $message)

  Equivalent to:

```
if (warnings::enabled($object))
  { warnings::warn($object, $message) }
```

- warnings::warnif_at_level($category, $level, $message)

  Like `warnings::warnif`, but $level specifies the exact call frame, 0 being the immediate caller.

- warnings::register_categories(@names)

  This registers warning categories for the given names and is primarily for use by the warnings::register pragma.

See also "Pragmatic Modules" in perlmodlib and *perldiag*.

Modules

- `warnings::register` - warnings import function

warnings::register

warnings import function

SYNOPSIS

```
use warnings::register;
```

DESCRIPTION

Creates a warnings category with the same name as the current package.

See *"Reporting Warnings from a Module" in warnings* for more information on this module's usage.

CHAPTER

SIX

CHANGELOG

What each version of pperl changed, one page per version, newest first.

A version is the time the version number was in force: it begins when pperl is set to that number and ends when it is set to the next one. The newest page is the version in development; its changes are added as they are made. Every page accounts for all the work of its version: each change is either described in an entry or was internal (tests, benchmarks, build machinery) with no observable effect. An entry opens with its subject in bold, so a page can be scanned for a module or a feature by name.

Version numbers that have no page, such as 0.6.4, 0.6.7 and 0.6.10, were never set; their changes are in the version before them.

6.1 pperl 0.6.25

In development since 2026-10-25.

6.2 pperl 0.6.24

2026-10-15 to 2026-10-25, 457 commits.

6.2.1 JIT and parallelization

- **Loops over arrays sized with $#a stay compiled**: a loop that stores into an array whose size was set with `$#a = $n`, directly or through a reference, now runs as compiled code. It used to fall back to the interpreter on every element until the JIT gave the loop up, and ran about three times slower than the same loop over an array filled with values first.
- **& | ^ under use v5.28 and later are compiled**: with the `bitwise` feature, which `use v5.28` and later versions turn on, the numeric &, | and ^ are separate operations, and a loop holding one of them ran in the interpreter. Such loops are now compiled, signed under `use integer` and unsigned otherwise, as perl computes them.
- **Index arithmetic no longer decides how a statement computes**: in `$y[$n] = $C[$i] + $C[$i + 64]` over an array of floating-point numbers, the integer `$i + 64` made the compiled loop treat the whole statement as integer arithmetic, and every element fell back to the interpreter until the loop was given up. Arithmetic that only computes an array index is now plain integer arithmetic, its overflow

checked, whatever the elements hold. Loops of this kind that ran about four times slower when every value they computed was 0.0, such as a reverb fed silence, now run as fast as on any other input.

- **Float arithmetic survives a run of zeros**: a loop that computes with arrays of floating-point numbers, such as an audio filter fed silence, kept falling back to the interpreter while every value it saw was zero, and was then replaced by a slower form that also ran the signal after the silence. An array of floats that also holds a value perl keeps as an integer too is now recognised as an array of floats.
- **A copied array element keeps its spelling**: in compiled code, copying an array element that holds a number written as a string, such as `my $x = $list->[$i]` of "-2.0", "0.10" or "1e1" after it had been compared numerically, gave the number instead: "-2", "0.1", "10". The copy is now the string, as in perl. Complete::Sah's completions of floating-point values were affected.
- **A `next` out of a branch that was cold no longer crashes**: a loop nest compiled while an `if` branch holding its own loop and a `next` had never run, as in `if ($four) { while (...) { ... } next }`, could crash pperl once that branch ran, when the enclosing sub returned. It runs as under perl now.
- **A loop that increments the position it reads no longer crashes**: a loop such as `for (my $k = 0; $k < length $s; $k++) { $n += ord substr($s, $k, 1) }` aborted pperl once it ran often enough to be compiled. Such loops now run compiled.
- **Negative array indexes stay compiled**: `$a[-1]`, or an index such as `$n - 100` that goes below zero, counts from the end of the array in compiled code. In a loop over an array of plain numbers, each such access used to fall back to the interpreter, and a loop doing it often was given up.
- **Loops over unsigned 64-bit integers stay compiled**: a loop whose numbers go past 9223372036854775807, perl's unsigned integers as in 64-bit hashes, masks and random numbers, or a `C` function returning `uint64`, fell back to the interpreter on every trip until the JIT gave the loop up, and one naming such a number as a constant, such as `0x9E3779B97F4A7C15`, was never compiled. Such loops now run compiled with perl's exact values, under `use integer` too; a result perl computes as a floating-point number still takes the interpreter's path. A loop that only reads a large integer, such as an argument of -9223372036854775808, no longer leaves the compiled code each time it starts either.

6.2.2 Language and runtime

- **END blocks run after an exit during compilation**: when a program exits or dies while it is still being compiled, in a `BEGIN` block or in the import a `-MModule=...` switch calls, the `END` blocks compiled so far now run and can set the exit status, as in perl. A failing test file that exited this way reported success, which broke the test suite of Test::Needs and every CPAN distribution that needs it. An `END` block that sets `$?` to 0 after `exit 5` now makes the exit status 0.
- **Arguments that are not UTF-8**: an argument that is not valid UTF-8, such as a file name in Latin-1, made pperl stop with an internal error before running anything. Arguments, `-e` code, script names and `-I` directories now reach the program byte for byte, as in perl. And `pperl -e CODE a -x` hands its program `a` and `-x` instead of rejecting `-x` as an unknown option.

- **A regex match creates no variable**: a pattern match no longer creates `${^RE_DEBUG_FLAGS}` in `main::`, and no longer looks that variable up on every match. Code that walks the main symbol table while matching names, such as Devel::Symdump, saw it appear under its iterator and warned "Use of each() on hash after insertion".
- **The built-in library is a directory on disk**: the modules built into pperl are a real directory now, `$Config{privlibexp}` under `~/.cache/pperl`, which `@INC`, `%INC` and `__FILE__` name. It is written the first time a program looks at it - a file test, `opendir`, `chdir`, `glob`, `abs_path` or reading a module as a file - never at startup, and holds the modules as perl installs them, documentation included, with perl's `pod/` files and `Config.pod`. Tools that search `@INC` as a filesystem, such as Pod::Find, Module::Path and Module::List, find pperl's own modules now.
- **@INC hooks see built-in modules**: a code reference at the front of `@INC`, as Test::Without::Module and `use lib sub {...}` put it there, is asked for a built-in module before pperl's own copy is used, as in perl. Such a hook can hide a built-in module or serve its own version of it. A directory in `@INC` still never replaces a built-in module.
- **Modules fall back to Perl when their compiled part is missing**: a module whose compiled part pperl does not have now fails to load with perl's message for that case, "Can't locate loadable object for module ... in @INC", instead of "dynamic loading not available". Modules that try their compiled part and go on in Perl without it look for exactly that message, so DateTime and others now run in their Perl implementation where they died before.
- **A built-in module's file runs however it is reached**: when a built-in module's file reaches perl without a plain `require` - served by an `@INC` hook such as lib::filter's or a FatPacker one, read with `do FILE`, or checked with `perl -c` - its compiled part now loads, as perl finds the module's shared object. Such a file used to die "Can't locate loadable object", which took Moo down with lib::filter.
- **Installed scripts run with pperl**: `$Config{perlpath}` and `$Config{startperl}` name the pperl binary that is running. They named `/usr/bin/perl`, so the commands a distribution installs with `pperl --cpan` started the system's perl, or failed on a machine without one.
- **pperl starts faster**: a short script runs in about a quarter less time, as the binary has less than half the addresses to fix up when it is loaded and a run no longer reads the CPU topology unless it goes parallel. The binary is also 5.5 MB smaller. A panic inside pperl itself, which is always a bug, no longer names a source file and line.
- **Catching errors from built-in modules no longer leaks memory**: a built-in module that died with an error built at run time left a few hundred bytes behind every time, so a program catching such errors in a loop with `eval` grew without bound. *Peta::FFI*, *Storable*, *Opcode*, *POSIX* and the other built-in modules now free everything before they die, and `opset` with an unknown name no longer leaks the set it was building, as it does under perl. The error messages are unchanged.

6.2.3 Modules

- ***DBI* 1.655**: the built-in DBI is 1.655, up from 1.651. `DBD::DBM` accepts only a module name as `dbm_type` and `dbm_mldbm`, so a file path given there is no longer loaded and run, and `DBD::File` no longer reads a table linked into a directory whose name merely begins with that of `f_dir`. These are the fixes for CVE-2026-78030 and CVE-2026-15392.
- **DBI: sql_type_cast and fetchrow_hashref as in *DBI* under perl**: `DBI::sql_type_cast` returns what DBI's compiled version returns, so `SQL_INTEGER` refuses "3.14", "1e3" and "inf", `DBIstcf_DISCARD_STRING` leaves only the number, and the two flags have DBI's values. A plain number with `SQL_INTEGER` and `DBIstcf_DISCARD_STRING` is handled too, where DBI 1.655 aborts perl. `fetchrow_hashref` with a key name that holds no column list, from `FetchHashKeyName` or its argument, sets the handle's error and returns undef instead of dying whatever `RaiseError` says, and a number as that name is taken as a name.
- **PDL: update_data_from reads the value of a tied source**: `$pdl->update_data_from($bytes)` fetches a tied or otherwise magical `$bytes` and copies its current value, as *PDL* does under perl. It used to copy whatever that scalar last held.
- ***PDL*: the operator overloads are PDL's own subs**: `PDL::overload_plus` and the other handlers PDL installs for its operators exist under their names and are what `overload::Method` returns, as with PDL under perl. An error raised through an operator, such as a broadcast mismatch in `$a + $b`, now names PDL's own line and the handler in its backtrace, and so does a warning such as "isn't numeric" for a string operand. A redefined `PDL::plus`, or a subclass's own `inplace`, is now what the operators use.
- **PDL::FFT loads quietly under -w**: `use PDL::FFT` under `-w` no longer warns "Subroutine PDL::realfft redefined", as it doesn't with *PDL* under perl.
- ***Pod::Text* and *Pod::Man* 6.1.1**: the POD formatters are those of podlators 6.1.1, up from the 6.0.2 that perl 5.44.0 ships. Formatting a document whose `=over` nesting brings the margin to the output width no longer loops forever while the output fills memory (CVE-2026-82560). `Pod::Man` lists with tags now use `.TP` and the fixed-width font is `CR`, for groff 1.24.
- ***Text::LineFold* no longer repeats its input**: `fold` on text holding form feeds, vertical tabs or other special breaks returned the whole text once for every piece between them, so the output grew with the square of the input (CVE-2026-8594). Each piece is folded once now; the Text::LineFold of CPAN still has the fault.
- ***Hash::Util::FieldHash* is built in**: perl's field hashes for inside-out classes, whose entries vanish with the object they are keyed by, together with `id`, `id_2obj`, `register` and idhashes. It was the one module of perl's own library that would not load, and `B::Hooks::EndOfScope`, `namespace::clean`, `namespace::autoclean` and Mojolicious, which need it, now install from CPAN and pass their tests.
- **Five more CPAN modules with compiled parts are built in**: `XString` 0.005, `Test::LeakTrace` 0.17, `PerlIO::utf8_strict` 0.010, `Scalar::Util::Numeric` 0.40 and `Sub::Identify` 0.14. Each passes its own test suite with the results it has under perl. Distributions that need one of them, such as DateTime, Specio, PPI and Template Toolkit, get past it when they are installed from CPAN.

- ***Sub::Name*** **is built in**: `Sub::Name` 0.28, which renames a sub for `caller` and stack traces, passes its own tests as under perl. It runs the code of `Sub::Util::set_subname`, which perl ships and which was taken from it, so renaming a sub under the debugger no longer leaks a reference to its `%DB::sub` entry with every call, as `Sub::Name` does under perl.
- ***B::COW*** **is built in**: `B::COW` 0.007 reports whether a string shares its buffer copy-on-write and the share count, with the same answers as under perl, and passes its own tests.
- ***Digest::SHA1*** **is built in**: `Digest::SHA1` 2.13, the SHA-1 module older code uses where newer code uses `Digest::SHA`, passes its own tests with the results it has under perl. Its digests are computed by the built-in `Digest::SHA`, with the processor's SHA instructions where it has them. `sha1_transform` given more than 64 bytes uses the first 64, where perl aborts.
- ***String::CRC32*** **is built in**: `String::CRC32` 2.100 computes the CRC-32 of a string or of what a filehandle reads, with the results it has under perl, and passes its own tests. The CRC is computed by the zlib of the built-in `Compress::Raw::Zlib`. A filehandle whose read fails, such as a closed one, gives the CRC of no data, where perl crashes.
- ***Crypt::OpenSSL::Random*** **is built in**: `Crypt::OpenSSL::Random` 0.17 draws bytes from OpenSSL's random-number generator and seeds it, in the builds that include *Net::SSLeay*, and passes its own tests. It reaches libcrypto through Net::SSLeay, so both draw from one generator. Asking for 0 bytes returns the empty string, where perl returns stray memory; a negative count returns false, and 0 from Net::SSLeay's `RAND_bytes`, where perl exits.
- ***URL::Encode*** **is built in**: `URL::Encode` 0.03 and its fast half `URL::Encode::XS` encode and decode URL-encoded strings and split query strings into their parameters, with the results they have under perl, and pass their own tests. The fast half is used, as under perl when it is installed, and is about 17 times as fast as the pure-Perl one.
- ***Text::LevenshteinXS*** **is built in**: `Text::LevenshteinXS` 0.03 computes the edit distance of two strings, with the results it has under perl, and passes its own tests. Long strings work: perl needs memory for a table of both lengths multiplied, and crashes when that memory is not there (two strings of 20000 bytes need 1.6 GB).
- ***Math::Random::MT*** **is built in**: `Math::Random::MT` 1.17, the Mersenne Twister random-number generator, gives the same sequences as under perl for the same seeds, and passes its own tests.
- ***Data::UUID*** **is built in**: `Data::UUID` 1.227 makes time-based and name-based UUIDs and converts them, passing its own tests with the results it has under perl. Its name-based UUIDs are computed by the built-in `Digest::MD5`. Where perl reads or writes past a string - a binary UUID shorter than 16 bytes, a Base64 UUID that is too short, too long or has bytes above 0x7F, a hex UUID that ends inside a byte - the result is zero-filled, cut to 16 bytes, or an error instead.
- ***Params::Util*** **is built in**: `Params::Util` 1.102, whose checks such as `_STRING`, `_HASH` and `_INSTANCE` many CPAN modules validate their arguments with, passes its own tests with the results it has under perl. It did not load at all before, so PPI, Package::DeprecationManager, Config::MVP and the modules that need them could not be installed from CPAN.

- ***Class::Load::XS* is built in**: the compiled `is_class_loaded` of `Class::Load::XS` 0.10, which Class::Load uses when it is there, passes its own tests with the results it has under perl. Class::Load itself, which loads it, is installed from CPAN as before.
- ***Template::Stash::XS* is built in**: the compiled stash of Template Toolkit 3.106, which the Template Toolkit uses by default, passes the Template Toolkit's own tests with the results they have under perl. The Template Toolkit itself, which did not install without it, now installs from CPAN with `pperl --cpan`. A method that dies "Can't locate object method" no longer overwrites the caller's arguments, and `set` on a value that is not a reference dies with an error where perl crashes.
- ***Package::Stash::XS* is built in**: `Package::Stash::XS` 0.32, the compiled implementation of `Package::Stash` that *Moose*, namespace::clean and many others read and change symbol tables through, passes its own tests with the results it has under perl. `Package::Stash` itself comes from CPAN and now uses it, as it does under perl, instead of its pure-Perl implementation.
- ***List::MoreUtils::XS* is built in**: the compiled backend of `List::MoreUtils` 0.430 passes its own tests and those of the front end with the results they have under perl, and `List::MoreUtils`, installed from CPAN, now uses it instead of its pure-Perl implementation. Where perl crashes or answers wrongly, pperl does not: a block that is a compiled sub, arrays with holes, objects overloading `@{}` over a hash, and `<=>` overloading that gives no number. `reduce_u`, `reduce_0` and `reduce_1` no longer overwrite the caller's `$_`, and `frequency` no longer leaks.
- ***Term::ReadKey* is built in**: `Term::ReadKey` 2.38 sets terminal modes, reads keys with a timeout or without blocking, and reports the terminal's size, speed and control characters as it does under perl; modules that need it, such as `CPAN::Uploader`, now install from CPAN. Where perl aborts, pperl does not: a timed read on a closed handle or on a descriptor of 1024 or above, and `SetTerminalSize` with a width or height ten characters long. `GetSpeed` of a handle that is not a terminal returns 0 for both speeds where perl returns leftover memory.
- ***Filter::Util::Exec*, *Filter::tee* and *Filter::decrypt* are built in**: the source filters of Filter 1.65 that run a program through a command (`Filter::exec`, `Filter::sh`, `Filter::m4`), copy it to a file or decrypt it work as they do under perl and pass the dist's own tests. Where perl crashes, pperl does not: these filters, and `filter_add` of *Filter::Util::Call*, called while nothing is being compiled. A command that stops reading early, such as `head -n 1` on a long source, no longer kills the program without a word or leaves it empty: what the command wrote is compiled. `Filter::cpp` is not available, because pperl's configuration names no C preprocessor.
- ***IO::Tty* and *IO::Pty* are built in**: IO-Tty 1.31 allocates pseudo-terminals, names them, sets their window sizes and defines the terminal constants as it does under perl, and passes the dist's own tests. Where perl crashes or reports a length it read from unrelated memory, pperl does not: `IO::Tty::unpack_winsize` of undef, a number or a reference dies saying the length is 0.
- ***Moose* loads**: the compiled part of Moose 2.4001 is built in, so Moose's own modules load and pass Moose's own tests with the results they have under perl. `pperl --cpan` installs Moose and what is built on it, Catalyst and Dist::Zilla among them: a distribution's check for a working C compiler (*ExtUtils::HasCompiler*) answers yes when the compiled part it needs is built in. Where perl crashes on a malformed

metaclass or method object, pperl dies with an error or leaves it alone.

- ***JSON::XS* is built in**: JSON-XS 4.04 encodes and decodes JSON, parses it incrementally and calls `TO_JSON`, `FREEZE` and `THAW` as it does under perl, and passes its own tests; *Types::Serialiser*, whose booleans JSON `true` and `false` decode to, is built in with it. Where perl crashes, pperl does not: a method called on something blessed into `JSON::XS` that `new` did not make dies with an error, and `JSON::XS::CLONE` called by hand no longer breaks `new`.
- ***YAML::XS* and *YAML::PP* are built in**: YAML-LibYAML 0.910.0 loads and dumps YAML with the settings, objects and output it has under perl and passes its own tests, over YAML::PP 0.43.0, pperl's YAML engine. YAML is read as the YAML 1.2 specification reads it, so the few documents libyaml reads otherwise, rejects or wrongly accepts follow the specification, and `Dump` escapes U+2028 and U+2029 so that what it writes loads back unchanged. Where perl crashes or refuses, pperl does not: the object interface loading a flow mapping inside a flow sequence, and dumping strings of latin-1 bytes. A document that does not parse dies with YAML::PP's account of the problem: nearly always the same document and line, in other words.
- ***FFI::Platypus* is built in**: FFI-Platypus 2.12 calls C functions with every type it offers, from integers, strings and arrays to records by value, closures and custom types, as it does under perl, and no C compiler is needed to install it. Where perl fails, pperl does not: reading an array member of a record no longer leaks memory, an index past an opaque array member warns instead of reading beyond the record, and a hash reference passed for a pointer no longer crashes. A regex capture or a tied scalar passed as an argument passes its value, where perl passes 0, or no string at all, which crashes `strlen($1)`, and a callback that a library calls from a thread of its own stops the program with a message where perl crashes.
- ***FFI::Build* is built in**: a CPAN module that ships C code for *FFI::Platypus* to call, built at install time with FFI::Build, now installs, passes its tests and runs under pperl when a C compiler is on `PATH`, as it does under perl. *Capture::Tiny*, which FFI::Build uses, is built in with it.
- ***DynaLoader* loads shared libraries**: `dl_load_file`, `dl_find_symbol`, `dl_unload_file`, `dl_findfile` and the rest work on any C library as they do under perl, and *FFI::CheckLib*, which finds libraries with them, is built in. A module's compiled part is still never loaded from a file: `XSLoader` and `DynaLoader::bootstrap` load only pperl's built-in modules. Unloading a library that failed to load no longer crashes, as it does under perl when FFI::CheckLib meets a linker script such as `libm.so`.
- ***XSLoader* checks the version a module asks for**: `XSLoader::load($module, $VERSION)` dies "... object version ... does not match bootstrap parameter ..." when the built-in compiled part is of another version, as it does under perl, and loads a built-in module's compiled part even when nothing has required the module yet.
- ***Peta::FFI* reaches more of any C library**: signatures gain fixed-width integers from `i8` to `u64`, `bool`, variadic functions such as `ioctl` and `snprintf`, strings the caller must free, and C objects as Perl objects whose destructor runs with their last reference. `function` and `attach` prepare a C function once and call it as a Perl sub, a function pointer can be called by its address, and `errno` reports what a call left behind. A callback that a library calls from a thread of its own now stops the program with a message instead of corrupting it, and *Peta::FFI::EventSource*

brings such a library's events to Perl through a file descriptor that *AnyEvent*, *EV*, Mojo::IOLoop or a `select` loop watches. `scan` finds the libraries in the directories it is given, or in `PETA_FFI_PATH` and the dynamic linker's own, and lists only the files this program can load.

- ***Peta::FFI*** **passes C structs, arrays and long doubles**: `record` declares a C struct as a Perl class with an accessor per member, and a signature passes and returns it by value or by pointer, callbacks included. Signatures gain pointers to numbers and strings for out-parameters, arrays the function reads and changes in place, `long double` and the complex types, and an output buffer that holds what the function wrote. `symbol`, `fetch`, `store` and `variable` read and write a library's global variables and any typed value in memory. *FFI::Platypus* now runs on the same engine, so whatever it can call, Peta::FFI can.
- ***Peta::FFI*** **reaches C unions**: `union` declares one as `record` declares a struct, with every member at its start, to be passed by pointer and read and written in memory, as `SDL_PollEvent` fills an `SDL_Event`. Passing a union by value is refused, because on some platforms that would call the function wrongly instead of failing. A record member that is itself a record now reads as an object of its class and is set from one.
- ***Peta::FFI*** **takes what C functions hand over**: a handle or a string a function stores through a pointer, as `sqlite3_open` does, becomes the caller's object or string, and arrays of handles, of records and of pointers ended by NULL can be passed. An array the function allocates itself, its length given by the result, by another argument or by a NULL at its end, comes back as a Perl array of objects, strings, records or numbers. Everything is freed with the library's own functions once nothing uses it, so a record taken from such an array still reads its strings for as long as it lives.
- ***Peta::FFI*** **reads arrays C lends and sets strings in records**: an array a function hands out from memory it keeps, as libxkbcommon hands out a keymap's keysyms, is written `&T[r]`, `&T[#k]` or `&T[0]` and is copied without being freed, whether it comes through an argument or, as `&T[#k]` or `&T[0]`, as the result. A record's string member can now be set from Perl: the record keeps its own copy for as long as it lives, `undef` passes NULL, and a string C put there is never freed by Perl. When C moves the strings between records, as sorting an array of them does, each string stays alive with the record that now points to it.
- ***Peta::FFI*** **reads byte buffers C allocates**: a buffer a function allocates and hands over through a pointer, with its length in the result or in another argument, is written `*P[r]` or `*P[#k]`. It arrives as one byte string, NULs and all, and is then freed with the library's own function, which is how librados's `rados_mon_command` returns its reply. Bytes a function only lends, `&P[r]` or `&P[#k]`, are copied and never freed, and a callback handed bytes with their length, `&P[#k]`, gets them as a string.
- ***Peta::FFI::Pool*** **runs C calls that may hang**: a function prepared with *Peta::FFI* runs on one of a pool's threads, with a deadline, so `statfs` on a dead NFS mount no longer needs a child process with a timeout. Each call is reported as an event, through a descriptor any event loop can watch as a *Peta::FFI::EventSource*: done, with its result and what it wrote back; timed out; or busy, when every thread is taken. A call that returns after its deadline changes nothing.
- ***Peta::FFI::Queue*** **takes callbacks from a library's own threads**: a closure made with `queue => $queue` may be called on any thread, as librados calls its monitor log and watch callbacks. It copies its arguments into the queue, returns a value given once, and its sub runs later, when Perl's event loop takes the queue's events

through a *Peta::FFI::EventSource*. A queue holds a bounded number of calls and counts those it had to drop.

