PetaPerl documentation

Experimental preview — draft documentation ***0.6.25***

PetaMem, s.r.o.

Oct 25, 2026

USER GUIDE

1 Introduction **3**
- 1.1 Goals . . . 3
- 1.2 Architecture Overview . . . 4
- 1.3 Quick Start . . . 5
- 1.4 Compatibility . . . 5
- 1.5 Platform Support . . . 5

2 Getting Started **7**
- 2.1 Installation . . . 7
- 2.2 First Script . . . 7
- 2.3 Command Line Options . . . 7
- 2.4 Notes . . . 7

3 CLI options **9**
- 3.1 Usage . . . 9
- 3.2 Perl-compatible options . . . 10
- 3.3 pperl-specific options . . . 10
- 3.4 Runtime options . . . 11
- 3.5 Regex JIT . . . 11
- 3.6 Module installation . . . 12
- 3.7 Daemon options . . . 12
- 3.8 Examples . . . 13
- 3.9 Module search paths: `-I`, `PERL5LIB`, `@INC` . . . 13
- 3.10 Environment variables . . . 14

4 How-To **15**
- 4.1 Guides . . . 15
- 4.2 Tutorials . . . 16
  - 4.2.1 PPerl Architecture . . . 16
    - JIT Compilation . . . 17
    - Auto-FFI (Peta::FFI) . . . 19
    - Native Modules . . . 29
    - Differences from Perl 5 . . . 32
  - 4.2.2 Concurrent Execution . . . 34
    - Parallel Execution . . . 34
    - Coroutines and event loops . . . 37
    - Threads . . . 41
  - 4.2.3 Regular expressions . . . 55
    - Who this is for . . . 56

How this guide is organised . . . 56
A first round-trip . . . 147
Conventions in the examples . . . 147
Related reference pages . . . 147
4.2.4 Performance . . . 148
Who this is for . . . 148
The one rule that survives everything . . . 148
How this guide is organised . . . 148
What this guide does not cover . . . 167
A note on numbers . . . 167
4.2.5 Object-oriented programming . . . 168
Which chapter you want . . . 168
When to use OO at all . . . 168
A note on scope . . . 169
4.2.6 Debugging Perl programs . . . 195
Which chapter do I want? . . . 196
The three layers of this guide . . . 196
Known gaps . . . 196
See also . . . 197
4.2.7 The Definitive Perl One-Liner Guide . . . 233
Which chapter do I want? . . . 233
The three layers of this guide . . . 233
Two examples before you start . . . 234
Read in this order on a first pass . . . 234
Bibliography . . . 234
4.2.8 Tying variables . . . 269
Which chapter you want . . . 270
How each chapter is built . . . 270
What ties cost . . . 270
Differences from upstream . . . 271
4.2.9 Coming from another language . . . 283
Which guide you want . . . 283
The one concept to read first . . . 284
A note on the runtime . . . 284
4.2.10 The Definitive Guide to 2D Graphics with Perl . . . 377
Which chapter do I want? . . . 378
The three arcs of this guide . . . 378
A note on the runtime . . . 378
Known gaps . . . 378
See also . . . 378
4.2.11 The Definitive Guide to 3D Graphics with Perl . . . 433
What this guide runs on . . . 434
Which chapter do I want? . . . 434
A note on the second dimension . . . 434
4.2.12 pack and unpack - a tutorial . . . 532
When you need pack and unpack . . . 532
How this tutorial is organised . . . 532
A first round-trip . . . 555
Conventions in the examples . . . 555
4.2.13 I/O streams - a tutorial . . . 555
What this chapter does not cover . . . 556

Where to go next . . . 556
Reference cross-links . . . 568
4.2.14 References - a tutorial . . . 568
Who this is for . . . 568
How this tutorial is organised . . . 568
Related reference pages . . . 587
4.2.15 Unicode - a tutorial . . . 587
The one idea . . . 587
The pipeline . . . 588
Chapters . . . 588
Conventions . . . 601
4.2.16 Boolean Logic for Perl Programmers - a tutorial . . . 601
Who this is for . . . 601
Scope . . . 601
How this tutorial is organised . . . 601
What you will be able to do after reading . . . 619
4.2.17 Interprocess communication - a tutorial . . . 620
Choosing a channel . . . 620
How this tutorial is organised . . . 620
What this tutorial does not cover . . . 634
4.2.18 Installing CPAN modules - a tutorial . . . 634
The one idea . . . 634
What you will need . . . 635
Chapters . . . 635
4.2.19 ipps, the interactive mode - a tutorial . . . 645
Starting it . . . 645
The one idea . . . 646
Chapters . . . 646

5 Reference **659**
5.1 Perl language . . . 659
5.1.1 Special variables . . . 659
Choose a family . . . 660
Variable namespaces . . . 697
The `English` module . . . 698
Localising special variables . . . 698
See also . . . 698
5.1.2 Built-in Functions . . . 699
A . . . 699
B . . . 699
C . . . 699
D . . . 700
E . . . 700
F . . . 701
G . . . 701
H . . . 702
I . . . 702
J . . . 702
K . . . 702
L . . . 703
M . . . 703

N . . . 703
O . . . 704
P . . . 704
Q . . . 704
R . . . 704
S . . . 705
T . . . 707
U . . . 707
V . . . 708
W . . . 708
Y . . . 708
__ (double-underscored) . . . 708
5.1.3 Operators . . . 1447
Choose a family . . . 1448
Cross-cutting concepts . . . 1485
See also . . . 1485
5.1.4 Data types . . . 1486
Choose a topic . . . 1486
Cross-cutting concepts . . . 1522
See also . . . 1523
5.1.5 Subroutines . . . 1523
Choose a topic . . . 1523
Defining a sub vs. calling a sub . . . 1559
The classic vs. modern split . . . 1560
See also . . . 1560
5.1.6 Locale handling . . . 1561
What a locale is . . . 1561
The `use locale` pragma . . . 1561
Locale categories . . . 1562
Setting the locale . . . 1562
Locale and Unicode . . . 1563
Locale leaks and safety . . . 1563
Parallel execution and locale . . . 1563
Environment variables . . . 1563
Differences from upstream . . . 1564
See also . . . 1564
5.1.7 Diagnostic messages . . . 1564
Reading an entry . . . 1565
Enabling and silencing warnings . . . 1565
A note on portability . . . 1565
The diagnostics . . . 1566
5.1.8 Security and taint mode . . . 1579
Taint mode . . . 1579
What gets tainted . . . 1580
Laundering and detecting tainted data . . . 1581
Cleaning up `%ENV` and `$ENV{PATH}` . . . 1581
Taint mode and `@INC` . . . 1582
Set-id scripts and the shebang race . . . 1582
Algorithmic complexity attacks . . . 1583
Differences from upstream . . . 1583
See also . . . 1583

5.2 Modules . . . 1584
5.2.1 AE . . . 1590
SYNOPSIS . . . 1590
DESCRIPTION . . . 1591

C Glossary **5527**

Index **5529**

A next-generation Perl 5 runtime written in Rust, with JIT and auto-parallelization. This documentation covers installation, usage, the built-in module reference, and the internals of the interpreter.

This is the **pperl 0.6.25** documentation, built . (translated ≈ words, %)

Getting started First steps: install pperl, run your first script, see what's different from system perl.

Getting Started How-To Task-oriented material. **Guides** are long-form and multi-chapter (regex, OO, debugging, concurrent execution, pperl architecture). **Tutorials** are single-sitting (pack, I/O streams, references, Unicode).

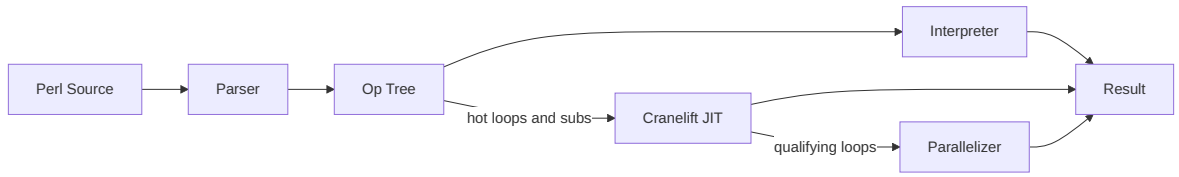
How-To Reference Per-module reference for every built-in module; Perl language reference (variables, functions, operators, regex); the changelog of every version.

Reference Index & glossary Alphabetical index of every documented module, function, and term; short glossary of project vocabulary.

genindex

CHAPTER

ONE



INTRODUCTION

pperl is a next-generation Perl 5 platform written in Rust, targeting Perl 5.44+ compatibility.

1.1 Goals

- **JIT Compilation** - Native code generation via Cranelift for hot loops and hot recursive subs, with byte-identical output to the interpreter
- **Auto-Parallelization** - Qualifying JIT-compiled `for` and `while` loops spread across CPU cores, only where the result is provably identical
- **Pure Perl Viability** - Fast enough that XS becomes optional

1.2 Architecture Overview

The parser and the interpreter follow perl5's own design: the same grammar, the same op tree, the same op-by-op execution. On top of that, the *JIT* compiles hot code to native machine code and declines whatever it cannot reproduce exactly, and the *parallelizer* spreads qualifying compiled loops across cores. Modules that perl5 implements in XS are built into pperl as *native modules*.

1.3 Quick Start

```
# Run a script
pperl script.pl

# Run one-liner
pperl -e 'print "Hello, World!\n"'

# Check syntax only
pperl -c script.pl
```

1.4 Compatibility

pperl aims for high compatibility with Perl 5.44+.

1.5 Platform Support

- **Linux only**, on the architectures Cranelift supports: x86-64, AArch64, RISC-V and IBM z/Architecture
- No Windows, macOS, or other platforms

CHAPTER

TWO

GETTING STARTED

2.1 Installation

Download binaries and find documentation at perl.petamem.com.

2.2 First Script

```
#!/usr/bin/env pperl
print "Hello from PetaPerl!\n";
```

2.3 Command Line Options

Option	Description
`-e 'code'`	Execute one-liner
`-E 'code'`	Like `-e`, with all optional features enabled (`say`, ...)
`-I dir`	Prepend `dir` to the module search path `@INC`
`-c`	Check syntax only
`-w`	Enable warnings
`-v`	Show version
`-V`	Show configuration, `%ENV` and `@INC`
`--no-jit`	Disable JIT compilation
`--no-parallel`	Disable auto-parallelization

See *CLI options* for the full option list.

2.4 Notes

- Defaults match perl: modern features (`say`, `state` and friends) are enabled by `use v5.44;` in scripts or `-E` for one-liners
- XS modules are not supported; native Rust reimplementations are provided for common modules
- Module search paths work as in perl: `-I` and the `PERL5LIB` environment variable are honored; `PPERL5LIB` additionally provides pperl-only paths (see *CLI options*)

CHAPTER

THREE

CLI OPTIONS

pperl accepts a small set of command-line flags. Most are `perl`-compatible; a handful are pperl-specific (JIT, parallelism). The authoritative list is whatever `pperl --help` prints; the tables below show those flags, extracted from the interpreter source and rendered here on every documentation build.

> **Note**
>
> The actual `pperl --help` output on the terminal is always in English - the binary does not localise help strings. Translated documentation shows the same flags with descriptions in the page's language so readers can study what each flag does; flag tokens (`-T`, `--threads=N`, ...) are always verbatim.

PetaPerl - Next-generation Perl 5 runtime

3.1 Usage

```
pperl [OPTIONS] [--] [SCRIPT [ARGS...]]
pperl -e 'code'
pperl -E 'code'
```

3.2 Perl-compatible options

Flag	Description
`-e 'code'`	Execute one-liner
`-E 'code'`	Like -e, but enable all optional features (say, ...)
`-Mmodule`	use module before executing (-MO=Deparse, -Mstrict)
`-mmodule`	use module () before executing (no imports)
`-Idirectory`	Prepend directory to @INC
`-c`	Check syntax only, don't execute
`-w`	Enable warnings
`-W`	Enable all warnings, even under 'no warnings'
`-X`	Disable all warnings, even under 'use warnings'
`-s`	Turn the program's -name[=value] arguments into variables
`-n`	Loop over input lines (no auto-print), like while(<>)
`-p`	Loop over input lines and auto-print, like a sed filter
`-a`	Autosplit each line into @F (with -n or -p)
`-F pattern`	Set the -a split pattern (implies -a)
`-l[octal]`	Auto-chomp input, set output record separator
`-0[octal]`	Set input record separator (-0 = NUL, -00 = paragraph)
`-i[ext]`	Edit files in place (optional backup extension)
`-T`	Taint mode (forced)
`-t`	Taint warnings
`-v`	Show version information
`-V`	Show configuration summary, %ENV and @INC
`-V:key`	Show the value of a Config key, e.g. -V:archname
`--shell [--norc]`	ipps, the interactive mode: type Perl, see the value, keep everything. Also entered by running pperl under the name ipps. –norc skips ~/.pperl/ipps/rc.pl
`-h, -?, --help`	Show this help message

3.3 pperl-specific options

Flag	Description
`--stats`	Show performance statistics (time, memory)

3.4 Runtime options

Flag	Description
`--no-jit`	Disable JIT compilation (on by default)
`--no-regex-jit`	Disable only the regex JIT, leaving the op JIT on
`--no-parallel`	Disable auto-parallelization (on by default)
`--threads=SPEC`	Parallel thread count. SPEC is one of:
`phys`	all physical cores (DEFAULT)
`log`	all logical cores (hyperthreads)
`phys-N`	physical minus N (min 1)
`log-N`	logical minus N (min 1)
`P%`	P percent of logical cores
`N`	an explicit count
`--parallel-thresh-old=N`	Minimum iterations to parallelize (default: 100)
`--jit-stats`	Print JIT summary to stderr at exit (see also PPERL_JIT_LOG)

3.5 Regex JIT

The regex JIT is separate from the op JIT and on by default. It compiles a pattern only after that pattern has matched against 64 KiB of subject, and only for the shapes it supports; anything else runs on the standard engine and is refused once, at pattern-compile time.

Flag	Description
`--no-r`	Disable the regex JIT, leaving the op JIT on. Costs nothing to leave on for workloads it helps, but a program whose patterns are ALL refused still pays a small per-match dispatch cost (~3%); turning it off removes that path completely. –no-jit disables it too, along with the op JIT.
`PPERL_`	The same switch as an environment variable, for wrapping a program you cannot pass flags to. PPERL_RXJIT=1 forces it ON even under –no-jit (a diagnostic, not a normal posture).
`PPERL_`	Report, per pattern, whether it was admitted, refused (with the reason) or compiled. Run this FIRST: it is what tells you whether a given workload is one of the ones worth disabling.

3.6 Module installation

Flag	Description
`--cp MODU ..`	Install CPAN distributions for pperl with the built-in CPAN client. Everything after this flag goes to it, as to the `cpan` command. Besides a module name it takes a git repository (URL ending in .git, optionally .git@REVISION), a directory (./DIR) or an archive file. Pure Perl only: pperl runs no XS. Modules built into the binary are reported as already installed, so they are never rebuilt.
`--cp --sy tem`	Install into the system overlay instead of the per-user tree ($PPERL_HOME, default ~/.pperl)

3.7 Daemon options

Flag	Description
`--dae- mon`	Run the fast-start daemon in the foreground
`--dae- mon=star`	Start the daemon in the background
`--dae- mon=stop`	Stop the running daemon for this binary
`--dae- mon=sta- tus`	Show daemon status and cached script templates
`--dae- mon-idle`	Daemon exits after SECS without a request (default: 900)
`--dae- mon-max-`	Cache at most N script templates (default: 100)
`--dae- mon-re- set`	Drop all cached script templates
`--dae- mon-re- set=FILE`	Drop the cached template for FILE only
`--via-da mon`	Route this run through the daemon. With a script file that means reusing its cached compiled image; the script itself stays a normal argument: pperl –via-daemon myscript.pl (PPERL_DAEMON=2 does the same without the flag)
`--via-da mon=trun`	Force the shared zygote: fork a ready interpreter but compile the script every run. For testing the daemon; it saves little. Same as PPERL_DAEMON=1
`--build-`	Print the binary identity that keys the daemon socket

3.8 Examples

```
pperl script.pl
```

Execute a Perl script

```
pperl -E 'say "Hello!"'
```

Execute a one-liner (-E enables say, state, etc.)

```
pperl -c script.pl
```

Check script syntax without executing

```
pperl script.pl arg1 arg2
```

Pass arguments to script (@ARGV)

For more information, see: https://perl.petamem.com/docs/eng/

Report bugs at: https://github.com/petamem/pperl-bugtracker/issues

3.9 Module search paths: -I, PERL5LIB, @INC

`-I dir` prepends `dir` to `@INC`, exactly like perl. Entries from `-I` and from the `PERL5LIB` environment variable (`PERLLIB` as the fallback; both ignored under taint mode) are additionally expanded: if the directory has versioned children (`5.44.99`, `5.40.0`, ...), those are added around the entry, nearest perl version first. This makes `local::lib`- and Carton-style trees built by a real perl work unmodified.

Two deliberate differences from perl:

- **No architecture subdirectories.** perl would also add `dir/5.44/x86_64-linux`-style children; pperl never does. It runs no compiled XS objects, so those directories hold nothing it could use, and skipping them avoids loading `.pm` wrappers that would die trying to bootstrap `.so` files.
- **Native modules win over every @INC entry.** Modules built into the pperl binary (see `PPERL_MODS` below) are served directly by `require`; a same-name `.pm` on disk is never loaded in front of them, no matter what `-I` says.

Two pperl-private search locations exist for parallel installations, so a module can be provided to pperl WITHOUT touching the shared perl trees:

- The `PPERL5LIB` environment variable: same syntax and expansion as `PERL5LIB`, honored immediately before it.
- The pperl overlay trees, probed before every host perl tree: `/usr/local/share/pperl/site_perl` (local overrides), `/usr/share/pperl/site_perl` and `/usr/share/pperl/vendor_perl` (packaged), each optionally with versioned children.

A `.pm` in either location outranks all host trees for pperl only - the host perl never looks there. Neither can outrank a module built into the binary.

The rest of `@INC` is built by probing the host's standard library trees (Arch, Debian and Fedora layouts) rather than baking one distribution's paths into the binary; `pperl -V`

prints the real result. Details and rationale: *differences from upstream* and the `@INC` reference in *program input*.

3.10 Environment variables

pperl sets several environment variables inside the process it runs, so scripts can introspect the running interpreter:

Variable	Meaning
`PPERL`	Version string (same as `pperl -v`)
`PPERL_FEATURES`	Comma-separated list of compiled-in Cargo features
`PPERL_MODS`	Comma-separated `Name/version` pairs for every native module
`PPERL_SHELL`	Shell integration flavor (no if `shell` feature off)
`PPERL_STATIC`	`yes` if the binary is musl-statically linked, else no

Run `pperl -V` to see all values for the current binary.

CHAPTER

FOUR

HOW-TO

Two kinds of task-oriented material live in this section. The distinction matters because it tells you how much time to put aside and what you'll walk away with.

Guides are long-form and multi-chapter. You read them the way you read a book - cover to cover, or chapter by chapter with each chapter building on the last. A guide covers a whole subject in depth. The regex guide, for instance, takes you from `m//` through Unicode properties and backtracking performance; the debugging guide covers everything from attaching `-d` to decoding production stack traces.

Tutorials are narrow and single-sitting. One tutorial, one topic, one specific question answered. You land on a tutorial with a task in mind and leave with it done. No larger arc, no required prior reading.

4.1 Guides

PPerl Architecture How pperl is built: the JIT, the FFI, native modules, and the concrete differences from upstream Perl 5.

PPerl Architecture Concurrent Execution Doing work in parallel: auto-parallelization, the ithreads reality, and how to choose between them.

Concurrent Execution Regular Expressions Perl regex from first principles through performance tuning.

Regular expressions Performance Making Perl run fast on pperl: measuring with the right tools, which classic idioms still pay off, and how to shape a loop so the JIT and parallelizer take it.

Performance Object-oriented Programming Modern `class`/`field`/`method` first, classical `bless` for maintainers, migration paths.

Object-oriented programming Debugging Finding and fixing bugs: the `-d` debugger, inspecting live state, production-path tools.

Debugging Perl programs One-Liners `pperl` at the shell: `-e`, implicit loops, progressive recipes, parameterised aliases, quoting gotchas.

The Definitive Perl One-Liner Guide Tying Variables Making a variable dispatch through a class: tied scalars, arrays, hashes, and filehandles, with a complete worked class for each.

Tying variables Coming from another language Perl by analogy for developers fluent in another language: each construct you already know mapped to its Perl coun-

terpart, with the gotcha the similarity hides. Python, PHP, Ruby, Lua, sed, awk, shell and Tcl.

Coming from another language 2D graphics Two-dimensional graphics in Perl, from the pixel up: the drawing algorithms, the raster and vector toolkits, reaching C libraries through pperl's native FFI, and two runnable capstones on SDL2 (a drawing app and a 2D game).

The Definitive Guide to 2D Graphics with Perl 3D graphics Three dimensions: the transform pipeline, meshes and model formats, a software rasteriser you write yourself, and the GPU through pperl's native `Peta::WebGPU` binding.

The Definitive Guide to 3D Graphics with Perl

4.2 Tutorials

Pack & Unpack Binary data layout: directives, endianness, network protocols, file formats.

pack and unpack - a tutorial Working with I/O Streams The full open story: modes, encoding layers, pipes, in-memory handles, error handling.

I/O streams - a tutorial Perl References Scalars, arrays, hashes, code, anonymous and weak references, nested structures.

References - a tutorial Unicode in Perl Text vs bytes, source encoding, PerlIO layers, Unicode regex, common pitfalls.

Unicode - a tutorial Boolean Logic for Perl Programmers Truthiness, all sixteen binary operators, De Morgan, NAND/NOR completeness, bitwise and regex applications.

Boolean Logic for Perl Programmers - a tutorial Interprocess Communication Runnable IPC cookbook: subprocesses, FIFOs, TCP and UDP sockets, socket pairs, System V semaphores and shared memory.

Interprocess communication - a tutorial Installing CPAN Modules `pperl --cpan`: where modules land, how pperl finds them, why the installer needs telling what pperl already has, and what the no-XS rule means in practice.

Installing CPAN modules - a tutorial The Interactive Mode `ipps`, the prompt that runs Perl: values as you would write them, variables that stay, Tab completion, commands to inspect, time and ask the JIT, and a start file for your own macros.

ipps, the interactive mode - a tutorial

4.2.1 PPerl Architecture

How pperl is built, what sets it apart from upstream Perl 5, and the subsystems a working programmer reaches for when they want more than "run this Perl script" - the JIT, the FFI, and the native-module layer.

This guide is descriptive, not a tutorial. Read it to understand *how* pperl does what it does and *why* certain things behave the way they do. Per-function behaviour lives in the *reference tree*.

JIT Compilation

pperl includes a JIT compiler built on Cranelift, the code generator used by Wasmtime. It compiles hot loops and hot recursive subs to native machine code, and hands qualifying loops to a parallelizer that spreads them across CPU cores. Both are automatic: no annotations, no pragmas, no configuration. Individual compiled shapes run 20x to 400x faster than perl5; across the whole project benchmark suite, including everything the JIT does not touch, pperl comes out about twice as fast.

Two properties define the design, and everything else follows from them:

1. **Exactness.** Compiled code produces byte-identical output to the interpreter, always. Not "close enough": the test harness compares pperl's output byte-for-byte against perl5 on every test, with the JIT and parallelizer on.
2. **Decline, never guess.** Anything the compiler cannot prove it can reproduce exactly, it declines. A declined loop runs on the interpreter at normal speed. There is no mode in which compiled code is "probably right".

What compiles

The compiler recognises whole constructs, not individual opcodes. As of mid-2026 the covered surface is:

- **Numeric loops**: `for` over integer ranges, `foreach` over one array, `while`/`until` including `while (@queue)` drain loops; nested loops; `if`/`else`, ternaries, `last`; integer and float arithmetic, comparisons, bitwise operations; `++`/`--` in both void and value positions.
- **Strings**: interpolation and concatenation, `sprintf` (`%d` forms), `length`, `index` with a constant needle, `uc`/`lc`, `chomp`, `reverse`, the `x` repeat, `substr` (read forms), string comparisons.
- **Arrays and hashes**: `$a[$i]` reads and writes, push/pop, list assignment, `scalar(@a)`, `$h{key}` reads and writes with constant or variable keys.
- **List functions**: `map` and `grep` with pure expression blocks, numeric `sort { $a <=> $b }` (and descending), `join` with a constant separator, `split` on a literal pattern.
- **Named sub calls**: calls to subs whose body is a `my (...) = @_;` prelude plus one pure numeric expression, including self-recursion. These compile as real native functions with register argument passing; a recursive call tree runs entirely in native code. Recursion compiles both inside loops and for a single top-level call like `fib(30)`.
- **Regex**: scalar `m//` matches (stored, branched, and capture-list forms) and `s/pat/replacement/` with a constant replacement, including `/g`. These run the real regex engine from compiled code, so `$&`, `$1`, `@-` and friends behave exactly as interpreted; what disappears is the per-operation interpreter dispatch around the engine.
- **Native-module calls**: the `Scalar::Util` operations that Perl compiles to single ops (`blessed`, `reftype`, `refaddr`, `weaken`, `unweaken`, `isweak`) compile directly; a curated set of pure XSUBs (`List::Util` `sum`/`sum0`/`min`/`max`/`product`,

`Scalar::Util` `looks_like_number` and `readonly`) runs from compiled loops as call-outs through the real `entersub`, with the callee re-verified at every loop entry.

The exactness machinery

The compiler attaches through Perl's own extension points: the peephole-optimizer hook discovers candidate loops after Perl's optimizer has finished, and the per-op function pointers of loop-entry and sub-call ops are redirected to trampolines. Everything below is driven from those trampolines.

Guards. At every loop entry the trampoline re-checks the world: variable types, magic and tie-ness, readonly-ness, aliasing between variables, whether a sub was redefined, whether `$/` still holds its default. Any mismatch means the interpreter runs this entry. After repeated failures the trampoline uninstalls itself and the loop costs nothing extra forever after.

Scratch state and abort/replay. Compiled code never writes anything observable until it completes. Scalars live in a private buffer; strings and arrays operate on scratch copies; hash writes are buffered. If anything leaves the provable domain mid-run (integer overflow where Perl would promote, a `substr` outside the string, a missing hash key, a pending signal, recursion depth at a cap), the run aborts: the scratch is discarded and the interpreter replays the whole loop from the start. Since nothing observable happened, the replay is exact, including any warnings Perl would have printed. Completion, by contrast, writes results back through Perl's own setter functions.

Two numeric modes. Loops compile in integer mode (checked 64-bit arithmetic; overflow aborts precisely where Perl promotes to a double) or float mode (IEEE doubles evaluated in Perl's own expression order, which is bit-exact with Perl's NV arithmetic). Values that might be integers in Perl carry exactness checks at the 2^53 boundary. Which mode runs is decided per entry from the actual types, and both variants can coexist for one loop.

Semantics that survive by construction. Perl's boolean false is the dual-natured `""`, which no numeric slot can spell - so stored booleans (comparison results, predicate returns) live in write-only slots that are written back as copies of Perl's own true/false values, exactly what the interpreter's assignment would store. The "Deep recursion" warning is reproduced by capping compiled recursion exactly where the warning would fire and letting the replay warn. Match variables after a loop show what the interpreter would show, because Perl itself restores match state at block exit.

Parallel execution

Loops with the right shape additionally parallelize: an integer range whose per-iteration work is independent except for sum-style reductions is chunked across a work-stealing thread pool. The gate is strict bit-exactness: integer reductions always qualify; float reductions only when reassociation provably cannot change the result. A loop that touches strings, arrays, hashes, or calls subs runs compiled but sequential. Trip-count thresholds keep small loops off the pool.

`--threads=N` sizes the pool; `--parallel-threshold=N` adjusts the minimum trip count; `--no-parallel` disables dispatch entirely.

Observing the JIT

- `--jit-stats` prints counters at exit: candidates found, loops compiled, entries run compiled, guard failures, deopts.
- `--no-jit` disables compilation. Comparing a run against `--no-jit` tells you whether the JIT was engaging at all.
- `PPERL_JIT_LOG=/path/file` appends one line per compiler event: `candidate ok`, `compile ok`, `compile skip reason=body-op:NAME` (the loop contained op NAME the compiler does not handle), `deopt reason=...` (a guard failed or a run aborted). The `reason=` vocabulary is the fastest way to learn why a specific loop is not compiling.

For test authors: the test harness understands a `# harness: jit-engage=compile` pragma that fails a test unless the JIT actually compiled something during it, preventing vacuous passes.

Limitations

- Perl-visible line numbers and `caller`-style introspection inside a compiled region reflect the loop entry, not the current statement. Debuggers and profilers see a compiled loop as one opaque unit.
- Native-module calls outside the compiled set (anything not in the pure allowlist, and any block-taking form like `first { }`) decline the loop.
- `s///e`, scalar `m//g`, patterns with embedded code blocks, ties, overloading, and tainting all decline.
- The first compiled entry of a loop costs roughly a millisecond of compilation; loops below the trip thresholds stay interpreted for that reason.

Numbers

Measured mid-2026 on the project benchmark suite (speedups are perl5 time divided by pperl time):

Shape	Speedup vs perl5
Mandelbrot 1000x1000, parallel	~400x
Sub calls (empty through 3-arg, and recursion)	20x to 60x
`fib(30)` as a single top-level call	~30x
Whole 97-benchmark suite, geometric mean	~2x

The whole-suite number includes benchmarks the JIT does not touch; the per-shape numbers are what compiled code delivers on its own ground.

Auto-FFI (Peta::FFI)

PetaPerl includes a built-in Foreign Function Interface that allows calling C library functions directly from Perl - without writing XS, without a C compiler, without any build step. This is a PetaPerl-exclusive feature with no perl5 equivalent.

Architecture

Any library the system can `dlopen` is reachable from pure Perl, at run time, with nothing compiled. There are two levels, and which one you use depends only on whether someone has already written a binding for the library you need.

- **Raw FFI** - the `Peta::FFI` module itself. Open a library, call any function in it by writing a type signature, declare its C object types as Perl classes, and use the memory and callback primitives that go with that. It works for every library, including one nobody has written a binding for.
- **A native binding** - a module presenting an ordinary Perl API that reaches the C library for you, with the signatures settled in one place and the C objects tied to the lifetime of Perl values. It is built on Peta::FFI's binding layer and is the later, faster and more comfortable form of the same reach. `Peta::FFI::Libc`, `Peta::FFI::UUID`, `Math::GMP` and `Cairo` are among the ones that ship. Where one covers your library, use it.

Raw FFI dispatches through **libffi**, so any signature you can spell works with no code generation and no build step. pperl also has *FFI::Platypus* built in, as a layer over Peta::FFI's engine: each of the two can express everything the other can, and code written for CPAN's FFI::Platypus runs unchanged. New code can use Peta::FFI directly.

Raw FFI

dlopen / call / dlclose

```
use Peta::FFI qw(dlopen call dlclose);

my $lib = dlopen("libm.so.6");
my $result = call($lib, "sqrt", "(d)d", 2.0);   # sqrt(2) = 1.4142..
↪.
print "sqrt(2) = $result\n";
dlclose($lib);
```

`call` parses the signature, looks the symbol up and prepares the call every time it runs, which suits a one-off call. The function may also be given by address instead of by name: a function pointer C handed out, such as an entry of a table of callbacks, has no name to look up.

Prepared functions: function / attach

A function you call more than a few times is better prepared once. `function` does the parsing, the lookup and the preparation once and returns a code reference; each call then pays only for converting its arguments and its result, roughly a quarter to a third of what `call` costs. `attach` does the same and installs the result as a named sub, in the calling package unless the name contains `::`

```
use Peta::FFI;

my $cairo   = Peta::FFI::dlopen("libcairo.so.2");
my $move_to = Peta::FFI::function($cairo, "cairo_move_to", "(odd)v
```

(continues on next page)

(continued from previous page)

```
 ↪");
$move_to->($cr, 10, 20);

package My::Zlib;
my $z = Peta::FFI::dlopen("libz.so.1");
Peta::FFI::attach($z, "zlibVersion", "()p");            #␣
 ↪My::Zlib::zlibVersion
Peta::FFI::attach($z, "crc32", "(Lpu32)L", as => "crc");
print zlibVersion(), "\n";
```

A prepared function keeps its library loaded for as long as the code reference or the sub lives, whatever `dlclose` is called on. A missing symbol or a bad signature croaks when the function is prepared, not on its first call.

Type Signature Format

The signature string `"(arg_types)return_type"` lists one type per position, optionally separated by blanks:

Code	C Type	Perl Mapping
`v`	`void`	return only; 1 is returned
`i`	`int`	integer
`l`	`long`	integer
`L`	`unsigned long` / `size_t`	unsigned integer
`i8 i16 i32 i64`	`int8_t` … `int64_t`	integer
`u8 u16 u32 u64`	`uint8_t` … `uint64_t`	unsigned integer
`b`	`bool`	true or false
`d`	`double`	float
`f`	`float`	float
`D`	`long double`	float (rounded to a double)
`cf cd`	`float` / `double complex`	`[re, im]`; a number is `[n, 0]`
`p`	`const char*`	string in; a returned string is copied
`s`	`char*` the caller frees	return only; copied, then freed
`P`	`void*` (mutable buffer)	output buffer; `\$buf` is written
`o`	opaque pointer	raw address as an integer
`<Class>`	a C object's pointer	an object of a declared handle type
`{Class}`	`struct` by value	an object of a declared record class
`*{Class}`	`struct *` / `union *`	the same object, by pointer
`*T`	`T *`	`\$scalar` in and out; `undef` is NULL
`T[N] T[]`	`T *` to an array	`\@array` in and out

Examples:

- `"(d)d"` - one double argument, returns double (e.g. `sqrt`)
- `"(p)L"` - one string argument, returns unsigned long (e.g. `strlen`)
- `"(ppi)i"` - two strings + int, returns int
- `"()i"` - no arguments, returns int (e.g. `getpid`)

- `"(o)i"` - one opaque handle, returns int (e.g. `sqlite3_close`)
- `"(u64 <My::Pool>)b"` - a 64-bit unsigned integer and a handle, returns bool
- `"(D)D"` - a long double in and out (e.g. `sqrtl`)
- `"(cd)d"` - a double complex in, a double out (e.g. `cabs`, which gives 5 for `[3, 4]`)

An unsigned type reads its argument as an unsigned integer, so `2**64-1` passes as itself rather than as -1, and a return above `2**63` comes back unsigned.

Pointers and arrays. `*T` is a pointer to one value and `T[N]` (a fixed count) or `T[]` (any length) a pointer to an array, for `T` a number type, `o`, `b` or `p` (so `p[]` is a `char **`). You pass a reference, the callee reads and writes through it, and afterwards the scalar or the array holds what C left there; `undef` passes NULL. As a return type, `*T` gives a reference to the value (`undef` for NULL) and an array type gives an array reference.

```
my $m = Peta::FFI::call($libm, "frexp", "(d*i)d", 40, \my $exp);   #␣
↪0.625, $exp = 6
Peta::FFI::call($libc, "qsort", "(i32[]LLo)v", \@v, scalar @v, 4,
↪$cmp);
```

`P` given a reference passes that scalar's own bytes, and after the call the scalar holds what C wrote, at the same length:

```
my $buf = "\0" x 64;
Peta::FFI::call($libc, "snprintf", "(PLp;i)i", \$buf, 64, "%d", 42);
```

Given a string or a number instead, `P` passes a zeroed scratch buffer of that length or that many bytes (at least 16), which nobody reads back.

A **variadic** function lists its named parameters, then a `;`, then the types this particular call passes through its `...`. `"(iL;o)i"` is `ioctl(int, unsigned long, ...)` passing one pointer, and `"(pi;u32)i"` is `open` with a mode.

`s` is for a C function that returns a string the caller must free. Perl gets a copy and the C string is freed at once, with libc's `free()` unless `function` or `attach` names the library's own free function with `free => "name"`. A library not written in C, a Rust one for instance, must name its own.

`o` is the code for every C API built on opaque structs, the `sqlite3 *` and `PGconn *` and `cairo_t *` kind. The address travels as an ordinary Perl integer, the runtime never dereferences it, and `undef` or `0` passes `NULL`. Never reach for `p` to carry such a pointer: `p` means "copy a string until the first NUL byte", which is both wrong and unsafe for anything that is not a string.

Typed handles

`o` leaves the pointer's lifetime to you. `handle_type` instead declares a Perl class for a C object type, together with the function that destroys it, and a signature can then name the type as `<Class>`:

```
Peta::FFI::handle_type("My::Schema", $lib, "schema_free");
my $compile = Peta::FFI::function($lib, "schema_compile", "(p)
↪<My::Schema>");
```

(continues on next page)

(continued from previous page)

```
my $schema = $compile->($schema_json) or die "invalid schema";
...                                   # schema_free runs when
 ↪$schema goes
```

- **As a result**, the returned pointer becomes an object of the class; a NULL pointer becomes `undef`, so a failed constructor reads as false.
- **As an argument**, an object of the class passes its pointer, and `undef` passes NULL. Anything else - another class's handle, a plain number, a released handle - croaks before C sees it.
- When the last reference to an object goes, the destructor runs with its pointer, exactly once. No `DESTROY` method is involved, so the class is free for your own methods and subclasses.

`Peta::FFI::release($schema)` runs the destructor early. The object stays in its class, and passing it to C afterwards croaks.

Records: C structs and unions

`record` declares a Perl class for a C struct, member by member in the order of the C declaration:

```
Peta::FFI::record("My::Point", x => "d", y => "d");
Peta::FFI::record("My::Rect",  origin => "{My::Point}", size => "
 ↪{My::Point}");

my $p = My::Point->new(x => 1.5, y => -2);
print $p->x, "\n";                                  # 1.5
$p->y(4);                                           # set

# struct Point point_add(struct Point, struct Point);
my $sum = Peta::FFI::call($lib, "point_add", "({My::Point}
 ↪{My::Point}){My::Point}", $p, $p);
# void point_scale(struct Point *, double);
Peta::FFI::call($lib, "point_scale", "(*{My::Point}d)v", $p, 2);
```

A member is an integer type, `f`, `d`, `b`, `o`, `p` (a `const char *` the record points to, read-only), a fixed array of numbers or `o` such as `u8[16]`, or another record by value, `{Class}`. The layout, each member's offset and the size and alignment of the whole, is the C compiler's for the platform, as libffi computes it, so you never write an offset.

`Class->new(member => value, ...)` makes a zeroed record and sets the members given. `$r->name` reads a member and `$r->name($value)` sets it; an array member also takes `($index)`, `($index, $value)` and an array reference. A member that is itself a record reads as a copy, an object of its class (`$rect->origin->x`), and is set from one. A record is a reference to the struct's bytes.

In a signature, `{Class}` passes or returns the struct by value, as `"(ii){Div}"` does for libc's `div`. `*{Class}` passes a pointer to the record's own bytes, which the callee may change in place; `undef` is NULL. Callbacks take and return records too: `closure("({My::Point})v", sub { ... })`.

`Peta::FFI::sizeof("{My::Point}")` and `alignof` give a type's size and alignment, for records and every other type.

`union` declares a C union the same way, with every member at offset 0: the union is as large as its largest member and as aligned as its strictest. SDL's event type is one:

```
Peta::FFI::record("Keysym", scancode => "i32", sym => "i32", mod =>
 ↪"u16", unused => "u32");
Peta::FFI::record("KeyEvent", type => "u32", timestamp => "u32",␣
 ↪windowID => "u32",
                  state => "u8", repeat => "u8", pad => "u8[2]",␣
 ↪keysym => "{Keysym}");
Peta::FFI::union("Event", type => "u32", key => "{KeyEvent}",␣
 ↪padding => "u8[56]");

my $ev = Event->new;                          # SDL_Event
while (Peta::FFI::call($sdl, "SDL_PollEvent", "(*{Event})i", $ev)) {
    print $ev->key->keysym->sym, "\n" if $ev->type == 0x300;   #␣
 ↪SDL_KEYDOWN
}
```

A union is passed by pointer, `*{Event}`, and is read and written whole by `fetch` and `store` and as a member of a record. Passing one by value, as `{Event}` or inside a struct passed by value, croaks: libffi has no union type, and a struct of the same size is passed differently on some platforms, which would make a wrong call rather than an error. Real C APIs nearly always pass unions by pointer.

Library variables

`symbol($lib, $name)` gives the address of a function or a variable in a library. `variable` binds a Perl scalar to a library's global variable: reading `$$var` reads the C variable at that moment, and assigning to it writes the variable.

```
my $optind = Peta::FFI::variable($libc, "optind", "i");
print $$optind, "\n";        # reads the C variable
$$optind = 1;                # writes it
```

The type is any that `store` can write; a `p` variable is read-only. The library stays loaded while the scalar lives.

errno

`Peta::FFI::errno()` returns errno as the last C call through Peta::FFI left it, read before Perl could change it. As in C, it means something only when the function reported a failure:

```
my $fd = Peta::FFI::call($libc, "open", "(pi;u32)i", $path, 0x40,␣
 ↪0644);
if ($fd < 0) {
    local $! = Peta::FFI::errno();
    die "open $path: $!";
}
```

Opaque pointers and memory

Most out-parameters need no memory handling of your own: `*o` takes a reference to a scalar the callee writes a pointer into.

```
Peta::FFI::call($lib, "sqlite3_open", "(p*o)i", ":memory:", \my
 ↪$db);
```

For memory that has to outlive a call, or that C hands you by address, there is the pointer toolbox; every address in it is a plain Perl integer, as with `o`. `alloc` and `free` obtain and release a zeroed block. `fetch($addr, $type)` and `store($addr, $type, $value)` read and write a value of any type at an address, records and arrays included:

```
my $n  = Peta::FFI::fetch($ptr, "i32");
my $xy = Peta::FFI::fetch($ptr, "d[2]");           # [1.5, -2]
my $pt = Peta::FFI::fetch($ptr, "{My::Point}");    # a My::Point␣
 ↪copy
```

For raw bytes, `peek` reads a count of them back as a Perl byte string and `peek_cstr` reads a NUL-terminated C string; `poke` writes bytes to an address. `pack_ptr` and `unpack_ptr` convert between an address and its machine-width byte representation.

Callbacks

C can call back into Perl. `closure` wraps a coderef as a real function pointer, using the same signature grammar as `call`, and returns its address for you to pass wherever the C API wants a function. The canonical shape is a comparator or a handler:

```
my $cmp = Peta::FFI::closure('(oo)i', sub {
    my ($pa, $pb) = @_;
    my $a = unpack "l", Peta::FFI::peek($pa, 4);
    my $b = unpack "l", Peta::FFI::peek($pb, 4);
    return $a <=> $b;
});

Peta::FFI::call($libc, "qsort", "(oLLo)v", $buf, $n, 4, $cmp);
Peta::FFI::closure_free($cmp);
```

Three rules go with it. The closure stays alive until `closure_free` is called with that address, so free it only once the C side has been told to stop using it; freeing an address twice is harmless, as `free(NULL)` is. A callback that dies does not propagate, because the error would have to unwind through the C caller's own stack frame: `$@` is set, the callback returns a zero of its declared return type, and you check `$@` after the C call that triggered it. And a closure may be called only on the interpreter's own thread, during a C call Perl made: a comparator, a progress handler, a visitor. A library that calls it from a thread of its own stops the program with a message saying so, because Perl cannot run there.

Events from a library's own threads

A library that produces events on threads of its own, such as a device monitor or a netlink listener, queues them instead and signals through a file descriptor that some are waiting. *Peta::FFI::EventSource* watches that descriptor and takes the events on Perl's thread. The library provides a function returning the descriptor, one returning the next event as an `s` string (NULL when the queue is empty), and a destructor declared with `handle_type` that stops its thread:

```
use Peta::FFI;
use Peta::FFI::EventSource;

Peta::FFI::handle_type('Example::Monitor', $lib, 'example_monitor_
↪free');
my $open = Peta::FFI::function($lib, 'example_monitor_open', '(p)
↪<Example::Monitor>');
my $fd   = Peta::FFI::function($lib, 'example_monitor_fd',   '(
↪<Example::Monitor>)i32');
my $next = Peta::FFI::function($lib, 'example_monitor_next', '(
↪<Example::Monitor>)s',
                               free => 'example_string_free');

my $source = Peta::FFI::EventSource->new($open->('block'), fd =>
↪$fd, next => $next);
my $guard  = $source->watch(sub { handle_event($_) for @_ });   #␣
↪AnyEvent
```

`->watch` uses AnyEvent. For EV or `select` there are `->fd` and `->drain`, and for loops that take filehandles (Mojo::IOLoop, IO::Select) there is `->fh`.

Library Discovery

```
use Peta::FFI qw(scan);

my $libs = scan();
# Returns hashref: { "libz.so.1" => "/usr/lib/libz.so.1", ... }

my $ours = scan("/opt/example/lib");
my $lib  = Peta::FFI::dlopen($ours->{"libexample.so"});
```

`scan` maps each library's file name to its path: every `lib*.so` and `lib*.so.*` file in the directories searched that this program can load. Linker scripts (`/usr/lib/libc.so` is one) and libraries of another architecture, such as 32-bit ones on a 64-bit system, are left out. A name found in more than one directory maps to the first one's file.

`scan(@dirs)` searches those directories, in that order, and no others. `scan()` searches the directories in `PETA_FFI_PATH` (colon-separated, like `PATH`) first, then where the dynamic linker looks for a bare name: `LD_LIBRARY_PATH`, the directories `/etc/ld.so.conf` names, and `/lib`, `/usr/lib` and their 64-bit forms.

Nothing else searches. `dlopen` with a bare name asks the dynamic linker, which never reads `PETA_FFI_PATH`; a library installed in a directory of its own is found by `scan` and

opened by the path it returns.

Native bindings

A native binding gives you a Perl API for one C library, with argument validation, return-value conversion, and error handling done for you. No type signatures, no addresses: you call functions and methods. Each C function's exact type is declared in the binding and called directly, which is faster than a prepared Peta::FFI function; the C objects free themselves when the Perl values holding them go away. A module loads even when its library is not installed, and the first call that needs the library dies with an install hint. A library too old to have a function the binding calls makes that call die, naming the C function.

Peta::FFI::Libc

Direct bindings to libc functions, grouped by category:

Process: `getpid`, `getppid`, `getuid`, `getgid`, `geteuid`, `getegid`

Strings: `strlen`, `strerror`

Environment: `getenv`, `setenv`, `unsetenv`

Math: `abs`, `labs`

System: `sleep`, `usleep`, `gethostname`, `uname`, `time`, `clock`

File operations: `access`, `unlink`, `rmdir`, `mkdir`, `chmod`, `chown`, plus the access-mode constants `F_OK`, `R_OK`, `W_OK`, `X_OK`

```
use Peta::FFI::Libc qw(getpid gethostname uname);

print "PID: ", getpid(), "\n";
print "Host: ", gethostname(), "\n";

my @info = uname();
print "OS: $info[0] $info[2] ($info[4])\n";
```

Peta::FFI::UUID

Bindings to libuuid (must be installed on the system):

```
use Peta::FFI::UUID qw(uuid_generate uuid_generate_random);

my $uuid = uuid_generate();           # e.g. "550e8400-e29b-41d4-
 ↪a716-446655440000"
my $rand = uuid_generate_random();    # random-based UUID
```

Functions: `uuid_generate`, `uuid_generate_random`, `uuid_generate_time`, `uuid_parse`, `uuid_is_null`, `uuid_unparse`.

If libuuid is not installed, `use Peta::FFI::UUID` dies with a diagnostic message.

Math::GMP

Arbitrary-precision integer arithmetic via libgmp, under the upstream `Math::GMP` name, so code written for the CPAN module runs unchanged:

```
use Math::GMP;

my $big = Math::GMP->new("123456789012345678901234567890");
my $sum = $big + 42;
print "$sum\n";
```

GMP integers are heap-allocated mpz_t values stored as blessed references. Operator overloading (`+`, `-`, `*`, `/`, `%`, `**`, `<=>`, `""`) works identically to the XS module.

If libgmp is not installed, `use Math::GMP` dies with a diagnostic message.

Cairo

The 2D vector graphics library, under the upstream `Cairo` name and with the upstream method signatures, so code written for CPAN `Cairo` runs unchanged with no CPAN distribution installed. It is the largest native binding that ships and the one to read if you want to see the pattern at full size: `Cairo::ImageSurface`, `Cairo::Context`, `Cairo::Path`, `Cairo::Pattern`, `Cairo::Matrix`, `Cairo::Font` and `Cairo::Region` each have their own reference page under `Cairo`.

```
use Cairo;

my $surface = Cairo::ImageSurface->create('argb32', 200, 200);
my $cr      = Cairo::Context->create($surface);
$cr->set_source_rgb(0, 0, 0);
$cr->arc(100, 100, 40, 0, 6.28318);
$cr->fill;
$surface->write_to_png('out.png');
```

If libcairo is not installed, the call site croaks with an install hint rather than the module failing to load. The *2D graphics guide* walks through how this binding is put together.

What raw FFI cannot do

Derive types from a header. Nothing reads your `.h` files. You read the C prototype and write the matching signature yourself, and you declare each record's and union's members yourself, in the order and with the types of the C declaration. A signature or a record that disagrees with the real declaration is undefined behaviour rather than an error you get told about.

When to Use FFI vs Native Modules

Scenario	Recommendation
Common CPAN module (List::Util, etc.)	The built-in native module
A library that a native binding covers	That binding (`Math::GMP`, `Cairo`, ...)
A system library that nothing wraps yet	Raw FFI
Frequent calls to the same function	`function` or `attach`
One-off experiment	`call`

`call` prepares the call every time it runs. A prepared function from `function` or `attach` pays only for converting its arguments and its result, roughly a quarter to a third of what `call` costs. A native binding calls the C function directly and is faster again; `Cairo`'s methods take less time per call than perl5's XS `Cairo`. Native modules such as List::Util, which implement the work itself, are fastest, at the speed of a built-in operator.

Native Modules

PetaPerl does not support XS (C extensions). Instead, performance-critical CPAN modules are reimplemented natively in Rust. These "native modules" provide the same Perl-level API as their XS counterparts but integrate directly with PetaPerl's runtime - enabling JIT compilation, auto-parallelization, and zero FFI overhead.

How It Works

When you write `use List::Util qw(sum min max)`, PetaPerl's module loader detects that `List::Util` has a native implementation and registers Rust function pointers directly. There is no compilation step, no `.so` loading, and no XS glue code.

Native functions are dispatched via `NativeFn` - a direct function pointer with O(1) call overhead, identical to built-in operators.

Available Native Modules

Core Utilities

Module	Functions	Notes
Scalar::Uti	blessed, reftype, refaddr, weaken, isweak, looks_like_number, ...	Full API
List::Util	sum, min, max, first, any, all, none, reduce, ...	MULTICALL optimized
Sub::Util	subname, set_subname	
Hash::Util	lock_keys, lock_hash, ...	

Digest / Crypto

Module	Functions	Notes
Digest::MD5	md5, md5_hex, md5_base64, OO interface	Full API
Digest::SHA	sha1, sha256, sha512, OO interface	Full API
MIME::Base64	encode_base64, decode_base64	
MIME::QuotedPrint	encode_qp, decode_qp	

File / System

Module	Functions	Notes
File::Basename	basename, dirname, fileparse	
File::Copy	copy, move	
File::Find	find, finddepth	
File::Glob	bsd_glob	
File::Path	make_path, remove_tree	
File::Spec	catdir, catfile, rel2abs, ...	
File::Temp	tempfile, tempdir	OO + functional
File::stat	stat (OO)	
Cwd	cwd, getcwd, abs_path	
Sys::Hostname	hostname	

I/O

Module	Functions	Notes
IO::File	OO file handle	
IO::Handle	OO handle base	
IO::Dir	OO directory handle	
IO::Pipe	OO pipe handle	
IO::Select	select wrapper	
IO::Socket	OO socket handle	
IO::Seekable	seek/tell mixin	
FileHandle	Legacy OO handle	
Socket	socket primitives	

Data / Encoding

Module	Functions	Notes
Data::Dumper	Dumper	
Storable	freeze, thaw, nstore, retrieve	
Encode	encode, decode, find_encoding	
JSON::PP	encode_json, decode_json	Via Pure Perl

Numeric / Math

Module	Functions	Notes
POSIX	floor, ceil, fmod, strtod, strftime, ...	Subset

version	Version object handling	Full OO API

Performance

Native modules run at the same speed as built-in operators since they share the same dispatch mechanism. For block-taking functions (first, any, all, reduce), PetaPerl uses MULTICALL optimization to avoid per-element subroutine call overhead.

Benchmarks (vs perl5 with XS):

Function	PetaPerl native	perl5 XS	Ratio
List::Util::sum	1.7x faster	baseline	
List::Util::min/max	2.9x faster	baseline	
List::Util::first	~1x	baseline	MULTICALL parity

Adding Native Modules

Native module documentation is extracted from the module's Rust source (`//!` module docs and `///` function docs) by `docs/sphinx/bin/20-reference` during the docs build.

Differences from Perl 5

PetaPerl targets full behavioral compatibility with Perl 5.44: same syntax, same pragmas, same runtime semantics, byte-identical output. The test harness compares every test's output against a real perl binary, so "works" below means "verified byte-exact". The differences that remain are deliberate design decisions, catalogued here.

Every claim on this page is re-verified against the current runtime when the page changes; historic limitations that no longer exist are removed rather than annotated.

Intentional Differences

No XS binary loading

PetaPerl never loads compiled extension objects (`.so` files). Instead, the three things XS is used for are served separately:

- **Speed**: the core XS module population (List::Util, Scalar::Util, Data::Dumper, Digest::*, Encode, Storable, POSIX, ...) ships as native modules inside the binary, and the JIT with auto-parallelization makes pure Perl itself competitive.
- **C libraries**: `Peta::FFI` calls into system libraries without any compilation (see the Cairo binding for a complete example).
- **Pure Perl fallbacks**: dists that ship one (most dual-life modules do) simply use it, on a faster interpreter.

A dist that strictly requires its own compiled XS object and offers no fallback will not run. `cpan install Some::XS::Module` is not a supported path and never will be.

Module loading and `@INC`

Three deliberate deviations, all consequences of pperl being one self-contained binary that runs no compiled XS objects:

- **Native modules have absolute priority.** A module built into the binary is served by `require` directly; a same-name `.pm` on disk can never shadow it, regardless of `-I` or `PERL5LIB`. Everything not built in resolves through `@INC` in normal first-hit-wins order.
- **Only pperl's own architecture directories.** pperl's archname is `x86_64-linux`, and the architecture directories of the trees you add are searched under that name, as perl searches its own: `<entry>/x86_64-linux` and `<entry>/<version>/x86_64-linux` of each `-I`, `PERL5LIB` and `PPERL5LIB` entry and of `~/.pperl/lib/perl5`, ahead of the entry. A host perl's own architecture children (`x86_64-linux-thread-multi` and the like) and its `archlib` are not searched: they hold that perl's compiled extensions. No `.so` is ever loaded from a searched directory either; a module whose compiled part is not built in dies with `Can't locate loadable object`, the message pure-Perl fallbacks test for. That is what lets library trees built by a real perl (`local::lib`, Carton) work unmodified.
- **Host library trees are probed, not baked.** `@INC` is constructed by checking the standard Arch, Debian and Fedora pure-perl tree locations for existence, and versioned children of those trees and of `-I`/`PERL5LIB` entries are ordered by nearness to pperl's own version: exact match first, then the same minor release descending,

then newer versions, then the plain directory, then older versions. A host perl of a different version is used gracefully as a last resort rather than rejected. `pperl -V` always shows the actual probed result.

Additionally, pperl-private search locations exist for parallel installations: the `PPERL5LIB` environment variable (honored before `PERL5LIB`, same rules), the per-user tree `pperl --cpan` installs into (`lib/perl5` under `$PPERL_HOME`, default `~/.pperl`) and the overlay trees under `/usr/local/share/pperl` and `/usr/share/pperl`, probed before every host tree. They allow shipping or overriding a `.pm` for pperl without touching the shared perl trees; the host perl never reads them, and nothing in them can outrank a built-in native module.

No interpreter threads

`use threads` is not supported (pperl is a non-threaded build, as are most distribution perls' recommended configurations). Perl-level concurrency options are `fork` and the automatic parallelization of qualifying loops, which uses native threads internally without exposing interpreter threading semantics.

Linux only

PetaPerl runs on Linux exclusively (any architecture supported by Cranelift: x86-64, AArch64, RISC-V, s390x). `$^O` is always `"linux"`.

Version identity

`$]` reports `5.044099` and `$^V` reports `v5.44.99`: a 5.44-class interpreter, above any released 5.44.x patch level. `use v5.44` and version checks against 5.44 or below behave exactly as on a real 5.44. `$Config{version}` reports `5.44.99`.

Modern features are NOT enabled by default: exactly like perl, `say`, `state` or signatures need `use feature ...` or a `use v5.XX` declaration. Scripts written for older perls run with their old semantics.

Command-line flags

Not supported:

Flag	Description
`-x`	Extract script from message
`-C`	Unicode handling of input and output

`-I`, `-M`/`-m`, `-n`/`-p`, `-l`, `-a`/`-F`, `-0`, `-i`, `-T`/`-t`, `-c`, `-d`, `-w`, `-e`/`-E` and `-V`/`-V:key` work as in perl. The one debugger variant that does not is `-dt`: it asks for thread support, and pperl is built without threads. pperl-specific flags (JIT, parallelism) are listed in *CLI options*.

Known Issues

Current, specific, and expected to shrink:

- **`charnames` emits redefinition warnings.** Loading `charnames` (or `\N{...}` names) prints `Subroutine re::is_regexp redefined` warnings before working correctly: the built-in `re` module pre-registers helpers that `_charnames.pm` also defines. Output is otherwise exact.
- **`B::Deparse` on subs with signatures.** The optree for signature parameters uses a newer internal representation than the deparser expects; deparsing such subs produces an "unexpected OP" note instead of the signature. Ordinary subs deparse exactly.
- **Embedding pperl in C hosts** (mod_perl-class, programs linking libperl) is out of scope until a concrete user appears.

4.2.2 Concurrent Execution

Doing work in parallel, or several things at once. There are three concurrency stories to know about, and they answer different questions:

- **Auto-parallelization** - `pperl`'s runtime detects parallelisable patterns in ordinary Perl and spreads them across cores without any user-level threading. This is the preferred answer for CPU-bound loops over large data.
- **Coroutines and event loops** - Coro, EV, Event and AnyEvent: many tasks that mostly wait - on sockets, timers, child processes - each written as straight-line code, taking turns in one interpreter. The answer for I/O-bound concurrency.
- **Classical ithreads (not implemented)** - Perl 5's `threads` and `threads::shared` model. pperl deliberately does not provide it: `use threads` fails at compile time. The chapter teaches the model so that you can read existing code, and most programs that used ithreads are better rewritten against the auto-parallel path.

Start with the *decision chapter* if you have an existing threaded program and are deciding how to port it; start with *parallel* if you are writing new code and want to understand when pperl speeds your loop up, and with *coroutines* if your program spends its time waiting.

Parallel Execution

PetaPerl automatically parallelizes eligible loops using Rayon, a work-stealing thread pool. Combined with JIT compilation, this enables dramatic speedups for compute-heavy workloads.

How It Works

When PetaPerl encounters a parallelizable loop, it:

1. **Analyzes the loop body** for side effects and shared mutable state
2. **Identifies reduction variables** (accumulators like `$sum += ...`)
3. **Distributes iterations** across threads using Rayon's work-stealing scheduler
4. **Combines results** using the detected reduction operations

Each thread gets its own copy of loop-local variables. Reduction variables are combined after all threads complete.

What Gets Parallelized

Parallel dispatch applies to JIT-compiled loops whose iterations are provably independent except for sum-style reductions:

- `for` over an integer range - the primary parallel shape. The range is chunked across threads; each thread accumulates private reduction copies that merge at the end.
- `while` loops whose condition is a counter bounded by a constant or read-only variable, with the counter incremented exactly once per iteration.

One gate is stricter than the side-effect analysis and deserves its own sentence: **bit-exactness**. Integer reductions always qualify. Floating-point reductions qualify only when reassociating the sum provably cannot change the result (for example when every contribution is integral and within the exact range of a double). An inexact float reduction runs compiled but sequential - pperl never trades determinism for cores.

Loops that touch strings, arrays, hashes, or call subs compile to native code but run on one core; see *Writing fast pperl* for how to split such loops.

CLI Control

```
# Default: parallelization enabled
pperl script.pl

# Disable parallelization
pperl --no-parallel script.pl

# Explicitly enable (default)
pperl --parallel script.pl

# Set thread count (default: number of CPU cores)
pperl --threads=4 script.pl

# Set minimum collection size for parallelization
pperl --parallel-threshold=1000 script.pl
```

The test harness runs with `--no-parallel` by default to ensure deterministic test output.

Performance

Mandelbrot Set (1000x1000, mid-2026)

Mode	Time	vs perl5
perl5	~12,500ms	1.0x
pperl JIT (sequential)	~160ms	~75x faster
pperl JIT + parallel (8 threads)	~30ms	~400x faster

Scaling

The work-stealing scheduler provides near-linear scaling for embarrassingly parallel workloads:

Threads	Mandelbrot 4000x4000	Scaling
1	baseline	1.0x
2	~50% time	~1.9x
4	~25% time	~3.8x
8	~13% time	~5.2x

Scaling is sub-linear due to memory bandwidth, cache effects, and reduction overhead.

Limitations

String Operations

String operations (`.=` concat, string building) are not parallelized. The JIT's string support uses extern calls back to the Rust runtime, which requires mutable access to shared state. When the JIT detects string variables in a loop, parallel dispatch is disabled.

Side-Effect Detection

The parallelization analyzer is conservative. Any of these disqualify a loop:

- I/O operations (`print`, open, file reads)
- Global variable writes
- Subroutine calls (unless proven pure)
- Regex operations with side effects (`s///`)

False negatives (missed parallelization opportunities) are safe - the loop simply runs sequentially. False positives (incorrect parallelization) would be bugs.

Determinism

Parallel execution may change the order of side effects. For this reason, parallelization is only applied when the analysis proves the loop body is free of observable side effects.

`map` and `grep` compile to sequential native loops (array state gates parallel dispatch off), so their output order is trivially the sequential one.

How Reduction Detection Works

The analyzer identifies reduction variables by scanning for accumulation patterns and subtracting reset patterns:

```
# Detected as reduction: $sum accumulates, never reset in loop
my $sum = 0;
for my $x (@data) {
```

(continues on next page)

(continued from previous page)

```
    $sum += $x;
}

# NOT a reduction: $temp is reset each iteration
for my $x (@data) {
    my $temp = $x * 2;  # reset (my declaration)
    $sum += $temp;       # $sum is still a reduction
}
```

The formula: `reductions = accumulations - resets`. This prevents false positives where a variable is both accumulated and reset within the loop body.

Coroutines and event loops

A **coroutine** is a thread of execution inside one interpreter: it has its own call stack, its own `$_` and `@_`, its own `local` values, and it runs until it chooses to let another one run. Perl's coroutine module is Coro; together with an event loop it lets a program wait on many sockets, timers and child processes at once while each task is written as plain straight-line code.

pperl runs Coro natively, with the event loops it is used with: EV, Event and AnyEvent, the layer that lets code run on any of them. Coro, EV and Event are part of the **native-max** module set; in a build without it, `use Coro` fails with `Can't locate Coro.pm in @INC`. AnyEvent, with its own pure-Perl loop, is in every standard build.

When to use them

Coroutines are cooperative: one runs at a time, on one CPU, and a switch happens only where the code asks for one. That makes them the right tool for work that mostly *waits* - network clients and servers, pipelines of I/O stages, many timers - and the wrong one for work that computes. For compute-bound loops use *auto-parallelisation*; for isolated subprocesses use `fork`.

Because nothing is preemptive, there are no data races: a variable cannot change under you between two statements unless one of them switches. There are no locks to take for ordinary data either, only coordination primitives for waiting on each other.

Starting and switching

`async` starts a coroutine; `cede` lets the others run; `join` waits for one to finish and returns its result:

```
use Coro;

my @workers = map {
    my $n = $_;
    async {
        for my $step (1 .. 3) {
            print "worker $n, step $step\n";
            cede;                          # let the others take a turn
```

(continues on next page)

(continued from previous page)

```
        }
        return $n * 10;
    };
} 1 .. 2;

print "result: ", $_->join, "\n" for @workers;
```

The two workers alternate step by step. The main program is itself a coroutine (`$Coro::main`); `$Coro::current` is always the one running. A coroutine ends when its block returns, with `terminate`, or when another one calls `$coro->cancel`. An uncaught `die` inside a coroutine ends the whole program, as it would in the main program.

`$coro->prio` sets a priority from `Coro::PRIO_MIN` to `Coro::PRIO_MAX` (default `PRIO_NORMAL`); higher priorities always run first.

Waiting for each other

Coro's modules cover the usual coordination patterns:

- `Coro::Channel` - a queue: `put` adds, `get` waits until there is something to take;
- `Coro::Semaphore` - a counting semaphore, with down/up and a scope-bound `guard`;
- `Coro::Signal` - wait until somebody sends a signal;
- rouse callbacks - turn any callback into a wait: `Coro::rouse_cb` makes a callback, `Coro::rouse_wait` blocks until it is called and returns its arguments.

A producer and a consumer connected by a bounded channel:

```
use Coro;
use Coro::Channel;

my $queue = Coro::Channel->new(4);      # holds at most 4 items

my $producer = async {
    $queue->put($_) for 1 .. 10;
    $queue->put(undef);                 # end marker
};

while (defined(my $item = $queue->get)) {
    print "got $item\n";
}
```

Blocking on I/O with an event loop

Coroutines pay off when a wait on a socket or a timer blocks only the coroutine that waits, not the program. That needs an event loop, and `Coro::AnyEvent` connects Coro to AnyEvent: whenever every coroutine is waiting, the loop runs until something is ready.

```
use Coro;
use Coro::AnyEvent;
use AnyEvent;

my @tasks = map {
    my ($name, $delay) = @$_;
    async {
        Coro::AnyEvent::sleep $delay;   # only this coroutine sleeps
        print "$name done after ${delay}s\n";
    };
} ["slow", 0.3], ["fast", 0.1];

$_->join for @tasks;
```

The same holds for files and sockets: `Coro::Handle` wraps a filehandle so that `readline`, `read` and `print` wait in the calling coroutine only, and `Coro::Socket` makes such handles for network connections. A server then handles each client in a coroutine of its own, written as if it were the only one.

Event loops

AnyEvent chooses its loop the first time it needs one. A loop the program has already loaded wins; otherwise it loads the best one available, which in a native-max build is `EV`, and falls back to its own pure-Perl loop elsewhere. Code written against AnyEvent, and Coro code using `Coro::AnyEvent`, `Coro::Handle` or `Coro::Socket`, runs unchanged on any of them.

EV and Event can also be used directly, with callbacks:

```
use EV;

my $count = 0;
my $tick = EV::timer 0.1, 0.1, sub {    # after 0.1s, then every 0.
↪1s
    print "tick ", ++$count, "\n";
    EV::break if $count == 3;
};

EV::run;                                # until EV::break
```

A watcher runs as long as the object `EV::timer` returned is alive; dropping the last reference stops it.

With coroutines, `Coro::EV` makes EV's loop and Coro's scheduler take turns, and adds waits of its own:

```
use Coro;
use Coro::EV;

async {
    Coro::EV::timer_once 0.2;           # this coroutine sleeps 0.2s
```

(continues on next page)

(continued from previous page)

```
    print "woke up\n";
};

EV::run;                                # returns once nothing is␣
↪left to wait for
```

`Coro::Event` does the same for Event, whose watchers block the coroutine that waits on them:

```
use Coro;
use Coro::Event;

async { Event::loop() };                # the event loop, in a␣
↪coroutine of its own

my $timer = Coro::Event->timer(interval => 0.1);
for my $tick (1 .. 3) {
    $timer->next;                       # waits for the next tick
    print "tick $tick\n";
}
```

A Coro::Event watcher starts when something first waits on it, so the loop has to run alongside the code that waits, not before it.

What each coroutine has of its own

Each coroutine has its own:

- call stack and lexical variables (a sub can be running in several coroutines at once, each with its own `my` variables);
- `$_`, `@_`, `$@`, `$/` and the current regex match (`$1` and friends);
- `local` values - a `local` in one coroutine is not seen by the others;
- `$SIG{__DIE__}` and `$SIG{__WARN__}`, and `%^H`.

Everything else is shared: package variables, `$,` and `$\`, open filehandles, and `$a` and `$b` - so two coroutines must not switch in the middle of a `sort` block that uses them in the same package.

C stacks

Most switches cost no memory beyond the coroutine's Perl-level stacks. A coroutine that switches away from *inside* a callback that the interpreter itself is running - a `sort` block, a tie method, a `DESTROY`, an overloaded operator - keeps a C stack of its own until it returns from there. Those stacks are 128 KiB each by default (`Coro::State::cctx_stacksize` sets the size, in pointers); code that recurses deeply inside such a callback, or through XS-level callbacks, may need more.

Porting from ithreads

A thread per connection, or a work crew fed from a `Thread::Queue`, becomes a coroutine per connection, or coroutines fed from a `Coro::Channel`, with blocking I/O through `Coro::Handle` or `Coro::AnyEvent`. The `:shared` attributes and every `lock` go away: nothing else runs between two statements of a coroutine unless one of them switches. If the threads were there to use several CPUs for computation, coroutines are not the replacement - see *Alternatives*.

See also

- Coro and its modules - the full interface; pperl runs Coro 6.57's own `.pm` files unchanged
- `Coro::State` - the engine under Coro
- `EV` and `Event` - the event loops, and `Coro::EV`, `Coro::Event` to run coroutines on them
- AnyEvent - the event-loop abstraction most Coro programs use
- `Guard` - run code when a scope ends, which Coro builds on
- *Alternatives* - choosing between coroutines, auto-parallelisation and `fork`

Threads

Perl 5's headline concurrency story is **interpreter threads** - *ithreads* for short - supplied by the core `threads` and `threads::shared` modules. Each ithread is a separate Perl interpreter running inside the same OS process, with its own pad, its own lexicals, and a copy of every package variable captured at spawn time. Data is shared between threads only when you opt in by attaching `:shared` to it.

This chapter teaches that model. The idiom, the vocabulary, and the pitfalls are the ones every Perl programmer who has touched concurrency has encountered, and you need to recognise them when reading existing Perl code.

pperl status - read this first

pperl **does not implement ithreads**. The `threads` module is not available, and without it the sharing primitives have no second interpreter to reach. At runtime:

- `use threads` fails at compile time.
- `threads::shared` is not part of pperl. Where a system perl5 provides it on `@INC` it loads, and `share` and `is_shared` do nothing.
- The `lock` built-in is a silent no-op, exactly as upstream Perl behaves when built without thread support. Code that sprinkles `lock` defensively for single-threaded compatibility runs unchanged.

That decision is deliberate. ithreads impose a per-interpreter data copy, constrain every core module's internals, and historically bred a long tail of subtle bugs around shared aggregates, signal delivery, and library thread-safety. pperl invests instead

in **runtime-level parallelism for pure Perl code** - JIT-compiled loop bodies dispatched across a Rayon work-stealing pool, with automatic reduction analysis and zero user-visible thread objects. See *Parallel Execution* for how that works and when it fires.

If you are porting an existing ithreaded program to pperl, read *Alternatives to ithreads* for the shapes that map cleanly - almost every `threads`-based program falls into one of three patterns, each with a simpler and faster pperl equivalent.

How this chapter is organised

ithreads basics

This chapter describes the perl5 ithreads model as it exists in upstream Perl 5.44. It is the vocabulary you need to read existing threaded Perl code. pperl does not run this code - see the landing page for the reason and *Alternatives* for the pperl-native equivalents.

What is a thread

A thread is a flow of control through a program with a single execution point. Every process has at least one thread - the *main* thread - and Perl's `threads` module lets a program spawn additional threads that run inside the same OS process.

Each ithread has **its own Perl interpreter**. When a new thread is created, the entire data state of the spawning thread is copied into the new one, like a fork but within the same process. After that moment the two interpreters are independent: modifying a variable in one does not affect the other, unless the variable is explicitly shared through `threads::shared`.

This distinguishes Perl ithreads from POSIX threads, Java threads, Win32 threads, and most other threading systems you may have met. Shared-everything is the default in those systems; shared-nothing is the default in Perl.

Checking for thread support

Thread support is a Perl build-time option. A program that needs threads should fail early if the interpreter was built without it:

```
use Config;
$Config{useithreads}
    or die "Recompile Perl with threads to run this program.\n";
```

Under pperl, `$Config{useithreads}` is **false** and the `threads` module does not load. The defensive `die` fires, which is the correct outcome - better than silently running the single-threaded code path on a program that needed concurrency.

Creating a thread

Load the `threads` module and call `threads->create`, passing a code reference to the subroutine the new thread should run:

```
use threads;
```

(continues on next page)

(continued from previous page)

```
my $thr = threads->create(\&worker);

sub worker {
    print "in the thread\n";
}
```

`create` takes a code reference - or an anonymous sub - and optional arguments passed to the subroutine. Control then continues in both the caller and the new thread. `new` is a synonym for `create`.

Passing arguments:

```
my $thr = threads->create(\&worker, 'first', 'second', 42);

sub worker {
    my @args = @_;
    # ...
}
```

Each argument is *copied* into the new thread. Modifications inside the thread are invisible to the caller, because the thread has its own interpreter state.

Joining a thread

A thread's subroutine can return a value. To wait for the thread to finish and collect its return, call `join`:

```
use threads;

my ($thr) = threads->create(\&worker);
my @result = $thr->join;
print "thread returned @result\n";

sub worker { return ('ok', 2, 'done'); }
```

`join` blocks until the thread exits, collects the return value, and performs the OS-level cleanup for the thread. The list-context assignment `my ($thr) = ...` is the idiom for spawning a thread whose return will be consumed as a list.

If several threads are outstanding, join them in turn:

```
my @thr = map { threads->create(\&worker, $_) } 1..4;
my @results = map { $_->join } @thr;
```

Detaching a thread

A *detached* thread runs until it finishes, then is cleaned up automatically. Its return value is discarded. Use `detach` when you do not care about the return and do not want to track the thread object:

```
my $thr = threads->create(\&background_work);
$thr->detach;
```

Once detached, a thread cannot be joined. A thread may also detach itself from inside its own body:

```
sub background_work {
    threads->detach;
    # ... long-running work ...
}
```

Process and thread termination

`die` or `exit` in **any** thread terminates the whole process - every other thread stops mid-execution, with no chance to finish. Perl also calls `exit` implicitly when the main thread falls off the end of the program, even if other threads are still running.

The canonical stumbling block:

```
use threads;

my $thr1 = threads->create(\&thrsub, 'one');
my $thr2 = threads->create(\&thrsub, 'two');

sub thrsub {
    my ($label) = @_;
    sleep 1;
    print "thread $label\n";
}
# Falls off the end. Perl warns "Perl exited with active threads:
# 2 running and unjoined" and aborts both threads.
```

Fix by joining before the main thread exits:

```
$thr1->join;
$thr2->join;
```

Three structural patterns

Most threaded programs fall into one of three shapes.

Boss/worker

A single *boss* thread collects or generates tasks and hands them to *worker* threads. The boss does little computation itself - its job is dispatch. Typical in GUI and server programs, where the main thread must stay responsive to events.

Work crew

Several threads run the same subroutine on different pieces of data. Closely maps to data-parallel problems: render tiles of an image, hash slices of a file, fold a large array. This is the pattern pperl's auto-parallelisation targets - see *Alternatives*.

Pipeline

Threads form a chain. Each one receives data, performs one step of processing, and forwards the result to the next. Handy for prime sieves and stream-processing workloads where each stage has its own state.

The three patterns are not exclusive; a non-trivial program uses several of them for different parts.