- **Loops that call C functions run compiled**: a loop calling a C function prepared with *Peta::FFI* or *FFI::Platypus* used to stay out of the JIT entirely. When the function takes and returns plain integers, pointers or floating-point numbers, the compiled loop now calls it directly; other calls, and any call while C holds a Perl callback, still go through the library as before.
- **C functions called often cost less**: a C function prepared with *Peta::FFI*'s `function` or `attach`, or attached with *FFI::Platypus*, that takes and returns plain numbers or pointers is compiled into machine code of its own once it has been called a few thousand times. A call of `labs` or `ldexp` outside a compiled loop then takes about 30% less time, with the same results and the same errors as before. A function that is seldom called is never compiled, so declaring a library's functions costs no more than it did.
- **Peta::LMDB and Peta::PCRE2 are now Peta::FFI::LMDB and Peta::FFI::PCRE2**: pperl's own modules for C libraries live under *Peta::FFI*, beside *Peta::FFI::UUID*. Programs that load *Peta::FFI::LMDB* or *Peta::FFI::PCRE2* work as before, with the class names, error class and `$Peta::FFI::LMDB::DBM_WRITE` renamed to match; the old names no longer load.
- ***Cairo* survives a libcairo without a function it calls**: when the installed libcairo lacks a function a Cairo method needs, as an older release does, calling the method stopped the whole program. It now dies with a message naming the function, which `eval` catches, as the other library modules already did.
- ***EV* and *Coro* no longer need a system perl**: the built-in `EV` and `Coro` start with `use common::sense`, which pperl did not carry, so they loaded only where a system perl's copy was on `@INC`, and `AnyEvent` otherwise fell back to its pure-Perl event loop without a word. `common::sense` 3.75 is built in now, with the warnings and features it sets under perl 5.44.
- ***Event* runs on libev, and EV and Event share signals**: `Event` now waits for descriptors, signals and time through libev, the engine behind `EV`, and reports the same readiness and conditions as before; its timers and event queues are its own, as they were. A signal that both modules watch now reaches the watchers of both. Under perl the module that installed its handler last took it, and an EV loop reading signals through a signalfd hid them from Event entirely.
- ***XML::Parser*, *HTML::TokeParser* and *PDL::IO::Pic* load without a system perl**: they need `File::ShareDir`, `HTML::Tagset` and `File::Which`, which pperl did not carry, and loaded only where a system perl's copy was on `@INC`. Those three are built in now, with `Class::Inspector`, which `File::ShareDir` needs; `HTML::LinkExtor` is fixed with them.
- **XML::Parser parses with libxml2**: `XML::Parser` and `XML::Parser::Expat` read documents with libxml2 2.15 or newer, and the expat library is no longer needed. Handlers see what they saw over expat: the same calls with the same arguments, character data split where expat splits it, the same positions and source text from `current_byte`, `recognized_string` and `original_string`, and expat's error messages. A document with `standalone="yes"` has the parameter entities of its internal subset read, as XML requires; expat left them unread and then refused the document.

- ***Devel::Cover* measures coverage**: the compiled part of *Devel::Cover* 1.52 is built in, so with the distribution installed by `pperl --cpan Devel::Cover`, `pperl -MDevel::Cover` collects statement, branch, condition and subroutine coverage, and `cover` reports it, with the same counts as perl. Devel::Cover's own test suite passes. While it collects, loops are not compiled, since compiled code would bypass the counting.
- **JSON::PP works in compiled code**: `JSON::PP` encodes and decodes with the same compiled engine as `JSON::XS`, with JSON::PP's own options, results and error messages, about 6 times faster at encoding and 14 times at decoding. CPAN's metadata files and everything else that reads or writes JSON through it gain with it. Where JSON::PP went wrong it no longer does: `decode_prefix` counts characters as documented, what a `FREEZE` method returns is encoded as JSON, the incremental parser keeps Latin-1 text and the rest of its buffer as they are, and bare keys keep their non-ASCII characters.
- ***Text::CSV* is built in**: Text::CSV 2.06 comes with pperl, and its pure-Perl engine `Text::CSV_PP` parses, warns and checks its settings as Text::CSV_XS 1.65 does. A CR at the very end of the input after an empty last field is error 2032, as after any other field; a failed `print` returns "" and warns where it was called; a separator, quote or line end longer than 16 bytes is refused. Installing Text::CSV with `pperl --cpan` gets the same engine, and Text::CSV_XS installs over it with all of its own tests passing.

6.2.4 Command line

- **pperl -S finds the program on PATH**: `pperl -S prove` runs the `prove` installed on the search path, as `perl -S` does; pperl rejected the switch.
- **A program's arguments are its own**: pperl's switches, such as `--parallel` or `--no-jit`, are read only before the program, as perl reads its own. After it, they reach the program in `@ARGV`; pperl used to take them out, so `tool.pl --parallel 4 list` saw only `4 list`.
- **pperl -v names the build and credits perl**: the first line names what kind of binary it is, its native tier and added features such as `dbi`, `pdl` or `shell`, the second is the copyright, and the text says pperl is "compatible to perl 5.44 by Larry Wall and others". `pperl -V` still lists everything. Tests that read `-v` as perl's, such as those of IPC::System::Simple and Expect, pass.
- **pperl –cpan no longer asks you to set PPERL5LIB**: pperl finds what it installs into your own tree without it, so the advice that ended every install is gone.
- **pperl –cpan –system installs where pperl looks**: a system-wide install now goes to `/usr/local/share/pperl/site_perl`, which every pperl searches, with its scripts and manuals beside it; it used to land in a directory pperl never looked in. It now stops before downloading anything when the account may not write there, and says to run it as root.
- **pperl –cpan applies distribution preferences**: a CPAN.pm distroprefs file under `~/.pperl/cpan/prefs` that matches a distribution now takes effect, including its patches, which are looked up beside it. A `.yml` preference used to be read only where the separate YAML distribution happened to be installed, and now uses pperl's built-in *YAML::XS*. Any patch a preference named stopped the install, because no patch command was configured.

- **pperl –cpan installs XS distributions it has a substitute for**: each run first fetches pperl's pure-Perl substitutes for distributions with a compiled part from `https://perl.petamem.com/downloads/cppan`, so a substitute published after your pperl applies to it too. Text::CSV_XS installs and runs on the Perl engine of Text::CSV, true, multidimensional and bareword::filehandles on perl's own features, Scalar::Readonly, Test::Taint, Regexp::Util, next::XS and Socket6 on its built-in modules, and Crypt::SSLeay (Net::SSL) on its OpenSSL binding, where it no longer builds under perl with OpenSSL 3; the few places where their own tests show a difference are marked as known in them. `PPERL_CPPAN_URL` names another address, and set empty it skips the fetch.
- **JavaScript::QuickJS runs on QuickJS-NG**: `pperl --cpan` installs JavaScript::QuickJS as a binding over the QuickJS-NG library (`libqjs.so.0`, on Arch Linux the `quickjs-ng` package), used where it is installed; without it the module installs, its tests skip and say why, and it works once the library is there. The distributions that need it, such as Data::Sah and the Perinci family, install with it. Where QuickJS-NG differs from the QuickJS the CPAN distribution bundles, its own behaviour shows: its error messages, and a Date's `getTime` as a floating-point number.
- **pperl –cpan downloads over https with curl or wget**: like perl's own first-run setup, it now finds `make`, `tar`, `gzip`, `gpg`, `wget` or `curl` and the other tools CPAN.pm uses on your `PATH`. A pperl built without TLS support therefore fetches from CPAN over https through `wget` or `curl` instead of falling back to plain http, and the XS substitutes come the same way.
- **pperl –cpan builds the pure-Perl form of a distribution**: it asks every build for the distribution's Perl-only variant, as `PUREPERL_ONLY=1` and `--pureperl-only` do, so a distribution such as Params::Validate that has a Perl implementation beside its compiled one installs instead of failing for want of a C compiler. A module that does not load without its compiled part is named and kept, not removed: *Params::Util* switches to its Perl half when its tests ask for it, and those tests now run.
- ***Config* names the C compiler**: `$Config{cc}`, its flags, its preprocessor and `gccversion` describe the C compiler found on `PATH` (cc, gcc or clang), so *FFI::Build* compiles the C libraries a distribution bundles and Devel::CheckLib's probes run. `usedl` and `dlsrc` say what perl's say on Linux, as *DynaLoader* loads shared libraries. Modules with a compiled part still load only when they are built in, and *ExtUtils::CBuilder*'s `have_compiler` still says no.
- **@INC includes the architecture directories of PERL5LIB and -I**: as under perl, each entry's `x86_64-linux` subdirectory, and that of each of its version directories, comes ahead of the entry when it exists. An installer puts a distribution's Perl files there whenever the distribution carries anything architecture-dependent, so modules installed into a local::lib by `cpanm -l`, Alien modules among them, are now found. `pperl --cpan` installs into its tree's architecture directory as perl's installers do, and pperl's own tree is searched the same way.
- **ipps runs programs as functions**: with the new `autorun` setting on, calling a sub that does not exist runs the program of that name and returns its output, a list of lines in list context, as in `whoami()` or `my @files = ls('*.pl')`. `:programs ls cat` makes such names subs that need no parentheses, whether `autorun` is on or not, and `:programs` alone lists them. A program that cannot be run is an error,

and the exit status is in `$?` as for backticks.

6.2.5 Documentation

- **Links in the changelog**: the entries of every version link the modules, built-in functions, command-line options, guides and tutorials they name to their pages, in every language of the documentation.

6.3 pperl 0.6.23

2026-10-11 to 2026-10-15, 101 commits.

6.3.1 Modules

- ***MIME::Base64*** **uses vector instructions**: on x86-64, `encode_base64` and `decode_base64` work 12 or 24 bytes at a time where the processor has SSSE3 or AVX2. A large text in lines of equal length is now also decoded on several threads, as large data already was encoded; a text laid out any other way, or with stray characters in it, decodes on one thread as before. The results are unchanged.
- ***Digest::SHA*** **uses the processor's SHA instructions**: the object interface (`Digest::SHA->new`, `add`, `addfile`) computes SHA-1 and SHA-256 with the processor's SHA instructions where it has them, as the functions such as `sha256_hex` already did. SHA-1 and SHA-512 are faster without them too. On x86-64 processors without the SHA instructions, SHA-1, SHA-224 and SHA-256 are faster in every form - functions, objects and HMAC.
- ***Encode*** **converts single-byte encodings faster**: `encode` and `decode` for iso-8859-x, the cp125x code pages, koi8 and the other single-byte encodings no longer search a table for every character, and a string perl holds as bytes is encoded without first being converted to UTF-8. A large `encode` or `decode` is also spread over several threads. The results, the check modes and the error messages are unchanged.
- ***Cwd::getcwd*** **is faster**: `getcwd` and the lexer no longer clear buffers of up to 4 KiB that are written before they are read.
- **%Config entries that are not defined are undef**: `$Config{...}` returned the string "undef", which is true, for 232 keys such as `d_faststdio` and `usedl`, so `if ($Config{d_faststdio})` took the branch for something the build does not have. They are undef now, as in perl; `config_vars` and `config_sh` still print them as `'undef'`.
- ***Compress::Raw::Zlib*** **needs no system zlib**: zlib is part of the binary now, as perl builds its own copy into the module, so `IO::Compress`, `Archive::Tar` and everything else on top of it work on a machine without `libz` and in the static build. Compression is 1.7 to 5.7 times as fast and decompression about twice as fast. A compressed stream is valid for every zlib but is not byte-for-byte the one perl writes, and `ZLIB_VERSION` reads `1.3.0-zlib-rs-0.6.8`.
- **SDL_Quit with a** ***Peta::WebGPU*** **surface still alive no longer crashes**: a program that called `SDL_Quit` while a surface or an unpresented frame was still in scope aborted with "double free or corruption" in about one run in ten. `SDL_Quit` now

releases their swap chains first; using such a surface or frame afterwards dies with a message saying the window system was shut down, and the device keeps working.

- ***Tie::Hash::Indexed*** **is built in**: the ordered hash of CPAN's Tie::Hash::Indexed 0.08 loads without installing anything, as a tied hash and with its object interface, iterators and *Storable* support. Three sequences that crash perl with the original module work: `pop`, `shift` or `clear` in the middle of an `each` loop, and `NEXTKEY` before any `FIRSTKEY`.
- ***PDL*****: broadcast_define and the dataflow inspectors**: `broadcast_define` and `thread_define` now exist, with `broadcastover` and `broadcastover_n` under them. `trans_parent` and `trans_children` return `PDL::Trans` objects with their methods and vtable, so `PDL::Core::pdump`, `pdump_trans` and `pdumphash` work, as do `flags` and the `*_nophys` readers. Also new: `add_threading_magic`, `remove_threading_magic`, `broadcast3`, `tocomplex`, `hdr_copy`, `hcpy` and `nslice_if_pdl`.
- **PDL: an ndarray's data is a Perl scalar**: the scalar that `get_dataref` returns is now the data itself for every ndarray above 32 bytes, so writing into it writes the ndarray, as in *PDL* under perl. That makes `new_around_datasv`, `new_around_pointer` and `set_data_by_file_map` (an ndarray over a memory-mapped file) available. `dump`, `bind` and `dowhenidle` are new too, and `datasv_refcount` of an ndarray without such a scalar dies.
- **PDL: ldouble is the platform's long double**: `ldouble` and `cldouble` now hold the C compiler's `long double`, the 80-bit format on x86-64, as *PDL* under perl does; they were a 128-bit type with different results. A single `ldouble` value no longer reads as 0 in `print`, `sclr` and conversions. The complex functions are exact: `csqrt(-4)` is `2i`, not `1.22464679914735e-16+2i`.
- **PDL: histograms, interpolate and the Image2D filters**: new are `histogram`, `whistogram`, their 2-D forms and `whist`; `wtstat`, `vcos`, `interpolate`, `diff2`, `diffcentred`, `partial`, `caverage` and `cavgover`; and in *PDL::Image2D* `conv2d`, `box2d`, `patch2d`, `patchbad2d`, `bilin2d`, `rescale2d` and `crop`. `hist` without bounds now chooses its bins from the data as *PDL* under perl does. `which` no longer counts bad values, `crossp` and `whichover` broadcast and keep the type, and `interpol` fills an ndarray given as fourth argument.
- ***PDL::ImageND***: `use PDL::ImageND` loads, with `convolveND`, `convolve`, `rebin`, `ninterpol`, `kernctr`, `circ_mean`, `circ_mean_p`, `contour_segments`, `contour_polylines`, `path_join`, `path_segs`, `combcoords`, `attract` and `repulse`. *PDL::FFT* imports `kernctr` from it again, as *PDL* under perl does.
- **PDL: range and indexND as in *PDL* under perl**: `range` accepts an index with fewer dimensions than the source and a size per dimension, honours every boundary condition (`forbid`, `truncate`, `extend`, `periodic`, `mirror`, one for all dimensions or one each), keeps the type, and its result is linked to the source, so a write into it reaches the source. `rangeb` is new. `indexND` gains the same.
- ***PDL::Transform***: `use PDL::Transform` loads: coordinate transformations as objects (`t_linear`, `t_scale`, `t_offset`, `t_rot`, `t_lookup`, `t_fits`, `t_spherical`, `t_radial` and the others), their composition and inversion, `apply` and `invert`, and `map` and `unmap`, which resample an image through a transformation. *PDL::Transform::Cartography* adds the map projections (`t_mercator`,

`t_orthographic`, `t_gnomonic` and the others), `graticule` and `clean_lines`; `earth_coast` and `earth_image` need their data files from an installed *PDL*.

- ***PDL*: headers belong to the ndarray**: an ndarray's header (`sethdr`, `gethdr`, `hdr`) is released with the ndarray; it used to stay in memory, and a later ndarray could come up with a stranger's header. With `hdrcpy` set, every operation now gives its result a deep copy of the header and the flag, where only slices did. `sethdr` refuses anything but a hash reference or undef.
- **PDL: accessors take their argument as *PDL* under perl does**: `nelem`, `dims`, `ndims`, `isnull`, `get_datatype`, `nbytes`, `sever`, `badflag` and the like accept a number or an array reference as a one-off ndarray and die on the class name, where they returned 0 or nothing. After an explicit `$pdl->DESTROY` any use of `$pdl` dies with "Fatal error: ndarray address is NULL". `dimincs` of a view gives the view's increments, and `readonly` refuses a null ndarray.
- **PDL: a negative zero prints as -0 in a matrix**: a matrix whose elements go through `$PDL::doubleformat` or `$PDL::floatformat` now formats each number itself, so `-0` keeps its sign. `$VERSION` is `2.096` in *PDL::Core* and unset in *PDL::Ufunc*, *PDL::Slices* and the other generated modules, as in *PDL*; they all said `2.103`.
- **PDL: set_debugging prints the trace**: with `PDL::Core::set_debugging(1)` *PDL* prints what it does, step by step, to standard output, as PDL under perl does; it printed nothing.
- **PDL: badflag spreads as in *PDL* under perl**: setting or clearing `badflag` now reaches the ndarrays it does in PDL: the parents of a view and their flowing children, not the other views of the same parent. Clearing it on a parent used to leave a view of a view set, and setting it never reached flowing children.
- ***PDL* 2.106**: the embedded PDL is 2.106, up from 2.104. `hclip` and `lclip` work in place, *PDL::Constants* has `DEG2RAD` and `RAD2DEG`, and `avgover`, `minover`, `maxover` and the other "over" synonyms are methods only, no longer imported by `use PDL`. A condition on an ndarray of several elements dies with the full message of PDL, its `PDL::overload_bool` line included. The two functions new in 2.105, `isnan` and `casinh`, are not there yet.
- ***Peta::Shell::Session* evaluates Perl line by line**: a new built-in module that runs pieces of Perl one after another and keeps what each leaves behind: `my` variables, pragmas, the current package. It says when a text is unfinished and returns the value of the last statement. It is the evaluator of ipps, the interactive mode.

6.3.2 Command line

- **pperl -v describes the runtime in one line**: the banner now says "It features JIT, auto-parallelization and GPU acceleration."
- **–shell starts ipps, the interactive mode**: `pperl --shell`, or pperl run under the name `ipps`, gives a prompt that runs Perl, prints the value of the last statement and keeps variables, subs and pragmas from line to line. It has line editing, history, a second prompt for unfinished input and a start file, `~/.pperl/ipps/rc.pl`; without a terminal it reads lines from standard input. A bare `pperl` still reads a program from standard input as perl does. The reserved `--interactive` switch is gone.

- **ipps has commands, settings and macros**: a line that starts with a colon and a word is a command: `:help` lists them. `:vars` shows the session's variables, `:time` and `:jit` run a line and report on it, `:dump` shows a value whole, `:source` a sub's code, `:which` where a module comes from; `:install`, `:load`, `:save`, `:set`, `:history`, `:reset` and `:quit` do what their names say. In `~/.pperl/ipps/rc.pl`, `Peta::Shell->macro`, `->command` and `->set` define words that expand to Perl, commands of your own and settings.
- **ipps runs a command of your shell after !**: a line that starts with `!` and a space is handed to your shell and runs on the terminal, as in `! ls -l *.pl`. It runs under `$SHELL -c`; the new `shell` setting changes that, for example to `bash -ic` for bash's aliases. Without the space, `!` is Perl's negation as before.
- **ipps completes with Tab**: the Tab key completes the word in front of the cursor: a variable of the session, a key of one of its hashes (`$data->{list}[0]{` too), a method of an object or class, a sub, a module after `use`, a file name inside a string, a command, and a file name where none of those fits. A second Tab lists the candidates when there are several, and the prompt and the line are drawn again below the list; that holds for every program that completes through *Term::ReadLine*.
- **ipps shows a value as it is written in Perl**: a number bare, a string in quotes, `undef`, `true` and `false`, an array or hash as its structure, an object with its class in front. A string gets the quotes that need the fewest escapes: `'$5 each'`, `q{it's}`, `"a\tb"`. Large values are cut with a note of what was left out, and the layout follows the width of the terminal. The value last shown is in `$ans`, and `@ans` when there were several.
- **–cpan runs the built-in CPAN client**: `pperl --cpan` installs with the CPAN client that is part of the binary and no longer needs `cpanm` on the machine, so it works where no perl5 is installed. The options after `--cpan` are those of the `cpan` command, `-T` in place of `--notest`. A git repository, a directory or an archive file can still be named in place of a module.
- **–cpan installs only what loads after a failed XS build**: when a distribution's compile fails, `--cpan` installs its Perl files as before, but a module that loads the compiled part is now loaded once first and left out, by name, if it cannot load without it. A module that is only the front of its compiled part used to be installed and then reported as up to date on the next run. A directory named on the command line is covered too.
- **Built-in Perl modules count as installed**: `--cpan` now also treats the Perl modules the binary carries, such as `Test::More`, as installed, at their versions. It used to read a host perl's copies of them, or try to install them where there was none. Asked for a module that is built in, `--cpan` says so and builds nothing, also when CPAN has a newer release.
- **–native-manifest is gone**: `--cpan` no longer writes pperl's module inventory to disk, and the `--native-manifest=DIR` option that wrote it for other installers is removed. The installer asks `Config::lib_file` instead.
- **Modules for other operating systems are no longer built in**: `ExtUtils::MakeMaker`'s and `ExtUtils::CBuilder`'s files for VMS, Windows, OS/2, AIX, macOS and other systems, 26 in all, and the `vmsish` pragma are no longer part of the binary. The `File::Spec` modules for other systems stay.
- **A host perl's core directories are no longer searched**: `@INC` no longer lists the

core library directories of a perl5 installed on the machine, because every module in them is built into pperl and was never loaded from there. The site and vendor directories are searched as before, now under whichever perl version the host has.

- **Makefile.PL builds the Perl part only**: `ExtUtils::MakeMaker` under pperl no longer tries to compile a distribution's C or XS, so a `Makefile.PL` needs no compiler, no perl header files and no perl5 on the machine. A module that cannot load without its compiled part is left out and named, the rest of the distribution is built, and its own tests decide whether it is installed. The "different ideas about the architecture" notice is gone, and `$Config{privlibexp}` and `$Config{archlibexp}` name the built-in library.
- ***Config::lib_files* lists the built-in library**: the new function `Config::lib_files()` returns the names of all library files inside the pperl binary, in the form `require` takes (`File/Temp.pm`).
- ***Config::jit_counts* says what the JIT has compiled**: the new function `Config::jit_counts()` returns two numbers, the loops the JIT has compiled to machine code since the program started and the loops it has seen. It returns the empty list when the JIT is off.
- ***Config::lib_file* says where a library file is**: the new function `Config::lib_file("Foo/Bar.pm")` returns the path under which pperl sees that file, a built-in one first, or `undef`. The path can be opened; a built-in module without Perl source reads as its package and version. `ExtUtils::MakeMaker`, `Module::Metadata` and `CPAN` ask it, so a `Makefile.PL` no longer reports a built-in prerequisite as not found.