Thread identity

Every thread has a numeric **thread ID** (TID). The main thread has TID 0; each subsequent thread gets the next integer. From inside a thread, ask for its own object with `threads->self` and its own TID with `threads->tid`:

```
my $me = threads->self;
my $id = threads->tid;
```

`threads->list` returns every non-detached thread currently running. A common clean-up idiom at end of main:

```
foreach my $thr (threads->list) {
    $thr->join;
}
```

yield - usually a no-op

```
threads->yield;
```

Hints to the OS scheduler that this thread is willing to give up the CPU. It is a hint only. On most modern operating systems `yield` is a no-op, and well-behaved code does not depend on it.

pperl status

Every snippet on this page fails at compile time under pperl because `use threads` fails. The cleanest migration path is not to translate the snippets but to identify which of the three structural patterns the original uses, then follow the matching section of *Alternatives*.

Thread-safety of modules

An upstream Perl note worth repeating: a module is **not** thread-safe unless its documentation says so. That caveat applies to the ithreaded program's code, to every CPAN module it uses, and to the C libraries behind any XS modules.

pperl's auto-parallelisation sidesteps this problem entirely: the parallel dispatch is opt-in per loop, the analyser refuses to parallelise any body with side effects, and there is no user-visible shared heap to serialise. See *Parallel Execution*.

- *Alternatives* - pperl-native concurrency patterns
- `fork` - process-level concurrency

Shared data

Under upstream Perl 5.44, sharing data between ithreads is explicit: variables are private by default, and become visible across threads only when the `:shared` attribute is applied or a value is passed through a thread-safe primitive. This chapter walks through the full upstream shared-data surface - `threads::shared`, `lock`, semaphores, queues, condition variables - and flags pperl's status at each section.

pperl status at a glance

None of the sharing primitives on this page crosses a thread boundary under pperl, because there is no second interpreter. The modules are not part of pperl; where a system perl5 provides them on `@INC` they load:

- `threads::shared`: `share` and `is_shared` do nothing.
- `:shared` is parsed but has no underlying interpreter to share to.
- `lock` is a silent no-op, as documented on its reference page.
- `Thread::Queue` and `Thread::Semaphore` work inside the one interpreter.

Reading this page is still worth your time if you maintain upstream Perl code or need to read existing ithreaded programs. For new concurrency on pperl, skip to *Alternatives*.

Shared and unshared variables

By default, every Perl variable in an ithread is private. When you spawn a thread, the child starts with a copy of the parent's data and goes its own way:

```
use threads;

my $private = 1;
```

(continues on next page)

(continued from previous page)

```
threads->create(sub { $private++ })->join;
print $private, "\n";   # 1 - parent untouched
```

To cross the thread boundary, mark the variable `:shared` and `use threads::shared`:

```
use threads;
use threads::shared;

my $shared :shared = 1;
threads->create(sub { $shared++ })->join;
print $shared, "\n";    # 2 - write survived into parent
```

For an aggregate, every element becomes shared automatically:

```
my @queue :shared;
my %counts :shared;
```

Only simple scalars and references to other shared variables may be stored into a shared aggregate. Storing a reference to an unshared variable dies - upstream refuses the assignment to protect the sharing boundary.

The `lock` built-in

`lock` places an advisory mutex on a shared datum for the rest of the enclosing block:

```
use threads;
use threads::shared;

my $total :shared = 0;

sub calc {
    while (my $result = compute_chunk()) {
        lock $total;            # block until mutex available
        $total += $result;
    }                            # mutex released here
}
```

Properties worth remembering:

- **Advisory only.** `lock` blocks other callers of `lock` on the same datum. A thread that reads or writes `$total` without calling `lock` is not serialised.
- **Block-scoped.** Release happens at block exit, not at the end of the `lock` statement. There is no `unlock`.
- **Recursive per thread.** The same thread may re-acquire a lock it already holds; other threads still block.
- **Works on aggregates.** `lock @queue`, `lock %h`, `lock &sub` are all valid.

Under pperl, `lock` accepts its argument and returns - no mutex, no blocking. See the `lock` reference page for the full behaviour and the *Differences from upstream* note.

Races

The canonical race:

```
use threads;
use threads::shared;

my $x :shared = 1;
my $t1 = threads->create(sub { my $foo = $x; $x = $foo + 1 });
my $t2 = threads->create(sub { my $bar = $x; $x = $bar + 1 });
$t1->join; $t2->join;
print $x, "\n";         # 2 or 3 - depends on scheduling
```

Two threads read `$x`, compute a new value, and write back. If both reads land before either write, both writes store the same value and one increment is lost. Even `$x++` on a shared scalar is not atomic.

The fix is to hold the lock across the read-modify-write:

```
{
    lock $x;
    $x++;
}
```

Under pperl this problem does not arise because auto-parallelisation does not expose shared mutable state to user code. The analyser declines to parallelise anything that writes a non-reduction global. See *Parallel Execution*, section *How reduction detection works*.

Deadlocks

Two threads, two locks, acquired in opposite order:

```
my $x :shared = 4;
my $y :shared = 'foo';

threads->create(sub { lock $x; sleep 1; lock $y })->join;
threads->create(sub { lock $y; sleep 1; lock $x })->join;
# Both threads wait forever.
```

The standard defences:

- **Fixed lock order.** Every thread that needs multiple locks acquires them in the same global order. Always `$x` before `$y`.
- **Short critical sections.** Hold a lock only for the work that must be serialised, not for anything else.
- **Fewer locks.** Protect the whole structure with one lock rather than one per field.

Queues - the preferred communication channel

`Thread::Queue` is a thread-safe FIFO. Producer threads enqueue, consumer threads dequeue, and the queue handles all synchronisation internally:

```
use threads;
use Thread::Queue;

my $q = Thread::Queue->new;
my $worker = threads->create(sub {
    while (defined(my $item = $q->dequeue)) {
        handle($item);
    }
});

$q->enqueue($_) for @tasks;
$q->enqueue(undef);     # sentinel: tell worker to stop
$worker->join;
```

dequeue blocks when the queue is empty. Enqueueing `undef` (or any agreed sentinel) is the conventional shutdown signal.

Queues replace most explicit `lock` / `cond_wait` patterns in modern Perl threaded code. They are harder to get wrong.

Under pperl the equivalent shape is a straight Perl array processed by a data-parallel loop, or a compiled `map`/`grep` - see *Alternatives*.

Semaphores

`Thread::Semaphore` is a counter with blocking down and up:

```
use threads;
use Thread::Semaphore;

my $sem = Thread::Semaphore->new(4);    # 4 concurrent I/O slots

sub do_io {
    $sem->down;
    # ... perform I/O; at most 4 threads here at once ...
    $sem->up;
}
```

With a starting count of 1, a semaphore behaves like a mutex but must be released explicitly - unlike `lock`, which is scope-released. Starting counts above 1 model pools of identical resources: a quota of concurrent open files, a number of allowed simultaneous HTTP calls, and so on.

Condition variables

`cond_wait` and `cond_signal` - paired with `lock` on a shared scalar - let one thread wait for another to signal a state change. They resemble POSIX `pthread_cond_wait` / `pthread_cond_signal`. For the overwhelming majority of cases a queue does the same job more simply; reach for condition variables only when a queue does not fit the data shape.

Process-scope side effects

Even with nothing shared at the Perl level, threads share the OS process. Anything that changes process state changes it for every thread:

- `chdir` - current working directory
- `chroot` - root directory, unrecoverable
- `umask` - default file mode mask
- `setuid` / `setgid` - effective user / group
- Signal dispositions - there is no per-thread signal mask in Perl

This is a classic source of "mysterious" cross-thread effects in otherwise shared-nothing code. Both upstream and pperl inherit this from the OS.

Differences from upstream

pperl has no `threads` module, so everything on this page runs in a single interpreter. `threads::shared`, `Thread::Queue` and `Thread::Semaphore` are not part of pperl; where a system perl5 provides them on `@INC` they load, the `:shared` attribute is accepted, and `cond_wait`, `cond_signal` and `lock` are no-ops. This matches upstream's behaviour under a build without thread support.

pperl exposes parallelism at a different layer - the JIT compiler dispatches eligible loop bodies across a Rayon thread pool, with automatic analysis of counter variables, reduction accumulators, and side effects. No user-visible synchronisation primitives are needed because the analyser refuses to parallelise any loop whose body is not trivially independent. See *Parallel Execution* for the details and *Alternatives* for the pperl-native patterns.

- `fork` - process-level concurrency with no shared memory

Alternatives to ithreads

pperl does not implement Perl's interpreter threads. That sounds like a loss until you look at *why* most programs reach for threads. Almost every upstream ithreaded program falls into one of three shapes:

- **Parallel compute over data** - "apply this function to each element of this large array, as fast as you can."
- **Parallel I/O** - "perform these N independent network or filesystem calls concurrently."
- **Background work with isolated state** - "run this task to the side, with no shared memory, and wait for the result."

pperl has a dedicated, better-performing answer for each.

Decision table

Your goal	Upstream tool	pperl-native answer
Parallelise a compute-heavy loop	`threads` + work-crew pattern	Auto-parallelisation (JIT + Rayon)
Transform a large list with `map` / `grep`	Work-crew thread pool	Compiled `map` / `grep`, or a data-parallel loop
Run I/O-bound tasks concurrently	`threads` + `Thread::Queue`	*Coroutines* with an event loop, or `fork` with pipes
Isolate a subtask with its own state	Detached thread	`fork`
Produce/consume pipeline	`threads` + `Thread::Queue` chain	`Coro::Channel` between *coroutines*, `fork` + pipes, or a sequential iterator
Synchronised counter	`:shared` + `lock`	Sequential accumulator + parallel reduction

Auto-parallelisation for compute loops

pperl's JIT detects loops whose bodies are free of I/O, global writes, and impure calls, then dispatches the loop body across a Rayon work-stealing pool. A scalar-accumulator like `$sum += ...` is recognised as a reduction and combined after all iterations finish.

```
my $sum = 0;
for my $i (1 .. 10_000_000) {
    $sum += $i * $i % 7;
}
print $sum, "\n";
```

Under pperl this compiles to a single Rayon-dispatched loop body. On a typical 8-core machine the speedup is in the 5-6x range over the sequential JIT, with no user-visible thread objects, no synchronisation code, and no shared state.

See *Parallel Execution* for the full story - what qualifies, how reduction detection works, and the CLI flags (`--no-parallel`, `--threads=N`, `--parallel-threshold=N`) that control the behaviour.

Porting a work-crew ithreaded loop typically means **deleting the threading code**. The sequential form is often the pperl-optimal form already.

Before:

```
use threads;
use threads::shared;

my $sum :shared = 0;
my @chunks = chunk_data(\@big);
my @workers = map {
    my $c = $_;
    threads->create(sub {
        my $local = 0;
        $local += process($_) for @$c;
        lock $sum; $sum += $local;
    });
} @chunks;
$_->join for @workers;
```

After:

```
my $sum = 0;
$sum += process($_) for @big;
```

The chunking, the per-thread accumulator, the lock - all gone. The JIT does the chunking. The reduction detector handles the accumulator. There is no shared variable to lock.

map and grep at native speed

For list-shaped transformations, the built-ins are already the natural idiom:

```
my @results  = map  { $_ * $k + 1 } @input;
my @filtered = grep { $_ % 7      } @input;
```

When the block is a pure expression, pperl compiles the whole map/grep to a native loop (see *Writing fast pperl*). This runs on one core - array state gates parallel dispatch off - but several times faster than the interpreted op machinery. When the work per element is a heavy NUMERIC computation, restructure as an index-range `for` loop with a reduction and the parallelizer can take it across cores.

Equivalent ithreaded code would involve a thread pool, an input queue, an output queue, a sentinel value to signal end-of-input, and per-thread accumulators.

fork - process-level concurrency

When work is **not** a pure compute loop - it involves I/O, subprocess management, or genuinely independent state - reach for `fork`. A forked child has:

- A full copy of the parent's memory, copy-on-write at the OS level.
- Its own file descriptor table (with shared underlying file descriptions).
- Complete isolation at the interpreter level - no shared Perl heap, ever.

```
my $pid = fork;
die "fork: $!" unless defined $pid;
if ($pid == 0) {
    # child
    exec 'processing-tool', @args
        or die "exec: $!";
}
# parent
waitpid $pid, 0;
```

Communication uses pipes, sockets, or the filesystem - the same inter-process primitives you would use between unrelated programs. That sounds heavier than in-process threading, and at the raw syscall level it is; but for program structure it is often simpler because there is no shared memory to guard.

Forking a work crew

The upstream `threads::shared` work-crew in the previous section translates to a fork-based equivalent when the work involves I/O:

```
my @pids;
for my $chunk (@chunks) {
    my $pid = fork // die "fork: $!";
    if ($pid == 0) {
        process_chunk($chunk);
        exit 0;
    }
    push @pids, $pid;
}
waitpid $_, 0 for @pids;
```

Results flow back through pipes, files, or a named collection point in `/tmp`. Whatever you would have used between separate programs.

Pipeline via fork and pipes

For pipeline-shaped workloads, Perl's open with a `|-` or `-|` form spawns a child with a pipe already attached:

```
open my $producer, '-|', 'find', '/data', '-type', 'f'
    or die "fork: $!";
```

(continues on next page)

(continued from previous page)

```
while (my $path = <$producer>) {
    chomp $path;
    # filter / process / forward
}
close $producer;
```

Each pipeline stage is its own process, scheduled by the OS, with no shared Perl state.

Isolated background work

The upstream pattern of `threads->create(sub { ... })->detach` - fire and forget - maps to a double-fork:

```
my $pid = fork // die "fork: $!";
if ($pid == 0) {
    # first child: fork again and exit immediately, orphaning
    # the grandchild to init so the parent does not have to wait
    my $grand = fork // die "fork: $!";
    exit 0 if $grand != 0;
    background_work();
    exit 0;
}
waitpid $pid, 0;    # reap the first child, not the grandchild
```

The grandchild runs to completion independently of the original program, no zombie is left behind, and state isolation is absolute.

Coroutines for work that waits

When the threads were there because each task spends most of its time *waiting* - on a socket, a timer, a child process - coroutines keep the thread-per-task structure without threads. Each task is a coroutine with its own call stack and lexicals, written as straight-line code; a wait blocks only that coroutine, and an event loop wakes it. Work crews fed from a `Thread::Queue` become coroutines fed from a `Coro::Channel`, and the `:shared` attributes and locks go away, since only one coroutine runs at a time. See *Coroutines and event loops*.

Choosing between them

- **Auto-parallelisation** wins for compute-bound loops over in-memory data: no process startup cost, no serialisation of results, JIT-compiled body.
- **Coroutines** win for many concurrent waits in one program - network clients and servers, timers, pipelines of I/O stages - with no copying and no locking, on one CPU.
- **fork** wins for subprocess work, for using several CPUs on work that is not a parallelisable loop, and for anything where the task should not inherit the parent's global state changes.

- **None of them** is the right answer for low-cost task dispatch in tight loops - the usual culprit there is a sequential loop that does not actually benefit from concurrency. Measure before adding any layer.

Reference cross-links

- `lock` - the only ithreads primitive with a reference page. Its *Differences from upstream* section is the canonical statement of pperl's divergence.
- `fork` - process-level concurrency, fully supported under pperl.
- `wait` - reap a child process.
- *Parallel Execution* - pperl's auto-parallelisation.
- *Coroutines and event loops* - Coro, EV, Event and AnyEvent, for tasks that wait.
- *Reference* - threading support is a runtime-level topic.

4.2.3 Regular expressions

A regular expression (regexp, regex) is a pattern that decides whether a string has a given shape, or pulls pieces out of a string that does. Perl treats regexps as a first-class sublanguage: they appear wherever you match (`m//`), substitute (`s///`), quote a pattern (`qr//`), or split on a separator (`split`).

This guide is the definitive pperl reference for regex. Each chapter covers one topic in three layers: an overview that orients you, a precise reference that defines what the construct does, and the gory details - corner cases, performance pathologies, and the

cross-engine differences that surprise a Perl-trained reader. The same chapter serves the reader who needs a one-paragraph answer and the reader who wants to know exactly when a pattern will misbehave.

Who this is for

Readers who know Perl well enough to use scalars, arrays, and hashes, but treat regexps as something to copy from elsewhere and hope works. After reading, you will read an unfamiliar pattern and know what it will match - and when it will refuse, and why.

How this guide is organised

The chapters are meant to be read in order on a first pass, but each stands on its own for later reference.

Basics

The smallest useful regexp is a plain string. `"Hello World" =~ /World/` asks: does the string on the left contain the pattern on the right? It does, so the expression is true.

```
if ("Hello World" =~ /World/) {
    print "matched\n";
}
```

The `//` enclose the pattern. The `=~` operator binds the pattern to the string you want to test. Without a binding operator, Perl applies the pattern to `$_` instead.

The match operator

The long form is `m//`:

```
"Hello World" =~ m/World/;
"Hello World" =~ m!World!;    # alternate delimiters
"Hello World" =~ m{World};    # paired delimiters
```

`m` lets you pick any delimiter. That matters when the pattern itself contains the default delimiter `/` - compare

```
"/usr/bin/perl" =~ /\/usr\/bin\/perl/;  # leaning toothpick syndrome
"/usr/bin/perl" =~ m!/usr/bin/perl!;    # clearer
```

Paired delimiters (`{}`, `()`, `[]`, `<>`) nest, which is useful when the pattern contains the delimiter character.

Without `m`, the leading slash is required: `/pat/` only. With `m`, the leading `m` is required: `m{pat}`, not `{pat}`.

A small but useful corner: `m''` (single quotes as delimiters) makes the pattern *single-quotish* - no variable interpolation, no doublequote escapes. Useful when the pattern is meant to contain literal `$` or `@` and you don't want to escape them.

```
'price: $10' =~ m'\$\d+';      # $-as-anchor would be /$\d+/
'price: $10' =~ m'$10';        # literal '$10' - no interpolation
```

Other regex operators

`m//` is one of four:

Operator	Purpose
`m//`	match - does the pattern match the string?
`s///`	substitute - replace the match with something else
`qr//`	compile a pattern object for reuse
`tr///` (also `y///`)	character-by-character translation

`tr///` is *not* a regex operator despite living in the same neighbourhood - it does character-class translation, not pattern matching. It is mentioned for completeness; see `tr` for its semantics.

`m`, `s`, and `qr` all share the regex syntax covered in this guide. The differences are in what they do *with* a successful match.

Pattern reuse with `qr//`

`qr//` compiles a pattern once and produces a reusable object. Use it when the same pattern is matched repeatedly, especially in loops:

```
my $word = qr/\b[a-z]+\b/;

for my $line (@lines) {
    while ($line =~ /$word/g) {
        print "$&\n";
    }
}
```

The compiled `qr//` object is dropped into other patterns by interpolation. It also lets you build patterns out of named pieces, which becomes essential for any regex over about ten lines:

```
my $name   = qr/[A-Z][a-z]+/;
my $number = qr/\d+/;
my $entry  = qr/$name \s+ $number/x;

"Alice 42" =~ /^$entry$/;   # matches
```

The same compile-once benefit, expressed at the right level of abstraction.

Binding: `=~` and `!~`

`=~` asks “does it match?”. `!~` asks “does it fail to match?”.

```
$s = "Hello World";

print "yes\n" if $s =~ /World/;   # yes
print "no\n"  if $s !~ /planet/;  # no
```

`!~` is not a separate regexp construct - it is the negated binding. It is equivalent to `not ($s =~ /pat/)`.

Matching against $_

If you omit the binding, the match is against `$_`:

```
for ("cat", "dog", "bird") {
    print "has an 'o'\n" if /o/;   # implicit: $_ =~ /o/
}
```

This is idiomatic in `while (<>)` loops, inside `grep` and `map`, and inside `for` loops that set `$_`.

Case sensitivity and the default anchor

Matches are case-sensitive and unanchored:

```
"Hello" =~ /hello/;    # does not match - case differs
"Hello" =~ /ell/;      # matches - inside the string is fine
```

To match case-insensitively, append `/i`. To constrain the match to the start or end of the string, use anchors. Both are covered in their own chapters.

When a pattern could match at several positions, Perl tries from the left and takes the first one that works:

```
"That hat is red" =~ /hat/;   # matches 'hat' in 'That', not in 'hat
↪'
```

The "leftmost match wins" rule is fundamental and pre-empts every other match preference: a match at an earlier position is always better than a match at a later position, regardless of what choices either match makes internally. This is sometimes called the *bump-along property*: the engine tries to match at position 0; if it fails, it bumps to position 1; if it fails, position 2; and so on, returning the first success.

Metacharacters

Most characters in a pattern match themselves. These do not:

```
{ } [ ] ( ) ^ $ . | * + ? \
```

Two more are special only in specific contexts:

- `-` is a metacharacter only inside a character class, where it forms a range (`[a-z]`). Outside `[…]` it is literal.
- `#` is a metacharacter only under the `/x` flag, where it introduces a comment to end of line. Without `/x` it is literal.

Each metacharacter has a special meaning covered later. To match a literal copy of one, put a backslash in front:

```
"2+2=4" =~ /2+2/;    # fails - '+' is a quantifier, needs escaping
"2+2=4" =~ /2\+2/;   # matches

"end." =~ /end\./;   # matches a literal dot
"end." =~ /end./;    # also matches - but . matches any character,
                     # so this would also match "endx", "end ", etc.
```

The backslash itself is a metacharacter, so a literal backslash in a pattern needs `\\`:

```
'C:\WIN32' =~ /C:\\WIN/;    # matches
```

A metacharacter that has nothing special to do in its context reverts to matching itself. `}` only closes a `{...}` quantifier; outside that context it is a literal `}`. This is convenient but easy to misread; see *Strict mode* below.

Strict mode: `use re 'strict'`

`use re 'strict'` turns previously-tolerated regex sloppiness into compile-time errors. Use it when you want the regex compiler to flag patterns that *probably* mean something different from what you wrote:

```
use re 'strict';

/abc{,1/;        # error: unescaped '{' in non-quantifier context
/(?-p)/;         # error: useless negation of always-on flag
/[a-]/;          # error: dash at end of class
```

Strict mode is per-lexical-scope, so it can be turned on for regex-heavy modules without affecting other code. It is not default because it would break working older patterns; new code should consider it.

Escape sequences

Non-printing characters use the same escapes as in double-quoted strings:

Sequence	Matches
`\t`	tab
`\n`	newline
`\r`	carriage return
`\f`	form feed
`\a`	alert (bell)
`\e`	escape (`\x1B`)
`\0`	NUL byte
`\xHH`	byte with hex value HH
`\x{...}`	Unicode codepoint with hex value
`\o{...}`	octal codepoint
`\cX`	control-X
`\N{...}`	Unicode character by name

```
"1000\t2000" =~ /0\t2/;      # matches
"a\x{263a}b" =~ /\x{263a}/;  # matches U+263A, WHITE SMILING FACE
```

The full Unicode story is in the *unicode* chapter.

Variables in patterns

A pattern is (by default) interpolated like a double-quoted string, so variables are substituted before matching:

```
my $word = "house";
"housecat" =~ /$word/;       # matches
"housecat" =~ /${word}cat/;  # matches - braces disambiguate
```

To match a literal `$` or `@`, escape it:

```
'price: $10' =~ /\$10/;      # matches a literal dollar sign
```

If a user-supplied string will be interpolated into a pattern and you want its metacharacters treated literally, use `quotemeta` - or its in-pattern equivalent `\Q…\E`:

```
my $input = "1+1";
"1+1=2" =~ /\Q$input\E/;     # matches the literal string
```

Without `\Q…\E` the `+` would be read as a quantifier.

How a regex is read

Perl reads a regex pattern in four phases. Knowing the phases explains a few "why does that work?" questions:

1. **Phase A**: the parser identifies the delimiter and finds the end of the pattern. `(?#…)` comments are removed.
2. **Phase B**: the pattern is parsed as a *double-quotish string* - variables interpolate, escape sequences cook, `\Q…\E` translates to `quotemeta`-style escaping.
3. **Phase C**: under `/x` or `/xx`, unescaped whitespace and comments after `#` are stripped.
4. **Phase D**: the regex compiler reads the result and turns it into the engine's internal form.

The order matters because phases B and D operate on different representations. `\Q$dir\E` cooks at Phase B, before the regex compiler sees it - by Phase D, the variable's contents are already escaped, and the regex compiler sees a literal pattern. Conversely, `\U…\E` is interpreted by Phase B as a string-cook directive (uppercase the contents), which is almost certainly *not* what you want inside a regex. The convention is: `\Q` and `\E` for regex purposes; `\U`, `\L`, `\u`, `\l` only when you know what you are doing.

`(?#comment)` is removed before Phase B sees the pattern at all. A literal `#` inside `(?#…)` is fine. A literal `)` is not - the comment ends at the first `)`.

Earliest match wins - the bump-along

Friedl puts it precisely:

> The match that begins earliest wins.

Position 0 is tried first, then 1, then 2, and so on. The engine *never* prefers a later, longer, or "more aesthetic" match over an earlier one. This is so foundational it shapes every other rule in this guide:

- "Greedy quantifiers grab as much as possible" - *at the current starting position.* The grabbing happens after the bump-along has chosen the position.
- "Leftmost alternative wins" - *at the current starting position.* The alternative chosen affects what is captured but not where the match starts.
- Anchors like ^ constrain *what positions are legal*, not what is preferred among legal ones.

Say what you mean

Friedl's recurring point: vagueness in the regex causes both correctness problems and performance problems. The example he hammers:

```
/-?[0-9]*\.?[0-9]*/
```

Read as English: "an optional sign, optional digits, optional decimal, optional digits." Read as code: every part is optional, so the pattern *matches the empty string* - at the start of any input, before the engine has even looked. Apply it to "nothing here" and it matches at position 0, capturing the empty string, returning success.

The fix is to require at least one digit on at least one side of the decimal:

```
/-?[0-9]+(\.[0-9]*)?|-?\.[0-9]+/
```

Two alternatives, each requiring at least one digit. The pattern now matches what its author intended.

The lesson generalises. A pattern that *can* match the empty string usually *will* match the empty string somewhere. If your match has to mean something, write requirements that force it to mean something.

Substitution at a glance

Replacing text uses the `s///` operator, which takes a pattern and a replacement string:

```
my $x = "feed the cat";
$x =~ s/cat/dog/;            # $x is now "feed the dog"
```

Substitution is covered in depth in its own chapter; it is mentioned here so you can combine it with the facts above. Most everything that applies to `m//` patterns applies inside `s///` patterns too.

Where to go next

Literal matches get you surprisingly far, but every real regexp uses character classes, anchors, or quantifiers. Character classes come next - they let one position in the pattern accept any of several characters.

If you are reading the guide for a specific question, the chapters are independent and the *index* lists them all. Patterns that read fine but run for hours are covered in *performance* - when in doubt, the answer is usually there.

- The *performance* chapter - what could go wrong.

Character classes

A character class matches exactly one character, chosen from a set you define. Where a literal `a` matches only `a`, the class `[abc]` matches any one of `a`, `b`, or `c`.

```
/cat/;               # matches 'cat'
/[bcr]at/;           # matches 'bat', 'cat', or 'rat'
/item[0123456789]/;  # matches 'item0' through 'item9'
```

The class still consumes one character of the string. `[bcr]at` never matches `at` (no letter present) and never matches `brat` (two letters where the class expects one).

Ranges

Inside `[...]`, a dash between two characters denotes a contiguous range in the underlying character set:

```
/[0-9]/;         # any ASCII digit
/[a-z]/;         # any ASCII lowercase letter
/[a-zA-Z]/;      # any ASCII letter
/[0-9a-fA-F]/;   # any hex digit
```

Ranges can be combined with individual characters:

```
/[0-9bx-z]aa/;   # matches '0aa'..'9aa', 'baa', 'xaa', 'yaa', 'zaa'
```

A dash that is first or last inside the class is literal:

```
/[-ab]/;         # matches '-', 'a', or 'b'
/[ab-]/;         # same
```

Negation

A caret ^ as the first character inside `[...]` inverts the class:

```
/[^a]/;          # any character except 'a'
/[^0-9]/;        # any non-digit
```

A caret elsewhere is literal:

```
/[a^]/;          # matches 'a' or '^'
```

A negated class still matches *one* character - `[^a]` does not match the empty string; it requires one non-a.

Special characters inside a class

Inside `[...]` the special set shrinks to - `]` `\` `^` `$` (and the pattern delimiter). The others - `.`, `*`, `+`, `?`, `(`, `)`, `{`, `}`, `|` - are literals in a class:

```
/[.+*]/;         # matches a literal '.', '+', or '*'
/[()]/;          # matches '(' or ')'
```

To match `]` inside the class, either escape it or put it first (after any leading ^):

```
/[\]]/;          # matches ']'
/[]ab]/;         # matches ']', 'a', or 'b'
```

`$` and `\` are slightly awkward because they interact with interpolation and escaping:

```
my $x = 'bcr';
/[$x]at/;        # matches 'bat', 'cat', or 'rat' - interpolated
/[\$x]at/;       # matches '$at' or 'xat' - '$' is literal
/[\\$x]at/;      # matches '\at' plus interpolation of $x
```

`\b` inside a character class means *backspace* (`\x08`), not "word boundary". Outside a class it is the word boundary assertion. This is the single most common dual-meaning trap in the regex syntax - see the *anchors and assertions* chapter for the boundary form.

Shorthand classes

Several common classes have shorthand names usable both inside and outside `[...]`:

Shorthand	Matches
`\d`	a digit
`\D`	a non-digit
`\w`	a word character (alphanumeric or _)
`\W`	a non-word character
`\s`	whitespace (space, tab, `\r`, `\n`, `\f`, more)
`\S`	non-whitespace
`\h`	horizontal whitespace (space, tab, Unicode)
`\H`	non-horizontal-whitespace
`\v`	vertical whitespace (`\n`, `\r`, `\f`, ...)
`\V`	non-vertical-whitespace
`\R`	linebreak: `\r\n`, `\n`, `\v`, `\f`, `\x{85}`, ...
`\N`	any character except `\n` (regardless of `/s`)

Under Unicode (the default), `\d`, `\w`, `\s` match more than just ASCII. `\d` matches any Unicode digit (Devanagari digits, Arabic-Indic digits, and many more), `\w` matches any letter in any script plus marks and connector punctuation, and `\s` adds Unicode space characters such as non-breaking space.

To restrict these to ASCII, add the `/a` modifier or use explicit ranges like `[0-9]` and `[A-Za-z_0-9]`.

```
"item0" =~ /\w\w\w\w\d/;      # matches
"abc\x{0660}" =~ /\w\w\w\d/; # matches: U+0660 is an Arabic-Indic␣
 ↪zero
"abc\x{0660}" =~ /\w\w\w\d/a;# does not match under /a
```

`\R` is the linebreak shorthand - it matches any of the recognised line-break sequences as one token. Useful for parsing text that may have CRLF, LF, or rarer line terminators interchangeably. Unlike a class, `\R` may match *two* characters (the CRLF case) and so cannot appear inside `[…]`.

`\N` (uppercase) means "any character except `\n`", and is *not* affected by the `/s` modifier. This is the dual meaning to be careful of: `\N{NAME}` (with brace) is a Unicode named-character escape (see the *unicode* chapter); bare `\N` is the non-newline class.

The period

`.` matches any single character except newline. Under the `/s` modifier (covered in the *modifiers* chapter), `.` also matches newline:

```
"a\nb" =~ /a.b/;        # does not match
"a\nb" =~ /a.b/s;       # matches
```

When you want "any character including newline" without `/s`, the classic idiom is `[\s\S]` (or `[\d\D]`):

```
"a\nb" =~ /a[\s\S]b/;   # matches without /s
```

The trick is that any character is either a whitespace or a non-whitespace; the class covers both.

Composing classes

You can mix shorthands, ranges, and individual characters inside one class:

```
/[\d\s]/;        # a digit or whitespace
/[A-Z\d_]/;      # uppercase letter, digit, or underscore
/[a-zA-Z\d]/;    # letter or digit (ASCII)
```

De Morgan's law matters: `[^\d\w]` is *not* `[\D\W]`. The first requires the character to be *both* non-digit and non-word. But every digit is a word character, so `[^\d\w]` simplifies to `[^\w]`, i.e. `\W`. Be careful when combining negated shorthands.

POSIX classes

POSIX character classes use the form `[:name:]` and only work inside `[…]`:

POSIX	Equivalent
`[:alpha:]`	alphabetic
`[:alnum:]`	alphanumeric
`[:digit:]`	digit (like `\d`)
`[:word:]`	word char (Perl extension)
`[:space:]`	whitespace (like `\s`)
`[:upper:]`	uppercase
`[:lower:]`	lowercase
`[:xdigit:]`	hex digit
`[:ascii:]`	0x00–0x7F
`[:cntrl:]`	control character
`[:graph:]`	printable, not space
`[:print:]`	printable, including space
`[:punct:]`	punctuation
`[:blank:]`	space or tab

Negate a POSIX class with ^ *inside* the colons:

```
/[[:^digit:]]/;   # same as \D
/[[:alpha:][:digit:]]/;  # letter or digit - equivalent to \w minus
↪'_'
```

POSIX classes follow the same Unicode-vs-ASCII rules as the shorthands: without `/a`, `[:alpha:]` is the Unicode alphabetic set.

POSIX also defines two related constructs that are rarely implemented:

- **Collating elements** `[.span-ll.]` - match a multi-character collation element as a single unit (e.g. Spanish `ll` historically).
- **Equivalence classes** `[[=n=]]` - match any character that is equivalent under the locale's collation rules (e.g. accented variants of n).

Perl recognises the syntax but treats both forms as the literal characters. In practice no portable script relies on these; they are documented for completeness.

Unicode properties

Unicode defines thousands of properties. The notation is `\p{Name}` for "has this property" and `\P{Name}` for "does not have this property":

```
/\p{Lu}/;              # any uppercase letter, any script
/\p{Greek}/;           # any character in the Greek script
/\p{Number}/;          # any numeric character
/\P{ASCII}/;           # any non-ASCII character
```

Short single-letter aliases exist for common properties and drop the braces: `\pL` is a letter, `\pN` a number, `\pP` punctuation. `\p{L}` is the same as `\pL`.

The *unicode* chapter covers properties in detail, including the compound form `\p{Name=Value}`, the `\X` grapheme cluster, and the charset modifiers `/a`, `/u`, `/l`, `/d`.

Extended bracketed classes - `(?[ ])`

The standard `[...]` syntax handles unions ("any of these characters") well but does not have set operations on classes. The extended form `(?[ ... ])` does:

Operator	Meaning
+ or |	union (the same characters either operand has)
&	intersection (in both)
-	difference (in left, not in right)
^	symmetric difference (in one but not both)
!	complement (everything except)

Whitespace inside `(?[...])` is ignored, so the operators read as arithmetic.

```
# Greek letters only:
/(?[ \p{Greek} & \p{Letter} ])/;

# Letters that are not Latin:
/(?[ \p{Letter} - \p{Latin} ])/;

# Hex digit, but not 'a' through 'f':
/(?[ [0-9A-Fa-f] - [a-f] ])/;
```

The construct is most useful when combining Unicode properties that overlap. Without it, the same expressions would require verbose lookaround or out-of-pattern logic.

`(?[...])` is itself a character class - it consumes one character and can be quantified:

```
/(?[ \p{Letter} & \p{ASCII} ])+ /x;   # ASCII letters
```

Caveat: `(?[...])` is its own little parser inside the regex parser. Inside it, only specific operators and operands are recognised. Mistakes produce specific compile-time errors, which in turn means *strict mode* (`use re 'strict'`) catches more bad class expressions when you use the extended form.

Negated class beats .*?

A common newcomer pattern: use .*? (non-greedy .) to match everything up to a delimiter, like <.*?>. The pattern works on the inputs you tested it on; on adversarial input it does not.

```
"<a> </a>"      =~ /<.*?>/;        # matches '<a>' - fine
"<a> <b>foo"    =~ /<.+?>foo/;     # matches '<a> <b>foo' - bad
```

In the second case the engine first matched <a>, then needed foo but found a space. Under that backtracking pressure the non-greedy .+? was forced to expand, gladly consuming the > of <a> and the space until foo lined up. The negated character class cannot give ground that way:

```
"<a> <b>foo" =~ /<[^>]+>foo/;      # matches '<b>foo' - [^>]+␣
↪refuses to cross '>'
```

Two reasons to prefer [^>]+ over .+? whenever the delimiter is a single character:

1. **Correctness**: the negated class is a hard barrier; the non-greedy form is a preference.
2. **Performance**: a negated class participates in the simple-repetition optimisation; .+? does not (the engine has to leave the inner loop on every iteration to test what follows). On long inputs this matters.

Worked example: an IP-address regex

The canonical "specificity vs. complexity" exercise. Five iterations, each fixing one category of vagueness:

1. Naive. "Four dot-separated digit groups."

```
/[0-9]*\.[0-9]*\.[0-9]*\.[0-9]*/;
```

Matches and then . . . . ? happily - every digit run is optional, so the pattern is satisfied by three dots and nothing else.

2. Require digits. Anchor the pattern.

```
/^[0-9]+\.[0-9]+\.[0-9]+\.[0-9]+$/;
```

Matches 1234.5678.9101112.131415. Each group has digits but no upper bound on count.

3. Bound the digit count, badly.

```
/^\d{3}\.\d{3}\.\d{3}\.\d{3}$/;
```

Matches 192.168.001.001 but rejects 1.2.3.4 - leading zeros not always written.

4. Allow 1 to 3 digits.

```
/^\d{1,3}\.\d{1,3}\.\d{1,3}\.\d{1,3}$/;
```

Now matches `1.2.3.4` and rejects `1234.5.6.7`. But it also matches `999.999.999.999` - beyond the 0–255 range.

5. Range-correct.

```
/^(?:25[0-5]|2[0-4]\d|[01]?\d\d?)\.
   (?:25[0-5]|2[0-4]\d|[01]?\d\d?)\.
   (?:25[0-5]|2[0-4]\d|[01]?\d\d?)\.
   (?:25[0-5]|2[0-4]\d|[01]?\d\d?)$/x;
```

Each group is one of: `25[0-5]` (250–255), `2[0-4]\d` (200–249), or `[01]?\d\d?` (0–199 in various forms). The pattern now matches *exactly* the strings that name a syntactically-valid IPv4 address.

The lesson is not "memorise this regex". It is the *progression*: each iteration tightened a specific kind of vagueness. The right regex for a problem is the one that admits exactly the right inputs and rejects everything else, and you only get there by asking what the *previous* regex actually allowed.

Cross-engine: shorthand classes

The `\d`, `\w`, `\s` shorthands are not portable. The *cross-engine* chapter has the full table; the relevant rows extracted:

Shorthand	Perl 5.44 (default)	PCRE	Emacs	POSIX BRE / ERE	RE2 / Go (default)
`\d`	ASCII (or Unicode under `/u`)	ASCI	NO (use `[0-9]` or `[[:digit:]]`)	NO	ASCII; Unicode under `(?u)`
`\w`	ASCII or Unicode	ASCI	yes (syntax-table-driver	NO	ASCII; Unicode under `(?u)`
`\s`	ASCII or Unicode	ASCI	yes	NO	ASCII; Unicode under `(?u)`
`\b` word boundary	yes	yes	yes (`\</\>` traditional)	NO	yes
`\h`, `\v`	yes	yes	NO	NO	NO

Two things to internalise:

1. POSIX BRE and ERE lack `\d`, `\w`, `\s` entirely. Portable shell scripts use `[0-9]`, `[[:alnum:]_]`, `[[:space:]]`.
2. Emacs has `\w` and `\s` but no `\d`. Emacs's `\s` syntax is *followed by* a syntax-class character (`\s-` for whitespace, `\sw` for word) - unique to Emacs.

POSIX bracket classes (`[[:digit:]]`, `[[:alpha:]]`, ...) are the universal portable spelling: every engine in the comparison recognises them.

A useful habit

Named and shorthand classes are almost always clearer than explicit ranges. `\d{4}-\d{2}-\d{2}` reads; `[0-9]{4}-[0-9]{2}-[0-9]{2}` needs a moment. Use the ranges only when you have a concrete reason - usually performance in a hot loop, or deliberately restricting to ASCII.

See also

- The *unicode* chapter - `\p{…}`, `\P{…}`, `\X`, the charset modifiers `/a`, `/u`, `/l`, `/d`.
- The *anchors and assertions* chapter - `\b` outside a class.
- The *cross-engine* chapter - full table of shorthand support across engines.
- `m` - the match operator.
- `qr` - compile a pattern for reuse.

Anchors and assertions

Anchors and assertions match *positions* rather than characters. They test where in the string you are, not what is there. A plain character class consumes one character; an anchor consumes none.

They are called *zero-width assertions* for that reason - they have width zero, but they assert a property must hold.

Start and end of string

^ matches at the start of the string. $ matches at the end, or just before a final newline.

```
"housekeeper" =~ /keeper/;    # matches - 'keeper' appears somewhere
"housekeeper" =~ /^keeper/;   # does not match - not at start
"housekeeper" =~ /keeper$/;   # matches - at end
"housekeeper\n" =~ /keeper$/; # matches - before the trailing
↪newline
```

Used together, ^…$ forces the pattern to account for the whole string:

```
"bert"    =~ /^bert$/;     # matches
"bertram" =~ /^bert$/;     # does not match
"dilbert" =~ /^bert$/;     # does not match
""        =~ /^$/;         # matches - empty string
```

For a literal string, `$s eq "bert"` is faster and clearer. ^…$ only earns its keep once the middle uses real regexp features.

Absolute versus line-relative anchors

Under the `/m` modifier, ^ and $ anchor at every line boundary inside the string, not just the outer ends:

```
my $x = "There once was a girl\nWho programmed in Perl\n";

$x =~ /^Who/;    # does not match - 'Who' is not at string start
$x =~ /^Who/m;   # matches - 'Who' is at start of second line
```

For the absolute ends *regardless of* `/m`, use the dedicated anchors:

- `\A` - absolute start of string.
- `\z` - absolute end of string.
- `\Z` - end of string, or just before a final newline. Similar to `$` but unaffected by `/m`.

```
$x =~ /^Who/m;    # matches, as above
$x =~ /\AWho/m;   # does not match - \A is string start, always

$x =~ /girl$/m;   # matches, end of first line
$x =~ /girl\Z/m;  # does not match - 'girl' is not at string end
$x =~ /Perl\Z/m;  # matches - end or before final newline
$x =~ /Perl\z/m;  # does not match - \z is strict end
```

Rule of thumb: `\A` and `\z` when you mean the whole string; ^ and `$` when you mean lines (usually with `/m`). `\A` and `\z` are also faster: the engine knows they constrain position, and skips bump-along retries that ^ permits.

The four newline modes can be summarised in a table. Choose the one matching what ^, `$`, and `.` should mean for your input:

Mode	^ matches at	$ matches at	. matches \n?
default	start of string only	end of string (and before final \n)	no
/m	start of every line	end of every line	no
/s	start of string only	end of string (and before final \n)	yes
/sm	start of every line	end of every line	yes

`\A`, `\Z`, `\z` are unaffected by either modifier.

Word boundaries

`\b` matches a position between a word character (`\w`) and a non-word character (`\W`), or between either and the edge of the string. It does not consume any character.

```
my $x = "Housecat catenates house and cat";

$x =~ /cat/;      # matches 'cat' inside 'Housecat'
$x =~ /\bcat/;    # matches 'cat' inside 'catenates'
$x =~ /cat\b/;    # matches 'cat' inside 'Housecat'
$x =~ /\bcat\b/;  # matches the standalone 'cat' at end
```

`\B` is the negation - a position that is *not* a word boundary.

`\b` outside `[…]` is a word boundary. `\b` *inside* `[…]` is the *backspace* character, `\x08`. The dual meaning is the single most common trap in the regex syntax. Always read `\b`'s

context before reading what it does.

\b and \W-starting items - the $3.75 gotcha

\b requires a transition between word and non-word characters. If both sides of the position are non-word characters, there is no boundary. This catches people building patterns by interpolation:

```
my $item = '$3.75';
my $regex = qr/\b\Q$item\E\b/;

"is $3.75 plus tax" =~ /$regex/;   # does NOT match
```

Why? After \Q$item\E cooks, the pattern is \b\$3\.75\b. The engine looks for a position immediately *before* $ where one side of the position is a word character. The character before $ in the input is a space (non-word), and $ itself is also non-word. There is no word/non-word transition; \b fails.

To anchor the start of $item regardless of its first character:

```
my $regex = qr/(?:^|\s)\Q$item\E(?:\s|$)/;
```

Use string-edge or whitespace anchors when the interpolated content might begin with a non-word character. \b is for contexts where you *know* the surrounded text is word-like.

Unicode word-boundary variants

Plain \b follows the \w/\W definition, which under Unicode covers letters, digits, marks, and connector punctuation. Real text - natural language with apostrophes, hyphens, numerics with commas - wants more nuance. Perl provides four semantic boundary variants:

Boundary	Meaning
\b{wb}	Unicode word boundary - handles don't, state-of-the-art
\b{sb}	sentence boundary
\b{lb}	line break (suitable for line wrapping)
\b{gcb}	grapheme-cluster boundary (same effect as \X)

```
"don't" =~ /.+?\b{wb}/x;   # matches whole word - apostrophe is␣
↪inside
"don't" =~ /.+?\b/x;       # stops at the apostrophe - plain \b␣
↪splits
```

For natural-language processing, \b{wb} and \b{sb} are almost always what you want. Plain \b is for ASCII identifier contexts.

`\G` - the last-match position

`\G` anchors at the position where the previous successful `/g` match ended on the same string. It is what makes tokenisation with `/g` in `while` loops robust.

```
my $s = "12abc34";
while ($s =~ /\G(\d+|[a-z]+)/gc) {
    print "got '$1'\n";
}
# prints: '12', 'abc', '34'
```

Without `\G`, the same pattern would re-scan from wherever it first matched, skipping over characters that didn't fit - quietly losing data. The `/gc` modifier preserves the position on failure; covered in the *modifiers* chapter.

Why `\G` matters: the synch-or-skip choice

Friedl's worked example. Find every five-digit ZIP code beginning with 44 in a run-together string:

```
my $s = "06192054410-44272-13901-44106-22134";
while ($s =~ /44(\d{3})/g) {
    print "got 44$1\n";
}
```

Without `\G`, the engine's bump-along is happy to find `44272` and `44106` correctly *and also* find `44272` from a different start position whenever a match earlier was rejected. The output is "right answer plus extra wrong ones".

With `\G` on every iteration, the engine cannot bump-along on failure - it must resume *exactly* where the last match ended. A failure terminates the loop:

```
while ($s =~ /\G\D*(44\d{3})/gc) {
    print "got $1\n";
}
```

`\G` effectively disables the bump-along, which is what synchronised tokenisation demands. The general rule: **if the correctness of your loop depends on every match being adjacent to the last, you need `\G`.**

`\G` reads the value `pos($string)` returns. Setting `pos` explicitly resets the anchor. On the first iteration of a `/g` loop (or any pattern not yet matched against this string), `\G` is equivalent to `\A`.

Lookahead

Lookahead checks what comes next without consuming it. Positive lookahead is `(?=…)`:

```
my $x = "I catch the housecat 'Tom-cat' with catnip";

$x =~ /cat(?=\s)/;   # matches 'cat' in 'housecat' - space follows
$x =~ /cat(?!\s)/;   # matches 'cat' in 'catch' - no space follows
```

`(?!…)` is negative lookahead: match only if the inner pattern does *not* apply. Zero-width, just like `^` and `$`.

```
"foobar" =~ /foo(?!bar)/;   # does not match
"foobaz" =~ /foo(?!bar)/;   # matches
```

Lookahead worked example: digits not followed by a period

A natural-sounding question that is harder than it looks: "match runs of digits not followed by a period."

The first try: `\d+(?!\.)`. Apply it to `OH 44272`:

```
"OH 44272" =~ /\d+(?!\.)/;   # MATCHES, matches '44272'
```

That looks right, but for the wrong reason. Greedy `\d+` first grabbed the entire digit run `44272`; the next character is end-of-string (not `.`), so `(?!\.)` succeeded straight away - the lookahead happened to hold without the engine ever needing to back off. The *intuitive* reading "the run of digits ends with something other than a period" is satisfied for the trailing-digits case, but the next example shows what happens when it doesn't.

Now apply it to `4423.45`:

```
"4423.45" =~ /\d+(?!\.)/;   # matches '442', not '4423'
```

The engine's first try: `\d+` matches `4423`. `(?!\.)` checks the next character: it is `.`, the negative lookahead fails. The engine backtracks: `\d+` matches `442`, the next character is `3`, not `.`, success. The pattern matches `442` - *not* the full digit run before the period. The greedy quantifier was willing to back off to make the lookahead succeed.

The fix: require the lookahead to also reject other digits, so the run cannot back off into "digit followed by digit".

```
"4423.45" =~ /\d+(?![\d.])/;   # matches '45' - correct
```

`\d+(?![\d.])` reads as "match a run of digits not followed by either another digit or a period". The greedy quantifier still expands maximally, but the lookahead now refuses to succeed in the middle of a digit run, so the only matching positions are the actual digit-run ends.

The lesson generalises: **a lookahead that excludes only one character can be defeated by a greedy quantifier backing off**. Always include the characters of the *atom* the quantifier matches in the lookahead's negation.

A related case: leading negative lookahead and the bump-along.

```
"cattle" =~ /(?!cat)\w+/;   # MATCHES, captures 'cattle'
```

The lookahead `(?!cat)` rejects position 0 (where `cat` would match). The engine bumps along: position 1 starts with `attle`, where `(?!cat)` succeeds, and `\w+` matches `attle`.

To force "first word that doesn't begin with `cat`", anchor the lookahead to a word boundary:

```
"cattle" =~ /\b(?!cat)\w+/;   # does not match
```

Now the lookahead applies at every word boundary, which in `cattle` is only position 0.

Lookbehind

Lookbehind checks what came before. Positive lookbehind is `(?<=…)`:

```
"cats and dogs" =~ /(?<=and )dogs/;   # matches 'dogs' after 'and '
```

Negative lookbehind is `(?<!…)`:

```
"prefix_foo suffix_foo" =~ /(?<!prefix_)foo/;
# matches 'foo' in 'suffix_foo'
```

Modern Perl supports variable-length lookbehind from 1 to 255 characters. Patterns like `(?<=cat|kitten)` are fine. Patterns where the lookbehind itself contains capturing groups produce an experimental warning (the captures' contents are not fully-defined when the lookbehind has variable length).

Because the lookbehind must finish before the current position, its maximum length is limited to 255 *characters* under default semantics. Under `/i`, a few characters fold to multi-character sequences (ß to `ss`), which counts the *expanded* length toward the 255 limit - so a 127-character lookbehind containing ß is fine, but 128 such characters is not.

A practical workaround for longer lookbehind: use `\K` (next section), which has no length limit.

`\K` - keep-left

`\K` is the lookbehind alternative. Everything matched *before* `\K` is excluded from `$&`, but is required to have matched. Pragmatically: "match this prefix, but don't include it in the output."

```
"feed the cat" =~ /the \Kcat/;   # matches; $& is 'cat'
```

Equivalent to `(?<=the )cat`, but:

- No length limit. `\K` works after any prefix.
- Often substantially faster than `(?<=…)`, because the engine does not need to look backward - it forgets the start of the match instead.
- Especially useful in substitution: `s/foo\Kbar/QUUX/` is cleaner than `s/(foo)bar/$1QUUX/`.

`\K` only forgets `$&` and `@-`/`@+[0]`; capture groups before `\K` are still set as captured. The construct may appear inside other lookarounds, though the behaviour there is described as "currently not well defined" - the conservative use is at the top level of a match or substitution.

Long-form lookaround aliases

Each lookaround construct has a verb-style spelling. Long-form aliases read more clearly in patterns that already use `(*VERB:…)` for backtracking control:

Standard form	Verb form (short)	Verb form (long)
`(?=…)`	`(*pla:…)`	`(*positive_lookahead:…)`
`(?!…)`	`(*nla:…)`	`(*negative_lookahead:…)`
`(?<=…)`	`(*plb:…)`	`(*positive_lookbehind:…)`
`(?<!…)`	`(*nlb:…)`	`(*negative_lookbehind:…)`

The verb forms are exactly equivalent to the standard forms. They are accepted; they are not idiomatic in handwritten Perl. You will see them in autogenerated patterns and PCRE2 ports.

Combining lookaround with split

Anchors and lookaround let `split` separate a string on invisible positions rather than visible characters:

```
my $str = "one two - --6-8";
my @toks = split / \s+            # whitespace
                 | (?<=\S) (?=-)  # non-space followed by '-'
                 | (?<=-)  (?=\S) # '-' followed by non-space
                 /x, $str;
# @toks = ("one", "two", "-", "-", "-", "6", "-", "8")
```

The second and third alternatives match *between* characters - no consumption. They are legal split separators because split is happy to split on a zero-width match.

Two zero-width assertions juxtaposed are AND-ed

A small but illuminating fact: when two lookarounds appear next to each other in a pattern, both must hold at the same position. This works as expected:

```
$x =~ /^(\D*)(?=\d)(?!123)/;
# Matches the leading non-digit run, but only if a digit follows
# AND that digit run does not begin with '123'.
```

Both `(?=\d)` and `(?!123)` apply at the same position; the engine treats their conjunction as the requirement. Without `(?=\d)`, the negative lookahead `(?!123)` is satisfiable by *any* non-123 continuation - including end-of-string or a non-digit, neither of which is what the author meant.

This generalises Friedl's framing: juxtaposition in a regex always means AND, except when written with `|`. `/ab/` means "a AND (then) b", just as `/^$/` means "start AND end" - except the AND is across positions for `ab` and at one position for the lookarounds.

Cross-engine: anchors and lookaround

The *cross-engine* chapter has the full table; the relevant rows extracted.

Anchors and newline handling

Concern	Perl 5.44	PCRE2	Emacs	POSIX BRE / ERE	RE2 / Go
^ start-of-string	yes	yes	start-of-buffer	yes	yes
^ after \n under multi-line	/m	(?m)	always (line-oriented)	not specified	(?m)
$ end-of-string	yes	yes	end-of-buffer	yes	yes
$ before final \n	yes	yes	no	varies	yes
\A / \z	yes	yes	\` / \'	no	yes
\Z	yes	yes	no	no	no (use \z)
\G	yes	yes	no	no	no

Lookaround and atomic constructs

Feature	Perl 5.44	PCRE2	Emacs	POSIX	RE2 / Go
Lookahead (?=…) / (?!…)	yes	yes	NO	NO	NO
Fixed-width lookbehind	yes	yes	NO	NO	NO
Variable-length lookbehind	yes (exp.)	yes	NO	NO	NO
\K	yes	yes	NO	NO	NO
Atomic group (?>…)	yes	yes	NO	NO	NO

Effectively, only PCRE2 (and other Perl-derived engines outside this table - Java, Python, .NET) supports lookaround. POSIX tools and RE2 / Go simply do not have it. Patterns that rely on lookaround do not port across this divide.

Summary

Anchor	Matches
`^`	start of string, or start of line under `/m`
`$`	end of string (before trailing `\n`), or end of line under `/m`
`\A`	absolute start of string
`\z`	absolute end of string
`\Z`	end of string or before trailing `\n`, ignores `/m`
`\b`	word boundary
`\B`	non-word-boundary
`\b{wb}`	Unicode word boundary
`\b{sb}`	sentence boundary
`\b{lb}`	line break
`\b{gcb}`	grapheme cluster boundary
`\G`	end of previous `/g` match (or `\A` if none)
`(?=…)`	positive lookahead
`(?!…)`	negative lookahead
`(?<=…)`	positive lookbehind
`(?<!…)`	negative lookbehind
`\K`	keep-left (forget the prefix from `$&`)

Quantifiers

A quantifier says "this previous thing, N times." It attaches to a single character, a character class, or a group, and turns a single-character match into a match of many.

```
/a*/;       # zero or more 'a'
/\d+/;      # one or more digits
/colou?r/;  # 'color' or 'colour'
```

The basic quantifiers

Quantifier	Meaning
`a?`	0 or 1 times
`a*`	0 or more times
`a+`	1 or more times
`a{n}`	exactly n times
`a{n,m}`	at least n, at most m
`a{n,}`	at least n
`a{,m}`	at most m

`*`, `+`, and `?` are exact synonyms for `{0,}`, `{1,}`, and `{0,1}`. The brace forms are mostly used when `n` and `m` are specific small numbers; the bare forms read more naturally for "any number of these".

The bounds `n` and `m` cannot exceed an engine-built constant (2147483646 on a 64-bit perl 5.44 - the actual limit appears in the error if you exceed it). For "any sane number" this is plenty; patterns hitting the limit are usually generated, not handwritten.

Whitespace inside `{…}` is tolerated but not required. `a{2, 4}` and `a{2,4}` are identical.

```
/[a-z]+\s+\d*/;             # word, spaces, any number of digits
/y(es)?/i;                  # 'y', 'Y', 'yes', or 'YES'
$year =~ /^\d{2,4}$/;       # 2, 3, or 4 digits
$year =~ /^\d{4}$|^\d{2}$/;# better: exactly 2 or exactly 4
```

The quantifier applies to the atom immediately before it:

- `ab?` - a then optional b.
- `(ab)?` - optional ab.
- `[ab]?` - optional a or b.

Group or class, then quantify.

Greedy by default

Basic quantifiers are *greedy*: they grab as much as the string allows and only give back if the rest of the pattern cannot match otherwise. Consider:

```
my $x = "the cat in the hat";
$x =~ /^(.*)(cat)(.*)$/;
# $1 = 'the '
# $2 = 'cat'
# $3 = ' in the hat'
```

Here `.*` in the middle works as you'd expect - it stops at `cat` because `cat` is the only place where the rest of the pattern can match. Now compare:

```
$x =~ /^(.*)(at)(.*)$/;
# $1 = 'the cat in the h'
```

(continues on next page)

(continued from previous page)

```
# $2 = 'at'
# $3 = ''
```

There are *two* places where `at` occurs - at the end of `cat` and at the end of `hat`. The first `.*` grabs as much as possible while still leaving room for `at` somewhere, so it grabs up to the *last* `at`.

Greedy gives back only what it must

```
"about 24 characters long" =~ /^.*([0-9]+)/;
# $1 = '4'
```

The greedy `.*` first matched the whole string. To make `[0-9]+` match, it had to give back enough characters to expose at least one digit. It gave back exactly one, leaving 4 to capture. The intuition that `.*` "stops at the digits" is wrong - it grabs everything, then the engine asks how little it can return.

Greediness vs. matching

The engine does not always match what the greedy interpretation suggests:

```
"27.625" =~ /(\d\d)([1-9]?)(\d+)/;
# $1 = '62'
# $2 = ''
# $3 = '5'
```

The first try fails: `\d\d` can match 27, but the next character is `.`, so neither branch of `[1-9]?` lets `\d+` proceed. Earliest-position-wins keeps moving the start until `\d\d` lands on 62. There, `[1-9]?` greedily tried 5, but then `\d+` had no remaining digit - so it gave the 5 back and went empty, leaving 5 for `\d+`. Optional quantifiers prefer the *longer* alternative (taking the character) but will give it up if necessary; the ordering rule "earliest position wins, then longest at that position" only constrains the *whole match*, not its individual captures.

Principles of the match

With greedy quantifiers, the engine follows four principles in order:

1. **Earliest position wins.** The whole pattern is tried starting at position 0, then 1, then 2, until a match is found. The earliest starting position always wins.
2. **Leftmost alternative wins** (in `a|b|c`).
3. **Greedy quantifiers grab as much as possible** while still letting the rest of the pattern match.
4. **Leftmost greedy quantifier gets priority.** If two `.*` compete for the same characters, the first one takes them.

Examples:

```
my $x = "The programming republic of Perl";

$x =~ /^(.+)(e|r)(.*)$/;
# $1 = 'The programming republic of Pe'
# $2 = 'r'
# $3 = 'l'
# .+ is leftmost greedy; grabs everything it can while leaving
# room for (e|r) somewhere.

$x =~ /(m{1,2})(.*)$/;
# $1 = 'mm'    -- m{1,2} matches at first 'm' in 'programming',
# $2 = 'ing republic of Perl'
#                takes the maximum 2.

$x =~ /.*(m{1,2})(.*)$/;
# $1 = 'm'
# $2 = 'ing republic of Perl'
# .* grabs all the way to the last 'm', leaving only one 'm' for
# m{1,2}.
```

Non-greedy quantifiers

Appending ? to any quantifier flips it from *grab as much as possible* to *grab as little as possible*.

Non-greedy	Meaning
a??	0 or 1, prefer 0
a*?	0 or more, prefer fewer
a+?	1 or more, prefer fewer
a{n,m}?	n to m, prefer n

The overall match still has to succeed, so the engine will *expand* the non-greedy quantifier one step at a time until it does.

```
my $x = "The programming republic of Perl";

$x =~ /^(.+?)(e|r)(.*)$/;
# $1 = 'Th'
# $2 = 'e'
# $3 = ' programming republic of Perl'
# .+? grabs as little as possible while allowing the match.
```

Non-greedy is usually what you want when scanning between delimiters:

```
my $html = '<b>bold</b> and <i>italic</i>';
while ($html =~ /<(\w+)>(.*?)<\/\1>/g) {
    print "$1: $2\n";
}
```

(continues on next page)

(continued from previous page)

```
# b: bold
# i: italic
```

With greedy `.*` the match would swallow the first `</b>` and stop at the final `</i>`, mangling the capture.

When non-greedy loses to a negated class

A common idiom: `<.*?>` to match a tag. A common bug: the same pattern, applied to broken input, expands the non-greedy quantifier across content it shouldn't. The cleaner form uses a negated character class:

```
"<a> body </a>"  =~ /<.+?>/;        # matches '<a>'  - fine
"<a> <b>foo"     =~ /<.+?>foo/;     # matches '<a> <b>foo' - wrong
"<a> <b>foo"     =~ /<[^>]+>foo/;   # matches '<b>foo' - locked to␣
↪one tag
```

When a token after `>` is required, the non-greedy form *expands* under backtracking pressure: the engine first tried `<a>`, found no `foo`, and forced `.+?` to grow across the `>` and beyond. The negated class cannot give ground that way - `[^>]` is a hard barrier, so the engine bumps the start position to `<b>` instead of swallowing intervening `>`s.

A negated class is also faster: it participates in the engine's simple-repetition fast path, which the non-greedy form disables.

Use `.+?` only when no negated class can express the same requirement. Use `[^X]+` whenever the delimiter is a single character.

Possessive quantifiers

Adding `+` after a quantifier (not `?`) makes it *possessive*: greedy, but it refuses to give anything back on backtracking. Once it matches, those characters are out of play for the rest of the pattern.

Possessive	Meaning
`a?+`	0 or 1, do not give back
`a*+`	0 or more, do not give back
`a++`	1 or more, do not give back
`a{n,m}+`	n to m, do not give back

The payoff is speed - on patterns that *should* fail, possessive quantifiers fail *immediately* instead of exhaustively backtracking.

```
# Ordinary greedy: backtracks once per character on 'abc   ' when
# the second \w+ cannot match.
/^\w+\s+\w+$/;

# Possessive: once \w+ claims the word characters, it keeps them.
```

(continues on next page)

(continued from previous page)

```
# No backtracking, no quadratic blowup on pathological input.
/^\w++\s+\w+$/;
```

The classic `'aaaa' =~ /a++a/`:

```
'aaaa' =~ /a++a/;   # never matches
```

`a++` gobbles all four a's. The trailing `a` then has nothing to match. Because `a++` refuses to give back, the engine fails immediately. (The same pattern with greedy `a+a` matches `'aaaa'` after backtracking.)

A common idiom for matching quoted strings without backtracking catastrophe:

```
/"(?:[^"\\]++|\\.)*+"/;
```

Each iteration of the inner group either gobbles an unlimited run of non-quote, non-backslash characters (possessively), or a single escape. Neither alternative is willing to give back, so failure is fast. The full treatment of this pattern lives in the *performance* chapter.

Possessive equals atomic-group sugar

Possessive quantifiers are exact syntactic sugar for an atomic group around the quantified atom. The following are equivalent:

Possessive form	Atomic-group form
`PAT*+`	`(?>PAT*)`
`PAT++`	`(?>PAT+)`
`PAT?+`	`(?>PAT?)`
`PAT{n,m}+`	`(?>PAT{n,m})`

The possessive notation is shorter; the atomic-group notation generalises further (you can wrap arbitrary alternations, not just quantified atoms). The *groups and captures* chapter covers atomic groups in detail.

Illegal possessive-and-non-greedy combinations

Possessive and non-greedy are contradictory; Perl rejects the combinations. There is an equivalent legal form for each:

Illegal	Legal equivalent
`X??+`	`X{0}`
`X+?+`	`X{1}`
`X{n,m}?+`	`X{n}`

If you find yourself wanting "non-greedy *and* possessive", what you actually want is a fixed count.

Choosing the right quantifier

- **Greedy** - the default, and right most of the time.
- **Non-greedy** - when scanning between a start and end marker that can both appear legitimately multiple times.
- **Possessive** - when the match either works in exactly one way or fails, and speed on failure matters.

When in doubt, write it greedy and add a test that fails if you got it wrong.

Zero-width quantification

A quantifier on a zero-width assertion is almost always a mistake. `\b*` is syntactically legal but matches the empty string at any word boundary, which is not useful. The engine rejects some of these explicitly with a "matches null string many times" warning under `use warnings`; for the rest, the results are usually not what the author meant.

The same caveat applies to quantified groups whose inner content can match nothing. If `(\w*)*` reaches an iteration where `\w*` matched zero characters, the outer `*` would loop forever. Perl breaks this loop automatically - see the *performance* chapter on zero-length-match termination.

Worked examples from `perlre`'s backtracking section

Eight variants of "find the digits at the end of a string". Each fails or succeeds for a different reason; reading them as a group is a fast way to internalise greedy and non-greedy behaviour.

```
$_ = "I have 2 numbers: 53147";

# Pattern              $1 captured              $2 captured
/(.*)(\d*)/         => "I have 2 numbers: 53147"  ""
/(.*)(\d+)/         => "I have 2 numbers: 5314"   "7"
/(.*?)(\d*)/        => ""                          ""
/(.*?)(\d+)/        => "I have "                   "2"
/(.*)(\d+)$/        => "I have 2 numbers: 5314"   "7"
/(.*?)(\d+)$/       => "I have 2 numbers: "       "53147"
/(.*)\b(\d+)$/      => "I have 2 numbers: "       "53147"
/(.*\D)(\d+)$/      => "I have 2 numbers: "       "53147"
```

Reading each:

- `(.*)(\d*)` - greedy `.*` eats everything; `\d*` is satisfied by the empty string. Matches but neither capture is what the author wanted.
- `(.*)(\d+)` - `.*` gives back enough to expose at least one digit, but only the *last* digit of the run.
- `(.*?)(\d*)` - both non-greedy: prefer the empty match; both captures are empty.
- `(.*?)(\d+)` - first non-greedy, second greedy. `.*?` expands until `\d+` can grab 2. Stops at the first digit run.

- `(.*)(\d+)$` - anchored: `\d+` must be at end. Greedy `.*` gives back digits until the last one is at end-of-string; result is the same "last-digit only" oddity.
- `(.*?)(\d+)$` - non-greedy and anchored: `.*?` expands until `\d+$` can grab the *whole* trailing digit run. Correct.
- `(.*)\b(\d+)$` - anchored, with `\b` to force the boundary before the digit run. Equivalent.
- `(.*\D)(\d+)$` - explicit non-digit before the digit run. Equivalent.

The lessons:

1. The quantifier (`.*` vs `.*?`) controls *greediness*, but anchoring (`$`, `\b`, `\D`) is what controls *which run is matched*.
2. Greedy is rarely "wrong" by itself; the wrongness is a missing anchor.

Cross-engine notes

Quantifier syntax is one of the most-divergent surfaces between regex engines. The full table is in the *cross-engine* chapter; the headline:

- **POSIX BRE** treats bare `+` and `?` as *literal characters*. Use `\+` and `\?` for the metacharacter forms.
- **POSIX ERE** has `+`, `?`, `{m,n}` as metacharacters (Perl-shaped) but no possessive quantifiers and no atomic groups.
- **RE2 / Go** has `+`, `?`, `*`, `*?`, but no possessive quantifiers, no atomic groups, and no backreferences. Linear-time guarantee replaces the need for them.

See also

- The *performance* chapter - catastrophic backtracking, unrolling the loop, and where possessive quantifiers earn their keep.
- The *groups and captures* chapter - atomic groups `(?>…)`, the general form of "no backtracking inside this construct".
- The *character classes* chapter - `[^X]+` as a faster, safer alternative to `.*?`.
- The *cross-engine* chapter - quantifier availability across families.
- `m`, `s`, `qr` - operator references.

Groups and captures

Grouping does two things, which are easy to confuse: it turns a sequence of pattern elements into a single unit for quantification and alternation, and it saves what that unit matched for later use.

```
/house(cat|keeper)/;       # 'house' followed by 'cat' or 'keeper'
/(ab){3}/;                 # 'abababab'
/(\d{3})-(\d{4})/;         # capture two groups separated by '-'
```

Beyond the plain (…) capturing form, Perl provides a small zoo of parenthesised constructs: non-capturing groups for clean grouping, named captures for self-documenting patterns, atomic groups for controlling backtracking, recursive subpatterns for nested structures, conditional patterns for branching on prior captures, and the branch-reset construct for parallel alternatives. This chapter covers all of them.

Capturing groups: $1, $2, ...

Every pair of unescaped parentheses in a pattern opens a capturing group. After a successful match the matched text of the nth group is in $n:

```
if ($time =~ /(\d\d):(\d\d):(\d\d)/) {
    my ($hours, $minutes, $seconds) = ($1, $2, $3);
}
```

In list context, a match returns the list of captured strings directly:

```
my ($h, $m, $s) = $time =~ /(\d\d):(\d\d):(\d\d)/;
```

If the pattern fails, the list is empty - a useful idiom for “parse or give up”:

```
my ($h, $m, $s) = $time =~ /(\d\d):(\d\d):(\d\d)/
    or die "not a time: $time";
```

There is no upper limit on the number of capture groups. Groups are numbered with the leftmost open parenthesis as group 1, the next as group 2, and so on:

```
/(ab(cd|ef)((gi)|j))/
  1  2      34
```

$1 captures the outer group, $2 the first inner, $3 the next, $4 the innermost.

Captured the empty string vs. did not match at all

A capture group that did not participate in the match has $n *undefined*. A group that participated and matched an empty string has $n defined and equal to "". The distinction matters:

```
"aba" =~ / a (x)* b \g1 a /x;   # does NOT match
"aba" =~ / a (x)? b \g1 a /x;   # does NOT match
"aba" =~ / a (x*) b \g1 a /x;   # matches; $1 = ""
"aba" =~ / a (x?) b \g1 a /x;   # matches; $1 = ""
```

In the first two cases, the quantifier is *outside* the group, so the group itself never closed (the engine matched zero iterations - the group was not entered at all). The backreference \g1 therefore has no value to compare against and fails. In the second two cases, the quantifier is *inside* the group, so the group ran exactly once and captured an empty string; \g1 matches the same empty string at that position.

The lesson: when a group is optional, put the quantifier inside if you want the empty-match-counts-as-match semantics.

Always check captures with `defined`, not for truth - an empty capture is defined but false under string semantics:

```
if ("x" =~ /(a)?(x)/) {
    print "1 is $1\n" if defined $1;   # $1 is undef here
    print "2 is $2\n" if defined $2;
}
```

Failed matches do not reset capture variables

If a match fails, `$1`, `$2`, ... keep their previous values from the last *successful* match in the same scope. This is a feature: it lets you write a series of more specific patterns and refer to the best match's captures afterwards.

```
"foo" =~ /(\w+)/ and "" =~ /(\d+)/;   # second fails
print $1;   # "foo" - first match's capture survives
```

It is also a common source of confusion. Always check the match's return value before reading the capture variables.

Non-capturing groups: `(?:…)`

If you only need the grouping for quantification or alternation, and don't want the capture, use `(?:…)`:

```
/(?:ab){3}/;            # 'ababab', no capture
/(?:\d+\.)*\d+/;        # a dotted decimal, no captures at all
```

Non-capturing groups are a small speed win and a larger clarity win. They signal "this grouping is for syntax, not data". They also prevent renumbering of the capturing groups you do care about:

```
# match a number - $1 = whole, $2 = optional exponent value
/([+-]?\ *(?:\d+(?:\.\d*)?|\.\d+)(?:[eE]([+-]?\d+))?)/;
```

Without the `(?:…)` wrappings, `$2`, `$3`, `$4` would all be set and the intended `$2` (the exponent) would shift to `$5`.

The scoped form `(?flags:…)` (e.g. `(?i:cat)`, `(?xms:…)`) attaches modifiers to the inner pattern only and is also non-capturing - see the *modifiers* chapter.

`split` also benefits from `(?:…)`. `split /(?:\s+)/` separates on runs of whitespace without inserting the separators into the output; `split /(\s+)/` leaves them in alternating positions.

Named captures

`(?<name>…)` or `(?'name'…)` names a group. Its match is accessible through the hash `%+`:

```
if ("2026-04-23" =~ /(?<year>\d{4})-(?<month>\d{2})-(?<day>\d{2})/)
 ↪{
    print "year = $+{year}\n";    # 2026
    print "month = $+{month}\n";  # 04
    print "day = $+{day}\n";      # 23
}
```

Named groups also populate `$1`, `$2`, ... in the usual left-to-right order, so code that uses both conventions works. Inside the pattern, reference a named group with `\k<name>` (or any of the brace/quote forms below):

```
/(?<quote>["'])(.*?)\k<quote>/;   # same quote at start and end
```

Names follow Perl-identifier rules (`[_A-Za-z][_A-Za-z0-9]*`); they cannot begin with a digit and cannot contain hyphens.

If two distinct groups share a name, `$+{name}` refers to the *leftmost defined* group in the match. This is unusual to want *outside* a branch reset (`(?|...)`), where shared names are idiomatic.

`(?P<name>...)` - Python/PCRE compatibility

For programmers porting from Python's `re` module or PCRE, Perl accepts the Python-style spellings:

Python form	Perl equivalent
`(?P<NAME>...)`	`(?<NAME>...)`
`(?P=NAME)`	`\k<NAME>`
`(?P>NAME)`	`(?&NAME)`

The Python forms work but are not idiomatic Perl; prefer the native forms in new code.

Backreferences

A backreference in a pattern demands that a later position match the *same text* an earlier group captured - not the same pattern, the same actual characters.

Form	Refers to
`\1` ... `\9`	first through ninth capturing group (legacy form)
`\g1`, `\g2`	numbered capture; equivalent to `\1`, `\2`
`\g{1}`	brace form; required when digits would otherwise follow
`\g-1`	most-recently-opened capturing group (relative)
`\g{-2}`	second-most-recently-opened group
`\k<name>`	named capture
`\k'name'`	same, single-quote form
`\k{name}`	same, brace form (allows surrounding spaces)
`\g{name}`	named, alternative spelling

Examples:

```
# Match a three-letter word followed by a space and the same word.
"the the other day" =~ /\b(\w{3})\s\1\b/;   # $1 eq 'the'

# Match a four-letter, three-letter, two-letter, or one-letter
# run followed by itself.
/^(\w{1,4})\1$/;    # 'beriberi', 'booboo', 'coco', 'mama', 'papa'
```

`\g{…}` versus `\1` for disambiguation

Use `\g{…}` (or `\k<…>`) when digits or octal-looking characters follow the reference, to avoid ambiguity:

```
/(\d)abc\g{1}23/;    # the '1' refers to group 1, '23' is literal
/(\d)abc\123/;       # '\123' is octal 0x53 ('S'), not group 1
```

Perl's rule for the bare numbered form: `\1` through `\9` always mean backreferences. `\10`, `\11`, … mean a backreference *only if* that many capture groups have opened earlier in the pattern; otherwise they are octal character literals. This is why `\g{...}` is the safer form when the pattern is built by concatenation.

If you use the brace form, optional surrounding spaces are permitted - `\g{ -1 }` and `\k{ name }` are valid.