6.3.3 Documentation

- ***A tutorial for ipps***: a new tutorial, "ipps, the interactive mode", walks through a first session, the commands, the start file with its settings and macros, and the places where a line at the prompt behaves differently from a line in a file.
- **Changelog translations**: the changelog pages of versions 0.5.6 to 0.6.22 are translated into the 41 languages of the documentation. Entries of earlier versions name the Benchmarks Game programs and group the digits of large numbers the same way on every page, and two entries of 0.6.22 that were cut in two on the page read as one again.
- **Reference sidebar starts collapsed**: the section navigation of the Reference shows one line per namespace when you enter it, and opens only the branch of the page you are reading. It used to open every namespace at once, which made the sidebar several hundred lines long.

6.4 pperl 0.6.22

2026-10-06 to 2026-10-11, 89 commits.

6.4.1 Language and runtime

- **%Config is complete**: it has every key perl 5.44's has, 1,261 of them, where it had 198. The `d_*` and `i_*` answers come from probing the C library and include tree the way Configure does, the type sizes and formats from the build target, the tools from `PATH`, and the version, signal and extension keys from the running interpreter. `ExtUtils::MakeMaker` no longer warns about uninitialized values on every `WriteMakefile`, `DirHandle`, `Net::protoent` and `Net::servent` no longer believe their functions are missing, and `$Config{PERL_VERSION}`, `$Config{d_readdir}`, `$Config{uidsize}` and the rest exist.
- **The library's data files** are in the binary and readable: the files perl's modules open by path beside themselves, such as `ExtUtils::Manifest`'s default `MANIFEST.SKIP` and the `unicore` tables `Unicode::UCD` reads. `make distdir` no longer copies `MYMETA.*` into the distribution directory, and `Unicode::UCD`'s `charblock`, `charscript` and friends no longer depend on a perl installed on the host. `@INC` starts with `./pperl-native`, the embedded tree's own entry.
- **The daemon and duplicated output handles**: a script run through the daemon with `PPERL_DAEMON=2` that duplicates `STDOUT`, `STDERR` or `STDIN` while it compiles - every script that loads `Test::More` does - printed its output only on the first run, and the program reading that first run's output never saw it end. Each run now writes to its own output and reads its own input.
- **$0 and the environment**: assigning a name longer than the command line to `$0` no longer destroys the environment that child processes inherit. A program that renamed itself and then ran `system`, a backtick or `exec` had its children start with almost no environment (no `HOME`, no `PATH` additions), while its own `%ENV` looked fine.

6.4.2 JIT and parallelization

- **Conditional expressions** in compiled loops: a `?:` whose arm reads an element through a reference (`$c ? $x->[$i] : 0`) or from a hash (`$c ? $h{$k} : 0`) no longer makes the loop leave compiled code each time that arm is taken. An arm that is an element of a plain array already stayed compiled.
- **Recursive subs called from compiled loops**: a loop such as `for (1 .. $n) { local $_; $sum += fib($k) }` died with `panic: pp_iter, type=9` once it compiled, when the sub it calls recurses; `Benchmark`'s `timethese` and `countit` of a recursive sub died the same way. The compiled loop mistook a deeper recursion level's frame for its own.
- **A regex run once no longer gets compiled**: the regex compiler decided by the size of the string a pattern was matched against, so a pattern used a single time on a large string, as `charnames::viacode` and `vianame` do for every lookup over the one-megabyte names table, was compiled for that one match and the compilation cost several times the match. A place in the program that builds a new pattern for every lookup and runs each once now compiles none of them after the first; a loop of a thousand charnames lookups runs in a fifth of the instructions, and a pattern that is reused compiles when it did.
- **Integers past 2^53 in compiled loops**: a loop that computes an integer beyond 9007199254740992 and divides by it next, such as the long division inside `Math::BigInt` on numbers held as floats

(`Math::BigFloat->new(2)->bpow(240)->broot(9)` with `Math::BigInt::FastCalc`), could get one quotient digit wrong the first time the loop ran on float-typed values after integer-typed ones; later runs were right. The compiled loop had taken a rounded copy of the exact integer perl kept. It now leaves compiled code for that pass, as it does whenever a value cannot be held exactly.

- **`$_` in a nested statement-modifier loop**: in a compiled loop that contains `EXPR for LO .. HI`, where EXPR calls a function and reads `$_` in its arguments, the first pass of every inner loop saw `$_` undefined: a "Use of uninitialized value `$_`" warning, and 0 where the value was wanted, so a range not starting at 0 gave wrong results.

6.4.3 Modules

- **Native modules in the release build**: the build's profile-guided optimisation now runs *POSIX*, Socket, *Errno*, Config, *Time::Piece*, *Sys::Syslog*, *IPC::SysV*, the DBM modules, *Unicode::Normalize*, *Unicode::UCD*, charnames, the Symbol and EBCDIC encodings, the `:encoding`, `:via` and `:mmap` layers, *File::Map*, *Hash::Util*, *Clone*, *Memoize*, *Math::BigInt::FastCalc*, B, *Opcode*, Safe, *PadWalker*, *Devel::Peek*, mro, attributes, source filters, *EV*, Event, Coro's loop bridges, *Peta::Dict*, *Peta::PCRE2*, *Peta::XS*, *Peta::FFI* and *Peta::LMDB* before it decides what is hot. None of these had been run by the build before, so the release binary carried them compiled for size rather than for speed.

- ***Errno* has every name the host defines**: `%!`, the constants and `@Errno::EXPORT_OK` now come from the errno.h of the machine pperl was built on and the headers it includes, read at build time the way perl's own Errno.pm is generated. `EFTYPE`, `EFSBADCRC` and `EFSCORRUPTED`, which current kernel headers define and the previous fixed table lacked, exist; on this host the list is identical to perl 5.44's, all 137 names.

- **The `-C` switch**: `pperl -CSAD script` and the other forms of perl's Unicode switch work, alone and at the end of a cluster such as `-wCSD`; they were refused with "Unknown option: -C", and only `PERL_UNICODE` in the environment had the effect.

- ***Compress::Raw::Bzip2*** exists, with `Compress::Raw::Bunzip2` and the `BZ_*` constants, over the system's libbz2. With it `IO::Compress::Bzip2`, `IO::Uncompress::Bunzip2`, `IO::Uncompress::AnyUncompress` and `Archive::Tar` read and write bzip2 data, `.tbz` archives among it, and `streamzip` makes bzip2 zip entries; they died with "Can't locate Compress/Raw/Bzip2.pm".

- ***Peta::ReadLine*** is the name of the readline module; `Term::ReadLine::Gnu` is an alias of it, so `use Term::ReadLine` still picks it up, a program that tests `$term->ReadLine eq "Term::ReadLine::Gnu"` (CPAN.pm, the debugger) still passes, and `Term::ReadLine::Gnu::XS::*` calls still work. `Peta::ReadLine->new` reports `Peta::ReadLine`, version 0.2.0; the alias reports the name it was asked by.

- ***Peta::ReadLine*'s function table and keymaps**: `get_all_function_names` lists the bindable commands (it returned one name of garbage), `get_function_name` finds a function's name, and `$attribs->{executing_keymap}` and `$attribs->{binding_keymap}` are Keymap objects that `get_keymap_name` and the

binding methods accept. `import Term::ReadLine::Gnu qw(:keymap_type)` and the other export tags work under the alias as they do under `Peta::ReadLine`.

- ***Peta::ReadLine*'s ignore_some_completions_function**: a completion with `$attribs->{ignore_some_completions_function}` set no longer dies with "panic: attempt to copy freed scalar" in the statement that called `complete_internal` or `call_function`.
- ***Peta::ReadLine* has its own line editor**: no readline, history or curses library is loaded any more, so line editing works where none is installed and in the static build. It behaves as GNU Readline 8.3 does - commands, key bindings, the init file, history, completion, signals, and the same screen after every key. In a UTF-8 locale the commands move, delete, change case and search by characters, not bytes. It identifies itself: `$attribs->{library_version}` is `8.3 (Peta::ReadLine 0.2.0)` and `$attribs->{gnu_readline_p}` is 0.
- ***Imager*** follows Imager 1.037. `getsamples` checks its arguments itself and says in `errstr` why a call failed (a row outside the image, a channel the image does not have); a failed call returns the empty list, or undef in scalar context. An image too large to allocate fails `Imager->new` with a message instead of ending the program, and `set_out_of_memory_handler` exists.
- ***Imager* drawing and images**: `box`, `line` (plain and anti-aliased) and `arc` draw; `getscanline`, `setscanline`, the palette rows and `setcolors` work; images convert between 8-bit, 16-bit and double samples and can be compared. `open_log`, `log` and `close_log` write Imager's log, and colours have `red`, `green`, `blue`, `alpha` and HSV conversion. Three results changed to what Imager gives: a 16-bit image read as 8-bit colours was one too bright for some values, `i_img_info`'s fourth value is the channel mask, and the colour count of a direct image is undef.
- ***Imager* I/O objects**: `Imager::IO` exists: `new_buffer`, `new_fd`, `new_fh`, `new_cb` and `new_bufchain` (and the `io_new_*` functions) make an I/O object over a string, a file descriptor, a file handle, Perl callbacks or a file in memory, with `read`, `write`, `seek`, `getc`, `gets`, `peekn`, `close` and the rest of the class. `io_slurp` of an object that is not a memory file dies with a message; under Imager itself it ends the program silently.
- ***Imager* PNM files**: Imager reads and writes PNM files (PBM, PGM and PPM, ASCII and binary, 8 and 16 bit), `read_multi` included, so `Imager->new(file => 'x.ppm')` and `$img->write(type => 'pnm')` work. `set_file_limits`, `get_file_limits` and `check_file_limits` bound what is read, and the format of a file is detected from its first bytes, with `add_file_magic` for signatures of your own.
- ***Imager* raw files**: `read` and `write` with `type => 'raw'` work: rows of bare 8-bit samples, interleaved by sample or by line, with `raw_datachannels` and `raw_storechannels` choosing which channels of the file are kept.
- ***Imager* BMP files**: Windows BMP files are read at 1, 4, 8, 16, 24 and 32 bits a pixel, run length encoded and with bit-field masks included, and written uncompressed. A grey image with an alpha channel is written with its own grey; under Imager itself each pixel takes its neighbour's value as alpha and half the row is garbage.
- ***Imager* TGA files**: Targa files are read and written: colour-mapped, direct colour and grey, run length encoded or not, at 8, 15, 16, 24 and 32 bits a pixel, with the

`compress`, `wierdpack` and `idstring` options. `%Imager::formats` now lists what Imager lists without any library: raw, pnm, bmp, tga and ifs.

- ***Imager*** **masked images**: `$img->masked` gives a view of part of an image, optionally written through a mask, that can be drawn into, copied and written to a file. `setsamples` is available, with its floating point and 16-bit forms, and so are `getsamples` with `type => 'float'` and `type => '16bit'`. A floating point sample outside 0 to 1 now wraps when stored in an 8- or 16-bit image, as in Imager, and `getmask` on a fresh image is -1.
- ***Imager*** **fills**: `box` and `arc` take a `fill`, and `Imager::Fill` makes solid, hatched, image and opacity fills with the twelve combine modes (`normal`, `multiply`, `add`, `darken`, hue and the rest).
- ***Imager*** **paste and crop**: `$img->paste` copies a rectangle of another image in, converting between sample depths and channel counts, and `$img->crop` cuts one out.
- ***Imager*** **circles and flood fill**: `circle` draws filled anti-aliased circles and, with `filled => 0`, outlines, plain or anti-aliased; `arc` with `filled => 0` draws the outline of an arc. `flood_fill` fills the region around a point with a colour or a fill, optionally up to a `border` colour, and `polybezier` draws a Bezier curve.
- ***Imager*** **polygons**: `polygon` and `polypolygon` fill anti-aliased polygons with a colour or a fill, by the even-odd or the non-zero winding rule, and `arc` with `aa => 1` draws an anti-aliased pie slice.
- ***Imager*** **rubthrough and compose**: `$img->rubthrough` lays another image over the image by its alpha channel, and `$img->compose` does so with a combine mode, an `opacity` and optionally a `mask` image.
- ***Imager*** **fountain fills**: `Imager::Fill->new(fountain => ...)` makes a gradient fill (linear, bilinear, radial, square, revolution or conical, with repeats, segments and super-sampling), and `$img->filter(type => 'fountain')` draws one over a whole image.
- ***Imager*** **channel operations**: `$img->convert` makes a new image by a matrix or a preset (`grey`, `noalpha`, `rgb`, `addalpha` and the single channels), `Imager->combine` makes one from channels of several images, `$img->map` runs channels through lookup tables, and `$img->flip` mirrors the image.
- ***Imager*** **quantisation**: `$img->to_paletted` turns a direct colour image into a paletted one, with the palette from median cut, the `addi` method, a fixed map or your own colours, and the pixels matched by closest colour, perturbation or error diffusion. `Imager->make_palette`, `getcolorcount`, `getcolorusage` and `getcolorusagehash` work.
- ***Imager*** **scaling**: `$img->scale`, `scaleX` and `scaleY` return a scaled copy, with the `normal`, `preview` and `mixing` methods.
- ***Imager*** **rotation**: `$img->rotate` turns an image by quarter turns (`right`) or by any angle (`degrees`, `radians`, with `back`), and `$img->matrix_transform` maps it through a 3 x 3 matrix.
- ***Imager*** **trim**: `$img->trim` and `trim_rect` find and remove the border of an image, by colour ranges (`colors`, `auto`) or by transparency (`alpha`).

- ***Imager*** **transform and transform2**: `Imager::transform2` computes an image from an expression per pixel (`rpnexpr`, or `expr` with Parse::RecDescent), reading up to three input images, and `$img->transform` moves pixels by two stack programs.
- ***Imager*** **filters**: `$img->filter` has every filter Imager has built in: `autolevels`, `autolevels_skew`, `bumpmap`, `bumpmap_complex`, `contrast`, `gaussian`, `gaussian2`, `gradgen`, `hardinvert`, `hardinvertall`, `mosaic`, `nearest_color`, `noise`, `postlevels`, `radnoise`, `turbnoise`, `unsharpmask` and `watermark`, beside `conv` and `fountain`. `$img->difference` and `rgb_difference` show where two images differ.
- ***Imager*** **object destructors**: calling the `DESTROY` of an Imager class on something that is not a reference dies with Imager's message, "is not a reference"; it named an expected type instead. `$Imager::_context` exists.
- ***Imager*** **plugin loader**: `Imager->load_plugin`, which loads filter plugins compiled from C, returns undef and sets `$Imager::ERRSTR` instead of dying with "Undefined subroutine". Such plugins cannot be loaded; Imager has documented that interface as deprecated since 2006.
- ***Peta::WebGPU*** **and fork**: a process that has opened a device can fork. The child used to hang for ever when it exited; now it ends normally. Using an inherited device, buffer or shader in the child dies with a message that says to open a device there, and the child can do so and compute on it. Where the parent has the `gl` backend open, the child's device comes from the other backends.
- ***Peta::WebGPU*** **batches**: `$gpu->batch(sub { ... })`, or `$gpu->begin` and `$gpu->commit`, send any number of dispatches to the card in one go, and `$pipeline->bind(\@buffers)` gives an object `run` takes in place of the pipeline and its buffer list, so a recurring dispatch no longer binds its buffers each time. A `write` inside a batch takes effect in order with the dispatches around it, and `$gpu->timed(sub { ... })` returns the nanoseconds the card spent on a batch. `$gpu->features` and `$gpu->has_feature` name the optional features of the device, which now has half-precision floats in shaders (`enable f16;`) and timestamp queries wherever the adapter does.
- ***Peta::WebGPU*** **buffers**: `$buffer->read($offset, $length)` reads a part of a buffer, so fetching one number no longer copies the whole buffer back from the card. `$buffer->write` takes a *PDL* ndarray of type `float`, `long` or `ulong` as well as a byte string.
- ***Peta::WebGPU*** **memory**: a buffer made with contents no longer takes twice its size on the card until the next dispatch; large contents go up in pieces. `$buffer->destroy` frees a buffer's memory at once, `$gpu->memory` reports what the device has allocated, and `Device->new(memory_limit => 90)` turns running out of card memory into an `Out of Memory` exception at 90 percent of the driver's budget. A program that frees buffers and at once makes new ones is no longer told the card is full while the freed memory is still on its way back, and an error message names the first failure, not one that followed from it.
- ***Peta::WebGPU*** **on OpenGL**: `Device->new(backend => 'gl')` opens on the NVIDIA driver, where it failed with "Parent device is lost". Drawing works there; compute needs OpenGL 4.3 or ES 3.1, and on an older context dies with a message that names the `vulkan` backend.

- ***Net::SSLeay*** **version constants**: `OPENSSL_VERSION_MAJOR`, `OPENSSL_VERSION_MINOR`, `OPENSSL_VERSION_PATCH` and `OPENSSL_VERSION_NUMBER` name the OpenSSL that is loaded. They kept the values of the release pperl was built beside, so after a system update to OpenSSL 3.6.5 `OPENSSL_VERSION_PATCH` still said 4.
- ***GD*** has the rest of GD 2.91: the affine matrices and transforms, `colorReplace` and its variants, `convolution`, `resolution`, the transposed, rotated, scaled and blurred copies, animated GIF, HEIF and AVIF, 48 functions in all. `GD::VERSION_STRING` is now libgd's version string and `GD::LIBGD_VERSION` its number (2.0303 for libgd 2.3.3), as in GD itself. `GD::Image->supported` and the `newFrom<Format>` methods follow what the installed libgd can read.
- ***GD*** **colorsTotal**: `$image->colorsTotal` on a truecolor image returns `undef`, as in GD itself. It returned 0.
- ***Config::config_vars*** and `-V` print the way Perl's `print` does: to the handle `select` chose, through a tied `STDOUT`, and in order with the program's other output. They wrote to the process's standard output directly, so a capture saw nothing and, on a pipe, their lines could come out ahead of text printed earlier. `Config::compile_date` and the matching line of `-V` read `Compiled at Oct 8 2026 20:42:44`, the layout `Config::Perl::V` parses; they named the compiler instead.
- ***Cairo***, ***Cwd***, ***Term::ReadLine::Gnu***: `Cairo::HAS_PS_SURFACE`, `HAS_PDF_SURFACE`, `HAS_SVG_SURFACE`, `HAS_RECORDING_SURFACE` and `HAS_FT_FONT` exist. `Cwd::CLONE` exists. `rl_save_state` returns a `readline_state_tPtr` object, which is freed with its last reference and is the only thing `rl_restore_state` accepts.

6.5 pperl 0.6.21

2026-09-28 to 2026-10-06, 271 commits.

6.5.1 Language and runtime

- **Unicode 17** reaches `\N{...}`, `charnames::viacode` and *Unicode::UCD*: they are perl 5.44's own, built into pperl, where pperl had read them from the host perl (5.42, Unicode 16) and did not know Unicode 17's characters. A program using one `\N{NAME}` no longer spends most of its run compiling the 1.2 MB character-name table (34 ms against a 4 ms baseline); the table is stored in the binary.
- **glob** and `<*>` match files with perl5's own matcher instead of the C library's `glob`: brace alternatives come back in the order written, `GLOB_NOCASE` no longer sorts by case, `^` inside `[...]`, `\*` and an empty `{}` mean what they mean in perl5. A directory error stops a glob as in perl5, and `File::Glob::GLOB_ERROR` reports the last glob's error code instead of always 0.

6.5.2 JIT and parallelization

- **Parallel loops**: compiled loops run on all cores. A counted `foreach`, `while` or C-style `for` loop whose body only computes - integer sums, bitwise reductions, sums of floats whose terms are whole numbers, reads of a hash with integer keys - is split into chunks whose result is bit for bit the sequential one, and a chunk that

reaches a call or an exit resumes sequentially at its first iteration, so perl dies or warns where it would. On 4 physical cores a 400-million-trip addition loop takes 0.13 s instead of 0.58 s, and the Benchmarks Game's mandelbrot written as a loop takes 4.13-4.26 s at N=16,000 instead of 10.95 s. Loops too short to repay the split stay sequential, and `--no-parallel` turns splitting off.

- **Floating-point loops** over arrays, also arrays reached through references, no longer leave compiled code at every float element: a matrix-vector product takes 9.5 ns per multiply-add instead of 248 (79 ns without the JIT), a 4096-element dot product 9.4 ns instead of 70. A `return \@y` elsewhere in the sub, or a `?:` that picks an array element (`$x[$i] > 0 ? $x[$i] : 0.0`), no longer keeps a loop interpreted; a small neural network trains at 16,000 samples per second with the JIT against 2,500 without, where it had run slower with the JIT (1,800 against 4,000). A float loop such as `$sum += ($x > $y)` no longer moves its sum through memory on every trip: 5.2 cycles per trip instead of 10.1.
- **Regular expressions** compiled by ReJIT: a successful match of a pattern without capture groups records its result itself instead of running the interpreter's matcher over the match again, and the Benchmarks Game's regex-redux (single-threaded, 5M) runs 32% fewer instructions and cycles; each compiled pattern reaching its state through its own engine saved a further 3% there. Scans for a literal probe 64 bytes per step and hand long stretches without a candidate to the C library's `memchr`: `/aab./` over 64K of `a` went from 0.14 to 1.02 times perl5's speed, and the other literal and character-class scans measured run 1.7 to 1.9 times as fast.
- **String operations** in compiled loops: 4-argument and lvalue `substr` replacement, `vec` read and assigned, the `x` repetition of a string and `join` over scalars compile, and so do string results stored into package variables and into array or hash elements, and truth tests of strings. A `substr` loop over a 4 MB string runs in 1.49 s instead of 3.65 s (perl5 4.59 s), a `vec` bit sieve in 0.56 s instead of 3.75 s (perl5 4.41 s). Loops that rebuild strings and then test or store them, such as `$s += length $g` over a package variable or `$w = $i & 1 ? "a" : ""`, no longer fall back to the interpreter on every trip.
- **Array references** in compiled loops: element reads, stores, `++` and `+=` through `$r->[...]`, `scalar(@$r)`, `$#$r`, and `push`, `unshift`, `pop` and `shift` through a reference compile, as do `shift @a` and a sub's implicit `shift` of `@_`. Compiled code now honours a tied scalar holding the reference and a class that overloads `@{}`, which it had bypassed, and a loop that reads an array through a reference while updating it by name sees its own updates. An object removed by pop in a compiled loop is destroyed at the end of its statement, as in perl, not after the next one.
- **Hashes, pushes and new arrays** in compiled loops: a plain hash element is looked up inline, an integer key without first being turned into a string, and the Benchmarks Game's k-nucleotide at 25M runs 19.2% fewer instructions. A short-lived array built in a loop (`my $v = [$i, $i + 1]`) compiles, and one that never leaves the loop is kept in registers: such a loop runs 20.3 times as fast. A loop that pushes computed values onto an array, such as a sieve's prime extraction, runs 2.93 times as fast.
- **List foreach loops** such as `for my $v (@a, @b)`, `for ($x, $y)` and `for (1, 5, 9)` compile, also nested in another compiled loop. A benchmark of such loops over two arrays runs in 0.276 s instead of 0.715 s (perl5 0.711 s).