Relative backreferences

`\g-1`, `\g{-1}` refer to the *immediately previous* capturing group; `\g{-2}` refers to the one before that; and so on. The distance is counted by *opened* parens, including unclosed ones. This matters when a pattern fragment is interpolated inside another:

```
my $pair = '([a-z])(\d)\g{-1}\g{-2}';   # a11a, g22g, x33x, ...

# Embed it: outer group shifts numbering by 1, but relative
# backreferences still work:
"code=e99e" =~ /^(\w+)=$pair$/;   # matches
```

Without relative backreferences, this would require knowing how many groups precede `$pair` at every interpolation site.

Named and relative references make long patterns robust against copy-paste.

Atomic groups: `(?>…)`

`(?>…)` is a non-capturing group whose contents, once matched, are *committed*. The engine cannot backtrack into the group on failure - only past it as a whole.

```
"aaab" =~ /a*ab/;       # matches: a* gives back one 'a'
"aaab" =~ /(?>a*)ab/;   # does not match: a* takes all, refuses to␣
↪give
```

The full treatment lives in the *performance* chapter. The construct is documented here because its syntax is a parenthesised group; structurally it belongs in the captures chapter alongside `(?:…)`.

Possessive quantifiers (`*+`, `++`, `?+`, `{n,m}+`) are exact syntactic sugar for `(?>…)` around the quantified atom. The following are equivalent:

Possessive	Atomic-group form
`PAT*+`	`(?>PAT*)`
`PAT++`	`(?>PAT+)`
`PAT?+`	`(?>PAT?)`
`PAT{n,m}+`	`(?>PAT{n,m})`

The long-form spelling `(*atomic:…)` is also accepted.

Recursive subpatterns

Perl regexps can refer back to a capture group as if it were a subroutine call. The construct re-runs the captured pattern at the current position. This makes genuinely recursive structures matchable - balanced parentheses, S-expressions, nested brackets - without falling out of the regex DSL.

Form	Recurses to
`(?R)`	the entire pattern
`(?0)`	same as `(?R)`
`(?1)`	group 1
`(?2)`	group 2 (and so on)
`(?-1)`	most-recently-opened group (relative)
`(?+1)`	next group to be opened (forward relative)
`(?&NAME)`	named group
`(?P>NAME)`	same as `(?&NAME)` (Python-compatible)

Note: relative recursion counts unclosed groups, just as relative backreferences do. `(?-1)` always means the most recently opened group whether or not it has closed.

A balanced-paren matcher:

```
my $bal = qr/
    (?(DEFINE)
        (?<paren>
            \(                  # opening paren
            (?:
                [^()]++         # non-paren run, possessive
              | (?&paren)       # or a balanced sub-group, recursively
            )*+
            \)                  # closing paren
        )
    )
```

(continues on next page)

(continued from previous page)

```
    (?&paren)
/x;

"((a)(b(c)))" =~ /^$bal$/;   # matches
```

The `(?(DEFINE)...)` block declares a named subpattern without matching anything itself; the `(?&paren)` after it invokes that subpattern, and the recursive `(?&paren)` inside the body is what gives the unbounded depth. `(?R)` would not work here - it recurses the *whole* enclosing pattern, including the `^` and `$` anchors that get added at the call site, which forces every level of recursion to demand start- and end-of-string.

A more nuanced recursive pattern: match a function `foo(...)` where the argument may itself contain balanced parens.

```
my $re = qr/(             # group 1: full function call
              foo
              (           # group 2: parens with content
                \(
                  (       # group 3: contents of parens
                    (?:
                       (?> [^()]+ )   # non-paren without␣
↪backtracking
                     |
                       (?2)           # recurse to group 2
                    )*
                  )
                \)
              )
            )/x;

'foo(bar(baz)+baz(bop))' =~ /$re/ and
    print "1: $1\n2: $2\n3: $3\n";
# 1: foo(bar(baz)+baz(bop))
# 2: (bar(baz)+baz(bop))
# 3: bar(baz)+baz(bop)
```

Capture state inside recursion

When a group recurses into itself, captures set inside the recursion are *not* visible to the caller after the recursion returns. The recursive call has its own capture state, which is discarded on return. This is why most recursive patterns wrap a secondary capture group around the recursive call when the matched text is needed:

```
/(?<NAME>(?&NAME_PAT))(?<ADDR>(?&ADDRESS_PAT))
 (?(DEFINE)
   (?<NAME_PAT>....)
   (?<ADDRESS_PAT>....)
 )/x
```

Here `$+{NAME}` is the outer capture; `$+{NAME_PAT}` is undefined because it lived only

inside the recursion.

The recursion-depth ceiling is compiled into the engine. Patterns that recurse without consuming input fail immediately rather than running forever - the engine detects the cycle.

`(DEFINE)` blocks

The `(?(DEFINE)…)` block holds named subpatterns that never run on their own - they are only invoked through `(?&NAME)`. This is how to write a regex that looks like a small grammar:

```
my $email = qr/
    \A (?&LOCAL) @ (?&DOMAIN) \z
    (?(DEFINE)
        (?<LOCAL>   [\w.+-]+ )
        (?<DOMAIN>  (?&LABEL) (?: \. (?&LABEL) )+ )
        (?<LABEL>   [a-zA-Z0-9] (?: [a-zA-Z0-9-]* [a-zA-Z0-9] )? )
    )
/x;
```

The DEFINE block at the end keeps the named subpatterns in one place; the top of the pattern reads as a clean specification.

Two cautions:

- Subpatterns in a DEFINE block *count toward* the absolute and relative numbering of capture groups in the surrounding pattern. Name everything in the DEFINE so you don't have to count.
- The optimiser is less effective on DEFINE-style patterns than on the equivalent inlined form. They run, but not always at top speed.

Conditional patterns: `(?(cond)yes|no)`

A conditional pattern picks between two sub-patterns based on a runtime test:

- `(?(N)YES|NO)` - match YES if group N matched something, else NO.
- `(?(<NAME>)YES|NO)` - same, but by name.
- `(?(?=LOOK)YES|NO)` - match YES if the lookahead succeeds.
- `(?(?{CODE})YES|NO)` - match YES if the code block returns true.
- `(?(R)YES|NO)` - match YES if currently inside a recursion.
- `(?(R1)YES|NO)` - match YES if recursing through group 1.
- `(?(R&NAME)YES|NO)` - match YES if recursing through named group.

The NO branch is optional; missing NO is treated as "always match".

Worked example: optionally-parenthesised text. If the input opens with `(`, require a closing `)`. Otherwise allow no parens:

```
m{ ( \( )?            # optional opening paren, group 1
   [^()]+             # body (no parens)
   (?(1) \) )         # if group 1 matched, require closing paren
}x;
```

Without conditional patterns, this would need an alternation covering both shapes; the conditional version exposes the intent.

Worked example: balanced grammar with named recursion. Useful inside a DEFINE block for context-sensitive validation:

```
qr/
    (?<expr>
        (?<atom>  [a-z]+ | \( (?&expr) \) )
        (?: \s* [+*] \s* (?&atom) )*
    )
/x
```

Conditionals are the part of regex that most resembles a real programming language; reach for them when an alternation of mutually-exclusive shapes would be unwieldy.

Branch reset: `(?|…)`

Inside `(?|…)`, every alternative branch starts numbering its captures at the same slot. After the group, numbering resumes one past the maximum across all branches. The full treatment is in the *alternation* chapter; the capture-numbering implications belong here.

```
# Before  ---------------branch-reset----------- after
/ ( a )  (?| x ( y ) z | (p (q) r) | (t) u (v) ) ( z ) /x
# 1            2         2  3        2     3     4
```

After this pattern matches:

- `$1` is always the leading `a`.
- `$2` is `y`, `(p q r)`, or `t` depending on branch.
- `$3` is undef from branch 1, `q` from branch 2, `v` from branch 3.
- `$4` is the trailing `z`.

If you use named captures inside `(?|…)`, use the *same names in the same order* in every branch:

```
/(?|  (?<a> x ) (?<b> y )
   |  (?<a> z ) (?<b> w )) /x;
```

Mixing names across branches works (Perl resolves to the leftmost defined name) but produces surprising results: every name references the same slot, so `$+{a}` and `$+{b}` may have the same value across different branches.

Position arrays: @- and @+

After a successful match, `@-` and `@+` hold the start and end offsets of the whole match and of each capture group:

- `$-[0]`, `$+[0]` - offsets of the whole match.
- `$-[n]`, `$+[n]` - offsets of the nth capture, or undef if the group did not participate.

```
my $s = "Mmm...donut, thought Homer";
if ($s =~ /^(Mmm|Yech)\.\.\.(donut|peas)/) {
    for my $i (1 .. $#-) {
        printf "Match %d: %s at (%d,%d)\n",
               $i,
               substr($s, $-[$i], $+[$i] - $-[$i]),
               $-[$i], $+[$i];
    }
}
# Match 1: Mmm at (0,3)
# Match 2: donut at (6,11)
```

Offsets are often easier than substrings when you need to modify the original string at the matched position.

@{^CAPTURE} - captures as an array

Perl exposes all numbered captures as a single array `@{^CAPTURE}`, indexed from 0 (where index 0 is $1, index 1 is $2, ...):

```
$string =~ /$pattern/ and my @captured = @{^CAPTURE};
```

This is convenient when the number of captures is variable or unknown - code that takes captures from a user-supplied pattern no longer has to count `(` to know how many $1/$2/... to read.

Subscripting requires the demarcated-curly form:

```
print "${^CAPTURE[0]}";    # equivalent to $1
```

`%{^CAPTURE_ALL}` and `%{^CAPTURE_NAMES}` exist for named-capture introspection - see `perlvar`.

Prematch, match, postmatch

Perl sets three special scalars after each match that expose the surrounding text:

- `$`` - everything before the match (the *pre-match*).
- `$&` - the match itself.
- `$'` - everything after the match (the *post-match*).

```
"the cat caught the mouse" =~ /cat/;
# $`   = 'the '
```

(continues on next page)

(continued from previous page)

```
# $&   = 'cat'
# $'   = ' caught the mouse'
```

The named variants `${^PREMATCH}`, `${^MATCH}`, `${^POSTMATCH}` are equivalent. Both forms are zero-cost; use whichever reads better.

`$+` and `$^N`

`$+` holds the match of the highest-numbered capture group that succeeded.

`$^N` holds the match of the most-recently-closed capture group - the rightmost `)` that completed. This is exactly what you want inside a `(?{...})` code block to access the latest capture without counting parens:

```
$_ = "The brown fox jumps over the lazy dog";
/the (\S+)(?{ $color = $^N }) (\S+)(?{ $animal = $^N })/i;
print "color = $color, animal = $animal\n";
# color = brown, animal = fox
```

See the *performance* chapter for the full embedded-code story.

POSIX subexpression maximisation - what other engines do

Some engines (any conformant POSIX NFA, plus engine implementations designed to mimic POSIX, plus most DFA hybrids) follow a different rule for which match wins when multiple are possible: *longest-leftmost*, with the constraint that *each subexpression captures the longest substring it can*.

For the pattern `(to|top)(o|polo)?(gical|o?logical)` against `topological`:

- Perl (and PCRE2, and any Traditional NFA) tries alternatives left-to-right. `(to|top)` matches `to`; the engine pushes on. The next character is `p`, so `(o|polo)` cannot take `o`; it takes `polo`. `(gical|o?logical)` matches `gical`. Done: `to` `polo` `gical`.
- POSIX semantics requires the *overall* match be longest, and among matches of equal length, each group's capture to be as long as it can be, from left to right. The first group takes `top`; that leaves `ological`, so the result is `top` `o` `logical`.

Modern engines essentially never use POSIX-NFA semantics, but some DFA-based tools (`grep`, `awk`) approximate it. The *cross-engine* chapter has the full table.

Cross-engine: captures and backreferences

This is the one feature where engines diverge most. The full table is in the *cross-engine* chapter; the relevant rows extracted:

Feature	Perl 5.44	PCRE2	Emacs	POSIX BRE	POSIX ERE	RE2/Go
Numbered captures	yes	yes	yes	yes	strict no, GNU yes	yes (no backrefs)
Backreferences in pattern (\1, ...)	yes	yes	yes	yes (\1–\9)	strict no	NO
Named captures (?<name>...)	yes	yes	NO	NO	NO	yes
Branch reset (?|...)	yes	yes	NO	NO	NO	NO
@{^CAPTURE} array	yes	NO	NO	NO	NO	NO (different API)
Recursive subpatterns (?R) etc.	yes	yes	NO	NO	NO	NO
Conditional patterns (?(c)y|n)	yes	yes	NO	NO	NO	NO

The single most important takeaway: **RE2 / Go regexp does not support backreferences at all**. This is not an oversight; it is the price RE2 pays for guaranteed linear-time matching. Patterns that need backreferences are not regular languages and cannot be matched by a DFA in linear time.

If you are porting Perl regexps to a Go service, audit them for backreferences before assuming the conversion is mechanical. Patterns like `/(?<a>\w+) and \k<a>/` simply cannot be expressed in RE2.

Alternation

Alternation is the | operator. It picks between two or more sub-patterns at the same position.

```
"cats and dogs" =~ /cat|dog|bird/;    # matches 'cat'
"cats and dogs" =~ /dog|cat|bird/;    # matches 'cat'
```

The order of the alternatives does not change *where* the overall pattern matches. The engine still honours "earliest position wins" - both patterns above match at position 0 because that's the earliest position where any alternative can match.

Leftmost alternative wins at a given position

Within a single starting position, alternatives are tried left to right and the first one that succeeds is used:

```
"cats" =~ /c|ca|cat|cats/;     # matches 'c' - first alternative
↪wins
"cats" =~ /cats|cat|ca|c/;     # matches 'cats' - first wins, longer
```

If one alternative is a prefix of another and you want the longer match, put it first. The engine does not look past the first successful alternative at the current position.

This is *Traditional NFA* behaviour, and it is what Perl, PCRE2, Python, and most modern engines implement. POSIX-conformant engines (notably some `awk` and `grep` implementations) follow the *longest-leftmost* rule instead - they would match `cats` regardless of alternative order. The *cross-engine* chapter has the comparison.

Friedl puts it succinctly:

> Greedy alternation is non-greedy in a Traditional NFA.

The pattern `tour|to|tournament` against `three tournaments won` matches `tour`, not `tournament`. The first alternative succeeds and the engine commits to it; longer alternatives further along the list are never tried.

Implications for ordering

An alternation that is part of a larger pattern can have its performance and correctness shaped by the order of alternatives:

- **Specificity first.** When you want the longest of several prefixes, put the longest first. `/web|website|websites/` matches `web` even on input `website`; `/websites|website|web/` matches `websites`.
- **Common case first.** Alternation is tried left-to-right; if 90% of your inputs hit alternative 3, the engine wastes time on alternatives 1 and 2 every time. Reorder by frequency.
- **Sibling captures.** When the alternatives capture, the order affects which `$n` is set - see *Alternation and capturing* below.

Combining-pieces formal rule

`perlre`'s "Combining RE Pieces" gives the precise statement underlying "leftmost wins". For two pattern pieces S and T:

> When S can match, it is a better match than when only T can match.

That is the formal version of the rule. "Better" means the engine prefers it. For two S matches, the same internal ordering applies (greediness rules within the alternative); likewise for T matches. Across alternatives, *the existence of a successful S match excludes consideration of T*.

This is why S|T cannot be reordered by the engine on its own: Perl does not search for the *best* alternative across the disjunction - it commits to S whenever S succeeds.

Grouping vs. alternation precedence

| has very low precedence. It splits the pattern at the *outermost* level containing it:

```
/ab|cd/;       # 'ab' OR 'cd'
/^ab|cd$/;     # '^ab' OR 'cd$' - probably not what you meant!
/^(ab|cd)$/;   # '^' + ('ab' or 'cd') + '$' - what you meant
```

To constrain alternation to part of a pattern, wrap it in a group. Non-capturing `(?:…)` is preferred unless you need the capture:

```
/house(?:cat|keeper)/;      # 'housecat' or 'housekeeper'
/house(cat|keeper)/;        # same, but $1 will be 'cat' or 'keeper'
```

The group creates a local scope for |. Outside the group | resumes its top-level role:

```
/^(?:foo|bar|baz)$|^xyz$/;   # ('foo'/'bar'/'baz') or 'xyz'
```

Empty alternatives

An empty alternative matches the empty string - a useful trick for “this or nothing”:

```
/house(cat|)/;          # 'housecat' or 'house'
/(19|20|)\d\d/;         # '19xx', '20xx', or just 'xx'
```

Modern style prefers `(?:…)?` over `(?:…|)`; they are equivalent, but the ? form is clearer:

```
/house(?:cat)?/;        # same as house(cat|), no capture
```

Watch for the backtracking cost when an empty alternative is combined with a quantifier - the engine can re-explore the same position many times. See the *performance* chapter on zero-length-match termination.

Cross-engine note

Strict POSIX, `lex`, and most older `awk` implementations *disallow* empty alternatives - `(this|that|)` is a syntax error. Perl 5.44, PCRE2, Rust’s `regex` crate, Python `re`, and modern engine implementations accept them. If a pattern needs to be portable to older POSIX tools, write `(?:this|that)?` instead - it expresses the same idea and is portable to the engines that reject an empty alternative.

Alternation inside character classes

Character classes are almost always what you want when alternating between single characters. `/a|b|c/` and `/[abc]/` match the same strings, but `[abc]` is faster, terser, and clearer:

```
/a|b|c/;      # works, but verbose
/[abc]/;      # use this
```

Alternation is for alternatives longer than one character (or ones that are themselves patterns). When each alternative is a single character, reach for a class. The engine

treats a class as a *single* atomic choice; an alternation as N choices to be explored in order.

Common-prefix factoring

A pattern like `/this|that|then|those/` defeats the engine's fixed-string-check optimisation: there is no literal prefix the engine can scan for cheaply. Refactoring to expose the common prefix turns the alternation into something the optimiser can work with:

```
/this|that|then|those/;       # no common prefix visible
/th(?:is|at|en|ose)/;         # common prefix 'th' exposed
```

The two patterns match the same strings, and the second is materially faster on large inputs. The engine scans for `th` using Boyer-Moore, then runs the small alternation only at candidate positions.

The general technique:

1. Find the longest literal prefix common to all alternatives.
2. Lift it outside the alternation.
3. Wrap the remainder in `(?:…)` so the alternation stays localised.

For lists of words with a few different prefixes, you can apply the rewrite recursively. For very long lists, see the *performance* chapter's section on matching many strings - once the list is in the thousands, a specialised matcher beats any alternation.

Alternation and capturing

Only one alternative inside a group can match at a time, so the group captures the matching alternative:

```
if ("bert" =~ /(cat|dog|bert|ernie)/) {
    print "matched $1\n";        # matched bert
}
```

Sibling groups outside the alternation retain their normal numbering:

```
/^(\w+):\s*(yes|no|maybe)$/;
# $1 = the key, $2 = the verdict
```

Inside a nested alternation, the groups are numbered left to right by opening paren, even across branches:

```
/(a)|(b)/;
# On match of 'a': $1 = 'a', $2 undef
# On match of 'b': $1 undef,  $2 = 'b'
```

Check with `defined $n`, not truth - an empty capture is different from an absent capture.

Branch reset: `(?|…)`

Parallel-capture patterns are the usual reason you pick up `(?|…)`. Inside `(?|…)`, every branch starts numbering its captures at the same slot. After the group, numbering resumes at one past the maximum across all branches.

```
# Without (?|…): need to know which branch matched.
if ($time =~ /(\d\d|\d):(\d\d)|(\d\d)(\d\d)/) {
    my ($h, $m) = ($1, $2);
    ($h, $m) = ($3, $4) unless defined $h;
}

# With (?|…): $1 and $2 come from whichever branch matched.
if ($time =~ /(?|(\d\d|\d):(\d\d)|(\d\d)(\d\d))/) {
    my ($h, $m) = ($1, $2);
}
```

With a trailing fixed piece:

```
if ($time =~ /(?|(\d\d|\d):(\d\d)|(\d\d)(\d\d))\s+([A-Z]{3})/) {
    # $1 = hours, $2 = minutes, $3 = zone (numbered after the group)
    print "hour=$1 minute=$2 zone=$3\n";
}
```

Rules inside `(?|…)`:

- Each branch independently numbers its capturing groups from the current group count.
- After the group, the outer numbering continues at one higher than the maximum count reached in any branch.
- Named groups keep their names; you can repeat a name across branches. Use the *same names in the same order* in every branch, or surprises ensue (see the *groups and captures* chapter).

Branch reset is the cleanest way to express "parse X in one of several equivalent formats, then reach for the same variables afterwards."

Alternation in `split`

`split` takes a regexp pattern, so alternation works there too:

```
my @words = split /\s+|-/, "one-two three  four-five";
# ('one', 'two', 'three', 'four', 'five')
```

If the separator pattern contains capturing groups, split includes the captured text in the output list - often surprising. Use `(?:…)` unless you want that:

```
split /(?:\s+|-)/, "a-b c";   # ('a', 'b', 'c')
split /(\s+|-)/,   "a-b c";   # ('a', '-', 'b', ' ', 'c')
```

The capturing form is occasionally what you want - preserving the exact separators between fields. Mostly you want non-capturing.

Summary

- `|` separates alternatives; leftmost that matches at the current position wins.
- Wrap alternations in `(?:...)` to localise them.
- Prefer character classes over single-character alternations.
- Lift common prefixes outside the alternation when you want the engine's literal-scan optimisation to fire.
- `(?|...)` resets capture numbering across branches - use it when the branches capture the same conceptual fields.

- `split` - alternation as separator syntax.

Modifiers

Modifiers change how a pattern is matched without changing the pattern itself. They appear after the closing delimiter of a match, substitution, or `qr//`:

```
"Hello" =~ /hello/i;        # case-insensitive match
$x =~ s/foo/bar/g;          # global substitution
my $re = qr/\d+/i;          # compiled pattern with /i
```

The same modifiers can be embedded inside a pattern with `(?flags)` or `(?flags:...)`, localising their effect to part of the pattern.

The full modifier set

Modifier	Effect
`/i`	case-insensitive matching
`/m`	multi-line: `^` and `$` match at every `\n`
`/s`	single-line: `.` matches `\n` too
`/x`	extended: ignore whitespace and `#` comments
`/xx`	extended-extended: also ignore whitespace inside `[…]`
`/g`	global: match as many times as possible
`/c`	do not reset `pos` on failure (with `/g`)
`/r`	`s///r` returns the result instead of modifying
`/e`	`s///e` evaluates the replacement as Perl code
`/ee`	`s///ee` evaluates, then evaluates the result too
`/n`	non-capturing: `(…)` act like `(?:…)`
`/p`	no-op; accepted for compat
`/o`	compile the pattern once (rarely needed; prefer `qr//`)
`/a`	`\d`, `\w`, `\s` restricted to ASCII
`/aa`	`/a`, plus `/i` does not cross ASCII/non-ASCII boundary
`/u`	Unicode semantics regardless of `use utf8`
`/l`	use current locale
`/d`	dual-mode semantics - avoid in new code

The first eight are the everyday modifiers; the charset modifiers `/a`, `/u`, `/l`, `/d` are covered in detail in the *unicode* chapter and summarised again here.

`/i` - case-insensitive

```
"Hello" =~ /hello/i;          # matches
"HELLO" =~ /[A-Z]/i;          # matches - class is insensitive too
"Grüße" =~ /GRÜSSE/i;         # matches under Unicode semantics
```

Unicode case folding includes mappings like ß → `ss`, German Eszett casefolding, and so on. The full table lives in the Unicode standard; for ASCII, `/i` does what you expect.

`/i` carries a negligible performance penalty for ASCII. The implementation folds case at *compile time* - the pattern carries the case-folded character set, the input is read once. Unicode case-folding is more involved (sequences like ß ↔ `ss`), but the extra work is bounded and rarely shows up in practice.

`/m` - multi-line

Changes where `^` and `$` match. Without `/m`, they match only at the outer ends of the string. With `/m`, they match at every embedded newline too.

```
my $x = "first\nsecond\nthird";

$x =~ /^second/;    # does not match
$x =~ /^second/m;   # matches - second is at start of a line
```

(continues on next page)

(continued from previous page)

```
$x =~ /first$/m;    # matches
$x =~ /third$/m;    # matches
```

`\A`, `\z`, `\Z` remain absolute string anchors even under `/m` - see the *anchors and assertions* chapter.

`/s` - single-line

Makes `.` match newline characters too.

```
my $x = "a\nb";
$x =~ /a.b/;        # does not match - . does not cross \n
$x =~ /a.b/s;       # matches
```

`/m` and `/s` are independent. They can both be used on the same match. Despite the names, they do not conflict:

```
$x =~ /^a.b$/sm;    # . matches newline AND ^,$ are line-aware
```

`/x` - extended pattern

Ignores literal whitespace and lets # introduce end-of-line comments. Crucial for any pattern more than a line long.

Before `/x`:

```
/^[+-]?\d+(\.\d*)?([eE][+-]?\d+)?$/;
```

After:

```
/^
    [+-]?           # optional sign
    \d+             # integer part
    (\.\d*)?        # optional fraction
    ([eE][+-]?\d+)? # optional exponent
 $/x;
```

Whitespace in the *pattern* is ignored; whitespace you want to match becomes `\s`, `\ ` , or `[ ]`:

```
/\w+ \s+ \w+/x;      # three tokens: word, space, word (literal␣
↪spaces ignored)
/\w+\s+\w+/x;        # equivalent
/key:[ ]value/x;     # literal space via bracket class
/key:\ value/x;      # literal space via backslash
```

starts a comment that ends at the next newline. To match a literal # under `/x`, escape it or put it in a class.

The "Pattern White Space" set under `/x` follows Unicode UAX#31: SPACE, CHARACTER TABULATION, LINE FEED, LINE TABULATION, FORM FEED, CARRIAGE RETURN,

NEXT LINE, PARAGRAPH SEPARATOR, LINE SEPARATOR. In practice you only meet ASCII space, tab, and newline.

/xx - extended in classes too

Inside `[...]` whitespace is *not* ignored under plain `/x` - `[ab c]` matches a, b, ' ', or c. To also ignore whitespace inside classes, use `/xx`:

```
/[ab c]/xx;          # matches 'a', 'b', or 'c' - space ignored
/[ab\ c]/xx;         # the \ is needed to match a literal space
/[ ! @ ]/xx;         # matches '!' or '@' - visible spacing
```

`/xx` is a superset of `/x`. It is convenient for character classes laid out for readability, especially with shorthand classes:

```
/[ \d \s \-_,. ]+/xx;   # digits, whitespace, common punctuation
```

`/xx` was added in Perl 5.26. Patterns built before that read fine; new code can reach for it freely.

/g - global

In scalar context, keeps a position in the string (`pos $x`) and advances each time the pattern matches, allowing iteration:

```
my $x = "cat dog house";
while ($x =~ /(\w+)/g) {
    print "$1 at ", pos($x), "\n";
}
# cat at 3
# dog at 7
# house at 13
```

In list context, returns all matches at once:

```
my @words = $x =~ /(\w+)/g;   # ('cat', 'dog', 'house')
```

If the pattern contains no captures, list context returns the whole matched text for each match:

```
my @digits = "abc123def456" =~ /\d+/g;   # ('123', '456')
```

With multiple captures, each iteration returns the tuple in order:

```
my @pairs = "a=1,b=2,c=3" =~ /(\w)=(\d)/g;
# ('a', '1', 'b', '2', 'c', '3')
```

`/c` - preserve position on failure

By default, a failed `/g` match resets `pos` to undef. Under `/gc`, `pos` stays at its previous value - crucial for hand-rolled lexers:

```
my $s = "123abc";
while (1) {
    if ($s =~ /\G(\d+)/gc)    { print "num $1\n"; next; }
    if ($s =~ /\G([a-z]+)/gc) { print "word $1\n"; next; }
    last;   # nothing matched; exit
}
```

See the *anchors and assertions* chapter for `\G`.

`/r` - non-destructive substitution

`s///` normally modifies the target string and returns the count. `s///r` leaves the target alone and returns the result:

```
my $name = "  Alice  ";
my $trimmed = $name =~ s/^\s+|\s+$//gr;
# $name is still "  Alice  "
# $trimmed is "Alice"
```

Enables substitution chains without intermediate variables:

```
my $clean = $input
    =~ s/\s+/ /gr          # collapse runs of whitespace
    =~ s/^ | $//gr         # trim ends
    =~ s/[^\x00-\x7f]//gr; # drop non-ASCII
```

Each `s///r` returns the transformed string, which the next one receives.

`/e` - evaluate the replacement

The replacement half of `s///e` is Perl code, not a double-quoted string. The return value of the code replaces the match:

```
my $x = "numbers: 1 2 3 4";
$x =~ s/(\d+)/$1 * 2/ge;
# $x is now "numbers: 2 4 6 8"
```

`/ee` evaluates twice: the code returns a string, which is then evaluated as Perl again. Rarely useful and easy to misuse - only reach for it when you are sure. The *substitution* chapter has worked examples.

`/n` - non-capturing

Makes every ordinary `(...)` behave like `(?:...)`. Useful when a long pattern has parentheses purely for grouping and you want to keep `$1`, `$2`, ... unset:

```
"hello" =~ /(hi|hello)/n;    # matches, but $1 is not set
```

Named captures `(?<name>…)` still capture under `/n`. Added in Perl 5.22.

/p - no-op

`/p` is a silent no-op. `${^PREMATCH}`, `${^MATCH}`, `${^POSTMATCH}` are always available. Accepted for backward compatibility, but contributes nothing in new code.

/o - compile once

`/o` disables re-compilation of a pattern that interpolates variables. Compiled patterns are also cached automatically, and `qr//` gives explicit control. `/o` is rarely the right tool; `qr//` is clearer and composes.

Charset modifiers - /a, /aa, /u, /l, /d

These control how the shorthand classes (`\d`, `\w`, `\s`), case folding, and the POSIX class set behave under Unicode and locale considerations. Brief summary here; the full treatment is in the *unicode* chapter.

Modifier	Behaviour
`/u`	full Unicode semantics. Default under `use v5.12+`.
`/a`	restrict `\d`, `\w`, `\s`, `[[:…:]]` to ASCII.
`/aa`	`/a` plus `/i` does not cross ASCII/non-ASCII.
`/l`	follow the current `use locale` POSIX locale.
`/d`	dual-mode semantics. Avoid in new code.

`/a`, `/u`, `/l`, `/d` are mutually exclusive - at most one can be in effect at a time. `/aa` is a refinement of `/a`. They are *set-once* modifiers: an inner `(?d:…)` cannot un-set an outer `/u`.

The everyday choice in modern code: `use v5.12` (or later) selects `/u` automatically, which is what you want for Unicode-correct text. Add `/a` only when the pattern must reject non-ASCII characters - typically because the input is known to be ASCII-only and you want to enforce that.

Inline modifiers

`(?flags)` turns flags on for the rest of the enclosing group (or pattern):

```
/(?i)yes/;          # case-insensitive, same as /yes/i
```

`(?flags:…)` scopes the flags to the inner group only and is non-capturing:

```
/Answer: ((?i)yes)/;   # only the 'yes' is case-insensitive
/Answer: ((?i:yes))/;  # clearer: scope is the group's contents
```

`(?-flags)` turns flags off. They can be combined:

```
/(?i-m:pattern)/;   # turn on /i, turn off /m, within this group
```

Inline modifiers are the right tool when different parts of a long pattern need different modifiers. They are also useful in patterns built by interpolation, where the embedded `(?i)` travels with the pattern fragment.

Caret form: `(?^…)`

`(?^flags)` is shorthand for "reset all flags, then apply these". The expansion is `d-imnsx` followed by the listed flags. So `(?^x:…)` means "default flags except `/x` is on, regardless of what flags were in scope outside".

The caret form is what Perl uses when stringifying compiled patterns; you may see it in error messages or `qr//` output. In hand-written code it is occasionally useful when interpolating a pattern fragment that should not inherit modifiers from its surroundings:

```
my $strict = qr/(?^:foo|bar)/;   # always default flags
# ... no matter how this is interpolated.
```

A negative flag is not legal after the caret (it would be redundant - the caret already cleared everything).

Mutually-exclusive flags

`/a` and `/aa` override each other (last one wins); same for `/x` and `/xx`. They are not additive. `(?xx-x:…)` turns *all* `x` behaviour off, not "subtract one `x` from two".

The charset family `/a`, `/d`, `/l`, `/u` is mutually exclusive; specifying one un-specifies the others. They cannot be turned *off* with a leading `-`, only switched between. So `(?-d:…)` is a fatal error; `(?dl:…)` is also fatal (two charset flags together).

`/p` is special: its presence anywhere in a pattern has a global effect (and that effect is a no-op).

Order of modifiers

On a match or substitution, the order of trailing modifiers is not significant. `/mgis` and `/sgmi` are identical. Pick a house style and stick to it.

How a regex is read - the four phases

For modifiers and inline forms to work, you have to understand that Perl reads a regex in *phases*. The phases:

1. **Phase A**: parser identifies the delimiter, finds the end of the pattern. `(?#…)` comments are removed here.
2. **Phase B**: pattern is parsed as a *double-quotish string*. Variables interpolate, escape sequences cook, `\Q…\E` translates to `quotemeta`-style escaping.
3. **Phase C**: under `/x` or `/xx`, unescaped whitespace and #-comments are stripped.
4. **Phase D**: the regex compiler reads the cooked, stripped pattern and turns it into the engine's internal form.

The order matters because phases B and D operate on different representations:

- `\Q$dir\E` cooks at Phase B, before the regex compiler sees it. By Phase D the variable's contents have already been metaquoted; the regex compiler sees a literal pattern.
- `\U...\E` is interpreted by Phase B as a string-cook directive (uppercase the contents), which is almost certainly *not* what you want inside a regex. Use `\Q` and `\E` for regex purposes; `\U` only when you want the pattern's *literal text* to be uppercased.
- `(?#comment)` is removed before Phase B sees the pattern at all. A literal # inside `(?#...)` is fine. A literal `)` is not - the comment ends at the first `)`.

The `/x` modifier applies at Phase C, between interpolation and compilation. That means whitespace introduced by an interpolated variable is *not* stripped by `/x`:

```
my $sub = " a b ";       # contains literal spaces
"axb" =~ / x $sub x /x;  # the spaces in $sub are NOT stripped
```

If you want the interpolated content to obey `/x`, you have to strip its whitespace at the source.

use re 'strict'

`use re 'strict'` raises a number of normally-tolerated regex sloppiness conditions to compile-time errors. It is per-lexical-scope. In strict mode:

- A `{` in a non-quantifier position is an error, not a literal.
- `[a-]` (dash at end of class) is an error.
- A useless negation of an always-on flag is an error.
- A `(?-d)` (trying to turn off `/d`) is an error rather than a warning.
- Unmatched `[` in a string is an error.

Strict mode is recommended for new regex-heavy code, especially generated patterns where small typos go unnoticed in a normal build. It is not default because it would break working older patterns.

```
use re 'strict';

/abc{,1/;           # error in strict; warning otherwise
/[a-]/;             # error in strict
```

Substitution

`s///` is the search-and-replace operator. Its general form is:

```
$target =~ s/pattern/replacement/modifiers;
```

It finds the first position where *pattern* matches in *target*, replaces that match with *replacement*, and returns the number of substitutions made. With `/g`, it does that for every non-overlapping match.

```
my $x = "Time to feed the cat!";
$x =~ s/cat/hacker/;          # $x is now "Time to feed the hacker!"
```

If the pattern does not match, the target is unchanged and `s///` returns a false value.

Operating on $_

Like `m//`, `s///` defaults to `$_` when no `=~` is given:

```
for (@lines) {
    s/\s+$//;       # trim trailing whitespace from each line
}
```

Counting substitutions

The return value of `s///` in scalar context is the number of replacements:

```
my $count = ($text =~ s/\btodo\b/done/gi);
print "cleared $count todos\n";
```

In boolean context, zero means no match.

The replacement string

The replacement is a double-quoted string, so variables and escape sequences interpolate:

```
my $suffix = ".bak";
$file =~ s/$/$suffix/;    # append .bak to the name

$x =~ s/\t/    /g;        # each tab becomes four spaces
```

Inside the replacement, `$1`, `$2`, `$&`, `$+` and friends refer to what the *current* match just captured:

```
my $y = "'quoted words'";
$y =~ s/^'(.*)'$/$1/;     # strip surrounding single quotes
# $y is now "quoted words"
```

Named captures work the same way through `$+{name}`:

```
"2026-04-23" =~ s/(?<y>\d{4})-(?<m>\d{2})-(?<d>\d{2})/$+{d}\/$+{m}\/
 ↪$+{y}/;
# result: "23/04/2026"
```

Escaping in the replacement

The replacement is interpreted as a double-quoted string, so the double-quote rules apply to *it*, independently of the pattern. Metacharacters like `*`, `+`, `?`, `$` retain their double-quoted meanings - only `$` and `@` trigger interpolation:

```
$x =~ s/(\w+)/[$1]/g;      # wrap every word in brackets
$x =~ s/\$/USD/g;          # replace literal '$' with 'USD'
```

Backslash escape sequences in the replacement follow the double-quote rules - `\t`, `\n`, `\x{…}` all work. The special case-modification escapes `\l`, `\u`, `\L`, `\U`, `\E`, `\Q` apply in the replacement too:

```
$x =~ s/(\w+)/\u$1/g;      # capitalise the first letter of each word
$x =~ s/(\w+)/\U$1\E/g;    # uppercase whole word
```

Warning: \1 versus $1 in the replacement

A long-grandfathered idiom: writing `\1`, `\2`, … in the replacement to mean "the first capture", "the second capture":

```
$pattern =~ s/(\W)/\\\1/g;      # works, but is a trap
```

Perl accepts `\1` through `\9` in the replacement of `s///` for historical compatibility with `sed`. **Use $1 through $9 instead.** The reason is that the replacement is a double-quoted string, where `\1` *normally* means a control-A character. The substitution operator's special-case rule kludges that double-quote interpretation to mean "first capture", but the edges are sharp.

Specifically: combining `\1` with `/e` re-introduces the double-quote meaning. Under `/e`, the replacement is *Perl code*; in Perl code, `"\1"` is control-A:

```
s/(\d+)/ \1 + 1 /eg;    # warning: \1 better written as $1
```

A second sharp edge: `\1` followed by digit characters is ambiguous. `\1000` could mean "first capture, then literal `000`", or it could mean "octal `\100` (@), then a literal `0`" - and you cannot disambiguate by writing `\{1}000`:

```
s/(\d+)/\1000/;      # ambiguous, best avoided
s/(\d+)/${1}000/;    # unambiguous
```

The rule for new code: **always use $1 in the replacement, never \1**. The `\1` form is grandfathered, not recommended.

/g - replace all

Without /g, s/// replaces only the first match. With /g, it replaces every non-overlapping match from left to right:

```
my $x = "I batted 4 for 4";
$x =~ s/4/four/;          # "I batted four for 4"
$x = "I batted 4 for 4";
$x =~ s/4/four/g;         # "I batted four for four"
```

/g in substitution is unrelated to /g in matching. Here it just means "do this again and again until the pattern stops matching."

Zero-length matches and s///g

A pattern that can match the empty string presents a problem under /g: every position would match again forever. Perl breaks this loop with a specific rule: **after a zero-length match, the next attempt at the same position is forbidden to also be zero-length**. The engine takes the second-best match instead.

The cleanest demonstration:

```
$_ = 'bar';
s/\w??/<$&>/g;
# Result: <><b><><a><><r><>
```

The non-greedy \w?? prefers the empty match. After producing one, the next iteration is forbidden from being zero-length too, so the engine takes the second-best match - a single \w character. Then another empty match, then another character, and so on, alternating until the string is consumed.

The pattern: zero-length matches alternate with one-character matches, and the substitution does not loop forever.

A useful corollary: s/(\d{3})/$1,/g does not insert a comma after every set of three digits *correctly* - it inserts after the first three from the left, then the next three, regardless of where you wanted the commas. To insert thousands separators, match from the right or use 1 while:

```
my $n = "1234567";
1 while $n =~ s/^(\d+)(\d{3})/$1,$2/;
# n is now "1,234,567"
```

The 1 while repeats until the substitution returns false (no more matches), which is exactly what we want for "every position, after settling".

/e - evaluate the replacement

Under /e, the replacement is Perl code, not a string. The code runs for every match and its return value replaces the match.

```
my $x = "numbers: 1 2 3 4";
$x =~ s/(\d+)/$1 * 2/ge;      # "numbers: 2 4 6 8"
```

The match variables $1, $2, ... are visible inside the code block.

Practical uses:

```
# Uppercase the first letter of every sentence.
$text =~ s/(^|\.\s+)(\w)/$1\U$2/g;

# Hex-encode non-ASCII bytes.
$bytes =~ s/([\x80-\xff])/sprintf "\\x%02x", ord $1/ge;

# Apply a lookup table.
my %subst = (red => 0xff0000, green => 0x00ff00, blue => 0x0000ff);
$css =~ s/\b(red|green|blue)\b/sprintf "#%06x", $subst{$1}/ge;
```

/ee - double-eval

`/ee` evaluates *twice* - first as code, then the result is itself evaluated as Perl. The use case is dynamic variable lookup by name:

```
our $greeting = "hello";
my $s = "greeting";
$s =~ s/(\w+)/"\$$1"/ee;          # first: '$greeting'; second:
 ↪'hello'
# $s is now "hello"
```

The replacement is a Perl expression - the explicit double-quotes make it produce the *string* `"$greeting"`. The first `e` evaluates that expression to the string `$greeting`. The second `e` treats that string as Perl, looking up the variable `$greeting` and yielding `hello`. The match position is replaced with the value `hello`.

The use case is narrow and the security implications are substantial: any input that reaches an `/ee` substitution is effectively executed as Perl. Treat `/ee` like `eval` - never on user-supplied data.

/r - non-destructive substitution

`/r` returns the new string instead of modifying the target. The target is untouched:

```
my $orig = "I like dogs";
my $new = $orig =~ s/dogs/cats/r;
# $orig is still "I like dogs"
# $new is "I like cats"
```

If the pattern does not match, `/r` returns the original string unchanged:

```
my $x = "I like dogs";
my $y = $x =~ s/elephants/cougars/r;
# $y eq "I like dogs"
```

The big win is chaining:

```
my $slug = $title
    =~ s/[^\w\s-]//gr          # drop punctuation
    =~ s/\s+/-/gr              # collapse spaces to dash
    =~ s/--+/-/gr;             # collapse runs of dashes
```

Each arrow returns a new string, which the next `s///r` receives.

`\K` in substitution

`\K` (covered in detail in the *anchors and assertions* chapter) shines in substitution. The pattern matches a prefix that establishes context, then `\K` excludes the prefix from the replacement target:

```
# Without \K - the prefix has to be re-output:
$_ =~ s/(foo)bar/$1/g;

# With \K - the prefix is matched but not part of $&:
$_ =~ s/foo\Kbar//g;
```

Both replace `foobar` with `foo`. The `\K` form is cleaner: no capture is needed, and the substitution pattern is shorter and faster.

`\K` works similarly in any substitution where a fixed prefix should match but not be replaced. It is the substitution-side twin of lookbehind.

Substitution and `pos()`

Successful `s///g` advances `pos($string)` past each match. After a zero-length match, the next attempt at the same position may not be zero-length, which is what breaks the loop. After substitution, `pos` is reset.

A subtle interaction: `s///g` will not re-scan a region that has just been matched. After each successful replacement the match position advances past the *matched* text - the length of the replacement does not matter. So:

```
my $x = "aaa";
$x =~ s/a/AA/g;
# $x is "AAAAAA" - three a's, each replaced with AA
# It is NOT an infinite loop: pos() moves past each matched 'a',
# so the just-inserted 'A's are never re-scanned.
```

This is sometimes surprising for substitutions whose replacement contains characters that the pattern would also match. The rule is “advance past the matched text, never re-scan it”.

Alternate delimiters

Both halves of `s///` can use matched brackets; the delimiters do not have to be the same:

```
s{pattern}{replacement}g;
s<pattern><replacement>g;
```

(continues on next page)

(continued from previous page)

```
s[pattern][replacement]g;
s(pattern)[replacement]g;    # legal, but avoid mixing for clarity
```

Any printable punctuation works in a single-character form:

```
s!/usr/local/!/opt/!g;
s#pattern#replacement#;
```

Useful when the pattern or replacement contains `/`.

Single-quoted substitution

`s'pattern'replacement'` treats both halves as single-quoted - no variable interpolation, no backslash escapes apart from `\'` and `\\`:

```
s'@users'@admins'g;     # literal '@users' becomes literal '@admins'
```

Rarely needed; mention it for completeness.

Combining with `/m`, `/s`, `/x`

Substitution modifiers compose with match modifiers, so you can get the full toolbox:

```
# Trim each line.
$x =~ s/^\s+|\s+$//mg;

# Collapse blank lines.
$x =~ s/\n{2,}/\n\n/g;

# Replace C-style comments across newlines.
$src =~ s{/\*.*?\*/}{}gs;   # /s lets . cross newlines
```

With `/x` the pattern is readable, with `/s` it spans newlines, with `/g` it repeats.

A real example

Turn a block of English into a slug - lowercase, hyphens instead of spaces, drop non-letters, collapse and trim:

```
sub slug {
    my ($s) = @_;
    return lc($s)
        =~ s/[^\w\s-]//gr     # remove punctuation
        =~ s/\s+/-/gr          # spaces to hyphens
        =~ s/-+/-/gr           # collapse hyphens
        =~ s/^-|-$//gr;        # trim leading/trailing hyphens
}

print slug("Hello, World! -- Regex Tutorial");
# prints: hello-world-regex-tutorial
```

Friedl's framing - "anything that isn't required will always be considered successful"

A pattern's optional pieces will always succeed if they can match nothing. This applies inside substitution as forcefully as in matching:

```
my $x = "no horizontal rule here";
$x =~ s/-*/<HR>/;
# Result: "<HR>no horizontal rule here"
```

The pattern `-*` matches zero or more dashes - and zero is always available, at the start of the string. `<HR>` is inserted at position 0. The pattern has succeeded by the engine's definition; it has failed by yours.

The fix is to require at least one dash:

```
$x =~ s/-+/<HR>/;       # no match; $x unchanged
```

The slogan: **always consider what will happen if there is no match**. Optional pieces are not free; they always succeed by matching nothing somewhere.

Things that look like substitution but aren't

`tr///` (also written `y///`) does character-by-character transliteration, not regexp substitution. It accepts two lists of characters; each occurrence of the nth character in the first list becomes the nth character in the second list. No regexp features apply:

```
my $x = "Hello";
$x =~ tr/A-Za-z/a-zA-Z/;     # swap case
(my $hex = $bytes) =~ tr/\x00-\xff//d;   # delete all bytes -␣
↪pointless
```

`tr///` is faster than `s///` for character-level work because it is not a regexp engine. See `tr` for full semantics.

Unicode

Perl's strings are Unicode strings. Every code point from `\x{0000}` through `\x{10FFFF}` is a valid character, regardless of the underlying byte encoding. Regexps operate on characters, not bytes - so `\w`, `\d`, `\s`, `.`, and `\X` all understand the Unicode world.

This chapter covers how to write Unicode characters in a pattern, how to match by Unicode property, and how the *charset modifiers* `/a`, `/u`, `/l`, `/d` tune the default character-class behaviour. It closes with *Script Runs*, the mechanism for rejecting strings that mix scripts when they shouldn't.

Writing Unicode in a pattern

Four ways to denote a specific code point:

Form	Example	Notes
`\xHH`	`\x41` (A)	Two hex digits, 0–255
`\x{…}`	`\x{263a}` (☺)	Any code point
`\o{…}`	`\o{101}` (A)	Octal
`\N{name}`	`\N{GREEK SMALL LETTER SIGMA}`	Unicode character name

```
/\x{263a}/;                  # WHITE SMILING FACE
/\N{GREEK SMALL LETTER SIGMA}/;  # σ
/\N{U+03C3}/;                # same codepoint via U+ form
```

Whitespace and underscores inside `\N{…}` and `\p{…}` are ignored, so you can write `\N{GREEK SMALL LETTER SIGMA}` or `\N{greek_small_letter_sigma}`.

Inside a character class, the same escapes work:

```
/[\x{0370}-\x{03ff}]/;       # any Greek block character
/[\N{SECTION SIGN}\N{PILCROW SIGN}]/;
```

`\N{NAME}` (named character) is *not* the same as `\N` (any character except `\n` - see the *character classes* chapter). The presence or absence of the brace is what selects.

Matching by property: `\p{…}` and `\P{…}`

Unicode classifies every code point by dozens of properties. The most useful in everyday patterns:

Property	Matches
`\p{L}`	any letter
`\p{Ll}`	lowercase letter
`\p{Lu}`	uppercase letter
`\p{Lt}`	titlecase letter
`\p{N}`	any numeric character
`\p{Nd}`	decimal digit
`\p{P}`	punctuation
`\p{M}`	mark (combining character)
`\p{S}`	symbol
`\p{Z}`	separator (including spaces)
`\p{C}`	control, format, unassigned, private-use
`\p{ASCII}`	code point 0–127
`\p{White_Space}`	any Unicode whitespace

`\P{X}` is the negation of `\p{X}` - matches any code point *not* in property X.

Short single-letter properties drop the braces:

```
/\pL/;    # letter - same as \p{L}
/\pN/;    # number
/\pM/;    # mark
```

Compound properties

Some properties have multiple values. The compound form `\p{Property=Value}` (or `\p{Property:Value}`) spells them out:

```
/\p{General_Category=Uppercase_Letter}/;    # same as \p{Lu}
/\p{Block=Greek_and_Coptic}/;
/\p{Numeric_Type=Decimal}/;
/\p{Bidi_Class=R}/;                          # right-to-left␣
↪characters
```

Case, spaces, and underscores are ignored in the property name and value, so `\p{gc=lu}` is the same as `\p{General_Category=Uppercase_Letter}`.

For the full list of properties and values, see `perluniprops` - that list is generated from Unicode data and is not duplicated here.

Matching by script

Scripts (writing systems) are properties too:

```
/\p{Latin}/;
/\p{Greek}/;
/\p{Cyrillic}/;
/\p{Arabic}/;
/\p{Han}/;            # Chinese, Japanese kanji, Korean hanja
/\p{Hiragana}/;
/\p{Katakana}/;
/\p{Hangul}/;
/\p{Script=Greek}/;   # compound form, same meaning
```

For linguistic classification, prefer `\p{Script_Extensions=…}` - it handles code points used by multiple scripts more sensibly than `\p{Script=…}`. Perl's `\p{Greek}` shorthand actually uses `Script_Extensions` under the hood.

Grapheme clusters: `\X`

A *grapheme cluster* is what users perceive as a single character. A Danish å can be one code point (`U+00E5`) or two (`a` followed by combining ring `U+030A`). Both look identical on screen. `\X` matches either - one atomic user-visible character.

```
my $s = "a\x{030A}";     # a + combining ring
length($s);              # 2  - code-point count
```

(continues on next page)

(continued from previous page)

```
$s =~ /./;                # matches just the 'a'
$s =~ /\X/;               # matches the whole cluster
```

Use `\X` when iterating visibly across user-facing text: cursor movement, column counting, truncation, anywhere "characters" means "what the user sees".

Extended bracketed character classes - `(?[…])`

The standard `[…]` form takes unions of characters; `(?[…])` adds set-algebra operators that combine Unicode properties:

```
# Letters that are Greek:
/(?[ \p{Letter} & \p{Greek} ])/;

# Letters that are not Latin:
/(?[ \p{Letter} - \p{Latin} ])/;

# Hex digits without 'a' through 'f':
/(?[ [0-9A-Fa-f] - [a-f] ])/;
```

Operators: `+` (or `|`) for union, `&` for intersection, `-` for difference, `^` for symmetric difference, `!` for complement. The construct is itself a character class - it matches one character - and quantifies normally. The *character classes* chapter covers it in full.

The charset modifiers

The flags `/a`, `/u`, `/l`, `/d` control how the shorthand classes (`\d`, `\w`, `\s`) and case folding behave. They are orthogonal to `/i`, `/m`, `/s`, `/x`. At most one can be in effect at a time; `/aa` is a refinement of `/a`.

`/u` - Unicode semantics

`\d`, `\w`, `\s`, `\b`, case folding, and `[[:alpha:]]` use full Unicode definitions. This is the default when `use v5.12` or later is in effect.

```
"item\x{0660}" =~ /\w+\d/u;   # matches - U+0660 is an Arabic-Indic␣
↪zero
"naïve" =~ /\w+/u;            # matches the whole word
```

Modern code should use `/u`. `use v5.12+` selects it automatically.

`/a` - ASCII-only classes

Restricts `\d`, `\w`, `\s`, `[[:…:]]` to the ASCII range. Useful when you *want* English-like text and no more:

```
"item\x{0660}" =~ /\w+\d/a;   # does not match - \d is [0-9] under /
↪a
"item0"        =~ /\w+\d/a;   # matches
```

/aa - strict ASCII

/aa (doubled) additionally prevents case-insensitive matches crossing the ASCII/non-ASCII boundary. Under plain /ia, K could match \x{212A} (KELVIN SIGN) because the Kelvin sign casefolds to k. Under /iaa it does not:

```
"K"        =~ /k/i;      # matches
"\x{212A}" =~ /k/i;      # matches - Kelvin sign casefolds to 'k'
"\x{212A}" =~ /k/iaa;    # does NOT match - ASCII-only i
```

/aa is the strict form when the input is genuinely ASCII-only and you want the engine to refuse Unicode matches even under /i.

/l - locale semantics

\d, \w, \s, case folding, and [[:alpha:]] follow the current POSIX locale. Only sensible after use locale. Rarely what you want - locale behaviour is implementation-specific and harder to reason about than /a or /u. Provided for legacy code that genuinely needs locale-dependent matching.

/d - dual-mode semantics

Under /d, \d, \w, \s depend on whether the target string is flagged as UTF-8 internally. This is the source of most "works on my machine" Unicode regexp bugs. **Avoid /d in new code.** The default under use v5.12 is /u.

If you inherit code where /d matters, the failure mode is: the same input string produces different match results depending on whether some upstream operation flagged the string UTF-8. The fix is use feature 'unicode_strings' (or use v5.12+), which makes the rules independent of the UTF-8 flag.

Which modifier is in effect?

Resolution order:

1. Explicit modifier on the regex (/a, /u, /l, /d).
2. use re '/u' (or other) in the lexical scope.
3. use locale selects /l.
4. use feature 'unicode_strings' (and use v5.12+) selects /u.
5. Otherwise, /d (the dual-mode fallback; avoid).

Programs should use use v5.12; (or later) at the top of each file; this gives you /u, which is what you want.

Pragma interactions

```
use v5.12;                          # implicit feature 'unicode_
↪strings'
use feature 'unicode_strings';       # explicit
```

(continues on next page)

(continued from previous page)

```
use re '/u';                          # set default modifier for this␣
↪scope
```

`use feature 'unicode_strings'` (included in `use v5.12`) makes all strings Unicode for character-class purposes, regardless of whether they are marked UTF-8 internally. Turn it on at the top of every file.

Case folding

Under `/iu` (the default), case-insensitive matching uses the full Unicode case-folding tables:

```
"Grüße" =~ /grüsse/iu;          # matches - ß folds to 'ss'
"Σίγμα" =~ /σίγμα/iu;            # matches - upper Σ ↔ lower σ
"İstanbul" =~ /istanbul/iu;    # matches - dotted I folds
```

Under `/ia`, fold only ASCII letters. Under `/iaa`, plus the Kelvin/K rule above.

The folding happens at compile time - pperl does not lowercase the input string at match time.

The \b{…} word-boundary variants

Beyond plain `\b`, Perl offers semantic variants that handle real-world text better:

Boundary	Meaning
`\b{wb}`	Unicode word boundary - handles `don't`, `state-of-the-art`
`\b{sb}`	sentence boundary
`\b{lb}`	line break (suitable for line wrapping)
`\b{gcb}`	grapheme cluster boundary (same effect as `\X`)

```
"don't" =~ /.+?\b{wb}/x;       # matches whole word - apostrophe is␣
↪inside
"don't" =~ /.+?\b/x;           # stops at the apostrophe - plain \b␣
↪splits
```

For natural-language processing, `\b{wb}` and `\b{sb}` are almost always what you want. Plain `\b` is for ASCII identifier contexts.

The *anchors and assertions* chapter has the broader boundary discussion; this chapter is the home for the Unicode-aware variants because their definitions are Unicode-driven.

Script runs

Different writing systems have visually-similar characters. The Latin a, the Cyrillic а (U+0430), and the Greek α (U+03B1) look indistinguishable. Used together - typically in a URL or identifier - they enable a *homograph attack*:

paypal.com

Could be all Latin (legitimate). Could be a Cyrillic a embedded in otherwise-Latin text (a phishing attack pointing to a different domain). The browser's URL renders identically; the bytes do not.

A *script run* is a sequence of characters all from the same Unicode script (per `Script_Extensions` and Unicode UTS 39). Most legitimate words are script runs; mixed-script strings are rare outside specific multilingual contexts and almost always suspicious.

Perl provides two constructs, each with a short spelling, to require that a matched sub-pattern be a script run:

Form	Meaning
`(*script_run:PAT)` / `(*sr:PAT)`	match PAT, then check it is a script run
`(*atomic_script_run:PAT)` / `(*asr:PAT)`	same, but atomic (faster, less backtracking)

```
# Match a domain label only if it is a script run:
$label =~ /(*sr: \w+ )/x or warn "mixed-script label";

# Atomic version: faster on adversarial input.
$label =~ /(*asr: \w+ )/x or warn "mixed-script label";
```

The atomic form is what you want in most production code - it prevents the script-run check from being defeated by catastrophic backtracking on a malicious input. `(*sr:…)` is the non-atomic equivalent (`(*sr:(?>PAT))` is the same as `(*asr:PAT)`).

Script run rules

A sequence is a script run if and only if all of:

1. **No code point in the sequence has the `Script_Extensions` property `Unknown`.** This excludes private-use and surrogate code points; you cannot smuggle them through.
2. **All characters come from the Common script, the Inherited script, and at most one other script.**
3. **All decimal digits come from the same set of ten.** Many scripts have their own digits (Arabic-Indic, Devanagari, etc.); a string mixing 1 (ASCII) with ١ (Arabic-Indic one) is *not* a script run, even if other characters are compatible.

Three pseudo-scripts get special handling:

- **Common** - punctuation, ASCII digits 0–9, mathematical symbols, emoji, full-width digits. These can appear in any script run *except* that all decimal digits in the sequence must still come from the same set of ten.
- **Inherited** - combining marks (accents, diacritics). These attach to the previous character and inherit its script.
- **Unknown** - unassigned code points and similar. A single-character string of unknown is allowed; a longer string containing one is not.

The relaxation for Common and Inherited is what allows real-world text to be a script run despite punctuation and combining marks. The strict-equality rule for digits is what defeats homograph attacks that mix digits from look-alike scripts.

When script runs help

- **URL parsing**: refuse domain labels that are not script runs.
- **Identifier validation**: programming-language identifiers should normally be script runs.
- **Form input sanitisation**: real names are script runs; mixed-script names are usually attacks or test data.

Script runs are a 2018-and-later feature. They are what Perl's regex engine adds to a problem the rest of the engine cannot solve directly: a property of the *whole* match, not of any single character.

Cross-engine: Unicode coverage

Feature	Perl 5.44	PCRE2	Emacs (limited)	POSIX	RE2 / Go
`\p{General_Category}`	yes	yes	partial	no	yes
`\p{Script}`	yes	yes	partial	no	yes
`\p{Property=Value}`	yes	yes	partial	no	yes
`\X` grapheme cluster	yes	yes	no	no	yes (`(?-X:...)` is something else)
`\b{wb}`, `\b{sb}`	yes	no	no	no	no
Script Runs `(*sr:…)`	yes	no	no	no	no
Default to Unicode `\d/\w`	under `/u`	no	no	no	no (Unicode under `(?u)`)

Perl is a leader here: `\b{wb}` and Script Runs are essentially unique to Perl among the comparison set. RE2 / Go and PCRE2 both default to ASCII for `\d`, `\w`, `\s`; RE2 enables Unicode under the `(?u)` flag. PCRE2 has property support but lacks the boundary variants and script runs. Emacs has property support that varies by build.

The full table is in the *cross-engine* chapter.

Encoding vs. character

A Perl string is always a sequence of code points. The bytes on disk are the I/O layer's concern - use `use utf8` for source-code literals, `:encoding(UTF-8)` on filehandles, and `decode`/`encode` from `Encode` when crossing the boundary. Patterns never operate on the encoded bytes; they always operate on code points.

```
use utf8;            # source code is UTF-8
use feature 'unicode_strings';
use open ':std', ':encoding(UTF-8)';  # STDIN/STDOUT/STDERR

while (my $line = <>) {
    $line =~ /\p{Lu}/ and print "has uppercase letter\n";
}
```

Get the I/O right once, and patterns just work on characters for the rest of the program.

Performance

Most regexps run in roughly linear time over the string. A well-written pattern that matches is fast; a well-written pattern that fails is also fast. The trouble comes from patterns that *could have* matched in many different ways - the engine explores those possibilities one after another, and pathological patterns can explore exponentially many.

This chapter is about recognising that trouble, avoiding it, and when you cannot avoid it, damping it with possessive quantifiers, atomic groups, and careful structure. The second half is about the machinery the engine quietly applies on your behalf, and how to write patterns that let those optimisations fire.

Perl uses a *Traditional NFA* - an engine that walks the pattern under the direction of the input rather than the other way around, saving its place at every choice point so it can resume after a dead end. That property is what makes captures, backreferences, and lookaround possible; it is also what makes the worst case exponential. Everything in this chapter is a corollary of that one fact.

How backtracking works

A regexp engine walks the string and the pattern in lockstep. When it reaches a choice - an alternation, a quantifier, an optional group - it makes a decision, remembers the choice on a stack, and continues. If a later position in the pattern fails, it pops the most recent choice, tries the next available decision, and resumes. This is *backtracking*.

Every `?`, `*`, `+`, `{…}`, and `|` is a potential backtrack point. A short string and few choice points: fast. A long string, nested choice points, and no match: exponential.

A worked example from `perlre`. To pull the word following `foo` out of `Food is on the foo table.`:

```
$_ = "Food is on the foo table.";
if (/\b(foo)\s+(\w+)/i) {
    print "$2 follows $1.\n";
}
# table follows foo.
```

The engine first matches `\b(foo)` against `Food`, loading `$1` with `Foo`. It then looks for `\s+` and finds `d` - failure. It backtracks, advances the start position, and continues searching until it finds the literal `foo` followed by whitespace, then a word.

A more revealing case. The pattern says "everything between `foo` and `bar`":

```
$_ = "The food is under the bar in the barn.";
if (/foo(.*)bar/) {
    print "got <$1>\n";
}
# got <d is under the bar in the >
```

Greedy `.*` ran all the way to the end of the string, then crawled back left until `bar` could finally match - at the *last* `bar`, not the first. Use `.*?` to stop at the first.

`perlre` has a longer version of this with eight variants - most wrong, all instructive - under `Backtracking`. The lesson is the same in each: a greedy quantifier always overshoots first; the correct *shape* (which anchors? non-greedy or negated class?) is what fixes the match, not adjusting the quantifier in place.

The state-saving cost

Friedl's mechanical model is worth keeping in mind. For an NFA, the *saved-state count* is roughly the number of characters that quantifier-governed subexpressions matched. `[0-9]+` against `1234` saves four states - one per digit, marking each as a "match could end here" point. When the engine eventually fails further along the pattern, it pops those four states one at a time, trying to find a way to make the match succeed.

A subtle detail: the `+` quantifier *requires* its first match, so it doesn't save a state for "match nothing here". `*` does, because zero matches are allowed. That asymmetry shows up in benchmark microcomparisons of `+` vs `*` patterns; on inputs where the quantifier really must match at least one thing, `+` is slightly faster because it has one fewer state to manage on failure.

Catastrophic backtracking

Consider this pattern trying to match a long string of `a`'s:

```
"aaaaaaaaaaaaaaaaaaaa" =~ /(a+)+b/;
```

The pattern cannot match - there is no `b`. But the engine has to *prove* it. Each `a` in the string can be assigned to the inner `+` or the outer `+` in many ways. For a 20-character string that is millions of combinations; for a 30-character string, billions. The engine tries them all.

The general shape to watch for: **nested indeterminate quantifiers on overlapping classes.**

```
/(a+)+/;              # dangerous
/(a|b)*c/;            # dangerous on a+b strings without trailing c
/(\w+)*\s/;           # dangerous on a run of word chars with no␣
↪space
/([^"]|\\.)*"/;       # dangerous on long unterminated strings
```

Every one of these has the same shape: an outer quantifier on a group whose inner content is itself indeterminate. Friedl's canonical scary example, the doublequoted-string regex `"(\\.|[^"\\]+)*"` applied where it cannot match, is documented to take roughly 3.2×10^{29} backtracks before giving up - many universe-lifetimes if the engine really did try them all. Perl does not try them all: its super-linear cache remembers where an iteration has already failed, which turns the exponential search into a quadratic one. Quadratic is still a trap. On perl 5.44 that pattern rejects an unterminated string of 1,000 characters in about 0.01 s, of 10,000 in about 0.8 s, and of 100,000 in about 80 s.

The disease is the same in every case. For each extra character the input grows, the number of ways the engine can apportion characters between the inner and outer quantifier *doubles*.

The cure is *determinism*: write the regex so that for any input there is exactly one way the engine can divide the work between inner and outer quantifier. The next sections cover the three techniques that achieve this.

Possessive quantifiers

A possessive quantifier (`++`, `*+`, `?+`, `{n,m}+`) is greedy *and* never gives back. It tells the engine: "once I've matched these characters, they are mine; do not revisit this decision on failure."

```
/(a++)+b/;    # at most one backtrack point
/(\w++)*\s/;  # bounded - \w++ takes all word chars in one shot
```

The trade-off: if a later part of the pattern needs those characters back, the match simply fails. Possessive is correct when there really is no other way for the match to succeed at that prefix.

Possessive quantifiers are syntactic sugar for an atomic group around the quantified atom. The following are equivalent:

Possessive form	Atomic-group form
`PAT*+`	`(?>PAT*)`
`PAT++`	`(?>PAT+)`
`PAT?+`	`(?>PAT?)`
`PAT{n,m}+`	`(?>PAT{n,m})`

The possessive notation is shorter; the atomic-group notation generalises further (you can wrap arbitrary alternations, not just quantified atoms).

A consequence of "possessive equals atomic": some combinations make no sense and Perl rejects them.

Illegal form	Equivalent legal form
`X??+`	`X{0}`
`X+?+`	`X{1}`
`X{n,m}?+`	`X{n}`

Non-greedy and possessive are contradictory. Use `X{0}`, `X{1}`, or `X{n}` if you really wanted to match exactly that many.

Atomic groups

`(?>…)` is a non-capturing group whose contents, once matched, are committed. Like a possessive quantifier, no backtracking happens inside it. The difference is that atomic groups wrap *arbitrary* patterns, not just quantified atoms.

```
"aaab"  =~ /a*ab/;       # matches - the a* gives back one 'a'
"aaab"  =~ /(?>a*)ab/;   # does not match - a* takes all, none to␣
↪give
```

Atomic groups are the most general tool for controlling backtracking. Use them around a block of pattern that should either fully match or not participate.

A classic application: balanced parentheses, fast on bad input.

```
# Unbounded: dangerous on unbalanced input
/ \( ( [^()]+ | \([^()]*\) )+ \) /x;

# With atomic group: fast failure on bad input
/ \( ( (?> [^()]+ ) | \([^()]*\) )+ \) /x;
```

The inner `(?>[^()]+)` says: gobble as many non-paren characters as possible and don't come back. That removes the ambiguity that makes nested `+` expensive.

`(?>…)` does not disable backtracking *outside* it. The engine can still backtrack past the construct as a whole, just not into it. So `((?>a*)|(?>b*))ar` against `bar` still matches: the outer alternation can backtrack between branches.

Nested atomic groups are *not* no-ops. Each extra layer further constrains what the inner pieces can give up. `(?>a[bc]*c)` matches `abc`; `(?>a(?>[bc]*)c)` does not, because the inner `(?>[bc]*)` ate the trailing `c` and refuses to release it.

The long-form spelling `(*atomic:…)` is also accepted; it reads better in pattern code that already uses verbs like `(*positive_lookahead:…)`.

Matching quoted strings - the canonical case

The "match a quoted string with backslash escapes" problem is the one everyone gets wrong on the first try.

Naive:

```
/"(?:[^"\\]|\\.)*"/;
```

This one is correct, and it is not the dangerous kind: its two alternatives cannot match the same character, so there is only one way to divide the input, and a failed match fails in linear time. The trap is a `+` inside the group, `/"(?:[^"\\]+|\\.)*"/`: a run of `a`'s can now be split between iterations in many ways, and perl takes about 0.6 s instead of 0.002 s to reject an unterminated string of 10,000 characters. The safe form:

```
/"(?:[^"\\]++|\\.)*+"/;
```

The inner `++` takes all non-quote, non-backslash characters in one bite. The outer `*+` refuses to give back across iterations. A failed match fails in linear time. The atomic-group equivalent is identical in behaviour:

```
/" (?> (?: (?> [^"\\]+ ) | \\. )* ) "/x;
```

- and demonstrates why the possessive form is preferable when it applies. It's terser without losing anything.

Unrolling the loop

The single most useful technique for replacing a non-deterministic pattern with a deterministic one. Friedl named it; engines have internalised it; every working regexp programmer should know it.

The pattern shape:

```
opening normal* (special normal*)* closing
```

- where `normal` and `special` are subexpressions that consume disjoint sets of characters. The construction guarantees there is exactly one way the engine can split the input between them, so no exponential exploration ever begins.

Three rules, all mandatory:

1. **`special` and `normal` cannot start a match at the same position.** If both can match the same character, the engine has freedom to choose; that freedom is exactly what causes exponential blowup.
2. **`special` cannot match the empty string.** A `special` that matches nothingness is invisible to the engine and removes the checkpoint that makes the construction deterministic.
3. **One application of `special` cannot be coverable by multiple applications of `special`.** If `special` is `\s+` and the input has three consecutive spaces, the engine could match them as one `special`, three `specials`, or various combinations - exponential blowup is back.

Worked example: doublequoted strings

Naive form, prone to catastrophic backtracking:

```
/"(?:\\.|[^"\\])*"/;
```

Unrolled form, no nested ambiguity:

```
/"[^"\\]*(\\.[^"\\]*)*"/;
```

`[^"\\]*` is the `normal*` - it eats every non-special character. `\\.` is the `special` - it consumes a backslash plus exactly the following character. The two cannot overlap (`normal*` cannot contain `\\`; `special` cannot match a non-`\\` character), and `special` always consumes exactly two characters.

The unrolled form runs in linear time on any input - matching or not. The naive form is exponential on inputs with many backslashes and no closing quote.

The same problem with possessive quantifiers also runs in linear time:

```
/"[^"\\]*+(?:\\.[^"\\]*+)*+"/;
```

Pick whichever the rest of your team reads more easily. Both work.

Worked example: C comments

The "match a C comment, surviving asterisks inside" problem. Naive comment match `\/\*.*?\*\/` works but is slow on long comments because `.*?` has to expand one character at a time.

Unrolled:

```
/\/\*[^*]*\*+([^/*][^*]*\*+)*\//;
```

Reading from left to right:

- `\/\*` - opening `/*`.
- `[^*]*` - `normal*`, zero or more non-asterisk characters.
- `\*+` - at least one asterisk.
- `([^/*][^*]*\*+)*` - zero or more iterations of: a non-slash, non-asterisk character, then more non-asterisks, then more asterisks. (The non-slash bit is what stops the run: an asterisk followed by a slash is the terminator we want.)
- `\/` - closing slash.

The construction makes every iteration of the outer `*` consume at least one character that no other iteration could have consumed. Result: linear time, no catastrophic-backtracking pattern.

The pedagogical value of working through this is in the *thought process*, not memorising the final regex. The asterisks-inside complication forces the extra `[^/*]` term; recognising why is what teaches you to spot the next case.

Worked example: the freeflowing regex

When you have multiple "skip me" subexpressions (strings, comments, constants in a parser-like context), build a single regex with all of them in alternation and an `OTHER+` clause for the bulk of the data:

```
my $DOUBLE = qr/"[^"\\]*(?:\\.[^"\\]*)*"/;
my $SINGLE = qr/'[^'\\]*(?:\\.[^'\\]*)*'/;
my $COMMENT = qr/\/\*[^*]*\*+(?:[^\/*][^*]*\*+)*\//;
my $LINECOM = qr/\/\/[^\n]*/;
my $OTHER  = qr/[^"'\/]+/;

while ($source =~ / $DOUBLE | $SINGLE | $COMMENT | $LINECOM | $OTHER
 ↪/xg) {
    ...
}
```

The `$OTHER` arm consumes the bulk of the input in long runs, which means the engine spends almost all its time inside one linear-time loop, not on the bump-along trying alternatives at every uninteresting character. The technique is decisive on parser-like workloads.

Reducing choice

If your pattern works but is slow, look for spurious choice:

- **Anchor where you can.** `^pat` and `pat$` let the engine reject most starting positions immediately. `\A` is even better than `^` when you mean "start of string" - the engine can refuse to retry at every position rather than only at line starts.
- **Replace alternation of single characters with a class.** `/a|b|c/` is slow compared to `/[abc]/`; the class is a single choice, the alternation is three.
- **Put the common alternative first.** Alternation is tried left-to-right, and Perl stops at the first success. If 90% of your inputs hit alternative 3, reorder.
- **Expose common prefixes.** `/this|that|them/` defeats the fixed-string optimisation; `/th(?:is|at|em)/` hands the engine the literal `th` to scan for first.
- **Prefer character classes to `..`** `[^\n]` is cheaper than `.` because the engine knows it will never match across lines. Same for `[^"]` instead of `.*?` between quotes.
- **Negated character classes beat `.*?`.** The non-greedy form has to leave the inner loop on every iteration to test what follows; the negated class participates in the simple-repetition fast path. `<([^>]+)>` is several times faster than `<(.+?)>` and also more correct: the negated class *cannot* cross a `>` even under backtracking pressure.

Compile once, match many

Every time a pattern with interpolated variables is used, Perl checks whether the text of the pattern changed. If it has not, the compiled form is reused. For patterns that really are fixed, the overhead is small but nonzero.

`qr` compiles a pattern once and produces a reusable object:

```
my $word = qr/\b[a-z]+\b/;
for my $text (@corpus) {
    while ($text =~ /$word/g) {
```

(continues on next page)

(continued from previous page)

```
        ...
    }
}
```

Using `qr` in a hot loop saves the recompile-or-check step and makes the code clearer. It also lets you build complex patterns out of named pieces, which is decisive for any regex over about ten lines.

The `/o` modifier ("compile once") was the Perl 4 mechanism for this. It still works but is rarely the right tool today: `qr//` is clearer, scopes better, and composes.

Avoiding capture overhead

Capturing groups cost a little - the engine has to track the start and end positions, and the surrounding optimisations (simple repetition in particular) may be disabled. If you don't use the capture, don't ask for it.

```
# Capturing even though $1 is never read:
/(\d{4})-(\d{2})-(\d{2})/;

# Non-capturing:
/(?:\d{4})-(?:\d{2})-(?:\d{2})/;
```

The `/n` modifier turns every `(…)` into `(?:…)` without editing the pattern - useful for long patterns. Named captures still capture under `/n`.

Even non-capturing parens may suppress the simple-repetition optimisation in some engines, so `(?:[a-z])+` is occasionally slower than `[a-z]+`. Drop unnecessary grouping; flatten patterns where you can without hurting readability.

Recursive patterns

Perl regexps support recursion - a pattern can refer back to one of its own groups. The construct is `(?R)` (or `(?0)`) for the whole pattern, `(?N)` for group N, `(?-N)` and `(?+N)` for relative references, and `(?&NAME)` for named groups.

A recursive pattern for a balanced parenthesis, any depth:

```
my $bal = qr/
    (?(DEFINE)
        (?<paren>
            \(                  # opening paren
            (?:
                [^()]++         # run of non-paren, possessive
              | (?&paren)       # or a balanced sub-group,␣
↪recursively
            )*+
            \)                  # closing paren
        )
    )
    (?&paren)
```

(continues on next page)

(continued from previous page)

```
/x;

"((a)(b(c)))" =~ /^$bal$/;   # matches
```

A named subpattern declared in a `(?(DEFINE)...)` block recurses into itself, not into the whole enclosing pattern. Using `(?R)` here would force every level of recursion to re-apply the call site's anchors (^ and $), which is rarely what you want.

Recursion makes genuinely recursive structures matchable without falling out of the regex DSL. It is also a strong signal that you might be reaching for the wrong tool. A real parser is often clearer; reach for recursive regexps when you want a one-line match-or-fail decision, not a parse tree.

There is a recursion-depth limit compiled into the engine (it can be raised by rebuilding from source). Patterns that recurse without consuming input fail immediately rather than running forever - the engine detects the cycle.

The interaction with capture groups deserves attention. When a group recurses into itself, captures set inside the recursion are *not* visible to the caller after the recursion returns. This is the practical reason most recursive patterns use possessive quantifiers and atomic groups for the inner content: capturing it serves no purpose because the data won't be there when the outer match finishes.

Embedded code

`(?{ code })` runs Perl code at the point the engine reaches it. The code's return value is set as `$^R`. Useful for instrumentation and for assertions whose condition is more naturally written in Perl than in regex syntax:

```
my $tries = 0;
"aaaaab" =~ /a*(?{ $tries++ })b/;
print "engine tried $tries times\n";
```

Two important properties:

- The block is *backtracking-safe* if you assign to `local` variables. `local $cnt = $cnt + 1` undoes itself when the surrounding match backtracks past the block. A bare assignment does not.
- The block sees the same lexical scope it was compiled in. A `qr//` containing `(?{ ... })` closes over the lexicals in scope at compile time, *not* at match time. This is the same rule that governs closures everywhere else in Perl.

`$^N` is particularly useful inside `(?{...})` - it holds the text matched by the most-recently-closed capture group, so you can save matches without counting parentheses:

```
$_ = "The brown fox jumps over the lazy dog";
/the (\S+)(?{ $color = $^N }) (\S+)(?{ $animal = $^N })/i;
print "color = $color, animal = $animal\n";
# color = brown, animal = fox
```

The big cost: `(?{ ... })` *globally disables* certain optimisations in the pattern. Patterns containing it can run much slower than patterns without it, even on inputs where the code block runs zero times.

`(*{ code })` is the *optimistic* form, introduced in Perl 5.37.7. Same syntax, same behaviour, except it does not disable optimisations. The trade-off: the engine may execute the block fewer times than the strict semantics of `(?{...})` would require. On a failing match it might not run at all. Use `(?{...})` when you depend on side effects firing in a documented order; use `(*{...})` when you don't.

`(??{ code })` is the *postponed regex*: the code's return value is treated as a pattern, compiled if it is a string (or used directly if it is a `qr//` object), and matched at that position. It enables genuinely runtime-shaped patterns:

```
my $inner = '(.)\1';
"ABBA" =~ /^(.)(??{ $inner })\1/;
print $1;   # 'A'
```

The inner pattern has its own capture state - captures inside `(??{...})` are not visible to the outer pattern. For balanced parens or other recursive structures, `(?R)`/`(?N)` is more efficient and also clearer.

User-supplied input must never reach `(?{...})` or `(??{...})`. Perl forbids it by default; `use re 'eval'` removes the safety catch and you should not.

Embedded-code execution frequency

The exact number of times `(?{...})` and `(??{...})` execute during a match is *unspecified*. The engine guarantees only:

- On a successful match, blocks on the accepting path execute in left-to-right order, the appropriate number of times for the quantifier they sit under.
- Blocks may execute zero, one, or many times during failed matches, depending on what optimisations the engine applies.

For example, in `"aaabcdeeeee" =~ /a(?{print "a"})b(?{print "b"})cde/`, the precise number of a's and b's printed is unspecified for *failed* matches. For a successful match each block runs at least once on the accepting path; if b was printed, an a was necessarily printed at least once before it.

Quantified blocks behave intuitively on success:

```
"good" =~ /g(?:o(?{ print "o" }))*d/;
# prints o twice
```

Code blocks intended to count, log, or trace must use the `(?{...})` form (deterministic on success); blocks that are purely advisory may use `(*{...})` (and accept the lower call count in exchange for not breaking optimisations).

Special backtracking control verbs

Perl provides verbs that direct the engine more precisely than ordinary atomic groups can. They all use the form `(*VERB)` or `(*VERB:NAME)`. They are zero-width (they consume no input) and only do something when *backtracked into* on failure.

The verbs interact with two package variables: `$REGERROR` and `$REGMARK`. After a match involving any verb that takes a `NAME`:

- `$REGMARK` is set to the name of the last `(*MARK:NAME)` executed, on success.
- `$REGERROR` is set to the name of the verb that caused the failure, on failure.

These are package globals (not magic variables; not localised automatically); use `local` if you need scoping.

`(*PRUNE)` and `(*PRUNE:NAME)`

Prunes the backtracking tree at the current point. After `A(*PRUNE)B`: if `B` fails, the engine does not backtrack into `A`. The match fails *at the current starting position*; the engine then advances to the next one as usual. To stop the whole match for good, use `(*COMMIT)`.

```
'aaab' =~ /a+b?(?{ print "$&\n"; $count++ })(*FAIL)/;
# Prints aaab, aaa, aa, a, aab, aa, a, ab, a - 9 times.

$count = 0;
'aaab' =~ /a+b?(*PRUNE)(?{ print "$&\n"; $count++ })(*FAIL)/;
# Prints aaab, aab, ab - 3 times.
```

`(*PRUNE)` is a more powerful `(?>...)`: it controls backtracking across pattern segments rather than within a fixed sub-pattern.

`(*SKIP)` and `(*SKIP:NAME)`

Like `(*PRUNE)`, plus: signals that the text leading up to the verb cannot be part of *any* match. The engine advances the start position to where the verb fired and retries from there:

```
'aaabaaab' =~ /a+b?(*SKIP)(?{ print "$&\n"; $count++ })(*FAIL)/;
# Prints aaab, aaab - 2 times.
```

If `(*SKIP:NAME)` fires and a `(*MARK:NAME)` was set earlier, the new start position is the mark's position, not the verb's. This is the only sane way to do "if branch X failed, advance past where branch X started" in a single pattern.

`(*MARK:NAME)`

A named pseudo-checkpoint. Does nothing on its own - but `(*SKIP:NAME)` uses it as a target, and `$REGMARK` after a successful match holds the most recently executed mark name. The shorthand `(*:NAME)` is identical to `(*MARK:NAME)`.

This lets a pattern record which alternative branch matched without using a separate capture group per branch:

```
/(?:foo(*MARK:F)|bar(*MARK:B)|baz(*MARK:Z))/;
# After a successful match, $REGMARK is "F", "B", or "Z".
```

The optimiser handles MARK/SKIP more efficiently than `/(?:(foo)|(bar)|(baz))/` because it does not have to track three parallel capture states.

(*THEN) and (*THEN:NAME)

Inside an alternation: on failure of the rest of the pattern, backtrack to the next alternative of the *innermost enclosing group with alternations*, skipping branches above that level. Outside an alternation, equivalent to `(*PRUNE)`. Loosely: "this branch and only this branch; if it fails, try the next sibling branch."

```
/(COND1 (*THEN) ACT1 | COND2 (*THEN) ACT2 | COND3 (*THEN) ACT3)/x;
```

Reads like an if/elsif/else inside the regex.

(*COMMIT) and (*COMMIT:arg)

The strongest brake. Like `(*SKIP)`, but instead of advancing the start position, the engine *gives up entirely*. No further attempts to find a match anywhere in the string.

```
'aaabaaab' =~ /a+b?(*COMMIT)(?{ print "$&\n"; $count++ })(*FAIL)/;
# Prints aaab - 1 time.
```

Use when a partial match has consumed enough to prove that no match exists anywhere later either.

(*FAIL) / (*F)

Always fails. Equivalent to `(?!)` but more readable. Useful only combined with `(?{...})`: when you want to count or log every attempted match without ever accepting one. `(?!)` is internally optimised into `(*FAIL)`.

(*ACCEPT) and (*ACCEPT:arg)

The opposite of `(*FAIL)`. Always succeeds, ending the match immediately. Inside nested patterns or recursion, only the innermost pattern is ended. Capture groups that have opened but not yet closed are marked as ending where `(*ACCEPT)` fires:

```
'AB' =~ /(A (A|B(*ACCEPT)|C) D)(E)/x;
# matches; $1 is "AB", $2 is "B", $3 is undef
```

`(*ACCEPT)` is most useful inside `(??{...})` or `(?(condition)...)` constructs where you want a fast-path success without finishing the pattern.

Zero-length-match termination

A repeated pattern that can match the empty string is a problem. Trivially:

```
'foo' =~ m{ ( o? )* }x;
```

Each iteration of the outer * matches the empty string, the position does not advance, the next iteration matches empty again - infinite loop in waiting. Perl breaks this loop in two different ways depending on which kind of repetition is involved.

Lower-level loops - the quantifiers *, +, {n,m} - are *interrupted* when the engine detects that an iteration matched zero-length. The construct

```
(?: NON_ZERO_LENGTH | ZERO_LENGTH )*
```

is silently treated as

```
(?: NON_ZERO_LENGTH )* (?: ZERO_LENGTH )?
```

The zero-length branch can run, but only *once*, after the non-zero branch is done.

Higher-level loops - the /g modifier on m// and s///, and the split operator - preserve a flag across iterations recording whether the previous match was zero-length. After a zero-length match the next attempt is forbidden to *also* be zero-length; the engine takes the second-best match instead. The canonical demonstration:

```
$_ = 'bar';
s/\w??/<$&>/g;
# Result: <><b><><a><><r><>
```

The non-greedy \w?? prefers an empty match. After producing one, the next iteration is forbidden from being zero-length too, so the engine takes the *second*-best match - a single \w character. Then another empty match, then another character, and so on, alternating until the string is consumed.

The state of "previous match was zero-length" is associated with the matched string and is reset by any assignment to pos. Zero-length matches at the end of the previous match are also ignored during split, which is why split // produces individual characters and not a trailing empty fragment.

Combining patterns: better and worse

perlre's "Combining RE Pieces" section gives a precise account of which match the engine prefers when a pattern admits more than one. The rules are mechanical, and worth knowing for the cases where intuition fails.

For two pattern pieces concatenated, ST:

- If S matches A better than A', then AB is better than A'B' (the leftmost piece's preference dominates).
- If S matches both A and A' equally, T's preference decides.

For alternation, S|T:

- `S` matching is always better than only `T` matching (left-to-right choice - Traditional NFA semantics).

For greedy and non-greedy quantifiers:

- `S{n,m}` is equivalent to trying `S{m}`, then `S{m-1}`, ..., then `S{n}` (greedy: maximum first).
- `S{n,m}?` is equivalent to trying `S{n}`, then `S{n+1}`, ..., then `S{m}` (non-greedy: minimum first).

For atomic groups, `(?>S)`:

- *Only the best match for* `S` is considered; backtracking is forbidden inside.

For lookaround, `(?=S)` / `(?<=S)`:

- Only the best match for `S` is considered (the same as atomic). This matters only if `S` has capturing parens whose contents are used outside.

The above rules describe *which match is chosen at a fixed starting position*. One additional rule covers position selection: **a match at an earlier position is always better than a match at a later position** - the bump-along property is more important than any preference within a single position.

Engine internals - what the optimiser does for you

A regex engine's compiler runs a small army of analyses on the pattern before matching begins. Knowing them lets you write patterns that *enable* them, rather than ones that defeat them.

First-character discrimination

If the pattern must begin with one of a small set of characters (`am|pm` ⇒ `[ap]`), the bump-along can scan the input for one of those characters using a fast inner loop, invoking the full engine only at candidate positions.

A pattern starting with `.`, or with a top-level alternation the engine cannot see through, defeats this. Modern engines (PCRE2, RE2, the Rust regex crate) go far beyond first-character discrimination - Boyer-Moore on prefix literals, byte-level SIMD scanning, Aho-Corasick fallback for many literal alternatives. Perl 5.44 does the simpler form well; the more aggressive techniques are why a benchmark may show RE2 outperforming Perl on inputs dominated by literal scanning.

Fixed-string check

If the pattern requires some literal substring (e.g. `Subject:` in `^Subject: (Re: )?(.*)`), the engine uses Boyer-Moore to skip to candidate positions cheaply. A naive pattern like `/this|that|these|those/` defeats this; rewriting as `/th(?:is|at|ese|ose)/` exposes the common prefix `th` for the optimiser to find.

Simple-repetition fast path

`x*`, `[a-f]+`, `.?` and other "single atom, simple quantifier" constructs are dispatched to a fast inner loop that bypasses the general engine machinery. Wrapping the atom in *capturing* parens disables this. Even non-capturing parens may, depending on the exact construct.

Length cognizance

If the pattern requires at least N characters, the engine can refuse to attempt matches in the last N positions of the string, and refuse to attempt matches at all in strings shorter than N.

Anchor implication

A pattern starting with `^` is attempted only once (or once per logical line under `/m`). Less obviously, a pattern starting with `.*` followed by an anchorable subpattern *can* be implicitly anchored, because by the time `.*` has consumed the whole string, no later starting position can possibly succeed. Modern engines recognise this; do not write `.*` at the start unless you mean it.

Compile caching

Compiling a regex to its internal form is non-trivial. Perl caches compiled patterns aggressively - patterns embedded in code are compiled once when the surrounding sub is compiled, and patterns assembled from interpolated variables are recompiled only when the resulting text actually changes. `qr//` makes this explicit. The `/o` modifier was the older mechanism; `qr//` has superseded it in idiom.

Matching many strings efficiently

If you have a fixed list of strings to match and the list is stable, building one big alternation is often the simplest win:

```
my @words = qw(the quick brown fox);
my $any = join '|', map quotemeta, @words;
my $re = qr/\b(?:$any)\b/;
for my $line (@lines) {
    next unless $line =~ /$re/;
    ...
}
```

`quotemeta` protects each word from containing accidental metacharacters. The `(?:…)` is non-capturing - unnecessary captures would cost more than they pay. If the list is large (thousands of strings), a specialised module that builds an Aho-Corasick or trie matcher will beat a giant alternation; the built-in engine compiles the alternation to an NFA that is fast but not asymptotically optimal for that workload.

Measuring

Claims about regexp speed are cheap; measurements are not. `Benchmark::timethese` makes it easy to compare two forms on real data:

```
use Benchmark qw(timethese);

my $text = "..." x 10000;

timethese(1000, {
    greedy     => sub { $text =~ /"(?:[^"\\]|\\.)*"/ },
    possessive => sub { $text =~ /"(?:[^"\\]++|\\.)*+"/ },
});
```

Always profile before optimising. "Obviously slow" patterns often aren't; "obviously fast" ones sometimes are pathological on real input. Friedl's framing remains the best summary: the fastest program is the one that finishes first.

Rules of thumb

- Write the pattern that reads best; profile.
- If matching is slow, look for nested quantifiers on overlapping classes.
- Fix them with possessive quantifiers, atomic groups, or unrolling.
- Anchor with `^`, `$`, `\A`, `\z`, or `\G` whenever the pattern can only legitimately start or end in those positions.
- Prefer classes to alternations of single characters.
- Prefer negated classes to non-greedy quantifiers when they describe the same set.
- Use `qr//` for patterns that run in a loop.
- Use `(?:…)` for groups you don't capture, or `/n` to suppress captures wholesale.
- Use `(*{...})` instead of `(?{...})` when the code block is advisory.
- When a real parser would be clearer than a pattern, write the parser.

- The *alternation* chapter - ordering, leftmost alternative wins.
- The *substitution* chapter - `/g` and zero-length match termination in substitution.
- `qr` - precompile patterns for repeated use.
- `pos` - read or set the `/g` match position; also resets the zero-length-match flag.

Cross-engine comparison

Perl regexps are not the only kind. A reader who knows Perl well will, sooner or later, meet a regex written for another tool - `sed`, `awk`, an Emacs Lisp buffer search, a Go service, an embedded PCRE2 library - and be expected to read it. The syntactic differences are usually small, the semantic differences are sometimes substantial, and the architectural differences (which inputs make the engine catastrophically slow) can be decisive.

This chapter is the single page that answers "what does X look like elsewhere?" for the five engine families a Perl-trained reader is most likely to encounter. It is not a porting tutorial; it is the comparison reference.

Engines covered

Five families, picked because each is widespread in its niche *and* materially different from Perl. Engines that are widespread but largely Perl-shaped (Java's `java.util.regex`, Python's `re`, ECMAScript, .NET) are out of scope; the differences are minor and a Perl reader can read them on sight.

Engine	Where you meet it	Family
PCRE2	nginx, PHP `preg_*`, command-line `pcre2grep`	Perl-extended
Emacs	Emacs Lisp regex search, `M-x replace-regexp`	Its own family
POSIX BRE	`sed` (default), `grep` (default), `ed`	POSIX Basic
POSIX ERE	`awk`, `egrep` / `grep -E`, `sed -E` / `sed -r`	POSIX Extended
RE2 / Go `regexp`	Go's standard library, Cloud Bigtable, code search	Linear-time hybrid

Versions anchored against in this chapter: PCRE2 10.44, Emacs 30.x, POSIX 1003.1-2024, Go 1.22 (RE2 tracks Go's regexp engine). The values in the tables below were verified against these versions; they will drift over time, and engine-specific updates should re-verify before relying on a row.

What's not in scope

The following engines are deliberately omitted from the tables. Each is widespread enough that you may meet it; in each case, the differences from Perl are small enough that a Perl reader can read the regex with little adjustment.

- **Java `java.util.regex`** - Perl-derived; differences are flag spellings and a few escape conventions.
- **Python `re`** - Perl-derived; biggest delta is variable-length lookbehind support arrived later than in Perl.
- **ECMAScript** (JavaScript) - Perl-derived; lookbehind only since ES2018, no possessive quantifiers, sticky flag `y` instead of `\G`. Modern V8 / SpiderMonkey converge on Perl's feature set.
- **.NET regex** - Perl-shaped, plus *balanced groups* (`(?<name-pop>…)`), which are unique. Niche enough to skip.

- **Rust `regex`** - RE2 lineage; the story is essentially Go's with a slightly different feature surface (it has fixed-width lookbehind, RE2 does not).
- **Vim** - different magic-mode semantics; Vim-internal.
- **Boost.Regex** - C++ niche; closely tracks PCRE2.

The five families, in a paragraph each

PCRE2

Perl-Compatible Regular Expressions, version 2 (PCRE2 replaced the original PCRE library in 2015). The reference implementation for "Perl regex outside of Perl". Reads almost identically to Perl 5.44 patterns and supports nearly the same feature set: backreferences, lookaround, atomic groups, possessive quantifiers, recursive subpatterns, named captures, conditional patterns, callouts. PCRE2 also has a JIT compiler that is sometimes faster than perl's.

Where PCRE2 differs from Perl 5.44:

- `(?{...})` and `(??{...})` - Perl runs arbitrary Perl code; PCRE2 has *callouts* (`(?C)` / `(?Cn)`) which call back into the host application. Not a security difference; just a different interface.
- A handful of flag spellings differ (`PCRE2_CASELESS` vs `/i`, etc.) at the API level, not in pattern syntax.
- Recursive subpattern atomicity: `(?R)` is *atomic* in PCRE2 by default; Perl allows backtracking into a recursed group.
- `(*VERB)` set is largely the same, with PCRE2 adding `(*UTF)`, `(*UCP)`, and other startup options.

For most patterns, "looks the same" is correct.

Emacs

GNU Emacs's regex engine is its own family. On the surface it looks BRE-shaped - `\(...\)` for grouping, `\{m,n\}` for counts - but inside it has Perl-lite features (non-greedy quantifiers, word boundaries) and Emacs-specific features (syntax classes `\sw`, category classes `\cC`) that no other engine has.

Notable Emacs-specific constructs:

- **Buffer anchors**: `\`` (backtick) is start-of-buffer, `\'` is end-of-buffer. Closer to Perl's `\A` / `\z` than to `^` / `$`.
- **Syntax classes**: `\sw` matches a "word-syntax" character as defined by the current buffer's syntax table; `\s-` matches whitespace-syntax. This is mode-dependent - the same regex matches different characters in C-mode vs Lisp-mode.
- **Category classes**: `\cC` matches a character in category C. Used heavily for CJK text classification.
- **No** `\d` shorthand - Emacs requires `[0-9]` or `[[:digit:]]`. (`\w`, `\s`, `\b` exist, but `\d` does not.)
- **No** lookahead, lookbehind, or `\K`.

If you read Emacs Lisp in 2026 you will see `\\(\\)` patterns constantly - that is the doubled escape required because Emacs Lisp string literals consume one level of backslash before the regex parser sees the rest.

POSIX BRE - `sed`, `grep`, `ed`

POSIX Basic Regular Expressions. The engine you get from `sed`, `grep`, and `ed` *with no flags*. The most surprising thing for a Perl reader: the metacharacter set is *smaller*. Bare `+`, `?`, `{m,n}`, `(`, `)`, and `|` are *literal characters*. The metacharacter forms are the backslashed variants: `\+`, `\?`, `\{m,n\}`, `\(`, `\)`, `\|` (the last is a GNU extension; strict POSIX BRE has no alternation at all).

```
# POSIX BRE, finds the literal text "a+b":
echo 'a+b' | grep 'a+b'

# To match "one or more a", under BRE:
echo 'aaab' | grep 'a\+b'
```

Backreferences (`\1`–`\9`) work in BRE (this is older than POSIX ERE's no-backreferences rule). POSIX classes `[[:digit:]]` etc. work. `\<` and `\>` (GNU extension) provide word boundaries. Shortened character escapes like `\d`, `\s`, `\w` are *not* supported.

`grep` and `sed` ship the same engine but flag-default to different families: GNU `grep -P` invokes PCRE2, `grep -E` is ERE, default `grep` is BRE. `sed -E` is ERE, default `sed` is BRE.

POSIX ERE - `awk`, `egrep`, `sed -E`

POSIX Extended Regular Expressions, the engine `awk` defaults to and the one selected by `egrep` (now `grep -E`) and `sed -E` / `sed -r`. Bare `+`, `?`, `{m,n}`, `(...)`, and `|` are metacharacters here; this is the family closest to "what a Perl-trained programmer expects" among the POSIX-conformant set.

What strict POSIX ERE does *not* have, by spec:

- **Backreferences in the pattern** (`\1`, `\2`, ...). They are legal in `sed` substitution replacements but not in match patterns. GNU extensions add them; portable scripts should not rely on this.
- Lookaround.
- Possessive quantifiers, atomic groups.
- `\d`, `\s`, `\w`, `\b` (use `[0-9]`, `[[:space:]]`, etc.).

The most common surprise: an ERE `\(` is a *literal opening paren*. Backslashing punctuation is sometimes a metacharacter and sometimes a no-op, with the rule being the opposite of BRE. Memorise: BRE backslash *enables* metacharacters; ERE backslash *disables* them.

RE2 / Go `regexp`

Google's RE2 is a fundamentally different architecture. RE2 constructs an NFA at compile time and uses a *lazy DFA* (constructing DFA states on demand and caching them) at match time. The result is *guaranteed linear time* in the input length, no matter the pattern.

The trade-off: RE2 cannot support features that take regular languages out of the regular-language family. Specifically:

- **No backreferences in patterns.** `\1`, `\g{1}`, `\k<name>` - none. A pattern like `(.)\1` simply cannot be compiled.
- **No general lookaround.** RE2 supports anchors and `\b` (zero-width assertions), but not `(?=...)`, `(?<=...)`, `(?!...)`, or `(?<!...)`.
- **No atomic groups, no possessive quantifiers, no recursive subpatterns, no embedded code.**

What RE2 *does* support, and what makes it pleasant for the common case:

- Named captures with the Python-shaped syntax `(?P<name>...)`.
- ASCII by default for `\d`, `\w`, `\s`; Unicode mode enabled with `(?u)`.
- The `(?flags)` and `(?flags:...)` modifier syntaxes.
- A swap-default-greediness flag `(?U)` - under it, `*` is non-greedy and `*?` is greedy. The opposite of Perl.

If you have ever written a Perl regex that catastrophically backtracked, RE2 is what you write next. The cost is the missing features above; the upside is the engine cannot be DoSed by a malicious input.

Go's standard `regexp` package wraps RE2 and adds a few Go-isms, none of which change the fundamentals.

Feature comparison tables

The remainder of this chapter is row-major: rows are features, columns are engines. This layout optimises for the "I know one engine, what does X look like in another?" use case. Cell values are concise and may simplify edge cases - verify against the engine's own reference for production code.

Quantifiers, grouping, alternation

Feature	Perl 5.44	PCRE2	Emacs	POSIX BRE	POSIX ERE	RE2 / Go
* zero-or-more	meta	meta	meta	meta	meta	meta
+ one-or-more	meta	meta	meta	literal (use \+)	meta	meta
? zero-or-one	meta	meta	meta	literal (use \?)	meta	meta
{m,n} interval	meta	meta	\{m,n\}	\{m,n\}	meta	meta
| alternation	meta	meta	meta	| (GNU)	meta	meta
(...) grouping	meta	meta	\(...\)	\(...\)	meta	meta
(?:...) non-capturing	yes	yes	no	no	no	yes
Possessive *+, ++, ?+	yes	yes	no	no	no	no
Non-greedy *?, +?	yes	yes	yes	no	no	yes
Atomic group (?>...)	yes	yes	no	no	no	no

The single highest-value row for a Perl reader meeting BRE: + and ? are *literal*. A regex like `colou?r` reads as "matches `colou?r` exactly" under BRE. The rule is consistent - BRE's metacharacter set is small; ERE expanded it; Perl expanded it further.

Character shorthand classes

What does `\d` match? It depends. The columns below show what character set each engine treats as digits, word characters, and whitespace under default settings.

Shorthand	Perl 5.44 (default)	Perl 5.44 + `/u`	PCRE2 (default)	Emacs	POSIX BRE	POSIX ERE	RE2 / Go (default)
`\d`	ASCII (or Unicode under `/u`)	Unicode	ASCII	NO	NO	NO	ASCII; Unicode under `(?u)`
`\w`	ASCII or Unicode	Unicode	ASCII	yes (syntax-table	NO	NO	ASCII; Unicode under `(?u)`
`\s`	ASCII or Unicode	Unicode	ASCII	yes	NO	NO	ASCII; Unicode under `(?u)`
`\b` word boundary	yes	yes	yes	yes (`\<`/`\>` traditional)	NO	NO	yes
`\h` horizontal WS	yes	yes	yes	NO	NO	NO	NO
`\v` vertical WS	yes	yes	yes	NO	NO	NO	NO

Two surprises here for a Perl reader:

1. POSIX BRE and ERE both lack `\d`, `\w`, `\s`. The portable forms are `[0-9]`, `[[:alnum:]_]`, `[[:space:]]`. Tools that accept `\d` (GNU `grep`, `awk` in some implementations) do so as a non-portable extension.
2. Emacs has `\w` and `\s` but no `\d`. The `\s` character is followed by a syntax-class character - `\s-` for whitespace, `\sw` for word - which is unique to Emacs.

POSIX bracket classes like `[[:digit:]]` and `[[:alpha:]]` work in every engine in the table; they are the portable spelling.

Anchors and newline handling

Feature	Perl 5.44	PCRE2	Emacs	POSIX BRE / ERE	RE2 / Go
^ start-of-string	yes	yes	start-of-buffer	yes	yes
^ after \n under multi-line	/m	(?m)	always (line-oriented)	not specified	(?m)
$ end-of-string	yes	yes	end-of-buffer	yes	yes
$ before final \n	yes	yes	no	varies	yes
. matches \n	/s	(?s)	no	no	(?s)
\A / \z	yes	yes	\` / \'	no	yes (\A, \z)
\Z (before optional final \n)	yes	yes	no	no	no (use \z)
\G (last-match position)	yes	yes	no	no	no

Emacs uses \` and \' for the buffer anchors, where most modern engines use \A and \z. The Emacs spelling is older; it predates POSIX. Mixing up ^ and \A matters in line-oriented Emacs code more than in Perl, because Emacs matches are often invoked in contexts that scan an entire buffer.

\G is Perl-specific (and PCRE2). RE2 / Go uses a different API on the *match object* (a Loc method that returns the next position) rather than embedding the position in the pattern.

Lookaround and atomic constructs

Feature	Perl 5.44	PCRE2	Emacs	POSIX	RE2 / Go
Lookahead (?=…) / (?!…)	yes	yes	NO	NO	NO
Fixed-width lookbehind (?<=…)	yes	yes	NO	NO	NO
Variable-length lookbehind	yes (exp.)	yes	NO	NO	NO
\K keep-left	yes	yes	NO	NO	NO
Atomic group (?>…)	yes	yes	NO	NO	NO
Possessive quantifiers	yes	yes	NO	NO	NO

Effectively: only PCRE2 (and other Perl-derived engines outside this table - Java, Python, .NET) supports lookaround. POSIX tools and RE2 / Go simply do not have it. Patterns that need lookaround do not port across this divide.

Captures and backreferences

Feature	Perl 5.44	PCRE2	Emac	POSIX BRE	POSIX ERE	RE2 / Go
Numbered captures	yes	yes	yes	yes	strict no, GNU yes	yes
Backreferences in pattern (\1–)	yes (1–99)	yes	yes	yes (\1–\9)	strict no, GNU yes	NO
Named captures (?<name>…)	yes	yes	NO	NO	NO	yes ((?P<name>…))
Branch reset (?|…)	yes	yes	NO	NO	NO	NO
Recursive subpatterns (?R)	yes	yes	NO	NO	NO	NO
Conditional patterns (?(c)y|n)	yes	yes	NO	NO	NO	NO
(?{…}) embedded code	yes	callouts	NO	NO	NO	NO
@{^CAPTURE} array	yes	NO	NO	NO	NO	NO (different API)

The single most important takeaway: **RE2 / Go regexp does not support backreferences**. Patterns like /(.)\1/ cannot be compiled. This is not an engine bug; it is the price RE2 pays for guaranteed linear time. Patterns containing backreferences are not regular languages and a true DFA cannot match them in linear time.

If you are porting Perl regexps to a Go service, the audit question is "does this pattern use backrefs?" - if so, the conversion is not mechanical.

Engine-architecture summary

Property	PCRE2 / Perl 5.44	Emacs	POSIX BRE / ERE (typical impl)	RE2 / Go
Algorithm	Traditional NFA + JIT (PCRE2)	Traditional NFA	DFA (GNU) / NFA (others)	Hybrid NFA → lazy DFA
Worst-case time	Exponential	Exponential	Linear (DFA)	Linear (guaranteed)
Backtracking model	yes	yes	DFA: no	no
Catastrophic backtracking risk	yes	yes	no (DFA)	no
Backreferences supported	yes	yes	varies	NO

POSIX BRE/ERE is implementation-dependent: GNU `grep` and `awk` use a hybrid DFA-with-NFA-fallback that is fast and not subject to catastrophic backtracking; older traditional implementations (historical `awk`, traditional `grep` on some BSDs) use a backtracking NFA. The portable assumption is "linear time, but verify if your input may be

hostile".

Selecting an engine when you have the choice

If you are writing the program (not reading code that already chose), the engine you pick is mostly determined by the language you are programming in. The exceptions are when the same library ships multiple engines, and when an external regex tool is your choice:

- **A Perl program**: Perl's built-in. No reason to reach outside.
- **A C program embedding regex**: PCRE2. The standard library's `regex.h` is POSIX BRE/ERE; PCRE2 is what you want for Perl-like behaviour.
- **A Go service handling untrusted input**: `regexp` (RE2). The linear-time guarantee is the headline feature; the missing backreferences and lookaround are usually acceptable.
- **A Rust program**: the `regex` crate. RE2-lineage; same linear-time guarantee.
- **Shell scripting**: prefer `grep -E` (ERE) and `sed -E` (ERE) over the BRE defaults for Perl-readability. Use `grep -P` (PCRE2) only when ERE genuinely is not enough.
- **An Emacs Lisp function**: Emacs's. Otherwise leave Emacs.

- **Basics** - `m//`, `s///`, the binding operators `=~` and `!~`, what counts as a metacharacter, how to escape, the four-phase parsing model.
- **Character classes** - bracketed classes `[…]`, negated classes, shorthand `\d \w \s`, POSIX classes, the extended bracketed form `(?[…])`, the IP-address worked example.
- **Anchors and assertions** - `^`, `$`, `\b`, `\A`, `\z`, `\G`, `\K`, lookahead, lookbehind, the `\b{…}` Unicode boundaries, juxtaposition-as-AND.
- **Quantifiers** - `*`, `+`, `?`, `{n,m}`, greedy vs. non-greedy vs. possessive, the principles of the match.
- **Groups and captures** - `(...)`, `(?:...)`, named captures, backreferences, atomic groups, recursive subpatterns, conditional patterns, branch reset.
- **Alternation** - `|`, precedence, common-prefix factoring, empty alternatives, branch reset.

- **Modifiers** - `/i`, `/m`, `/s`, `/x`, `/xx`, `/g`, `/c`, `/r`, `/e`, `/n`, `/p`, `/o`, `/a`, `/aa`, `/u`, `/l`, `/d`, inline forms `(?i…)`, scoped forms `(?i:…)`, the four-phase parsing model, `use re 'strict'`.
- **Substitution** - `s///` in depth: the replacement string, `/e`, `/ee`, `/r`, `\K` in substitution, zero-length match termination.
- **Unicode** - `\p{…}`, `\P{…}`, `\X`, scripts, the charset modifiers, case folding, script runs, encoding vs. character.
- **Performance** - backtracking, catastrophic patterns, unrolling the loop, atomic groups, possessive quantifiers, recursive patterns, embedded code, special backtracking control verbs, internal optimisations the engine applies on your behalf.
- **Cross-engine** - comparison against PCRE2, Emacs, POSIX BRE, POSIX ERE, and RE2 / Go.

A first round-trip

The shortest useful regexp program - find three-letter words repeated back to back, separated by a single space:

```
my $text = "I said the the other day";
if ($text =~ /\b(\w{3})\s\1\b/) {
    print "Repeated: $1\n";        # Repeated: the
}
```

- `\b` is a word boundary - the pattern only fires at word edges.
- `(\w{3})` captures exactly three word characters into `$1`.
- `\s` is one whitespace character between the two copies.
- `\1` is the backreference: match the same three characters again.

Every more complicated pattern in the guide is layered on that idea - anchor where you need to, describe what you want, capture what you want back.

Conventions in the examples

- Example output appears as an inline `#  …` comment beside the expression that produces it.
- Examples assume default modifiers unless they show `/i`, `/x`, etc.
- Where a pattern is shown on its own (no =~), treat it as a fragment the surrounding text will combine with a string.
- When a Unicode character is needed, examples use `\x{263a}` or `\N{GREEK SMALL LETTER SIGMA}` so the rendered text matches the source.

Related reference pages

The guide is a teaching reference; these are the operator references the guide refers to throughout.

- `m` - the match operator.

- `s` - substitution.
- `qr` - compile a pattern for reuse.
- `split` - split a string on a regexp.
- `pos` - read or set the `/g` match position.
- `quotemeta` - escape metacharacters in a string.
- `tr` - character-by-character translation. Often confused with regexp substitution but unrelated in semantics.

4.2.4 Performance

How to make Perl run fast on pperl, and - just as important - how to tell whether it already does. This guide is the actionable layer: where the classic Perl performance advice still holds, where pperl's JIT and auto-parallelizer have quietly made it irrelevant, and where pperl rewards code shaped in ways upstream Perl never cared about.

It is deliberately not a tour of the machinery. The JIT, the parallel scheduler, the native-module dispatch and the FFI each have their own chapter in the *architecture guide*; this guide tells you what to *write* so they fire, and points at those chapters for the *why*.

Who this is for

A working Perl programmer with a program that is too slow, or one they want to keep fast. You know how to write the code; you want to know which habits pay off here, which are now dead weight, and how to measure the difference without guessing.

You do not need to understand Cranelift, Rayon, or the interpreter's inner loop. Where a behaviour depends on them, this guide states the behaviour and links the chapter that explains it.

The one rule that survives everything

Measure first. Every other rule in this guide is conditional on a measurement you have not yet taken. Perl performance intuition, honed on the upstream interpreter, mispredicts on pperl in both directions: code you expect to be slow is sometimes compiled to native machine code and runs faster than C; code you expect the JIT to rescue sometimes falls back to the interpreter because one string operation crept into a numeric loop.

The profiler does not lie and your intuition, ported from another runtime, does. Start at *Measuring*.

How this guide is organised

Measuring

You cannot tune what you have not measured, and on pperl the usual measuring tools split into three groups: the ones that work unchanged, the ones that work because they are plain Perl running on a faster interpreter, and the one everybody reaches for that does not work at all. This chapter sorts them out and shows how to read what the working ones tell you.

The tool that does not work: Devel::NYTProf

`Devel::NYTProf` is the standard line-and-subroutine profiler on upstream Perl. It is an XS module - it hooks the interpreter through a C extension. pperl ships no XS layer, so `Devel::NYTProf` does not load. Neither does any other XS-based profiler (`Devel::DProf`, `Devel::Profiler`'s XS paths).

This is not a gap to be worked around with a pure-Perl reimplementation of NYTProf's output format. What pperl offers instead is visibility into the layer that actually decides performance - the JIT - plus full transparency to the platform profiler. Use those.

Where the time goes: the JIT log

pperl does not currently ship a line-or-sub profiler of its own (the one it once had belonged to a retired execution engine and never saw the current runtime). What it does ship is precise visibility into the optimization layer, which for pperl-specific tuning is usually the question you are actually asking: is my hot loop compiled, and if not, why not?

- `--jit-stats` prints counters at exit: candidates found, loops compiled, entries run compiled, guard failures, deopts.
- `PPERL_JIT_LOG=/path/file` appends one line per compiler event. The `compile skip reason=...` lines name the exact operation that kept a loop interpreted.

For symbol-level CPU attribution, use the platform profiler on a release build - `perf record ./target/release/pperl script.pl` then `perf report`. pperl is a native binary; perf sees straight through it, including JIT-compiled frames.

Whole-program timing: the benchmark runner

When the question is "how fast is pperl on this, versus system perl, with and without JIT and parallelism", the project benchmark runner answers it directly. `bench/run-perlbench` always runs `/usr/bin/perl` as the baseline (normalised to 100) and compares pperl in up to four configurations.

```
./bench/run-perlbench                # no JIT, no parallel
./bench/run-perlbench +J             # add the JIT-enabled run
./bench/run-perlbench +P             # add the parallel run
./bench/run-perlbench +J+P           # all four combinations
./bench/run-perlbench -t arith       # only benchmarks matching
↪"arith"
```

Every runner shares one iteration count, derived from the slowest runner's empty-loop rate, so the reported ratios compare like with like. The `+J` / `+P` columns are exactly the comparison you want when deciding whether a piece of code benefits from the JIT or the parallelizer: if `+J` is no faster than the plain run, the loop is not being compiled, and *Writing fast pperl* explains why and what to change.

Plain-Perl tools that work: Benchmark and Time::HiRes

The classic in-program measuring tools are plain Perl. They run on pperl through the normal module path - `Benchmark` is reachable on the standard include path and executes as Perl on the pperl interpreter; `Time::HiRes` is provided natively. Both behave exactly as a Perl programmer expects.

`Benchmark` for A/B comparison of two ways to write the same routine:

```
use Benchmark qw(cmpthese);

my @data = (1 .. 100_000);

cmpthese(-3, {            # run each for ~3 CPU-seconds
    grep_count => sub { my $n = grep { $_ % 2 == 0 } @data },
    loop_count => sub { my $n = 0; $_ % 2 or $n++ for @data },
});
```

`Time::HiRes` for ad-hoc wall-clock timing of a single block:

```
use Time::HiRes qw(time);

my $t0 = time;
do_the_work();
printf "took %.3f s\n", time - $t0;
```

A caution that matters more on pperl than on upstream: `Benchmark` drives your code by calling a code reference over and over, and that per-call dispatch is Benchmark's own overhead, not your code's. A loop *inside* the callback still JIT-compiles (loops compile wherever they live, file scope or sub body), but for small bodies the harness call cost dominates and the comparison understates the real speed. When the thing you are timing is a loop that should JIT, prefer `bench/run-perlbench` or a `Time::HiRes` span around the loop in situ (see *JIT compilation*).

Turning the optimisers off to isolate a cause

Two flags let you attribute a speedup - or a slowdown - to the right layer:

```
pperl --no-jit script.pl          # interpreter only, no native
↪compilation
pperl --no-parallel script.pl     # single-threaded, no Rayon
↪dispatch
```

Run a program three ways - default, `--no-jit`, `--no-parallel` - and the differences tell you which optimiser is carrying the work. If `--no-jit` barely changes the time, the JIT was not engaging on this code, and the loop shape is the thing to look at. If `--no-parallel` barely changes it, the parallelizer declined the loop - usually because of a side effect it could not rule out (see *Parallel execution*).

A measuring discipline

1. Time the program default versus `--no-jit` versus `--no-parallel`. The differences tell you which layer carries the work.
2. If a hot routine is a loop you expected to be compiled, confirm with `run-perlbench +J` or by timing it `--no-jit` versus default. A loop that does not speed up under the JIT is shaped wrong, not slow.
3. Only now change code. Re-measure the same way. Keep the change if the number moved and the program still produces the same output.

Performance claims are cheap; the JIT log and the benchmark ratio are not. Trust the measurement.

See also

- *Writing fast pperl* - once you have found the hot loop, how to shape it so the JIT and parallelizer take it.
- *Idioms* - which classic optimisations are still worth applying before you reach for the measuring tools.
- *JIT compilation* - what the JIT compiles and why interpreted op timings disappear for compiled loops.
- *Parallel execution* - what the `+P` column and `--no-parallel` flag are exercising.
- *Regex performance* - if the measurement points at a regexp, the cause and cure live there, not here.

Idioms

Perl carries decades of performance folklore - habits that paid off on the upstream interpreter and got passed down as rules. Some of that advice is timeless. Some of it is now actively pointless on pperl, because the JIT or the compile-time folder already does the work. And a few new habits matter here that no upstream Perl programmer ever needed.

This chapter triages the classic idioms into three buckets:

- **Still valid** - the advice holds; the cost it avoids is real on pperl too.
- **Made moot** - pperl's compiler or JIT already eliminates the cost, so the contortion buys nothing and only hurts readability.
- **New** - relevant *because* of how pperl compiles, with no upstream precedent.

A blanket caveat runs through the whole "made moot" bucket: the JIT only takes a loop when the loop is *shaped* for it. A loop heavy with subroutine calls, regexp matches, or string building is not compiled and runs on the interpreter - where the classic advice re-applies in full. So "the JIT handles it" is true *for loops the JIT handles*. *Writing fast pperl* is the companion chapter on making sure your loop is one of them.

Still valid

These survive the move to pperl unchanged. The cost they avoid is paid on the interpreter, and most hot code touches the interpreter somewhere.

- **Hoist invariant work out of loops.** Computing the same value every iteration is wasted work whether the loop is interpreted or compiled. The JIT does not hoist arbitrary expressions for you; move the invariant out yourself.
- **Avoid needless copies of large structures.** Passing a big array by value, or slicing it just to count, copies. Pass a reference, use an aliased loop variable, or work in place. pperl's value model has the same copy costs Perl always had.
- **Precompile regexps used in a loop with `qr`.** The regex engine and its compile cache work as on upstream; a pattern built fresh each iteration pays to recompile. This is regex territory - see *regex performance*.
- **Choose the right data structure.** A hash lookup beats a linear scan at the same sizes it always did. Algorithmic complexity is unaffected by any runtime; an $O(n^2)$ loop is slow even fully JIT'd.
- **Read files in the right-sized chunks.** Line-by-line versus slurp-and-split is an I/O question, and I/O is not JIT-compiled. The upstream trade-offs carry over directly.
- **Prefer built-in list operations to hand-rolled loops where the built-in is native.** `sum`, `min`, `max`, `first` from `List::Util` run at built-in speed with no XS layer (see *native modules*). A hand-written accumulator loop *may* JIT to the same speed, but the native built-in gets you there without depending on the loop shape.

Made moot

These were real wins on upstream Perl. On pperl the compiler or JIT already removes the cost, so applying the idiom by hand buys nothing and usually costs clarity.

Hand-inlining hot arithmetic

The old habit of unrolling a tight arithmetic loop, or manually inlining a small arithmetic helper to dodge call overhead, targets a cost the JIT removes. A numeric `for` or `while` loop over integer or float accumulators is compiled to native machine code, with the loop variables held in CPU registers - see *JIT compilation*. Hand-unrolling such a loop makes it longer and harder to read without beating the compiler.

```
# Don't hand-unroll this. The JIT compiles the natural form to
# native code with $i and $sum in registers.
my $sum = 0;
for my $i (1 .. 1_000_000) {
    $sum += $i * $i;
}
```

The contortion only pays off if the loop does *not* JIT - and if it doesn't, the fix is to make it JIT (remove the call or string op that disqualified it), not to unroll it by hand.

DEBUG-constant logging guards

The idiom of guarding expensive logging behind a compile-time false constant -

```
use constant DEBUG => 0;
# ...
warn "state: @stuff\n" if DEBUG;
```

- costs exactly nothing on pperl, which is the whole point of the idiom, and pperl delivers it completely. When `DEBUG` is a false constant, the compiler folds the `if DEBUG` guard at compile time: the disabled statement collapses to a no-op, with no condition test and no branch left in the compiled program. The interpolation `"@stuff"` is never built. You can leave guarded logging in hot paths with a clear conscience; a false `DEBUG` constant erases it.

This is the idiom working *as designed* - keep writing it. What is moot is any further cleverness on top: you do not need to comment out the logging, move it behind a sub, or strip it for production. The constant does it.

Folding constant expressions yourself

Precomputing a constant arithmetic result, or a constant call to a pure built-in, and storing it in a variable to "avoid recomputing it" buys nothing - the compiler folds constant expressions and constant-argument pure built-ins (`sin`, `cos`, `sqrt`, `chr`, `ord`, and the like) at compile time, as long as the call is in a valid domain. `my $two_pi = 2 * 3.14159265358979;` and `my $root = sqrt(2);` are computed once, at compile time, whether or not you "help" by hoisting them.

The one nuance: folding is skipped for arguments outside a function's domain (`sqrt` of a negative, `log` of zero), so those fall through to run time and croak there exactly as they should. You never need to fold a constant by hand to gain speed.

Stripping dead constant-condition loops

A `while (0) { ... }` or a block guarded by a constant-false condition is eliminated at compile time - the body is removed, not merely skipped at run time. (A C-style `for (; 0; ...)` is handled slightly differently: the body is never entered, though the loop scaffolding op may remain.) Conditionally-compiled-out code behind a false constant carries no run-time weight; you do not need to physically delete it to make the program faster.

New

These have no upstream analogue. They matter because of how pperl compiles and parallelizes, and getting them wrong silently forfeits the largest speedups pperl offers.

Keep numeric hot loops numeric

The single most valuable new habit. The JIT compiles a numeric loop and, when parallelization is enabled (the default) and the loop is a clean reduction over a known range, dispatches it across threads - the difference between a 76× and a 431× speedup on the Mandelbrot benchmark (see *parallel execution*).

A string operation inside that loop forfeits the parallel half. When the JIT sees a string variable in the loop - a `.=` concat target, a string accumulator - it demotes the loop to a *sequential* compiled loop: still native code, but no longer spread across threads.

```
# Numeric reduction - JIT-compiled and eligible for parallel
 ↪dispatch.
my $total = 0;
for my $i (0 .. $n) {
    $total += compute($i);      # (only if compute() itself stays
 ↪numeric/inlinable)
}

# A string built in the same loop demotes it to sequential JIT -
# the parallel dispatch is gated off the moment a string var
 ↪appears.
my $log = "";
for my $i (0 .. $n) {
    $total += $i * $i;
    $log .= "$i ";              # forfeits parallel dispatch for this
 ↪loop
}
```

If you need both the numeric reduction and the string accumulation, split them into two loops: the numeric one parallelizes, the string one runs as a sequential compiled loop. Mixing them costs you the parallel speedup on the numeric work for no gain on the string work.

Shape reductions as accumulate-never-reset

The parallelizer recognises a reduction variable by seeing it accumulated and never reset inside the loop body (the analysis subtracts reset patterns from accumulation patterns; a variable that is both is not treated as a reduction). Writing your accumulator in the plain `$sum += ...` form, declared *before* the loop and never re-initialised inside it, is what lets the loop be claimed for parallel execution.

```
my $sum = 0;                    # declared outside - a reduction
for my $x (@data) {
    $sum += weight($x);         # accumulate, never reset →
 ↪parallelizable
}
```

Re-initialising the accumulator inside the loop, or interleaving a reset, defeats the recognition and the loop runs sequentially. This is covered in full under *reduction detection*.

Let the loop JIT - don't hide it in a sub

The JIT compiles *loops*, not subroutine bodies. A hot numeric loop written at file scope or inside a larger routine compiles fine; the same arithmetic refactored so each iteration is a subroutine call does not - the call frame is interpreter territory, and the per-call overhead is exactly what the JIT cannot remove. When a loop is hot and numeric, keep its body inline rather than factoring each iteration into a sub for tidiness. Factor for clarity elsewhere; keep the inner loop flat.

- *Measuring* - confirm an idiom actually moved the number before and after applying it.
- *JIT compilation* - what compiles, why hand-inlining arithmetic is redundant.
- *Parallel execution* - the reduction analysis and the side-effect gate behind the "new" idioms.
- *Sorting* - the sort-specific idioms (Schwartzian, Guttman-Rosler) get their own chapter.

Sorting

`sort` is where a surprising amount of a program's time hides, because the cost is not the sort - it is the comparator, called O(n log n) times. A comparator that does real work per call multiplies that work by the log of the list size. This chapter is about recognising when the comparator is the bottleneck and the two transforms that fix it.

The reference page for `sort` defines the operator, the comparator contract, and the `$a`/`$b` mechanics. This chapter assumes you know those and focuses on speed.

The comparator is the cost

`sort` itself is a stable mergesort - fast, and not something you can improve from Perl. What you control is how much work happens *inside* each comparison. Two facts set the budget:

- The comparator runs O(n log n) times. For a 100,000-element list that is well over a million calls.
- On pperl, the comparator block is a callback, and callbacks run on the interpreter. The JIT compiles loops, not `sort` comparator bodies (see *JIT compilation*), so you cannot rely on the JIT to rescue an expensive comparator the way it rescues a numeric loop. The comparator's cost is paid in full, every call.

That second fact is the pperl-specific reason the transforms below matter as much here as on upstream Perl - arguably more, because the JIT's speedups elsewhere make an un-transformed sort stand out more sharply in a profile.

The diagnosis is always the same: if *Measuring* shows time concentrated in a comparator, the key is being recomputed on every comparison. Compute it once instead.

The Schwartzian transform

When the sort key is expensive to derive from each element - a substring extraction, a field lookup, a length, a computation - the naive sort recomputes it on every comparison:

```
# Slow: the key (-M $_) is computed twice per comparison, O(n log n)␣
↪times.
my @sorted = sort { -M $a <=> -M $b } @files;
```

The Schwartzian transform computes each key exactly once, sorts on the precomputed key, then discards it - a `map`, a `sort`, a `map`:

```
my @sorted =
    map  { $_->[1] }                        # 3. strip the key, keep␣
↪the element
    sort { $a->[0] <=> $b->[0] }            # 2. sort on the␣
↪precomputed key
    map  { [ -M $_, $_ ] }                  # 1. compute the key once␣
↪per element
    @files;
```

Read it bottom to top: the lower `map` builds a `[key, element]` pair for each element (n key computations), the `sort` compares only the cheap precomputed `$_->[0]` (no key computation in the comparator), and the upper `map` throws the key away. The expensive key is computed n times instead of O(n log n) times.

Use it whenever the key costs more than a numeric or string compare to derive. For a 100,000-element list sorted by a key that takes a microsecond to compute, the naive form spends seconds in key computation alone; the transform spends a tenth of a second.

The pieces are `map` and `sort` - the `sort` reference page shows the same transform as a worked example.

The Guttman-Rosler transform

The Schwartzian transform sorts arrayrefs, which costs an arrayref allocation and a dereference per comparison. When the key can be encoded as a fixed-width *string* prefix, the Guttman-Rosler transform (GRT) goes further: it packs the key and the element into a single string, sorts those strings with the default string `sort` (no comparator block at all), then strips the prefix.

```
my @sorted =
    map  { substr($_, 8) }                          # 3. strip the␣
↪8-char key prefix
    sort                                            # 2. plain␣
↪string sort, no comparator
    map  { pack('N', $_->{priority}) . $_->{name} } # 1. fixed-width␣
↪key + payload
    @records;
```

The win has two parts. First, the key is precomputed once, as in the Schwartzian. Second - and this is the GRT's distinct advantage - the `sort` has *no comparator block*, so there is no per-comparison callback at all. Default string `sort` compares the packed strings directly, which avoids the callback cost entirely. Removing the comparator callback matters more on pperl precisely because that callback would run on the interpreter.

The cost of the GRT is that the key must be encodable so that a bytewise string comparison produces the order you want:

- Integers must be packed big-endian (`pack 'N'` / `pack 'Q>'`) so that byte order matches numeric order, and offset to be non-negative (string comparison has no sign bit).

- Floats and signed numbers need bias encoding to sort correctly as bytes - fiddly enough that the Schwartzian is usually the better choice unless the sort is genuinely hot.
- Every key must be the *same width*, or a short key's payload bleeds into the comparison.

Reach for the GRT when the sort is hot, the key is an unsigned integer or a string, and the Schwartzian still shows up in the profile. For anything else, the Schwartzian is simpler and almost always fast enough.

Cheaper comparators without a transform

Not every slow sort needs a transform. Sometimes the comparator is just written more expensively than it needs to be.

- **Compare numbers with <=>, strings with cmp.** Using `cmp` on numbers stringifies both sides every comparison; using `<=>` on strings is a numification trap. Match the operator to the data.
- **Order tiebreakers cheapest-first.** A multi-key comparator with `||` stops at the first non-zero result. Put the discriminating, cheap key first so most comparisons never reach the expensive one:

```
sort { $a->{rank} <=> $b->{rank}        # cheap, decides most
↪pairs
    || $a->{name} cmp $b->{name} }      # only when ranks tie
       @rows;
```

- **Sort once, reverse separately.** To sort descending, sorting ascending and calling `reverse` is often clearer and no slower than inverting the comparator, and it keeps the comparator in its cheapest form.

Decision order

1. Profile. If *Measuring* does not put the time in the sort, leave it alone.
2. If the comparator recomputes a key, apply the Schwartzian transform. This fixes the great majority of slow sorts.
3. If the sort is still hot and the key is an unsigned integer or a string, consider the Guttman-Rosler transform to drop the comparator callback entirely.
4. Re-measure after each change.

See also

- `sort` - the operator reference: comparator contract, `$a`/`$b`, stability.
- `map` - the transform half of both the Schwartzian and Guttman-Rosler forms.
- `reverse` - descending sorts without inverting the comparator.
- *Measuring* - confirm the comparator is the cost before transforming it.
- *JIT compilation* - why a `sort` comparator block is not JIT-compiled, so its cost is paid in full.

Writing fast pperl

The other chapters in this guide are about removing cost. This one is about earning the speedups pperl offers that no other Perl has: the JIT that compiles hot loops to native code, and the parallelizer that spreads a qualifying loop across CPU cores. Both are automatic - you do not call them, annotate for them, or configure them. But they only fire on code *shaped* the right way, and a single misplaced operation can shut either one off silently.

This chapter is the positive program: write the loop like this, and the compiler takes it. The *JIT* and *parallel execution* chapters explain the machinery; this one tells you what to type.

The shape the JIT wants

The JIT targets **loops** - `for` and `while` - whose bodies are arithmetic and comparison over numeric variables. When it recognises that shape, it compiles the body to native machine code and holds the loop variables in CPU registers instead of on the interpreter stack. That is where the order-of-magnitude speedups come from.

A loop the JIT compiles cleanly:

```
my $sum = 0;
for my $i (1 .. 1_000_000) {
    $sum += $i * $i;
}
```

Integer and floating-point arithmetic (+, -, *, /), comparisons (<, >, <=, >=, ==), and control flow (`if`, `last`) inside the loop all compile. Nested loops compile too, several levels deep, each level connected to the next. The natural, idiomatic form is the fast form - you do not unroll, hoist into temporaries, or otherwise distort it.

What pushes a loop back onto the interpreter

The JIT declines a loop whose body does work it cannot prove it can reproduce exactly. When it declines, the loop runs on the interpreter - at interpreter speed, which is still fast for non-numeric work, but without the native-code multiplier. The coverage is broad (arithmetic, strings, array and hash elements, push/pop, map/grep, numeric `sort`, `join`/`split`, regex matches and constant substitutions, calls to small pure subs, and the common `Scalar::Util`/`List::Util` operations - `blessed`, `reftype`, `weaken`, `sum`, `min`, `max` and friends), so the practical disqualifiers are fewer than you might expect:

- **Calls to subs with side effects.** A call compiles when the sub's body is a `my (...) = @_;` prelude plus one pure numeric expression - including recursion. A sub that touches globals, does I/O, uses `return`, or takes references to `@_` declines the loop. Keep hot helpers small and pure and the call costs almost nothing; factoring work OUT of a sub is no longer the advice.
- **I/O.** A `print`, a file read, a system call - I/O-bound work does not benefit from native compilation and is not compiled.
- **Regex beyond the compiled forms.** Scalar matches and `s/pat/constant/` (including `/g`) compile; `s///e`, scalar `m//g`, and patterns with embedded code do not.

See *regex performance* for tuning the engine's own work.

- **Magic in any form.** Tied variables, overloaded objects, `local`, taint mode.

None of these is an error; the loop simply runs the interpreted way. But if a loop you expected to be fast is not, run it `--no-jit` versus default (*Measuring*): if the times match, the JIT was already declining it. Set `PPERL_JIT_LOG=/tmp/jit.log` and read the `compile skip reason=...` lines to see exactly which operation is responsible (*JIT compilation*).

Keep strings out of numeric loops

The JIT *does* handle one string operation - `.=` concat-assign, and clearing a string with `$x = ""` - through calls back into the runtime. So a string-building loop still compiles. But this is the one case where the shape of the loop changes *which optimisers* apply, and it is the highest-value rule in this chapter.

When the JIT sees a string variable in a loop, the loop compiles as a **sequential** native loop - but parallel dispatch is gated off. The parallelizer needs the loop body free of the shared-mutable-state that string building requires, so the moment a string variable appears, the loop is no longer spread across threads. It still runs as compiled native code; it just runs on one core.

The practical consequence: a numeric reduction that *would* parallelize loses that parallelism if you build a string in the same loop.

```
# Parallelizable: pure numeric reduction.
my $total = 0;
for my $i (0 .. $n) {
    $total += $i * $i;
}

# Same arithmetic, but the string build demotes it to a
# single-core compiled loop - the parallel speedup is forfeited.
my $report = "";
my $total  = 0;
for my $i (0 .. $n) {
    $total  += $i * $i;
    $report .= "$i ";
}
```

If you need both, split the work into two loops. The numeric loop parallelizes; the string loop runs as a sequential compiled loop. Mixing them costs the parallel speedup on the numeric half and gains nothing on the string half.

The shape the parallelizer wants

When parallelization is enabled - it is on by default; `--no-parallel` turns it off - a JIT-compiled loop is dispatched across threads if the analysis can prove it safe. Two conditions carry the most weight:

A reduction shaped as accumulate-never-reset. The parallelizer recognises a reduction variable by seeing it accumulated and never reset inside the loop. Declare the ac-

cumulator before the loop, use the plain += form, and never re-initialise it inside the body:

```
my $sum = 0;                    # declared outside the loop
for my $x (@data) {
    $sum += score($x);          # accumulate only → recognised as a␣
↪reduction
}
```

Re-initialising `$sum` inside the loop, or interleaving a reset, defeats the recognition (the analysis subtracts reset patterns from accumulation patterns) and the loop runs sequentially. Full detail in *reduction detection*.

A loop body free of observable side effects. The analyzer is deliberately conservative. Any of these disqualifies a loop from parallel dispatch:

- I/O (`print`, open, file reads)
- Writes to package/global variables
- Subroutine calls not proven pure
- Side-effecting regex operations (`s///`)

A missed parallelization is safe - the loop just runs sequentially. An *incorrect* one would be a bug, so the analysis errs toward declining. That conservatism is why keeping the loop body small, local, and free of globals is what gets it parallelized.

map and grep compile too

`map` and `grep` with pure expression blocks compile to native loops:

```
my @out      = map  { $_ * $k + 1 } @data;
my @filtered = grep { $_ % 7 }      @data;
```

The block must be a side-effect-free expression over `$_`, loop variables, and constants; mutating `$_` (which writes through to the source array) or producing a boolean as the map VALUE declines. Like all array work, compiled map/grep runs sequentially - array state gates parallel dispatch off - but the native-loop speedup over the interpreted op machinery is itself several-fold.

When the work is not a loop

Not every program is a numeric loop, and the JIT and parallelizer have nothing to offer code that is call-bound, I/O-bound, or string-shaped. For that code the rest of this guide applies in full:

- Pick native built-ins over hand-rolled loops where they exist - `List::Util` runs at built-in speed.
- Apply the classic still-valid idioms from *Idioms*: hoist invariants, avoid copies, precompile regexps.
- Transform expensive sorts (*Sorting*).

- Call C through the *FFI* only when the call frequency is low - the per-call marshalling cost makes it the wrong tool inside a hot inner loop.

A checklist for a hot loop

1. Is the body expressible work - arithmetic, strings, element access, compiled regex forms, pure sub calls? If yes, the JIT compiles it. If not, `PPERL_JIT_LOG` names the disqualifying operation - address that first.
2. Is there a string operation in the loop? If so, and the loop is otherwise a numeric reduction, split the string work out so the numeric loop can parallelize.
3. Is the accumulator declared outside the loop and only accumulated, never reset? That is what makes it a recognised reduction.
4. Is the body free of I/O, global writes, and impure calls? That is what lets the loop parallelize.
5. Measure default versus `--no-jit` versus `--no-parallel` (*Measuring*) to confirm which optimiser is engaging.

- *Idioms* - which classic optimisations still matter and which the compiler already handles.
- *Sorting* - the one common hot path the JIT does not reach.

Fast start-up: the daemon

Every `pperl` invocation normally pays the full start-up bill: process creation, interpreter initialisation, and - the expensive part for real programs - compiling your script and every module it `use`s. The daemon lets repeated invocations of the same script skip that bill: a resident process keeps a fully compiled image of the script, and each new run is a fork of that image that goes straight to execution.

The feature is strictly **opt-in**, per invocation. Nothing changes for plain `pperl script.pl`, and whenever the daemon cannot serve a request exactly, pperl silently falls back to a normal cold run. Correctness never depends on the daemon; only speed does.

Quick start

```
pperl --daemon=start                    # start the daemon (background)

pperl --via-daemon report.pl            # first run: compiles, caches
pperl --via-daemon report.pl            # every further run: fork + run
```

(continues on next page)

(continued from previous page)

```
pperl --daemon=status                  # what is cached, what is live
pperl --daemon=stop                    # shut it down
```

`PPERL_DAEMON=2 pperl report.pl` is the same request without the flag, which is the more convenient form when the command line is not yours to change.

The first opted-in run of a script builds its *template*: the daemon compiles the script (including all `used` modules and `BEGIN` blocks) and keeps the result resident. Every later run of the same script forks the template and only executes.

When it pays

The saving is your script's compile time: parsing plus module loading plus `BEGIN` work. For a script that loads a handful of modules this is routinely the dominant part of start-up, and a template run can be several times faster end to end. For a trivial script that loads nothing, the saving roughly equals the daemon's own overhead and the result is a wash - never a meaningful loss.

As everywhere in this guide: measure your own script, on your own machine, before drawing conclusions - see *Measuring*.

A worked example

Here is a script of the kind that benefits: it does almost no work, but it loads seven modules before it can start.

```
#!/usr/bin/env pperl
use strict;
use warnings;
use Getopt::Long;
use List::Util qw(sum max);
use POSIX qw(strftime);
use File::Spec;
use Time::HiRes qw(time);
use Data::Dumper;

# The contract, honoured in one line: INIT runs per invocation, so a
# run from a template gets its own start time and its own random␣
 ↪seed.
INIT { $^T = time; srand() }

my $top = 3;
GetOptions('top=i' => \$top) or die "usage: report.pl [--top N]\n";

my %sales = (north => [10, 42, 7], south => [3, 19, 88], west => [5,␣
 ↪5, 5]);
my @ranked = sort { sum(@{$sales{$b}}) <=> sum(@{$sales{$a}}) } keys␣
 ↪%sales;

printf "%s  top %d of %d regions\n",
```

(continues on next page)

(continued from previous page)

```
    strftime('%F %T', localtime), $top, scalar @ranked;
printf "  %-6s total %3d  peak %3d\n",
    $_, sum(@{$sales{$_}}), max(@{$sales{$_}})
    for @ranked[0 .. $top - 1];
```

Start a daemon, then time the same twenty runs with and without it:

```
pperl --daemon=start

time (for i in $(seq 20); do pperl report.pl >/dev/null; done)

pperl --via-daemon report.pl >/dev/null        # builds the template
time (for i in $(seq 20); do pperl --via-daemon report.pl >/dev/
↪null; done)
```

On the machine this page was written on, that is 0.47 s against 0.08 s: about 24 ms per cold run, about 4 ms per run from the template. Nothing in the program changed; what disappeared is the compile of the script and of the seven modules, which the first run paid once.

Two things about those numbers are worth internalising. The saving is a fixed amount of *start-up* time, not a percentage of your program: a script that then works for a minute saves the same 20 ms as this one. And the saving scales with what you `use`, not with how long the script is - the modules are almost always the expensive part.

Checking whether a run was served

Because a decline is silent, “it got faster” is the wrong way to tell whether the daemon is doing anything. Ask the daemon:

```
pperl --daemon=status
```

```
build 0.6.8-10307.2a84282.6a670d70.10d8b48
uptime 42s
served 21
live 0
templates 1
template /home/you/report.pl pid 38109 served 21 age 39s ready
```

`served` counts requests the daemon handled; a run that fell back cold never appears there. `templates` lists one line per compiled script, with the process holding the image, how often it has been forked, and whether it is `ready` or still `parsing`.

For a single run, ask the program itself. A served run is a child of the daemon (or of its template), never of your shell:

```
pperl -e 'print getppid, "\n"'                 # your shell
pperl --via-daemon -e 'print getppid, "\n"'    # the daemon
```

If both print the same pid, the request was declined and pperl ran the program itself - which is always correct, just not faster.

What running from a template means

A template run executes your script's *run phase* only. Compilation already happened, once, when the template was built. pperl guarantees that the following are fresh and correct for every run:

- `@ARGV`, `%ENV`, the current directory, umask
- standard input, output and error (your redirections and pipes)
- the process id `$$`
- exit codes, and death by signal (a killed script kills the invoking `pperl` the same way)
- the `__DATA__` handle - each run reads it from the start, independently of other runs

What is **not** re-done is anything your code did at compile time. `BEGIN` blocks, and module code executed at `use` time, ran once when the template was built; their side effects are part of the image every run inherits. Consequences you own when you opt a script in:

- `$^T` (the script start time) and the random-seed state date from template creation. If your script cares, re-stamp them at the start of the run phase:

```
INIT { $^T = time; srand(); }
```

- Values read from `%ENV` *at compile time* (inside `BEGIN` or at `use` time) were the values of the run that built the template. Read configuration at run time, or in an `INIT` block, if it must track the invoking environment.
- File handles, sockets or database connections opened at compile time are shared with every run. Open connections at run time - the same rule long established for preloading application servers.

If a script cannot satisfy this contract, simply do not opt it in; `PPERL_DAEMON=2` is per invocation, not global.

Editing the script, and the cache

The daemon notices when the script file itself changes and rebuilds the template automatically on the next run - editing your script never serves you a stale image.

Edits to *modules* the script loads are not detected automatically. After changing a module, drop the affected template by hand:

```
pperl --daemon-reset=report.pl   # forget this script's template
pperl --daemon-reset             # forget all templates
```

Templates are a bounded cache: at most `--daemon-max-scripts` of them (default 100). When the limit is reached, the least recently used template is dropped to make room.

`--daemon-idle` (default 900 seconds) is a single value that two independent clocks use. A *template* exits when it has served nothing for that long, releasing its memory while the daemon keeps running and its other templates stay cached. The *daemon's* own clock only starts once nothing of its own is left alive - no request in flight, no template - so it never shuts down out from under a cached script. With the defaults, a script you stop

using loses its template about fifteen minutes later, and a daemon with nothing left to hold exits about fifteen minutes after that.

Neither exit costs you anything but time: with the template gone the next run compiles the script again, and with the daemon gone the run is an ordinary cold start. A daemon is never restarted for you, so if a machine runs opted-in scripts around the clock, either raise `--daemon-idle` or run the daemon as a service (below).

When pperl falls back to a cold run

The daemon refuses - and the client falls back to a normal run, silently and correctly - whenever it could not reproduce the invocation exactly:

- no daemon is running for this pperl binary
- environment variables that shape interpreter start-up differ from the daemon's (`PERL_HASH_SEED`, `PERL_PERTURB_KEYS`, `PERL_RAND_SEED`, `PERL_INTERNAL_RAND_SEED`, `PERL_UNICODE`, `LANG`, any `LC_*`, any `MALLOC_*`)
- the command-line flags differ from the ones the template was built with (a template stores one configuration)
- the template is still being built by a concurrent first run
- the invocation is a `-e` one-liner (templates cache script files)
- `--interactive` or `--stats` is in effect

Opting a script in without typing it every time

`PPERL_DAEMON=2` in front of every invocation is fine for a measurement and tedious for daily use. Two ways to make the opt-in part of the script or the command instead.

In the shebang, which travels with the script and makes the preload-safety promise visible to whoever reads it next:

```
#!/usr/bin/env -S pperl --via-daemon
```

Or as a shell function, when the script is not yours to edit:

```
report() { pperl --via-daemon "$HOME/bin/report.pl" "$@"; }
```

`--via-daemon` and `PPERL_DAEMON=2` are the same request and share one template, so a script with the shebang above still hits the cache when you run it once by hand with the environment variable, and the other way round.

The flag names an intent, not a boundary: given a script file it uses that script's template, and the script itself stays an ordinary argument. `pperl --via-daemon=report.pl` is not a thing - that value slot takes `trunk`, nothing else (see below), and pperl will tell you so.

Running the daemon as a service

`pperl --daemon` runs in the foreground and logs to standard error, which is what a service manager wants. A systemd user unit:

```
# ~/.config/systemd/user/pperl-daemon.service
[Unit]
Description=pperl start-up daemon

[Service]
Type=simple
ExecStart=/usr/local/bin/pperl --daemon --daemon-idle=86400
Restart=on-failure

[Install]
WantedBy=default.target
```

```
systemctl --user enable --now pperl-daemon.service
```

A long `--daemon-idle` is the point of running it this way: the unit is meant to be there when the next invocation arrives, whenever that is. The value must be a positive number of seconds; there is no "never".

One thing to remember after upgrading pperl: the daemon is keyed to the binary it was started from, so the new binary will not talk to the old daemon. Nothing breaks - runs are simply cold again until you `systemctl --user restart pperl-daemon.service`.

Security and identity

The daemon serves exactly one user: its socket lives in a directory with owner-only permissions and every connection's peer user id is verified. It also serves exactly one *build* of pperl: the socket is keyed to the binary's identity (`pperl --build-id` prints it), so after a pperl upgrade the old daemon is simply never contacted again and exits on its idle timeout.

Limitations

- Job control is approximate: the running script is a child of the daemon, not of your shell. Signals you send to `pperl` (including `Ctrl-C`) are forwarded to the script, but `Ctrl-Z` suspends only the foreground `pperl`, not the script process.
- One template per script path, holding one flag configuration. Invoking the same script with different flags falls back to a cold run rather than rebuilding the template.
- A one-liner cannot be cached. A template is keyed on a script file, which is also what tells pperl the cached image has gone stale; `-e` and `-E` have neither, so they only ever get the reduced mode below. This is not a `-E` limitation - `-E` is `-e` with features enabled and takes exactly the same path.
- `--via-daemon=trunk` (or `PPERL_DAEMON=1`) is that reduced mode: it forks a ready interpreter but still compiles the script on every run. It saves almost nothing, and

it exists so the daemon's own tests can exercise that boundary. There is no reason to ask for it in normal use.

- **Measuring** - the tools that actually work under pperl. The upstream XS profilers (`Devel::NYTProf`) do not load; the JIT log, the platform profiler, and the `bench/run-perlbench` runner do. How to read their output and how to A/B two versions of a routine.
- **Idioms** - a triage of the classic Perl performance idioms. Each is tagged: still valid, made moot by the JIT or parallelizer, or newly relevant because of how pperl compiles. The idioms that were folklore on upstream Perl are not all folklore here.
- **Sorting** - `sort` in depth: the Schwartzian transform, the Guttman-Rosler transform, `sort` subroutine cost, and when the comparator is the bottleneck.
- **Writing fast pperl** - the positive program: how to structure a hot loop so the JIT compiles it, how to shape a reduction so the parallelizer claims it, and the one mistake - mixing string work into a numeric loop - that silently disables both.
- **Fast start-up: the daemon** - opt-in start-up acceleration for repeatedly invoked scripts: a resident daemon keeps each script's compiled image and every run forks it, skipping parsing and module loading. What it guarantees per run, the preload-safety contract your script signs, and when pperl silently falls back to a normal cold start.

What this guide does not cover

The mechanisms live elsewhere and this guide does not repeat them:

- *JIT compilation* - what gets compiled, the caching model, the variable-type analysis.
- *Parallel execution* - the reduction analysis, the side-effect gate, the CLI thread controls.
- *Regex performance* - backtracking, catastrophic patterns, the engine's optimiser. Regex speed is its own discipline; nothing in this guide duplicates it.
- *Native modules* - why `List::Util` and friends run at built-in speed with no XS layer.
- *Auto-FFI* - calling C without XS, and the per-call marshalling cost that makes it the wrong tool for a hot inner loop.

A note on numbers

Concrete speedups in this guide are reproduced from the architecture and concurrency chapters, which carry the measured figures and the benchmark that produced them. Where this guide states a speedup without a number, the qualitative behaviour is established but the exact figure depends on your machine, your data, and your build - run `bench/run-perlbench` and trust your own measurement over any printed ratio.

4.2.5 Object-oriented programming

Perl has two object systems living side by side: the **modern `class`/`field`/`method`** syntax introduced in 5.38 (codename *Corinna*), and the **classical `bless`/`@ISA`** model that predates it by three decades. pperl supports both, and both appear in real code you will read and maintain.

The short version:

- For **new code**, use `class`. The syntax is first-class, the constructor is generated for you, fields are genuinely private, and single inheritance has a clean declarative form.
- For **legacy code**, understand `bless`, `@ISA`, and the `$self = shift` convention. You will meet them in every pre-5.38 codebase, every mainline CPAN distribution, and much of core Perl itself.
- **Moose, Moo, Class::Accessor, Object::Pad** are the CPAN ecosystems that papered over the classical model's rough edges while the core feature was still being designed. They are a historical chapter; new code reaches for core `class` instead.

This how-to tree covers both systems end-to-end. Read the chapters in order on a first pass, or jump to the one that matches the code in front of you.

Which chapter you want

- *Modern classes* - `class`, `field`, `method`, `ADJUST`, `:param`, `:reader`. The recommended way to write OO in pperl.
- *Classical OO* - `bless`, `@ISA`, `sub new`, accessors by hand, `SUPER::`. The model you will maintain in existing code.
- *Inheritance and method resolution* - how method lookup works, `isa`, `can`, `DOES`, MRO, and the pitfalls of multiple inheritance.
- *Roles and delegation* - composition patterns for behaviour shared across unrelated classes.
- *Migrating from classical to modern* - a mechanical recipe for converting a `bless`-based class to the `class` feature, and the places where the translation is not mechanical.