- **Loop conditions** that combine comparisons with &&, || or ?:, and `while ($x)` or `until ($done)` on a plain value, compile; such conditions had kept 133 loops in 14 of 21 real programs interpreted. A sub whose last statement is a compiled `while` loop no longer returns a wrong value in list context.
- **More loops compile.** `defined $v` is tested when the loop runs instead of assumed when it compiles, and `ref $x` as a condition, `<=>` under `use integer`, a C-style `for` that stores into array elements (`for (my $k = 0; $k < $n; $k += $q) { $a[$k] = 1 }`) and a call to a sub defined further down the file no longer keep a loop interpreted.
- **Fewer compiled loops give up.** Loops that compiled but left compiled code at every entry until pperl stopped trying now stay compiled: a `foreach` over constants, a `foreach my $q (@q)`, whose loop variable is a value the array holds as well, a copy of a string or of undef into a `my`, `$b[$i] += 1` over whole-number floats from a division, and a `my $last = ''` written on a rare branch. A modifier `if` as a loop's last statement no longer grows perl's stack: a 10-million-trip loop that took 27.1 MB against the interpreter's 10 MB takes 14.6 MB and 227.8M instructions instead of 507.8M. A loop that keeps leaving compiled code for any other reason is given up after about 4,096 entries instead of retried forever.
- **JIT overhead**: a program that compiles nothing pays less for the JIT; on a module-loading test file the cost over `--no-jit` fell from 32.5M to 14.5M instructions. An `s///` with an expression replacement is no longer taken for a loop to compile, which had made one module's test file 61% slower with the JIT (now 4.3%), and short `foreach` loops over lists and arrays are no longer compiled when they cannot repay the compile.
- **Integers stay integers.** Values written by compiled loops keep the integer or floating-point form perl gives them: an integral result stored into an array element, by +=, or computed through `int()` stays an integer where it had become a float, as *Devel::Peek* and B showed, and later integer reads of it stay compiled. A loop that pperl tried and failed to compile no longer turns an integer variable into a float, which had left 14 string-function benchmarks about 10% slower with the JIT than without.
- **Compiled stores** no longer run a tied variable's `STORE` or an object's `DESTROY` in the middle of compiled code: a store to a tied destination could leave a loop reading a reallocated array or crash it, and an object whose last reference was overwritten was destroyed when the loop ended instead of at the next statement. A lexical written both by a loop and by subs it calls, such as a variable a closure captures, keeps every write.
- ***Memoize***: the cache compiled code uses for a memoized function of numbers no longer makes small integer arguments evict each other. A memoized `fib` over the arguments 0 to 31 made 1.25M avoidable calls in 20M; its loop now also runs in parallel.

6.5.3 Modules

- **The perl 5.44 core library** ships inside pperl: every `.pm` and `.pl` file perl 5.44 installs is embedded, 733 more than before, and pperl no longer takes core modules from the host perl. On a host without perl the previous binary could not load *Encode*, *File::Temp*, *Test::More*, *Math::BigInt*, *JSON::PP*, *Unicode::UCD* or autodie, and

on a host with perl 5.42 it loaded 5.42's versions. `threads` and `threads::shared` ship their 5.44 modules too.

- ***Net::SSLeay*** **and IO::Socket::SSL**: Net::SSLeay 1.96 is native in the full build, over OpenSSL 3 loaded at run time, with the 709 functions its distribution provides for that OpenSSL; a function the loaded library lacks stays undefined, as in a perl5 build against that library, so feature tests such as `defined &Net::SSLeay::X` answer correctly. IO::Socket::SSL 2.099 ships beside it. Both distributions' test suites, and AnyEvent's including its TLS test, match perl 5.44 running the original modules.
- ***DB_File***, ***GDBM_File***, ***NDBM_File*** **and** ***ODBM_File*** are native and keep their databases in LMDB files, through liblmdb loaded at run time, instead of Berkeley DB or gdbm; DB_File supports Hash, Btree and Recno, and a gdbm or Berkeley DB file is recognised and refused, never written. GDBM_File writes and reads gdbm's ASCII and binary dump formats, so gdbm 1.26 loads pperl's dumps and pperl loads gdbm's, which is how existing gdbm files move over. By default writes are held in one transaction until `sync`, `untie` or `close`; `$Peta::LMDB::DBM_WRITE = 'through'`, or GDBM_File's sync mode, commits each write, and a crash loses writes but never the file.
- ***Peta::LMDB*** is new: LMDB's environments, transactions, databases and cursors for Perl, with key comparators written in Perl and errors raised as `Peta::LMDB::Error` objects. The DBM modules above are built on it.
- ***LMDB_File*** 0.14 is native over the same library, and its distribution's tests match perl 5.44 with the original module. Closing an environment explicitly, closing it twice, or using a transaction of a closed environment no longer crashes; perl5 with the original module aborts or segfaults there.
- ***Class::XSAccessor*** 1.19 is native, including the faster call path it gives its accessors. Moo uses it for attribute accessors; before, Moo found the host perl's build, could not load it, and warned "Class::XSAccessor exists but failed to load" before falling back to pure Perl.
- ***XML::Parser*** 2.59 is native in the full build, over libexpat 2.6.0 or newer loaded at run time, so XML::Dumper and the other modules built on XML::Parser work. Its distribution's tests match perl 5.44 with the original module built against the same libexpat.
- ***Unicode::LineBreak*** **and** ***HTML::Parser*** are native. Unicode::LineBreak 2019.001, with *Unicode::GCString* and *Text::LineFold*, breaks lines and grapheme clusters by the Unicode 17 rules and passes Unicode 17's LineBreakTest and GraphemeBreakTest; Thai, Lao, Khmer and Myanmar text is segmented through the system's ICU. HTML::Parser 3.86 matches perl5 with the original module on its whole test suite.
- ***Unicode::Normalize*** 1.32 is native and passes its distribution's tests and Unicode 17's NormalizationTest, 400,680 cases.
- ***Devel::Size*** 0.87 is native, and its distribution's tests match perl 5.44 with the original module.
- ***File::DosGlob***, ***Sys::Syslog*** **and** ***Math::BigInt::FastCalc*** are native: File::DosGlob 1.12, Sys::Syslog 0.36 and Math::BigInt::FastCalc 0.5020.

- ***PDL*** loads as on perl5: `PDL.pm`, *PDL::Lite* and *PDL::LiteF* are upstream's, so `require PDL` loads nothing until `import`, and `use PDL` gives upstream's exports, now including `rcols`, `wcols`, `rfits`, `wfits`, `rpic`, `wpic`, `rim` and `wim`, less 22 functions pperl does not have yet. *PDL::IO::Misc*, *PDL::IO::Pnm*, *PDL::IO::FITS*, *PDL::IO::Pic*, *PDL::ImageRGB*, *PDL::Image2D* and *PDL::Compression* load, *PDL::Types* and *PDL::Constants* are upstream's, and `use PDL::LiteF` no longer leaves every operation dying with "PDL core struct is NULL". A pperl built with PDL loads libquadmath when *PDL::Core* loads, no longer at startup, where it slowed every number-to-string conversion of every program.
- ***PDL*** **computations** that gave wrong answers now match PDL 2.104: `median` and `oddmedian` of a multi-dimensional ndarray, `avg`, sums of byte and 64-bit ndarrays, `stats`, `dim(-1)`, `nbad` and `approx`; seeded `random` numbers equal perl5's bit for bit. In-place operations on a converted type (`$d &= 0; $d |= 1` on doubles) no longer die and leak, `cat` of ndarrays of different types no longer writes garbage, and `clip`, `hclip` and `lclip` take `->inplace`, an output and undef bounds as upstream does (`lclip` died).
- ***PDL*** **errors and operators** follow upstream: errors go through `PDL::barf` with its backtrace, operations upstream does not run in place refuse `->inplace` (a reduction had written its result over its input), and `ne`, `lt`, `gt`, `le`, `ge` and `cmp` on ndarrays die as on perl5 instead of comparing element by element. `matmult` and `x` report upstream's dimension-mismatch message and promote vectors as upstream does, `-$x` keeps an unsigned type, and `abs` of a complex value is its modulus. Loading PDL under `-w` no longer warns about redefined subroutines, and the binary operators read their swap flag as an integer, running get-magic. An out-of-range dimension given to `broadcast` croaks at the first computation, where perl5 reads memory it does not own.
- ***PDL*** **multithreading**: as in PDL 2.104, an operation on an ndarray of at least 1 Mi elements is split across threads by default, with upstream's controls (`set_autopthread_targ`, `set_autopthread_size`, `online_cpus` and the rest); the thread count follows `--threads`, and `--no-parallel` turns the splitting off. Warnings and errors raised in the threads arrive after the join through `PDL::cluck` and `PDL::barf`, as upstream's do. Reading ASCII and PNM data is not split, where upstream's threaded readers crash.
- ***PDL*** **subclasses and redefinitions** are honoured by the functions pperl runs natively for speed - `new`, `null`, the type constructors, `flat`, whole-array reductions such as `sum` and `max`, `at`, `set` and string conversion: each takes its shortcut only for a plain PDL while the subs upstream's Perl would call are unchanged, and runs upstream's Perl otherwise. A list assignment to `flat`'s result no longer clobbers the caller's variable, a format argument to string conversion is no longer ignored, and string conversion clears `$@` as upstream's does.
- ***Imager*** follows Imager 1.036, including its paletted images: every palette has 256 entries, and an index past the colours in use is rejected or read as black. *Imager::Font::FT2* is native, over FreeType loaded at run time, and the Imager and FT2 tests match perl5 with the original Imager 1.036.
- ***Exporter***, ***Carp*** **and** ***File::Temp*** are perl 5.44's own modules (Exporter 5.79, Carp 1.54) instead of pperl's replacements, and the modules built into pperl export through the real Exporter as their originals do: `Errno->can('import')` is `\&Exporter::import`, and Config no longer inherits from Exporter.

- ***List::Util***: `reduce` with a block that branches, such as `reduce { $a > $b ? $a : $b } 1 .. 500`, no longer hangs with the JIT on, and it compiles: 2000 reductions over 2000 elements take 314M cycles against 363M on perl5. `min` and `max` over more than 65,536 numbers return the element itself, as perl5 does, not a new number: `max` of numeric strings returns `"0300000"`, not `300000`.
- ***EV* and Event**: an EV periodic watcher's callback no longer leaks two values per call, which had kept the watcher from ever being freed, and setting its reschedule callback takes effect, where EV 4.37 never calls it or fails every fire. EV's signal names IOT, CLD and POLL mean their signals instead of out-of-range numbers. `Event::queue` with a wrong number of arguments dies with a usage message instead of crashing, and destroying an `Event::generic::Source` that still has watchers no longer frees it twice.
- ***Cairo*** checks its methods' arguments before reading them and reports a wrong call as the Cairo module does (`Usage: Cairo::Matrix::translate(matrix, tx, ty)`), and the `MIME_TYPE_*` and `OUTLINE_ROOT` constants are constants folded at compile time.
- **Native modules in release builds** are part of the profile-guided optimisation training: *List::Util*, *Scalar::Util*, *Encode*, *MIME::Base64*, *Digest::MD5*, *Digest::SHA*, *Storable*, *Data::Dumper*, *Coro* and others had been built as code the training never ran. Digest::SHA's final padding, Encode's single-byte encoder and Cwd's `abs_path` also no longer do work their C originals skip.
- **%Config** describes what pperl provides: `nonxs_ext`, `extensions` and `known_extensions` name its pure-Perl and native extensions as Configure would, and `bin`, `scriptdir`, `sitebin`, `sitescript`, `vendorbin`, `vendorscript` and their `*exp` forms are defined, as in perl 5.44. Test suites that check `$Config{extensions}` no longer skip, and Pod::Find no longer warns about an uninitialised `scriptdir`.
- **Peta modules** are versioned 0.2.0, below 1.0.0 until their interfaces are final; *Peta::XS*, which was 1.0, moves down with them. `Peta::FFI::UUID`'s `uuid_unparse` and `uuid_is_null` die on anything but a 16-byte UUID instead of padding or cutting it.
- **Smaller module changes.** *Sub::Exporter::Progressive* 0.001013 ships, for *File::Map*. *POSIX* functions that return a system call's status give a modifiable undef on failure, `Config::config_re` leaves a bad pattern's error in `$@`, *Digest::SHA* leaves its argument downgraded as perl5 does, `Coro::State::nice` returns the previous priority, `Math::GMP::_gmp_build_version` exists, and *Errno* reports its version as 1.39. *GD* and *Term::ReadLine::Gnu* without their C library fail at `require`, and GD's writers croak on failure, `interlaced(0)` turns interlacing on and `alphaBlending` and `saveAlpha` return nothing, all as the GD module does.

6.5.4 Command line

- **CPU features**: `pperl -V` lists the CPU extensions the binary was compiled for and those the JIT uses on the machine it runs on; `--jit-stats` prints them as a `cpu=` line.

6.5.5 Distribution

- **Minimal builds**: a pperl built without the standard native modules (`native-min`) answers `require Imager`, `GD::Simple`, `Memoize::Expire` or `SDL2::Image` with "Can't locate ..." naming the missing capability, instead of loading the Perl half and failing later.

6.5.6 Documentation

- **Changelog**: this changelog, with one page per version from 0.5.6 on. Every change of a version is accounted for, either in an entry or as internal work.
- **Index**: one page per initial letter, plus one for symbols, under a letter overview. Every entry is the name itself and links to its page; a function also appears under its own name with its module in parentheses, as in `access (POSIX)`, and a pragma as `open (pragma)` beside the built-in `open`. Besides modules and functions it now lists perl's special variables and operators under perl's own index terms, the command-line options and environment variables, the topics of every guide and tutorial, and every version of this changelog, with each module under the versions that changed it.
- **^^ and ^^=**: the operator reference documents perl's high-precedence logical exclusive or; it said there was no ^^.
- **Errata**: the chapter on errors in perl's own documentation is withdrawn. A page removed from the documentation is now also removed from the published site, where it had stayed reachable by its address.
- **Module reference**: the native modules' pages document what a user calls, with synopses whose output is the same on perl 5.44 and pperl, the upstream version implemented, and a section on differences from upstream citing the tests that pin them. Every function is published under its Perl name (`B::CV::GV`, not `cv_gv`); *PDL*, *Net::SSLeay*, *EV*, Event, *Storable*, *POSIX*, *Coro*, *Compress::Raw::Zlib*, *Unicode::Normalize*, *Peta::LMDB* and the DBM modules gained full references, and Cairo's pages moved from `Peta::FFI::Cairo` to `Cairo`.
- **Bundled modules**: the 755 pure-Perl modules embedded in pperl have reference pages made from their own POD, with highlighted code and corrections where the original text does not apply to pperl; text about building XS modules is left out. XSLoader's page describes how it starts native modules under pperl.
- **Graphics guides**: the 2D and 3D graphics guides are translated into all 41 languages of the documentation, and factual errors in their English were corrected.
- **Translations**: the German translation covers the native module reference pages, *SDL2*, *Peta::WebGPU* and the debugging guide, and every language's catalogues follow the reference pages to their new places.

6.6 pperl 0.6.20

2026-09-27, 21 commits.

- **Static binaries** start again. Every statically linked (musl) pperl stopped with a segmentation fault before running a line: the code that records the program's arguments, which an assignment to `$0` rewrites, received none from musl and read

garbage. They also build again: POSIX's six locale categories that only glibc defines (`LC_ADDRESS`, `LC_IDENTIFICATION`, `LC_MEASUREMENT`, `LC_NAME`, `LC_PAPER`, `LC_TELEPHONE`) are reported on musl as perl5 built on musl reports them, "Your vendor has not defined *POSIX* macro".

- ***Peta::Dict*** no longer crashes in a compiled loop that counts numeric-string keys, such as `for my $k (@keys) { $h{$k}++ }`. A key that grew the table during the loop left the compiled code reading the table's freed memory.
- **Regular expressions** compiled by ReJIT search each string once instead of twice. Regex-redux runs 9% fewer instructions; scans for a long literal and for a pattern that starts with `.` take about half and under a third of the cycles they took. No measured pattern got slower.
- **Release archives**: every binary of a release is built with profile-guided optimisation, and a release is one archive holding the binaries, their SHA-256 sums and a build record (commit, target, features). Before it is packed, each binary must print the locale and format numbers under four locale settings exactly as perl5 built against the same C library does.

6.7 pperl 0.6.19

2026-09-17 to 2026-09-27, 526 commits.

6.7.1 Language and runtime

- **Modules compiled into pperl** are loaded the way perl5 loads a file it finds on `@INC`. Such a module no longer sees the lexical variables and pragmas of the code that requires it: `my $VERSION = "mine"; require Guard` overwrote the caller's `$VERSION`. `%INC` and `__FILE__` name the module `./pperl-native/<name>` instead of `native`.

6.7.2 JIT and parallelization

- **mandelbrot**: the Benchmarks Game's mandelbrot compiles its per-pixel loop as one piece. A labelled `next` or `last` out of an inner loop is a jump inside compiled code, an append to a fresh `my $line` no longer leaves it, and the loop's floating-point values stay in registers instead of being reloaded from the stack; at size 16,000 the program runs 362.6G instructions, from 1,160.8G. The range checks on floating-point results are combined into one test per statement, which takes 28.9% of the instructions off mandelbrot at size 2,000.
- **Independent loop iterations**: a counted `foreach` whose iterations do not depend on each other runs four of them side by side in SIMD vectors, and overflow checks that the loop's own tests make unnecessary are proved away and dropped. mandelbrot at size 16,000 takes 19.36 s of CPU time with the vectors, from 31.08 s, and runs 164.3G instructions with the checks dropped, from 217.4G. In the release build it takes 12.13 s.
- **binary-trees**: a recursive subroutine that walks a tree through array references, or builds and returns new arrays, compiles as a function. When one such call builds a tree that the next call in the same statement only walks, the tree is built in a private area that is freed in one step; any failure throws the area away and runs

the statement again interpreted. With the private area, the Benchmarks Game's binary-trees at depth 21 takes 4.29 s of CPU time instead of 26.1 s.

- **fannkuch-redux**: a block inside a compiled loop no longer ends it, so the Benchmarks Game's fannkuch-redux keeps its whole permutation step in compiled code; at n=9 it runs 1,301M instructions, from 2,824M. Statements of its flip loop no longer write perl's stack pointer, `@a = @b` between two integer arrays copies the values directly, a two-index `while ($lo < $hi)` loop checks its bounds once, and loop tests are placed next to their bodies. At n=12 the program takes 53.53 s of CPU time, where Node.js takes 57.42 s.
- **fasta**: a constant that an earlier division left carrying a floating-point value no longer forces its expression into doubles, so the Benchmarks Game's fasta computes `($seed * IA + IC) % IM` in integers, as perl5 does: 7.52 s of CPU time at 25,000,000 becomes 3.64 s. A modulo by a literal compiles to a multiplication (18.09 s to 14.83 s), and short appends and `substr($s, $i, 1)` copy their bytes inline.
- **spectral-norm**: a small numeric function called from a loop, such as `eval_A` in the Benchmarks Game's spectral-norm, no longer pays per call for a signal check, a stack probe and stack resets it cannot need, and a loop counter or read-only integer is checked against the 1e15 limit once when the loop is entered instead of at every use. spectral-norm at N=5,500 takes 2.39 s of CPU time, from 3.04 s; Node.js takes 2.76 s.
- **Memoized functions in compiled code**: the compiled cache probe of a memoized function covers one to four numeric arguments, recursive functions such as `ackermann` and `tak`, and calls in `return f(...)` position. A cache hit is 64.3 times faster than on perl5 with CPAN *Memoize* for `fib`, 51.1 times for a two-argument `dist` and 64.2 times for `ackermann(2, $k)`. Deep memoized recursion stays compiled where the recursion warning is off, to a depth sized from the C stack that is actually left. A memoized function whose argument is a string no longer warns `Argument "..." isn't numeric`.
- **Nested loops** compile as one unit in more shapes: a `foreach` over an array or an array reference (`for (@a)`, `for my $x (@$ref)`) inside a compiled loop keeps its state in registers, as do inner loops under a `do {} while` loop, inside one branch of an `if`, or three levels deep. Whether a nest is worth compiling is judged by the work of all its trips, not by its outer body alone. fannkuch-redux at n=12 runs 25.1% fewer instructions.
- **Recursive subroutines** compiled by the JIT no longer fall back to the interpreter beyond 90 levels: they recurse in compiled code as deep as the C stack allows and issue perl's "Deep recursion" warning at level 100 themselves, naming the line perl names. Where a `__WARN__` handler, a fatal warning or a tied `STDERR` could see the call frames, the call is run again interpreted.
- **Subroutines that update outer variables**: a loop that calls a short subroutine writing a variable of an enclosing scope or a package variable, such as `sub add { my ($d) = @_; $acc += $d; 0 }`, compiles together with the call. The writes are made when the call returns, after every check, so a call that has to run again interpreted never writes twice.
- **JIT compile time**: a loop the JIT would reject after compiling it is rejected before its machine code is generated. Short runs gain most: mandelbrot at size 120 runs 11.5% fewer instructions and spectral-norm at N=500 8.1% fewer.

- **Regular expressions**: ReJIT compiles a pattern anchored at the start of the string, such as `/^bankrupt[a-z]+/`, once its interpreted matches have cost as much as a compile, instead of as soon as the subject is long. Such a pattern matched 500 times against a 71 KB string runs 3.52M instructions instead of 5.31M.
- **Number flags after compiled loops**: a compiled loop that copies integers (`my $t = $p[$i]`, `@p[$i, $j] = @p[$j, $i]`) leaves them integers instead of floating-point numbers, and `--` of an integral float keeps it a float. The values were right before; the flags, visible through `Devel::Peek`, were not.
- **Compiled loops** no longer give wrong answers in these cases: `@c = ($c[0] + 1, $c[1])` died with "Can't coerce ARRAY to integer in foreach loop iterator"; `$a[$i] += 1` past the largest integer wrapped to a negative number; `defined(wantarray)` was true in void context; and a second loop over the same non-`my` variable, `for $i (-3 .. -1)` after `for $i (0 .. 3)`, read the first loop's counter. A loop whose computed bound is NaN dies with "Range iterator outside integer range" instead of aborting pperl, and an array a compiled loop iterates is no longer kept alive past its scope, which had stopped a blessed array's `DESTROY` from running.
- **Compiled subroutines** no longer lose an update to an array element, as in `sub bump { my $i = shift; $acc[$i % 4] += $i; $i }`, or an assignment whose operator writes straight into a lexical, as in `$t = sin($i)`.
- **Warnings from compiled loops**: under `use warnings`, `$x--` from -1e20 in a compiled loop warns "Lost precision when decrementing" on every iteration as perl does, where it warned 65 times in 50,000; the same holds for `++` and for array and hash elements. A warning raised in a loop's condition names the line perl 5.44 names.

6.7.3 Modules

- ***Coro*** 6.57 runs, with *Coro::State* native and the distribution's own Perl modules; its 20 upstream test files pass on the assembler and the `setjmp` context-switch backends alike. Hot loops inside a coroutine compile, because the JIT now compiles on a stack of its own instead of the coroutine's 128 KiB one. Coro is part of builds with the `native-max` feature. Two cases in which perl5 crashes - a Coro::State call on a blessed hash that is not a coroutine, and the `:cede` layer without an interval - croak or fall back to the default interval instead.
- ***EV*** **and Event**: EV 4.37 with libev 4.33 and Event 1.28 are native, with *Coro::EV* and *Coro::Event* on top, in `native-max` builds; EV's 11 upstream test files pass. With EV present, *AnyEvent* picks it as its event loop, as on a perl5 that has EV installed. `EV::Periodic`'s `reschedule_cb` keeps its callback alive, where perl5 frees it after the first call of the getter.
- ***AnyEvent*** **and** ***Guard***: AnyEvent 7.17 ships with pperl and Guard is native, both in default builds. `Guard::cancel` on a reference to a plain value croaks, where perl5 sometimes crashes.
- **Native modules**: each module that is XS on perl5 and native in pperl ships its distribution's own `.pm` unchanged, among them B, *POSIX*, Socket, *Storable*, *Encode*, IO, *Data::Dumper*, *Scalar::Util*, *List::Util*, *Time::HiRes*, *Fcntl*, *File::Glob*, *Clone* and *PadWalker*, and none of them is loaded from the host perl's library any more. The native part is installed when the `.pm` calls `XSLoader::load`,

as in perl5, so `ref \$Socket::{AF_INET}` is `GLOB` and `B::svref_2object(\&List::Util::sum)->FILE` is `ListUtil.c`. A module left out of a build fails with perl5's own "Can't locate ..." message.

- ***Peta::Dict*** is new: `tie my %h, 'Peta::Dict'` binds a hash to an open-addressed table in which an integer and its decimal string are one key and `"05"` is another, as in a Perl hash; on perl5 the same source runs on a pure-Perl Peta::Dict with identical output. A compiled loop reads and writes such a hash through an in-register probe of the table instead of a method call per access, and `$h{$k}++` increments an integer stored in the table in place. The result of a bitwise operator is stored as an integer, as in perl, so a key built with `<<`, `|` and `&` stays one. The Benchmarks Game's k-nucleotide, counting packed keys in a Peta::Dict, takes 42.86 s of CPU time at 25,000,000 with the in-place increment, from 51.05 s.
- ***Peta::WebGPU*** draws as well as computes: surfaces, render pipelines and render passes with vertex and index buffers, uniforms, depth buffers and face culling, into an *SDL2* window or into a texture whose pixels can be read back without a display. A vertex layout written as a list of formats, `['float32x3', 'float32x3']`, gets its offsets and stride computed, and enum names are WebGPU's own spellings. SDL2 windows report the window-system handles this needs through `$win->wm_info`.
- ***Encode***'s Perl half is upstream Encode 3.24's, and its encoding tables are generated at build time from the distribution's `.ucm` files, matching upstream's for all 103 encodings. `encode_utf8(undef)` returns undef and `encode_utf8(42)` returns `"42"`, where both returned an empty string, and Encode's functions have perl5's prototypes, so `encode_utf8 $a, "\n"` is no longer one call with two arguments.
- **Crashes in native modules**: error messages containing a `%` sign no longer crash the native modules that raised them. *Digest::SHA* no longer crashes on a foreign object or computes a wrong digest past 512 MiB of input, *Storable* no longer passes a class name to a string `eval`, and *GD* and *SDL2* no longer free an image twice or crash on surfaces.
- ***Memoize***: a memoized recursive function no longer crashes pperl at depth; without the JIT it segfaulted at 20,000 levels, where perl5 runs 500,000. A numeric function such as `eval_A` memoized before it was ever called no longer crashes pperl on its first call.
- ***PDL*** **operators**: `+=`, `-=`, `*=` and the other assignment operators modify an ndarray in place, so aliases and slices see the change, where they built a new ndarray; `PDL::mult($a, $b, $c, 0)` writes its result into `$c`. `.=` broadcasts over dimensions, keeps 64-bit values exact, wraps bytes as C does and refuses a read-only target. `xchg`, `transpose` and `dummy` return views that write through to their parent and keep its type, where they returned double-precision copies.
- ***PDL*** **exports and loading**: `use PDL` exports what upstream exports, each name from the sub-module that owns it - 228 names, where a hand-written list exported about 58 that perl5 does not and lacked about 122 that it does; `glue` and `topdl` are no longer exported. *PDL::Exporter* and *PDL::IO::Storable* ship with pperl instead of being loaded from the host perl. `use PDL; use PDL::Lite` under `-w` no longer warns that `main::pdl` was redefined, a regression of 0.6.18, and `\&PDL::Ufunc::sumover` is the same subroutine as `\&PDL::sumover`.
- ***PDL*** **broadcasting**: `broadcast`, `broadcast1`, `broadcast2` and `broadcastI` re-

order dimensions as upstream does instead of returning the same ndarray, and `unbroadcast` puts them back, where it used to drop trailing size-1 dimensions. A reduction given an output ndarray, `maximum($src, $out)`, writes into it, and PDL error messages no longer print garbage.

- ***PDL***: methods called on a result not yet computed, such as `isempty`, `copy` or `transpose` on `$a + $b`, no longer treat it as empty, and `dims` in scalar context returns the number of dimensions. `svd` and `ylinvals` work on slices, `tritosquare` fills the lower triangle, and `pctover`, `oddpctover`, `pct`, `oddpct` and `inner` compute as upstream, broadcasting and bad values included. Element reads and writes of 64-bit, unsigned and complex ndarrays no longer pass through a double.
- ***List::Util*** **and** ***Scalar::Util***: `sum`, `sum0` and `product` switch to floating point when an integer total would overflow, where `sum(IV_MAX, 1)` wrapped to a negative number, and they honour tied and overloaded arguments. Scalar::Util's `isvstring`, `openhandle` and `looks_like_number`, and List::Util's `pairs` and `mesh`, behave as upstream's own tests expect.
- ***Math::GMP*** functions called with a plain number as the first argument, such as `Math::GMP::bsqrt(16)` or `stringify(42)`, return the answer instead of crashing, and every function checks its argument count as perl5's does. `2 ** Math::GMP->new(3)` is 8, not 9.
- ***File::Glob***: under `-T`, every name returned by `glob`, `<*.c>`, `bsd_glob` and `csh_glob` is tainted, as in perl5; all of them came back untainted.
- ***GD***: `copyRotate90`, `copyRotate180`, `copyRotate270`, the `copyFlip` methods, `crop`, `contrast` and `smooth` work as in the GD distribution.
- ***Cwd***: `fast_abs_path` follows Cwd.pm, so for an empty string or a symbolic-link loop it returns undef with `$!` set to ENOENT.

6.7.4 Command line

- **The debugger** starts with `pperl -d`, `-de0` and `-d:Module` as with perl5, where `-d` was accepted and ignored and the other forms were rejected. The default *Term::ReadLine::Gnu* front end no longer aborts at the first prompt, and a piped debugger session matches perl 5.44's byte for byte.
- **Command-line switches**: `-T` and `-t` combine with other switches (`-Tw`), `-W` and `-X` are perl5's and take effect in command-line order, and `-s` is perl5's switch parsing again; pperl's own statistics are `--stats` only. A program given with `-e` no longer gains an empty last line, so a warning at its end names line 1, as in perl5.

6.7.5 Documentation

- **Translations**: the guides, tutorials and errata, and the module reference pages, were brought to complete translation in all 41 languages, except the pages held for rewrite. Shipped translations were reviewed in every language, and wrong terms, headings and link labels left in English, double-encoded text and bold text that rendered as literal asterisks were repaired.
- ***Coroutines guide***: a new chapter of the concurrency guide, Coroutines and event loops, covers *Coro*, *EV*, Event and AnyEvent: starting and switching corou-

tines, channels, semaphores and signals, blocking I/O through *Coro::AnyEvent* and *Coro::Handle*, and how *AnyEvent* picks its loop. It is translated into all 41 languages.

- **Graphics guides**: the 2D guide has a new chapter on raster drawing with *GD*, and examples in its other chapters were corrected after running them. The 3D guide gains its GPU part on *Peta::WebGPU* - a device and window, the render pipeline, a 3D scene with depth buffer, culling, instancing and lighting - and two capstones, a modeller and a 3D game.
- **Corrections**: about 250 statements in the guides about what pperl supports were run against pperl and perl5, and the false ones corrected: the one-liner switches `-n`, `-p`, `-a`, `-F`, `-i` and `-l` work, threads are not available, and `-d` starts the debugger. Errors that translators reported in the regular-expression guide, the tutorials and the perlfunc pages were checked on perl 5.44 and fixed, among them the bound of `{n,m}` and the version that introduced `any` and `all`. The introduction's architecture diagram shows the runtime pperl has.
- **Module reference**: the module reference pages state what each function does, checked against perl 5.44, with the differences from upstream listed where there are any, and no longer carry implementation notes. Mistakes that translators reported were fixed, among them the precedence in the *Fcntl* `S_IS*` examples and the behaviour of *Hash::Util*'s `lock_hash`.

6.8 pperl 0.6.18

2026-09-10 to 2026-09-16, 78 commits.

- ***Memoize*** is native and no longer loaded from the host perl's library; its `Memoize::*` helper modules ship with pperl. `memoize`, `unmemoize` and `flush_cache` support `NORMALIZER`, `INSTALL` and the `MEMORY`, `HASH`, `TIE`, `FAULT` and `MERGE` caches, checked against the Memoize 1.17 distribution's own tests. A memoized function of one or two numeric arguments keeps its results in a cache that compiled code reads directly, and a loop calling it compiles: a memoized `fib(30)` called in a loop costs 43 instructions per call, against 2858 on perl5 with Memoize and 1682 on pperl without the JIT.
- **Foreach loops** over an array or an array reference (`for my $e (@$table)`) compile when nested in another compiled loop, and a `last` that leaves one compiles to a jump, also from inside an `if (...) { ...; last }` block. Appending an array element to a string (`$line .= $e->[0]`, `$s .= $a[$i]`) compiles too. fasta, whose character-selection loop combines all three, runs 49.3% fewer instructions at 250,000.
- **Integer array loops**: a compiled loop that copies scalars and swaps or stores elements of an integer array (`@p[$i,$j] = @p[$j,$i]`, `$p[$k] = $k`) keeps both integers and runs without leaving compiled code. fannkuch-redux at n=9, whose flip loop has this shape, runs 38.6% fewer instructions.
- **Loop unrolling**: the JIT compiles a `for` loop over a constant range of at most eight iterations, such as `for my $i (0 .. 4)`, as straight-line copies of its body, and does the same for a loop nested in it whose bounds become constant in each copy, such as `for my $j ($i + 1 .. 4)`. nbody's pair loop becomes ten independent chains of `sqrt` and division, and nbody at 50,000,000 steps runs 21.9% fewer instructions.

- **Substring counting**: a loop that counts substrings in a hash, `$h{substr($seq, $i, $k)}++`, compiles when the offset is a lexical loop variable (`for my $i (...)`) rather than `$_`. k-nucleotide at 250,000 runs 11.0% fewer instructions.
- ***SDBM_File*** blesses the tied object into the class `tie` was given, so a subclass works: after `tie %h, 'My::DBM', ...`, `ref tied %h` is `My::DBM`, not `SDBM_File`. `Memoize::AnyDBM_File` relies on this.
- ***PDL***: `nan` and `inf` build an ndarray of the dimensions they are given (`nan(4, 4)`) instead of ignoring their arguments; without arguments they still return a 0-dimensional value. `PDL::zeroes(4,4)` takes its first argument as the class and fails, as on perl5, while the `zeroes` and `zeros` that `use PDL` imports still take dimensions alone.

6.9 pperl 0.6.17

2026-09-06 to 2026-09-09, 96 commits.

6.9.1 Language and runtime

- **`__END__` in bundled modules** no longer opens a `DATA` handle. A module shipped inside pperl that ends in `__END__` followed by POD, `strict` and `warnings` among them, had a `DATA` handle reading that POD; as in perl5, only `__DATA__` gives a module a `DATA` handle.

6.9.2 JIT and parallelization

- **nbody**: the Benchmarks Game's nbody at 200,000 steps runs 293M instructions, from 2,778M. At its official 50,000,000 steps it runs 47.65G instructions in 6.36 s of CPU time, where Node.js takes 49.66G and 6.0 s. Besides the call and array work below, compiled loops keep floating-point values in registers instead of reloading them from memory, check a loop's constant bound once instead of on every iteration, and skip checks that cannot fail, such as overflow on `$j + 1` of a loop counter and the domain test on `sqrt` of a sum of squares. Placing the arrays' buffers so that loads and stores to different arrays no longer stall the processor cut nbody's CPU cycles by 18%.
- **Calls to subroutines that loop**: a compiled loop that calls a subroutine with loops of its own, such as nbody's `advance()`, now compiles together with the called body, where before each call left compiled code and entered it again twice. The subroutine's `my` variables are held in registers, and its call frame is pushed and popped inside compiled code. `$_[0]` in a subroutine called from one place with a numeric literal argument reads the literal directly.
- **Arrays of numbers** whose elements are all floating-point numbers, or all integers, when a compiled loop starts are read and written as flat memory, without a type check per element. For the loop's duration such an array's values are kept in a buffer and written back when the loop is left, and an index that is a loop counter is checked against the array's size once, at the loop's start. On nbody the buffer alone saves 15.3% of the instructions.
- **Calls to small numeric subroutines** no longer leave compiled code: a loop calling a function such as `eval_A` in the Benchmarks Game's spectral-norm, a `use inte-`

ger body that reads `$_[0]` and `$_[1]` directly, passes the arguments in registers, and the function's own `my` variables are registers too. spectral-norm at N=500 runs 440.0M instructions, from 776.5M, and at its official N=5,500 takes 3.25 s of CPU time, from 5.33 s.

- **Nested `while` and C-style `for` loops** inside a compiled loop compile as part of it, and an unlabelled `last` or `next` out of them is a jump. The Benchmarks Game's fannkuch-redux at n=9 runs 30.7% fewer instructions (6,650M to 4,609M).
- **Number types after compiled loops** match perl5's. `$v = $i * 0.5` and `sqrt(4)` stay floating-point numbers even when the result is integral, an integer literal or a `use integer` result stays an integer, and an integer variable such as `$t = ($i <=> 250)` no longer carries a floating-point copy perl5 would not have. The values were right before; the flags, visible through `Devel::Peek`, were not.
- **Loops left half-compiled by 0.6.16** compile fully again: a loop whose variables are all assigned before they are read (`$t = ($i <=> 250)`), one that updates a package variable (`$G = $G + 1`), and one whose counter was used as a float during its first iterations (`sin($i)`). They had fallen back to a slower, checked mode; for the package-variable loop that was 2.2 times the instructions.
- **JIT compile time**: a subroutine the JIT would compile and then reject as a numeric function is rejected before machine code is generated. nbody's fixed compile cost falls from 157M to 107M instructions, and the Benchmarks Game's mandelbrot at size 120, a run that is mostly compilation, executes 9.5% fewer instructions.

6.9.3 Modules

- ***Peta::WebGPU*** is new: GPU compute on the wgpu library, in builds with the `webgpu` feature. `Peta::WebGPU::Device->new` opens a device with the adapter's own limits, compiles WGSL shaders, creates storage and uniform buffers and pipelines, and runs compute passes; `have_gpu()` and `adapters()` report what the machine has. A shader or validation error is a Perl exception with wgpu's message, and a method with no natural result returns its object, so `or die` works and calls chain. A *PDL* ndarray uploads to a buffer directly (`$gpu->storage_buffer(float(1 .. 8))`); a double-typed one is refused with the conversion to use, since WGSL has only 32-bit numbers.
- ***SDL2***: 25 object methods that die on failure, among them `clear`, `copy`, `draw_line`, `fill_rect`, `present`, the `save_*` methods and every `set_*`, returned nothing on success, so `$ren->clear or die` died when it worked. They now return a true value, the object where there is no natural result, and calls chain: `$ren->set_draw_color(30, 30, 40, 255)->clear`. The direct `SDL_*` functions still return what the C functions do.
- **Loading modules under `-w`** prints no warnings perl5 does not print. `use POSIX ()`, and with it `use Imager`, printed 27: constant subroutines shared with *Fcntl* reported as redefined, and two "Ambiguous call resolved as CORE::open()". `use PDL; use PDL::MatrixOps` printed 48 redefinitions, `use PDL::Lite; use PDL` 532 and `use PDL::LiteF; use PDL` 631, because PDL's sub-modules were loaded twice.
- ***PDL*** **printing** follows upstream PDL's rules. Elements print as perl prints numbers, so `pdl(1.0) - pdl(0.88096)` shows `0.11904`, not `0.11904000000000003`; `$PDL::doubleformat` and `$PDL::floatformat` exist and take effect, and

`$PDL::toolongtoprint` is honoured. A 3-D ndarray prints as nested blocks instead of one flat list, `PDL->null` as `Null`, an empty ndarray as `Empty[0]`, and a 2-D ndarray ends with its newline.

- ***PDL***: append on a slice no longer aborts pperl and `glue` no longer fails with "Not physical but doesn't have parent"; neither needs `->sever` first. `-=`, `+=`, `*=`, `/=`, `**=` and `%=` on an ndarray no longer warn "Use of uninitialized value in subroutine entry". `pdl('BAD')` is a 0-dimensional ndarray, `pdl('[[5]]')` stays 2-dimensional, and `norm` normalises a vector as upstream's does instead of dividing the whole ndarray by its Frobenius norm. `use PDL ()` no longer defines `main::pdl`.

6.9.4 Documentation

- **Module reference**: the *Imager* and *GD* pages include documentation that was written but never published: Imager's colour classes, its kinds of image and the channel mask, and `GD::Image` and `GD::Font`.
- **Graphics guides**: the 2D graphics guide is fully translated again in all 41 languages after its move to *SDL2*. The 3D guide's chapter on opening a window with an OpenGL context is withdrawn, since pperl's GPU binding is *Peta::WebGPU*, and the guides' examples save their images with `$ren->save_png`.

6.10 pperl 0.6.16

2026-08-29 to 2026-09-06, 134 commits.

6.10.1 JIT and parallelization

- **Regular expressions** are compiled to machine code once a pattern has searched 64 KiB of text. The compiler covers literals, character and *POSIX* classes, alternations, captures, greedy and non-greedy quantifiers, `\b` and `\B`, and case-insensitive matching under `/aa`; a pattern it cannot compile runs on the regular engine and, once refused, costs next to nothing per match. It is on by default, and `--no-jit` turns it off together with the JIT for Perl code. Its results matched perl5's on all 29 files of PCRE2's regression test corpus.
- **Regex search**: a compiled pattern finds candidate start positions 16 bytes at a time, testing up to three of its leading characters at once, also when it starts with an alternation, a character class or a case-insensitive literal. An anchored pattern is tried only where it can match. The Benchmarks Game's regex-redux at 250,000 runs in 1.74 billion instructions, against 9.80 billion in 0.6.15.
- **Numeric loops** keep their variables in machine registers also when the loop body reads and writes array elements, and their intermediate results no longer pass through Perl values; each array is checked once when the loop is entered instead of at every statement. The Benchmarks Game's nbody at 200,000 steps runs 35.8% fewer instructions, and the Benchmarks Game's mandelbrot 14.1% fewer at size 400 and 7.7% fewer at size 120.
- **Nested counted loops**: a `for` loop over a range nested in a compiled loop, such as `for my $j ($i + 1 .. $n)`, with a lexical loop variable or without one, no longer pushes a Perl loop context on every pass. Its counter lives in a register, and

the context is built only if control leaves compiled code while the loop is open. nbody runs another 34.8% fewer instructions, 2.80 billion against 4.29 billion.

- **Compound assignment** to array and hash elements compiles: `$a[$i] += $x`, `-=` and `*=` no longer keep their whole loop from compiling, and nbody, which updates its velocities this way, runs 18.25% fewer instructions. `|=`, `&=`, `^=`, `<<=` and `>>=` compile on scalar variables, and `||=`, `&&=` and `//=` on lexical and package scalars.
- **Hash elements** with a constant or lexical key, `$h{$k}` and `$h{'name'}` on a lexical hash, compile in a loop both as values and as assignment targets, as in `$sum += $h{$k}` or `$h{$k} += 1`; before, only a computed key compiled. Appending one to a string, `$s .= $h{'name'}`, compiles too.
- **Package variables** no longer keep a loop from compiling when they are incremented or assigned: `$count++` and `$total = $total + $x` on a package variable compile, as does assigning a package variable or a conditional expression to an array or hash element.
- **Increments in expressions**: `++` and `--` on an array or hash element compile when their result is used, as in `my $old = $a[$i]++`, and so do `$x = $g++` on a package variable and `($c ? $x : $y)++`.
- **Many lexical variables**: loops in a sub or file with many lexical variables compile as they do in small ones. Variables and temporaries beyond the 64th of their sub or file were never kept in registers, and some statements using them, such as `$t{"k$i"} += 1`, kept their loop from compiling.
- **Short loops** that cannot repay the cost of compiling them stay interpreted: a counted `for` loop is compiled only once it has run, or its bounds show it will run, enough iterations for its size, counted across all its runs. Loops that call a sub, and `while` loops, compile as before. Short programs whose loops ran a few hundred times used 4 to 8 times the instructions they need with `--no-jit`.
- **Subroutine calls with computed arguments** in a compiled loop, such as `f($i, $i + 1, $i + 2)`, are compiled into the loop again; in 0.6.15 such a loop ran no faster than without the JIT. A loop making a three-argument call runs a 15.6th of the instructions, and every Benchmarks Game program measured ran fewer as well.
- **Numeric subroutine calls** from a compiled loop pass their arguments in registers when the sub takes two numbers through `my ($a, $b) = @_` or reads `$_[0]` and `$_[1]` directly. A loop calling a sub that reads `$_[0]` directly could crash or die with “Modification of a read-only value”; it now gives perl5’s results.
- **Conditional assignments** such as `my $v = $c ? 1 : $i / 7;` followed by arithmetic on `$v` give perl5’s result in a compiled loop. If only the integer branch had run when the loop was compiled, the fraction was later read as an integer, and the sum was wrong but plausible.
- **Element stores** in a compiled loop keep a value’s string: with `$x` holding `"0.0"` after a numeric read, `$a[$i] = $x` stored `0` and now stores `"0.0"`, as perl5 does. The same applied to hash elements and to slice assignments.
- **Crashes in compiled loops**: some nested loops, among them an inner `for (1 .. $n)` whose body never reads `$_`, ended in a segmentation fault in compiled code. They now run as on perl5.

6.10.2 Modules

- ***SDL2*** is a new native binding to libSDL2: windows, renderers, textures, OpenGL contexts, events and timers, both as SDL's own C functions one for one and as objects (`SDL2::Window`, `SDL2::Renderer`, `SDL2::Texture`, `SDL2::GLContext`) that free their handles when they go out of scope. `SDL2::Surface`, `SDL2::Image` and `$renderer->save_png`, `save_jpg` and `save_bmp` load and save images, and `$renderer->set_target($texture)` draws into a texture. Its 709 constants are taken from the installed SDL2 headers, not typed in.
- ***GD*** loads: `use GD` reaches the system's libgd through a native binding, and GD's own Perl modules, including `GD::Polygon`, `GD::Polyline` and `GD::Simple`, run unchanged on top of it. Images can be drawn, compared and written as PNG and JPEG. `$im->clone` after `filledPolygon` returns a correct copy, where perl5's GD crashes on a libgd defect.
- ***Imager*** loads, as a first part: images of all four kinds can be created, described, and have their pixels written and read back, with `Imager.pm` and its Perl modules running unchanged. Drawing, file formats, transforms, filters and fonts are not yet available.
- ***Peta::PCRE2*** is a new native module that binds the system's libpcre2-8: `new`, `match`, `count`, `substitute`, `capture_count`, `jit`, `version` and `jit_available`, and 12 `PCRE2_*` constants. Without libpcre2 installed, its functions croak.
- ***Cairo*** without libcairo installed croaks with the name of the package to install on every call; before, the second call hung.

6.10.3 Command line

- **`--no-regex-jit`** turns off the regex compiler and leaves the JIT for Perl code running; `PPERL_RXJIT=0` does the same from the environment, and `--help` describes both. `PPERL_RXJIT_STATS=1` reports for each pattern whether it was compiled or refused, and why.

6.10.4 Distribution

- **Profile-guided builds** of the release binary now train on programs that exercise the JIT and the regex compiler; before, those parts were barely run during training and were optimised for size. On the first build with the extended training, every Benchmarks Game program measured ran fewer instructions, the Benchmarks Game's revcomp 6.2% fewer.

6.10.5 Documentation

- ***3D graphics guide***: a new guide with chapters on the mathematical foundations, a software rasteriser, shading, meshes, model formats (OBJ and STL readers and writers), modelling operations, scene graphs, and opening a window with an OpenGL context through *SDL2*. Every example was run, and the outputs shown are what pperl printed.
- ***2D graphics guide***: the GUI chapter and both capstone projects, a paint program and a game, are rewritten on the native *SDL2* binding and run on pperl. The chap-

ters on `Peta::FFI` now cover callbacks and its memory primitives, which they had called out of reach.

- **Module reference**: 49 new pages, among them `Peta::PCRE2`, 18 for *Cairo* and 14 for *PDL*, and the catalogues of all 41 translation languages were updated to match.

6.11 pperl 0.6.15

2026-08-21 to 2026-08-29, 125 commits.