When to use OO at all

OO is a tool, not a style. Reach for it when:

- The problem has a small vocabulary of nouns (user, session, request, record) and a larger vocabulary of verbs acting on each.
- A piece of data carries invariants that should be enforced at one point in the code, not at every call site.
- You expect the implementation behind a set of operations to change while the operations themselves stay stable.
- You are modelling a category with variants and want polymorphism to pick the right behaviour.

Do not reach for OO when:

- The program is small, linear, and has no reusable nouns.
- A plain hash of hashes or a closure is enough.
- The only reason to write a class is "it felt more professional." A twelve-line script does not need a class.

A note on scope

This tree is a tutorial, not a reference. The exhaustive syntax tables live in the per-keyword reference pages:

- `class`
- `field`
- `method`
- `bless`
- `ref`
- `isa`

Link into them whenever you need the full signature surface; this tree gives you the working-programmer overview.

Modern classes

The `class` feature is the recommended way to write object-oriented code in pperl. It replaces the hand-rolled constructor, the manual accessor generation, the hash-slot bookkeeping, and the `use parent` dance with a single declarative syntax. You describe *what* the class is; the runtime arranges *how* it is implemented.

This chapter walks through the feature as a working programmer would meet it: first a minimum class, then fields and attributes, then methods, then construction-time hooks, then inheritance. Each section is short on purpose; when you want the full surface of a keyword, follow the cross-link into its reference page.

Enabling the feature

The feature is flagged experimental in Perl 5.44 and pperl mirrors that status. Every file that uses it opens with:

```
use v5.38;
use feature 'class';
no warnings 'experimental::class';
```

The `use v5.38` line already enables the `class` feature on its own, but being explicit makes the dependency visible to anyone reading the file.

A minimal class

```
use v5.38;
use feature 'class';
no warnings 'experimental::class';

class Point {
    field $x :param;
    field $y :param;

    method distance_from_origin {
        return sqrt($x ** 2 + $y ** 2);
    }
}

my $p = Point->new(x => 3, y => 4);
say $p->distance_from_origin;                # 5
```

Three things to notice:

- There is no `sub new`. The runtime generates the constructor from the `field` declarations. A user-written `sub new` inside a `class` body is a compile-time error on purpose - the generated one knows how to wire up `:param`, run initialisers, and trigger `ADJUST` blocks in the right order.
- Fields are referenced by their *declared name* inside methods, not through `$self->{x}`. The instance storage is genuinely private; no code outside the class body can poke at it.
- The `method` keyword takes care of `$self`. You never write `my $self = shift`.

Fields

A `field` is per-instance storage. Every object of the class gets its own slot; every method and every `ADJUST` block sees the field as if it were a lexical.

```
class Counter {
    field $value = 0;
    field $step  = 1;

    method tick  { $value += $step }
    method value { $value }
}
```

Fields accept scalars, arrays, and hashes:

```
class Registry {
    field $name;
    field @items;
    field %seen;
}
```

Attributes on fields

Field attributes take the declarative work off your hands.

- **`:param`** - bind this field to a constructor argument. If the caller omits it, the field is either left unset or takes the declared default.
- **`:param(alt)`** - bind to a different constructor name.
- **`:reader`** - generate a read-only accessor with the field's name minus the sigil.
- **`:reader(custom)`** - generate a reader under a different name.
- **`:writer`** - generate a setter (`set_FIELDNAME`).

```
class User {
    field $name  :param :reader;
    field $email :param :reader :writer;
    field $role  :param :reader = 'guest';
}

my $u = User->new(name => 'Ada', email => 'ada@example.org');
say $u->name;                                   # Ada
$u->set_email('ada@analytical.org');
say $u->role;                                   # guest
```

Default values

Defaults use one of three operators, each with a different rule:

- **`=`** - apply when the caller *omitted* the parameter entirely.
- **`//=`** - also apply when the caller passed `undef`.
- **`||=`** - also apply when the caller passed any false value.

```
class Window {
    field $title :param         = 'untitled';
    field $width :param         //= 640;
    field $shown :param         ||= 1;
}
```

Pick `=` unless you have a concrete reason to allow the stronger forms. Silent promotion of `undef` or `0` to a default is a bug magnet.

Fields are not lexicals in the usual sense

Fields look like lexicals inside a method body, but they have tighter rules:

- You cannot `our` a field, you cannot `local` one, and you cannot take a reference to one and export it.
- Fields are private to the class. Subclasses do **not** inherit a parent's fields; if a subclass needs a parent's state, it asks for it through a method.

- A field's initialiser runs before `$self` is bound. Inside `field $x = EXPR`, you can use earlier fields by name and you can use `__CLASS__`, but you cannot use `$self`. Anything that needs the fully constructed instance belongs in an `ADJUST` block.

Methods

A `method` is a subroutine that auto-binds `$self` and reads the enclosing class's fields by name.

```
class File {
    field $path :param :reader;

    method slurp {
        open my $fh, '<', $path or die "open $path: $!";
        local $/;
        return <$fh>;
    }

    method rename ($new) {
        rename $path, $new or die "rename: $!";
        $path = $new;
    }
}
```

Methods use signatures automatically - `use feature 'signatures'` is implied inside a class body. `$self` is the method's implicit first argument and does **not** appear in the signature.

Private methods

A method declared with `my` is lexical to the class body and is invoked through the `->&` operator:

```
class Safe {
    field $secret :param;

    my method check ($n) { $n == $secret }

    method unlock ($n) {
        return $self->&check($n) ? 'open' : 'denied';
    }
}
```

`my method` is the closest pperl has to a hard-private method; no external caller can reach it because the name does not live in the package at all.

Construction hooks: ADJUST

An `ADJUST` block runs after field initialisation, with `$self` already bound. It is the place for:

- Post-construction validation.

- Derived fields that depend on other fields.
- Opening a handle or connecting to a resource whose lifetime matches the object.

```
class TempFile {
    field $prefix :param = 'tmp';
    field $path;
    field $fh;

    ADJUST {
        $path = "/tmp/$prefix-$$-" . int(rand 1_000_000);
        open $fh, '>', $path or die "open $path: $!";
    }

    method write ($data) { print {$fh} $data }
    method path { $path }
}
```

Multiple `ADJUST` blocks in one class run in declaration order. In an inheritance chain, the parent's `ADJUST` blocks run before the child's.

Inheritance

A class inherits from at most one parent using the `:isa` attribute:

```
class Shape {
    field $colour :param :reader = 'black';
    method area { 0 }
}

class Circle :isa(Shape) {
    field $radius :param :reader;
    method area { 3.14159265 * $radius ** 2 }
}
```

Only **methods** are inherited. Fields are per-class storage. A subclass that needs the parent's state asks through a reader:

```
class Labelled :isa(Shape) {
    field $label :param :reader;
    method describe { "$label (" . $self->colour . ')' }
}
```

Multiple inheritance is not supported. `:isa(A, B)` is a syntax error, and a class cannot carry more than one `:isa` attribute. The *inheritance chapter* explains why, and covers the role-based alternative.

Calling up the chain

`SUPER::` still works, exactly as it does for `bless`-based classes:

```
class Dog :isa(Animal) {
    method introduce {
        $self->SUPER::introduce;
        say "and I can fetch";
    }
}
```

__CLASS__

Inside a field initialiser or a method body, `__CLASS__` is the class currently being constructed. In a subclass, `__CLASS__` refers to the subclass even inside an inherited method or an inherited field initialiser. Use it for factory-style hooks:

```
class Base {
    sub DEFAULT_X { 10 }
    field $x = __CLASS__->DEFAULT_X;
    method x { $x }
}

class Tuned :isa(Base) {
    sub DEFAULT_X { 99 }
}

say Tuned->new->x;                          # 99
```

Interoperation with classical OO

A `class`-declared class is a regular package. Code that uses `ref`, the `isa` operator, `UNIVERSAL::isa`, and `UNIVERSAL::can` keeps working:

```
my $c = Circle->new(radius => 2);
say ref $c;                                 # Circle
say $c isa Shape ? 'yes' : 'no';            # yes
say $c->can('area') ? 'yes' : 'no';         # yes
```

A classical class can subclass a modern class and vice versa, as long as the classical side goes through methods (never through `$self->{fieldname}`) - see the *migration chapter* for the full interop story.

Edge cases worth knowing

- **Do not write `sub new`.** The constructor is generated. A user-written `new` inside a `class` body is rejected at compile time.
- **Treat `@ISA` as read-only** for `class`-declared classes. Runtime manipulation is undefined behaviour.
- **`$self` is read-only** inside a method. Assigning to `$self` is a runtime error.
- **`package` cannot reopen a `class`.** Once a namespace has been declared with `class`, a later `package` statement for the same name is a compile-time error, and vice

versa.

- **Statement-form scope.** `class Foo;` consumes the rest of the enclosing block, typically the rest of the file. A subsequent `class` or `package` ends the body; there is no way to close a statement-form class early.

Where to go next

- *Inheritance and method resolution* - the full story of how method lookup works across `:isa` chains and across mixed classical/modern hierarchies.
- *Roles and delegation* - the recommended answer to "I want to share behaviour across unrelated classes."
- *Migrating from classical to modern* - if you are staring at a `bless`-based class and wondering what the equivalent `class` block looks like.

Classical OO

Before the `class` feature landed in 5.38, Perl's OO was built from three primitives: a package, a reference, and the `bless` function. Those three primitives are still present - the modern `class` keyword sits on top of the same machinery - and every pre-5.38 codebase, plus most of CPAN, still uses them directly.

This chapter is for reading and maintaining that code. If you are writing a new class, start with the *modern class chapter* instead.

The three primitives

1. **A package** defines a namespace. Any package can be a class; the difference is purely how it is used.
2. **A reference** holds instance data. The convention is a hash reference, but any reference type works.
3. **`bless`** tags the referent with a class name, so that method dispatch through the reference looks up subs in that package.

That is the whole model. Everything else - constructors, accessors, inheritance, roles - is a convention built on top.

A minimal class

```
package File;

sub new {
    my ($class, %args) = @_;
    my $self = {
        path    => $args{path},
        content => $args{content},
    };
    return bless $self, $class;
}
```

(continues on next page)

(continued from previous page)

```
sub path    { $_[0]{path} }
sub content { $_[0]{content} }

sub print_info {
    my $self = shift;
    print "This file is at $self->{path}\n";
}

1;
```

Key conventions, each load-bearing:

- **`sub new`** is the constructor. It is an ordinary method; the language has no constructor keyword. By convention it is named `new` and returns the blessed reference.
- **`my ($class, %args) = @_`** unpacks the invocant first, then the named arguments. A class-method call `File->new(path => ...)` passes the class name as the first argument.
- **`bless $self, $class`** attaches the class tag. Using `$class` (the actual invocant) rather than a hard-coded `'File'` is what makes the constructor *inheritance-safe*: a subclass inheriting `new` will bless into the subclass's name.
- **`return` is usually omitted** after `bless` because `bless` returns its first argument. `bless $self, $class` as the last expression in the sub is idiomatic. We write it explicitly here for readability.

Accessor methods by hand

The model gives you no accessors; you write them. The terse form exploits the fact that `$_[0]` is the invocant:

```
sub path    { $_[0]{path} }
sub content { $_[0]{content} }
```

The named-parameter form is clearer and what you should write when the accessor does anything non-trivial:

```
sub path {
    my $self = shift;
    return $self->{path};
}
```

A read/write accessor:

```
sub name {
    my $self = shift;
    $self->{name} = shift if @_;
    return $self->{name};
}
```

This is the boilerplate the *modern class feature* replaces with `:reader` and `:writer`.

Why hash references

Hash references dominate because they let you add and rename fields without changing the layout, and because named keys survive a `Data::Dumper` or `JSON::encode` round-trip. Array references are faster and more compact but fragile: renumbering a slot breaks every access site.

Hash-backed instances have one serious drawback: no encapsulation. Any caller can reach into the object's internals with `$obj->{path}`. The classical model has no tool to stop them - self-discipline and code review are the only defences. This is the single biggest reason to prefer the *modern class feature* for new code.

Inheritance with `@ISA`

Inheritance is a package-level list named `@ISA`. Method dispatch walks it when the current package does not define the method.

```
package File::MP3;
our @ISA = ('File');

sub print_info {
    my $self = shift;
    $self->SUPER::print_info;
    print "Title: $self->{title}\n";
}

1;
```

`SUPER::` means "look for this method starting one step up the ISA chain from the package the current method was *compiled in*" - not from the object's class. That subtlety matters in diamond inheritance; the *inheritance chapter* covers it.

Declaring the parent - four ways

There are four spellings of the same idea. Prefer the third for new code you are still maintaining in the classical style.

```
# 1. Raw @ISA assignment.
package Child;
our @ISA = ('Parent');

# 2. use base.
package Child;
use base 'Parent';          # deprecated in modern Perl

# 3. use parent.
package Child;
use parent 'Parent';        # current recommendation for classical

# 4. @ISA with a require.
package Child;
```

(continues on next page)

(continued from previous page)

```
require Parent;
our @ISA = ('Parent');
```

`use parent` handles the load of the parent module and the `@ISA` push in one line. `use base` is an older variant that also imports `Exporter`-style fields; avoid it.

The `$self` invocant

Every method is a subroutine whose first argument is either the class name (for class methods like `new`) or the object (for instance methods). The convention is to shift it into a variable named `$self`:

```
sub method {
    my $self = shift;
    ...
}
```

Or unpack it together with other arguments:

```
sub method {
    my ($self, $arg1, $arg2) = @_;
    ...
}
```

There is no runtime enforcement. If you forget to shift `$self`, your first user-supplied argument silently becomes `$self` and chaos ensues. Static analysers catch this; the language does not.

Destructors

A `DESTROY` method, if defined, runs when the object's refcount falls to zero. Use it to release external resources:

```
sub DESTROY {
    my $self = shift;
    close $self->{fh} if defined $self->{fh};
}
```

Pitfalls that bite every project at least once:

- `DESTROY` runs at unpredictable times. Do not rely on it for correctness-critical cleanup - explicit `$obj->close` beats implicit destruction.
- `DESTROY` can see a partially constructed object if `new` croaked mid-way. Defensive `defined` checks are cheap insurance.
- During global destruction (`END` time), dependencies may already be gone. A `DESTROY` that walks references can fail with "Attempt to free unreferenced scalar" or similar. Wrap risky cleanup in `eval { ... }`.

AUTOLOAD

If a method call finds no matching sub in the class or its ancestors, Perl looks for an AUTOLOAD sub. The called method's name appears in our $AUTOLOAD:

```
our $AUTOLOAD;
sub AUTOLOAD {
    my $self = shift;
    my $name = $AUTOLOAD;
    $name =~ s/.*::/;
    return if $name eq 'DESTROY';       # critical
    ...
}
```

The DESTROY guard is mandatory: without it, object destruction triggers AUTOLOAD with $name = 'DESTROY' and you either misbehave or crash.

AUTOLOAD is powerful and easy to abuse. The cases it earns its keep:

- Lazy accessor generation - synthesise an accessor on first call, then install it as a real sub via typeglob assignment so the next call is direct.
- Forwarding - delegate unknown methods to a contained object (but see *Roles and delegation* for a cleaner approach).

Cases where it hurts more than it helps: pretending to be a full-blown MOP, catching typos as silent no-ops, implementing "classes" whose entire surface is AUTOLOAD.

A worked example

A classical Counter class with read/write accessor and inheritance:

```
package Counter;

sub new {
    my ($class, %args) = @_;
    my $self = {
        value => $args{value} // 0,
        step  => $args{step}  // 1,
    };
    return bless $self, $class;
}

sub value {
    my $self = shift;
    $self->{value} = shift if @_;
    return $self->{value};
}

sub step { $_[0]{step} }

sub tick {
    my $self = shift;
```

(continues on next page)

(continued from previous page)

```
    $self->{value} += $self->{step};
}

1;
```

A subclass that doubles the step:

```
package Counter::Double;
use parent 'Counter';

sub new {
    my ($class, %args) = @_;
    $args{step} //= 2;
    return $class->SUPER::new(%args);
}

1;
```

Compared with the *modern class* version, the classical form is about three times as many lines and every one of them is a place to get it wrong.

When classical OO is the right call

Despite everything, there are legitimate reasons to stick with `bless`-based classes:

- **You are maintaining existing code.** Rewriting a working classical class into `class` form is a migration project, not a free lunch - see the *migration chapter*.
- **You need to support older Perl.** If your code must run on Perl before 5.38, the `class` feature is unavailable.
- **You need array-backed or code-backed objects.** `class` only creates hash-backed instances. If you are building a performance-critical structure with array-reference instances, classical `bless` is still the answer.
- **You are doing something the `class` feature deliberately forbids** - reopening the package from outside, multiple inheritance, or deep metaprogramming via `@ISA` manipulation.

A historical note on CPAN OO systems

Because the classical model leaves so much to convention, CPAN grew an ecosystem of modules that layer declarative syntax on top:

- **Moose** - feature-complete OO system with a type miniature, roles, method modifiers, a full introspection API, and a large extension ecosystem. Heavy at load time; the dominant choice for large applications built between 2007 and roughly 2020.
- **Moo** - a subset of Moose's API without the introspection layer. Lighter, pure-Perl, API-compatible enough to let a Moo class and a Moose class share an inheritance tree.

- **Class::Accessor** - generates simple accessors and `new`. Minimal, pure-Perl, no roles.
- **Class::Tiny** - the smallest of the accessor-generator modules. All accessors are read/write, no type checks.
- **Object::Pad** - the experimental prototype that became the core `class` feature. Still installable on CPAN for code that needs the feature on older Perls.
- **Role::Tiny** - role composition for projects that do not use Moose but still want `does`-style sharing.

These systems are **historical context** in pperl. New code in pperl should use the core `class` feature, which covers the ground that Moose/Moo pioneered without the load-time and dependency cost. When you inherit a codebase that uses one of them, learn just enough of its surface to stay productive and plan the migration with the *migration chapter*.

Inheritance and method resolution

Method lookup in Perl is simple in the single-inheritance case and genuinely subtle once diamonds or mixed class systems enter the picture. This chapter covers the full story: the MRO algorithms, `SUPER::`, the `isa` operator, `can`, `DOES`, and the interaction between classical and modern classes in one hierarchy.

The lookup algorithm

When you write `$obj->foo(@args)`, Perl does the following:

1. Determine the class. For an object, it is the class the referent was blessed into; for a class-method call, it is the invocant itself.
2. Walk the class's **method resolution order** (MRO) in sequence. For each package in the order, look for a sub named `foo`.
3. The first match wins. If no match is found in any class on the MRO, walk again looking for `AUTOLOAD`.
4. If no `AUTOLOAD` is found either, throw `Can't locate object method "foo" via package "Class"`.

The MRO is what the class's `@ISA` chain linearises to. The linearisation rule depends on which MRO is in effect.

The two MROs: `dfs` and `c3`

Perl ships two MRO algorithms:

- **`dfs`** - depth-first search of `@ISA`. The default. Walk each parent, and each parent's parents, left-to-right, diving fully into each subtree before moving on.
- **`c3`** - the C3 linearisation used by Python, Raku, and many others. Guarantees monotonicity: a subclass never appears later than one of its ancestors in the lookup order.

For single inheritance the two are identical: the list walks straight up the chain.

For multiple inheritance they diverge. Consider the diamond:

```
    A
   / \
  B   C
   \ /
    D
```

- **`dfs`**: `D, B, A, C, A` (collapsed to `D, B, A, C`). A method on `C` that overrides `A` is **shadowed** by `A` because `A` is reached through `B` first.
- **`c3`**: `D, B, C, A`. C's override is visible.

C3 is almost always what you want under multiple inheritance. Opt in per-class:

```
use mro 'c3';
package Diamond::D;
our @ISA = ('Diamond::B', 'Diamond::C');
```

For classes declared with `class`, multiple inheritance is not supported at all, so the MRO choice is purely a linear walk and the default `dfs` is fine.

SUPER::

`$self->SUPER::foo(@args)` calls `foo` in one of the parent classes of *the package the current method was compiled in*. That last phrase is the one everyone gets wrong.

```
package Animal;
sub speak { 'some sound' }

package Dog;
our @ISA = ('Animal');
sub speak { 'woof' }

package Puppy;
our @ISA = ('Dog');
sub speak {
    my $self = shift;
    return $self->SUPER::speak;
}
```

`Puppy::speak` calls `SUPER::speak`. Perl looks up from **Puppy** (the compilation package), not from `ref($self)`. The search starts in Puppy's `@ISA`, so it finds `Dog::speak` and returns `'woof'`.

This matters when methods are inherited and the child calls `SUPER::` from within. Because `SUPER::` is anchored to the compile-time package, a method inherited from `Dog` and invoked on a `Puppy` object will still call `Animal::` via its `SUPER::`, not `Dog`. Usually that is the right behaviour; when it is not, reach for explicit chain navigation with `next::method`, covered below.

`next::method` - the MRO-aware SUPER

`mro::next::method` (exposed as `$self->next::method(@args)`) walks the live MRO from the current method's *actual* call position, not from the compile-time package:

```
use mro 'c3';

sub speak {
    my $self = shift;
    return $self->next::method;
}
```

Under C3 with a diamond, `next::method` is what you want; `SUPER::` can skip a sibling branch because it only consults the left-most ancestor.

The `isa` operator

The `isa` operator tests class membership without the footgun of `UNIVERSAL::isa` called as a function:

```
if ($obj isa 'File::MP3') { ... }
if ($obj isa File::MP3)   { ... }     # bareword form
```

Both `bless`-based and `class`-declared classes answer `isa` correctly, and subclass relationships flow through `:isa` and `@ISA` identically.

Three rules worth remembering:

- `isa` returns false (not an error) when given a non-object. `42 isa Foo` is false. `undef isa Foo` is false.
- `isa` respects the live MRO at the moment of the call. If code pushes onto `@ISA` at runtime, `isa` sees it. (This is another reason pperl rejects `@ISA` manipulation for `class`-declared classes - the guarantees would become muddy.)
- Prefer the `isa` operator over `UNIVERSAL::isa($obj, 'Class')`. The operator short-circuits on non-objects instead of croaking; the function-call form is also defeated by overloaded objects.

`can`

`$obj->can('method')` returns a code reference if the object has a method by that name, `undef` otherwise:

```
if (my $code = $obj->can('save')) {
    $code->($obj, @args);
}
```

Uses:

- Feature-detection before calling: avoids the `Can't locate object method` error.
- Dispatching to a method by name from a string held in a variable - more readable than the `$obj->$name` form when the method might not exist.

Non-uses:

- Do **not** use `can` to decide whether an object implements a conceptual role. A class can define a `save` method that does something completely unrelated to persistence. For role membership, see *roles and delegation*.

DOES

`$obj->DOES('RoleOrClass')` is the role-aware counterpart to `isa`. By default `DOES` delegates to `isa`, so for classes without explicit role machinery the two behave the same. Role systems (classical Moose, Moo, and the future core role feature) override `DOES` to also return true for roles the class consumes.

```
if ($obj->DOES('Printable')) { ... }
```

In pperl, `DOES` is the right method to check when you want to ask "does this object implement the contract?" rather than "does this object inherit from this class?"

Mixed classical / modern hierarchies

`class`-declared and `bless`-based classes interoperate in both directions, subject to a handful of rules.

A modern class inheriting from a classical class

```
package Shape;                              # classical
sub new {
    my ($class, %args) = @_;
    return bless { colour => $args{colour} // 'black' }, $class;
}
sub colour { $_[0]{colour} }

use feature 'class';
class Circle :isa(Shape) {                  # modern inherits classical
    field $radius :param :reader;
    method area { 3.14159265 * $radius ** 2 }
}
```

This works. The modern class's generated constructor delegates to the parent's new, and methods inherited from the classical parent appear on the modern child. The parent's hash-slot state lives *alongside* the child's field storage.

Caveat: the modern child cannot reach into the parent's hash. `$self->{colour}` is not legal inside a method of `Circle`; you must call `$self->colour`.

A classical class inheriting from a modern class

```
use feature 'class';
class Animal {
    field $name :param :reader;
```

(continues on next page)

(continued from previous page)

```
    method speak { 'some sound' }
}

package Dog;                                # classical inherits modern
our @ISA = ('Animal');
sub new {
    my ($class, %args) = @_;
    return $class->SUPER::new(%args);
}
sub speak { 'woof' }
```

This also works - the modern parent's generated constructor is inherited, and `SUPER::new` resolves to it. The classical child must not try to mutate the parent's fields directly; fields are private to the class that declared them.

What fails in mixed hierarchies

- **Reaching `$self->{fieldname}` across the boundary.** Modern fields are not hash slots, and classical hash slots are not visible as fields. Always cross the boundary through a method.
- **Multiple inheritance into a modern class.** The `:isa` attribute only takes one target. If you need to mix behaviour from multiple places, see *roles and delegation*.
- **Runtime `@ISA` manipulation on a modern class.** Undefined behaviour. Treat `@ISA` as read-only for any class declared with `class`.

Why multiple inheritance usually hurts

Every language with multiple inheritance eventually discovers the same pathologies. Method lookup becomes order-dependent; diamond problems force you to think about linearisation; the "I inherited twice from the same root" case tangles initialisation. Roles - composition of behaviour without an inheritance relationship - solve the underlying sharing problem without the pathologies.

In pperl the `class` feature forbids multiple inheritance deliberately. Classical code that uses it should be migrating towards a role model; the *roles chapter* is the next stop.

Further reading

- `class` - full syntax of modern class declarations including `:isa`.
- `bless` - the primitive under classical inheritance.
- `ref` - reports a blessed reference's class name.
- `isa` - the preferred class-membership operator.
- *Roles and delegation* - the composition-based alternative to multiple inheritance.
- *Migration* - walking an existing hierarchy from classical to modern.

Roles and delegation

Inheritance answers "what is this object?" Roles and delegation answer a different question: "what can this object do?" When two unrelated classes need to share behaviour, forcing them under a common parent is the wrong tool. Composition - giving each class the behaviour it needs without pretending they are related - is the right one.

This chapter covers the three composition patterns that pperl code uses in practice:

1. **Mixin-style sharing** via a tiny helper package.
2. **Role composition** via `Role::Tiny` or a Moose-family system in legacy code.
3. **Delegation** - forwarding methods to a contained object.

The core `class` feature does not yet ship a role primitive. That is a deliberate staging decision upstream: the `class` feature landed first, roles are a separate proposal. Until the core role feature ships, the patterns in this chapter are the working answers.

The problem

Imagine a `Radio` class and a `Computer` class. Both have an on/off switch. They are not related - a radio is not a computer, and neither specialises a hypothetical `Machine`. A `HasOnOffSwitch` parent class would be an artificial grouping whose only purpose is reuse of two methods.

Three solutions, in increasing order of ambition:

- Copy the `turn_on` / `turn_off` methods into each class. Tolerable for two classes, painful for ten.
- Extract them into a helper package, use one of the sharing mechanisms below.
- Use a role system with formal composition semantics.

Pattern 1: manual mixin

The smallest possible "share these methods" mechanism is a plain package that installs subroutines into the consuming class at `use` time:

```
package HasOnOffSwitch;

sub import {
    my $target = caller;
    no strict 'refs';
    *{"${target}::turn_on"}  = sub { $_[0]->{is_on} = 1 };
    *{"${target}::turn_off"} = sub { $_[0]->{is_on} = 0 };
    *{"${target}::is_on"}    = sub { $_[0]->{is_on} };
}

1;
```

Used:

```
package Radio;
use HasOnOffSwitch;

sub new { bless { is_on => 0 }, shift }
```

This works. It is also brittle: it reaches into the consuming class's hash directly (`$_[0]->{is_on}`), which is exactly the encapsulation violation that classical hash-backed OO is famous for. It breaks if the consumer is a `class`-declared class, because fields are not hash slots.

Use this pattern only for very small shared behaviour in a classical codebase. For anything larger, use a real role system.

Pattern 2: `Role::Tiny`

`Role::Tiny` is the lightweight role system that works with plain classical classes, with `Moo`, and with `Moose` (on the consuming side). It is the closest thing to a portable role primitive in the CPAN ecosystem.

```
package HasOnOffSwitch;
use Role::Tiny;

sub turn_on  { $_[0]->is_on(1) }
sub turn_off { $_[0]->is_on(0) }

requires 'is_on';       # the consumer must provide this accessor

1;
```

A consumer picks the role up with `with`:

```
package Radio;
use Role::Tiny::With;
with 'HasOnOffSwitch';

sub new    { bless { is_on => 0 }, shift }
sub is_on  { @_ > 1 ? $_[0]{is_on} = $_[1] : $_[0]{is_on} }
```

What `Role::Tiny` gives you over the manual mixin:

- **Requirements.** `requires 'is_on'` fails at composition time if the consumer does not supply `is_on`. The manual mixin fails silently at the first method call.
- **Conflict detection.** Consuming two roles that both define the same method is a composition-time error, not silent last-definition-wins.
- **Method modifiers** - `before`, `after`, `around` - if you want them.

`Role::Tiny` is **not** the same thing as Moose's role system. Its reach is intentionally narrow. If the codebase already uses Moose, use `Moose::Role`; if it uses Moo, use `Moo::Role`.

Pattern 3: Moose-family roles

Legacy codebases built on Moose or Moo use `Moose::Role` and `Moo::Role` respectively. The surface looks like the role system the core `class` feature will eventually gain:

```
package HasOnOffSwitch;
use Moose::Role;

has is_on => (is => 'rw', isa => 'Bool', default => 0);

sub turn_on  { $_[0]->is_on(1) }
sub turn_off { $_[0]->is_on(0) }

1;

package Radio;
use Moose;
with 'HasOnOffSwitch';

1;
```

In pperl, Moose still works. New code should not reach for it - the runtime cost and dependency weight are both large, and the core `class` feature now covers the declarative side of what Moose was built for. When the core role feature lands, migrating from `Moose::Role` to the core role will be the natural next step.

Pattern 4: delegation

Delegation says "I don't do this myself, but I hold something that does." Instead of inheriting behaviour, contain an object that provides it, and forward methods to it.

The manual form:

```
use feature 'class';

class Player {
    field $radio :param;

    method turn_on  { $radio->turn_on }
    method turn_off { $radio->turn_off }
    method is_on    { $radio->is_on }
}
```

Each forwarded method is three lines of mechanical plumbing. For two or three methods that is fine; for a wide surface, reach for `Class::Method::Delegate` or a Moose `handles` accessor:

```
package Player;
use Moose;

has radio => (
    is      => 'ro',
```

(continues on next page)

(continued from previous page)

```
    handles => ['turn_on', 'turn_off', 'is_on'],
);
```

`handles` generates the forwarders at class-build time.

When to delegate vs inherit

- **Delegate** when the contained object is a *collaborator* - something the owner *has* rather than *is*. A `Player` has a `Radio`; a `Player` is not a kind of `Radio`.
- **Inherit** when the child genuinely *is* a specialised parent. A `Circle` is a kind of `Shape`; a `File::MP3` is a kind of `File`.

If the answer to "is-a or has-a?" is not immediate, the relation is probably has-a. Defaulting to composition is almost always the less wrong call - you can refactor composition into inheritance with less pain than the reverse.

Delegation with lazy construction

A common pattern: the collaborator is expensive to build, so build it on first access. With the modern `class` feature:

```
use feature 'class';

class Logger {
    field $path :param;
    field $fh;

    method fh {
        unless ($fh) {
            open $fh, '>>', $path or die "open $path: $!";
        }
        return $fh;
    }

    method log ($msg) {
        print {$self->fh} $msg, "\n";
    }
}
```

`fh` is a reader that also handles the one-shot construction. Callers see a plain method; the lazy cache is private.

What not to do

- **Multiple inheritance to share two methods.** You pay the full MRO cost for a tiny win, and the next person to inherit from your class inherits the MRO pain too. Use a role or a mixin.
- **`AUTOLOAD` as a delegator.** Convenient in the five-minute demo, impossible to introspect, and it eats typos. Write explicit forwarders or use `handles`.

- **Roles that carry state.** A role that defines both methods and attributes is really a mini-class. The cleanest role defines behaviour that the consuming class's state supports; the role requires the accessors it needs and trusts the consumer to provide them. The manual-mixin example in pattern 1 got this wrong by reaching into `$_[0]->{is_on}` directly.
- **Deep delegation chains.** If `$player->radio->volume->level` appears repeatedly, add a `volume_level` accessor on `Player`. Train-wreck method chains are a composition smell.

Further reading

- *Modern classes* - the base layer that composition sits on top of.
- *Inheritance and method resolution* - when the answer really *is* inheritance.
- *Migration* - how role-based legacy code translates into the core `class` model (spoiler: mostly unchanged; roles migrate last).
- `class` - reference for the modern class syntax.
- `isa` - class-membership test; pair with `DOES` for role membership.

Migrating from classical to modern

If you are maintaining a `bless`-based codebase and wondering what the equivalent `class` block looks like, this chapter is the recipe. The translation is mostly mechanical, but the places where it is not mechanical are where real design decisions surface - and where the migration pays for itself.

Before starting, read the *modern class chapter* for the syntax you are translating *into*, and skim the *classical OO chapter* for any constructs the existing code uses that you may not remember in detail.

When to migrate

Migration is not free. Do it when you get real value:

- The class is under **active development**. You are about to add fields, add methods, or change the constructor contract. Doing that work against the `class` feature is less error-prone than doing it against hand-rolled hash slots.
- The class has **unclear encapsulation**. Callers reach into `$obj->{fieldname}` directly, and you want to stop that without rewriting every call site at once. The `class` feature makes the violation a compile-time error the moment you switch.
- The class sits on top of **Moose or Moo**, and you are paying the load-time cost without using the dependency-heavy features. The modern `class` is a straightforward replacement for most Moose/Moo classes that only use `has` and `with`.

Do **not** migrate a class that is working and frozen. A stable classical class that will not see new code for another five years is exactly as good as its modern equivalent, and the migration itself will introduce bugs that the stable class does not have.

The mechanical translation

Take this classical class:

```
package Counter;

sub new {
    my ($class, %args) = @_;
    my $self = {
        value => $args{value} // 0,
        step  => $args{step}  // 1,
    };
    die "step must be positive" if $self->{step} <= 0;
    return bless $self, $class;
}

sub value {
    my $self = shift;
    $self->{value} = shift if @_;
    return $self->{value};
}

sub step { $_[0]{step} }

sub tick {
    my $self = shift;
    $self->{value} += $self->{step};
}

1;
```

The modern form:

```
use v5.38;
use feature 'class';
no warnings 'experimental::class';

class Counter {
    field $value :param :reader :writer = 0;
    field $step  :param :reader         = 1;

    ADJUST {
        die "step must be positive" if $step <= 0;
    }

    method tick { $value += $step }
}

1;
```

The mapping, piece by piece:

Classical construct	Modern construct
`package Counter;`	`class Counter { ... }`
`sub new { ... bless ... }`	*(deleted - generated)*
Constructor argument defaulting with `//`	`= DEFAULT` or `:param ... = DEFAULT`
`$args{foo}` stored in `$self->{foo}`	`field $foo :param`
Read-only accessor	`:reader`
Read/write accessor	`:reader :writer`
Validation at the end of new	ADJUST block
`$self->{foo}` inside a method	`$foo` (the field name)
`my $self = shift`	*(deleted - implicit)*
`use parent 'Base';` / `our @ISA = ('Base')`	`class Sub :isa(Base) { ... }`
`$self->SUPER::foo(@args)`	unchanged - still works

The non-mechanical parts

Everything above is rote translation. The places where you need to think are all variants of "the classical code was doing something the `class` feature does not do the same way."

Multiple inheritance

`class` does not support `:isa(A, B)`. If the classical class has `@ISA = ('Parent1', 'Parent2')`, you have three options:

1. **Collapse to single inheritance.** Usually the second parent is a mixin or role in disguise. Migrate it into a *role* and consume it with `with`.
2. **Collapse to composition.** If the second parent is a collaborator rather than an ancestor, migrate to delegation instead of inheritance.
3. **Do not migrate the class.** If the multiple inheritance is genuinely load-bearing and neither of the above fits, the class is a poor fit for the modern feature. Leave it classical until the core role feature lands.

In practice option 1 or 2 applies to about 95% of the multiple-inheritance cases in real code.

Direct hash access from callers

If external callers do `$counter->{value}` rather than `$counter->value`, migrating the class will break them. The compiler error is clean and local - the error message names the site - but the migration is no longer a drop-in.

Mitigation strategy:

1. **Audit first.** Grep for `$obj_name->{` patterns across the codebase. The count is usually small.
2. **Add an accessor** to the classical class that covers every accessed field.
3. **Replace** `$obj->{fieldname}` call sites with `$obj->fieldname()` in a dedicated commit.

4. **Then migrate** the class to modern form.

Splitting the refactor into two phases keeps each commit small and bisectable.

AUTOLOAD

`AUTOLOAD` in a classical class has no modern equivalent. The `class` feature does not let you catch missing method calls.

If the `AUTOLOAD` is doing one of the common patterns, translate it:

- **Lazy accessor synthesis** - declare the accessors explicitly as fields with `:reader` or `:writer`. The `class` feature's code generation replaces what `AUTOLOAD` was doing.
- **Delegation to a contained object** - replace with explicit forwarder methods (see *roles and delegation*) or with a Moose-style `handles` accessor if the codebase can depend on Moose.
- **A generic proxy** - keep the class classical. The `class` feature is not the right tool.

DESTROY

`class` does not introduce a first-class destructor form. If the classical class has a `DESTROY`, write it as a plain method inside the `class` block - it is invoked through the same refcount hook:

```
class Logger {
    field $fh;

    ADJUST { ... }

    sub DESTROY {
        my $self = shift;
        close $self->{fh} if $self->{fh};
    }
}
```

Note the wart: inside `DESTROY` you cannot name the field by its declared name, because `sub` bodies do not see field bindings. Either use a regular method that `DESTROY` delegates to, or accept the slight asymmetry.

A cleaner pattern when the lifetime is under your control is to add an explicit `close` method and call it deterministically, leaving `DESTROY` as a belt-and-braces backup.

Non-hash instances

If the classical class does `bless \@self, $class` or `bless \$self, $class` - an array-backed or scalar-backed instance - the modern feature has no equivalent. Hash-like instance layout is baked in. Keep these classes classical.

Tied hashes / overloading

`use overload` and `tie` integrations work unchanged in a `class` block. Nothing special to do.

Migrating Moose / Moo classes

The translation from Moose to `class` is cleaner than from classical because Moose is already declarative. The rough map:

Moose / Moo	Modern `class`
`use Moose;` / `use Moo;`	`use feature 'class';` plus block
`has foo => (is => 'ro', ...)`	`field $foo :param :reader`
`has foo => (is => 'rw', ...)`	`field $foo :param :reader :writer`
`has foo => (default => sub { ... })`	`field $foo = EXPR` (or `ADJUST`)
`extends 'Parent'`	`class Sub :isa(Parent) { ... }`
`BUILD { ... }`	`ADJUST { ... }`
`with 'Role::Name'`	*(wait for core roles)*
`has foo => (isa => 'Int', ...)`	*(no direct equivalent)*
`method_modifiers` (before/after/around)	*(no direct equivalent)*

The gap items - type constraints, method modifiers, roles - are what keeps some Moose codebases on Moose for now. If your Moose use is limited to `has`, `extends`, and `BUILD`, the migration is straightforward. If it depends heavily on Moose's type system or method modifiers, the migration is a project, not a commit.

Testing the migration

A class migration that changes no external behaviour should pass the existing test suite unchanged. Steps:

1. Ensure the class has tests covering its public API. If it does not, write them **before** migrating - the tests are your migration safety net.
2. Migrate the class.
3. Run the tests. A clean pass is the completion signal.
4. Grep the codebase for `$obj->{...}` reaches into the migrated class's instances. Fix any hits.
5. Remove any now-dead `use parent`, `use base`, explicit `sub new`, or accessor boilerplate the old form needed.

If step 3 fails, the failures usually fall into a short list:

- **Direct hash access** in a method that the old form tolerated and the new form rejects. Replace with field references.
- **A constructor argument that was silently accepted.** The generated constructor is strict about `:param` names. Either declare the parameter or change the call site.

- **A field initialiser that referenced `$self`.** Field initialisers run before `$self` is bound. Move the dependent logic into an `ADJUST` block.

What you get out of it

The classical-to-modern migration is unusual in that the result is both shorter and more correct:

- **Shorter.** The `Counter` example above drops from ~20 lines to ~10, and the removed lines are all boilerplate.
- **Private fields.** External code can no longer reach in. The encapsulation you used to defend in review is now defended by the compiler.
- **No forgotten `bless`.** The generated constructor is always inheritance-safe; you cannot ship a constructor that accidentally blesses into the wrong class.
- **No forgotten `$self = shift`.** The implicit bind cannot go missing.
- **A named feature flag.** `no warnings 'experimental::class'` documents at the top of the file what the class depends on.

4.2.6 Debugging Perl programs

Perl ships with an unusually complete debugging surface: a built-in statement-by-statement debugger, a regex-engine tracer, a documented API for writing alternative debuggers, and a CPAN ecosystem of profilers, leak finders, post-mortem tools, and IDE integrations. pperl's reimplementation preserves the interpreter's hook points - `$^P`, `DB::DB` and `DB::sub` fire as they do in perl5 - so perl5's own debugger, `perl5db.pl`, runs unchanged where a system perl5 provides it on `@INC`. `Devel::Cover` measures coverage, its compiled part built in (see *coverage*). Other tools that are XS extensions, such as `Devel::NYTProf`, do not load.

`pperl -d script.pl` starts the debugger, and so do `-de0`, `-d:Module` and a `#!/usr/bin/perl -d` first line; a session is the same as perl5's. The one exception is `-dt`: it asks `perl5db.pl` for thread support, and on pperl's threadless build that dies with `This Perl not built to support threads`.

Which chapter do I want?

Symptom	Start here
Program misbehaves and I want to inspect it live	*interactive-debugger*
Program crashes with a cryptic message	*exceptions*
I want to sprinkle prints and dumps	*print-and-die*
I want to turn more mistakes into compile errors	*preflight*
I need to stop on a specific line or condition	*breakpoints*
I need to see what a data structure actually holds	*inspecting-state*
I want to see every line / sub as it executes	*tracing*
I want breakpoints in VS Code / Neovim	*ide-dap*
I want to know which code my tests never run	*coverage*

The three layers of this guide

- **Orientation** - this page.
- **Working programmer** - the chapters listed above. Each is self-contained; reading a single one is enough to solve the problem it names.

Known gaps

Debugging surfaces where the ecosystem itself is thin, or where pperl's implementation has not reached parity with upstream. Named here so readers do not waste time on them.

- **Regex tracer output format.** pperl's regex engine is a native reimplementation; `use re 'debug'` produces a trace but node names and field formats are not byte-identical to perl5's. Consumers that parse the trace (few exist) will need adjustment.
- **`B::*` introspection modules.** pperl provides `B` and `O` natively. `B::Deparse` and `B::Concise` are pure Perl on top of them: where a system perl5 provides them on `@INC` they run under pperl and agree with perl5 on ordinary code. Less-used members of the family reach further into the op graph, where pperl's representation differs, and may still need adjustment.
- **XS-dependent introspection modules.** `Devel::Peek`, `Devel::FindRef`, `Devel::Gladiator`, `Devel::Refcount`, `Devel::Size`, `Devel::MAT::Dumper`, `Devel::Leak` family - all reach the SV through XS (C-level macros against the SV pointer). pperl mirrors perl5's SV layout faithfully, but XS loading is not supported; these modules therefore need native (Rust) reimplementations that expose the same Perl-level API. Pure-Perl `Devel::Peek`-workalike functionality is already provided natively by the built-in `Devel::Peek`; the others are in progress.
- **Enbugger on Perl $\geqslant$ 5.38.** Last release 2012; works anecdotally on modern perls but has no active maintainer. The `gdb-inject-perl` path is more reliable.
- **Async provenance.** No Perl equivalent to Node's `AsyncLocalStorage`: a `Future` that fails in a distant callback carries no automatic record of who scheduled it.
- **Sentry breadcrumbs.** `Sentry::Raven` is functional but maintenance-only; no first-class breadcrumb support. The OpenTelemetry Perl SDK is the forward path

for new installations.

- **`Perl::LanguageServer` attach-to-running-process.** Launch is supported; post-hoc attach is not.

- `perlfunc/die`, `perlfunc/warn`, `perlfunc/eval`, `perlfunc/caller` - the language primitives the debugger and the stack-trace tools are built on.
- *PPerl Architecture guide* - how pperl is built and why the debugger surface works as it does.

Preflight: catching bugs before runtime

This chapter covers the pragmas, compile-time checks, and runtime hygiene settings that prevent most bugs from reaching the debugger at all. A clean preflight is the shortest path to a short debugging session.

Readers who already `use v5.36` or later run under strict and warnings by default and can skip straight to the diagnostics and autoflush sections. The rest of this chapter assumes you might be maintaining older code where neither is implicit.

Strict and warnings

Since Perl 5.36, `use v5.36;` (and any declaration of a higher version) implicitly enables `use strict;` and `use warnings;`. Modern scripts do not write those lines - the version declaration covers both:

```
use v5.40;
```

`use strict` refuses three classes of sloppy code at compile time: undeclared variables (`strict vars`), symbolic references (`strict refs`), and barewords used as strings (`strict subs`). `use warnings` turns on runtime diagnostics for uninitialised reads, lossy numeric conversions, filehandles used after close, and several dozen other sharp edges.

Legacy code that uses neither still benefits from both: add them, fix the symbols they complain about, commit.

Narrow opt-outs remain useful:

```
no strict 'refs';                  # genuine symbolic deref
no warnings 'uninitialized';       # known-safe defaulting
no warnings 'experimental::try';   # on 5.36, 5.38 - see below
```

Never blanket-disable: `no warnings;` with no category list is almost always wrong.

Promote warnings to fatal for a region:

```
local $SIG{__WARN__} = sub { die $_[0] };
```

Useful at program top during development; the first warning becomes a stack-trace-producing crash.

use diagnostics

Expands each warning or fatal message into the full paragraph from `perldiag`:

```
use diagnostics;
```

The output is verbose - too verbose for production - but during debugging it explains what a terse message like "Odd number of elements in hash assignment" actually means and how to fix it.

Post-hoc version: pipe a program's stderr through the `splain` command to annotate warnings after the fact.

Compile-time checks

`perl -c script.pl` parses the script and runs every `BEGIN` / `use`, then stops before the first runtime statement. A clean `-c` means the file and its dependencies compile; it does not mean the program runs correctly.

```
perl -c script.pl
script.pl syntax OK
```

Combine with `-w` to enable warnings globally for the compile phase and any compile-time code:

```
perl -cw script.pl
```

`perl -MO=Deparse script.pl` prints what perl actually parsed - precedence misparses, constant-folded branches, `for` rewritten as `while`. Use it to verify that perl saw what you meant:

```
perl -MO=Deparse script.pl
```

`perl -MO=Deparse,-p` forces full parenthesisation and makes precedence explicit.

`perl -MO=Concise script.pl` prints a compact op-tree dump; mostly for readers doing deep optimisation work.

autodie: make failure throw

Built-ins that signal failure via false return values (`open`, `close`, `chdir`, `unlink`) are easy to forget to check. `autodie` replaces them with versions that throw:

```
use autodie qw(open close chdir);

open my $fh, '<', $path;     # now dies on failure; no `or die` needed
```

`autodie` is lexical: only calls in its scope are affected. Narrow the opt-out for a specific call site:

```
{
    no autodie 'open';
```

(continues on next page)

(continued from previous page)

```
    open my $fh, '<', $path or warn "cannot read $path: $!";
}
```

Prefer `autodie` to the retired `Fatal` module, which did not cover functions returning counts.

Unbuffered output

When diagnostic output vanishes before a crash, or arrives interleaved oddly with `warn` messages, the cause is almost always block-buffered stdout. Set `$|` at the top of the script:

```
$| = 1;
```

Every `print` now flushes immediately. The cost is a small I/O-throughput hit; the gain is that what you see on the terminal matches what the program has actually done, in order.

For a specific filehandle without changing the selected one:

```
use IO::Handle;
$log_fh->autoflush(1);
```

Common early diagnostics and what they mean

Diagnostic	Meaning
`Global symbol "$x" requires explicit package name`	Strict is on and `$x` was never declared; add `my`.
`Odd number of elements in hash assignment`	A list assigned to a hash has odd count; a `qw(...)` or string with an embedded space produced two values where one was expected.
`Use of uninitialized value in ...`	An `undef` reached an operator. Usually a typo in a variable name or a missing return.
`Name "main::x" used only once: possible typo`	A package variable was referenced exactly once. Almost always a typo or a missing `my`.
`Can't locate Foo.pm in @INC`	A `use` or `require` could not find the module. Check spelling, `@INC`, `PERL5LIB`.
`Reference found where even-sized list expected`	`my %h = { ... }` - braces build a hashref; use parens.

- *print-and-die* - when preflight is not enough and you need structured runtime diagnostics.
- *exceptions* - turning failure paths into typed exceptions the caller can match on.

Print debugging, warn, and the Carp family

This chapter covers non-interactive diagnostics: inserted prints, variable dumps, stack traces from inside the program. These techniques remain the fastest path to understanding "what does my code actually see here?" for bugs that are cheap to reproduce.

Readers who already know about `print` and `warn` will find here the structured variants that earn their keep: the Carp caller-reporting family, `Data::Dumper` and its modern replacements, and the stack-trace-everywhere one-liners.

warn vs print - pick the right stream

`warn` writes to STDERR; `print` defaults to STDOUT. Use `warn` for diagnostics: it keeps program output clean, survives STDOUT redirection, and is the stream loggers already capture.

```
warn "*** foo=[$foo] bar=[@bar]\n";
```

Wrap values in literal brackets so trailing whitespace and newlines are visible in the output. `"foo=[$foo]"` reveals `foo=[ ]` where `"foo=$foo"` just shows `foo= .`

Without a trailing `\n`, `warn` (and `die`) append `at FILE line N.` from the caller's perspective. With `\n`, they do not. Rule of thumb: append `\n` for user-facing messages; omit it for developer diagnostics where you want location.

Cheap location tags from the compiler:

```
warn "reached $0 " . __FILE__ . ':' . __LINE__ . "\n";
warn "in @{[__SUB__->name]}\n";          # 5.16+
```

The Carp family - report from the caller

When a library function fails, pointing at the library's own source is almost never useful. `Carp`'s family reports from the caller's frame:

Function	Reports from	Fatal?	Stack trace?
`carp`	caller	no	no
`croak`	caller	yes	no
`cluck`	caller	no	full
`confess`	caller	yes	full

```
use Carp;

sub open_config {
    my $path = shift // croak "open_config: missing path";
    open my $fh, '<', $path or croak "cannot read $path: $!";
    return $fh;
}
```

Library code should use `croak`/`carp`, not `die`/`warn` - the error message points at the caller's line, which is where the fix goes.

Stack traces without touching the code

`Carp::Always` installs `$SIG{__DIE__}` and `$SIG{__WARN__}` to route through `Carp::confess` / `Carp::cluck`. Run a misbehaving script with:

```
perl -MCarp::Always script.pl
```

Every `die` and `warn` produces a full stack. No source changes. This is the first thing to reach for when a program dies with a useless one-line message.

`Devel::Confess` is a drop-in equivalent with fewer edge cases around overloaded objects:

```
perl -d:Confess script.pl
```

Both modules add cost to every `warn` and `die`; use them while investigating, not in steady production.

For a permanent in-code install:

```
use Carp;
$SIG{__DIE__}  = sub { return if $^S; Carp::confess(@_) };
$SIG{__WARN__} = sub { Carp::cluck(@_) };
```

`return if $^S;` - "return if we are inside `eval`". Without this guard every caught exception pays the trace cost. See *exceptions* for the full `$SIG{__DIE__}` pattern.

Dumping data structures

Pass a **reference** to every dumper; dumping a bare hash or array prints its flat-list form and loses the structure.

`Data::Dumper` - universal, core, eval-roundtrippable

```
use Data::Dumper;

$Data::Dumper::Sortkeys = 1;
$Data::Dumper::Indent   = 1;
$Data::Dumper::Terse    = 1;
$Data::Dumper::Deepcopy = 1;

warn Dumper(\%config);
```

- `Sortkeys` makes output diff-stable.
- `Indent=1` is the readable setting (0 = flat, 2 = default, 3 = with array indices).
- `Terse=1` suppresses `$VAR1 =` prefixes when you do not need round-trip-ability.
- `Deepcopy=1` disables the "seen this ref before" `$VAR1->{...}` tracking - prints the data, not a graph reconstruction.

`Data::Dumper::Concise` is a drop-in with sensible defaults pre-applied; the DBIx::Class / Moose community standard.

`Data::Printer` - coloured, modern, readable

```
use DDP;
p %config;                      # not a reference - DDP handles both
```

`Data::Printer` prints better-looking output than `Data::Dumper`, colours by type, handles objects specially (class, attributes, overloads), and does not try to round-trip. Prefer it when the goal is reading the dump, not re-ingesting it.

`Data::Dump` - compact one-liner

```
use Data::Dump qw(dd);
dd \%config;                    # prints to STDERR in compact form
```

Gisle Aas's `Data::Dump`. Useful when the default `Data::Dumper` output is too verbose for a single warn line.

When to reach for which

- `Data::Dumper` when you might feed the output back into `eval` or compare two dumps.
- `Data::Printer` (DDP) when a human is reading the output.
- `Data::Dump` when you want a one-line summary.
- `Data::Dumper::Concise` on projects already using it.

Conditional debug prints

A compile-time constant is optimised out entirely when false:

```
use constant DEBUG => 0;

warn "state=$state\n" if DEBUG;
```

With `DEBUG => 0`, the `if DEBUG` test is folded at compile time and the `warn` never appears in the op tree - zero runtime cost.

Wire to the environment so the flag is flippable without editing:

```
use constant DEBUG => $ENV{APP_DEBUG} // 0;
```

Multiple channels via bitmask:

```
use constant { WEB => 1, SQL => 2, REGEX => 4 };
my $DEBUG = $ENV{APP_DEBUG} // 0;

sub dbg { my $c = shift; warn "[DBG] @_\n" if $DEBUG & $c }

dbg WEB,   "request $req_id start\n";
dbg SQL,   "query: $sql\n";
```

(continues on next page)

(continued from previous page)

```
dbg REGEX, "matched: $&\n";         # (unless you care about perf - see below)
```

Source-filter alternative: `Smart::Comments`

```
use Smart::Comments;

my @stuff = compute();
### @stuff                  # prints: @stuff: [...]
### Checking key: $key      # print, plus asserts $key is truthy
### Processing |=| ... for @stuff
```

Lines beginning `###` are rewritten into prints (and, with special syntax, progress bars and assertions). The module is a source filter - it rewrites the program text before compile - so reported line numbers can drift by one. When not imported, the `###` comments compile to nothing. The drift is the price of not cluttering the code with explicit `warn` lines.

Taint and $& - incidental costs to know about

Referencing `$&`, `$\``, or `$'` **anywhere** in the program forces perl to maintain these match-context globals for **every** regex match in the entire program, including matches inside loaded modules. Historically this imposed a noticeable slowdown; on modern perls the cost is smaller but non-zero, and the rule still applies: do not touch them if you can avoid it.

Use `@-` / `@+` (match position arrays), named captures, or the `/p` modifier with `${^MATCH}`, `${^PREMATCH}`, `${^POSTMATCH}` instead. The `/p` variants impose the cost only for matches that opt in.

Timestamped logging

Hand-rolled `warn` with `localtime` is adequate for one-off investigations:

```
use Time::HiRes qw(gettimeofday);
sub t { my ($s, $us) = gettimeofday; sprintf "%d.%06d", $s, $us }
warn sprintf "[%s] state=%s\n", t(), $state;
```

For anything more structured, use a logging framework rather than rolling your own:

- `Log::Any` - library-safe; emit logs without picking a backend. Pair with an adapter (`Log::Any::Adapter::Log4perl`, `::Stdout`, `::Syslog`) in the application.
- `Log::Log4perl` - category / level / appender / layout; config file-driven.
- `Log::Dispatch` - lower-level router; often used under `Log::Any`.

Standard levels, lowest to highest: `TRACE`, `DEBUG`, `INFO`, `WARN`, `ERROR`, `FATAL`. Gate `TRACE` / `DEBUG` behind an env flag in production.

Find out more

- *exceptions* - die, $@, $SIG{__DIE__}, typed exception classes, the modern try/catch.
- *interactive-debugger* - when inserting prints costs more than launching perl -d.
- *tracing* - full-program line-by-line trace without editing the source.

Exceptions, die, and typed error objects

This chapter covers how to raise, catch, and classify runtime failures: die and eval, the native try/catch, special-variable hygiene ($@, $!, $?), $SIG{__DIE__}, and the design of exception classes.

Readers who know die and eval { } will find here the modern replacements for string-dispatching on exception messages and the hazards of $SIG{__DIE__} that the stock eval pattern silently hides.

die and eval

die throws an exception; the nearest enclosing eval { } catches it and leaves the message in $@:

```
eval {
    risky();
};
if (my $err = $@) {
    warn "caught: $err";
}
```

Without a trailing \n, die's argument gets at FILE line N. appended from the caller's frame. With \n, no location is appended - use for messages that will be shown to users, omit for messages you want to trace.

Never use the string form eval "..." for exception handling. It compiles its argument and has every hazard of user-supplied code.

The native try/catch

On Perl 5.34 and later, a dedicated try/catch is available behind a feature flag. Since 5.40 it is non-experimental:

```
use v5.40;
use feature 'try';

try {
    risky();
}
catch ($e) {
    warn "caught: $e";
}
```

`finally` remains experimental as of 5.44. Expect:

```
use feature 'try';
no warnings 'experimental::try';
```

on perls between 5.34 and 5.40.

For code that must run on 5.34 or 5.36 and also on newer perls, `Feature::Compat::Try` picks the core feature where available and falls back to `Syntax::Keyword::Try`:

```
use Feature::Compat::Try;

try { risky(); }
catch ($e) { warn "caught: $e" }
```

Why native `try` over `Try::Tiny`

`Try::Tiny` still works and remains common. Prefer the native form for new code: it avoids the sub-call frame that `Try::Tiny` introduces (which shows up in stack traces), has zero startup cost, and composes with the `isa` operator cleanly.

These are retired - do not adopt:

- `TryCatch` - abandoned.
- `Error.pm` - superseded.
- `Exception::Class::TryCatch` - superseded by `Throwable`.

`$@` clobbering - the classic `eval` hazard

`$@` is set by `eval`; it is also observable globally. Any code that runs between `eval`'s return and your check on `$@` - a `DESTROY` method, a tied-variable handler, an unrelated nested `eval` - can overwrite it. Always copy first:

```
eval { risky(); };
my $err = $@;
return unless $err;
```

Native `try`/`catch` and `Syntax::Keyword::Try` avoid this pitfall by giving you the error as the `catch` parameter; raw `eval` does not. Prefer the former for any code that takes exceptions seriously.

Special variables adjacent to exceptions

Variable	Set by	Read immediately because...
`$@`	`eval { }` / `die`	any intervening call can overwrite.
`$!`	Last failed system call	any following syscall overwrites.
`$?`	`system` / backticks child	the next child overwrites.
`$^E`	Extended OS error	on non-Unix; on Linux usually mirrors `$!`.

`$?` decoding after `system` / backticks:

```
if ($? == -1)         { warn "child failed to start: $!" }
elsif ($? & 127)      { warn "child killed by signal " . ($? & 127)␣
↪}
elsif ($? & 128)      { warn "core dumped" }        # combined with␣
↪above
else                  { my $exit = $? >> 8; ... }
```

Classifying exceptions: dispatch on type

For non-trivial programs, distinguishing "user not found" from "database is down" from "programming error" by parsing error strings is fragile. Throw typed objects and match on them:

```
use v5.40;
use feature 'try';
use Scalar::Util qw(blessed);

try {
    do_business();
}
catch ($e) {
    if    ($e isa MyApp::Err::NotFound)    { return http_404($e) }
    elsif ($e isa MyApp::Err::AuthFailure) { return http_403($e) }
    elsif ($e isa MyApp::Err)              { return http_500($e) }
    elsif (blessed($e) && $e->isa('DBIx::Class::Exception')) {
        return http_500($e);
    }
    else {
        MyApp::Err::Unknown->throw(cause => "$e");
    }
}
```

The `isa` operator (stable on 5.36+) does the right thing for overloaded objects and is zero-cost when the left operand is not a reference. Pair it with a typed wrapper at the outermost boundary so everything downstream is a `MyApp::Err`.

Designing exception classes

The 2026 default: `Throwable` role from CPAN, optionally via `Throwable::SugarFactory` for declarative hierarchies.

Minimum-viable class:

```
package MyApp::Err::NotFound;
use Moo;
with 'Throwable';

has resource => ( is => 'ro', required => 1 );
has id       => ( is => 'ro', required => 1 );
```

(continues on next page)

(continued from previous page)

```
sub message {
    my $self = shift;
    sprintf 'not found: %s/%s', $self->resource, $self->id;
}

1;
```

Usage:

```
MyApp::Err::NotFound->throw(resource => 'user', id => $uid);
```

`throw` is provided by the role; it dies with `$self` (the blessed object). `->new` without `throw` builds without raising.

Declarative form via `Throwable::SugarFactory`:

```
package MyApp::Err;
use Throwable::SugarFactory;

exception 'GenericError'      => 'something bad happened';
exception 'NotFound'           => 'resource not found'
                                  => (has => [ id => (is => 'ro')␣
↪]);
exception 'AuthFailure'        => 'auth failed'
                                  => (has => [ reason => (is => 'ro
↪') ]);
exception 'AuthFailureExpired' => 'session expired'
                                  => (extends => 'AuthFailure');
1;
```

This generates: the class, a `not_found(id => ...)` constructor-and-throw helper, a `is_not_found($e)` predicate, and `->to_hash` on every instance for JSON serialisation.

What a class must have

1. **A class name** - so `$e isa MyApp::Err::X` dispatches.
2. **Structured fields** - `id`, `resource`, `code`.
3. **A human `message`** - without it, `warn $e` prints `MyApp::Err=HASH(0x...)`.
4. **Serialisation** - `->to_hash` for logging / aggregators / JSON APIs.
5. **Origin** - file + line captured at `throw`. `Throwable` captures these automatically.
6. **A stack trace** if the error is worth investigating later: `with 'StackTrace::Auto'` adds `->stack_trace`.

When not to use a class

Plain-string `die` remains correct for short scripts, one-offs, and any case where no caller will dispatch on the error:

```
die "permission denied: $path\n";
```

The trailing `\n` suppresses file-and-line appending; the message is user-facing.

Hash-ref `die - die { type => 'not_found', id => $uid } -` is a transitional form. The moment a caller writes `if (ref $e eq 'HASH' && $e->{type} eq 'not_found')` three times, refactor to a class.

Retired exception frameworks - do not adopt:

- `Error.pm` - use `Throwable` (role-based) or `Exception::Class`.
- `Class::Throwable` - functional; `Throwable` is the modern choice.
- `Exception::Class::TryCatch` - superseded by native `try`.

`$SIG{__DIE__}` - handle with care

`$SIG{__DIE__}` fires on every `die`, **including** `die` inside `eval`. A naive install turns every caught exception into noise:

```
# WRONG: fires on every eval that catches an error
$SIG{__DIE__} = sub { Carp::confess(@_) };
```

The `$^S` special variable tells you whether you are inside an `eval`: true means "yes, someone is going to catch this"; false means "this is reaching the top". Guard on it:

```
$SIG{__DIE__} = sub {
    return if $^S;                # inside eval - not for us
    my ($err) = @_;
    eval { ship_to_sentry($err) };    # never let the handler itself
↪die
    warn "reporter failed: $@" if $@;
    die $err;                     # re-raise
};
```

For Sentry / aggregator integration, wrap the reporter call in its own `eval` - a failing error reporter must not obscure the original exception.

Before installing on top of an existing handler, chain:

```
my $previous = $SIG{__DIE__};
$SIG{__DIE__} = sub {
    return if $^S;
    my ($err) = @_;
    eval { ship_to_sentry($err) };
    warn "reporter failed: $@" if $@;
    goto &$previous if $previous;
    die $err;
};
```

`$SIG{__WARN__}` - turn warnings fatal, or route them

Symmetric to `$SIG{__DIE__}`, fires on every `warn`:

```
$SIG{__WARN__} = sub { die $_[0] };      # promote warnings to
↪exceptions
```

Useful during development as a tripwire; rarely wanted in production. More common production use: route warnings through a logger.

- `perlfunc/die`, `perlfunc/eval`, `perlfunc/warn`, `perlvar` - reference pages for the language primitives.

The interactive debugger

This chapter covers `perl -d`: launching a program under the debugger, the prompt, the essential motion and inspection commands, and the stack-navigation vocabulary. After this chapter you can investigate any running program interactively.

Readers start from knowing `print` / `warn` work but are not enough: you need to stop, look around, peek at variables, walk the call stack, then resume. That is what this chapter delivers.

Launching

For any script `app.pl`, prepend `-d`:

```
perl -d app.pl --verbose input.txt
```

Arguments after the script name pass to the script as normal.

Common launch forms:

Form	Purpose
`perl -d script.pl args`	Debug the given script.
`perl -d -e 'CODE'`	Debug a one-liner expression.
`perl -de 0`	Interactive REPL sandbox.
`perl -d:Module script.pl`	Load `Devel::Module` as debugger.
`perl -d:NYTProf script`	Profile via NYTProf plugin.
`perl -S -d script.pl`	Search `$PATH` for the script.

`-d` causes the compiler to emit per-statement hook points; the interpreter preloads `perl5db.pl` before the first runtime line.

Never pipe input to `perl -d` and never use `/dev/stdin` - the debugger needs a TTY to read commands from. Launch from a real terminal.

The prompt

```
Loading DB routines from perl5db.pl version 1.77
Editor support available.

Enter h or 'h h' for help, or 'man perldebug' for more help.

main::(app.pl:4):     my $key = 'welcome';
  DB<1>
```

The line `main::(app.pl:4):` shows the next line **about to execute** - nothing in the program has run yet. Compile-time code (`BEGIN`, `use`) already ran; the first prompt comes before the first runtime statement.

`DB<1>` - the number is a command counter that increments on each command. `!N` recalls command number N. `DB<<N>>` with double brackets means you are inside a nested debugger (one expression you stepped into called another breakable expression).

The debugger always shows the line about to execute, never the line just executed.

Quitting

```
  DB<1> q
```

Not `quit`, not `exit`. Typing `exit` runs Perl's `exit` inside the debugger's `eval`, which is not the same. `^D` at the prompt works on most terminals.

Help

```
  DB<1> h               # one-screen summary
  DB<1> h h             # full help (long - use the pager)
  DB<1> h b             # help on one command
  DB<1> |h h            # pipe full help through $ENV{PAGER}
```

Where am I?

`v` views a window around the current line. `l` lists a specified range:

```
  DB<1> v
1       #!/usr/bin/perl
2       use v5.40;
3
4==>    my $key = 'welcome';
5:      my %data = (
6               'this'    => qw(that),
7               'tom'     => qw(and jerry),
8               'welcome' => q(Hello World),
9               'zip'     => q(welcome),
10      );
```

- `==>` marks the next line to execute.

- `:` marks executable lines - you can set a breakpoint there.
- Lines without `:` are not breakable (comments, blanks, continuations of a multi-line statement).

Navigation:

Command	Effect
`v`	View a window around the current line.
`v LINE`	View a window around LINE.
`l`	List the next window; repeat advances.
`l LINE`	List just LINE.
`l MIN-MAX`	List a range.
`l SUB`	List the first window of SUB.
`-`	Previous window.
`.`	Snap view back to the current line.
`f FILE`	Switch display to FILE (regex against `%INC`).
`/PAT/`	Forward search in source.
`?PAT?`	Backward search.

Motion: `s`, `n`, Enter, `c`, *`r`*

The four essential motion commands:

Command	Effect
`s`	Step - execute next statement; descend into subroutines.
`n`	Next - execute next statement; step over subroutines.
`<Enter>`	Repeat the last `s` or `n`.
`c`	Continue until next breakpoint or end.
`c LINE`	Continue to a one-shot breakpoint at LINE, then stop.
`c SUB`	Continue to the first line of SUB.
`r`	Return from the current sub; stop at the caller.

```
DB<1> s                         # descend into the call
DB<2> n                         # stay at this level
DB<3>                           # <Enter> repeats the last motion
DB<4> c 42                      # run to line 42 once
DB<5> r                         # pop the current frame
```

A multi-line statement steps atomically - one `s` executes a whole multi-line hash assignment.

On a line that calls no subroutines, `s` and `n` are indistinguishable.

Printing values: p and x

```
  DB<1> p $key
welcome

  DB<2> p join ',', sort keys %data
this,tom,welcome,zip
```

`p EXPR` evaluates EXPR in the program's current package and prints the scalar-context result followed by a newline. `p` is flat - for a reference it prints `HASH(0x...)`, not contents.

For structures, use `x`:

```
  DB<3> x \%data
0  HASH(0x5651f9a82358)
   'this' => 'that'
   'tom' => 'and'
   'welcome' => 'jerry'
   'zip' => 'Hello World'
```

Always pass a **reference** (`x \%h`, `x \@a`) - `x %h` dumps the flat key/value list, which hides the structure.

See *inspecting-state* for the full inspection vocabulary (`V`, `X`, `y`, `m`, `M`, `i`, depth controls).

The call stack: T, s, r

`T` prints a backtrace - the chain of sub calls that led to the current line:

```
  DB<1> T
$ = main::handle_request(ref(HTTP::Request)) called from file 'app.
 ↪pl' line 47
$ = main::dispatch('GET', '/users/42') called from file 'app.pl'␣
 ↪line 19
@ = main::main() called from file 'app.pl' line 12
```

- `$` - called in scalar context.
- `@` - called in list context.
- `.` - void context.
- Arguments are shown with `Data::Dumper`-style truncation; the exact length cap is the `maxTraceLen` option.

Navigate the stack with `s` (into a call) and `r` (out of the current frame). There is no "frame up / frame down" command: re-step if you go too deep, or use `b` to set a breakpoint at the caller and `c` to reach it.

To inspect an outer frame's lexicals, use `y LEVEL` from *inspecting-state* - it reads via `PadWalker` and shows the enclosing scope's `my` variables.

Evaluating Perl at the prompt

Anything the debugger does not recognise as a command is `eval`'d as Perl code in package `DB` at the current lexical scope:

```
DB<1> $counter = 0                  # mutate state
DB<2> @ARGV = qw(new args)          # mutate @ARGV
DB<3> $obj->reset                   # call a method
DB<4> m/(\w+)/ && p $1              # match against $_
```

A fresh `my $x` at the prompt vanishes when the command returns - the prompt has its own lexical scope. Use a bareword, `our`, or chain on one line:

```
DB<1> our $tmp = compute();         # survives
DB<2> $tmp = compute(); p $tmp      # one-line chain
```

Force Perl interpretation when an expression looks like a debugger command:

```
DB<1> ; h EXPR                     # ; prefix forces eval
DB<2> + h EXPR                     # + prefix works too
```

Restart and rerun

`R` restarts the program via `exec()`. History, breakpoints, actions, options, and the command line are preserved:

```
DB<1> R
```

`rerun` re-executes without leaving the debugger, preserving state:

Form	Effect
`rerun`	Restart, replaying no prior commands.
`rerun -N`	Restart and replay up to N commands back.
`rerun N`	Restart from history entry N.

Redefining a sub mid-session

Paste the entire `sub NAME { ... }` at the prompt. Or edit a replacement file and load it:

```
DB<1> do 'fixed.pl'
```

Subsequent calls use the new definition. Existing stack frames continue with the old body.

Commands so far

Command	Effect
h, h CMD, h h	Help: summary / one command / full.
|CMD	Pipe the output through $ENV{PAGER}.
q	Quit.
v, v LINE	View source around current / LINE.
l, l LINE, l SUB, l MIN-MAX	List.
.	Snap to current line.
-	Previous window.
f FILE	Switch display to FILE.
/PAT/, ?PAT?	Search forward / backward.
s	Step into.
n	Step over.
<Enter>	Repeat last s / n.
r	Return from current sub.
c, c LINE, c SUB	Continue / one-shot breakpoint.
p EXPR	Print (scalar context).
x EXPR	Dump (structured, pass a reference).
T	Stack backtrace.
R	Restart via exec().
rerun [N|-N]	Restart with history replay.

Breakpoints, actions, and watches

This chapter covers stopping the debugger at a specific point - a line, a subroutine, a condition, a value change - and the prompt-hook machinery that lets you run code automatically at each stop.

Readers arriving here know how to launch perl -d and step one line at a time. The next skill is to skip straight to the interesting place and stop only when the problem is about to manifest.

Breakpoints on lines and subs

Command	Effect
`b`	Breakpoint on the current line.
`b LINE`	Breakpoint at LINE in the current file.
`b LINE COND`	Conditional; break when COND is true.
`b FILE:LINE`	Cross-file; FILE matches a `%INC` entry.
`b FILE:LINE COND`	Conditional cross-file.
`b SUB`	Break at the first line of SUB (SUB must be compiled).
`b SUB COND`	Conditional sub breakpoint.
`b $coderef`	Break at the sub referenced by `$coderef` (no COND supported).
`b compile SUB`	Break after SUB finishes compiling, before its body runs.
`b postpone SUB`	Break the first time SUB is called, even if not yet loaded.
`b load FILE`	Break when FILE is `required` / do'd.
`B LINE`	Delete breakpoint at LINE.
`B *`	Delete all breakpoints.
`disable [FILE:]LINE`	Disable without removing.
`enable [FILE:]LINE`	Re-enable.
`L`	List breakpoints, actions, and watches.
`L b`	List breakpoints only.

Conditions are **raw expressions**, not `if (…)`:

```
  DB<1> b 237 $count > 10
  DB<2> b 42 /unauthorized/i
  DB<3> b validate_payload ref($obj) eq 'HASH' && keys %$obj
```

Breakpoints settle only on lines that contain executable code. A blank line, a pure comment, or a continuation of an earlier statement refuses:

```
  DB<1> b 3
Line 3 not breakable.
```

A line carries one breakpoint and one action at most; adding a second overwrites the first.

Timing matrix

Where in the program lifecycle a breakpoint fires matters - especially for code in `BEGIN` blocks or modules that are `required` lazily.

Goal	Command
Stop at the first runtime statement	Default - the debugger already stops there.
Stop inside a `BEGIN { }` block	Insert `$DB::single = 1;` inside the block.
Stop before a sub's body runs (after it compiles)	`b compile SUB`
Stop on first call of a sub not yet loaded	`b postpone SUB`
Stop when a file is `required` or do'd	`b load /full/path/from/%INC`
Stop at a specific line	`b LINE`
Stop at a line only when a condition holds	`b LINE COND`

`$DB::single = 1;` inside a `BEGIN` block is the trick for compile-time debugging: writing `b` at the prompt only works after the debugger is running, but `BEGIN` code runs before the first prompt. Drop the assignment into the block, launch under `-d`, and the debugger stops at the next breakable line inside the block.

Accessing `$DB::single` when not under `-d` autovivifies `DB::` harmlessly - the pattern is safe to commit.

Listing and managing breakpoints

```
  DB<1> L
app.pl:
 42:   $user = User->load($id);
       break if (1)
 91:   dispatch($req);
       break if ($req->method eq 'POST')

  DB<2> disable 42
  DB<3> enable 42
  DB<4> B 42
  DB<5> B *
```

`disable` / `enable` toggle a breakpoint without forgetting its condition - useful when you want to skip a hot breakpoint temporarily and re-arm it later.