6.11.1 JIT and parallelization

- **The previous JIT engine is removed.** It had been off by default and was chosen with `PPERL_JIT2=0`; that setting now runs pperl without a JIT, and the engine that was already the default is the only one. `--jit-stats` no longer prints the old engine's counters, which were always zero, and reports how many compiled regions were installed and how many loops were tracked.
- **List assignments in compiled loops** keep all their elements. `@w = ($i, "$str$i")` in a compiled loop assigned only the string, and `@out = ($c ? $x : $y, $i)` in a rarely taken branch of a compiled loop lost its first element.
- **Compiled loops** give perl5's results in three more cases. A sub call that is the last statement of a sub could lose its return value when compiled into a loop; `$x = chr($n)` into a tied variable did not call the tie's `STORE`; and `pop(@$r) + $#$r` in one statement read the array's last index from before the `pop`.
- **Calls to two-argument subs**: a sub that reads `$_[0]` and `$_[1]` directly and keeps a `my` variable, as `eval_A` in the Benchmarks Game's spectral-norm does, is compiled and called from the compiled loop that uses it, where before the loop made a regular Perl call. spectral-norm at N=500 runs 11.7% fewer instructions.
- **Long-running loops**: a counted `for` loop that averages at least 256 iterations each time it is entered is compiled a second time. The new version checks the types of the loop's floating-point variables and arrays in a first iteration, then runs the remaining iterations in a copy of the body without those checks and with the loop counter in a register; a loop that leaves this copy too often goes back to the first version. spectral-norm at N=500 runs 17.9% fewer instructions from this, and with the previous entry's change 792.4 million in all, against 1,099.9 million before.
- **Array slices and element stores**: swapping two elements with a slice, `@p[$i, $j] = @p[$j, $i]`, and storing into an element, `$p[$j] = $p[$j + 1]` or `$count[$k]++`, compile in a loop over a lexical array. The Benchmarks Game's fannkuch-redux at n=9 runs 22.5% fewer instructions from the slice alone. It needed more instructions than perl5 before; now perl5 needs 1.12 times as many.
- **Compound assignment to array elements**, such as `$vxs[$i] -= $dx * $mm2`, no longer keeps a loop from compiling: the element is fetched by the interpreter and the arithmetic around it is compiled. The Benchmarks Game's nbody at 200,000 steps runs 8.61 billion instructions instead of 13.46 billion. It needed more instructions than perl5 before; now perl5 needs 1.31 times as many.
- **Counted loops without a loop variable**, such as `for (1 .. 50)`, keep their counter in a register, and a compiled loop updates less interpreter bookkeeping at

each statement, while `die` and `warn` still report the right line. Further specialised versions of a loop are compiled only once the loop has run long enough to repay them. The Benchmarks Game's mandelbrot at its official size of 16,000 runs 25.8% fewer instructions, 1,541 billion against 2,077 billion.

- **Compiled loops that keep falling back** to the interpreter are noticed in every case and handed back to it; before, a loop could take its slow path on 99,936 of 100,000 iterations indefinitely. A loop whose called sub is redefined is compiled again instead of staying interpreted for the rest of the run.
- **`$#array` and `$#_`** compile inside a loop, as `$#$ref` already did; before, either kept the statement using it from compiling.

6.11.2 Modules

- ***List::Util***: `first`, `any`, `all`, none and `notall` with a block, and `reduce`, run their block as compiled code when the list has at least 64 elements. Against perl5 with its own List::Util, `first` is 1.61 times as fast, `any`, `all` and none 1.88 to 1.90 times and `reduce` 1.10 times, where before they ran at 0.82 to 0.86 times perl5's speed. `min` and `max` return the element itself, call overloaded `>` and tied values' `FETCH`, and compare numbers above 2**53 as perl5 does.

6.12 pperl 0.6.14

2026-08-18 to 2026-08-21, 45 commits.

- **Recursive subroutines** compile to machine code. A subroutine that takes one argument (`$_[0]`, `my ($n) = @_` or `shift`), returns a number and calls itself, such as `fib` or `check_tree` in the Benchmarks Game's binary-trees, runs compiled, its recursive calls included. Its body may branch, return through `return EXPR` or a conditional expression, and test `ref $_[0]`; a loop that calls it calls the compiled code directly.
- **binary-trees**: a call whose argument is another call, as in `$check += check_tree(bottomup_tree($d))`, reaches the compiled `check_tree` while `bottomup_tree` still runs in the interpreter. At depth 16 binary-trees takes 2.76 s instead of 4.07 s, 1.5 times as fast as perl5, where it ran at parity before.
- **Subroutine calls in compiled loops**: a loop that calls an ordinary subroutine, one with a real `@_` that may write package variables, compiles together with the called body, with the call frame perl5 would build. Arguments may be computed expressions such as `tally($i % 97)`, the sub's return value can be used, and several call sites of one sub in a loop all compile. A sub that was redefined or re-aliased, a call resolved through `AUTOLOAD`, and a call into a sub that is already running take the regular call path.
- **Subroutine call overhead** in compiled loops is lower: compiled code sets up and removes the sub's frame itself, without pushing the argument mark or the sub onto the stack. Temporary arguments are not copied when the sub cannot alias or capture them, and a scalar return value is not copied when the sub has nothing to clean up on return. A loop calling `sub tally { $SUM += $_[0]; $CNT += 1 }` two million times runs 1.84 times as fast as on perl5, and a loop adding up the return value of a sub without `my` variables 1.74 times as fast.

- **`wantarray` and `caller`** compile in a sub called from a compiled loop when they are used as a truth value, as in `wantarray ? 2 : 1` or `run() unless caller`.
- **Array references in compiled loops**: `$m[$i][$j]`, `$_[0][0]`, `$x->[$i]`, `$$y[$i]`, `$#$x`, pop `@$x` and slices such as `my ($a, $b, $c) = @$x[-3..-1]` compile, as do `unshift` and blocks that open their own scope. Negative indexes such as `$x->[-1]` no longer leave compiled code on every iteration. In the Benchmarks Game's pidigits, the inner loop of *Math::BigInt::Calc*'s arithmetic now compiles in full.
- **`push` in compiled loops**: `$n = push @a, $x;` assigns the array's new length on every iteration. `$n` kept the value it had when the loop was compiled, so after 200,000 pushes it read 64.

6.13 pperl 0.6.13

2026-08-15 to 2026-08-18, 35 commits.

6.13.1 JIT and parallelization

- **Element increments** compile: `$h{$key}++` and `$a[$i]--` in a loop no longer keep it from compiling, also when the hash key is a computed string, as in `$h{substr($seq, $i, $k)}++`. The first increment of a new element creates it as an integer, as perl5 does. The Benchmarks Game's k-nucleotide at its official input runs in 74.1 s instead of 99.2 s, 1.30 times as fast as perl5.
- **`@_` element reads** compile: `$_[$j]` and `$_[0]` inside a sub no longer keep its loops from compiling. The Benchmarks Game's spectral-norm, whose inner loops read `$_[$j]`, compiles them and at N=5,500 runs in 17.8 s instead of 61.8 s; perl5 takes 64.6 s.
- **Inlined subroutines**: a loop that calls a short sub by name, one without branches or recursion that takes its arguments through `my (...) = @_`, `my $x = shift` or `$_[k]`, compiles with the sub's body in place of the call. A sub that only reads a lexical of its file, such as `sub f { $g }`, is inlined too, and redefining an inlined sub takes effect as on perl5. A loop calling a three-argument sub runs 18.1 times as fast as on perl5, and one using the return value of a two-argument sub 17.7 times.
- **Loops that call subroutines** compile when the calls are the only part of the loop the JIT cannot compile: the calls run in the interpreter between stretches of compiled code, and hot loops inside the called sub still run compiled. A `die`, a `last` that leaves the sub, and recursion behave as on perl5.
- **`use integer`**: integer addition, subtraction, multiplication, division and modulus, the six numeric comparisons and the shift operators compile under the pragma, with perl5's wrapping integer results; before, they were left to the interpreter. Benchmark loops under `use integer` run 3.7 to 4.4 times as fast as on perl5.
- **Foreach over arrays**: `for my $x (@a)` and `for my $x (@$ref)` compile, where only loops over a range did before; reversed and indexed forms stay in the interpreter. A benchmark loop over an array runs 4.94 times as fast as on perl5, against 0.74 times before.

- **Lexical array reads** with a variable or constant index, `$a[$j]` and `$a[3]`, compile in a loop, also inside an inlined sub reading an array of its file.

6.13.2 Modules

- ***Storable*** freezes faster: a benchmark freezing an array, which ran at 0.895 times perl5's speed, runs about 1.2 times as fast as perl5.
- ***Digest::MD5*** computes digests in 2.2% more cycles than perl5's Digest::MD5, down from 13.4% more.
- ***Math::GMP*** reads a tied or otherwise magical argument before converting it, as perl5 does, and `_gmp_lib_version` returns a v-string.

6.13.3 Documentation

- **Peta::FFI::Cairo reference**: its pages are translated into 41 languages, where their prose was untranslated before. They were corrected against the module, among them the description of reference counting, and `Context::get_matrix` and `get_font_matrix` are documented for the first time.
- **Command-line options page**: the page built from `pperl --help` lost every wrapped line of an option's description, 11 lines across `--cpan`, `--cpan --system`, `--via-daemon`, `--via-daemon=trunk` and `--interactive`, and did not list `--native-manifest=DIR` at all. It now shows the complete text.

6.14 pperl 0.6.12

2026-08-07 to 2026-08-14, 94 commits.

6.14.1 JIT and parallelization

- **The new JIT engine is the default.** The rebuilt JIT replaces the previous engine. It compiles the hot path of a loop to machine code and leaves the code around the loop, and the branches the loop rarely takes, to the interpreter. A loop whose compiled code keeps falling back to the interpreter is handed back to the interpreter entirely.
- **The previous JIT engine** remains available with `PPERL_JIT2=0`. It is still faster on loops whose bodies hold many statements: the Benchmarks Game's mandelbrot at size 16,000 takes 36.8 s on it and 204.7 s on the new engine. It is also the only one of the two that runs loops in parallel, so under the new default, auto-parallelization no longer applies to loops.
- **Arithmetic in compiled loops**: integer and floating-point `+`, `-`, `*`, `/`, `%` and `**`, the assignments `+=`, `-=`, `*=`, `/=` and `%=`, numeric comparisons including `<=>`, the bitwise and shift operators, `int`, `abs`, unary minus, `!`, `sqrt`, `sin`, `cos`, `exp`, `log`, `++` and `--` compile, on lexical and package variables. Integer values stay integers in compiled code, as they do in perl5. Benchmark loops of addition, multiplication, division and modulus run 4.27 to 5.06 times as fast as on perl5.
- **Strings in compiled loops**: `length`, `eq`, `ne`, `lt`, `gt`, `le`, `ge`, `cmp`, concatenation, interpolation, `.=`, `uc`, `lc`, `ucfirst`, scalar `reverse`, `ord`, `chr`, `substr` and `index`

compile, as do assignments of strings to variables. Loops that concatenate run 2.09 to 2.48 times as fast as on perl5, and loops using `substr` or `index` 2.90 and 2.99 times.

- **Arrays and hashes in compiled loops**: reading and assigning elements of lexical arrays and hashes, `$a[$i]`, `$a[3]` and `$h{$k}`, compiles, as do `push`, `pop` and list assignments such as `@a = (...)`, `%h = (...)`, `($x, $y) = ($y, $x)` and `my ($p, $q) = (...)`. A benchmark loop writing array elements runs 4.57 times as fast as on perl5, one reading them 3.10 times.
- **Conditionals in compiled loops**: `if`/`else` blocks, the conditional operator `?:`, `my` declarations and `defined` inside a loop body compile with the rest of the loop. A loop assigning a conditional expression runs 2.89 times as fast as on perl5.

6.14.2 Modules

- ***Encode*** encodes into the single-byte encodings, such as Latin-1, without searching a table for every character: a 1 KB string encodes at 5.8 times perl5's speed, where it ran at 0.69 times. Strings of 64 KiB and more are encoded on several cores unless `--no-parallel` is given.
- ***List::Util***: `sum`, `min`, `max` and `product` over 65,536 or more integers are computed on several cores unless `--no-parallel` is given.

6.14.3 Documentation

- **Module reference translations**: the pages of `B`, `IO`, `Data::Dumper`, `PerlIO::mmap` and `Time::HiRes` in all 41 translation languages follow their corrected English text. Changed descriptions read in English until they are translated again.

6.15 pperl 0.6.11

2026-08-05 to 2026-08-07, 21 commits.

- **JIT compilation** takes less time in the release binary, which no longer runs a consistency check over every piece of machine code the JIT generates. The check is kept in debug builds.
- ***File::Temp***: the documentation of `safe_level` describes what it does. `STANDARD`, `MEDIUM` and `HIGH` are all honoured, and a parent directory that fails the check is rejected with `Parent directory (...) is not safe`; the page still said that the setter had no effect and that higher levels were lowered to `STANDARD`.
- **Translations**: the description of `B`'s `children` method read as the description of `length` in 37 of the 41 languages and was empty in two; it is correct in all 41. The Estonian and French reference pages had translated argument placeholders such as `LENGTH` and `SCALAR` inside code, so the text explained arguments the English signature above it does not have; they match the signature again.

6.16 pperl 0.6.9

2026-07-28 to 2026-08-05, 211 commits.

6.16.1 Language and runtime

- **SIGPIPE** stops a program whose output pipe was closed, as on perl5: `pperl generate.pl | head` ran forever. pperl keeps the `SIGPIPE` disposition it was started with instead of ignoring the signal, so the exit status is 141, and `$SIG{PIPE}` handlers and `$SIG{PIPE} = 'IGNORE'` behave as on perl5.
- **`$0`**: assigning to it, as cpanm and Starman do to label their processes, no longer crashes pperl or writes into unrelated memory. The assignment changes the process's command line as `ps` and `/proc/self/cmdline` show it, also for names longer than the original command line, so Starman's renamed workers can be told apart.

6.16.2 JIT and parallelization

- **mandelbrot**: the Benchmarks Game's mandelbrot, with its thread pool replaced by a plain loop over scanlines and its kernel unchanged, now runs its kernel compiled; before, the kernel never compiled. At size 2000 it takes 0.62 s of CPU time on one core, against 4.96 s wall-clock and 19.7 s CPU time for the published four-thread entry on perl5.
- **Loops that now compile**: `for (LIST)` with the implicit `$_` compiles, as do `next LABEL` and `last LABEL` aimed at an enclosing compiled loop, and a `for` loop over an array nested in another compiled loop, which now compiles together with it. A loop body may begin with `my $x;` or `my ($a, $b);`, assign a list such as `my ($a, $b) = (0, 0)`, and append with `.=` to a variable declared without a value; each of these kept the loop from compiling.
- **Element updates**: the assignment operators `+=`, `-=`, `*=`, `/=`, `|=`, `&=`, `^=`, `<<=` and `>>=` and the operators `++` and `--` compile on array and hash elements and on elements reached through references, such as `$m[$i][$j] += $x`, also when the index is computed, as in `$a[$i + 1]` or `$a[$i % 2]`. `sqrt` compiles too.
- **Subroutines called from compiled loops** compile together with the loop also when they use arrays, hashes or strings, use package variables, or assign to a `my` variable they close over, as in `my $acc; sub add { $acc += $_[0] }`. Arguments read through `@_` or as `$_[0]` compile, also in a sub that never copies them, such as `sub f { $_[0] * $_[1] }`, and a call with literal arguments such as `f(3, 5)` no longer keeps its loop from compiling.
- **Wrong results in compiled loops**: a nested range loop whose body assigns its loop variable or whose lower bound is an expression, a sub assigning to `$_[0]`, and a sub adding to a variable it closes over could abort or give wrong results in compiled code. They now give perl5's results.

6.16.3 Modules

- ***Encode*** provides all 124 encodings of the upstream distribution, up from 21: the single-byte tables generated from the Unicode mapping data, UTF-16, UTF-32 and UCS-2, the 21 multi-byte CJK encodings, ISO-2022, gsm0338, hz, UTF-7 and the MIME encoded-word codecs. Each was checked against perl5's Encode, the CJK tables over every two-byte sequence. Names resolve through upstream's alias rules, so `windows-1252`, `latin2`, `sjis` or `macintosh` work without a perl5 installation, and `Encode->encodings` lists the loaded encodings until `":all"` is asked for.
- ***Encode*** **error handling**: the `CHECK` argument of `encode`, `decode` and `from_to` is honoured. `FB_CROAK` dies, `FB_PERLQQ`, `FB_HTMLCREF` and `FB_XMLCREF` substitute escapes, and `FB_QUIET` and `FB_WARN` return what was converted and leave the rest in the source variable, as on perl5; before, every mode behaved as the default. The UTF-16 and UTF-32 encodings report surrogates, noncharacters and partial characters with perl5's messages.
- **`:encoding` layers** no longer replace a character that straddles a read buffer boundary with U+FFFD; a 6 KiB file of three-byte characters lost characters at three places. `:encoding(UTF-16LE)`, `:encoding(koi8-r)` and the other new encodings work for reading and writing, `$PerlIO::encoding::fallback` is reset on the layer's first use as on perl5, and `require PerlIO::encoding` at run time no longer dies with "Out of memory during stack extend".
- ***Storable*** writes and reads perl5's format byte for byte: an image stored by perl5 retrieves on pperl and the other way round, and with `$Storable::canonical` both write identical bytes. Hooks (`STORABLE_freeze`, `STORABLE_thaw`, `STORABLE_attach`), code references, regexps, tied and restricted hashes, weak references and images written by Storable versions before 0.7 are handled, and the module's Perl half is upstream's `Storable.pm`. Storable's own test suite passes all 2,728 assertions it passes on perl5. Freezing a tied hash stored none of its keys; it now stores the tie object, as perl5 does.
- **Thawing untrusted data**: a *Storable* image whose class name was crafted Perl code ran that code when it was thawed; class methods are now looked up without compiling anything. A truncated image returns undef without setting `$@`, a corrupt one croaks with perl5's message, and an image that blesses a file name into `CGITempFile` warns as perl5 does (CVE-2015-1592).
- ***POSIX***: `use POSIX;` imports POSIX's default export list; it imported nothing, so `floor`, `INT_MAX` or `WIFEXITED` had to be fully qualified, and Test::TCP did not install. The functions perl5 implements in Perl, such as `POSIX::localtime` and `POSIX::stat`, exist, C-only names such as `POSIX::malloc` croak with perl5's advice, `use POSIX qw(locale_h)` works, and a call with the wrong number of arguments croaks with perl5's usage message where `POSIX::abort(1,2,3)` aborted and `POSIX::_exit(1,2,3)` exited. perl5's own POSIX test suite gives the same results on pperl, all 4,514 assertions.
- ***POSIX*** **time functions**: `POSIX::strftime` derives the weekday, the day of the year, daylight saving time and the UTC offset from the date instead of trusting optional arguments; called with six fields, `%a`, `%j`, `%V`, `%z` and `%Z` were wrong. POSIX::strftime::Compiler, which Plack and Starman depend on, now installs with `--cpan`. `strftime` no longer cuts its result at 1024 bytes, `asctime` accepts six arguments, `ctime` honours `$ENV{TZ}`, and `difftime` truncates its arguments to integers as perl5 does.

- ***POSIX* signals**: `POSIX::SigAction` and `POSIX::SigRt` exist, so `sigaction` works in its documented form, with a code reference as handler, a signal name such as `"INT"`, and the `SAFE` flag as perl5 reports it. `sigaction` given an array or scalar reference instead of a `POSIX::SigAction` crashed the interpreter, and one that croaked left signals blocked; both now behave as on perl5. `POSIX::SigSet` objects check their arguments, `addset(-1)` croaks, and can be subclassed.
- ***POSIX* constants**: the 16 terminal speed constants such as `B9600` had wrong values (13 instead of 9600), and `FP_NAN`, `FP_INFINITE`, `FP_ZERO` and `FP_NORMAL` were permuted, so `fpclassify(0.0)` returned 4 instead of 2. `ULONG_MAX` is exact, `MB_CUR_MAX` follows the locale, `FLT_ROUNDS` follows `fesetround`, and `ARG_MAX`, `LDBL_EPSILON`, `LDBL_MAX` and `LDBL_MIN` croak as on perl5 instead of returning approximations. POSIX gained 104 constants and re-exports Fcntl's record-locking constants `F_GETLK`, `F_SETLK` and `F_SETLKW`.
- ***POSIX* locale**: under a locale such as `de_DE.UTF-8`, `POSIX::strtod("3,5")` returns 3.5, `localeconv()` reports the locale's separators, and `setlocale(LC_ALL)` returns the locale's name, as on perl5. `localeconv` returns all 24 keys, with -1 for fields the locale leaves unspecified, and `mblen`, `mbtowc` and `wctomb` answer as perl5's do at the edges, `mblen("")` being 0.
- ***POSIX* arguments and results**: POSIX functions read arguments that come from a regex capture or a tied variable; `POSIX::floor($1)` returned 0. Functions perl5 declares as returning a system result, such as `sysconf`, `mkfifo` and `setuid`, give `undef` on failure and "0 but true" for zero, so `defined(mkfifo(...)) or die` works. `strtol` and `strtoul` accept the `0b` prefix, `strtoul` returns values above the signed range, `strtod` in scalar context returns the number, and the `POSIX::Termios` speed setters accept a baud rate.
- **DBD::SQLite** is a new driver over the system's libsqlite3. It passes 98 of the 103 test files of DBD::SQLite 1.78's own suite and supports user-defined functions, aggregates and collations, the commit, rollback, update and authorizer hooks, online backup, the catalogue methods and the fts3 Perl tokenizer. Values bind and fetch with the storage class and bytes upstream's driver gives them, strings with embedded NUL bytes included, and SQL that issues its own `BEGIN` works.
- **DBD::Pg** supports PostgreSQL arrays in both directions, `COPY` through `pg_putcopydata` and `pg_getcopydata` as well as `pg_putline` and `pg_getline`, savepoints, asynchronous queries (`pg_async`, `pg_ready`, `pg_result`, `pg_cancel`), `cancel`, `bind_param_inout` and `pg_enable_utf8`. It exports the `PG_*` type constants, where `use DBD::Pg ':pg_types'` died, and reports `PRECISION`, `SCALE`, `NULLABLE`, `ParamValues`, `ParamTypes`, `pg_lib_version` and the type names in `pg_type` as upstream's driver does.
- **DBD::Pg placeholders and quoting**: `quote` honours its type argument, so `quote(3.14, SQL_FLOAT)` is unquoted and an invalid float dies, and identifiers that are reserved words are quoted. A placeholder written `\?` stays a literal `?` operator, `:1` and binding by name (`bind_param('$1', ...)`) work, `pg_placeholder_dollaronly` and `pg_placeholder_nocolons` are honoured, and an array slice `arr[1:2]` is not taken for a placeholder. `do` without bind values sends the statement unchanged, statements such as `SET search_path TO ?` run with placeholders, and only `bytea` parameters are sent in binary form; an integer parameter beside a `bytea` one made the server reject the statement.
- **DBD::MariaDB** is a new driver over libmariadb, and DBD::mysql is now

a compatibility layer over it that keeps the `dbi:mysql:` names and the `mysql_*` attributes. Both gained asynchronous queries (`async => 1`, `mysql_async_ready`, `mysql_async_result`, `mysql_fd`), `table_info`, `column_info`, `primary_key_info`, `foreign_key_info` and `statistics_info`, the full `get_info` table, `ChopBlanks`, implicit reconnect and the numeric `mysql_serverversion` and `mysql_clientversion`. Placeholders inside comments and after `LIMIT` are handled as upstream's driver handles them.