Actions: run code automatically at a line

An **action** runs Perl code before the specified line executes, without stopping. Use for passive observation:

```
  DB<1> a 42 print "entering: user_id=$user_id\n"
  DB<2> a 91 warn "POST body:\n" . Dumper($body) if $req->method eq
↪'POST'
  DB<3> L a
app.pl:
 42: ...
       action: print "entering: user_id=$user_id\n"
```

(continues on next page)

(continued from previous page)

```
  DB<4> A 42              # delete action at line 42
  DB<5> A *               # delete all actions
```

Ordering at a breakable line:

1. Breakpoint condition is tested.
2. Trace output is printed (if tracing on).
3. Action runs.
4. Prompt appears (if breakpoint hit or stepping).
5. The line itself executes.

Actions and breakpoints coexist on the same line - one of each maximum.

Watches: break on value change

A watch reports the old and new value when a tracked expression changes, and drops you at the prompt:

```
  DB<1> w $global_count
  DB<2> c
Watchpoint 0:   $global_count changed:
    old value:  42
    new value:  43
main::tick(app.pl:118):    ++$global_count;
  DB<3> W $global_count   # delete this watch
  DB<4> W *               # delete all watches
```

Watches are evaluated at every breakable line. Expressions must reference globals or accessible aliases; lexical `my` variables are not watchable directly. When a lexical matters, use `Tie::Watch` in the code to install a watcher at tie time, or assign via a package-scoped alias.

Watches add per-statement cost proportional to the number of watches and the expense of each expression. Keep them narrow and remove them when done.

Prompt hooks: run code at every stop

< / > install Perl code to run automatically before / after every prompt. { / {{ do the same for debugger commands:

Command	Effect
`< CMD`	Perl code before each prompt (= after the line just executed).
`<< CMD`	Append to the pre-prompt list.
`< ?`	List pre-prompt code.
`< *`	Delete all pre-prompt code.
`> CMD` / `>> CMD`	Perl code after each prompt (= before next line).
`{ DBCMD`	Debugger command (not Perl) pre-prompt.
`{{ DBCMD`	Append to the pre-prompt debugger-command list.

Typical use: timestamp every step:

```
  DB<1> < print "stop: ", scalar localtime, "\n"
  DB<2> > print "start: ", scalar localtime, "\n"
```

Or always show the current line and a watched variable:

```
  DB<1> { v
  DB<2> { p $important
```

Multi-line: escape the newline with \:

```
  DB<1> < for my $f (@important_files) {    \
cont:     print "  $f: ", (-s $f) // 'n/a', "\n"; \
cont: }
```

Aliases

Persistent command shortcuts via =:

```
  DB<1> = len s/^len(.*)/p length($1)/
  DB<2> = quit s/^quit(\s*)/exit/
  DB<3> =                      # list all aliases
```

Aliases live in %DB::alias and apply at dispatch time. Define once in .perldb for across-session persistence.

One-shot breakpoints

c LINE sets a breakpoint at LINE, continues, and clears the breakpoint when it hits:

```
  DB<1> c 42
```

Simplest way to say "just run to line 42 and stop there". No manual b / B pairing.

Breaking on import / first-call lazily

When a sub lives in a module that may not be loaded yet, b SUB fails:

```
  DB<1> b MyApp::Worker::dispatch
Subroutine not yet compiled.
```

b postpone waits for the sub to finish compiling:

```
  DB<1> b postpone MyApp::Worker::dispatch
  DB<2> c
```

For files loaded by require / do, b load breaks on first load:

```
  DB<1> b load /usr/share/perl5/MyApp/Worker.pm
```

The filename must match the full path in %INC, not just the module name.

Find out more

- *inspecting-state* - what to look at once a breakpoint fires.
- *tracing* - when you want to watch what happens *without* stopping.

Inspecting state

This chapter covers the debugger's data-inspection vocabulary: `x`, `V`, `X`, `y`, `m`, `M`, `i`, and the options that control how deeply aggregate values are dumped. After this chapter you can ask any running program "what does this variable, this package, this object actually look like right now?"

Readers arrive here knowing `p EXPR` prints a scalar. The rest of the inspection commands earn their keep the moment the answer "what is this?" requires more than a single value.

x: dump structures

`x EXPR` pretty-prints in list context, recursing into references:

```
  DB<1> x \%config
0  HASH(0x5651f9a82358)
   'debug' => 1
   'dsn' => 'dbi:SQLite::memory:'
   'timeout' => 30
   'users' => ARRAY(0x5651f9b28a10)
      0  'alice'
      1  'bob'
      2  'carol'
```

Always pass a **reference** for aggregates. `x %h` dumps the flat key/value list, which hides the structure. `x \%h` does what you want.

```
  DB<2> x \@list
0  ARRAY(0x5651f9b28a10)
   0  'alice'
   1  'bob'
   2  'carol'

  DB<3> x $obj
0  MY::Class=HASH(0x5651fa01c2b0)
   'id' => 42
   'prefs' => HASH(0x5651fa01c330)
      'theme' => 'dark'
```

For deep or cyclic structures, cap the recursion:

```
  DB<4> x 2 \%tree      # recurse 2 levels deep
  DB<5> x 1 $obj        # one level
```

If the first token of the expression is numeric, parenthesise:

```
  DB<6> x (3 + $offset)     # without parens, 3 is mis-parsed as
↪depth
```

V and X: package variables

`V [PKG [VARS]]` dumps the globals of a package:

```
  DB<1> V main
$counter = 42
@ARGV = (
    0  '--verbose'
    1  'input.txt'
)
%ENV = (
    'PATH' => '/usr/bin:/bin'
    ...
)
```

With a second argument, filter variables:

```
  DB<2> V MyApp $config $last_user       # only these
  DB<3> V MyApp ~^config                 # regex: names matching /^
↪config/
  DB<4> V MyApp !^_                      # regex: names NOT matching
↪/^_/
```

`X` is `V` for the current package:

```
  DB<5> X                # dump current package's globals
  DB<6> X $foo @bar      # filtered
```

`V` / `X` do **not** see lexicals (`my` variables). For those, use `y`.

y: lexicals in enclosing scope

`y LEVEL [VARS]` reads lexical `my` variables via `PadWalker`:

```
  DB<1> y 0               # lexicals of the current sub
my $req = HTTP::Request=HASH(0x...)
my $user_id = 42
my @errors = ()

  DB<2> y 1               # one frame up (the caller's lexicals)
my $request_count = 118
my $dispatcher = MyApp::Dispatcher=HASH(0x...)

  DB<3> y 0 $req $user_id  # only those
```

`y` requires `PadWalker` version 0.08 or later. It works only inside a sub (the outer script body has no pad to walk).

`m`: methods of an object or class

`m EXPR` lists methods callable on an object or class:

```
  DB<1> m $user
via UNIVERSAL: isa can DOES VERSION DESTROY
via MyApp::Model: save load delete update
via MyApp::Role::Auditable: audit_log record_event

  DB<2> m 'MyApp::Worker'
via UNIVERSAL: ...
via MyApp::Worker: dispatch retry cancel
```

Groups methods by the package that provides them - useful for spotting which role or superclass a method comes from.

`M` and `i`: modules and inheritance

`M` lists loaded modules with versions:

```
  DB<1> M
  'DBI' (version 1.643)
  'JSON::PP' (version 4.16)
  'MyApp::Model' (version undef)
  ...
```

`i CLASS` or `i $obj` prints the inheritance tree:

```
  DB<2> i $user
MyApp::User 0.12
   MyApp::Model 0.42
      Moo::Object ?
```

Useful for "where is this method actually coming from?" when method resolution crosses several roles.

`S`: subroutine names

`S [[!]PAT]` lists sub names matching (or not matching) a pattern:

```
  DB<1> S ^MyApp::Worker::
MyApp::Worker::cancel
MyApp::Worker::dispatch
MyApp::Worker::retry

  DB<2> S !^(main|DB|UNIVERSAL)::      # everything except these
```

`S` alone lists everything - long.

p vs x: which to use when

Want	Use
A single scalar's value, plain	`p $x`
A joined / formatted expression	`p join ',', sort keys %h`
A hash or array	`x \%h`, `x \@a`
An object's fields	`x $obj`
Only the top level	`x 1 $deep_tree`
Package variables of `Pkg`	`V Pkg`
Lexicals of current sub	`y 0`
Method list of `$obj`	`m $obj`
`@ISA` chain of `$obj`	`i $obj`

Special case: `p` is a flat print. For a reference, `p $ref` prints `HASH(0x…)`. Use `x $ref` for the contents.

Depth and compactness options

Dump output is shaped by options set via the `o` command. The relevant settings for inspection:

Option	Effect
`dumpDepth`	Recursion depth (negative = unlimited). Default 4.
`arrayDepth`	First N array elements only; empty = all.
`hashDepth`	Same, for hashes.
`compactDump`	Short arrays on one line.
`veryCompact`	Tighter yet.
`globPrint`	Dump glob contents.
`DumpReused`	Fully expand repeated references (beware cycles).
`quote`	`"` or `'` or `auto` (default).
`undefPrint`	How `undef` renders.
`bareStringify`	Print overload-stringified form.

Set an option in a session:

```
  DB<1> o dumpDepth=6
  DB<2> o compactDump=1
  DB<3> o arrayDepth=20
  DB<4> o compactDump?              # query current value
```

Set options at startup via `PERLDB_OPTS` or in `.perldb`:

```
PERLDB_OPTS="dumpDepth=6 compactDump=1" perl -d script.pl
```

Inspecting SV internals

`Devel::Peek` exposes the scalar's internal storage - type flags, refcount, PV/NV/IV layout, magic chain - when the question is "what kind of scalar is this really?":

```
  DB<1> use Devel::Peek; Dump($sv)
```

Primarily for investigating tied variables, overloaded objects, or performance anomalies where the answer depends on whether a scalar is currently stored as an integer, a string, or both.

Note: `Devel::Peek` in pperl is a compat layer - it reports a pperl-specific `Sv` layout rather than perl5's SV layout. Fields like `REFCNT`, `FLAGS`, `PV`, `IV`, `NV` have equivalents; the exact output differs. See the *pperl-architecture guide* for layout details.

Evaluating at the prompt

Anything unrecognised as a command is evaluated as Perl. Use it to drill deeper than a single command:

```
  DB<1> p keys %{ $obj->{prefs} }
theme,locale,tz

  DB<2> x [ grep { !defined $_->{parent} } @nodes ]
  DB<3> x { map { $_->id => $_->name } @users }
```

For one-off assertions without stopping:

```
  DB<1> die "unexpected" if ref $obj ne 'MyApp::User'
```

Program I/O vs debugger I/O

The debugger's own input and output go through `$DB::IN` and `$DB::OUT`, which are opened to `/dev/tty` directly. The program can redirect STDIN / STDOUT / STDERR freely; the debugger prompt still shows up. Conversely, `p EXPR` output does not contaminate a program's captured stdout.

Find out more

- *breakpoints* - stop where you can inspect; this chapter is about what to look at once stopped.
- *tracing* - watch values change over time without stopping at every step.

Tracing: watching execution flow

This chapter covers traces that record what a program did without stopping it: the debugger's `t` command and trace options, the `Devel::Trace` module family, and the regex-engine tracer. Use tracing when the bug is "which code path actually ran?" rather than "what value does X have at line N?".

Readers coming in know how to set breakpoints and inspect state. A trace is the complement - "follow every step and tell me about it" rather than "stop at one interesting place".

t: trace inside the debugger

`t` toggles per-statement tracing. Every breakable line prints a location marker before executing:

```
  DB<1> t
Trace = on

  DB<2> c
main::(app.pl:5):           my $key = 'welcome';
main::(app.pl:6):           my %data = (
main::handle_request(app.pl:42):   my $user = load_user($req);
main::load_user(app.pl:87):        my ($req) = @_;
main::load_user(app.pl:88):        return unless $req;
...
```

Restricting the depth:

```
  DB<3> t 2           # toggle with maximum sub-depth 2
  DB<4> t 0 my_work() # trace one expression only
```

The `frame` option controls what the trace prints at sub calls and returns:

Bit	Flag	Effect
1	enter	Print on sub entry.
2	exit	Print on sub exit.
4	ctx+args	Include call context and arguments.
8	tied/ref	Mark tied-variable and reference sub calls.
16	return	Print the return value.

Set `frame` via `o`:

```
  DB<5> o frame=15       # enter + exit + ctx/args + tied/ref
```

Common combinations:

- `frame=2`: just entry/exit traces, one line per call - the call-tree view.
- `frame=6`: add caller context and argument dump - full trace.
- `frame=30`: like `frame=6` plus return values.

Trace output goes to the debugger's output stream. Redirect it to a file so it does not drown the interactive session:

```
  DB<6> o LineInfo=trace.out
```

Read the file in another terminal:

```
tail -f trace.out
```

Non-interactive tracing: NonStop + AutoTrace

For "record a full execution trace with no interaction", combine `NonStop=1` (no prompts) and `AutoTrace=1` (tracing on from start):

```
PERLDB_OPTS="NonStop=1 AutoTrace=1 frame=2 LineInfo=trace.out" \
  perl -d script.pl
```

The program runs straight through; `trace.out` captures every breakable line and every sub entry. Ideal for CI-mode failure capture, headless servers, or any environment where a TTY prompt is unavailable.

Add `inhibit_exit=0` to let the program fall off the end without the "Debugged program terminated" prompt.

Devel::Trace: every line, without the debugger

`Devel::Trace` traces every line of every file to STDERR. No command-line interaction. No breakpoints. Simple and loud:

```
perl -d:Trace script.pl 2> trace.out
```

```
>> app.pl:4: my $key = 'welcome';
>> app.pl:5: my %data = (
>> app.pl:11: print "$data{$key}\n";
```

Run it once, grep the output for the puzzle. Output size is proportional to program run length - use on a minimal reproducer, not the whole test suite.

Variants:

- `Devel::DumpTrace` - same plus per-line variable values.
- `Devel::TraceUse` - "which modules were loaded, in what order, by whom":

  ```
  perl -d:TraceUse script.pl
  ```

- `Devel::TraceINC` - narrower: just the `require` chain with timing.
- `Devel::Trace::Subs` - call-flow and stack-trace generator for "which subs actually ran".

Tracing a specific region

The `$DB::trace` variable toggles tracing from Perl code:

```
$DB::trace = 1;
interesting_region();
$DB::trace = 0;
```

Assigning to `$DB::trace` when not under `-d` autovivifies the variable harmlessly - the code is safe to commit and runs as a no-op outside the debugger.

Same pattern for single-stepping a region:

```
$DB::single = 1;        # break here when next statement runs under
↪-d
```

Regex tracing: `use re 'debug'`

The regex engine has its own tracer. Enable lexically inside a region, or on the command line:

```
{
    use re 'debug';
    $str =~ /(\w+)\s+(\w+)/;
}
```

```
perl -Mre=debug -e '"hello world" =~ /(\w+)\s+(\w+)/'
```

Compile-phase output shows what the optimiser did:

- `Compiling REx 'PATTERN'` - the source pattern.
- `size N` - internal node-table size.
- `anchored 'SUB' at K` / `floating 'SUB' at K..LIMIT` - which substring the engine will look for as a pre-filter.
- `stclass TYPE` - the starting-character class.
- `minlen N` - no match possible on input shorter than N.
- Node listing - the compiled program.

Runtime output shows each step:

```
  POS <PRE-MATCH> <POST-MATCH>    |  NODE_NUM: OPNAME
```

Indentation reflects backtracking depth; `failed...` and `failed, try continuation...` mark backtracks; `Match successful!` / `Match failed.` close the trace.

If no runtime output appears at all, the optimiser decided the match without entering the engine - either `minlen` pre-filtered or the pattern was folded to a constant test.

pperl's regex engine is a native reimplementation, not a port of perl5's. The trace is functionally equivalent but the exact node names and field formats are not byte-identical to upstream. Parsing the trace programmatically (few tools do) will need adjustment.

Partial switches narrow the output:

```
use re 'debugcolor';                    # ANSI colour
use re debug => 'EXECUTE';              # runtime only, no compile
↪output
```

`Devel::TraceUse` for module-load bugs

A program that runs slowly at startup, or a "why is this module loaded at all?", is almost always a module-graph question. `Devel::TraceUse` prints the full `use`/`require` tree:

```
perl -d:TraceUse script.pl
Modules used from script.pl:
   1. strict 1.12, script.pl line 2 [main]
   2. warnings 1.58, script.pl line 2 [main]
   3. DBI 1.643, script.pl line 5 [main]
      4. Carp 1.52, DBI line 13 [DBI]
      5. DynaLoader 1.47, DBI line 14 [DBI]
   ...
```

Indentation shows the dependency chain. Cross-reference with the line number in the parent file to see where each load happens.

Combining traces with the debugger

Trace to a file, step interactively:

```
PERLDB_OPTS="frame=6 LineInfo=trace.out" perl -d app.pl
```

The debugger prompt appears normally; `trace.out` accumulates the call-tree as you step and continue. Useful when a call chain is too deep to follow by stepping but you still want to stop at specific points to inspect.

Find out more

- *breakpoints* - stopping at a specific point rather than recording every step.
- *inspecting-state* - the commands that answer "what is this value?".

IDE and DAP integration

This chapter covers editor-driven debugging: `Perl::LanguageServer` in VS Code and its counterparts in Neovim / Emacs / IntelliJ, remote-over-SSH debugging, and container-mode debugging via `kubectl` or `docker`.

Readers who reach for an IDE rather than a terminal prompt will find here the minimum viable setup, the config keys that matter, and the known fragility points (Coro, path mapping, attach vs launch).

The landscape

Two wire protocols, both with Perl backends:

Protocol	Perl backend	Status
DAP	`Perl::LanguageServer`	Active.
DBGp	`Devel::Debug::DBGp`	Stagnant since 2018.

For new setups, use DAP via `Perl::LanguageServer`. DBGp survives only where an existing client (vim vdebug, pugdebug) is already in use.

`Perl::LanguageServer` bundles an LSP (code intelligence, diagnostics, go-to-definition) and a DAP (debugger) adapter in one process. The LSP half works on any Perl file in the editor; the DAP half runs only during a debug session.

Minimal VS Code setup

CPAN side - install into the Perl the debuggee will run under:

```
cpanm Perl::LanguageServer
```

Editor side - install the `richterger.perl` extension:

```
Ctrl-P  →  ext install richterger.perl
```

`.vscode/launch.json`:

```
{
  "version": "0.2.0",
  "configurations": [
    {
      "type": "perl",
      "request": "launch",
      "name": "Debug current file",
      "program": "${workspaceFolder}/${relativeFile}",
      "stopOnEntry": true,
      "args": [],
      "cwd": "${workspaceFolder}",
      "env": {},
      "reloadModules": true
    }
  ]
}
```

Open a `.pl` or `.pm`, set breakpoints in the gutter, press `F5`. The Debug Console accepts any Perl expression, evaluated in the current stack frame.

`.vscode/settings.json` for `@INC` and interpreter selection:

```
{
  "perl.perlInc": [
    "${workspaceFolder}/lib",
    "${workspaceFolder}/local/lib/perl5"
  ],
  "perl.perlCmd": "/usr/bin/perl"
}
```

Capabilities

`Perl::LanguageServer` supports the DAP features that matter:

- Launch, pause, step in / over / out, return.
- Conditional and unconditional breakpoints, added at any time.
- Variable inspection across stack frames.
- **Set variable** - change a value mid-session from the editor.
- Watch expressions.
- Evaluate-in-context at the Debug Console.
- Module hot-reload via `reloadModules: true`.

Not supported:

- **Attach to a running process.** `request: "attach"` is not implemented; only `"launch"` (the LS starts the debuggee itself).

Remote debugging over SSH

Edit locally; debug on a remote host. `settings.json`:

```
{
  "perl.sshCmd": "ssh",
  "perl.sshAddr": "deploy@host.example",
  "perl.sshUser": "deploy",
  "perl.sshWorkspaceRoot": "/srv/app",
  "perl.pathMap": [
    ["/srv/app", "${workspaceFolder}"]
  ]
}
```

`Perl::LanguageServer` runs on the remote host; the editor stays local. `pathMap` translates filenames the debuggee reports (`/srv/app/lib/X.pm`) to local editor paths (`${workspaceFolder}/lib/X.pm`).

Breakpoints that silently fail to bind are almost always a `pathMap` mismatch.

Container-mode debugging

`launch.json` accepts container keys that invoke `docker`, `podman`, `docker-compose`, or `kubectl`:

Key	Values
`containerCmd`	`"docker"`, `"docker-compose"`, `"podman"`, `"kubectl"`
`containerMode`	`"run"` (fresh container) or `"exec"` (existing)
`containerName`	Image (for `run`) or container name (for `exec`)
`containerArgs`	Extra args passed to the container runtime.
`pathMap`	`[["/in/container", "/on/host"], ...]`

Attach to an already-running Docker container:

```
{
  "type": "perl",
  "request": "launch",
  "name": "Debug in container",
  "program": "/app/bin/worker.pl",
  "containerCmd": "docker",
  "containerMode": "exec",
  "containerName": "my-running-worker",
  "pathMap": [["/app", "${workspaceFolder}"]]
}
```

Kubernetes pod:

```
{
  "type": "perl",
  "request": "launch",
  "name": "Debug in pod",
  "program": "/app/bin/worker.pl",
  "containerCmd": "kubectl",
  "containerMode": "exec",
  "containerName": "my-pod-abc123",
  "containerArgs": ["-n", "staging", "--container", "app"],
  "pathMap": [["/app", "${workspaceFolder}"]]
}
```

Constraints:

- **`Perl::LanguageServer` must be installed inside the image.** Bake it into the Dockerfile or build a dev-image variant.
- `pathMap` is the single biggest failure mode. Breakpoints that never bind mean the debuggee reports a path that does not translate.

Other editors

- **Neovim** - use `nvim-dap` with `Perl::LanguageServer` as the adapter. The adapter spec is a short Lua snippet that points at `perl -MPerl::LanguageServer -e '...'`.
- **Emacs** - `dap-mode` with the same adapter.
- **IntelliJ** - `Devel::Camelcadedb` + the JetBrains Perl plugin. Not DAP; proprietary protocol. Viable but outside the `Perl::LanguageServer` ecosystem.
- **Sublime Text** - DAP clients exist via plugins; use `Perl::LanguageServer` as the adapter.

Special-mode launches

`launch.json` keys for non-default invocation:

Key	Effect
`useTaintForDebug`	Injects `-T` into the debuggee's perl invocation.
`sudoUser`	Re-execs the debuggee as that user (needs passwordless sudo).
`reloadModules`	Enables module hot-reload during the session.
`stopOnEntry`	Break at the first statement.

Gotchas

- **BEGIN-time errors** surface as DAP "output" events, not as stopped-at-breakpoint events. Use `stopOnEntry: true` to get a stop at all if the script dies in `BEGIN`.
- **Application `$SIG{__DIE__}`** can swallow exceptions before the debugger's handler runs. Wrap the app's handler in an `if ($^S)` guard (see *exceptions*).
- **Watch expressions re-evaluate on every step.** Avoid expensive or side-effect expressions.
- **No source maps.** Perl has no concept equivalent to a JavaScript source map. Source filters (`Smart::Comments`) can shift reported line numbers by one; breakpoints in filtered files may land on the wrong line.
- **`Future::AsyncAwait` stepping.** Works for simple cases; stepping through complex `await` chains is unreliable. Drop to `perl -d` for deep async investigation, or use logging.
- **Windows native** - `Perl::LanguageServer`'s stdin handling is broken on Windows. WSL works.
- **Coro.** `Perl::LanguageServer` relies on Coro internally; the most-cited fragility point is Coro interacting badly with unusual build configurations. If the server refuses to start, check Coro's install log first.

- *interactive-debugger* - `perl -d` directly, when the IDE stack is overkill or unavailable.

Coverage: which code your tests run

A coverage report answers a question the debugger cannot: which statements, branches, conditions and subroutines a test run never reached. pperl runs `Devel::Cover`, the coverage tool perl5 uses, and reports the same numbers perl5 does.

Installing Devel::Cover

The compiled part of `Devel::Cover` is built into pperl. Its Perl modules and its `cover` command come from CPAN:

```
pperl --cpan Devel::Cover
```

They land under `~/.pperl` (or `$PPERL_HOME`, see *Installing CPAN modules*): the modules in `~/.pperl/lib/perl5`, which pperl searches without being told, and the command as `~/.pperl/bin/cover`.

If `PERL5LIB` points at a perl5 tree that already has Devel::Cover, `pperl --cpan` finds that copy, reports the module as up to date and installs nothing. Run it with `PERL5LIB` unset. Keep the perl5 tree's copy out of covered runs, too: pperl needs its own.

Measuring a program

Load `Devel::Cover` with `-M`, then run `cover` in the same directory:

```
pperl -MDevel::Cover yourprog.pl
pperl ~/.pperl/bin/cover
```

The run collects into `cover_db/` in the current directory. `cover` prints a summary per file and writes an HTML report to `cover_db/coverage.html`. For a program `prog.pl` that calls one of the two subs of its module `lib/Shape.pm`:

```
------------ ------ ------ ------ ------ ------ ------
File           stmt   bran   cond    sub   time  total
------------ ------ ------ ------ ------ ------ ------
lib/Shape.pm   50.0   50.0   33.3   50.0    0.0   45.4
prog.pl       100.0    n/a    n/a  100.0  100.0  100.0
Total          81.8   50.0   33.3   75.0  100.0   70.0
------------ ------ ------ ------ ------ ------ ------
```

Every option of `Devel::Cover` and of `cover` works as under perl5: `cover -report text` for a plain-text report, `-report json` for JSON, `cover -delete` to start over. A pod column appears when `Pod::Coverage` is installed, as it does under perl5.

Measuring a test suite

`HARNESS_PERL_SWITCHES` adds `-MDevel::Cover` to every test the harness starts. Run `prove` itself under pperl, so that the tests run under pperl too; `-S` finds `prove` on the `PATH`:

```
HARNESS_PERL_SWITCHES=-MDevel::Cover=-ignore,^t/ pperl -S prove -l t
pperl ~/.pperl/bin/cover
```

`-ignore,^t/` keeps the test files themselves out of the report. `prove --exec pperl` does not apply `HARNESS_PERL_SWITCHES`, under perl5 either, nor `-l`; with `--exec`, put both in the command itself: `prove --exec "pperl -Ilib -MDevel::Cover=-ignore,^t/" t`.

Choosing what is reported

Devel::Cover leaves out modules that belong to the installation, `~/.pperl/lib/perl5` among them. The check it uses for that does not know `PPERL5LIB` or `PPERL_HOME`, so with either set, modules from those trees are covered and reported like your own code. In that setup, choose the files with `-select` and `-ignore`, both regular expressions over file names:

```
pperl -MDevel::Cover=-select,^lib/,-ignore,^t/ yourprog.pl
```

Speed

While Devel::Cover collects, pperl does not compile loops to machine code: compiled code would run past the counters Devel::Cover reads. A covered run is therefore as fast as pperl's interpreter, not as fast as a normal pperl run. A run without `-MDevel::Cover` is unaffected.

4.2.7 The Definitive Perl One-Liner Guide

A Perl one-liner is a complete program delivered as an argument to `pperl -e` (or `-E`), run directly from the shell. It occupies the same niche as `awk`, `sed`, and ad-hoc shell pipelines, with a richer regex engine, a full standard library, and the ability to grow into a real script the moment one line stops being enough.

This guide is for a Linux shell user who already composes `grep`/`sed`/`awk`/`xargs` pipelines and has written a small Perl script or two. It teaches the command-line surface end to end: the switches, a progressive recipe catalogue, regex-driven transformations, numeric work, how to wrap recipes into reusable shell aliases, and the traps that cost time.

The binary is `pperl`. Every example in this guide is copy-pasteable into a Linux shell. pperl is a Rust reimplementation of Perl 5; its command-line interface matches Perl 5.44.

Which chapter do I want?

You want to ...	Start here
Know what each switch (`-n`, `-p`, `-a`, ...) does	*switches*
Browse recipes from trivial substitutions up to data reductions	*progression*
Match, extract, or rewrite text with regexps	*regex-recipes*
Sum, average, generate primes, convert IPs, do date arithmetic	*numeric*
Turn a one-liner into a reusable shell function or alias	*aliases*
Debug quoting, encoding, in-place edits, and record-separator surprises	*gotchas*

The three layers of this guide

- **Orientation** - this page.
- **Working programmer** - the six chapters above. Each stands on its own; skim the ones relevant to your current problem.
- **Deep reference** - the compact switch/variable table at the end of *switches*.

Two examples before you start

A sed/awk user reading this guide wants to see what a one-liner buys them. Two demonstrations.

Sum the numbers in the last column of a whitespace-separated file

```
pperl -lane '$s += $F[-1]; END { print $s }' data.txt
```

`-l` chomps input newlines and appends one on output. `-a` splits each line into `@F`. `-n` wraps the program in an implicit read loop. `$F[-1]` is the last column. `END { … }` runs once after input is exhausted. No temporary file, no `awk 'BEGIN{…}END{…}'`, no boilerplate.

Extract every unique IPv4 address from a log, newest first

```
pperl -lne 'print for /\b(?:\d{1,3}\.){3}\d{1,3}\b/g' access.log \
  | awk '!seen[$0]++'
```

The one-liner handles the hard part (finding all matches per line, not just the first), the awk keeps the first sighting of each. Written as two short tools, each doing one job - that is the working mode of this guide.

Read in this order on a first pass

1. *switches* - the vocabulary.
2. *progression* - the recipes, ordered by difficulty.
3. *regex-recipes*, *numeric* - applied pieces.
4. *aliases* - lifting what you use daily into shell functions.
5. *gotchas* - the traps, once you are running into them.

On later passes, go directly to whichever chapter names the problem you are holding.

Bibliography

This guide is not derived from any single book. It was researched the way a technical writer would research the topic - perldoc, CPAN module documentation, conference talks, blog posts, mailing-list archives, and the books listed below - and then distilled in several passes: removing references to tools and versions nobody runs anymore, collapsing the same advice repeated by different authors into one statement, and merging multiple partial treatments of one topic into a single complete treatment. The result covers more ground than any single source we consulted, because no single source covers the whole field. It is also more densely cross-linked than any of them: when the regex chapter touches something the regex guide already explains in depth, that is one click away - not a chapter you have to find by yourself in another volume.

The two books below are the closest published companions in print form. Buy them if the one-liner idiom is a daily tool for you and you want a printed reference on the shelf.

- Peteris Krumins, *Perl One-Liners: 130 Programs That Get Things Done*, No Starch Press, 2014.
- Sundeep Agarwal, *Perl One-Liners Guide* (learnbyexample), 2023.

The switches

Every one-liner is a combination of a program (passed to `-e` or `-E`) and a handful of switches that wrap implicit behaviour around it. This chapter covers the switches you will reach for. Each one earns its keep in the progression, regex, and numeric chapters that follow.

Readers coming from `awk` or `sed` already know what per-line iteration, field splitting, and in-place editing look like; the question is which pperl flag turns each on.

`-e` - run a program given on the command line

```
pperl -e 'print "hello\n"'
```

`-e` takes the Perl source as its argument. Multiple `-e` chunks concatenate; they behave as one program with semicolons between them.

```
pperl -e 'my $x = 41;' -e 'print $x + 1, "\n"'    # 42
```

Use single quotes around the program so the shell leaves `$_`, `$1`, `\n`, and backticks alone. See *gotchas* for what goes wrong with double quotes.

`-E` - `-e` plus the modern feature set

`-E` is `-e` with all optional features enabled: `say`, `state`, `fc`, the `//` defined-or operator, unicode string semantics under `use feature 'unicode_strings'`, and more.

```
pperl -E 'say "hello"'                    # instead of print "hello\
 ↪n"
pperl -E 'say "pi = " . (atan2(1,1)*4)'
```

Reach for `-E` when writing new one-liners. Reach for `-e` only when copy-paste compatibility with very old scripts matters.

`-n` - wrap an implicit read loop around the program

`-n` turns the program into the body of a loop over every line of every input file (or STDIN if none are given). The loop is exactly:

```
while (<>) {
    # your program
}
```

`$_` holds each input line, including its trailing newline. Nothing is printed automatically - you decide what reaches STDOUT.

```
# Print lines containing "error"
pperl -ne 'print if /error/' app.log
```

Equivalent long form, shown once so the mechanical expansion is clear:

```
while (<>) {
    print if /error/;
}
```

Every subsequent `-n` recipe in this guide relies on that expansion - assume it without re-stating.

`BEGIN { ... }` runs before the loop, `END { ... }` runs after. Both are ordinary Perl blocks and compose with `-n` cleanly.

```
# Count lines matching a pattern
pperl -ne '$n++ if /WARN/; END { print "$n\n" }' app.log
```

`-p` - like `-n`, but print `$_` after each iteration

```
pperl -pe 's/foo/bar/g' input.txt
```

Mechanical expansion:

```
while (<>) {
    # your program
} continue {
    print or die "-p destination: $!";
}
```

Reach for `-p` when the output is the (possibly modified) input. Reach for `-n` when the output is a summary, a filtered subset, or nothing at all.

`-l` - line-end handling

`-l` does two things at once:

1. On input, `chomp` each line as it is read under `-n` / `-p`. `$_` no longer ends in `"\n"`.
2. On output, set `$\` (the output record separator) so every `print` appends `"\n"`.

```
# Print just the first field of each tab-separated line
pperl -F'\t' -lane 'print $F[0]' table.tsv
```

Without `-l`, you would either write `print "$F[0]\n"` (the newline moves into the program) or produce glued output.

`-l` accepts an optional octal argument that sets `$\` to a different character: `-l012` keeps newline (the default), `-l0` sets `$\` to NUL, and so on. The common use is the no-argument form.

`-a` - autosplit into @F

Combined with `-n` or `-p`, `-a` splits `$_` on whitespace and puts the fields into `@F`. The default split is `split(' ', $_)` - it trims leading whitespace and treats any run of whitespace as one separator.

```
# Third column of every line
pperl -lane 'print $F[2]' data.txt

# Reverse column order
pperl -lane 'print "@{[reverse @F]}"' data.txt
```

`@F` is zero-indexed. `$F[-1]` is the last field. `scalar @F` is the field count.

`-F` - change the split pattern

`-F` sets the delimiter used by `-a`. The argument is a regex; a literal comma is `-F,`, a colon is `-F:`, a tab is `-F'\t'`.

```
# Second field of a colon-separated file
pperl -F: -lane 'print $F[1]' /etc/passwd

# Split on any run of commas or semicolons
pperl -F'[,;]+' -lane 'print scalar @F' mixed.csv
```

`-F` implies `-a`, so the split happens whether or not you spell `-a` out. The common idiom `-F: -lane` is colon-split, chomped, with `@F` available.

Quoting a tab requires a literal tab in the shell or the regex form:

```
pperl -F'\t' -lane 'print $F[0]' data.tsv       # regex form, always␣
↪safe
pperl -F'        ' -lane 'print $F[0]' data.tsv     # literal tab -␣
↪fragile
```

`-i` - edit files in place

`-i` rewrites the file `pperl` is reading from, replacing its contents with whatever `-p` prints. The whole file's output goes to a temporary file; when the loop finishes, that temporary replaces the original.

```
# Replace CRLF with LF in every .txt under cwd (no backup)
pperl -i -pe 's/\r\n/\n/g' *.txt

# Same, keeping a .bak copy beside each original
pperl -i.bak -pe 's/\r\n/\n/g' *.txt
```

Always use `-i.bak` (or another suffix) until you have verified the edit against a representative file. A bug in the program with bare `-i` destroys the input. See *gotchas*.

`-i` has no effect without `-p` (or explicit prints under `-n`): if nothing is printed, the replacement file is empty.

`-M` and `-m` - load modules before the program runs

`-Mmodule` is equivalent to `use module;` at the top of the program. `-Mmodule=sym1,sym2` is `use module qw(sym1 sym2);`.

```
pperl -MList::Util=sum -lane 'print sum @F' data.txt
pperl -MPOSIX=strftime -le 'print strftime("%F", localtime)'
pperl -MData::Dumper -e 'print Dumper({a=>1, b=>[2,3]})'
```

Lower-case `-m` is `use module ()` - the module is loaded but imports nothing; it is rarely needed on the command line.

Modules most common in one-liners: `List::Util` (sum/min/max/uniq/any), `POSIX` (strftime, mktime, fmod), `Data::Dumper` (inspect structures), `JSON::PP` (parse/emit JSON), `Text::CSV` (quoted CSV), `MIME::Base64`, `Digest::MD5`, `Digest::SHA`, `Socket`.

`-0` - set the input record separator

Perl normally reads a line at a time. `-0NNN` sets `$/` to the character with the given octal code, changing what "one record" means for `<>`, `<STDIN>`, and the `-n` / `-p` loop.

Common forms:

Form	What `$/` becomes	Effect
`-0`	`"\0"` (NUL)	Read NUL-delimited records (matches `find -print0`).
`-0777`	`undef`	Slurp the whole file as one record.
`-00`	`""`	Paragraph mode: blank lines separate records.
`-0NNN`	`chr(0NNN)`	Any single octal byte.

```
# Count files from find -print0
find . -type f -print0 | pperl -0 -ne '$n++; END { print "$n\n" }'

# Slurp, then run a cross-line regex
pperl -0777 -ne 'print "yes\n" if /BEGIN.*?END/s' text.txt

# Print every paragraph containing "TODO"
pperl -00 -ne 'print if /TODO/' notes.txt
```

Paragraph mode (`-00`) interacts with `-l`: without `-l`, the blank separator stays attached to each record; with `-l`, it is chomped.

`-C` - Unicode on stdio and/or `@ARGV`

`-C` enables Unicode handling on specified streams. The argument is either a number (bitmask) or a string of letters.

```
pperl -CSD -ne 'print' input.txt      # stdin, stdout, stderr all␣
↪UTF-8
pperl -CA  -e  'print $ARGV[0]' äöü   # @ARGV treated as UTF-8
pperl -CSA -nE 'say length'           # S + A
```

Letter codes: `I` = stdin, `O` = stdout, `E` = stderr, `S` = `I+O+E`, `A` = `@ARGV`, `D` = set default I/O layers (includes file opens).

For a fully UTF-8 session, `-CSD`. For one-off processing of named UTF-8 files, `-CSAD`. See *gotchas* for the symptoms that tell you `-C` is missing.

Reference table

Every switch, its mechanical expansion, and the chapter where it first shows up in a recipe.

Switch	Expands to	First used in
`-e CODE`	Run CODE as the program	*progression*
`-E CODE`	`-e` plus all current features enabled	*progression*
`-n`	`while (<>) { CODE }`	*progression*
`-p`	`while (<>) { CODE } continue { print }`	*progression*
`-l`	chomp input under `-n`/`-p`; set `$\ = "\n"` for output	*progression*
`-a`	Auto-split `$_` into `@F`	*progression*
`-F PAT`	Change `-a` split pattern to regex PAT	*progression*
`-i[EXT]`	Edit in place; with EXT, keep backup `original + EXT`	*progression*
`-M MOD`	`use MOD;` before program	*numeric*
`-M MOD=X`	`use MOD qw(X);`	*numeric*
`-0`	`$/ = "\0"` - NUL-delimited records	*progression*
`-00`	`$/ = ""` - paragraph mode	*progression*
`-0777`	`$/ = undef` - slurp entire file	*progression*
`-C`	Enable Unicode on stdio, `@ARGV`, and/or default layers	*gotchas*

Special variables the switches set up

Short catalogue; full definitions live in `perlvar`.

Vari-able	Role under `-n`/`-p`
`$_`	The current input line (chomped if `-l`, raw otherwise).
`$.`	Current input line number (not reset between files by default).
`$/`	Input record separator. `-0` family changes it.
`$\`	Output record separator appended by `print`. `-l` sets it to `"\n"`.
`$,`	Output field separator inserted between `print`'s arguments.
`$"`	Separator between array elements when interpolated in `"@array"`.
`@F`	Auto-split fields under `-a`.
`@ARGV`	Remaining command-line arguments; filenames are consumed as processed.
`$ARGV`	Name of the file currently being read (`"-"` means STDIN).

Find out more

- *progression* applies every switch in recipes of increasing complexity.
- `perlvar` lists every special variable pperl defines, not just the ones the switches touch.
- `perlop` covers `qr//`, the flip-flop operator, and the diamond operator used by the `-n` / `-p` loops.

Progressive recipes

This chapter works from trivial substitutions up through reductions, extraction, and structured output. Each section reuses the switches introduced in the previous one, so a reader going straight through builds up the idiom vocabulary without ever meeting a new flag mid-recipe.

Readers coming from `awk`/`sed` should recognise the first sections; the interesting material starts around *Reductions across lines* and *Context-windowed filters*.

Every recipe is copy-pasteable. When a sample input matters, it is shown inline so the expected output is unambiguous.

The baseline: `-e` and `-E`

The shortest one-liner. No I/O loop, no field splitting - just a program that runs once.

```
pperl -e 'print 2 ** 32, "\n"'                    # 4294967296
pperl -E 'say 2 ** 32'                            # same, with -E/
 ↪say
pperl -E 'say for 1 .. 5'                         # 1\n2\n3\n4\n5
```

The `,` in `print` separates arguments; the output field separator `$,` (default empty) goes between them.

Filtering: `-n` + `print if`

`-n` wraps the program in a read loop over every line of every input file (or STDIN). Nothing is printed unless the program says so.

```
# Sample input
$ printf 'gate\napple\nwhat\nkite\n' > words.txt

pperl -ne 'print if /at/' words.txt               # gate, what
pperl -ne 'print unless /e/' words.txt            # what
pperl -ne 'print if /^[aeiou]/' words.txt         # apple
```

The regex match is against `$_` by default; `/at/` is short for `$_ =~ m/at/`.

Multiple conditions

```
# Lines containing both "ERROR" and "timeout"
pperl -ne 'print if /ERROR/ && /timeout/' app.log

# Lines containing neither
pperl -ne 'print if !/ERROR/ && !/timeout/' app.log

# Events A, B, C appearing in order on one line
pperl -ne 'print if /A.*B.*C/' events.log
```

By line number

```
pperl -ne 'print if $. == 1'                    # head -n 1
pperl -ne 'print if $. <= 10'                   # head -n 10
pperl -ne 'print if 17 .. 30'                   # lines 17-30␣
↪(range op)
pperl -ne 'print if /START/ .. /END/'           # regex range,␣
↪inclusive
pperl -ne 'print unless $. % 2'                 # even lines
```

The range operator `..` in scalar context is a flip-flop: compared against `$.` when both endpoints are integers, against `$_` when they are patterns. See `perlop`.

By length

Use `-l` so the counted length excludes the trailing newline.

```
pperl -lne 'print if length >= 80' src.c        # long lines
pperl -lne 'print if length() < 5' words.txt    # short lines
```

Bare `length` with no argument applies to `$_`.

Substitution: `-p` + `s///`

`-p` is `-n` plus an implicit `print` after each iteration. Use it when the output is the (possibly modified) input.

```
# Replace every "foo" with "bar"
pperl -pe 's/foo/bar/g' input.txt

# First occurrence per line only
pperl -pe 's/foo/bar/' input.txt

# Conditional: replace only on lines that also match BAZ
pperl -pe 's/foo/bar/g if /BAZ/' input.txt
```

Case transformations

```
pperl -nle 'print uc'                                    # to uppercase
pperl -nle 'print lc'                                    # to lowercase
pperl -nle 'print ucfirst lc'                            # Sentence case
pperl -ple 's/(\w+)/\u$1/g'                              # Title Case Per␣
↪Word
```

`uc`, `lc`, and `ucfirst` with no argument operate on `$_`.

Whitespace normalisation

```
pperl -ple 's/^\s+//'                                    # trim left
pperl -ple 's/\s+$//'                                    # trim right
pperl -ple 's/^\s+|\s+$//g'                              # trim both
pperl -ple 's/\s+/ /g'                                   # collapse runs
pperl -ne  'print if /\S/'                               # drop blank␣
↪lines
```

Line-ending conversion

```
pperl -pe 's/\r\n/\n/g' win.txt                          # DOS  → UNIX
pperl -pe 's/(?<!\r)\n/\r\n/g' unix.txt                  # UNIX → DOS
```

The lookbehind `(?<!\r)` avoids producing `\r\r\n` when the input is already DOS-encoded. See *regex-recipes* for lookarounds in depth.

Field-oriented work: `-a` and `-F`

`-a` auto-splits each line into `@F`. `-F` changes the delimiter.

```
$ cat table.txt
brown bread mat hair 42
blue cake mug shirt -7
yellow banana window shoes 3.14

# Second field
pperl -lane 'print $F[1]' table.txt
# bread, cake, banana

# Last field
pperl -lane 'print $F[-1]' table.txt
# 42, -7, 3.14

# Count fields per line
pperl -lane 'print scalar @F' table.txt
# 5, 5, 5

# Lines whose last field is negative
```

(continues on next page)

(continued from previous page)

```
pperl -lane 'print if $F[-1] < 0' table.txt
# blue cake mug shirt -7
```

Custom delimiter

```
# /etc/passwd: print username (field 1) and shell (last field)
pperl -F: -lane 'print "$F[0] $F[-1]"' /etc/passwd

# Tab-separated
pperl -F'\t' -lane 'print $F[2]' metrics.tsv

# Comma or semicolon, one or more
pperl -F'[,;]+' -lane 'print scalar @F' mixed.csv
```

Proper CSV (quoted fields with embedded commas) is not a job for `-F`. Use `-MText::CSV` - see *numeric* for the pattern.

Rejoining fields

Interpolating `@F` inside double quotes uses `$"` (default: one space) as the separator.

```
# Reverse field order, space-separated
pperl -lane 'print "@{[reverse @F]}"' table.txt

# Reverse field order, colon-separated
pperl -F: -lane 'local $" = ":"; print "@{[reverse @F]}"' /etc/
 ↪passwd
```

`@{[ EXPR ]}` is the array-ref-then-deref idiom that lets arbitrary expressions be interpolated into a double-quoted string.

Reductions across lines

The move from per-line filters to cross-line computation.

Counts

```
# wc -l
pperl -lne 'END { print $. }' big.txt

# grep -c pattern
pperl -lne '$n++ if /pattern/; END { print $n + 0 }' file

# Count blank lines
pperl -lne '$n++ if /^$/; END { print $n + 0 }' file

# Total fields across the file
pperl -lane '$t += @F; END { print $t }' table.txt
```

The `$n + 0` idiom prints `0` rather than empty when the counter was never incremented.

Sums, minima, maxima

Use `List::Util` via `-M`.

```
# Per line
pperl -MList::Util=sum -lane 'print sum @F' data.txt
pperl -MList::Util=min -lane 'print min @F' data.txt
pperl -MList::Util=max -lane 'print max @F' data.txt

# Across all lines
pperl -MList::Util=sum -lane '$s += sum @F; END { print $s }' data.
↪txt
pperl -MList::Util=max -alne '$m = max($m // (), @F); END { print $m␣
↪}' data.txt
```

`$m // ()` returns an empty list when `$m` is undefined, so the first iteration does not pass `undef` to `max`. See *numeric* for the full arithmetic chapter.

Longest and shortest line

```
pperl -ne '$l = $_ if length > length $l; END { print $l }' file
pperl -ne '$s = $_ if $. == 1 || length < length $s; END { print $s␣
↪}' file
```

Unique lines (first sighting only)

```
pperl -ne 'print unless $seen{$_}++' file

# Or the List::Util one-liner (slurps):
pperl -MList::Util=uniq -e 'print uniq <>' file
```

The first form streams - memory scales with distinct lines, not total lines. The second slurps everything into memory, then emits. Prefer the first for large inputs.

Duplicates only

```
# Print each duplicate line once, when first seen for the second␣
↪time
pperl -ne 'print if ++$seen{$_} == 2' file
```

Context-windowed filters

Printing the line *around* a match, not just the match itself.

```
# Line immediately before each match (grep -B 1, with caveats)
pperl -ne '/pattern/ && $prev && print $prev; $prev = $_' file
```

(continues on next page)

(continued from previous page)

```
# Line immediately after each match (grep -A 1)
pperl -ne 'print if $p; $p = /pattern/' file

# tail -n 10
pperl -ne 'push @a, $_; shift @a if @a > 10; END { print @a }' file
```

For rich `-A` / `-B` / `-C` behaviour, `grep` is the right tool. One-liners fit when the window rule is unusual (e.g. "print the line matching X, plus every line until the next blank line").

```
# Print from /SECTION/ to the next blank line
pperl -ne 'print if /SECTION/ .. /^$/' file
```

Record mode: `-0`, `-00`, `-0777`

Switch away from line-based reading when the natural record is not a line.

Slurp with `-0777`

```
# Single-shot regex across the whole file
pperl -0777 -ne 'print "match\n" if /BEGIN.*?END/s' text.txt

# Replace only the first occurrence across the file
pperl -0777 -i.bak -pe 's/TODO/DONE/' notes.txt
```

`-0777` sets `$/ = undef`. The entire file comes in as one `$_`. The `/s` modifier makes `.` match newlines. See *regex-recipes* for the full multi-line story.

Paragraph mode with `-00`

`-00` sets `$/ = ""`. Each read returns everything up to the next blank-line delimiter.

```
# Paragraphs containing "TODO"
pperl -00 -ne 'print if /TODO/' notes.md

# Reverse paragraph order
pperl -00 -e 'print reverse <>' notes.md
```

NUL-delimited records with `-0`

```
# Count files produced by find -print0
find . -type f -print0 | pperl -0 -ne '$n++; END { print "$n\n" }'

# Convert NUL-delimited stream to newline-delimited
find . -type f -print0 | pperl -0 -pe 's/\0/\n/'
```

In-place editing with `-i`

`-i` overwrites each input file with what `-p` prints. `-i.bak` keeps a backup.

```
# Lowercase every occurrence of HOSTNAME in every .conf (keep␣
↪backup)
pperl -i.bak -pe 's/HOSTNAME/\L$&/g' *.conf

# Delete every line matching DEPRECATED (no backup - only do this
# after you've validated the pattern on one file)
pperl -i -ne 'print unless /DEPRECATED/' file.txt
```

The backup files pile up. Clean them up with `rm *.bak` once verified. See *gotchas* for the classic in-place traps.

Structured output

CSV-like (lightweight - commas are not quoted)

```
# Rebuild a TSV as CSV (naive, assumes no commas in fields)
pperl -F'\t' -lane 'print join ",", @F' data.tsv

# Add a column of line numbers
pperl -lane 'print join "\t", $., @F' data.tsv
```

JSON (stdlib)

```
# Emit one JSON object per line (no commas in values assumed)
pperl -MJSON::PP -F: -lane '
    print JSON::PP->new->encode({
        user => $F[0], uid => 0+$F[2], shell => $F[-1]
    })
' /etc/passwd
```

Multi-line one-liners like this are where an *alias* starts to pay for itself.

Numbered input

```
pperl -pe '$_ = "$. $_"'                          # 1 gate, 2 apple,␣
↪...
pperl -pe 's/^/sprintf "%5d  ", $./e'             # padded width
```

The `/e` modifier on `s///` treats the replacement as Perl code. See *regex-recipes*.

Find out more

- *regex-recipes* - the regex-dependent one-liners: captures, lookaround, named groups, `/e`, `/r`.
- *numeric* - arithmetic, statistics, randoms, date math.

- *aliases* - turn the recipes you use weekly into shell functions.
- *gotchas* - quoting, encoding, `-i` backups, record-separator surprises.
- `perlop` - the flip-flop operator, the diamond operator, `s///`, `tr///`, quoting forms.

Regex-driven one-liners

The previous chapter kept regexps at the level `sed` or `awk` users already know: literal patterns inside `m//` and `s///`. This chapter covers one-liners whose shape depends on a regex feature beyond plain matching - extractions, captures, lookarounds, code-in-replacement, and non-destructive rewrites.

Readers who already know the constructs (`(?:...)`, `(?<name>...)`, `(?=...)`, the `/e` and `/r` modifiers) can skim for the command-line framing. Readers who know what `/g` does but have never written `/e` will get the most out of reading straight through.

For the regex language itself, see the *regular expressions guide*.

Extracting all matches

`/g` in list context returns every match, not just the first.

```
# Every integer in the input
pperl -ne 'print "$_\n" for /-?\d+/g' file.txt

# Every IPv4-shaped substring
pperl -lne 'print for /\b(?:\d{1,3}\.){3}\d{1,3}\b/g' access.log

# Every HTTP header value (naive: no folded headers)
pperl -nE 'say $1 if /^[\w-]+:\s*(.+)$/' headers.txt
```

`say` (enabled by `-E`) appends a newline, saving one `"\n"` and keeping the program short.

Non-greedy quantifiers

`*?`, `+?`, `??`, `{n,m}?` - match as few characters as possible.

```
# Everything between the first < and the next > (tag-by-tag)
pperl -lne 'print for /<(.+?)>/g' markup.html

# Every quoted string (double quotes, no escape handling)
pperl -lne 'print for /"([^"]*)"/g' config.txt
```

The negated character class `[^"]*` is usually a faster and safer non-greedy than `.*?` when you know what must not appear inside.

Captures in substitution

The right-hand side of `s///` can reference left-hand captures.

```
# Swap every "word1 word2" pair
pperl -pe 's/(\w+)\s+(\w+)/$2 $1/g' file.txt

# Quote every unquoted key in key=value pairs
pperl -pe 's/(\w+)=/$1="/g; s/=([^"\n]+)/"$1"/g' config.txt

# Increase every trailing number by one
pperl -pe 's/(\d+)$/$1 + 1/e' file.txt
```

`/e` - replacement is Perl code

The `/e` modifier treats the replacement as code; its return value is what gets substituted in.

```
# Number every word in the file (global counter)
pperl -pe 's/(\w+)/++$i . ".$1"/ge' file.txt

# Number words per line (counter reset each line)
pperl -pe '$i = 0; s/(\w+)/++$i . ".$1"/ge' file.txt

# Wrap every integer in base 16
pperl -pe 's/\d+/sprintf "0x%x", $&/ge' file.txt

# Convert Celsius-labelled numbers to Fahrenheit
pperl -pe 's/(\d+)C\b/sprintf "%.1fF", $1 * 9 / 5 + 32/ge' weather.
↪txt
```

`/ge` together: evaluate the right-hand side as code, do it for every match. `$&` is the whole matched text; `$1`, `$2`, ... are captures.

`/ee` evaluates twice - the first `e` produces a string, the second evaluates that string. Useful when the replacement string is itself dynamic code read from input; needed rarely, a hazard often.

`/r` - non-destructive substitution

`/r` returns the modified string instead of rewriting `$_`. The original stays intact.

```
# Print filename and its .bak variant side by side
ls *.txt | pperl -pe '$_ = $_ . ($_ =~ s/$/.bak/r)'

# Compute a transformed version without touching $_
pperl -ne 'my $upper = $_ =~ tr/a-z/A-Z/r; print $_, $upper' file.
↪txt
```

Reach for `/r` when a single line needs to be printed in two forms, or when the transformation is conditional and you want the untouched line back in the failure branch.

Named captures

`(?<name>...)` captures into `$+{name}` and into `%+`.

```
# Parse combined-log-format access lines
pperl -nE '
    if (/^(?<ip>\S+).*?"(?<method>\S+) (?<path>\S+)/) {
        say "$+{ip} $+{method} $+{path}";
    }
' access.log
```

Named captures pay for themselves once the pattern has more than two groups, or when the same group needs to be referenced both in the pattern and in the replacement code.

Lookahead and lookbehind

Zero-width assertions: match a position where the surrounding text satisfies a condition, without consuming the condition itself.

```
# Digits preceded by $ (e.g. "$42" → 42, ignore "42")
pperl -lne 'print for /(?<=\$)\d+/g' prices.txt

# Words NOT followed by "!"
pperl -lne 'print for /\b\w+\b(?!!)/g' shouts.txt

# Insert CRLF only where LF is not already preceded by CR
pperl -pe 's/(?<!\r)\n/\r\n/g' unix.txt
```

Common pairs:

Lookaround	Meaning
`(?=X)`	Next characters match `X`
`(?!X)`	Next characters do not match `X`
`(?<=X)`	Preceding characters match `X`
`(?<!X)`	Preceding characters do not match `X`

Lookbehind in pperl supports variable-length patterns; see *regular expressions: anchors and assertions*.

Multi-line matches across slurped input

`-0777` slurps the entire file into `$_`. The regex modifiers that matter in that mode:

- `/s` - `.` matches `\n`.
- `/m` - `^` and `$` match at every line start/end, not just the start/end of the whole string.

```
# Every BEGIN...END block (non-greedy), each on one output line
pperl -0777 -lne '
    while (/BEGIN(.*?)END/sg) {
```

(continues on next page)

(continued from previous page)

```
        (my $body = $1) =~ s/\n/ /g;
        print $body;
    }
' text.txt

# Paragraphs where every line starts with ">"
pperl -00 -ne 'print if /\A(?:>.*\n?)+\z/m' mail.txt
```

`\A` and `\z` anchor the whole string start and end, unaffected by `/m`. Use them when `/m` is on but you really do mean the whole string.

Transliteration with `tr`

`tr` (also spelt `y`) is character-by-character substitution. Not a regex, but a close neighbour - and the right tool for character-set jobs.

```
pperl -pe 'tr/A-Za-z/N-ZA-Mn-za-m/'                    # ROT13
pperl -pe 'tr/A-Za-z/a-zA-Z/'                          # swap case
pperl -pe 'tr/a-z//d'                                  # delete lowercase␣
↪letters
pperl -pe 'tr/ \t/ /s'                                 # squeeze␣
↪whitespace runs to one space

# Count commas on each line (tr returns the count)
pperl -ne 'print tr/,//, "\n"' data.csv
```

The `d` flag deletes characters in the left set that have no counterpart on the right. The `s` flag squeezes runs. The `c` flag complements the left set (everything NOT listed).

Parsing delimited substrings

CSV with quoted commas

A quick-and-dirty split that honours double-quoted fields:

```
pperl -ne '
    my @F = /"([^"]*)"|([^,]+)/g;
    @F = grep defined, @F;
    print join("|", @F), "\n";
' quoted.csv
```

Correct and fast enough for a one-off. For anything that must handle embedded quotes (`"he said ""hi"""`), use `Text::CSV`; see *numeric*.

URL query strings

```
# Each key=value pair on its own line
pperl -lne 'print for /([^?&=]+)=([^&]*)/g' urls.txt
```

Practical extraction one-liners

Words by length

```
# Words of exactly 5 characters
pperl -lne 'print for /\b\w{5}\b/g' file.txt
```

Numbers with units

```
pperl -lne 'print for /\b\d+(?:\.\d+)?\s*(?:ms|s|kb|mb|gb)\b/gi'␣
↪timings.txt
```

HTTP User-Agent from a request log

```
pperl -nE 'say $1 if /^User-Agent: (.+)$/' request.log
```

Balanced braces (as many as pperl's regex engine supports)

pperl's regex engine supports recursion via `(?R)` and `(?1)`, so single-level brace balancing is a one-liner:

```
pperl -0777 -nE 'say $& while /\{(?:[^{}]|(?R))*\}/g' code.txt
```

For deeply nested structures, reach for a parser. Regex is the right tool up to the complexity where it stops being one.

Find out more

- *regular expressions guide* - the language underneath every recipe here, including modifiers, performance, and Unicode.
- `m` - the match operator.
- `s` - substitution, the full set of modifiers.
- `tr` - transliteration reference.
- *progression* - simpler `s///` recipes without captures or code.
- `perlop` - the `qr//` form for precompiling patterns referenced by name inside a one-liner.

Numeric and date one-liners

pperl as a calculator, stats tool, and date-arithmetic engine. This chapter collects the recipes that turn numeric columns, timestamps, and IP addresses into useful output without a script file.

The assumed baseline is a reader who has read *switches* and *progression*. The `-lane` / `-MList::Util=...` idioms used below were introduced there.

Where this chapter reaches for performance: large numeric reductions are one of the cases where pperl's JIT earns its cost. A `for (1 .. 100_000_000) { $s += $_ }` accumulation runs as compiled machine code after the interpreter warms up. You do not opt in - it triggers automatically on arithmetic-heavy numeric loops.

Plain-arithmetic one-liners

```
pperl -E 'say 2 ** 64'                                  # 1.
↪84467440737096e+19
pperl -E 'say 2 ** 64 - 1'                              # rounds (float)
pperl -MMath::BigInt -E 'say Math::BigInt->new(2)->bpow(64)'
                                                        #␣
↪18446744073709551616

pperl -E 'say 7 / 3'                                    # 2.33333333333333
pperl -E 'say int(7 / 3)'                               # 2
pperl -E 'say 7 % 3'                                    # 1
pperl -E 'say sqrt(2)'                                  # 1.4142135623731
pperl -E 'say atan2(1, 1) * 4'                          # 3.14159265358979␣
↪(pi)
```

`sprintf` controls output width and precision:

```
pperl -E 'printf "%.4f\n", 22/7'                        # 3.1429
pperl -E 'printf "%10.2f\n", 42.5'                      #      42.50
pperl -E 'printf "%08d\n", 42'                          # 00000042
pperl -E 'printf "%x %o %b\n", 255, 255, 255'           # ff 377 11111111
```

Sums, minima, maxima, averages

`List::Util` ships with Perl 5 - no install needed.

Per line

```
pperl -MList::Util=sum -lane 'print sum @F'                 data.txt
pperl -MList::Util=min -lane 'print min @F'                 data.txt
pperl -MList::Util=max -lane 'print max @F'                 data.txt

# Per-line mean
pperl -MList::Util=sum -lane 'print sum(@F) / @F'           data.txt
```

Across all lines

```
# Total sum
pperl -MList::Util=sum -lane '$s += sum @F; END { print $s }' data.
↪txt

# Running min / max using // (defined-or)
```

(continues on next page)

(continued from previous page)

```
pperl -MList::Util=min -alne '$m = min($m // (), @F); END { print $m
 ↪}' data.txt
pperl -MList::Util=max -alne '$m = max($m // (), @F); END { print $m
 ↪}' data.txt

# Mean of one column (third), ignoring blank lines
pperl -lane 'next unless /\S/; $s += $F[2]; $n++;
             END { printf "%.4f\n", $s / $n }' data.txt
```

`$m // ()` returns an empty list when `$m` is undefined, so the first iteration does not taint `min`/`max` with an undef. See `perlop` for `//`.

Sum a single column

```
# Sum of column 3 (zero-indexed: $F[2])
pperl -lane '$s += $F[2]; END { print $s }' data.txt

# Negative or zero entries only
pperl -lane '$s += $F[2] if $F[2] <= 0; END { print $s }' data.txt
```

Standard deviation

```
pperl -lane '
    $n++; $s += $_; $s2 += $_**2 for @F;
    END {
        my $n2 = $n * @F;    # total count (assumes rectangular
 ↪data)
        my $mean = $s / $n2;
        printf "mean=%.4f sd=%.4f\n",
            $mean, sqrt($s2 / $n2 - $mean ** 2);
    }
' data.txt
```

For anything beyond mean+sd, reach for `Statistics::Descriptive`:

```
pperl -MStatistics::Descriptive -lane '
    BEGIN { our $stat = Statistics::Descriptive::Full->new }
    $stat->add_data(@F);
    END { printf "median=%.2f mean=%.2f sd=%.2f\n",
          $stat->median, $stat->mean, $stat->standard_deviation }
' data.txt
```

Random numbers and sampling

```
# 10 random integers in [5, 15)
pperl -E 'say join ",", map { int(rand(10)) + 5 } 1 .. 10'
```

(continues on next page)

(continued from previous page)

```
# 8-character random lowercase password
pperl -E 'say join "", map { ("a".."z")[rand 26] } 1 .. 8'

# 8-character random alphanumeric
pperl -E 'say join "", map { ("a".."z", 0..9)[rand 36] } 1 .. 8'

# Random UUID (using Data::UUID)
pperl -MData::UUID -E 'say Data::UUID->new->create_str'

# Shuffle the fields of each line
pperl -MList::Util=shuffle -alne 'print join " ", shuffle @F' data.
↪txt

# Pick one random line from a file (reservoir sample, size 1)
pperl -ne 'rand($.) < 1 && ($pick = $_); END { print $pick }' file.
↪txt
```

The reservoir trick is the right answer when the file is too large to slurp or its line count is unknown - every line has an equal probability of being the one printed, with exactly one pass.

Factorials, GCD, LCM, primes

```
# Factorial
pperl -E '$f = 1; $f *= $_ for 1 .. 20; say $f'
pperl -MMath::BigInt -E 'say Math::BigInt->new(100)->bfac'

# GCD / LCM (built into Math::BigInt under bgcd / blcm)
pperl -MMath::BigInt=bgcd -anle 'print bgcd(@F)' nums.txt
pperl -MMath::BigInt=blcm -anle 'print blcm(@F)' nums.txt

# Euclid's algorithm for two numbers
pperl -le '$n=20; $m=35; ($m,$n) = ($n, $m % $n) while $n; print $m'
```

Primality:

```
# Regex-based primality test (Abigail). Input: one integer per line.
pperl -lne '(1 x $_) !~ /^1?$|^(11+?)\1+$/ && print "$_ prime"'␣
↪nums.txt

# Reliable for large numbers: use Math::Prime::Util
pperl -MMath::Prime::Util=is_prime -lne '
    print "$_ prime" if is_prime($_)
' nums.txt
```

The regex trick is a curiosity; `Math::Prime::Util` is the serious answer.

IP ↔ integer

```
# Dotted-quad → 32-bit integer
pperl -MSocket -le 'print unpack "N", inet_aton "127.0.0.1"'
# 2130706433

# Integer → dotted-quad
pperl -MSocket -le 'print inet_ntoa pack "N", 2130706433'
# 127.0.0.1
```

`unpack "N"` reads four bytes as a big-endian 32-bit unsigned integer. The matching `pack "N"` writes one.

Date and time

Today, now, epoch

```
pperl -E 'say time'                                    # epoch seconds
pperl -E 'say scalar localtime'                        # Mon Apr 22␣
↪14:31:07 2026
pperl -E 'say scalar gmtime'                           # same, UTC
pperl -MPOSIX=strftime -E 'say strftime "%F %T", localtime'
                                                       # 2026-04-22␣
↪14:31:07
```

`strftime` is the clean way to format; `localtime` in list context returns `(sec, min, hour, mday, mon, year, wday, yday, isdst)`.

Date arithmetic

`POSIX::mktime` normalises out-of-range fields (month 13 becomes month 1 of next year, day 32 becomes day 1 of next month, etc.), so date arithmetic means "subtract N from a field, mktime, strftime".

```
# Yesterday's date
pperl -MPOSIX=strftime -MPOSIX=mktime -E '
    my @t = localtime;
    $t[3] -= 1;
    say strftime "%F", localtime mktime @t
'

# 30 days ago
pperl -MPOSIX=strftime -MPOSIX=mktime -E '
    my @t = localtime;
    $t[3] -= 30;
    say strftime "%F", localtime mktime @t
'

# First Monday of next month
pperl -MPOSIX=strftime -MPOSIX=mktime -E '
```

(continues on next page)

(continued from previous page)

```
    my @t = localtime;
    $t[3] = 1; $t[4]++;             # first of next month
    my $epoch = mktime @t;
    my @nm = localtime $epoch;
    $epoch += ((8 - $nm[6]) % 7 || 7) * 86400 if $nm[6] != 1;
    # ^ if not already Monday, advance to next Monday
    say strftime "%F", localtime $epoch
'
```

For anything more elaborate (time zones, business-day math, ISO weeks), reach for `DateTime`:

```
pperl -MDateTime -E '
    my $d = DateTime->now->subtract(days => 30);
    say $d->strftime("%F %T %Z")
'
```

Timestamps in logs

```
# Sum the durations (last field, milliseconds) of lines matching
 ↪"slow"
pperl -lane '$s += $F[-1] if /slow/; END { print $s, " ms total" }'␣
 ↪app.log

# Count events per hour (assumes ISO timestamp first field)
pperl -lane '
    (my $hour = $F[0]) =~ s/:\d{2}:\d{2}.*//;
    $h{$hour}++;
    END { print "$_ $h{$_}" for sort keys %h }
' events.log
```

CSV and TSV

TSV with no embedded tabs: `-F'\t'` is fine. Real CSV needs `Text::CSV`:

```
# Sum the third column of a properly quoted CSV
pperl -MText::CSV -E '
    my $csv = Text::CSV->new({ binary => 1 });
    my $total = 0;
    while (my $row = $csv->getline(*STDIN)) {
        $total += $row->[2];
    }
    say $total
' < data.csv

# Re-emit a CSV with only selected columns
pperl -MText::CSV -E '
    my $csv = Text::CSV->new({ binary => 1, eol => "\n" });
```

(continues on next page)

(continued from previous page)

```
    while (my $row = $csv->getline(*STDIN)) {
        $csv->print(*STDOUT, [ @{$row}[0, 2, 4] ]);
    }
' < data.csv > trimmed.csv
```

The `binary => 1` option keeps bytes intact; the `eol => "\n"` option makes `print` append newlines.

JSON

`JSON::PP` ships with Perl; `Cpanel::JSON::XS` is faster if it is installed.

```
# Extract the "name" field from each line of NDJSON
pperl -MJSON::PP -lne '
    my $o = JSON::PP->new->decode($_);
    print $o->{name};
' events.ndjson

# Convert each line of TSV to JSON
pperl -MJSON::PP -F'\t' -lane '
    print JSON::PP->new->encode({ id => $F[0], name => $F[1] })
' data.tsv

# Pretty-print a single JSON document
pperl -MJSON::PP -0777 -ne '
    print JSON::PP->new->pretty->encode(JSON::PP->new->decode($_))
' small.json
```

For large JSON, streaming parsers (`JSON::Streaming::Reader`) beat slurping; single-document files under a few hundred megabytes are fine with the above.

Base64, URL encoding, hex

```
# Base64 encode/decode (of a whole file)
pperl -MMIME::Base64 -0777 -ne 'print encode_base64($_)' file
pperl -MMIME::Base64 -0777 -ne 'print decode_base64($_)' file.b64

# URL encode/decode
pperl -MURI::Escape -lne 'print uri_escape($_)'   < urls.txt
pperl -MURI::Escape -lne 'print uri_unescape($_)' < encoded.txt

# Hex ↔ integer
pperl -E 'printf "%x\n", 255'                     # ff
pperl -E 'say hex "ff"'                           # 255

# Hex dump of a file (like xxd -p)
pperl -0777 -ne 'print unpack "H*", $_' file.bin
```

(continues on next page)

(continued from previous page)

```
# Reverse: hex dump → bytes
pperl -0777 -ne 'chomp; print pack "H*", $_' file.hex > file.bin
```

Find out more

- *aliases* - wrap the recipes you use weekly into shell functions with positional arguments.
- *progression* - the reduction idioms these numeric recipes build on.
- `sprintf`, `printf` - formatted output.
- `time`, `localtime`, `gmtime` - the built-ins underneath the date recipes.

From one-liner to shell alias

A one-liner is disposable by design. The moment you type the same one twice, something has earned a place in your shell config. This chapter covers the mechanics of lifting a pperl recipe into a bash or zsh shell function, how to parametrise it, and when to stop and write a real script instead.

Assumed baseline: you have a bash or zsh shell, a `~/.bashrc` or `~/.zshrc` (or an `rc.d` / `functions` directory your shell sources), and the patience to close and reopen one terminal after editing it.

Alias versus function

Bash and zsh have two mechanisms. They are not interchangeable.

- `alias` is textual substitution. It runs at the start of a command line, replacing the alias name with its value before the shell re-parses. No arguments, no pipelining quirks beyond what substitution gives you.
- A shell function is a named piece of shell code. It takes positional arguments (`$1`, `$2`, `$@`), reads stdin like any other command, and can pipe into and out of other commands.

Rule of thumb. If the recipe takes no arguments, alias is enough. If it needs any argument (a column number, a regex, a filename), use a function.

Alias - the zero-argument recipe

```
# In ~/.bashrc
alias sum-stdin='pperl -MList::Util=sum -lane '"'"'print sum @F'"'"'
alias count-lines='pperl -lne '"'"'END { print $. }'"'"'
```

The quoting is ugly because a bash single-quoted string cannot contain a single quote; the idiom `'"'"'` closes-and-reopens. This is the main reason to prefer functions: they let you quote the Perl once, cleanly.

Function - the common case

```
# In ~/.bashrc
sum-stdin() { pperl -MList::Util=sum -lane 'print sum @F'; }
count-lines() { pperl -lne 'END { print $. }'; }
```

Usage is the same:

```
$ printf '1 2 3\n4 5 6\n' | sum-stdin
6
15
```

Parametrised functions

The shell interpolates `$1`, `$@`, `"$1"` into the function body before executing it. Inside the Perl program, the shell-level `$1` appears as a literal value - Perl's own `$1` (the regex capture) is untouched by shell interpolation only if you quote with single quotes.

The mixture is solvable with care. Two idioms cover almost every case.

Idiom 1: shell-interpolated column / value

Use double quotes around the Perl program so the shell expands `$1`, then escape Perl's own `$` with `\$`.

```
# Sum column N of stdin: sumcol N
sumcol() {
    pperl -MList::Util=sum -lane "\$s += \$F[$1]; END { print \$s }"
}

# Usage
$ cat data.tsv
10 apple 3
15 pear  7
20 plum  2
$ sumcol 2 < data.tsv
12
```

Every `\$` is a literal dollar sign for Perl; every `$1` (unescaped) is the first positional argument expanded by the shell.

Idiom 2: program in single quotes, data via environment

Single-quoted Perl stays readable, and values reach the program via `%ENV`.

```
# Grep with a pperl regex: pgrep PATTERN [FILE...]
pgrep() {
    local pat=$1
    shift
    pat="$pat" pperl -ne 'print if /$ENV{pat}/' "$@"
}
```

(continues on next page)

(continued from previous page)

```
$ pgrep '\berror\b' app.log
```

This keeps $1 (Perl capture) usable and avoids the backslash cascade.

Idiom 3: mixing both

```
# Replace column N's commas with semicolons, in place: csv-fix N␣
↪FILE...
csv-fix() {
    local col=$1
    shift
    col="$col" pperl -i.bak -F'\t' -lane '
        my $c = $ENV{col};
        $F[$c] =~ tr/,/;/;
        print join("\t", @F);
    ' "$@"
}
```

The column number arrives in `$ENV{col}` - no escaping dance. The file list propagates via `"$@"` so spaces in filenames survive.

Practical aliases worth keeping

Annotated list of recipes that earn their place in a shell config for anyone who processes text at the command line daily.

`sumcol N` - sum column N (whitespace-separated)

```
sumcol() {
    pperl -MList::Util=sum -lane "\$s += \$F[$1]; END { print \$s }"
}
```

`sumcolf N FS` - sum column N with custom field separator

```
sumcolf() {
    local col=$1 fs=$2
    col="$col" pperl -MList::Util=sum -F"$fs" -lane '
        $s += $F[$ENV{col}]; END { print $s }
    '
}

$ sumcolf 3 : < /etc/passwd    # sum of UIDs
```

`colstats N` - min / max / mean / count for column N

```
colstats() {
    col="$1" pperl -MList::Util=qw(min max sum) -lane '
        my $c = $ENV{col};
        push @v, $F[$c];
        END {
            printf "n=%d min=%g max=%g mean=%.4f\n",
                scalar @v, min(@v), max(@v), sum(@v) / @v
        }
    '
}
```

`uniq-stream` - streaming unique, keeping first sighting

```
uniq-stream() { pperl -ne 'print unless $seen{$_}++'; }
```

Unlike `sort -u`, order is preserved. Unlike `uniq`, input need not be sorted.

`extract PAT` - print every match of a regex, one per line

```
extract() { pat="$1" pperl -lne 'print for /$ENV{pat}/g'; }

$ extract '\b\d{3}-\d{4}\b' < phonebook.txt
555-1212
555-9876
```

`between A B` - print everything between regex A and regex B, inclusive

```
between() {
    a="$1" b="$2" pperl -ne 'print if /$ENV{a}/ .. /$ENV{b}/'
}

$ between 'BEGIN cert' 'END cert' < bundle.pem
```

`json-pretty` - pretty-print a single JSON document

```
json-pretty() {
    pperl -MJSON::PP -0777 -ne '
        print JSON::PP->new->pretty->canonical->encode(
            JSON::PP->new->decode($_)
        )
    '
}
```

`passwd-json` - /etc/passwd as NDJSON

```
passwd-json() {
    pperl -MJSON::PP -F: -lane '
        print JSON::PP->new->encode({
            user => $F[0], uid => 0+$F[2], gid => 0+$F[3],
            home => $F[5], shell => $F[-1]
        })
    ' < /etc/passwd
}
```

`words-by-freq` - count word frequencies, sorted

```
words-by-freq() {
    pperl -ne '
        $w{lc $_}++ for /\b[[:alpha:]]+\b/g;
        END { print "$w{$_} $_\n" for sort { $w{$b} <=> $w{$a} }␣
↪keys %w }
    '
}

$ words-by-freq < essay.txt | head -20
```

`strip-comments LANG` - strip comments for a few common languages

```
strip-comments() {
    case "$1" in
        sh|py|rb|pl) pperl -pe 's/(?<!\\)#.*//' ;;
        c|cpp|rs|java|js) pperl -0777 -pe 's{//[^\n]*|/\*.*?\*/}{}gs
↪' ;;
        sql|lua) pperl -pe 's/--[^\n]*//' ;;
        *) echo "unknown language: $1" >&2; return 1 ;;
    esac
}
```

When to stop and write a script

The one-liner → alias transition ends when:

- The program needs an `if` / `else` branch longer than a single `? :` conditional.
- There are more than two or three `-M` modules.
- You find yourself debugging via trial-and-error on the command line.
- The program is the only alias in your config that gets a comment above it explaining what it does.
- A colleague is going to run it.

Move to a script file. Drop the switches into the shebang line and let the program read naturally:

```
#!/usr/bin/env pperl
use strict;
use warnings;
use List::Util qw(sum);

my $col = shift @ARGV // die "usage: $0 COLUMN [FILE...]\n";
my $total = 0;
while (<>) {
    my @f = split;
    $total += $f[$col];
}
print "$total\n";
```

Give it a sensible name, `chmod +x`, and move on. The one-liner did its job: it was the shortest path from "I have an idea" to "I know this works"; the script is the path from "I know this works" to "my colleague can read it."

Find out more

- *progression* - the recipes these aliases wrap.
- *gotchas* - quoting inside shell functions and aliases.
- *numeric* - more candidates for the alias list, especially the date-arithmetic ones.

Traps and surprises

The ways pperl one-liners silently do something other than what the shell user meant. Each section names a trap, shows its symptom, and gives the fix. Read straight through once to prime the pattern-match; come back when a recipe is misbehaving.

Quoting hell

The single biggest source of wasted time in one-liner work.

Single quotes are your friend

Under bash and zsh, text inside single quotes is not interpolated. No `$VAR` expansion, no backtick execution, no `!` history substitution (zsh doesn't do `!`; bash does, and it bites). Use single quotes for Perl programs unless you have a reason not to.

```
# Correct
pperl -ne 'print if /$var/' file              # Perl sees literal
 ↪$var

# Trap
pperl -ne "print if /$var/" file              # shell expands $var␣
 ↪before pperl sees it
```

The ! surprise in interactive bash

```
$ pperl -E 'say "hello!"'
bash: !": event not found
```

Bash's history expansion fires on unquoted `!` (and some escaped forms). Workarounds:

- `set +H` in `~/.bashrc` disables history expansion.
- Escape the `!` when writing the command: `"hello\!"`.
- Keep the shell's single-quoted string around the program - `!` is inert inside `'...'` once history expansion is off.

A single quote inside a single-quoted string

Bash has no escape for it. The workaround is the four-character close-open dance: `'\''` reads as close-quote, literal-quote, open-quote.

```
# Want Perl to see:  print "it's here"
pperl -e 'print "it'\''s here\n"'
```

For any program with more than one embedded apostrophe, give up on `'...'` and use `q/.../` inside double quotes:

```
pperl -e "print q/it's here/, qq/\n/"
```

or move the program into a file.

The $ escape cascade under double quotes

If you quote the Perl program in double quotes (because you want `$1` to interpolate from the shell), Perl's own variables need `\$`:

```
col=3
pperl -lane "\$s += \$F[$col]; END { print \$s }"      # works
```

That is legible once. After the third such one-liner in a row, move to environment variables:

```
col=3
col=$col pperl -lane '$s += $F[$ENV{col}]; END { print $s }'
```

See *aliases#parametrised-functions*.

Locale and encoding

pperl's default I/O is bytes. If your input is UTF-8, Perl still sees a byte string until you ask for otherwise.

The symptom

```
$ echo 'héllo' | pperl -lne 'print length'
6                                                  # "h" + 2 bytes for é
↪+ 3 more = 6
$ echo 'héllo' | pperl -CSD -lne 'print length'
5                                                  # correct
```

The fix is `-C` (see *switches*):

- `-CSD` - STDIN/STDOUT/STDERR and file opens all UTF-8.
- `-CS` - stdio only.
- `-CA` - treat `@ARGV` as UTF-8.

Regex matching on UTF-8

Without `-C`, `\w` matches ASCII word characters only. With `-C`, `\w` matches Unicode letters/digits as defined by Perl's Unicode property tables.

```
# Count "word" characters in a multilingual file
pperl -CSD -lne '$c += () = /\w/g; END { print $c }' file.txt
```

Mojibake on the way out

If pperl is reading UTF-8 cleanly but the terminal shows garbled characters, the problem is further down - likely `LC_ALL` or the terminal's own encoding. `locale` and `tput` diagnose it; this is not a pperl problem.

`-i` in-place editing

Always `.bak` until verified

```
# Destructive if the pattern is wrong
pperl -i -pe 's/OLD/NEW/g' *.conf

# Safe
pperl -i.bak -pe 's/OLD/NEW/g' *.conf
# ...verify...
rm *.conf.bak
```

A wrong pattern with bare `-i` replaces the file's contents with something useless. There is no recovery short of version control. Use `-i.bak`, confirm, delete.

The empty-file trap

`-i` writes whatever `-p` (or `-n` plus explicit prints) emits. If the program prints nothing, the file becomes empty.

```
# Wrong: -i with -n and no print - empties the file
pperl -i -ne '/KEEP/ && print' file.txt      # prints only lines
↪matching KEEP

# Same thing, probably what you meant: keep the matching lines
pperl -i -ne 'print if /KEEP/' file.txt
```

Both are correct. The point: under `-n`, you own every byte of output.

In-place across many files with ownership caveats

`-i` creates a new file and renames. On Linux, this means the new file inherits the calling user's ownership and umask. Root-owned configs edited by non-root users will fail; root-owned configs edited by root will keep the mode but may lose SELinux context. Know your threat model before pointing `-i` at `/etc`.

The diamond operator <> and magic open

<> (the "diamond") is what `-n` / `-p` reads from. It reads from each argument in `@ARGV` as a filename, falling back to STDIN if `@ARGV` is empty.

The "-" is STDIN

If an argument is `"-"`, <> reads STDIN at that point. Useful for interleaving:

```
echo prefix | pperl -ne 'print' - trailer.txt
# prints: prefix, then contents of trailer.txt
```

Filename metacharacters (and why they matter less than they used to)

Historically, bare <> treated `">foo"` as "open foo for writing" - a two-argument open that read the mode from the filename. Modern Perl's <> uses three-argument open internally, so filenames starting with <, >, |, or containing pipes are treated as plain filenames. No attack surface on input filenames with modern pperl.

Filename is in $ARGV

```
pperl -lne 'print "$ARGV: $_" if /\bERROR\b/' *.log
```

`$ARGV` updates as each file opens. `"-"` is the special value for STDIN.

$. keeps counting across files

`$.` is not reset when <> moves to the next file. If you want per-file line numbers:

```
pperl -lne 'close ARGV if eof; print "$ARGV:$.: $_" if /TODO/' *.pl
```

`close ARGV if eof` resets `$.` when the current file ends.

Record-separator traps

`-l` removes then restores - once

`-l` chomps input and sets `$\` to the chomped separator for output. Fine under `-n` / `-p`. But `-l` applied twice (say, you added `-l` after `-0`) confuses people:

```
# Read NUL-delimited input, output newline-terminated
pperl -0 -lpe ''                              # correct: -l sets $\
 ↪= "\n"

# But if you write -l0 Perl parses that as -l with argument 0:
pperl -l0 -pe ''                              # $\ becomes NUL -
 ↪probably NOT what you wanted
```

Put `-l` after `-0` (no argument to `-l`) when you want the standard pair.

Paragraph mode keeps trailing blanks

`-00` (paragraph mode) sets `$/ = ""`. Perl reads up to and including the blank-line separator. Without `-l`, the separator stays attached to each paragraph; printing it back out preserves the blank line. With `-l`, the separator is chomped and `$\ = "\n"` appends one newline on output - paragraphs collapse.

```
$ printf 'a\n\nb\n\nc\n' | pperl -00 -pe ''
a

b

c
$ printf 'a\n\nb\n\nc\n' | pperl -00 -lpe ''
a
b
c
```

Know which one you want.

`-0777` and `$.`

Under `-0777`, each file is one record. `$.` increments per record, so `$.` is the number of files processed, not the number of lines.

```
pperl -0777 -e 'while (<>) { print "file $.: length=", length, "\n"
 ↪}' *.txt
# file 1: length=1024
# file 2: length=2048
```

The -F interpretation of its argument

`-F` takes a regex. Perl versions before 5.10 required you to write the delimiters; modern pperl accepts both forms:

```
pperl -F:      -lane '...'                    # bare: Perl quotes it
pperl -F/:/    -lane '...'                    # explicit delimiters
pperl -F'\t'   -lane '...'                    # tab - regex form
```

The common mistake is a literal tab in a shell where the terminal swallowed it:

```
pperl -F'        ' -lane '...'                  # fragile: tab may␣
↪be a space in your paste
```

Write `-F'\t'` unless you are pasting from known-good source.

Operator precedence around `print`

`print` has lower precedence than most operators. This trips people whose `awk` reflex is wrong for Perl:

```
# Wrong: prints into a filehandle named "..."
pperl -ne 'print "out.txt" $_'

# Right: parentheses or commas
pperl -ne 'print $_, "\n"'
pperl -ne 'print("foo\n")'

# Wrong: the binary || applies to print's argument list
pperl -ne 'print if $_ || "never"'            # works but obscure

# One particular case worth memorising:
pperl -ne 'print (1+1)*2'                     # prints 2, not 4
# ^ print(1+1) is the function call; *2 is applied to its return␣
↪value
```

When in doubt, put parentheses around `print`'s arguments or end the program with an explicit semicolon.

`tr` is not a regex

`tr` / `y` take character sets, not patterns. `tr/\d/X/` does NOT match digits - it replaces literal backslash-d characters.

```
pperl -pe 'tr/0-9/X/'                         # replace digits with␣
↪X (character range)
pperl -pe 's/\d/X/g'                          # replace digits with␣
↪X (regex)
```

Use `tr` for character-class work (case conversion, deletion, ranges) and `s///` when you need any regex machinery.

BEGIN and END scope

`BEGIN { ... }` and `END { ... }` blocks are part of the program, not the loop body. Variables declared with `my` inside `BEGIN` are not visible to the loop body. Use `our` or global variables for state that needs to persist from `BEGIN` into the loop:

```
# Wrong: $greeting is not in scope inside the loop
pperl -ne 'BEGIN { my $greeting = "Hi"; } print "$greeting $_"'

# Right: declare without my, or use our
pperl -ne 'BEGIN { $greeting = "Hi"; } print "$greeting $_"'
```

In practice, most `BEGIN` blocks do setup with side effects (`$\ = "\n"`, setting a format) rather than bindings.

die and the \n convention

`die` without a trailing `\n` appends `" at -e line N.\n"` to its message. With a trailing `\n`, it prints the message as-is. Choose deliberately:

```
# Developer diagnostic - want the location
pperl -E 'die "unreachable" if $x > 100'

# User-facing message - don't leak program structure
pperl -E 'die "bad input\n" unless /\d+/'
```

The same rule applies to `warn`.

Missing newline at end of file

If the last line of an input file has no trailing newline, `-l` still chomps what's there (nothing), and `$_` still lacks a `\n`. `-p` reprints it without a final newline, and the next line of shell output runs into it. Rarely a correctness problem; often a display problem.

```
pperl -pe '' no-final-newline.txt              # output lacks␣
↪trailing \n
```

4.2.8 Tying variables

A **tied** variable looks like an ordinary scalar, array, hash, or filehandle, but every read, write, and iteration on it is rerouted through methods you write. The variable is the public face; a class of your design is the machinery behind it. Assigning to a tied scalar calls your `STORE`; reading a tied hash key calls your `FETCH`; running `keys` over a tied

hash drives your FIRSTKEY and NEXTKEY. The caller writes plain Perl and never sees the class.

That indirection is what makes tie powerful. A hash can be a façade over an on-disk database. A scalar can recompute itself on every read. A filehandle can collect everything printed to it into a string. The code using the variable does not change; only the class behind it does.

This guide is about **writing the class** - the part perltie calls the implementation. The built-in side (tie, tied, untie) and the full method menus per variable type are already documented on the tie reference page. This guide links there for signatures and concentrates on what those pages do not teach: how to build a working tie class, what each method must return, and exactly when the runtime calls it.

Which chapter you want

Each variable type has its own constructor and its own method set. Read the chapter that matches the sigil in front of you.

- *Tied scalars* - TIESCALAR, FETCH, STORE, DESTROY. The smallest tie interface; start here to learn the shape of all the others.
- *Tied hashes* - TIEHASH plus the iteration protocol (FIRSTKEY / NEXTKEY), EXISTS, DELETE, CLEAR, and SCALAR. The richest of the data types.
- *Tied arrays* - TIEARRAY, the size protocol (FETCHSIZE / STORESIZE / EXTEND), and the mutators (PUSH, POP, SHIFT, UNSHIFT, SPLICE).
- *Tied filehandles* - TIEHANDLE and the I/O hooks (PRINT, PRINTF, WRITE, READLINE, READ, GETC, and friends).

How each chapter is built

Every chapter follows the same shape:

- **The contract by example.** Rather than restate the method menu (the tie reference page already lists every signature), each chapter builds one complete, runnable class and explains each method as it appears.
- **Call timing.** The non-obvious part of tie is *when* the runtime invokes each hook - which operator triggers which method, in which context, with which arguments. Each chapter spells this out.
- **Minimum viable vs. full.** The fewest methods you can define and still have a usable tie, then the rest of the menu and what each one buys you.
- **The easy way.** Each data type ships a Tie::* base class that implements the tedious methods in terms of a few core ones. Inherit from it and override only the interesting hooks.

What ties cost

Every operation on a tied variable is a method call. A tied hash lookup is a FETCH dispatch where a plain hash lookup is a single memory access - visibly slower in a tight loop. Tie is the right tool when the indirection earns its keep (a variable backed by a file, a computed value, a logging façade), not when you simply want a fancier hash. For bulk

work over a tied container, read it into a plain array or hash once, operate, and write back.

Differences from upstream

The tie mechanism is Perl 5.44's own, so tie classes behave exactly as they do on upstream Perl.

Tied scalars

A tied scalar is the smallest tie interface and the best place to learn the shape of all the others. You define a constructor and two accessor methods; from then on, every read of the variable calls one of them and every write calls the other.

The class needs four methods, two of them optional:

- `TIESCALAR` - the constructor, called once by `tie`.
- `FETCH` - called on every read of the variable.
- `STORE` - called on every write to the variable.
- `DESTROY` - called when the tied variable goes away (optional).

The full signature list is on the `tie` reference page. This chapter shows what each method does by building one.

A complete class

A counter that clamps writes so the value never drops below zero:

```
use v5.36;

package Counter {
    sub TIESCALAR {
        my ($class, $start) = @_;
        my $n = $start // 0;
        return bless \$n, $class;
    }
    sub FETCH { my $self = shift; return $$self }
    sub STORE {
        my ($self, $value) = @_;
        $$self = $value < 0 ? 0 : $value;   # never go below zero
    }
    sub DESTROY { }
}

tie my $hits, 'Counter', 10;
say $hits;            # 10
$hits = 25;
say $hits;            # 25
$hits = -7;
say $hits;            # 0
```

The object behind the scalar can be anything blessed - here a reference to a plain number. The `LIST` after the class name in the `tie` call (`10`) is passed straight to `TIESCALAR`.

The method contract

`TIESCALAR classname, LIST`
: The constructor. It receives the class name and whatever extra arguments were passed to `tie`. It must return a blessed reference; that reference becomes the tied object and the return value of the `tie` call. A common shortcut is a blessed scalar ref holding the value, as above, but a blessed hash ref is just as valid when the class needs more state.

`FETCH this`
: Called every time the variable is read. It takes only the object. Whatever it returns is what the reader sees. `FETCH` is where a computed scalar earns its keep: it can recompute, look something up, or log the access and return a stored value.

`STORE this, value`
: Called every time the variable is assigned. It receives the object and the single new value. Its return value is ignored - the assignment expression's value comes from a subsequent `FETCH`, not from `STORE`. This is where validation, clamping, or write-through to a backing store lives.

`DESTROY this`
: Called when the tied variable is destroyed (scope exit, or the last reference dropping). Define it only when the class holds a resource that needs releasing - an open handle, a lock. A counter has nothing to clean up, so its `DESTROY` is empty or omitted entirely.

Call timing

- Reading in any context calls `FETCH`. `say $hits`, `$x = $hits + 1`, and `"$hits"` each trigger one `FETCH`.
- Assignment calls `STORE` with the right-hand value. `$hits = 25` calls `STORE($obj, 25)`.
- Compound assignment reads then writes: `$hits += 5` calls `FETCH`, adds 5, then `STORE`. So does `$hits++`.
- The value of an assignment expression comes from `FETCH`, not `STORE`'s return. After `my $r = ($hits = -7)`, `$r` is `0` because the clamp ran in `STORE` and the expression's value was fetched back.

Minimum viable class

The smallest useful tied scalar defines exactly `TIESCALAR`, `FETCH`, and `STORE`. Omit `DESTROY` unless you allocate something. A class with only `TIESCALAR` and `FETCH` produces a read-only scalar: it ties fine, but the first assignment dies with `Can't locate object method "STORE"`.

The easy way: inherit from `Tie::StdScalar`

`Tie::StdScalar` (shipped inside `Tie::Scalar`) implements `TIESCALAR`, `FETCH`, `STORE`, and `DESTROY` over a blessed scalar ref. Inherit from it and override only the hook you want to change:

```
package Uppercase {
    use Tie::Scalar;
    our @ISA = ('Tie::StdScalar');
    sub STORE { my ($self, $v) = @_; $$self = uc $v }
}

tie my $shout, 'Uppercase';
$shout = 'hello';
say $shout;          # HELLO
```

`STORE` upper-cases on the way in; `FETCH` and the constructor come from the base class unchanged.

`Tie::Scalar` itself is the *abstract* base - it defines `FETCH` and `STORE` that croak, so subclassing it directly means supplying your own `TIESCALAR`. Reach for `Tie::StdScalar` when you want a working constructor for free; reach for `Tie::Scalar` only when you intend to write every method anyway and want the interface documented by inheritance.

- *Tied hashes* - the next step up: a constructor plus an iteration protocol
- `Tie::Scalar` - the base-class module; `Tie::StdScalar` is the concrete version you usually want

Tied hashes

A tied hash is the richest of the tie types, because a hash does more than read and write single elements - it iterates, it reports its size, it tests for key existence, and it clears. Each of those is a separate hook. Hashes were the first Perl data type to be tied (the original use case was binding `%hash` to an on-disk DBM file), and the interface still reflects that heritage.

The full method menu is on the `tie` reference page. This chapter builds one class and explains each hook, with attention to the part that trips people up: the iteration protocol.

A complete class

A hash whose keys are case-insensitive - `$h{Name}` and `$h{NAME}` address the same slot:

```
use v5.36;

package CaseInsensitive {
    sub TIEHASH  { my $class = shift; return bless {}, $class }
    sub STORE    { my ($self, $key, $val) = @_; $self->{lc $key} =
 ↪$val }
    sub FETCH    { my ($self, $key) = @_; return $self->{lc $key} }
    sub EXISTS   { my ($self, $key) = @_; return exists $self->{lc
 ↪$key} }
    sub DELETE   { my ($self, $key) = @_; return delete $self->{lc
 ↪$key} }
    sub CLEAR    { my $self = shift; %$self = () }
    sub FIRSTKEY { my $self = shift; my $reset = keys %$self; return␣
 ↪each %$self }
    sub NEXTKEY  { my $self = shift; return each %$self }
    sub SCALAR   { my $self = shift; return scalar %$self }
}

tie my %h, 'CaseInsensitive';
$h{Name}  = 'Ada';
$h{EMAIL} = 'ada@example.org';

say $h{name};                           # Ada
say $h{email};                          # ada@example.org
say exists $h{NAME} ? 'yes' : 'no';     # yes
say scalar %h ? 'nonempty' : 'empty';   # nonempty

for my $k (sort keys %h) {
    say "$k => $h{$k}";
}
# email => ada@example.org
# name => Ada
```

The object is a blessed hash ref used as the real storage; the hooks lower-case the key before touching it. Notice that iteration returns the *stored* (lower-cased) keys, which is exactly what a case-insensitive hash should do.

The method contract

`TIEHASH classname, LIST`
: The constructor. Returns a blessed reference - usually but not necessarily a hash ref - that becomes the tied object.

`FETCH this, key` / `STORE this, key, value`
: Single-element read and write, the same pair as for scalars but with a key argument. `STORE`'s return value is ignored.

`EXISTS this, key` / `DELETE this, key`
: Back the `exists` and `delete` built-ins. `DELETE`'s return value becomes `delete`'s

return value; to match a plain hash, return what FETCH would have returned for that key before removing it.

CLEAR this
Triggered when the whole hash is emptied, typically by assigning the empty list (%h = ()). Remove everything.

FIRSTKEY this / NEXTKEY this, lastkey
The iteration protocol - see below. Together they drive keys, values, and each.

SCALAR this
Called when the hash is evaluated in scalar or boolean context (scalar %h, if (%h), and since 5.28 keys %h in boolean context). Return a value that is true when the hash is non-empty and false when empty.

DESTROY this and UNTIE this
Optional cleanup hooks, identical in role to the scalar case. UNTIE is covered under the untie gotcha below.

The iteration protocol

This is the part of the hash interface that has no analogue in the scalar one, and the part that most often goes wrong.

When a keys, values, or each iteration begins, the runtime calls FIRSTKEY to get the first key, then NEXTKEY repeatedly, passing the previously returned key each time, until a method returns the empty list or undef. Both are always called in scalar context and should return just a key; the runtime calls FETCH itself to get each value.

Two rules keep iteration correct:

- **FIRSTKEY must reset any internal iterator.** When the backing store is a real hash, evaluate keys %$self in void or scalar context first - that resets Perl's per-hash each cursor - then call each. The throwaway my $reset = keys %$self in the example does exactly this. Skip it and a fresh keys %h may resume from wherever the last iteration stopped.
- **Signal the end with the empty list.** When the backing store is not a real hash and has no each of its own, return the empty list (or undef) once you have handed out the last key.

Why SCALAR is worth defining

Without a SCALAR method, the runtime guesses at the hash's truth in boolean context, and the guess can be wrong - notably, it may report a hash as non-empty right after you have emptied it by repeated DELETE. If if (%tied_hash) matters to your callers, define SCALAR and return the real answer, as the example does with scalar %$self.

Call timing

- $h{k} reads → FETCH; $h{k} = $v → STORE.
- exists $h{k} → EXISTS; delete $h{k} → DELETE.
- %h = () → CLEAR; %h = (a => 1) → CLEAR then STORE.

- `keys %h` / `values %h` / `each %h` → `FIRSTKEY` once, then `NEXTKEY` per step. `keys` and `values` in list context call `FETCH` for each key as well.
- `scalar %h`, `if (%h)` → `SCALAR` (if defined).
- A hash slice `@h{qw(a b)}` calls `FETCH` once per key; there is no slice hook.

Minimum viable class

A read/write tied hash needs at least `TIEHASH`, `FETCH`, and `STORE`. If callers will ever iterate it, add `FIRSTKEY` and `NEXTKEY` - without them, `keys` and `each` see an empty hash. Add `EXISTS` and `DELETE` if callers use those built-ins; without them, `exists`/`delete` die at the point of use. `SCALAR` and `CLEAR` round out correctness for boolean tests and bulk emptying.

The easy way: inherit from `Tie::StdHash`

`Tie::StdHash` (shipped inside `Tie::Hash`) implements the entire menu over a blessed hash ref. Inherit from it and override only the hooks that should behave differently:

```
package LoudHash {
    use Tie::Hash;
    our @ISA = ('Tie::StdHash');
    sub STORE { my ($self, $k, $v) = @_; $self->{$k} = uc $v }
}

tie my %loud, 'LoudHash';
$loud{greeting} = 'hi';
say $loud{greeting};                # HI
```

Only `STORE` changes; `FETCH`, `EXISTS`, the iteration protocol, and the constructor all come from the base class. `Tie::Hash` (the parent) is the abstract version that supplies a default `TIEHASH` and `new` but leaves the access methods for you to write; `Tie::StdHash` is the concrete one you usually want.

See also

- `tie` - the built-in and the full hash method menu
- `tied` - reach the backing object for class-specific methods
- `each` - the iterator that `FIRSTKEY` / `NEXTKEY` implement; its own page documents the end-of-iteration contract
- `exists` and `delete` - the built-ins behind `EXISTS` and `DELETE`
- *Tied scalars* - the simpler interface this one builds on
- `Tie::Hash` - the base-class module; `Tie::StdHash` is the concrete version

Tied arrays

A tied array has two layers of interface. The lower layer - `FETCH`, `STORE`, `FETCHSIZE`, `STORESIZE`, `CLEAR` - is mandatory and handles element access and resizing. The upper layer - `PUSH`, `POP`, `SHIFT`, `UNSHIFT`, `SPLICE`, `DELETE`, `EXISTS` - is optional and lets the array respond to the matching built-ins; without a given hook, that built-in either falls back to the lower layer or dies.

The full menu is on the `tie` reference page. This chapter builds a class, then explains the size protocol and the optional mutators, with their call timing verified against the running interpreter.

A complete class

A numeric array whose empty slots read back as `0` instead of `undef`, and whose `STORESIZE` pads new slots with `0`:

```
use v5.36;

package ZeroFill {
    sub TIEARRAY  { my $class = shift; return bless { data => [] },
 ↪$class }
    sub FETCH     { my ($self, $i) = @_; return $self->{data}[$i] //
 ↪0 }
    sub STORE     { my ($self, $i, $v) = @_; $self->{data}[$i] = $v
 ↪}
    sub FETCHSIZE { my $self = shift; return scalar @{ $self->{data}
 ↪} }
    sub STORESIZE {
        my ($self, $n) = @_;
        my $data = $self->{data};
        if ($n > @$data) {
            push @$data, (0) x ($n - @$data);   # pad with 0, not
 ↪undef
        } else {
            $#$data = $n - 1;
        }
    }
    sub CLEAR { my $self = shift; $self->{data} = [] }
    sub PUSH  { my $self = shift; push @{ $self->{data} }, @_;
 ↪return scalar @{ $self->{data} } }
    sub POP   { my $self = shift; return pop @{ $self->{data} } }
}

tie my @a, 'ZeroFill';
$a[0] = 11;
$a[2] = 33;                 # FETCH on the skipped slot 1 reads back
 ↪0
say scalar @a;              # 3
say $a[1];                  # 0
$#a = 4;                    # STORESIZE grows the array, padding with
```

(continues on next page)

(continued from previous page)

```
↪0
say "@a";                   # 11 0 33 0 0
push @a, 44;
say pop @a;                 # 44
```

The object is a blessed hash ref wrapping a real array in its `data` slot - a common pattern, because the class usually wants room for state beyond the array itself.

The mandatory layer

`TIEARRAY classname, LIST`
: The constructor; returns a blessed reference that becomes the tied object.

`FETCH this, index` / `STORE this, index, value`
: Single-element read and write. A negative index is translated to a positive one - the runtime calls `FETCHSIZE` first and adds it to the index - unless the class sets `$NEGATIVE_INDICES` to a true value, in which case the raw negative index reaches `FETCH` and `STORE`.

`FETCHSIZE this`
: Returns the number of elements. This backs `scalar @array` and the high-water mark for `$#array`. It is the single most-called method on a tied array, since the runtime needs the size to normalise negative indices and to bound iteration.

`STORESIZE this, count`
: Sets the array's length. Growing should fill the new slots with the class's notion of "empty" (here, `0`); shrinking should drop the excess. This backs `$#array = N` and assignment-driven resizing.

`CLEAR this`
: Empties the array - triggered by `@array = ()`.

The size protocol in practice

`FETCHSIZE` and `STORESIZE` are where tied arrays differ most from tied hashes. Three things to keep straight:

- **`$#a` reads through `FETCHSIZE` and writes through `STORESIZE`.** Setting `$#a = 4` calls `STORESIZE($obj, 5)`.
- **Skipped slots are the class's problem.** Assigning `$a[2]` when the array has length 1 calls `STORE($obj, 2, ...)` directly - the runtime does *not* call `STORESIZE` to fill the gap. If a read of slot 1 should return `0` rather than `undef`, `FETCH` has to say so (the `// 0` in the example).
- **`EXTEND` is advisory.** When the runtime expects an array to grow - for instance just before a large assignment - it may call `EXTEND this, count` as a hint to pre-allocate. It is always safe to leave `EXTEND` undefined or empty; it is purely an optimisation opportunity, and making it behave like `STORESIZE` is a bug, because the runtime calls `EXTEND` at times when it does not actually want the visible length to change.

The optional mutators

Each of `push`, `pop`, `shift`, `unshift`, `splice`, `delete`, and `exists` dispatches to the uppercase hook of the same name when the class defines it. Their call timing, confirmed against the interpreter:

- `push @a, 1, 2` → one `PUSH` call with the whole list.
- `pop @a` → `POP`; `shift @a` → `SHIFT`; `unshift @a, 0` → `UNSHIFT`.
- `splice @a, 1, 1, 'x', 'y'` → one `SPLICE` call carrying offset, length, and the replacement list; its return value becomes `splice`'s.
- `exists $a[0]` → `EXISTS`; `delete $a[0]` → `DELETE`.

When a mutator hook is **absent**, behaviour depends on the operator. `Tie::Array` (below) supplies fallbacks for the common five in terms of the mandatory layer; without that base class, calling an unimplemented mutator dies at the point of use.

Call timing

- `$a[$i]` → `FETCH`; `$a[$i] = $v` → `STORE`.
- `scalar @a`, normalising a negative index → `FETCHSIZE`.
- `$#a = $n`, `@a = (...)` resizing → `STORESIZE` (and `CLEAR` first for whole-array assignment).
- push/pop/shift/unshift/splice/delete/exists → the matching uppercase hook when defined.
- An array slice `@a[1, 3]` calls `FETCH` once per index; there is no slice hook.

Minimum viable class

The smallest tied array defines `TIEARRAY`, `FETCH`, `STORE`, `FETCHSIZE`, and `STORESIZE`. With those five, element access, `scalar @a`, `$#a`, and iteration all work. Add `CLEAR` so `@a = ()` behaves. Add the mutators only for the built-ins your callers actually use - or inherit them.

The easy way: inherit from `Tie::Array`

`Tie::Array` implements `PUSH`, `POP`, `SHIFT`, `UNSHIFT`, and `SPLICE` in terms of the mandatory five, so a subclass that supplies `TIEARRAY`, `FETCH`, `STORE`, `FETCHSIZE`, and `STORESIZE` gets all the list mutators for free:

```
package Logging {
    use Tie::Array;
    our @ISA = ('Tie::Array');
    sub TIEARRAY  { my $class = shift; return bless { data => [] },
↪$class }
    sub FETCH     { my ($self, $i) = @_; return $self->{data}[$i] }
    sub STORE     { my ($self, $i, $v) = @_; warn "store $i\n";
↪$self->{data}[$i] = $v }
    sub FETCHSIZE { my $self = shift; return scalar @{ $self->{data}␣
```

(continues on next page)

(continued from previous page)

```
 ↪} }
    sub STORESIZE { my ($self, $n) = @_; $#{ $self->{data} } = $n -␣
 ↪1 }
}

tie my @log, 'Logging';
push @log, 'x', 'y';        # PUSH inherited; calls STORE twice␣
 ↪(warns)
say "@log";                 # x y
```

`push @log, 'x', 'y'` works without a `PUSH` method because the inherited one expands into two `STORE` calls - which is why the example warns twice. `Tie::Array` does not define `TIEARRAY` itself, so the subclass must supply the constructor; its default `DELETE` and `EXISTS` simply croak, so override them if your callers need `delete` and `exists`.

- `tied` - reach the backing object
- `splice` - the most intricate mutator the `SPLICE` hook stands in for
- `push` and `pop` - the mutators `Tie::Array` derives from the mandatory layer
- *Tied hashes* - the other rich container interface
- `Tie::Array` - the base-class module that supplies the list mutators

Tied filehandles

A tied filehandle reroutes I/O the way a tied scalar reroutes reads and writes. Print to it and your `PRINT` runs; read a line and your `READLINE` runs. The classic uses are redirecting output somewhere unusual (into a string, across a network, through a filter) and embedding Perl in a host program that needs `STDOUT` and `STDERR` handled specially.

The interface is larger than the others but mostly optional: you implement only the operations the handle will actually receive. The full menu is on the `tie` reference page; this chapter builds a class and explains the hooks and their timing.

A complete class

A write-only handle that collects everything printed to it into a string:

```
use v5.36;

package Collector {
    sub TIEHANDLE { my $class = shift; my $buf = ''; return bless \
 ↪$buf, $class }
    sub PRINT     { my $self = shift; $$self .= join($, // '', @_);␣
 ↪return 1 }
```

(continues on next page)

(continued from previous page)

```
    sub PRINTF    { my $self = shift; my $fmt = shift; $$self .=␣
↪sprintf($fmt, @_); return 1 }
    sub buffer    { my $self = shift; return $$self }
}

tie *OUT, 'Collector';
print OUT "hello ";
print OUT "world\n";
printf OUT "%d items\n", 3;
my $obj = tied *OUT;
print $obj->buffer;
# hello world
# 3 items
```

The object is a blessed scalar ref holding the accumulated text. The extra `buffer` method is reached through `tied`, not through any I/O operation - that is the standard way a tie class exposes operations with no filehandle syntax.

Tying the glob, not the scalar

The first argument to `tie` for a handle must be a glob - it begins with an asterisk:

- To tie a named handle: `tie *OUT, 'Collector'`.
- To tie a handle held in a scalar `$fh`: `tie *$fh, 'Collector'`. Writing `tie $fh, ...` ties the *scalar* `$fh`, not the handle inside it - a common and confusing mistake.

The method contract

`TIEHANDLE classname, LIST`
: The constructor; returns a blessed reference of any kind. It can hold whatever internal state the handle needs.

`PRINT this, LIST`
: Backs `print` and `say`. It receives the printed list. Honour `$,` (the output field separator) between items and `$\` (the output record terminator) at the end if you want full fidelity - `print` does not insert them for you.

`PRINTF this, format, LIST`
: Backs `printf`. It receives the format string and arguments; run them through `sprintf` yourself.

`WRITE this, scalar, length, offset`
: Backs `syswrite` - the raw, buffer-oriented write, distinct from `PRINT`.

`READLINE this`
: Backs `<$fh>` and `readline`. In scalar context return the next line or `undef` at end of input; in list context return all remaining lines or an empty list. The returned strings should include the input record separator `$/`, matching what a real handle gives you.

`READ this, scalar, length, offset` / `GETC this`
: Back `read` / `sysread` and `getc` respectively.

OPEN, CLOSE, EOF, BINMODE, FILENO, SEEK, TELL
: Back the corresponding built-ins when used on the handle. Implement the ones that make sense for your backing store and leave the rest out.

DESTROY this / UNTIE this
: Optional cleanup, identical in role to the other tie types. A handle class often closes its backing resource here.

Call timing

- `print FH @list` and `say FH @list` → `PRINT`. `say` additionally localises `$\` to `"\n"` around the call, so a `PRINT` that honours `$\` handles `say` with no special case.
- `printf FH $fmt, @args` → `PRINTF`.
- `syswrite FH, $buf, $len, $off` → `WRITE`.
- `<FH>` / `readline FH` → `READLINE`, in the surrounding context.
- `read`/`sysread` → `READ`; `getc FH` → `GETC`.
- `close FH`, `eof FH`, `binmode FH`, `seek`, `tell`, `fileno`, `open FH, ...` → the matching uppercase hook when defined.

A note on `STDERR`: when `STDERR` is tied, its `PRINT` is what issues warnings and error messages. The runtime disables the tie for the duration of that call, so you can `warn` from inside `PRINT` without triggering infinite recursion.

Minimum viable class

There is no single mandatory method beyond `TIEHANDLE` - you implement whichever operations the handle will receive. An output-only handle needs `TIEHANDLE` plus `PRINT` (and usually `PRINTF`). An input-only handle needs `TIEHANDLE` plus `READLINE` (and perhaps `GETC` / `READ`). Operations whose hook is missing die at the point of use, so define exactly the set your callers exercise.

The easy way: inherit from `Tie::StdHandle`

`Tie::StdHandle` (shipped inside `Tie::Handle`) ties a handle onto a real underlying one: its `OPEN` opens an actual file and the I/O hooks forward to it. Inherit from it and override only the operations you want to intercept:

```
package Doubler {
    use Tie::StdHandle;
    our @ISA = ('Tie::StdHandle');
    sub READLINE {
        my $self = shift;
        my $line = $self->SUPER::READLINE;
        return defined $line ? $line . $line : undef;   # echo each␣
↪line twice
    }
}

my $data = "a\nb\n";
```

(continues on next page)

(continued from previous page)

```
tie *DUP, 'Doubler';
tied(*DUP)->OPEN('<', \$data);
print while defined($_ = <DUP>);
# a
# a
# b
# b
```

`READLINE` calls up to the base class for the real next line, then doubles it; every other operation flows through `Tie::StdHandle` unchanged. `Tie::Handle` (the parent) is the abstract base that documents the interface and supplies a default `PRINT`/`PRINTF` in terms of `WRITE`; `Tie::StdHandle` is the concrete, ready-to-use one.

- `readline` - its page documents the scalar/list return contract `READLINE` must honour
- *Tied scalars* - the simplest tie type, a good warm-up for the handle interface
- `Tie::Handle` - the base-class module; `Tie::StdHandle` is the concrete version

4.2.9 Coming from another language

You already know how to program. You reach for a hash, a loop, a function, a regex without thinking - in some other language. These guides teach Perl by mapping what you already do onto how Perl does it, one construct at a time. Your dictionary is a Perl hash; here is the syntax, and here is the one place the analogy leaks.

Each guide assumes you are **fluent in the source language and new to Perl**. It does not teach the source language back to you. It teaches the Perl side of each pairing: the syntax, the idiom, and - most useful of all - the gotcha that the surface similarity hides.

Every guide in this series covers the **same topics in the same order**, so the mapping is comparable across languages and the series grows cleanly as new languages are added. The order moves from what every language shares (variables, strings, numbers) through Perl's distinctive shapes (sigils, the array/hash split, and **context** - the one idea no other language has), into structure (subroutines, references, modules, objects), and out through the working surface (regex, I/O, error handling, idioms), ending with a per-language collection of the traps that actually bite.

Which guide you want

- *Python to Perl* - sigils where Python has none, the array/hash split where Python has `list` and `dict`, comprehensions rewritten as `map`/`grep`, and the context concept Python has no word for.

- *PHP to Perl* - you already have `$`, but in Perl it shifts by access, PHP's one `array` splits into `@array` and `%hash`, and `.` versus `+` (and `==` versus `eq`) stop being interchangeable.
- *Ruby to Perl* - blocks become Perl blocks and closures, method-calls-on-everything become plain functions, and Ruby's "only `nil` and `false` are falsy" inverts into Perl's truthiness.
- *Lua to Perl* - the one table type splits into `@array` and `%hash`, indexing turns 0-based, Lua patterns become real regex, and multiple-return-values are your bridge to Perl's context.
- *Sed to Perl* - the same `s///` you already know, sed's `y///` becomes `tr///`, address ranges become the `/a/ .. /b/` flip-flop, and the hold space becomes an ordinary Perl variable.
- *Awk to Perl* - Perl grew out of awk, so almost everything maps directly: fields become `@F` and `split`, `NR` becomes `$.`, associative arrays become hashes, and `BEGIN`/`END` keep their names.
- *Shell to Perl* - for when a shell script outgrew itself: `$(cmd)` becomes `qx{}`, the `[ ]`/`-f` file tests carry straight over, and the `${var#...}` parameter expansions become real regex.
- *Tcl to Perl* - a carry-over for Tcl maintainers: `set x` becomes `my $x`, `[expr {}]` disappears into native operators, lists and `array` become Perl arrays and hashes, and `regsub` becomes `s///`.

The one concept to read first

If you read only one section of whichever guide matches your background, read **Context**. Every other language in this series collapses a collection to a count, a first element, or a boolean with explicit syntax (`len(x)`, `x[0]`, `bool(x)`). Perl does it through *context*: the same expression yields a list in one place and a single scalar in another, decided by where you wrote it. It is the source of most "why did my array become the number 3?" confusion, and once it clicks the rest of Perl falls into place.

A note on the runtime

These guides target `pperl`, a faithful Rust reimplementation of Perl 5.44. Every Perl example that runs as a script was executed on `pperl` and shows real output. The text-processing guides (sed, awk, shell) lead with the classic `perl -ne`/`perl -pe` one-liner forms, the idiomatic Perl equivalent, and pair each with the explicit-loop script the switches expand to - the form you grow a one-liner into.

Python to Perl

You know Python. You write list comprehensions in your sleep, you reach for a `dict` without thinking, and `for x in xs:` is muscle memory. This guide maps each of those habits onto Perl, so you can be productive in `pperl` in an afternoon instead of relearning programming from scratch.

Two shocks land in the first five minutes, so meet them now:

- **Perl uses braces and semicolons, not indentation.** There is no significant whitespace. A block is `{ ... }`; a statement ends with `;`. Indent for your own sanity, but the parser ignores it.
- **Variables wear sigils.** A scalar is `$x`, an array is `@x`, a hash is `%x`. The sigil is part of how you read the variable, not just its name. This is the single biggest surface difference from Python, and section one is about nothing else.

Every example here runs on `pperl`, a Rust reimplementation of Perl 5.44. Each Perl snippet was executed on `pperl`; the `# ...` comments show its real output. Start your scripts with:

```
use v5.44;
```

That one line turns on `strict` (no accidental globals), `warnings`, the `say` built-in (a `print` with a trailing newline, like Python's `print`), subroutine signatures, and the modern feature set used throughout this guide.

How to read this

- *Variables and sigils* - the `$`/`@`/`%` shift.
- *Strings* - interpolation and concatenation.
- *Numbers* - one surface type, float division.
- *Arrays and lists* - your `list`, plus `map`/`grep`.
- *Hashes* - your `dict`.
- *Context* - the concept Python has no word for. Read this one.
- *Truthiness* - what counts as false, with surprises.
- *Control flow* - `if`, loops, the postfix forms.
- *Subroutines* - `def` becomes `sub`.
- *References* - nested data and closures.
- *Regular expressions* - regex as syntax, not a library.
- *File and stream I/O* - open, line reads, slurp.
- *Modules and packages* - `import` becomes `use`.
- *Objects* - the modern `class` syntax.
- *Error handling* - `try`/`except` becomes `eval` or `try`/`catch`.
- *Idioms* - the daily one-liners.
- *Gotchas coming from Python* - scan before you write.

Variables and sigils

In Python a name just names a value. In Perl the **sigil tells you the shape**: `$` for a single value, `@` for an ordered list, `%` for a key/value map. `my` declares a lexically scoped variable, the Perl equivalent of an ordinary local binding.

```
name = "Ada"
langs = ["Python", "Perl"]
ages = {"Ada": 36, "Linus": 56}
```

```
use v5.44;
my $name = "Ada";
my @langs = ("Python", "Perl");
my %ages  = (Ada => 36, Linus => 56);
say $name;            # Ada
say $langs[0];        # Python
say $ages{Ada};       # 36
```

The gotcha: when you reach *into* an aggregate for one element, the sigil follows the value you get back, not the container. A single element of `@langs` is a scalar, so it is `$langs[0]`, not `@langs[0]`; one value from `%ages` is `$ages{Ada}`. The `@`/`%` form is the whole collection; the `$` form is one piece of it.

Strings

Double quotes interpolate variables, single quotes do not. There is no f-string because the default string *is* an f-string. Concatenation is `.`, not `+` (which is reserved for numbers).

```
name = "Ada"
greeting = f"Hello, {name}"
shout = "AB" * 3
```

```
use v5.44;
my $name = "Ada";
my $greeting = "Hello, $name";   # Hello, Ada
my $literal  = 'Hello, $name';   # Hello, $name  (no interpolation)
my $joined   = "AB" . "CD";      # ABCD
my $shout    = "AB" x 3;         # ABABAB
```

The gotcha: string repetition is `x`, not `*`, and the join operator is `.`, not `+`. Mixing them up is the most common first-day typo for a Python developer. Array elements and hash values interpolate inside double quotes too: `"First: $langs[0]"` works as written.

Numbers

Perl has one numeric type at the surface; you do not declare `int` vs `float`. Division always produces a float, exactly like Python 3.

```
print(7 / 2)        # 3.5
print(7 // 2)       # 3
print(2 ** 10)      # 1024
print(10 % 3)       # 1
```

```
use v5.44;
say 7 / 2;          # 3.5
```

(continues on next page)

(continued from previous page)

```
say int(7 / 2);      # 3
say 2 ** 10;         # 1024
say 10 % 3;          # 1
```

The gotcha: comparison and equality operators come in two families, and you pick by the *operands' type*, not the variables'. Numbers use `==`, `!=`, `<`, `>`, `<=>`; strings use `eq`, `ne`, `lt`, `gt`, `cmp`. `"10" == "10.0"` is true (numeric), but `"10" eq "10.0"` is false (string). Using `==` on strings, or `eq` on numbers, is a frequent and quiet bug.

Arrays and lists

A Perl array is your Python `list`. The verbs are renamed but the operations are the same, and negative indices work as you expect.

```
nums = [1, 2, 3, 4, 5]
nums.append(6)
last = nums.pop()
print(len(nums))    # 5
print(nums[1:3])    # [2, 3]
```

```
use v5.44;
my @nums = (1, 2, 3, 4, 5);
push @nums, 6;
my $last = pop @nums;       # 6
say scalar @nums;           # 5
say "@nums[1,2]";           # 2 3   (a slice)
```

Comprehensions become `map` and `grep`. `map` transforms (Python's `[f(x) for x in xs]`); `grep` filters (Python's `[x for x in xs if p(x)]`). `$_` is the current element, Perl's implicit loop variable.

```
squares = [x * x for x in nums]
evens   = [x for x in nums if x % 2 == 0]
desc    = sorted(nums, reverse=True)
```

```
use v5.44;
my @nums    = (1, 2, 3, 4, 5);
my @squares = map  { $_ * $_ }   @nums;   # 1 4 9 16 25
my @evens   = grep { $_ % 2 == 0 } @nums; # 2 4
my @desc    = sort { $b <=> $a }  @nums;  # 5 4 3 2 1
```

The gotcha: `sort` compares as strings by default, so `sort (10, 9, 100)` gives `10 100 9`. For numbers you must pass a comparator: `sort { $a <=> $b } @nums`. `$a` and `$b` are the two elements being compared, and `<=>` is the numeric three-way operator (`cmp` is its string sibling).

Hashes

A Perl hash is your Python `dict`. Declared with `%`, accessed one value at a time with `$h{key}`.

```python
h = {"apple": 3, "pear": 5, "plum": 2}
print(h["apple"])                # 3
print(sorted(h.keys()))          # ['apple', 'pear', 'plum']
print("pear" in h)               # True
del h["plum"]
for k in sorted(h):
    print(k, "=>", h[k])
```

```perl
use v5.44;
my %h = (apple => 3, pear => 5, plum => 2);
say $h{apple};                           # 3
say join ",", sort keys %h;              # apple,pear,plum
say exists $h{pear} ? "yes" : "no";      # yes
delete $h{plum};
for my $k (sort keys %h) {
    say "$k => $h{$k}";
}
```

The gotcha: membership is `exists $h{key}`, not Python's `in`, and the fat comma `=>` is the idiomatic key/value separator. `=>` also auto-quotes the bareword on its left, so `apple => 3` needs no quotes around `apple`. A hash has no order; iterate `sort keys %h` when you want a stable one.

Context

This is the chapter to read twice. Python has no equivalent, and almost every "Perl is weird" story traces back to it.

Every expression in Perl runs in either **list context** or **scalar context**, decided by where it appears, not by what it is. The same array behaves differently in each. Assigning an array to a *scalar* gives its length; assigning it to a *list* (a parenthesised set of variables) copies elements.

```perl
use v5.44;
my @list = (10, 20, 30);

my $count = @list;          # scalar context -> 3 (the length)
say $count;                 # 3

my ($first) = @list;        # list context -> first element copied
say $first;                 # 10

my ($a, $b) = @list;        # 10 and 20
say "$a $b";                # 10 20
```

The parentheses on the left are the whole difference. `my $x = @list` asks "how many?" and gets 3. `my ($x) = @list` asks "give me the elements" and gets `10`. A Python devel-

oper reads both as "assign the list," which is exactly the trap.

A subroutine can ask which context it was called in, with `wantarray`, and return different things accordingly:

```
use v5.44;
sub items {
    return wantarray ? (1, 2, 3) : "three items";
}
my @got = items();          # list context
my $msg = items();          # scalar context
say "@got";                 # 1 2 3
say $msg;                   # three items
```

Built-ins use this too. `scalar @array` forces scalar context to get a count; a regex match with `/g` returns the list of matches in list context and a true/false in scalar context. The classic idiom for "count the matches" forces a list assignment in scalar context with the so-called *countof* form:

```
use v5.44;
my $n = () = "a1b2c3" =~ /\d/g;
say $n;                     # 3
```

The gotcha: there is no single answer to "what does this array do" - it depends on the surrounding expression. When something returns a number you expected to be a list (or vice versa), context is the first suspect. Reach for `scalar` to force a count and parentheses on the left to force element copying.

Truthiness

Perl's false values are a short, specific list: the number `0`, the empty string `""`, the string `"0"`, and `undef` (Perl's None). **Everything else is true** - and that includes some strings a Python developer assumes are false.

```
use v5.44;
for my $v (0, 1, "", "0", "00", "0.0", "false") {
    say "'$v' is ", ($v ? "true" : "false");
}
```

This prints, exactly:

```
'0' is false
'1' is true
'' is false
'0' is false
'00' is true
'0.0' is true
'false' is true
```

The gotcha: `"00"` and `"0.0"` are **true** in Perl, even though they look numerically zero, because only the exact string `"0"` is false. The string `"false"` is true (it is a non-empty, non-`"0"` string). And unlike Python, an empty array or empty hash is not itself a false *value* - in boolean context an array yields its length, so `if (@list)` is true when the list

is non-empty, which is the test you want. For a "use this if defined, else a default" choice, use defined-or `//`, which falls back only on `undef` (not on `0` or `""`):

```
use v5.44;
my %cfg = (host => "localhost");
my $port = $cfg{port} // 8080;   # key absent -> undef -> 8080
say $port;                       # 8080
```

Control flow

The keywords are familiar; the spelling differs. `elif` is `elsif`, and there is no `:` and no indentation - blocks are braced.

```
if n < 0:
    sign = "neg"
elif n == 0:
    sign = "zero"
else:
    sign = "pos"

for x in nums:
    print(x)

while running:
    step()
```

```
use v5.44;
my $sign;
if    ($n < 0)  { $sign = "neg"  }
elsif ($n == 0) { $sign = "zero" }
else            { $sign = "pos"  }

for my $x (@nums) { say $x }

while ($running) { step() }
```

Perl adds two things Python does not have. **Postfix modifiers** let a simple statement carry its own condition or loop, which reads naturally for one-liners:

```
use v5.44;
say $_ for @nums;                # loop, one statement
say "negative" if $n < 0;        # guarded statement
$sum += $_ for @nums;            # accumulate
```

And `unless`/`until` are the negated forms of `if`/`while`, for when the positive phrasing reads awkwardly: `say "ok" unless $error`.

The gotcha: the ternary chains the same as Python's, but with `?`/`:`, not `if`/`else`: `my $sign = $n < 0 ? "neg" : $n == 0 ? "zero" : "pos"`. The C-style `?:` is the idiom; there is no `x if c else y` form.

Subroutines

`def` becomes `sub`. Modern Perl has signatures that look much like Python's parameter lists, including defaults.

```python
def greet(name, greeting="Hello"):
    return f"{greeting}, {name}!"

def total(*nums):
    return sum(nums)
```

```perl
use v5.44;
sub greet ($name, $greeting = "Hello") {
    return "$greeting, $name!";
}
say greet("Ada");           # Hello, Ada!
say greet("Linus", "Hi");   # Hi, Linus!

sub total (@nums) {
    my $sum = 0;
    $sum += $_ for @nums;
    return $sum;
}
say total(1, 2, 3, 4);      # 10
```

Keyword arguments map to a hash parameter, since `key => value` pairs flatten into a list that a `%opts` signature gathers up:

```perl
use v5.44;
sub connect_to (%opts) {
    return "host=$opts{host} port=$opts{port}";
}
say connect_to(host => "localhost", port => 8080);
# host=localhost port=8080
```

The gotcha: a sub returns the value of its last expression even without `return`, and the return is **context-sensitive** (see *Context*). If you `return @list`, the caller gets the list in list context but the *count* in scalar context. Be deliberate about what you return when it might be used either way.

References

Perl's arrays and hashes do not nest directly; you nest them through **references**, which are the Perl analogue of Python's object handles (in Python every container is already a reference, so this step is invisible to you there). A reference is a scalar that points at an aggregate. Take one with `\`, follow it with `->`.

```python
data = {"name": "Ada", "langs": ["Perl", "Python"]}
print(data["langs"][1])     # Python
data["langs"].append("Ruby")
```

```
use v5.44;
my $data = { name => "Ada", langs => ["Perl", "Python"] };
say $data->{name};                  # Ada
say $data->{langs}[1];              # Python
push $data->{langs}->@*, "Ada";     # postfix deref to push
say "@{$data->{langs}}";           # Perl Python Ada
```

`{ ... }` builds an anonymous hash reference and `[ ... ]` an anonymous array reference - the literal building blocks of nested data, matching Python's `{}` and `[]` literals. The `->` arrow follows a reference one step; between two subscripts it is optional, so `$data->{langs}[1]` and `$data->{langs}->[1]` are the same.

Anonymous subs are closures, exactly like Python's `lambda` but with no single-expression limit:

```
use v5.44;
my $double = sub ($n) { $n * 2 };
say $double->(21);          # 42
```

The gotcha: the postfix deref forms (`->@*`, `->%*`, `->$*`) are the modern, readable way to dereference a whole aggregate, and `"@{ ... }"` is how you interpolate a dereferenced array into a string. The older `@$ref` and `${$ref}{key}` forms still work and appear in existing code, but reach for the arrow and postfix forms in new code.

Regular expressions

In Python regex is the `re` library. In Perl it is **syntax**: `=~` binds a pattern to a string, `m//` matches, `s///` substitutes. Capture groups land in `$1`, `$2`, and named captures in `%+`.

```
import re
m = re.search(r"(\d{4})-(\d{2})-(\d{2})", s)
if m:
    year, month, day = m.groups()
t = re.sub(",", ";", "a,b,c")
parts = "one,two,three".split(",")
```

```
use v5.44;
my $s = "2026-06-20";
if ($s =~ /(\d{4})-(\d{2})-(\d{2})/) {
    say "$1 $2 $3";                 # 2026 06 20
}
if ($s =~ /(?<year>\d{4})/) {
    say $+{year};                   # 2026
}
(my $t = "a,b,c") =~ s/,/;/g;       # a;b;c
my @parts = split /,/, "one,two,three";   # one two three
```

A `/g` match in list context returns *all* captures, which is the direct analogue of `re.findall`:

```
use v5.44;
my @nums = "x1y2z3" =~ /(\d)/g;     # 1 2 3
say "@nums";
```

The gotcha: `s///` modifies its target *in place* and returns the number of substitutions, not a new string. That is why the example copies first with `(my $t = "a,b,c")` and then substitutes on the copy - otherwise you would be editing a string literal. To get a new string without touching the original, use the `/r` flag: `my $t = $s =~ s/,/;/gr`.

File and stream I/O

The idiom is the three-argument open with a lexical filehandle, the direct counterpart of Python's `with open(...) as f:`. The angle-bracket operator `<$fh>` reads a line, the same role as iterating a Python file object.

```
with open("/tmp/sample.txt", "w") as f:
    for i in range(1, 4):
        f.write(f"line {i}\n")

with open("/tmp/sample.txt") as f:
    for line in f:
        print("got:", line.rstrip())
```

```
use v5.44;
my $path = "/tmp/sample.txt";

open my $wh, '>', $path or die "cannot write: $!";
print {$wh} "line $_\n" for 1 .. 3;
close $wh;

open my $rh, '<', $path or die "cannot read: $!";
while (my $line = <$rh>) {
    chomp $line;
    say "got: $line";       # got: line 1 ... got: line 3
}
close $rh;
```

To slurp every line at once, read the handle in list context:

```
use v5.44;
open my $fh, '<', "/tmp/sample.txt" or die $!;
my @lines = <$fh>;          # all lines, including newlines
say scalar @lines;          # 3
```

The gotcha: a line read with `<$fh>` keeps its trailing newline; call `chomp` to strip it (Python's `line.rstrip()` reflex). And open returns false on failure rather than raising, so the `or die "...: $!"` idiom is mandatory - `$!` is the system error message, Perl's `errno`.

Modules and packages

`import` becomes `use`. The namespace separator is `::`, not `.`, and a module `Foo::Bar` lives at `Foo/Bar.pm` on the include path `@INC` (Perl's `sys.path`). A module's import list is a selection of names, much like `from module import name`.

```
from math import sqrt
import json
data = json.loads(text)
```

```
use v5.44;
use List::Util qw(sum0 max first);
say sum0(1 .. 10);                          # 55
say max(3, 7, 2);                           # 7
say first { $_ % 2 == 0 } (1, 3, 4, 5);  # 4
```

The standard library is large and much of what you would reach to PyPI for ships in core or on CPAN, the Perl package archive. `List::Util`, `Scalar::Util`, `POSIX`, `File::Spec`, and `Data::Dumper` are the everyday ones.

The gotcha: `use` runs at *compile time*, not at the point in the file where it appears, so the order of `use` lines relative to your code does not matter the way `import` placement does. Importing is also opt-in per name: `use List::Util qw(sum0 max)` brings exactly `sum0` and `max` into your namespace, nothing else.

Objects

For new code, Perl 5.44 has a first-class `class` syntax that will look familiar coming from Python. Fields are declared with `field`, methods with `method`, and `$self` is available inside every method just as `self` is in Python (you do not list it as a parameter).

```
class Point:
    def __init__(self, x=0, y=0):
        self.x = x
        self.y = y
    def to_string(self):
        return f"({self.x}, {self.y})"
    def move(self, dx, dy):
        self.x += dx
        self.y += dy
        return self

p = Point(x=3, y=4)
print(p.to_string())        # (3, 4)
p.move(1, 1)
print(p.to_string())        # (4, 5)
```

```
use v5.44;
use feature 'class';

class Point {
```

(continues on next page)

(continued from previous page)

```
    field $x :param = 0;
    field $y :param = 0;
    method to_string { return "($x, $y)" }
    method move ($dx, $dy) {
        $x += $dx;
        $y += $dy;
        return $self;
    }
}

my $p = Point->new(x => 3, y => 4);
say $p->to_string;          # (3, 4)
$p->move(1, 1);
say $p->to_string;          # (4, 5)
```

The constructor is generated for you: `:param` marks a field that the auto-built `new` accepts as a named argument, and `= 0` is its default. Inheritance is `:isa`:

```
use v5.44;
use feature 'class';

class Point3D :isa(Point) {
    field $z :param = 0;
    method z { return $z }
}

my $q = Point3D->new(x => 1, y => 2, z => 3);
say $q->to_string, " z=", $q->z;   # (1, 2) z=3
```

The gotcha: the `class` feature is still marked experimental in Perl 5.44, and on `pperl` the "class is experimental" notices print to **stderr** even with `no warnings 'experimental::class'` in scope. They do not touch your program's output, so a script that prints to stdout behaves exactly as shown above; just expect the notices on the error stream. For the older `bless`-based object model you will meet in existing code, and for roles, inheritance details, and migration, see the *Object-oriented Programming guide*.

Error handling

Python's `try`/`except` has two counterparts. The classic one wraps code in `eval { }` and inspects `$@` (the caught error) afterward:

```
try:
    risky(-1)
except Exception as e:
    print("caught:", e)
```

```
use v5.44;
my $result = eval { risky(-1) };
if ($@) {
```

(continues on next page)

(continued from previous page)

```
    print "caught: $@";     # caught: negative!
}
```

The modern form is `try`/`catch`, which reads almost exactly like Python's:

```
use v5.44;
use feature 'try';

try {
    risky(-4);
}
catch ($e) {
    print "caught: $e";     # caught: negative!
}
```

where the raising side is `die`:

```
use v5.44;
sub risky ($n) {
    die "negative!\n" if $n < 0;
    return sqrt $n;
}
```

The gotcha: `die` with a string that ends in `\n` produces exactly that message; `die` with a string that does *not* end in a newline gets `" at SCRIPT line N.\n"` appended automatically. End your error strings with `\n` when you want a clean message and omit it when you want the file-and-line trace. Note also the two error variables: `$@` is the last caught exception (Python's `except ... as e`), while `$!` is the last *system* error (a failed open, the `errno` string).

Idioms

A few patterns you will see daily and want in your fingers.

Sort a list by a computed key (the Schwartzian transform - Python's `sorted(xs, key=f)` done by hand, decorate then sort then undecorate):

```
use v5.44;
my @words = qw(apple fig pear);
my @by_length =
    map  { $_->[1] }
    sort { $a->[0] <=> $b->[0] }
    map  { [ length $_, $_ ] } @words;
say "@by_length";           # fig pear apple
```

Build a hash from a list, the dict-comprehension analogue (`{w: len(w) for w in words}`):

```
use v5.44;
my @words = qw(apple pear fig);
```

(continues on next page)

(continued from previous page)

```
my %len = map { $_ => length $_ } @words;
say "$_ => $len{$_}" for sort keys %len;
# apple => 5
# fig => 3
# pear => 4
```

And `pperl` is a command-line tool in the `awk`/`sed` niche. The implicit-loop one-liner is the Perl developer's everyday reflex:

```
pperl -lane '$s += $F[-1]; END { print $s }' data.txt
```

The gotcha: read the *One-Liners guide* for the switches (`-n`, `-p`, `-a`, `-l`, `-e`) and the dozens of recipes built on them; it is one of the highest-leverage things to learn coming from a shell-and-Python background.

Gotchas coming from Python

The traps, collected for a final scan before you start writing:

- **Sigils change with usage.** One element of `@a` is `$a[0]`; one value of `%h` is `$h{k}`. The container sigil and the element sigil differ.
- **`.` joins strings, `+` adds numbers.** Never `+` two strings to concatenate; that coerces them to numbers and warns.
- **Two comparison families.** `==`/`<`/`<=>` for numbers, `eq`/`lt`/`cmp` for strings. Pick by operand type, not by variable.
- **`sort` is string-sorted by default.** Pass `{ $a <=> $b }` for numeric order.
- **Context.** `my $x = @a` is the *length*; `my ($x) = @a` is the *first element*. The parentheses are the whole difference. Re-read *Context* when a value comes back the wrong shape.
- **Truthiness surprises.** `"0"` is false, but `"00"` and `"0.0"` are **true**. Only `0`, `""`, `"0"`, and `undef` are false.
- **`s///` edits in place** and returns a count; use the `/r` flag to get a new string instead.
- **`open` does not raise.** Use `open ... or die "...: $!"`.
- **`chomp` your line reads.** `<$fh>` keeps the trailing newline.
- **Non-ASCII source needs `use utf8;`.** Under `use v5.44;` a literal non-ASCII byte in your source is a compile error without it. Keep string data ASCII unless you specifically add `use utf8;`.
- **The `class` feature prints experimental notices to stderr** on `pperl`. Correct output, noisy error stream.

PHP to Perl

You know PHP. You reach for `$arr['key']` without thinking, `foreach ($items as $item)` is muscle memory, and you join strings with `.` because of course you do. Perl and PHP are close cousins: both are sigil-using, pragmatic, get-the-job-done languages,

and PHP borrowed heavily from Perl in its early days. This guide maps your PHP habits onto Perl so you can be productive in `pperl` in an afternoon.

Two shocks land in the first five minutes, so meet them now:

- **The `$` sigil is not the whole story.** In PHP every variable is `$x`, always. In Perl the sigil changes with how you *access* the value: `@a` is the whole array but `$a[0]` is one element; `%h` is the whole hash but `$h{k}` is one value. The dollar you already know marks a single scalar; `@` and `%` are new and section one is about nothing else.
- **PHP's one `array` becomes Perl's two types.** A PHP `array` is an ordered map that does duty as both list and dictionary. Perl splits that into `@array` (integer-indexed) and `%hash` (string-keyed), and you choose up front which one you have. This split drives the Arrays and Hashes sections.

Every example here runs on `pperl`, a Rust reimplementation of Perl 5.44. Each Perl snippet was executed on `pperl`; the `# ...` comments show its real output. Start your scripts with:

```
use v5.44;
```

That one line turns on `strict` (no accidental globals), `warnings`, the `say` built-in (a `print` with a trailing newline, like PHP's `echo` plus `PHP_EOL`), subroutine signatures, and the modern feature set used throughout this guide.

How to read this

- *Variables and sigils* - the `$`/`@`/`%` shift.
- *Strings* - interpolation and `.` concatenation.
- *Numbers* - `==` vs `eq`, the classic PHP trap.
- *Arrays and lists* - half of your `array`.
- *Hashes* - the other half of your `array`.
- *Context* - the concept PHP has no word for. Read this one.
- *Truthiness* - what counts as false, with surprises.
- *Control flow* - `if`, loops, the postfix forms.
- *Subroutines* - `function` becomes `sub`.
- *References* - nested data and closures.
- *Regular expressions* - regex as syntax, not `preg_*`.
- *File and stream I/O* - `fopen`, line reads, slurp.
- *Modules and packages* - `require`/`use` becomes `use`.
- *Objects* - the modern `class` syntax.
- *Error handling* - `try`/`catch`, the same idea.
- *Idioms* - the daily one-liners.
- *Gotchas coming from PHP* - scan before you write.

Variables and sigils

You already use `$`, so the first half of Perl's sigils is free. The new idea is that **the sigil marks the access, not the variable**. The whole array is `@a`; one element is `$a[0]`. The whole hash is `%h`; one value is `$h{k}`. PHP keeps `$` on everything and varies the brackets (`$a[0]`, `$h['k']`); Perl varies the sigil instead. `my` declares a lexically scoped variable, the equivalent of an ordinary local binding.

```
$name = "Ada";
$langs = ["PHP", "Perl"];
$ages = ["Ada" => 36, "Rasmus" => 56];
```

```
use v5.44;
my $name  = "Ada";
my @langs = ("PHP", "Perl");
my %ages  = (Ada => 36, Rasmus => 56);
say $name;            # Ada
say $langs[0];        # PHP
say $ages{Ada};       # 36
say scalar @langs;    # 2
```

The gotcha: when you reach *into* an aggregate for one element, the sigil follows the value you get back, not the container. A single element of `@langs` is a scalar, so it is `$langs[0]`, not `@langs[0]`; one value from `%ages` is `$ages{Ada}`. Read the leading sigil as "what shape am I getting" - `$` for one thing, `@` for a list, `%` for the whole map - and the brackets as "from where."

Strings

Concatenation is `.`, exactly as in PHP. Double quotes interpolate variables, single quotes do not - the same split PHP makes between `"..."` and `'...'`. There is no `sprintf`-into-the-string syntax to learn because the default double-quoted string already interpolates.

```
$name = "Ada";
$greeting = "Hello, $name";
$literal  = 'Hello, $name';
$joined   = "AB" . "CD";
$shout    = str_repeat("AB", 3);
```

```
use v5.44;
my $name = "Ada";
my $greeting = "Hello, $name";   # Hello, Ada
my $literal  = 'Hello, $name';   # Hello, $name  (no interpolation)
my $joined   = "AB" . "CD";      # ABCD
my $shout    = "AB" x 3;         # ABABAB
```

The gotcha: string repetition is the `x` operator, not a function - `"AB" x 3`, not `str_repeat`. Interpolating an array or hash element needs no curly-brace escape: `"First: $langs[0]"` and `"Name: $h{name}"` both work as written, where PHP would make you write `"{$arr['k']}"`. To interpolate the result of an *expression*, wrap it in `@{[`

`... ]}`: `"sum: @{[ 2 + 3 ]}"` prints `sum: 5`.

Numbers

Perl has one numeric type at the surface; you do not declare `int` vs `float`. The thing that will actually bite you is operators, so read the gotcha twice.

```
echo 7 / 2;           // 3.5
echo intdiv(7, 2);    // 3
echo 2 ** 10;         // 1024
echo 10 % 3;          // 1
```

```
use v5.44;
say 7 / 2;          # 3.5
say int(7 / 2);     # 3
say 2 ** 10;        # 1024
say 10 % 3;         # 1
```

The gotcha: Perl has **two operator families and you pick by operand type, not by the variable**. Numbers use `==`, `!=`, `<`, `>`, `<=>`; strings use `eq`, `ne`, `lt`, `gt`, `cmp`. And `+` is *always* numeric - there is no operator overloading the way PHP's `+` does array union. Concatenate with `.`, add with `+`, and never cross them:

```
use v5.44;
say "12" . "3";     # 123   (string concat)
say "12" + "3";     # 15    (numeric add)
say "10" == "10.0" ? "same" : "diff";   # same  (numeric compare)
say "10" eq "10.0" ? "same" : "diff";   # diff  (string compare)
```

PHP retired the loose `==` mess in modern versions; Perl never had it, but it solves the same problem by making you say which comparison you mean. `"10" == "10.0"` is true (numeric), `"10" eq "10.0"` is false (string). Using `==` on strings, or `eq` on numbers, is the single most common PHP-to-Perl bug.

Arrays and lists

Here is where PHP's one `array` splits in two. When you used an `array` as a numerically indexed list - `$items[0]`, `array_push`, `foreach` over values - that is a Perl **array**, declared with `@`. The verbs are renamed but the operations are the same, and negative indices work as you expect.

```
$nums = [1, 2, 3, 4, 5];
$nums[] = 6;
$last = array_pop($nums);
echo count($nums);              // 5
print_r(array_slice($nums, 1, 2)); // [2, 3]
```

```
use v5.44;
my @nums = (1, 2, 3, 4, 5);
push @nums, 6;
```

(continues on next page)

(continued from previous page)

```
my $last = pop @nums;       # 6
say scalar @nums;           # 5
say "@nums[1,2]";           # 2 3   (a slice)
```

Your `array_map` and `array_filter` become `map` and `grep`. `map` transforms (PHP's `array_map`); `grep` filters (PHP's `array_filter`). `$_` is the current element, Perl's implicit loop variable, the way the callback's parameter is in PHP - except you do not name it.

```
$squares = array_map(fn($x) => $x * $x, $nums);
$evens   = array_filter($nums, fn($x) => $x % 2 == 0);
rsort($nums);   // descending, in place
```

```
use v5.44;
my @nums    = (1, 2, 3, 4, 5);
my @squares = map  { $_ * $_ }    @nums;  # 1 4 9 16 25
my @evens   = grep { $_ % 2 == 0 } @nums; # 2 4
my @desc    = sort { $b <=> $a }  @nums;  # 5 4 3 2 1
```

The gotcha: `sort` compares as strings by default, so `sort (10, 9, 100)` gives `10 100 9`. For numbers you must pass a comparator: `sort { $a <=> $b } @nums`. `$a` and `$b` are the two elements being compared, and `<=>` is the numeric three-way operator (`cmp` is its string sibling). Note also that `grep` keeps elements, returning a new list, where PHP's `array_filter` preserves keys - Perl arrays have no keys to preserve, so the result is simply re-indexed.

Hashes

The other half of PHP's `array` - the part you used with string keys, `$config['host']`, `array_key_exists`, `foreach ($h as $k => $v)` - is a Perl **hash**, declared with `%` and accessed one value at a time with `$h{key}`.

```
$h = ["apple" => 3, "pear" => 5, "plum" => 2];
echo $h["apple"];                  // 3
$keys = array_keys($h);
sort($keys);
echo array_key_exists("pear", $h) ? "yes" : "no";  // yes
unset($h["plum"]);
foreach ($h as $k => $v) {
    echo "$k => $v\n";
}
```

```
use v5.44;
my %h = (apple => 3, pear => 5, plum => 2);
say $h{apple};                          # 3
say join ",", sort keys %h;             # apple,pear,plum
say exists $h{pear} ? "yes" : "no";     # yes
delete $h{plum};
for my $k (sort keys %h) {
    say "$k => $h{$k}";                 # apple => 3 ... pear => 5
```

(continues on next page)

(continued from previous page)

```
}
```

The gotcha: membership is `exists $h{key}` (the key is present) or `defined $h{key}` (the key is present *and* its value is not undef) - between them they cover PHP's `array_key_exists` and `isset`. The fat comma `=>` is the idiomatic key/value separator and auto-quotes the bareword on its left, so `apple => 3` needs no quotes around `apple`. A Perl hash has **no insertion order** (unlike a PHP array, which keeps it); iterate `sort keys %h` when you want a stable order. To walk key and value together, PHP's `foreach ($h as $k => $v)` becomes either `for my $k (keys %h)` or, when you want both at once, `while (my ($k, $v) = each %h)`.

Context

This is the chapter to read twice. PHP has no equivalent, and almost every "Perl is weird" story traces back to it.

Every expression in Perl runs in either **list context** or **scalar context**, decided by where it appears, not by what it is. The same array behaves differently in each. Assigning an array to a *scalar* gives its length; assigning it to a *list* (a parenthesised set of variables) copies elements.

```
use v5.44;
my @list = (10, 20, 30);

my $count = @list;          # scalar context -> 3 (the length)
say $count;                 # 3

my ($first) = @list;        # list context -> first element copied
say $first;                 # 10

my ($x, $y) = @list;        # 10 and 20
say "$x $y";                # 10 20
```

The parentheses on the left are the whole difference. `my $x = @list` asks "how many?" and gets 3 - this is where `count($arr)` lives, just spelled by context instead of a function. `my ($x) = @list` asks "give me the elements" and gets `10`. A PHP developer reads both as "assign the array," which is exactly the trap.

A subroutine can ask which context it was called in, with `wantarray`, and return different things accordingly:

```
use v5.44;
sub items {
    return wantarray ? (1, 2, 3) : "three items";
}
my @got = items();          # list context
my $msg = items();          # scalar context
say "@got";                 # 1 2 3
say $msg;                   # three items
```

Built-ins use this too. `scalar @array` forces scalar context to get a count - that is the

explicit `count()` you were looking for. A regex match with `/g` returns the list of matches in list context and a true/false in scalar context.

The gotcha: there is no single answer to "what does this array do" - it depends on the surrounding expression. When something returns a number you expected to be a list (or vice versa), context is the first suspect. Reach for `scalar` to force a count and parentheses on the left to force element copying.