- ***DBI***: with `InactiveDestroy` set, DBD::Pg and DBD::MariaDB leave the connection open when a handle is destroyed, so a forked child no longer closes its parent's connection. A true `Taint` attribute no longer croaks, `NAME_hash` is defined for a statement without columns, and the drivers' `$VERSION` strings use upstream's `_01` form instead of a `-pperl1` suffix that version checks could not parse.
- ***Peta::FFI***: `Peta::FFI::closure` turns a Perl code reference into a C function pointer that a C library can call, and `closure_free` releases it. A `die` in the Perl code does not unwind through the C caller.
- ***HTTP::Parser::XS*** is native, with the same results as the 0.17 module on 26,000 differential cases; it is the parser Plack, Starman and Twiggy use. On input where scanning dominates it is 6.0 times as fast as the module on perl5, and as fast on a typical ten-header request.
- ***Time::Piece***: `use Time::Piece` works, where it died with a dynamic-loading error. Time::Piece 1.41's Perl modules run on a native implementation of its compiled part, and the distribution's own 15 test files pass, 1,142 assertions.
- ***Term::ReadLine::Gnu*** provides all 160 functions of the 1.47 module's compiled part and runs the distribution's own `Gnu.pm`, embedded in pperl rather than taken from a perl5 installation. Perl callbacks such as `completion_entry_function` and those added with `add_defun` are called; before, they were stored and ignored.
- **`glob`**: the built-in `glob` and `<*.c>` use *File::Glob*, as on perl5, instead of starting a shell for every call. Results no longer depend on the locale's collation order, `$File::Glob::DEFAULT_FLAGS` is honoured, and 200 globs take about 10 ms instead of 520 ms. File::Glob's constants have perl5's values, `bsd_glob` sorts names differing only in case as perl5 does, and `use File::Glob ':bsd_glob'` replaces `glob`.
- **Socket** has the 118 constants and seven functions it lacked, among them `pack_ip_mreq` and its relatives, without which joining a multicast group was impossible, and `sockaddr_un`. `unpack_sockaddr_un` validates its argument, the deprecated `AI_IDN_*` and `NI_IDN_*` constants croak as on perl5, and the `:crlf` tag exports `$CR`, `$LF` and `$CRLF`.
- ***Fcntl*** has the record-locking constants `F_GETLK`, `F_SETLK`, `F_SETLKW`, `F_RDLCK`, `F_WRLCK` and `F_UNLCK`, and 48 more. A plain `use Fcntl` exports upstream's 68 names, `:Fcompat` and `:mode` hold the right names, `S_ENFMT` and `S_ISTXT` are absent as on perl5 on Linux, and the `S_IS*` functions return perl5's true and false values.
- ***File::Temp***: `unlink0` compares the file handle with the path before deleting, so a file swapped in after creation is no longer removed, and the `MEDIUM` and `HIGH` safety levels are enforced instead of being treated as `STANDARD`. A File::Temp object keeps its file name and unlink flag in its glob, so `${*$fh}` gives the name, and `File::Temp::cleanup()` no longer deletes the file of an object that is still alive.

- **Imports from native modules**: overwriting a sub imported from a native module, as *Net::Ping* does with Socket's `SO_BINDTODEVICE`, freed the module's own sub and could crash the program later; imports now hold a reference, as on perl5. Import lists accept `/pattern/` entries (`use POSIX qw(/^S_I/)`) and variables, and twelve native modules, among them Socket, *Cwd* and *Scalar::Util*, report perl 5.44's module versions, so `use Socket 2.041` works.
- **B** has every method perl5's B has, among them the `B::REGEXP` methods *B::Deparse* needs for a sub that uses a regexp, and `B::COP::label`, without which deparsed code lost its loop labels. `B::OP->size` returns the op's size in bytes instead of its class number, `B::hash` and `B::cstring` give perl5's results, and four list-returning methods such as `B::AV::ARRAY` no longer write past the stack and corrupt memory. B's own test suite passes 535 of the 539 assertions it passes on perl5.
- **mro**: an `@ISA` chain deeper than 100 classes no longer dies with "Recursive inheritance detected"; linearisations are cached as in perl5, and every depth measured, up to 500, behaves as on perl5. The C3 "Inconsistent hierarchy" error carries perl5's merge trace, `mro::get_linear_isa($class, 'dfs')` honours its second argument and croaks on an unknown name, and a failing `next::method` names the method and the class.
- **Config**: `%Config` has the `extensions` and `static_ext` keys, listing the native modules the binary contains, and answers 174 of perl5's keys, up from 107. Test suites that check `$Config{extensions}` before running, as perl5's own do, no longer skip themselves, and `Config::config_re` matches as perl5's does.
- ***Devel::Peek***: `DumpProg` and `runops_debug` work, `use Devel::Peek ':opd=stP'` sets the debugging flags, and the module's exports and variables, such as `$D_flags` and `%EXPORT_TAGS`, match perl5's.
- ***IO::Handle***: `ungetc` accepts every code point perl5 accepts, including those above U+10FFFF, and treats negative and very large arguments as perl5 does; `setbuf` croaks only on output handles.
- ***Data::Dumper***, ***List::Util***, ***Time::HiRes***: `print Dumper($x)` printed its arguments before the dump, and `Time::HiRes::stat` in scalar context returned a wrong value; both behave as on perl5. `List::Util::shuffle` and `sample` follow `srand`, so `srand(42)` gives perl5's permutation; `shuffle` returned the same order on every call, and `sample` could return its count argument.
- **Other native modules**: `Cwd::fast_realpath` exists, `Hash::Util::hash_seed` returns the full 32-byte seed, and `Hash::Util::bucket_ratio` of an empty hash is 0. SDBM_File's methods called with too few arguments croak with a usage message instead of crashing, and `attributes::get` finds the handler of a glob aliased from another package.

6.16.4 Command line

- **Programs on standard input**: pperl reads the program from standard input the three ways perl5 does, `pperl < prog.pl`, `pperl - < prog.pl` and `pperl /dev/stdin < prog.pl`, with `$0` set as perl5 sets it. All three were refused.
- **`--cpan`**: `pperl --cpan MODULE...` runs cpanm under pperl, installing into the library tree pperl searches, and `--cpan --system` installs into `/usr/local/share/pperl`. When building a distribution's C part fails, it installs the pure-Perl

files, which many such distributions fall back to, and names each distribution it did this for; Params::Validate installs and runs this way. Modules installed into `~/.pperl` (or `$PPERL_HOME`) are found without setting `PPERL5LIB`.

- **Command-line switches**: `--` ends switch processing and is removed from the arguments, as on perl5; pperl listed it in its usage text but rejected it. Several `-e` or `-E` switches form one program, joined by newlines, where only the last one used to run, and the Makefiles *ExtUtils::MakeMaker* writes rely on both. With `-e`, a program argument that looks like a switch reaches `@ARGV`.
- **`-I` in option clusters**: `pperl -wIlib` is `-w` plus `-Ilib`, as on perl5; it died with "Unknown option: -I".

6.16.5 Documentation

- **Translations**: the catalogues of all 41 translation languages were brought up to date with the English pages for the first time since April, and the pages that had none, among them the CPAN tutorial, *HTTP::Parser::XS* and *Time::Piece*, are translated in every language. Slovak gained the complete perlfunc reference, and Hebrew and Greek the module reference, which raised them from 79.3% and 76.2% to 93.0% and 92.9%.
- **Translation fixes**: 665 translated headings in all 41 languages that begin with a number, a dash, # or >, among them the numbered headings of the licence page, were displayed in English and now appear translated. Links to the perlfunc categories carry the translated category name, about 9,500 labels, and the line "Fully compatible with upstream Perl 5.44." is translated again on the 217 perlfunc pages of 40 languages where it had fallen back to English.
- ***CPAN tutorial***: a new tutorial covers installing CPAN modules with `pperl --cpan`, the modules already built into pperl, how modules that need a C compiler are handled, and troubleshooting.
- **Module reference**: 14 module descriptions on the index pages that were cut off mid-sentence, among them *HTTP::Parser::XS*, are complete, and the pages for *IO::Handle*, *Time::HiRes*, *PerlIO::mmap* and *Data::Dumper* show descriptions instead of implementation notes. `List::Util::shuffle` has its own page.
- **perlfunc reference**: factual errors were corrected on the pages for `abs`, `semop`, `shmget`, `send`, `crypt`, `getnetbyaddr`, `getservbyport`, `qq` and `exists`; `shmget` now states that a key of 0 is `IPC_PRIVATE`.
- ***How-to page***: guides and tutorials are separate sections of cards, and the entry for programmers coming from other languages names every guide that exists, PHP, Ruby, Lua, sed, awk, shell and Tcl included.

6.17 pperl 0.6.8

2026-07-27 to 2026-07-28, 3 commits.

- **`--cpan`** installs pure-Perl CPAN distributions for pperl. Modules built into pperl count as installed at pperl's own version, not at the host perl's, so they are never rebuilt.

- ***ExtUtils::MakeMaker***: a distribution's `Makefile.PL` runs and writes the same Makefile as on perl5. `B::svref_2object(\$v)->MAGIC` died for lack of a `B::MAGIC` class, which stopped every `Makefile.PL`; `B::MAGIC` now exists with its accessors. `$Config{eunicefix}` is `:` as on perl5, so MakeMaker no longer executes the Makefile it has just written.
- **The daemon**: `pperl --via-daemon script.pl` runs the script from its cached compiled image, as `PPERL_DAEMON=2` does; the reduced mode that a bare `--via-daemon` used to select is now `--via-daemon=trunk`, and any other value is refused with the accepted forms. `--via-daemon=script` and `PPERL_DAEMON=2`, documented as the same request, kept separate caches, so a script run both ways was never served from its cached image again; they now share one.
- **Safe**: a subroutine signature inside a `Safe` compartment was denied, because `Opcode` took its op tags from the host perl's `Opcode.pm`, which lacks the signature ops of perl 5.44. The tag table is now part of pperl, and the host perl's `Opcode.pm` is no longer loaded.
- ***Encode***: an encoding alias registered at run time works with `encode` and `decode`, not only with `resolve_alias`.
- ***PDL***: slicing a slice no longer checks bounds against an unset shape, `sever` detaches an ndarray from its parent, and operations with a scalar on a `flowing` ndarray no longer leave empty results or crash.
- ***Daemon guide***: the chapter "Fast start-up: the daemon" gains a worked example (about 24 ms per cold run against about 4 ms from the cached image, on the machine it was written on), how to check whether a run was served, how to opt in from a shebang line or a shell function, a systemd user unit, and an exact description of `--daemon-idle`.

6.18 pperl 0.6.6

2026-07-26 to 2026-07-27, 12 commits.

6.18.1 Modules

- ***Compress::Raw::Zlib*** is native and uses the system's zlib, so `Compress::Zlib`, the pure-Perl `IO::Compress::Gzip` and `DBM_Filter::compress` work. Its version, `ZLIB_VERNUM`, compressed lengths, CRC-32 and Adler-32 checksums and status codes match perl5's. bzip2 is not covered.
- **Import lists**: `use` of a native module accepts Exporter's full grammar: `!name` and `!:tag` remove names, a list that begins with a removal starts from the default exports, and `:DEFAULT` is a tag. `use Compress::Raw::Zlib qw(!crc32 !adler32)`, as *IO::Compress* writes it, imported nothing and left the module unusable. Unknown names are reported together in one error, as *Exporter* does.
- ***Storable*** no longer warns "Attempt to free unreferenced scalar" when a stored structure refers to the same value more than once. Weak references come back from `thaw` and `dclone` as weak references, without the "panic: del_backref" error.
- ***PDL***: assigning through a slice, as in `$a->slice("1:3") .= pdl(10,20,30)`, works; it died with "dimension mismatch" or set the parent's elements to zero.

- **`use re`**: `use re 'taint'`, `use re 'eval'` and `use re '/aa'` take effect; they were silently ignored.
- ***POSIX***, **Socket and** ***Encode*** gain export tags: POSIX `:math_h`, Socket `:crlf`, `:addrinfo` and `:all`, Encode `:all`, `:default`, `:fallbacks` and `:fallback_all`. POSIX also has `strxfrm`.
- ***Devel::Peek***: `SvREFCNT($x)` works as documented; every call died with a usage message.
- ***Hash::Util***: `hash_traversal_mask` reads and sets a hash's traversal mask, and returns `undef` for a hash that has none, as on perl5; it always returned 0.

6.18.2 Command line

- **The daemon** can keep a compiled image of a script: `--via-daemon=script` or `PPERL_DAEMON=2` runs the script from it, so a repeated run skips compiling the script and the modules it loads as well as starting the interpreter. `--daemon-max-scripts=N` limits how many scripts are kept (100 by default; the least recently used goes first), and `--daemon-reset` drops one script's image, or with no path all of them, and exits.
- **`--interactive`**, in builds that offer it, says on standard error that it is not implemented and exits with status 2. It printed a banner and reported success without running anything.

6.18.3 Distribution

- **Benchmark suite**: pperl's benchmark suite ships as a separate archive with its documentation and runs outside a source tree. It finds pperl through `--pperl=PATH`, `$PPERL`, a `pperl` beside it or on the `PATH`, and `--display` shows saved results without a pperl binary.

6.19 pperl 0.6.5

2026-07-23 to 2026-07-26, 16 commits.

6.19.1 JIT and parallelization

- **`next` and `last` in compiled loops**: a `while` loop whose body uses `next`, such as the statement parser of DBD::mysql, crashed the JIT compiler and left the JIT disabled for the rest of the run; such loops now compile, as do `foreach` loops with `next`. A `last` inside `do {...} while` leaves the enclosing loop, as in perl, where the compiled code ended only the `do` block.

6.19.2 Modules

- **DBD::Pg and DBD::mysql** are part of pperl, written in Perl over PostgreSQL's libpq and the MySQL client library, so `DBI->connect("dbi:Pg:...")` and `dbi:mysql:` work with no driver to build. DBD::Pg takes `?`, `$1` and `:name` placeholders and binary `bytea` parameters (`{pg_type => 17}`) and reports the SQLSTATE;

DBD::mysql fetches binary data intact. Both are tested against live PostgreSQL and MariaDB servers.

- **DBD::Sybase** is included, written in Perl over FreeTDS's ct-lib: it connects by server name or by `host=` and `port=`, runs queries with ? placeholders and transactions, and reports errors through `err`, `errstr` and `state`. It has not yet been tested against a live server.
- ***Peta::FFI*** 0.02 passes C pointers as opaque values (signature type `o`, with `undef` as NULL) and reads, writes, allocates and frees C memory with `peek`, `peek_cstr`, `poke`, `alloc`, `free`, `pack_ptr` and `unpack_ptr`. That is enough to drive a C library such as SQLite from pure Perl.
- ***DBI***: in a pperl built without database support, `use DBI` stops with a message naming the missing capability instead of loading the host perl's DBI and failing inside *XSLoader*.
- **Magical arguments to native modules** are read correctly: `md5_hex($1)`, `sha1_hex(substr(...))`, `encode_base64(substr(...))` and `$md5->add(substr($d, $o, $n))` all processed an empty string.
- **Default imports**: `use Socket;` imports Socket's default list again, and *File::Path* no longer dies calling `getcwd`; eleven native modules had an `import` that did nothing. A native module's own `import` is no longer replaced by the generic one.
- ***Time::HiRes***: importing `stat`, `sleep` or `time` from Time::HiRes overrides the builtin only in the importing package, as on perl5. It overrode it for the whole program, which broke `stat(_)` everywhere else; *File::Copy* imports it, and `require CPAN` died with `Bareword "_" not allowed while "strict subs" in use`.
- ***File::Temp*** exports what perl5's does, with the `:POSIX`, `:mktemp` and `:seekable` tags and the `STANDARD`, `MEDIUM`, `HIGH` and `SEEK_*` constants, and its objects can `seek`. `tempfile()` without `DIR` creates the file in the current directory instead of dying, and a forked child that exits no longer removes the parent's temporary files.
- ***Storable*** keeps booleans: a boolean value (perl 5.36 and later) comes back from `freeze` and `thaw` or `dclone` as a boolean.
- ***Opcode*** is native, providing the operator masks that `Safe` compartments are built from.
- ***IPC::SysV*** is native: its constants, `ftok`, `shmat`, `shmdt`, `memread` and `memwrite`, and what the `stat` methods of *IPC::Msg*, *IPC::Semaphore* and *IPC::SharedMem* need.
- **Warnings when loading modules**: loading `re`, `mro`, `version`, `Encode`, `Math::GMP`, `Config`, `attributes` or `Time::HiRes` no longer warns that a subroutine was redefined, and `use Config`, `B`, `Storable` and `PerlIO::encoding` no longer cause "used only once: possible typo" warnings that perl5 does not give. `version` objects use perl's built-in implementation for all their methods, as on perl5, instead of a mix of two.
- ***Scalar::Util***: `readonly` returns the same value as on perl5, the flag word (such as 134283264) rather than 1. `readonly`, `tainted` and `dualvar` are faster; a benchmark of `readonly` went from 0.66 to about 0.95 times perl5's speed.
- **Config**: `$Config::VERSION` is set and equals `$]`, as on perl5, and the `d_pw*` keys that *User::pwent* requires are present, so `User::pwent` loads.

- ***POSIX***: `strtol` and `strtoul` with one argument use base 0 instead of warning `Argument "*main::strtol" isn't numeric`, and `POSIX::sprintf` no longer warns "Use of uninitialized value in subroutine entry".

6.19.3 Command line

- **The daemon**: `pperl --daemon` runs a background daemon that holds a ready interpreter (`--daemon=start`, `stop` and `status` manage it), and `pperl --via-daemon script.pl` or `PPERL_DAEMON=1` runs a script in a process forked from it, with the caller's standard streams and working directory. When no daemon answers, the script runs normally. `--build-id` prints the binary identity the daemon is keyed on. On its own this measured about 0.6 ms slower than a normal start, so it is opt-in.

6.19.4 Documentation

- **Translations**: the "*Graphics with Perl*" guide is translated into the remaining 31 languages and so into all 41. In the Arabic, Persian and Hebrew translations, 72 arrows that pointed the wrong way are corrected.
- ***Daemon guide***: a new chapter of the performance guide, "Fast start-up: the daemon", describes the daemon, in English and in all 41 translations.
- **perl 5.44 in the documentation**: the introduction, the page of differences from Perl 5, the coming-from guides, the errata and the perlfunc pages state compatibility with perl 5.44 instead of 5.42.
- **Getting started and errata**: Getting started lists `-E`, `-I` and `-V`, drops `--cache`, and describes the module search path as it behaves: `-I` works alongside `PERL5LIB` and `PPERL5LIB`. The errata page on identifier length gives perl 5.44's limit of 1019 bytes, which pperl matches, and withdraws the claim that pperl differs above 251 bytes.

6.20 pperl 0.6.3

2026-07-18 to 2026-07-23, 35 commits.

6.20.1 Language and runtime

- **Start-up**: pperl starts no worker threads until a loop first runs in parallel, so a program that never does starts none; creating them took about 1 ms of every start. In the benchmark suite's start-up rows pperl went from 1.277 to 1.136 times perl5's start-up time (geometric mean).

6.20.2 JIT and parallelization

- **Subroutines called from compiled loops** compile together with the loop when their body contains loops of its own (`while`, C-style `for`, ranges, nested loops) or reads a lexical variable of the enclosing scope, a closure.

- **Array references in compiled loops**: `for (@$A)`, `$A->[$i][$j]` and loop bounds such as `scalar(@$A)` compile, so matrix code written over arrays of arrays, such as a matrix difference or a matrix product's triple loop, compiles as one nest of loops.
- **Hashes in compiled loops**: hash elements with computed keys, such as `$h{$i & 1023}`, can be read and written in a compiled loop, and `%h = (key => value, ...)` with constant keys and numeric values compiles too.
- **Strings in compiled loops**: `substr`, `uc`, `lc`, `ucfirst`, `lcfirst` and `reverse` compile as parts of larger expressions, as in `length(substr($s, 0, $n))`, and so do string comparisons and concatenations of array elements. Loops whose condition is a pattern match without `/g` or a `length`, such as `while ($s =~ /x/)` or `while (length $s)`, compile.
- **Nested loops**: C-style `for (;;)` loops nested in other loops compile. Whether a loop is worth compiling is judged by the work of its body, inner loops included, so `for (0..10) { for (0..9999) {...} }` compiles although its outer loop runs only 11 times.
- **`do {...} while` and `do {...} until`** loops compile.
- **`map` and `grep`** statements of the form `@dst = map {...} @src` compile on their own, outside any loop, when the source array is large enough to repay the compilation.
- **More loops compile**: whether a loop compiled could depend on the code around it, for example on a preceding statement with a `?:` conditional; such loops now compile. So do loops that use the result of a comparison as a number, as in `$n += ($x > $y)` or `$a[$i == 0]`.
- **Parallel reductions over arrays**: a loop that adds up values read from arrays it does not write, such as `$sum += $a[$i]`, runs in parallel on several cores.
- **JIT compilation cost**: finding and compiling a program's loops takes less time. A program of 600 short loops ran in 0.371 s instead of 0.577 s, and the search for loops now grows with the size of the program rather than with its square.

6.20.3 Modules

- ***MIME::Base64***: `encode_base64` encodes inputs of 1 MiB and more on several cores, with output identical to the serial encoder; on 32 MiB it is 2.85 times as fast as perl5's MIME::Base64.
- ***Digest::SHA***: methods that return their object, such as `add`, kept an extra reference to it, so a Digest::SHA object was never freed.
- ***POSIX***: `POSIX::read` accepts a reference to its buffer as well as the buffer itself, as on perl5, and the data it reads is tainted under `-T`.
- ***PDL***: `lu_backsub` given its right-hand side as a plain Perl value no longer reads freed memory.

6.20.4 Command line

- **Version reporting**: `pperl -v` and `pperl -V` name perl 5.44 as the version pperl is compatible with, and `$Config{version}` is 5.44.99, matching `$^V`; all three said 5.42.0.

6.20.5 Documentation

- **Translations**: the "*Graphics with Perl*" guide is translated into German, French, Italian, Czech, Greek, Danish, Hebrew, Ukrainian, Croatian and Spanish.

6.21 pperl 0.6.2

2026-07-16 to 2026-07-18, 35 commits.

6.21.1 Language and runtime

- **Pragmas built into the binary**: `strict`, `warnings`, `feature`, `builtin`, `lib`, `0` and `DynaLoader` are part of the pperl binary, in the versions that match its interpreter, instead of being read from disk. pperl looked for its own `warnings.pm` next to the binary, and where it did not find it, `no warnings 'experimental::class'` could switch off the wrong warning.
- **`PPERL5LIB`** works like `PERL5LIB` for pperl alone and is searched before it. The trees `/usr/local/share/pperl/site_perl`, `/usr/share/pperl/site_perl` and `/usr/share/pperl/vendor_perl` are searched before the host perl's library trees, so a module can be installed for pperl without touching the trees perl5 uses. Neither can replace a module built into pperl.

6.21.2 JIT and parallelization

- **Grids in compiled loops**: reads and stores through nested array references, such as `$grid->[$y][$x]` and `$a[$i][$j]`, compile, at any depth from two to eight levels, and mix with plain array and hash elements in the same loop. A rectangular grid of numbers is copied into a flat buffer once when the loop starts. An output grid that the loop fills from an empty `[]` is built as perl5 builds it, with undefined rows and short rows left as they are. A Game of Life program runs 10.4 times as fast as with `--no-jit`.
- **Conditions and loop control in compiled loops**: `next`, and `next if` and `last if` with compound conditions such as `A || B`, `A && B` or `!$a && !$b`, compile inside loop bodies, as do `foreach` loops over integer ranges nested to any depth, the conditional operator `?:` used as a value, and `&&` and `||` over plain values.
- **Nested `for my` loops**: a `for my $j (...)` loop inside another `for my $i (...)` loop compiled nothing; such nests now compile. A matrix difference written as `$C[$i][$j] = $A->[$i][$j] - $B->[$i][$j]` over two nested loops, as in Math::Matrix, runs compiled.
- **Loops the JIT cannot speed up** no longer make a program slower than `--no-jit`. A loop whose compiled runs keep being abandoned, a loop of fewer than 64 iterations that is entered again and again, and a parallel attempt that keeps failing are

given up after a few tries instead of paying their set-up cost on every entry. Loops the JIT does speed up are unaffected.

- **Parallel grid loops**: a loop that reads one grid and writes each cell of another grid once runs on several cores, with the same output for any thread count. Input grids are shared between the threads instead of being copied for each of them, and the work is cut into fewer pieces when copying the output grid would cost more than the work. A grid map ran 1.51 times as fast on four threads as on one.
- **Parallelization threshold**: whether a loop runs in parallel depends on an estimate of its total work, its iterations times the measured cost of its body, instead of a fixed minimum number of iterations. A nested loop of 501 outer iterations runs in parallel, one of 101 stays sequential.
- **`blessed` in compiled loops**: a compiled loop calling *Scalar::Util*'s `blessed` leaked memory on every iteration until the system killed the process. 50 million calls used 12.7 GB; they now use 31.6 MB.

6.21.3 Modules

- **B**: `B::HV::ARRAY` and the `B::GV` methods `FORM`, `IO` and `CVGEN` exist, so code that walks a package's symbol table through B works.
- ***Digest::SHA***: `sha256`, `sha1` and `sha512` on short inputs run 1.9 to 3.0 times as fast as on perl5, where they ran at about half its speed, and the object interface 1.96 times as fast.
- ***MIME::Base64*** **and** ***MIME::QuotedPrint***: `MIME::Base64::encode` and `decode`, and `MIME::QuotedPrint::encode` and `decode`, exist as on perl5, as aliases that are not exported. Encoding or decoding a string with characters above 255 dies with "Wide character in subroutine entry", as on perl5.
- ***Storable***: `freeze` of an array runs at 1.05 times perl5's speed, where it ran at 0.52.
- ***Scalar::Util*** loads *List::Util*, as it does on perl5. Code that calls `List::Util::first { ... } @list` with only Scalar::Util loaded, as *DBD::File* does, died with "Can't call method first".

6.21.4 Command line

- **`-M` and `-m`** load a module before the program runs, as on perl5, with import arguments as in `-Mconstant=ANSWER,42`; pperl rejected both switches before. `pperl -MO=Deparse` prints the program back as source and `pperl -MO=Concise` prints its op tree.
- **`--threads`** accepts `phys` (all physical cores), `log` (all logical cores, hyperthreads included), `phys-N` and `log-N` (N fewer, at least one), `P%` of the logical cores, or a number, which is taken as given even beyond the number of cores. Without `--threads`, pperl uses all physical cores; it used all logical cores before.

6.21.5 Documentation

- **Differences from Perl 5**: the page is rewritten to list the deliberate differences that remain (no loading of compiled extensions, the module search path, no interpreter threads, Linux only, the version pperl reports) and the current known issues. Limitations that no longer exist are removed from it.

6.22 pperl 0.6.1

2026-07-16, 1 commit.

- **`@INC`** is built by probing the host's library trees in the Arch, Debian and Fedora layouts, instead of holding one distribution's fixed paths. A directory from `-I` or `PERL5LIB` that holds versioned subdirectories, as `local::lib` and Carton trees built by perl5 do, has them added, nearest perl version first; architecture subdirectories are never added. A module built into pperl is always loaded in preference to a `.pm` file of the same name on disk.
- **`-E`, `-V` and `-V:key`**: `-E` enables `say` and the other optional features, as on perl5; it ran as `-e` before. `-V` prints perl5's configuration summary with the real `@INC`, including the effect of `-I` and `PERL5LIB`, and `-V:key` prints one configuration value, as in `-V:archname`.
- ***Peta::XS*** is a new module that lets pure Perl read facts about a value, such as its reference count, and attach magic: Perl callbacks that run when a variable is read, written or freed, as Variable::Magic offers on perl5. A program asks for its capabilities by name at `use` time, and one pperl does not provide is refused at compile time.

6.23 pperl 0.6.0

2026-07-11 to 2026-07-15, 54 commits.

6.23.1 Language and runtime

- **The interpreter is faster**: with the JIT off, pperl averages 108.6 on the perlbench suite, where perl5 scores 100, up from 85. Every benchmark of the suite scores at least 84, and the `while` loop and sub call benchmarks run faster than on perl5.

6.23.2 JIT and parallelization

- **The JIT compiler and auto-parallelization** work in pperl's default runtime; in 0.5.6 they worked only under `--pp`. Numeric `for`, `while` and `until` loops, nested loops and `if`/`else` in loop bodies compile to machine code, with integer arithmetic checked for overflow and floating-point expressions evaluated in perl's order, so results are those of the interpreter. A sum over 100 million integers takes 0.14 s against perl5's 2.76 s, and a 1000x1000 Mandelbrot render 214 ms against 12.5 s.
- **Parallel loops**: a counting loop whose iterations only add to sums runs on several cores, with the result of a sequential run. A floating-point sum is split across cores only when every partial sum is exact; other floating-point sums run compiled on one core. Loops too short to pay for the threads stay sequential: 100,000 iterations

for a flat loop, 512 for one with a nested loop. The 1000x1000 Mandelbrot render takes 51 ms in parallel.

- **Strings in compiled loops**: concatenation and `.=`, `sprintf` with `%d` formats, `length`, `index` with a constant string, string comparisons, `uc`, `lc`, `ucfirst`, `lcfirst`, `chomp`, `reverse`, `x` and `substr` compile. A loop calling `index` with a constant string makes 253 million calls per second, perl5 26 million.
- **Arrays and hashes in compiled loops**: array elements with constant or computed indexes, `push`, `pop`, list assignment, `$#a`, `foreach` over an array or over the default `$_`, `while (@a)` and hash elements compile, as do `defined`, `ref` and `++` or `--` used as a value.
- **`map`, `grep`, `sort`, `join` and `split` in compiled loops**: `map` and `grep` blocks that compute a value, `sort { $a <=> $b }` and its descending form, `join` over an array and `split` on a literal pattern compile. `map` takes 0.13 and `grep` 0.17 of the time perl5 takes.
- **Subroutine calls in compiled loops**: calls to named subs compile with the loop, including subs that take their arguments with `shift` or a signature, declare `my` variables, return early, or call themselves or each other recursively. A signature sub with optional parameters compiles once per argument count, and a branch that calls `die`, `warn`, `croak` or `confess` no longer keeps a sub from compiling. A recursive sub such as `fib` compiles on its own as well: `fib(30)` takes 17 ms instead of 538 ms, and the "Deep recursion" warning comes at the same depth as on perl5.
- **Regular expressions in compiled loops**: matches, captures and substitutions with a constant replacement, `s/PAT/TEXT/` and `s/PAT/TEXT/g`, compile and run perl's regex engine, so `$&`, `$1` and `@-` are set as in the interpreter. Patterns with `(?{ })`, `m//g`, `s///e` and `s///r` stay interpreted.
- ***Scalar::Util* and *List::Util* in compiled loops**: `blessed`, `reftype`, `refaddr`, `weaken`, `unweaken`, `isweak`, `looks_like_number` and `readonly` from Scalar::Util and `sum`, `sum0`, `product`, `min` and `max` from List::Util can be called in a compiled loop.

6.23.3 Modules

- ***B::Deparse* and *B::Concise* work**: the `B` module was revised against perl5's, so `B::Deparse` turns code references back into source and `B::Concise` prints op trees. Deparsing interpolated strings and chained element access such as `$h->{a}{b}` works, where it died. `B::CV::XSUB` and `B::CV::XSUBANY` exist, and loading `B` no longer warns about a missing `B::OBJECT` package.
- ***Data::Dumper*** supports `Freezer` and `Toaster`, `Deparse`, `Sortkeys` with a code reference, `Purity` and `Deepcopy`, a `Seen` hash given by the caller, globs and regexps, with perl5's rules for quoting numbers. With `Sortkeys` under `use locale`, keys sort in the locale's collation order. It runs at about perl5's speed.
- ***XSLoader***: `XSLoader::load` succeeds for every module built into pperl, as for a statically linked module on perl5. A module that loads its compiled part in an `eval` and falls back to pure Perl on failure no longer takes the slower fallback: *Data::Dumper* did, and ran 2 to 5 times slower.
- ***List::Util***: `first`, `any` and the other functions that take a block call it as perl5 does, without a full sub call per element; `first` and `any` took 6 to 7 times perl5's time and

take 1.2 times. `uniq` keeps `undef` as `undef`, `uniqint` returns integers and honours an overloaded `int`, and `uniqnum` keeps integers above 2**53 apart.

- ***Sub::Util***: calling `set_subname` again and again on the same sub no longer gets slower with every call or leaks memory.
- ***Scalar::Util***: `blessed`, `refaddr`, `reftype`, `weaken`, `unweaken` and `isweak` are the `builtin::` functions, as in Scalar::Util on perl5.
- **Function prototypes**: the functions of *Time::HiRes*, *Scalar::Util*, *MIME::Base64* and *MIME::QuotedPrint* carry the prototypes perl5 gives them. With Time::HiRes's `time` imported, `time - $t0` subtracts instead of calling `time(-$t0)`.
- ***File::Spec***: the Unix functions that are XS on perl5 are native in pperl; `canonpath` runs at perl5's speed, where it took 12.8 times as long.

6.23.4 Command line

- **The `--pp` runtime is removed.** pperl has one runtime; `--pp` and the options only it supported, `--cache`, `--flush`, `--daemon`, `--client`, `--stop`, `--optree`, `--from-json`, `--trace`, `--timeout`, `--dump-optree` and `--compare-bytecode`, are gone. `-c` checks syntax with the parser that runs the program, so its messages and exit codes are perl5's; it used the other runtime's parser before.

6.23.5 Distribution

- **Static and cross-architecture builds**: pperl builds as a static x86-64 binary against musl, and as static AArch64 and RISC-V binaries with the JIT and auto-parallelization. Release binaries come with SHA-256 sums, and each must pass a smoke test, run under emulation for AArch64 and RISC-V.

6.23.6 Documentation

- **One runtime in the documentation**: the "Runtimes" page, the reference pages of the `--pp` runtime's modules in every language and every mention of `--pp` are removed, and the reference section is titled "Reference".
- ***JIT guide***: the architecture guide's JIT chapter is rewritten for the compiler of this release, covering what it compiles, how it keeps results exact and how to watch it work. The pages on writing fast pperl code, on measuring and on concurrent execution are brought in line with it.
- **Module reference**: the pages of *Devel::Peek*, *Hash::Util*, *List::Util*, *Math::GMP*, the *PDL* modules, *Peta::FFI*, *SDBM_File* and mro are expanded and corrected, and their code examples are highlighted as Perl.
- **Serbian translation**: links in ten perlfunc pages showed control characters instead of their labels; they are repaired, and the Serbian PDF builds.

6.24 pperl 0.5.6

2026-04-18 to 2026-07-08, 226 commits.

6.24.1 Language and runtime

- **Exit status**: pperl exits with the status the program ends with, wrapped to 8 bits as in perl5. It exited with 0 whatever the program did, so `exit 3` or an uncaught `die` reported success to the shell, and a parent's `$?` read 0 for such a child.
- **Taint mode**: `-T` turns on taint mode and `-t` its warn-only form, as in perl5; both switches were ignored, and `-t` switched on pperl's execution tracing, which is now `--trace`. *Scalar::Util*'s `tainted` reports whether a value is tainted, where it always returned false.
- **Experimental warnings**: `no warnings 'experimental::class'` silences the warnings that `class`, `field` and `method` raise, as in perl5; they were printed regardless.

6.24.2 Modules

- ***Cairo*** is native: `use Cairo` provides the interface of the CPAN Cairo module 1.109 over the system's libcairo, with no distribution to install and nothing to compile. Contexts, surfaces, patterns, matrices, fonts, regions and paths are covered, including the PNG, PDF, PostScript and SVG stream callbacks, MIME data, the tied `Cairo::Path` view and glyph arrays. `Cairo::FtFontFace->create` is not available, because it needs Font::FreeType.
- ***File::Map*** 0.71 is native: `map_file`, `map_handle`, `map_anonymous`, `sys_map`, `remap`, `protect`, `sync`, `advise` and `unmap` map files and anonymous memory into Perl strings.
- **Startup** no longer sets up every native module: a native module is set up when the program first loads it. Setting all of them up took about 8 ms on every run, loaded libgmp, libreadline and three other libraries, and left modules the program never asked for in `%INC`.
- ***PDL***: `matmult` no longer reads memory it has already freed, `interpol` takes its arguments in upstream's order, and `lgamma` in scalar context returns the logarithm instead of the sign. `at` on an empty or null ndarray croaks "Position out of range" instead of returning undef, and arithmetic between a float ndarray and a fractional number gives a double result, as upstream. `setvaltobad` and `setbadtonan` work, `inplace` included, where they croaked.
- ***PDL* input and output**: ndarrays can be stored and retrieved with *Storable* through *PDL::IO::Storable*, `dclone` included. PDL::IO::FlexRaw no longer dies with "Operation '!=': no method found", `mapfraw` maps a file into an ndarray through *File::Map*, and `hdr` creates an empty header hash on first use, as upstream.
- ***Storable***: `dclone` copies through an object's `STORABLE_freeze` and `STORABLE_thaw` hooks, as perl5's does, and an object frozen by a hook is thawed into a scalar or an array again, where it always came back as a hash.
- ***File::Glob***: `bsd_glob` and `csh_glob` no longer corrupt memory and crash when a pattern matches more than about 128 names. `bsd_glob` sorts case-insensitively by default, as in perl5, and loading File::Glob no longer warns that `import` was redefined or that `DEFAULT_FLAGS` was used only once.
- **Long result lists**: *List::Util*'s `zip`, `mesh` and `unpairs` and their variants, *Hash::Util*'s `legal_keys`, `hidden_keys`, `bucket_info` and `bucket_stats`, `re::regnames`,

Data::Dumper and PDL's `list` no longer corrupt memory when they return more than about 128 values.

- **Imported functions**: a function imported from a native module, such as *List::Util*'s `first` in `first { ... } @list`, no longer draws a "used only once: possible typo" warning.
- ***File::Temp***: files and directories created with `CLEANUP => 1` are removed when the program ends; every such program left an empty directory behind in the temporary directory.
- ***POSIX* and Socket**: `use POSIX ':sys_wait_h', ':errno_h'` and POSIX's other export tags import their names, where only importing the names one by one worked, and Socket exports `SOMAXCONN`.

6.24.3 Command line

- **One-liner switches**: `-n`, `-p`, `-a`, `-F`, `-l`, `-0` and `-i` work as in perl5, where pperl rejected them; `-l` and `-0` take an optional octal value and `-i` edits files in place. pperl's interactive shell, which `-i` used to start, is reached with `--interactive` only.

6.24.4 Documentation

- **Documentation site**: the documentation moved to a new site with a PDF edition, a language picker, a license page, a page of command-line options taken from `pperl --help`, a glossary and an index. Every page links to its Markdown source, in the reader's language on translated pages. The module reference pages were rewritten from implementation notes into descriptions for Perl programmers.
- **Language reference**: every built-in function has its own page, 234 in all, indexed alphabetically and by category. perlop, perlvar, perldata and perlsub are split into topic pages, such as the operator families and the groups of special variables, and perldiag (the diagnostics pperl emits), perllocale, perlsec and a page on `BEGIN`, `END` and the other phase blocks are new. An errata chapter records where perl's own documentation is wrong or stale.
- ***Guides and tutorials***: new guides cover regular expressions in twelve chapters, among them a comparison with PCRE2, *POSIX* and RE2 syntax, as well as object-oriented Perl, debugging, concurrent execution, performance, writing tie classes, pperl's architecture and Perl one-liners. New tutorials cover `pack` and `unpack`, I/O streams, references, Unicode with a collection of recipes, boolean logic and interprocess communication.
- ***Coming from other languages***: a new series teaches Perl by comparison with Python, PHP, Ruby, Lua, sed, awk, the shell and Tcl, with every Perl example run on pperl.
- ***Graphics guide***: "Graphics with Perl" covers 2D graphics in twelve chapters: raster and vector foundations and the classic drawing algorithms in plain Perl, the toolkits from *Imager*, *GD* and ImageMagick to *Cairo*, SVG, charts and GUI toolkits, binding a C library through *Peta::FFI* with Cairo as the example, and two Prima projects, a drawing program and a 2D game.

- **Translations**: the documentation is translated into 41 languages, among them German, French, Spanish, Chinese, Japanese, Russian, Arabic and Hebrew, and right-to-left languages are laid out right to left. perlop, perlvar, perldata, perlsub, perldiag and the "Coming from" series are translated completely in all 41; text not yet translated reads in English. The language picker shows how much of each language is translated.

APPENDIX

A

DISCLAIMER & BUG REPORTS

A.1 PetaPerl is not upstream Perl

PetaPerl is an independent, from-scratch Perl 5 runtime written in Rust. It is **not** a build of the CPAN reference perl interpreter. Many modules you are used to from CPAN - `PDL`, `Scalar::Util`, `Storable`, `POSIX`, and dozens more - ship with PetaPerl as **native Rust implementations** built into the interpreter. No XS, no C compiler required, no CPAN install step.

This has one consequence that matters to every user:

Important

Any bug, missing feature, or behavioral difference you observe when using a module name that exists on CPAN (`PDL::Ufunc`, `Scalar::Util`, `IO::File`, ...) while running under PetaPerl is **our bug, not upstream's.**

Do **not** file these issues against the upstream CPAN project. Upstream maintainers are volunteers working on a codebase that is not the one you are running.

A.2 Bug reports

PetaPerl is a **research preview under high-velocity change**. A public bug-reporting mechanism is not yet in place.

Note

What we ask you to do today:

- **Do not file issues against upstream CPAN projects** for behaviour you observe in pperl's native re-implementations. Upstream maintainers work on a different codebase and can't fix ours. This is the one message this page exists to deliver.
- **Hold on to your findings.** A minimal reproducing script, the output of `pperl -V`, and a short description of expected vs. actual behaviour are the three things any future tracker will ask for. Saving them now means less work later.
- **Check whether it's already known.** Every module page carries a *Differences from upstream* section listing deliberate divergences. If your observation matches a bullet there, it's not a bug - it's documented behaviour.

When a public tracker opens, this page will be updated with the submission URL.

A.3 Intent of compatibility

PetaPerl aims at ~100% behavioral compatibility with **Perl 5.44** and with the specific versions of the CPAN modules we ship (see `pperl -V`, `PPERL_MODS`). Where we diverge, we diverge deliberately and document it.

Older language forms (e.g. `use v5.18;` features that differed from later versions) are not a compatibility target. PetaPerl follows current upstream Perl, not historical upstream Perl.

A.4 Upstream's contributions

The CPAN modules whose names we carry represent years of work by volunteer maintainers who deserve credit for the interface design and original implementation even when our code shares no lines with theirs. We thank them, and we do not want their inboxes flooded with issues produced by a runtime they did not write. That is the single most important reason this page exists.

A.5 License

See the *License* page for the full terms of the PetaMem Research Preview License that governs your use of this Software.

APPENDIX

B

LICENSE

B.1 PetaMem Research Preview License

Copyright © 2026 PetaMem s.r.o. (IČ: 26512521), Prague, Czech Republic. All rights reserved.

B.1.1 1. Definitions

“Software” means pperl (PetaPerl), a Perl 5-compatible interpreter implemented in Rust, distributed in binary form under this License, including any accompanying documentation. “Licensor” means PetaMem s.r.o. “You” means the individual or entity exercising permissions granted by this License.

B.1.2 2. Grant

Subject to the terms below, Licensor grants You a worldwide, royalty-free, non-exclusive, non-transferable license to use, copy, run, benchmark, evaluate, and redistribute the Software in unmodified binary form, for any purpose, commercial or non-commercial, for so long as the Software’s version number is below 1.0.

B.1.3 3. Attribution and Non-Appropriation

You shall not represent the Software, in whole or in part, as Your own work, nor remove, obscure, or alter any copyright notices, version identifiers, author attributions, or license texts contained in or accompanying the Software. Any redistribution must preserve this License and all original notices intact.

B.1.4 4. Reverse Engineering

Reverse engineering, disassembly, and decompilation of the Software for the purposes of interoperability, security research, academic study, and personal curiosity are expressly permitted. Publication or redistribution of source code, derived source, or modified binaries obtained through such activity is not granted under this License and is prohibited.

B.1.5 5. Research Preview Status

The Software is a research preview. Its interfaces, behavior, file formats, performance characteristics, and licensing terms may change without notice in any subsequent release. This License applies only to the version of the Software with which it was distributed.

B.1.6 6. No Warranty

THE SOFTWARE IS PROVIDED “AS IS”, WITHOUT WARRANTY OF ANY KIND, EXPRESS OR IMPLIED, INCLUDING BUT NOT LIMITED TO THE WARRANTIES OF MERCHANTABILITY, FITNESS FOR A PARTICULAR PURPOSE, NON-INFRINGEMENT, AND ACCURACY. YOU ASSUME ALL RISK ARISING FROM YOUR USE OF THE SOFTWARE.

B.1.7 7. Limitation of Liability

TO THE MAXIMUM EXTENT PERMITTED BY APPLICABLE LAW, IN NO EVENT SHALL LICENSOR BE LIABLE FOR ANY DIRECT, INDIRECT, INCIDENTAL, SPECIAL, CONSEQUENTIAL, OR EXEMPLARY DAMAGES ARISING OUT OF OR IN CONNECTION WITH THE SOFTWARE OR THIS LICENSE, REGARDLESS OF THE LEGAL THEORY ASSERTED, EVEN IF ADVISED OF THE POSSIBILITY OF SUCH DAMAGES.

B.1.8 8. Termination

This License and all rights granted hereunder terminate automatically upon Your breach of any term. Upon the public release of version 1.0 or later of the Software, this License ceases to apply to subsequent versions, which will be governed by their own license terms.

B.1.9 9. Reservation of Rights

All rights not expressly granted are reserved by Licensor. No rights in source code, trademarks, patents, or trade secrets are conveyed by this License except as explicitly stated. “PetaMem”, “PetaPerl”, and “pperl” are used here as identifiers of the Software and its origin; no trademark license is granted.

B.1.10 10. Governing Law and Venue

This License shall be governed by and construed in accordance with the laws of the Czech Republic, without regard to conflict of law provisions. The exclusive venue for any dispute arising hereunder shall be the competent courts of Prague, Czech Republic.

APPENDIX

C

GLOSSARY

Terms, acronyms, and project-specific vocabulary.

pperl
: The PetaPerl runtime - a Rust reimplementation of Perl 5, binary name `pperl`. Reads the same Perl source code the stock `perl` interpreter does. A behavioural mirror of `perl5`: semantics, edge cases, magic. Where a test disagrees with upstream perl5, pperl is the one that's wrong. Adds a JIT and auto-parallelization on top.

SV
: Scalar Value. A Perl scalar as represented in pperl's runtime - the enum lives in `src/runtime/sv.rs` and mirrors `perl5`'s SV layout where the semantics depend on it.

JIT
: Just-In-Time compilation. pperl compiles hot loops to machine code via Cranelift; triggered automatically on eligible `for`/`while` bodies.

named unary operator
: A Perl built-in that takes **exactly one argument** at a specific precedence level - tighter than comparison operators, looser than the arithmetic and shift operators. Unlike a **list operator** (which greedily slurps the rest of the expression), a named unary takes its one argument and stops there. Examples: `defined`, `exists`, `ref`, `scalar`, `length`, `uc`/`lc`, `chr`/`ord`, `int`, `abs`, `sqrt`, `sin`/`cos`, `log`, `exp`, `-e`/`-r`/`-f`/... file tests. See `perlop` precedence row 10.

list operator
: A Perl built-in that takes a **list of arguments** and, at the right-hand side of the operator, greedily consumes the rest of the expression. Examples: `print`, `sort`, `push`, `unshift`, `join`, `split`. Contrast with **named unary operator**.

This is an initial seed. Terms referenced by `{term}` roles elsewhere in the docs should be added here when they appear.