Truthiness

Perl's false values are a short, specific list: the number `0`, the empty string `""`, the string `"0"`, and `undef` (Perl's `null`). **Everything else is true.** This is close to PHP's rules but not identical, and the differences are quiet.

```
use v5.44;
for my $v (0, 1, "", "0", "00", "0.0", "false") {
    say "'$v' is ", ($v ? "true" : "false");
}
```

This prints, exactly:

```
'0' is false
'1' is true
'' is false
'0' is false
'00' is true
'0.0' is true
'false' is true
```

The gotcha: `"00"` and `"0.0"` are **true** in Perl, even though PHP treats `"0"` and only `"0"` as the falsy string too - Perl agrees on `"0"` but not on its look-alikes. The string `"false"` is true (it is a non-empty, non-`"0"` string), the same as in PHP. And unlike PHP's empty-array-is-falsy rule, an empty Perl array is not itself a false *value*: in boolean context an array yields its length, so `if (@list)` is true exactly when the list is non-empty, which is the test you want. For "use this if defined, else a default," use defined-or `//`, the equivalent of PHP's `??`, which falls back only on `undef` (not on `0` or `""`):

```
use v5.44;
my %cfg = (host => "localhost");
my $port = $cfg{port} // 8080;   # key absent -> undef -> 8080
say $port;                       # 8080
```

Control flow

The keywords are familiar; the spelling differs in two small ways. `elseif` is `elsif` (one e), and conditions need parentheses while blocks need braces - there is no `:`/`endif` alternate syntax.

```
if ($n < 0) {
    $sign = "neg";
} elseif ($n == 0) {
```

(continues on next page)

(continued from previous page)

```
    $sign = "zero";
} else {
    $sign = "pos";
}

foreach ($nums as $x) {
    echo $x;
}

while ($running) {
    step();
}
```

```
use v5.44;
my $sign;
if    ($n < 0)  { $sign = "neg"  }
elsif ($n == 0) { $sign = "zero" }
else            { $sign = "pos"  }

for my $x (@nums) { say $x }

while ($running) { step() }
```

Perl adds two things PHP does not have. **Postfix modifiers** let a simple statement carry its own condition or loop, which reads naturally for one-liners:

```
use v5.44;
say $_ for @nums;                # loop, one statement
say "negative" if $n < 0;        # guarded statement
$sum += $_ for @nums;            # accumulate
```

And `unless`/`until` are the negated forms of `if`/`while`, for when the positive phrasing reads awkwardly: `say "ok" unless $error`.

The gotcha: the ternary is `?`/`:`, the same as PHP's, and chains the same way: `my $sign = $n < 0 ? "neg" : $n == 0 ? "zero" : "pos"`. Perl has no `switch`/`match` statement in core; a chained ternary or a dispatch hash (`$handler{$key}->()`) is the idiom, and a `for`-on-a-single-value block is the common substitute for a `switch`.

Subroutines

PHP's `function` becomes Perl's `sub`. Modern Perl has signatures that look much like PHP's parameter lists, including default values.

```
function greet($name, $greeting = "Hello") {
    return "$greeting, $name!";
}

function total(...$nums) {
```

(continues on next page)

(continued from previous page)

```
    return array_sum($nums);
}
```

```
use v5.44;
sub greet ($name, $greeting = "Hello") {
    return "$greeting, $name!";
}
say greet("Ada");           # Hello, Ada!
say greet("Rasmus", "Hi");  # Hi, Rasmus!

sub total (@nums) {
    my $sum = 0;
    $sum += $_ for @nums;
    return $sum;
}
say total(1, 2, 3, 4);      # 10
```

The variadic `...$nums` becomes a trailing array parameter `@nums`, which gathers all remaining arguments. PHP's named arguments (or the common `$opts` array convention) map to a hash parameter, since `key => value` pairs flatten into a list that a `%opts` signature gathers up:

```
use v5.44;
sub connect_to (%opts) {
    return "host=$opts{host} port=$opts{port}";
}
say connect_to(host => "localhost", port => 8080);
# host=localhost port=8080
```

The gotcha: a sub returns the value of its last expression even without `return`, and the return is **context-sensitive** (see *Context*). If you `return @list`, the caller gets the list in list context but the *count* in scalar context. Be deliberate about what you return when it might be used either way.

References

PHP arrays nest directly: an `array` can hold another `array` and you just keep subscripting. Perl arrays and hashes do not nest directly; you nest them through **references**, scalars that point at an aggregate. This is the same machinery as PHP's `&$x` references and its object handles, but in Perl you reach for it whenever you build nested data. Take a reference with `\`, follow it with `->`.

```
$data = ["name" => "Ada", "langs" => ["Perl", "PHP"]];
echo $data["langs"][1];      // PHP
$data["langs"][] = "Ruby";
```

```
use v5.44;
my $data = { name => "Ada", langs => ["Perl", "PHP"] };
say $data->{name};                  # Ada
```

(continues on next page)

(continued from previous page)

```
say $data->{langs}[1];              # PHP
push $data->{langs}->@*, "Ruby";    # postfix deref to push
say "@{$data->{langs}}";           # Perl PHP Ruby
```

`{ ... }` builds an anonymous hash reference and `[ ... ]` an anonymous array reference - the literal building blocks of nested data, matching the `[...]` and `[k => v]` literals you already write in PHP. The `->` arrow follows a reference one step; between two subscripts it is optional, so `$data->{langs}[1]` and `$data->{langs}->[1]` are the same. The arrow is also exactly the method-call arrow you know from PHP OO - same symbol, both for "reach inside" and "call a method."

Anonymous subs are closures, exactly like PHP's `fn` and `function() use (...)`, but with no `use` clause needed - they capture lexicals automatically:

```
use v5.44;
my $double = sub ($n) { $n * 2 };
say $double->(21);          # 42
```

The gotcha: the postfix deref forms (`->@*`, `->%*`, `->$*`) are the modern, readable way to dereference a whole aggregate, and `"@{ ... }"` is how you interpolate a dereferenced array into a string. The older `@$ref` and `${$ref}{key}` forms still work and appear in existing code, but reach for the arrow and postfix forms in new code.

Regular expressions

In PHP regex is the `preg_*` function family with pattern strings like `'/\d+/'`. In Perl it is **syntax**: `=~` binds a pattern to a string, `m//` matches, `s///` substitutes - no delimiters-inside-a-string, no function call. Capture groups land in `$1`, `$2`, and named captures in `%+`.

```
if (preg_match('/(\d{4})-(\d{2})-(\d{2})/', $s, $m)) {
    [$_, $year, $month, $day] = $m;
}
$t = preg_replace('/,/', ';', "a,b,c");
$parts = explode(",", "one,two,three");
```

```
use v5.44;
my $s = "2026-06-20";
if ($s =~ /(\d{4})-(\d{2})-(\d{2})/) {
    say "$1 $2 $3";                 # 2026 06 20
}
if ($s =~ /(?<year>\d{4})/) {
    say $+{year};                   # 2026
}
(my $t = "a,b,c") =~ s/,/;/g;       # a;b;c
my @parts = split /,/, "one,two,three";   # one two three
```

A `/g` match in list context returns *all* captures, the direct analogue of `preg_match_all`:

```
use v5.44;
my @nums = "x1y2z3" =~ /(\d)/g;     # 1 2 3
say "@nums";
```

The gotcha: `s///` modifies its target *in place* and returns the number of substitutions, not a new string - unlike `preg_replace`, which returns a fresh string. That is why the example copies first with `(my $t = "a,b,c")` and then substitutes on the copy - otherwise you would be editing a string literal. To get a new string without touching the original (the `preg_replace` reflex), use the `/r` flag: `my $t = $s =~ s/,/;/gr`.

File and stream I/O

The idiom is the three-argument open with a lexical filehandle, the counterpart of PHP's `fopen` into a `$handle`. The angle-bracket operator `<$fh>` reads a line, the same role as `fgets`.

```
$wh = fopen("/tmp/sample.txt", "w");
for ($i = 1; $i <= 3; $i++) {
    fwrite($wh, "line $i\n");
}
fclose($wh);

$rh = fopen("/tmp/sample.txt", "r");
while (($line = fgets($rh)) !== false) {
    echo "got: " . rtrim($line) . "\n";
}
fclose($rh);
```

```
use v5.44;
my $path = "/tmp/sample.txt";

open my $wh, '>', $path or die "cannot write: $!";
print {$wh} "line $_\n" for 1 .. 3;
close $wh;

open my $rh, '<', $path or die "cannot read: $!";
while (my $line = <$rh>) {
    chomp $line;
    say "got: $line";       # got: line 1 ... got: line 3
}
close $rh;
```

To slurp every line at once, read the handle in list context - the moral equivalent of `file()`:

```
use v5.44;
open my $fh, '<', "/tmp/sample.txt" or die $!;
my @lines = <$fh>;          # all lines, including newlines
say scalar @lines;          # 3
```

The gotcha: a line read with `<$fh>` keeps its trailing newline; call `chomp` to strip it (the

`rtrim` reflex, but `chomp` removes only the record separator). And `open` returns false on failure rather than raising or warning, so the `or die "...: $!"` idiom is mandatory - `$!` is the system error message, Perl's `errno` (PHP's `error_get_last()`).

Modules and packages

PHP's `require`/`include` and Composer's autoloader become Perl's `use`. The namespace separator is `::`, not `\`, and a module `Foo::Bar` lives at `Foo/Bar.pm` on the include path `@INC` (Perl's `include_path`). A module's import list is a selection of names to bring into your namespace.

```
require 'vendor/autoload.php';
use App\Util\ListHelper;
$sum = ListHelper::sum(range(1, 10));
```

```
use v5.44;
use List::Util qw(sum0 max first);
say sum0(1 .. 10);                      # 55
say max(3, 7, 2);                       # 7
say first { $_ % 2 == 0 } (1, 3, 4, 5);  # 4
```

PHP's huge flat standard-function namespace (`count`, `in_array`, `array_map`, `implode`, `sprintf`, ...) maps in Perl partly to built-in operators and partly to a few everyday modules. The common translations:

PHP	Perl
`count($a)`	`scalar @a`
`in_array($x, $a)`	`grep { $_ eq $x } @a`
`array_map($f, $a)`	`map { ... } @a`
`array_filter($a, $f)`	`grep { ... } @a`
`implode(",", $a)`	`join ",", @a`
`explode(",", $s)`	`split /,/, $s`
`sprintf(...)`	`sprintf(...)` (same)
`isset($h[$k])`	`exists $h{$k}` / `defined $h{$k}`
`array_sum($a)`	`sum0 @a` (`List::Util`)

`List::Util`, `Scalar::Util`, `POSIX`, `File::Spec`, and `Data::Dumper` are the everyday modules; most of what you would pull from Packagist ships in core or on CPAN, the Perl package archive.

The gotcha: `use` runs at *compile time*, not at the point in the file where it appears, so the order of `use` lines relative to your code does not matter the way `require` placement can in PHP. Importing is also opt-in per name: `use List::Util qw(sum0 max)` brings exactly `sum0` and `max` into your namespace, nothing else - there is no global function table the way PHP exposes every built-in everywhere.

(Web request data - PHP's `$_GET`, `$_POST`, `$_SERVER` superglobals - has no language-level analogue in Perl; that is the job of a CGI or PSGI layer, not the core language, and is out of scope for this guide.)

Objects

For new code, Perl 5.44 has a first-class `class` syntax that will look familiar coming from PHP. Fields are declared with `field`, methods with `method`, and `$self` is available inside every method just as `$this` is in PHP (you do not list it as a parameter).

```
class Point {
    public function __construct(
        public int $x = 0,
        public int $y = 0,
    ) {}
    public function to_string(): string {
        return "({$this->x}, {$this->y})";
    }
    public function move(int $dx, int $dy): static {
        $this->x += $dx;
        $this->y += $dy;
        return $this;
    }
}

$p = new Point(x: 3, y: 4);
echo $p->to_string();        // (3, 4)
$p->move(1, 1);
echo $p->to_string();        // (4, 5)
```

```
use v5.44;
use feature 'class';

class Point {
    field $x :param = 0;
    field $y :param = 0;
    method to_string { return "($x, $y)" }
    method move ($dx, $dy) {
        $x += $dx;
        $y += $dy;
        return $self;
    }
}

my $p = Point->new(x => 3, y => 4);
say $p->to_string;          # (3, 4)
$p->move(1, 1);
say $p->to_string;          # (4, 5)
```

The constructor is generated for you, like PHP's promoted constructor properties: `:param` marks a field that the auto-built `new` accepts as a named argument, and `= 0` is its default. The method-call arrow `->` is the same one you use in PHP. Inheritance is `:isa`, the counterpart of `extends`:

```
use v5.44;
```

(continues on next page)

(continued from previous page)

```
use feature 'class';

class Point3D :isa(Point) {
    field $z :param = 0;
    method z { return $z }
}

my $q = Point3D->new(x => 1, y => 2, z => 3);
say $q->to_string, " z=", $q->z;   # (1, 2) z=3
```

The gotcha: the `class` feature is still marked experimental in Perl 5.44, and on `pperl` the "class is experimental" notices print to **stderr** even with `no warnings 'experimental::class'` in scope. They do not touch your program's output, so a script that prints to stdout behaves exactly as shown above; just expect the notices on the error stream. The older object model - a package, a hash blessed into it with `bless`, and `@ISA` for inheritance - is what you will meet in existing code and most of CPAN; for it, for roles, and for migration advice, see the *Object-oriented Programming guide*.

Error handling

PHP's `try`/`catch` has a direct counterpart in modern Perl, and it reads almost identically. The raising side is `die` (PHP's `throw`):

```
function risky($n) {
    if ($n < 0) {
        throw new Exception("negative!");
    }
    return sqrt($n);
}

try {
    risky(-4);
} catch (Exception $e) {
    echo "caught: " . $e->getMessage() . "\n";
}
```

```
use v5.44;
use feature 'try';

sub risky ($n) {
    die "negative!\n" if $n < 0;
    return sqrt $n;
}

try {
    risky(-4);
}
catch ($e) {
    print "caught: $e";     # caught: negative!
```

(continues on next page)

(continued from previous page)

```
}
```

The older, still-common form wraps code in `eval { }` and inspects `$@` (the caught error) afterward - the same pattern as PHP code written before exceptions were idiomatic:

```
use v5.44;
my $result = eval { risky(-1) };
if ($@) {
    print "caught: $@";     # caught: negative!
}
```

The gotcha: `die` with a string that ends in `\n` produces exactly that message; `die` with a string that does *not* end in a newline gets `" at SCRIPT line N.\n"` appended automatically. End your error strings with `\n` when you want a clean message and omit it when you want the file-and-line trace. Note also the two error variables: `$@` is the last caught exception (PHP's `$e`), while `$!` is the last *system* error (a failed open, the `errno` string).

Idioms

A few patterns you will see daily and want in your fingers.

Sort a list by a computed key (the Schwartzian transform - PHP's `usort` with a precomputed key, done in one expression: decorate, sort, undecorate):

```
use v5.44;
my @words = qw(apple fig pear);
my @by_length =
    map  { $_->[1] }
    sort { $a->[0] <=> $b->[0] }
    map  { [ length $_, $_ ] } @words;
say "@by_length";           # fig pear apple
```

Build a hash from a list, the `array_combine`/`array_column` analogue (here, word to its length):

```
use v5.44;
my @words = qw(apple pear fig);
my %len = map { $_ => length $_ } @words;
say "$_ => $len{$_}" for sort keys %len;
# apple => 5
# fig => 3
# pear => 4
```

And `pperl` is a command-line tool in the `awk`/`sed` niche - the same job you might reach for a quick PHP CLI script to do. The implicit-loop one-liner is the Perl developer's everyday reflex:

```
pperl -lane '$s += $F[-1]; END { print $s }' data.txt
```

The gotcha: read the *One-Liners guide* for the switches (`-n`, `-p`, `-a`, `-l`, `-e`) and the dozens

of recipes built on them; it is one of the highest-leverage things to learn coming from a PHP-and-shell background.

Gotchas coming from PHP

The traps, collected for a final scan before you start writing:

- **Sigils change with usage.** One element of `@a` is `$a[0]`; one value of `%h` is `$h{k}`. PHP keeps `$` everywhere; Perl varies the sigil by what shape you are getting.
- **One PHP `array` is two Perl types.** Decide up front: integer keys and order means `@array`; string keys means `%hash`. They are not interchangeable.
- **Two comparison families.** `==`/`<`/`<=>` for numbers, `eq`/`lt`/`cmp` for strings. Pick by operand type, not by variable. `==` on strings or `eq` on numbers is the classic bug.
- **`.` joins strings, `+` only adds numbers.** Perl's `+` never does array union or concatenation; mixing `.` and `+` corrupts your data silently or warns.
- **`sort` is string-sorted by default.** Pass `{ $a <=> $b }` for numeric order.
- **Hashes have no order.** Unlike a PHP array, iteration order is not insertion order; `sort keys %h` when you need stability.
- **Context.** `my $x = @a` is the *count*; `my ($x) = @a` is the *first element*. The parentheses are the whole difference. Re-read *Context* when a value comes back the wrong shape.
- **Truthiness surprises.** `"0"` is false, but `"00"` and `"0.0"` are **true**. Only `0`, `""`, `"0"`, and `undef` are false. An empty array is not a false value - `if (@a)` tests non-empty.
- **`s///` edits in place** and returns a count, unlike `preg_replace`; use the `/r` flag to get a new string instead.
- **`open` does not raise.** Use `open ... or die "...: $!"`.
- **`chomp` your line reads.** `<$fh>` keeps the trailing newline.
- **Web superglobals are not core.** `$_GET`/`$_POST` belong to a CGI or PSGI layer, not the language.
- **Non-ASCII source needs `use utf8;`.** Under `use v5.44;` a literal non-ASCII byte in your source is a compile error without it. Keep string data ASCII unless you specifically add `use utf8;`.
- **The `class` feature prints experimental notices to stderr** on `pperl`. Correct output, noisy error stream.

Ruby to Perl

You know Ruby. You pass blocks to `each` and `map` without thinking, you reach for a `Hash` by reflex, and `arr.select { |x| ... }` is muscle memory. This guide maps each of those habits onto Perl, so you can be productive in `pperl` in an afternoon instead of relearning programming from scratch.

Two shifts land in the first five minutes, so meet them now:

- **Sigils mark the type, not the scope.** Ruby uses `@var` for instance state, `$var` for globals, and a bare `var` for locals. Perl uses `$x` for a single value, `@x` for an ordered

list, %x for a key/value map - the sigil tells you the *shape* of the data, and it is the same whether the variable is local or global. Section one is about nothing else.

- **Not everything is an object.** In Ruby `"foo".upcase` and `[1, 2].sum` are method calls because numbers, strings, and arrays are all objects. Perl is pragmatic: a scalar is not an object, there is no universal base class, and those operations are plain functions - `uc "foo"`, `sum @a`. You call methods only on things you blessed into a class.

Every example here runs on `pperl`, a Rust reimplementation of Perl 5.44. Each Perl snippet was executed on `pperl`; the `# ...` comments show its real output. Start your scripts with:

```
use v5.44;
```

That one line turns on `strict` (no accidental globals), `warnings`, the `say` built-in (a `print` with a trailing newline, like Ruby's `puts`), subroutine signatures, and the modern feature set used throughout this guide.

How to read this

- *Variables and sigils* - the $/@/% shift.
- *Strings* - interpolation and concatenation.
- *Numbers* - one surface type, float division.
- *Arrays and lists* - your `Array`, plus block-taking `map`/`grep`.
- *Hashes* - your `Hash`, and where symbols go.
- *Context* - the concept Ruby has no word for. Read this one.
- *Truthiness* - what counts as false, and it differs sharply.
- *Control flow* - `if`, loops, the postfix forms.
- *Subroutines* - `def` becomes `sub`.
- *References* - nested data, and blocks as values.
- *Regular expressions* - regex as syntax, like Ruby's.
- *File and stream I/O* - open, line reads, slurp.
- *Modules and packages* - `require` becomes `use`.
- *Objects* - the modern `class` syntax.
- *Error handling* - `begin`/`rescue` becomes `eval` or `try`/`catch`.
- *Idioms* - the daily one-liners.
- *Gotchas coming from Ruby* - scan before you write.

Variables and sigils

In Ruby a sigil tells you *scope*: `@x` is an instance variable, `$x` a global, `x` a local. In Perl the **sigil tells you shape**: `$` for a single value, `@` for an ordered list, `%` for a key/value map. `my` declares a lexically scoped variable, the Perl equivalent of an ordinary local binding - it is how you get a local in Perl, where Ruby just uses a bare name.

```ruby
name  = "Ada"
langs = ["Ruby", "Perl"]
ages  = {"Ada" => 36, "Yukihiro" => 60}
```

```perl
use v5.44;
my $name  = "Ada";
my @langs = ("Ruby", "Perl");
my %ages  = (Ada => 36, Yukihiro => 60);
say $name;            # Ada
say $langs[0];        # Ruby
say $ages{Ada};       # 36
```

The gotcha: when you reach *into* an aggregate for one element, the sigil follows the value you get back, not the container. A single element of `@langs` is a scalar, so it is `$langs[0]`, not `@langs[0]`; one value from `%ages` is `$ages{Ada}`. The `@`/`%` form is the whole collection; the `$` form is one piece of it. (And forget the Ruby mapping: a Perl `$x` is never "a global" the way Ruby's `$x` is - the `$` here just means "one value.")

Strings

Double quotes interpolate variables, single quotes do not, exactly like Ruby's `"..."` versus `'...'`. The Ruby `#{expr}` form has a direct counterpart for plain variables and a slightly longer one for arbitrary expressions. Concatenation is `.`, not `+`.

```ruby
name     = "Ada"
greeting = "Hello, #{name}"
total    = "Total: #{6 * 7}"
shout    = "AB" * 3
```

```perl
use v5.44;
my $name = "Ada";
my $greeting = "Hello, $name";     # Hello, Ada
my $literal  = 'Hello, $name';     # Hello, $name  (no
 ↪interpolation)
my $total    = "Total: @{[ 6 * 7 ]}";  # Total: 42
my $joined   = "AB" . "CD";        # ABCD
my $shout    = "AB" x 3;           # ABABAB
```

The gotcha: a bare `"$name"` interpolates a variable just like Ruby's `#{name}`, but to interpolate an *expression* you wrap it in the `@{[ ... ]}` form (it builds a throwaway array and inlines it). String repetition is `x`, not `*`, and the join operator is `.`, not `+`; `+` on strings coerces them to numbers and warns. Array elements and hash values interpolate inside double quotes too: `"First: $langs[0]"` works as written.

Numbers

Perl has one numeric type at the surface; you do not distinguish `Integer` from `Float`. Division always produces a float, like Ruby's `Float` division when either operand is a float.

```
puts 7.0 / 2        # 3.5
puts 7 / 2          # 3   (integer division in Ruby)
puts 2 ** 10        # 1024
puts 10 % 3         # 1
```

```
use v5.44;
say 7 / 2;          # 3.5   (always float)
say int(7 / 2);     # 3
say 2 ** 10;        # 1024
say 10 % 3;         # 1
```

The gotcha: comparison and equality operators come in two families, and you pick by the *operands' type*, not the variables'. Numbers use `==`, `!=`, `<`, `>`, `<=>`; strings use `eq`, `ne`, `lt`, `gt`, `cmp`. This has no Ruby analogue - Ruby's `==` dispatches on the object's class, while Perl's `==` always means *numeric* equality. `"10" == "10.0"` is true (numeric), but `"10" eq "10.0"` is false (string). Using `==` on strings, or `eq` on numbers, is a frequent and quiet bug.

Arrays and lists

A Perl array is your Ruby `Array`. The big shift is method calls becoming functions: Ruby's `arr.push(x)`, `arr.pop`, `arr.length` become `push @arr, x`, `pop @arr`, `scalar @arr` - the array is an argument, not a receiver.

```
nums = [1, 2, 3, 4, 5]
nums.push(6)
last = nums.pop          # 6
puts nums.length         # 5
puts nums[1, 2].join(" ")  # 2 3
```

```
use v5.44;
my @nums = (1, 2, 3, 4, 5);
push @nums, 6;
my $last = pop @nums;       # 6
say scalar @nums;           # 5
say "@nums[1,2]";           # 2 3   (a slice)
```

Ruby's block-taking iterators are the richest part of this mapping. `map`, `select`, and `sort_by` become Perl `map`, `grep`, and `sort`, which take a `{ ... }` block exactly the way Ruby methods do. Inside the block, `$_` is the current element - Perl's implicit block variable, the role Ruby's `|x|` parameter plays.

```
squares = nums.map    { |x| x * x }
evens   = nums.select { |x| x.even? }
desc    = nums.sort   { |a, b| b <=> a }
```

```
use v5.44;
my @nums    = (1, 2, 3, 4, 5);
my @squares = map  { $_ * $_ }    @nums;  # 1 4 9 16 25
my @evens   = grep { $_ % 2 == 0 } @nums; # 2 4
my @desc    = sort { $b <=> $a }  @nums;  # 5 4 3 2 1
```

The gotcha: `sort` compares as strings by default, so `sort (10, 9, 100)` gives `10 100 9`. For numbers you must pass a comparator: `sort { $a <=> $b } @nums`. `$a` and `$b` are the two elements being compared (the equivalent of Ruby's `|a, b|`), and `<=>` is the numeric three-way operator - the very same spaceship you know from Ruby (`cmp` is its string sibling).

Hashes

A Perl hash is your Ruby `Hash`. Declared with `%`, accessed one value at a time with `$h{key}`. The fat comma `=>` you already use in Ruby hash literals works here too, and it auto-quotes the bareword on its left.

```
h = {apple: 3, pear: 5, plum: 2}
puts h[:apple]                          # 3
puts h.keys.sort.join(",")              # apple,pear,plum
puts h.key?(:pear)                      # true
h.delete(:plum)
h.sort.each { |k, v| puts "#{k} => #{v}" }
```

```
use v5.44;
my %h = (apple => 3, pear => 5, plum => 2);
say $h{apple};                          # 3
say join ",", sort keys %h;             # apple,pear,plum
say exists $h{pear} ? "yes" : "no";     # yes
delete $h{plum};
for my $k (sort keys %h) {
    say "$k => $h{$k}";
}
```

The gotcha: Perl has **no symbol type**. Where Ruby reaches for `:apple` as a lightweight, interned key, Perl just uses the string `"apple"` - and the `=>` fat comma auto-quotes it, so `apple => 3` and `$h{apple}` need no quotes. A Ruby symbol and a Ruby string are different objects; in Perl there is only the string, so the `:sym` versus `"sym"` distinction simply vanishes. Membership is `exists $h{key}`, not Ruby's `key?`, and a hash has no order - iterate `sort keys %h` when you want a stable one.

Context

This is the chapter to read twice. Ruby has no equivalent, and almost every "Perl is weird" story traces back to it.

Every expression in Perl runs in either **list context** or **scalar context**, decided by where it appears, not by what it is. The same array behaves differently in each. Assigning an array to a *scalar* gives its length; assigning it to a *list* (a parenthesised set of variables) copies elements. Ruby never overloads assignment this way - `a = arr` always

just aliases the array - so this is genuinely new.

```
use v5.44;
my @list = (10, 20, 30);

my $count = @list;          # scalar context -> 3 (the length)
say $count;                 # 3

my ($first) = @list;        # list context -> first element copied
say $first;                 # 10

my ($a, $b) = @list;        # 10 and 20
say "$a $b";                # 10 20
```

The parentheses on the left are the whole difference. `my $x = @list` asks "how many?" and gets 3. `my ($x) = @list` asks "give me the elements" and gets `10`. The Ruby reflex reads both as "assign the array," which is exactly the trap.

A subroutine can ask which context it was called in, with `wantarray`, and return different things accordingly:

```
use v5.44;
sub items {
    return wantarray ? (1, 2, 3) : "three items";
}
my @got = items();          # list context
my $msg = items();          # scalar context
say "@got";                 # 1 2 3
say $msg;                   # three items
```

Built-ins use this too. `scalar @array` forces scalar context to get a count; a regex match with `/g` returns the list of matches in list context and a true/false in scalar context. The classic idiom for "count the matches" forces a list assignment in scalar context with the so-called *countof* form:

```
use v5.44;
my $n = () = "a1b2c3" =~ /\d/g;
say $n;                     # 3
```

The gotcha: there is no single answer to "what does this array do" - it depends on the surrounding expression. When something returns a number you expected to be a list (or vice versa), context is the first suspect. Reach for `scalar` to force a count and parentheses on the left to force element copying.

Truthiness

This is the sharpest break from Ruby in the whole guide. In Ruby only `nil` and `false` are falsy - `0` and `""` are both **true**. In Perl the false values are a short, specific list: the number `0`, the empty string `""`, the string `"0"`, and `undef` (Perl's `nil`). Everything else is true.

```
use v5.44;
for my $v (0, 1, "", "0", "00", "0.0", "false") {
    say "'$v' is ", ($v ? "true" : "false");
}
```

This prints, exactly:

```
'0' is false
'1' is true
'' is false
'0' is false
'00' is true
'0.0' is true
'false' is true
```

The gotcha: `0` and `""` are **false** in Perl but **true** in Ruby - the single most disruptive habit to unlearn. A Ruby guard like `if count` fires for `count == 0`; the Perl `if ($count)` does not. On the other side, `"00"` and `"0.0"` are **true** in Perl even though they look numerically zero, because only the exact string `"0"` is false. And unlike Ruby, where you might lean on `nil` checks, Perl distinguishes "false" from "undefined" with defined-or `//`, which falls back only on `undef` (not on `0` or `""`):

```
use v5.44;
my %cfg = (host => "localhost");
my $port = $cfg{port} // 8080;   # key absent -> undef -> 8080
say $port;                       # 8080
```

Control flow

The keywords are familiar; the spelling differs. `elsif` is Perl's `elsif` (Ruby's `elsif` too - one of the few exact matches), and blocks are braced, with no `then` and no terminating `end`.

```
if    n < 0  then sign = "neg"
elsif n == 0 then sign = "zero"
else              sign = "pos"
end

nums.each { |x| puts x }

while running
  step
end
```

```
use v5.44;
my $sign;
if    ($n < 0)  { $sign = "neg"  }
elsif ($n == 0) { $sign = "zero" }
else            { $sign = "pos"  }
```

(continues on next page)

(continued from previous page)

```
for my $x (@nums) { say $x }

while ($running) { step() }
```

Perl's **postfix modifiers** are the direct counterpart of Ruby's trailing `puts x if cond` and `do_it while cond` - a simple statement carrying its own condition or loop:

```
use v5.44;
say $_ for @nums;                # loop, one statement
say "negative" if $n < 0;        # guarded statement
$sum += $_ for @nums;            # accumulate
```

And `unless`/`until` are the negated forms of `if`/`while`, just like Ruby's `unless`/`until`: `say "ok" unless $error`.

The gotcha: the ternary uses `?`/`:`, not Ruby's `cond ? a : b` - which is actually identical, so this one is free. There is no `x if c else y` expression form; chain ternaries instead: `my $sign = $n < 0 ? "neg" : $n == 0 ? "zero" : "pos"`.

Subroutines

`def` becomes `sub`. Modern Perl has signatures that look much like Ruby's parameter lists, including defaults. And the good news a Ruby developer wants to hear: **the last evaluated expression is the return value**, exactly as in Ruby - `return` is optional.

```
def greet(name, greeting = "Hello")
  "#{greeting}, #{name}!"
end

def total(*nums)
  nums.sum
end
```

```
use v5.44;
sub greet ($name, $greeting = "Hello") {
    return "$greeting, $name!";
}
say greet("Ada");           # Hello, Ada!
say greet("Yukihiro", "Hi"); # Hi, Yukihiro!

sub area ($w, $h) { $w * $h }   # no return needed; last expr wins
say area(3, 4);             # 12

sub total (@nums) {
    my $sum = 0;
    $sum += $_ for @nums;
    return $sum;
}
say total(1, 2, 3, 4);      # 10
```

Ruby keyword arguments map to a hash parameter, since `key => value` pairs flatten into a list that a `%opts` signature gathers up:

```
use v5.44;
sub connect_to (%opts) {
    return "host=$opts{host} port=$opts{port}";
}
say connect_to(host => "localhost", port => 8080);
# host=localhost port=8080
```

The gotcha: a sub returns the value of its last expression even without `return` (the Ruby reflex carries over), but in Perl that return is also **context-sensitive** (see *Context*). If you `return @list`, the caller gets the list in list context but the *count* in scalar context. Be deliberate about what you return when it might be used either way.

References

Perl's arrays and hashes do not nest directly; you nest them through **references**, a scalar that points at an aggregate. In Ruby every container is already a reference, so nesting is invisible to you there; in Perl you take a reference with `\` (or build one with `[ ]`/`{ }`) and follow it with `->`.

```
data = {name: "Ada", langs: ["Perl", "Ruby"]}
puts data[:langs][1]      # Ruby
data[:langs].push("Python")
```

```
use v5.44;
my $data = { name => "Ada", langs => ["Perl", "Ruby"] };
say $data->{name};                  # Ada
say $data->{langs}[1];              # Ruby
push $data->{langs}->@*, "Python";  # postfix deref to push
say "@{$data->{langs}}";           # Perl Ruby Python
```

`{ ... }` builds an anonymous hash reference and `[ ... ]` an anonymous array reference - the literal building blocks of nested data, matching Ruby's `{}` and `[]` literals. The `->` arrow follows a reference one step; between two subscripts it is optional, so `$data->{langs}[1]` and `$data->{langs}->[1]` are the same.

The payoff for a Ruby developer is blocks-as-values. A Ruby block, `proc`, or `lambda` becomes a Perl anonymous sub: a closure stored in a scalar, called with `->`. It closes over its lexicals exactly like a Ruby block:

```
use v5.44;
my $doubler = sub { map { $_ * 2 } @_ };
say join ",", $doubler->(1, 2, 3);  # 2,4,6

my $factor = 10;
my $scaler = sub ($x) { $x * $factor };  # closes over $factor
say $scaler->(5);                   # 50
```

The gotcha: a Perl anonymous sub is a value you must *store and call explicitly* with `->( )` - there is no implicit `yield`, no block passed invisibly alongside the arguments. When

a builtin wants a block (`map`/`grep`/`sort`, or `first`/`reduce` from `List::Util`), you write the `{ ... }` inline; when you want to pass a callable around as data, you make a `sub { ... }` and call it through its scalar. The postfix deref forms (`->@*`, `->%*`, `->$*`) are the modern, readable way to dereference a whole aggregate.

Regular expressions

Good news: Perl regex will feel like home. Ruby borrowed its regex literal `/.../`, its `=~` operator, and `$1`/`$2` capture variables straight from Perl. The match operator `m//`, the substitution `s///`, and named captures in `%+` round it out.

```ruby
s = "2026-06-20"
if s =~ /(\d{4})-(\d{2})-(\d{2})/
  puts "#{$1} #{$2} #{$3}"
end
t = "a,b,c".gsub(",", ";")
parts = "one,two,three".split(",")
```

```perl
use v5.44;
my $s = "2026-06-20";
if ($s =~ /(\d{4})-(\d{2})-(\d{2})/) {
    say "$1 $2 $3";                 # 2026 06 20
}
if ($s =~ /(?<year>\d{4})/) {
    say $+{year};                   # 2026
}
(my $t = "a,b,c") =~ s/,/;/g;       # a;b;c
my @parts = split /,/, "one,two,three";   # one two three
```

A `/g` match in list context returns *all* captures, the direct analogue of Ruby's `String#scan`:

```perl
use v5.44;
my @nums = "x1y2z3" =~ /(\d)/g;     # 1 2 3
say "@nums";
```

The gotcha: where Ruby's `gsub` returns a new string and leaves the original alone, Perl's `s///` modifies its target *in place* and returns the number of substitutions. That is why the example copies first with `(my $t = "a,b,c")` and then substitutes on the copy. To get a new string without touching the original - the `gsub` behaviour you expect - add the `/r` flag: `my $t = $s =~ s/,/;/gr`.

File and stream I/O

The idiom is the three-argument open with a lexical filehandle, the counterpart of Ruby's `File.open(path, mode) do |f| ... end`. The angle-bracket operator `<$fh>` reads a line, the same role as Ruby's `f.each_line` or `f.gets`.

```ruby
File.open("/tmp/sample.txt", "w") do |f|
  (1..3).each { |i| f.write("line #{i}\n") }
end
```

(continues on next page)

(continued from previous page)

```ruby
File.open("/tmp/sample.txt") do |f|
  f.each_line { |line| puts "got: #{line.chomp}" }
end
```

```perl
use v5.44;
my $path = "/tmp/sample.txt";

open my $wh, '>', $path or die "cannot write: $!";
print {$wh} "line $_\n" for 1 .. 3;
close $wh;

open my $rh, '<', $path or die "cannot read: $!";
while (my $line = <$rh>) {
    chomp $line;
    say "got: $line";       # got: line 1 ... got: line 3
}
close $rh;
```

To slurp every line at once, read the handle in list context:

```perl
use v5.44;
open my $fh, '<', "/tmp/sample.txt" or die $!;
my @lines = <$fh>;          # all lines, including newlines
say scalar @lines;          # 3
```

The gotcha: a line read with `<$fh>` keeps its trailing newline; call `chomp` to strip it - Ruby's `line.chomp` is the same verb, and Perl borrowed the name. And `open` returns false on failure rather than raising the way Ruby's `File.open` does, so the `or die "...: $!"` idiom is mandatory; `$!` is the system error message, Perl's equivalent of the message in Ruby's `Errno` exception.

Modules and packages

`require`/`include` becomes `use`. The namespace separator is `::`, which you already know from Ruby constants like `Set::Foo`; Perl uses it everywhere, for both packages and the names inside them. A module `Foo::Bar` lives at `Foo/Bar.pm` on the include path `@INC` (Perl's `$LOAD_PATH`). A module's import list is a selection of names, much like pulling specific methods into scope.

```ruby
require "set"
nums = [1, 2, 3, 4].sum
biggest = [3, 7, 2].max
```

```perl
use v5.44;
use List::Util qw(sum0 max first);
say sum0(1 .. 10);                      # 55
say max(3, 7, 2);                       # 7
say first { $_ % 2 == 0 } (1, 3, 4, 5);  # 4
```

The standard library is large, and much of what you would reach to RubyGems for ships in core or on CPAN, the Perl package archive. `List::Util`, `Scalar::Util`, `POSIX`, `File::Spec`, and `Data::Dumper` are the everyday ones.

The gotcha: `use` runs at *compile time*, not at the point in the file where it appears, so the order of `use` lines relative to your code does not matter the way `require` placement can. Importing is opt-in per name: `use List::Util qw(sum0 max)` brings exactly `sum0` and `max` into your namespace, nothing else - there is no monkey-patching of built-in types the way Ruby lets you reopen `Array`.

Objects

Ruby is everything-is-an-object; Perl is pragmatic, and the difference showed up already in *Arrays* (functions, not methods). But when you *do* want objects, Perl 5.44 has a first-class `class` syntax that will look familiar. Fields are declared with `field`, methods with `method`, and `$self` is available inside every method just as `self` is in Ruby (you do not list it as a parameter).

```ruby
class Point
  attr_accessor :x, :y
  def initialize(x: 0, y: 0)
    @x = x
    @y = y
  end
  def to_string
    "(#{@x}, #{@y})"
  end
  def move(dx, dy)
    @x += dx
    @y += dy
    self
  end
end

p = Point.new(x: 3, y: 4)
puts p.to_string           # (3, 4)
p.move(1, 1)
puts p.to_string           # (4, 5)
```

```perl
use v5.44;
use feature 'class';

class Point {
    field $x :param = 0;
    field $y :param = 0;
    method to_string { return "($x, $y)" }
    method move ($dx, $dy) {
        $x += $dx;
        $y += $dy;
        return $self;
    }
```

(continues on next page)

(continued from previous page)

```
}

my $p = Point->new(x => 3, y => 4);
say $p->to_string;          # (3, 4)
$p->move(1, 1);
say $p->to_string;          # (4, 5)
```

The constructor is generated for you, the equivalent of Ruby's `attr_accessor` plus `initialize` collapsed into the field declarations: `:param` marks a field that the auto-built `new` accepts as a named argument, and `= 0` is its default. Inheritance is `:isa`, the counterpart of Ruby's `class Point3D < Point`:

```
use v5.44;
use feature 'class';

class Point3D :isa(Point) {
    field $z :param = 0;
    method z { return $z }
}

my $q = Point3D->new(x => 1, y => 2, z => 3);
say $q->to_string, " z=", $q->z;   # (1, 2) z=3
```

The gotcha: the `class` feature is still marked experimental in Perl 5.44, and on `pperl` the "class is experimental" notices print to **stderr** even with `no warnings 'experimental::class'` in scope. They do not touch your program's output, so a script that prints to stdout behaves exactly as shown above; just expect the notices on the error stream. Note also that `field` gives you a `:reader` for read access but no Ruby-style `attr_accessor` setter by default - you write a `method` to mutate, as `move` does above. For the older `bless`-based object model you will meet in existing code, and for roles, inheritance details, and migration, see the *Object-oriented Programming guide*.

Error handling

Ruby's `begin`/`rescue`/`ensure` has two counterparts. The classic one wraps code in `eval { }` and inspects `$@` (the caught error) afterward - note that `eval` here is exception *trapping*, not Ruby's `eval` of a string:

```
begin
  risky(-1)
rescue => e
  puts "caught: #{e.message}"
end
```

```
use v5.44;
my $result = eval { risky(-1) };
if ($@) {
    print "caught: $@";     # caught: negative!
}
```

The modern form is `try/catch/finally`, which reads almost exactly like `begin/rescue/ensure`:

```
use v5.44;
use feature 'try';

try {
    risky(-4);
}
catch ($e) {
    print "caught: $e";     # caught: negative!
}
finally {
    say "done";             # done   (runs either way, like ensure)
}
```

where the raising side is `die` - Perl's `raise`:

```
use v5.44;
sub risky ($n) {
    die "negative!\n" if $n < 0;
    return sqrt $n;
}
```

The gotcha: `die` with a string that ends in `\n` produces exactly that message; `die` with a string that does *not* end in a newline gets `" at SCRIPT line N.\n"` appended automatically. End your error strings with `\n` when you want a clean message and omit it when you want the file-and-line trace. The `finally` block, like Ruby's `ensure`, runs whether or not an exception was thrown. Note also the two error variables: `$@` is the last caught exception (Ruby's `rescue => e`), while `$!` is the last *system* error (a failed open). Under `pperl`, the `try/catch/finally` feature prints an "experimental" notice on stderr; stdout is unaffected.

Idioms

A few patterns you will see daily and want in your fingers.

Sort a list by a computed key. Ruby has `sort_by` built in; the Perl hand-rolled form is the Schwartzian transform - decorate, sort, undecorate - and is worth recognising on sight:

```
use v5.44;
my @words = qw(apple fig pear);
my @by_length =
    map  { $_->[1] }
    sort { $a->[0] <=> $b->[0] }
    map  { [ length $_, $_ ] } @words;
say "@by_length";           # fig pear apple
```

Build a hash from a list, the Ruby `words.to_h { |w| [w, w.length] }` analogue:

```
use v5.44;
my @words = qw(apple pear fig);
```

(continues on next page)

(continued from previous page)

```
my %len = map { $_ => length $_ } @words;
say "$_ => $len{$_}" for sort keys %len;
# apple => 5
# fig => 3
# pear => 4
```

And `pperl` is a command-line tool in the `awk`/`sed` niche - the role `ruby -e` and `ruby -ne` fill for shell glue. The implicit-loop one-liner is the Perl developer's everyday reflex:

```
pperl -lane '$s += $F[-1]; END { print $s }' data.txt
```

The gotcha: read the *One-Liners guide* for the switches (`-n`, `-p`, `-a`, `-l`, `-e`) and the dozens of recipes built on them; it is one of the highest-leverage things to learn coming from a shell-and-Ruby background.

Gotchas coming from Ruby

The traps, collected for a final scan before you start writing:

- **Sigils mark shape, not scope.** `$x`/`@x`/`%x` say single/list/map; they are not Ruby's instance/global/local markers. One element of `@a` is `$a[0]`; one value of `%h` is `$h{k}`.
- **Not everything is an object.** `uc "foo"` and `sum @a` are functions, not methods on a string or array. You call methods only on blessed references.
- **Truthiness is the big one.** `0` and `""` are **false** in Perl but **true** in Ruby. `if ($count)` is false when `$count` is `0`. Only `0`, `""`, `"0"`, and `undef` are false; `"00"` and `"0.0"` are **true**.
- **No symbols.** `:name` has no Perl equivalent; hash keys are plain strings, and `=>` auto-quotes the bareword on its left.
- **`.` joins strings, `+` adds numbers.** Never `+` two strings to concatenate; that coerces them to numbers and warns. String repeat is `x`, not `*`.
- **Two comparison families.** `==`/`<`/`<=>` for numbers, `eq`/`lt`/`cmp` for strings. Pick by operand type, not by variable - unlike Ruby's class-dispatched `==`.
- **`sort` is string-sorted by default.** Pass `{ $a <=> $b }` for numeric order.
- **Context.** `my $x = @a` is the *length*; `my ($x) = @a` is the *first element*. The parentheses are the whole difference. Re-read *Context* when a value comes back the wrong shape.
- **`s///` edits in place** and returns a count, unlike Ruby's `gsub`; use the `/r` flag to get a new string instead.
- **`open` does not raise.** Use `open ... or die "...: $!"`.
- **Blocks are not implicit.** A stored `sub { ... }` is called explicitly with `->( )`; there is no `yield` and no invisible block argument.
- **Non-ASCII source needs `use utf8;`.** Under `use v5.44;` a literal non-ASCII byte in your source is a compile error without it. Keep string data ASCII unless you specifically add `use utf8;`.

- **The `class` feature prints experimental notices to stderr** on `pperl`. Correct output, noisy error stream.

Lua to Perl

You know Lua. You build a table without thinking, you reach for `setmetatable` to get objects and operators, and `for k, v in pairs(t)` is muscle memory. This guide maps each of those habits onto Perl, so you can be productive in `pperl` in an afternoon instead of relearning programming from scratch.

Two shocks land in the first five minutes, so meet them now:

- **Lua's one table becomes two Perl types.** Lua has a single aggregate, the table, that you use as both an array (`{1, 2, 3}`) and a map (`{k = "v"}`). Perl splits that into two distinct things: an ordered `@array` keyed by integers and a `%hash` keyed by strings. Deciding "is this a list or a lookup?" up front is the central new habit, and the *Arrays* and *Hashes* sections are about nothing else.
- **Variables wear sigils.** Lua names are bare: `x`, `t`, `f`. In Perl a scalar is `$x`, an array is `@x`, a hash is `%x`. The sigil is part of how you read the variable, not just decoration. This is the single biggest surface difference from Lua, and section one is about nothing else.

Every example here runs on `pperl`, a Rust reimplementation of Perl 5.44. Each Perl snippet was executed on `pperl`; the `# ...` comments show its real output. Start your scripts with:

```
use v5.44;
```

That one line turns on `strict` (every variable must be declared with `my`, the cure for Lua's accident-prone implicit globals), `warnings`, the `say` built-in (a `print` with a trailing newline, like Lua's `print`), subroutine signatures, and the modern feature set used throughout this guide.

How to read this

- *Variables and sigils* - the `$`/`@`/`%` shift, and `local x` becoming `my $x`.
- *Strings* - interpolation, and `..` concatenation becoming `.`.
- *Numbers* - one surface type, float division.
- *Arrays and lists* - half of your table, 0-based not 1-based.
- *Hashes* - the other half of your table.
- *Context* - the concept Lua has no word for. Read this one.
- *Truthiness* - what counts as false, and it differs sharply from Lua.
- *Control flow* - `if`, loops, the postfix forms.
- *Subroutines* - `function` becomes `sub`; real closures.
- *References* - nested data and closures.
- *Regular expressions* - real regex, not Lua patterns.
- *File and stream I/O* - open, line reads, slurp.

- *Modules and packages* - `require` becomes `use`.
- *Objects* - metatables become the modern `class` syntax.
- *Error handling* - `pcall` becomes `eval` or `try`/`catch`.
- *Idioms* - the daily one-liners.
- *Gotchas coming from Lua* - scan before you write.

Variables and sigils

In Lua a name just names a value, whatever its shape. In Perl the **sigil tells you the shape**: `$` for a single value, `@` for an ordered list, `%` for a key/value map. `my` declares a lexically scoped variable, the exact role of Lua's `local`. Where Lua lets a bare assignment silently create a global, `use v5.44` turns that into a compile error: every variable is `my` unless you say otherwise.

```lua
local name = "Ada"
local langs = {"Lua", "Perl"}
local ages = {Ada = 36, Linus = 56}
```

```perl
use v5.44;
my $name = "Ada";
my @langs = ("Lua", "Perl");
my %ages  = (Ada => 36, Linus => 56);
say $name;            # Ada
say $langs[0];        # Lua
say $ages{Ada};       # 36
```

The gotcha: when you reach *into* an aggregate for one element, the sigil follows the value you get back, not the container. A single element of `@langs` is a scalar, so it is `$langs[0]`, not `@langs[0]`; one value from `%ages` is `$ages{Ada}`. The `@`/`%` form is the whole collection; the `$` form is one piece of it. In Lua the table name `t` never changes whether you write `t`, `t[1]`, or `t.key`; in Perl the leading mark changes with what you are accessing.

Strings

Double quotes interpolate variables, single quotes do not. There is no `string.format` reflex needed for the common case, because the default string already interpolates. The big swap: concatenation is `.`, where Lua uses `..`

```lua
local name = "Ada"
local greeting = "Hello, " .. name
local shout = string.rep("AB", 3)
```

```perl
use v5.44;
my $name = "Ada";
my $greeting = "Hello, $name";   # Hello, Ada
my $literal  = 'Hello, $name';   # Hello, $name  (no interpolation)
my $joined   = "AB" . "CD";      # ABCD
my $shout    = "AB" x 3;         # ABABAB
```

The gotcha: Lua's concatenation operator `..` does not exist in Perl; the single dot `.` joins strings and the `x` operator repeats them (Lua's `string.rep`). Array elements and hash values interpolate inside double quotes too, so `"First: $langs[0]"` works as written, which removes most of the `..` chaining a Lua developer reaches for.

Numbers

Perl has one numeric type at the surface; you do not pick between integer and float, much as Lua 5.3+ presents a single `number` to most code. Division always produces a float.

```lua
print(7 / 2)        -- 3.5
print(math.floor(7 / 2))  -- 3
print(2 ^ 10)       -- 1024.0
print(10 % 3)       -- 1
```

```perl
use v5.44;
say 7 / 2;          # 3.5
say int(7 / 2);     # 3
say 2 ** 10;        # 1024
say 10 % 3;         # 1
```

The gotcha: comparison and equality operators come in two families, and you pick by the *operands' type*, not the variables'. Numbers use `==`, `!=`, `<`, `>`, `<=>`; strings use `eq`, `ne`, `lt`, `gt`, `cmp`. `"10" == "10.0"` is true (numeric), but `"10" eq "10.0"` is false (string). Lua has only `==` and coerces nothing across the string/number line; Perl instead asks *you* to choose the comparison, and using `==` on strings (or `eq` on numbers) is a frequent quiet bug.

Arrays and lists

Here is half of the great table split. A Lua sequence (`{10, 20, 30}`, the table used as an array) becomes a Perl `@array`. The first and loudest difference: **Perl arrays are 0-based**, where Lua arrays conventionally start at index 1.

```lua
local t = {"x", "y", "z"}
print(t[1])    -- x   (Lua: first element is index 1)
print(t[3])    -- z
print(#t)      -- 3   (length)
```

```perl
use v5.44;
my @t = ("x", "y", "z");
say $t[0];          # x   (Perl: first element is index 0)
say $t[2];          # z
say $t[-1];         # z   (negative indices count from the end)
say scalar @t;      # 3   (length; @t in scalar context is its size)
```

The mutators are renamed but familiar. `table.insert`/`table.remove` become `push`/`pop`/`shift`/`unshift`:

```
use v5.44;
my @nums = (10, 20, 30);
push @nums, 40;              # add to the end
my $last = pop @nums;        # 40, removed from the end
say scalar @nums;            # 3
say "@nums[0,1]";            # 10 20   (a slice)
```

Lua reaches for explicit `for i = 1, #t do ... end` loops to transform or filter; Perl has `map` (transform) and `grep` (filter), with `$_` as the current element:

```
use v5.44;
my @nums    = (1, 2, 3, 4, 5);
my @squares = map  { $_ * $_ }   @nums;   # 1 4 9 16 25
my @evens   = grep { $_ % 2 == 0 } @nums; # 2 4
my @desc    = sort { $b <=> $a }  @nums;  # 5 4 3 2 1
```

The gotcha: beyond 0-based indexing, `#t` has no single Perl spelling - you use `scalar @a` for an array's length and `keys %h` for a hash's. And `sort` compares as strings by default, so `sort (10, 9, 100)` gives `10 100 9`. For numbers you must pass a comparator: `sort { $a <=> $b } @nums`. `$a` and `$b` are the two elements being compared, and `<=>` is the numeric three-way operator (`cmp` is its string sibling).

Hashes

Here is the other half of the table split. A Lua table used as a map (`{name = "Ada", age = 36}`, or `t["key"]`) becomes a Perl `%hash`. Declared with `%`, accessed one value at a time with `$h{key}`.

```
local h = {apple = 3, pear = 5, plum = 2}
print(h.apple)              -- 3
print(h["pear"])            -- 5
h.plum = nil                -- delete a key
for k, v in pairs(h) do
    print(k, v)
end
```

```
use v5.44;
my %h = (apple => 3, pear => 5, plum => 2);
say $h{apple};                          # 3
say join ",", sort keys %h;             # apple,pear,plum
say exists $h{pear} ? "yes" : "no";     # yes
delete $h{plum};
for my $k (sort keys %h) {
    say "$k => $h{$k}";                 # apple => 3 ... pear => 5
}
```

The gotcha: Lua merges the array and the map into one table and keeps both an array part and a hash part inside it; Perl keeps them strictly apart, so you decide up front whether a thing is an `@array` (integer positions, ordered) or a `%hash` (string keys, unordered). Membership is `exists $h{key}`, the counterpart of Lua's `h[k] ~= nil` test, and the fat comma `=>` is the idiomatic key/value separator that auto-quotes the bare-

word on its left (so `apple => 3` needs no quotes). A hash has no order, so iterate `sort keys %h` when you want a stable one; Lua's `pairs` is unordered for the same reason.

Context

This is the chapter to read twice. Lua has no general equivalent, and almost every "Perl is weird" story traces back to it. But Lua *does* give you the one bridge that makes it click: **multiple return values**.

In Lua, `local a, b = f()` spreads a function's several return values across several variables, and `#t` or `select("#", ...)` collapses a list to a count. Perl generalises that idea into a property of *every* expression. Every expression runs in either **list context** or **scalar context**, decided by where it appears. The same array behaves differently in each: assigned to a *scalar* it gives its length, assigned to a *list* (parenthesised variables) it copies elements.

```
use v5.44;
my @list = (10, 20, 30);

my $count = @list;          # scalar context -> 3 (the length)
say $count;                 # 3

my ($first) = @list;        # list context -> first element copied
say $first;                 # 10

my ($a, $b) = @list;        # 10 and 20
say "$a $b";                # 10 20
```

The parentheses on the left are the whole difference. `my $x = @list` asks "how many?" and gets 3. `my ($x) = @list` asks "give me the elements" and gets `10`. The list form `my ($a, $b) = @list` is exactly Lua's `local a, b = ...` - the bridge you already know.

A subroutine returning several values is the same as a Lua function with multiple `return` values; the caller's context decides what comes back:

```
use v5.44;
sub minmax (@nums) {
    my @s = sort { $a <=> $b } @nums;
    return ($s[0], $s[-1]);
}
my ($lo, $hi) = minmax(4, 1, 9, 2);
say "$lo $hi";              # 1 9
```

A sub can even ask which context it was called in, with `wantarray`, and answer differently - something Lua functions cannot do:

```
use v5.44;
sub items {
    return wantarray ? (1, 2, 3) : "three items";
}
my @got = items();          # list context
my $msg = items();          # scalar context
```

(continues on next page)

(continued from previous page)

```
say "@got";                # 1 2 3
say $msg;                  # three items
```

The gotcha: there is no single answer to "what does this array do" - it depends on the surrounding expression, where Lua resolves multiple-value spreading at the specific call site only. When something returns a number you expected to be a list (or vice versa), context is the first suspect. Reach for `scalar` to force a count and parentheses on the left to force element copying.

Truthiness

This is a sharp break from Lua, so slow down. In Lua **only `nil` and `false` are falsy** - the number `0` and the empty string `""` are both *true*. Perl draws the line in a completely different place. Its false values are: the number `0`, the empty string `""`, the string `"0"`, and undef (Perl's `nil`). **Everything else is true.**

```
use v5.44;
for my $v (0, 1, "", "0", "00", "0.0", "false") {
    say "'$v' is ", ($v ? "true" : "false");
}
```

This prints, exactly:

```
'0' is false
'1' is true
'' is false
'0' is false
'00' is true
'0.0' is true
'false' is true
```

The gotcha: a Lua developer's instinct that `0` is true will silently flip the meaning of every `if ($count)`. In Perl `0` and `""` *are* false, so `if ($n)` is false when `$n` is zero - usually what you want, but the opposite of Lua. Going the other way, `"00"` and `"0.0"` are **true** even though they look numerically zero, because only the exact string `"0"` is false. For a "use this if defined, else a default" choice - Lua's `x = y or default` idiom, which trips on `0` and `false` - use Perl's defined-or `//`, which falls back only on undef (Perl's `nil`):

```
use v5.44;
my %cfg = (host => "localhost");
my $port = $cfg{port} // 8080;   # key absent -> undef -> 8080
say $port;                       # 8080
```

Control flow

The keywords are familiar; the spelling differs. Lua's `elseif` is Perl's `elsif`, there is no then/do/end, and blocks are braced rather than keyword-delimited.

```
if n < 0 then
    sign = "neg"
elseif n == 0 then
    sign = "zero"
else
    sign = "pos"
end

for _, x in ipairs(nums) do
    print(x)
end

while running do
    step()
end
```

```
use v5.44;
my $sign;
if    ($n < 0)  { $sign = "neg"  }
elsif ($n == 0) { $sign = "zero" }
else            { $sign = "pos"  }

for my $x (@nums) { say $x }

while ($running) { step() }
```

Perl adds two things Lua does not have. **Postfix modifiers** let a simple statement carry its own condition or loop, which reads naturally for one-liners:

```
use v5.44;
say $_ for @nums;                # loop, one statement
say "negative" if $n < 0;        # guarded statement
$sum += $_ for @nums;            # accumulate
```

And `unless`/`until` are the negated forms of `if`/`while`, for when the positive phrasing reads awkwardly: `say "ok" unless $error`.

The gotcha: Perl has no `x if c else y` statement; the conditional expression is the C-style ternary with `?`/`:`, which Lua usually fakes with `c and x or y`. The Perl form is direct and chains: `my $sign = $n < 0 ? "neg" : $n == 0 ? "zero" : "pos"`. Loop control is `last`/`next` where Lua has `break` and (in 5.4) `goto continue`.

Subroutines

`function` becomes `sub`. Modern Perl has signatures that name their parameters, including defaults, rather than Lua's positional `...` and manual `arg` handling.

```
local function greet(name, greeting)
    greeting = greeting or "Hello"
    return greeting .. ", " .. name .. "!"
```

(continues on next page)

(continued from previous page)

```lua
end

local function total(...)
    local sum = 0
    for _, n in ipairs({...}) do sum = sum + n end
    return sum
end
```

```perl
use v5.44;
sub greet ($name, $greeting = "Hello") {
    return "$greeting, $name!";
}
say greet("Ada");           # Hello, Ada!
say greet("Linus", "Hi");   # Hi, Linus!

sub total (@nums) {
    my $sum = 0;
    $sum += $_ for @nums;
    return $sum;
}
say total(1, 2, 3, 4);      # 10
```

Lua's named-argument idiom (passing a single table, `f{host=..., port=...}`) maps to a hash parameter, since `key => value` pairs flatten into a list that a `%opts` signature gathers up:

```perl
use v5.44;
sub connect_to (%opts) {
    return "host=$opts{host} port=$opts{port}";
}
say connect_to(host => "localhost", port => 8080);
# host=localhost port=8080
```

The gotcha: a sub returns the value of its last expression even without `return` (like Lua's explicit-only return, except Perl also has the implicit last-value form), and the return is **context-sensitive** (see *Context*). If you `return @list`, the caller gets the list in list context but the *count* in scalar context - a degree of freedom Lua's multiple-return does not have.

References

Perl's arrays and hashes do not nest directly; you nest them through **references**, a scalar that points at an aggregate. In Lua every table is already a reference (assigning a table shares it, never copies), so this concept is invisible to you there; in Perl you take a reference explicitly with `\`, and follow it with `->`.

```lua
local data = {name = "Ada", langs = {"Perl", "Lua"}}
print(data.langs[2])        -- Lua
table.insert(data.langs, "Ruby")
```

```
use v5.44;
my $data = { name => "Ada", langs => ["Perl", "Lua"] };
say $data->{name};                  # Ada
say $data->{langs}[1];              # Lua
push $data->{langs}->@*, "Ruby";    # postfix deref to push
say "@{$data->{langs}}";           # Perl Lua Ruby
```

`{ ... }` builds an anonymous hash reference and `[ ... ]` an anonymous array reference - the literal building blocks of nested data. The `->` arrow follows a reference one step; between two subscripts it is optional, so `$data->{langs}[1]` and `$data->{langs}->[1]` are the same.

Anonymous subs are real closures, exactly like Lua's closures over upvalues - one of the cleanest carry-overs in the whole guide:

```
use v5.44;
sub counter ($start) {
    my $n = $start;
    return sub { return $n++ };
}
my $c = counter(10);
say $c->();                 # 10
say $c->();                 # 11
say $c->();                 # 12
```

The gotcha: the postfix deref forms (`->@*`, `->%*`, `->$*`) are the modern, readable way to dereference a whole aggregate, and `"@{ ... }"` is how you interpolate a dereferenced array into a string. The older `@$ref` and `${$ref}{key}` forms still work and appear in existing code, but reach for the arrow and postfix forms in new code.

Regular expressions

This is an upgrade, not a translation. Lua has **patterns** - `string.match`, `string.gsub`, character classes like `%d` - which are deliberately *not* regular expressions and lack alternation, quant, and backreferences. Perl has full regex as **syntax**: `=~` binds a pattern to a string, `m//` matches, `s///` substitutes. Capture groups land in `$1`, `$2`, and named captures in `%+`.

```
local s = "2026-06-20"
local y, m, d = string.match(s, "(%d+)-(%d+)-(%d+)")
local t = string.gsub("a,b,c", ",", ";")   -- a;b;c
```

```
use v5.44;
my $s = "2026-06-20";
if ($s =~ /(\d{4})-(\d{2})-(\d{2})/) {
    say "$1 $2 $3";                 # 2026 06 20
}
if ($s =~ /(?<year>\d{4})/) {
    say $+{year};                   # 2026
}
```

(continues on next page)

(continued from previous page)

```
(my $t = "a,b,c") =~ s/,/;/g;       # a;b;c
my @parts = split /,/, "one,two,three";   # one two three
```

A `/g` match in list context returns *all* the matches, the direct analogue of looping `string.gmatch`:

```
use v5.44;
my @nums = "x1y2z3" =~ /(\d)/g;     # 1 2 3
say "@nums";
```

The gotcha: the metacharacters differ from Lua patterns - Perl uses `\d` where Lua uses %d, */+/? quantifiers, `|` alternation, and `(?<name>...)` named groups, none of which Lua patterns support. And `s///` modifies its target *in place* and returns the number of substitutions, not a new string, where Lua's `gsub` returns a new string. That is why the example copies first with `(my $t = "a,b,c")` and then substitutes on the copy. To get a new string without touching the original, use the `/r` flag: `my $t = $s =~ s/,/;/gr`.

File and stream I/O

The idiom is the three-argument open with a lexical filehandle, the counterpart of Lua's `io.open`. The angle-bracket operator `<$fh>` reads a line, the role of Lua's `fh:read("l")` or the `fh:lines()` iterator.

```
local f = io.open("/tmp/sample.txt", "w")
for i = 1, 3 do
    f:write("line " .. i .. "\n")
end
f:close()

f = io.open("/tmp/sample.txt", "r")
for line in f:lines() do
    print("got:", line)
end
f:close()
```

```
use v5.44;
my $path = "/tmp/sample.txt";

open my $wh, '>', $path or die "cannot write: $!";
print {$wh} "line $_\n" for 1 .. 3;
close $wh;

open my $rh, '<', $path or die "cannot read: $!";
while (my $line = <$rh>) {
    chomp $line;
    say "got: $line";       # got: line 1 ... got: line 3
}
close $rh;
```

To slurp every line at once, read the handle in list context:

```
use v5.44;
open my $fh, '<', "/tmp/sample.txt" or die $!;
my @lines = <$fh>;          # all lines, including newlines
say scalar @lines;          # 3
```

The gotcha: a line read with `<$fh>` keeps its trailing newline (Lua's `fh:lines()` strips it, `fh:read("L")` keeps it); call `chomp` to strip it. And `open` returns false on failure rather than raising, much like Lua's `io.open` returning `nil, err`, so the `or die "...: $!"` idiom is mandatory - `$!` is the system error message, Perl's `errno`.

Modules and packages

Lua's `require` becomes Perl's `use`. The namespace separator is `::`, not `.`, and a module `Foo::Bar` lives at `Foo/Bar.pm` on the include path `@INC` (Lua's `package.path`). Unlike Lua's `require`, which returns a table you assign yourself, `use` imports selected names directly into your namespace.

```
local sqrt = math.sqrt
local sum = 0
for i = 1, 10 do sum = sum + i end
```

```
use v5.44;
use List::Util qw(sum0 max first);
say sum0(1 .. 10);                      # 55
say max(3, 7, 2);                       # 7
say first { $_ % 2 == 0 } (1, 3, 4, 5);  # 4
```

Here is a pleasant surprise coming from Lua's deliberately tiny standard library: Perl ships a large built-in set, and much of what you would hand-roll or pull from LuaRocks is in core or one `use` away on CPAN, the Perl package archive. `List::Util`, `Scalar::Util`, `POSIX`, `File::Spec`, and `Data::Dumper` are the everyday ones.

The gotcha: `use` runs at *compile time*, not at the line where it appears, so its placement relative to your code does not matter the way a `require` call's does. Importing is opt-in per name: `use List::Util qw(sum0 max)` brings exactly `sum0` and `max` into your namespace, nothing else.

Objects

Lua has no built-in object system; you build one from tables and metatables - `setmetatable(t, {__index = Class})` for method lookup and inheritance, `__add`/`__eq` for operators. Perl 5.44 gives you a first-class `class` syntax instead, so the common case needs no metatable wiring. Fields are declared with `field`, methods with `method`, and `$self` is available inside every method (you do not pass it as the first parameter the way Lua's `self` / colon-call does).

```
local Point = {}
Point.__index = Point

function Point.new(x, y)
```

(continues on next page)

(continued from previous page)

```
    return setmetatable({x = x or 0, y = y or 0}, Point)
end
function Point:to_string()
    return "(" .. self.x .. ", " .. self.y .. ")"
end
function Point:move(dx, dy)
    self.x = self.x + dx
    self.y = self.y + dy
    return self
end

local p = Point.new(3, 4)
print(p:to_string())        -- (3, 4)
p:move(1, 1)
print(p:to_string())        -- (4, 5)
```

```
use v5.44;
use feature 'class';

class Point {
    field $x :param = 0;
    field $y :param = 0;
    method to_string { return "($x, $y)" }
    method move ($dx, $dy) {
        $x += $dx;
        $y += $dy;
        return $self;
    }
}

my $p = Point->new(x => 3, y => 4);
say $p->to_string;          # (3, 4)
$p->move(1, 1);
say $p->to_string;          # (4, 5)
```

The constructor is generated for you, replacing Lua's hand-written `Point.new`: `:param` marks a field that the auto-built new accepts as a named argument, and `= 0` is its default. Inheritance, which Lua builds from a chain of `__index` metatables, is the `:isa` attribute:

```
use v5.44;
use feature 'class';

class Point3D :isa(Point) {
    field $z :param = 0;
    method z { return $z }
}

my $q = Point3D->new(x => 1, y => 2, z => 3);
say $q->to_string, " z=", $q->z;   # (1, 2) z=3
```

The gotcha: the `class` feature is still marked experimental in Perl 5.44, and on `pperl` the "class is experimental" notices print to **stderr** even when you try to silence them. They do not touch your program's output, so a script that prints to stdout behaves exactly as shown above; just expect the notices on the error stream. Lua's operator metamethods (__add, __eq, and friends) map to Perl's `overload` pragma rather than to `class`; for that, the older `bless`-based object model, roles, and inheritance details, see the *Object-oriented Programming guide*.

Error handling

Lua's protected call `pcall(f)` - which returns `false, err` instead of unwinding - has two Perl counterparts. The classic one wraps code in `eval { }` and inspects `$@` (the caught error) afterward:

```lua
local ok, err = pcall(function() risky(-1) end)
if not ok then
    print("caught: " .. err)
end
```

```perl
use v5.44;
my $result = eval { risky(-1) };
if ($@) {
    print "caught: $@";     # caught: negative!
}
```

The modern form is `try`/`catch`, which reads more like a conventional exception block than `pcall`'s boolean-return dance:

```perl
use v5.44;
use feature 'try';

try {
    risky(-4);
}
catch ($e) {
    print "caught: $e";     # caught: negative!
}
```

where the raising side is `die`, Perl's `error`:

```perl
use v5.44;
sub risky ($n) {
    die "negative!\n" if $n < 0;
    return sqrt $n;
}
```

The gotcha: `die` with a string that ends in `\n` produces exactly that message; `die` with a string that does *not* end in a newline gets `" at SCRIPT line N.\n"` appended automatically (Lua's `error` does a similar position-prefixing unless you pass level `0`). End your error strings with `\n` when you want a clean message and omit it when you want the file-and-line trace. Note also the two error variables: `$@` is the last caught exception, while `$!` is the last *system* error (a failed open, the `errno` string).

Idioms

A few patterns you will see daily and want in your fingers.

Sort a list by a computed key (the Schwartzian transform - decorate, sort, undecorate in one pipeline, the Perl reflex where Lua passes a comparator function to `table.sort`):

```
use v5.44;
my @words = qw(apple fig pear);
my @by_length =
    map  { $_->[1] }
    sort { $a->[0] <=> $b->[0] }
    map  { [ length $_, $_ ] } @words;
say "@by_length";           # fig pear apple
```

Build a hash from a list, turning a sequence into a lookup table in one step:

```
use v5.44;
my @words = qw(apple pear fig);
my %len = map { $_ => length $_ } @words;
say "$_ => $len{$_}" for sort keys %len;
# apple => 5
# fig => 3
# pear => 4
```

And `pperl` is a command-line tool in the `awk`/`sed` niche, a role Lua does not target. The implicit-loop one-liner is the Perl developer's everyday reflex:

```
pperl -lane '$s += $F[-1]; END { print $s }' data.txt
```

The gotcha: read the *One-Liners guide* for the switches (`-n`, `-p`, `-a`, `-l`, `-e`) and the dozens of recipes built on them; it is one of the highest-leverage things to learn coming from a scripting background where this niche was someone else's job.

Gotchas coming from Lua

The traps, collected for a final scan before you start writing:

- **One table becomes two types.** A Lua table is an `@array` (integer-keyed, ordered) *or* a `%hash` (string-keyed, unordered) in Perl, never both at once. Decide which you have before you reach for it.
- **Arrays are 0-based.** Lua's `t[1]` is Perl's `$t[0]`; the last element is `$t[-1]`. This is the most common porting off-by-one.
- **Sigils change with usage.** One element of `@a` is `$a[0]`; one value of `%h` is `$h{k}`. The container sigil and the element sigil differ - the bare Lua name `t` has no such shift.
- **Concatenation is `.`, not `..`.** Lua's `..` does not exist; `.` joins strings and `x` repeats them.
- **Truthiness is inverted at zero.** In Lua `0` and `""` are *true*; in Perl they are **false**. Only `0`, `""`, `"0"`, and `undef` are false, so `"00"` and `"0.0"` are surprisingly **true**.

- **Two comparison families.** ==/</<=> for numbers, eq/lt/cmp for strings. Pick by operand type; Lua's single == has no equivalent split.
- **`sort` is string-sorted by default.** Pass `{ $a <=> $b }` for numeric order.
- **Context.** `my $x = @a` is the *length*; `my ($x) = @a` is the *first element*. The list form is your friend `local a, b = f()`; the scalar form is new. Re-read *Context* when a value comes back the wrong shape.
- **Regex is not Lua patterns.** Perl has full regex (\d, |, *, named groups); Lua patterns (%d, no alternation) are a different, smaller language. `s///` edits in place and returns a count; use `/r` for a new string.
- **`open` does not raise.** Use `open ... or die "...: $!"`, the way Lua's `io.open` returns `nil, err`.
- **`chomp` your line reads.** `<$fh>` keeps the trailing newline that Lua's `lines()` would have stripped.
- **Non-ASCII source needs `use utf8;`.** Under `use v5.44;` a literal non-ASCII byte in your source is a compile error without it. Keep string data ASCII unless you specifically add `use utf8;`.
- **The `class` feature prints experimental notices to stderr** on `pperl`. Correct output, noisy error stream. Operator metamethods map to the `overload` pragma, not to `class`.

Sed to Perl

You know `sed`. You think in `s/old/new/`, you address lines with `/pattern/` and `$`, you reach for `-n` and `p` to print selectively, and `-i` to edit files in place. This guide maps each of those habits onto Perl, so you can keep every reflex you have and pick up the things sed makes hard.

The one idea to carry in from the first line: **Perl is a near-superset of sed for text work.** Everything sed does, Perl does - usually with the *same* `s///` syntax - plus a real regex engine, real variables, and arbitrary code in the replacement. The awkward corners of sed (the hold space, multi-line tricks, anything resembling arithmetic) become ordinary Perl that you would write without thinking. This guide leads with the one-to-one mappings and then shows where Perl simply removes a sed limitation.

Every runnable example here was executed on `pperl`, a Rust reimplementation of Perl 5.44; the `# ...` comments show its real output. Start scripts with:

```
use v5.44;
```

That one line turns on `strict`, `warnings`, and the `say` built-in (a `print` with a trailing newline), the modern feature set used throughout.

How to read this

- *The line cycle* - sed's implicit loop becomes `while (<$fh>)` and `$_`.
- *Substitution: `s///`* - the same operator, with real regex.
- *Transliteration: `y///` becomes `tr///`* - the y command, renamed.

- *Addresses and ranges* - line numbers, patterns, and `/a/ .. /b/`.
- *Deleting, printing, quitting:* `d`, `p`, `q` - `next`, `print`, `last`.
- *The hold space becomes a variable* - where sed is hard and Perl is trivial.
- *In-place editing and I/O* - `-i`, reading files, pipes.
- *One-liners and switches* - `-n`, `-p`, `-e`, `BEGIN`/`END`.
- *Gotchas coming from sed* - scan before you write.

The line cycle

sed runs your script once per input line, with the current line in its pattern space, and prints the pattern space at the end of the cycle (unless `-n`). Perl's equivalent is an explicit loop with the line in `$_`, the implicit topic variable. The `-p` switch reproduces "auto-print every line"; `-n` reproduces "print nothing unless I say so."

```
sed 's/bar/BAR/' input.txt
```

```
perl -pe 's/bar/BAR/' input.txt
```

The same loop written out in full - what `-p` expands to - opens the file and iterates it explicitly. `$_` is the current line, exactly like sed's pattern space:

```
use v5.44;
open my $fh, '<', '/tmp/data.txt' or die "open: $!";
while (<$fh>) {           # each line lands in $_
    s/a/A/g;              # operate on $_ by default
    print;               # print $_ (note: keeps the newline)
}
# Apple
# bAnAnA
# cherry
```

(The input file held `apple`, `banana`, `cherry`.) The gotcha: a line read with `<$fh>` keeps its trailing newline, just as sed's pattern space does. `print` with no argument prints `$_` including that newline, so it round-trips cleanly; `chomp` only when you intend to strip it. The line number is in `$.`, the sed analogue of the line counter you reach for with `$=` in GNU sed scripts.

Substitution: `s///`

This is the headline: **sed's `s///` and Perl's `s///` are the same operator.** The flags line up too - `g` is global, `i` is case-insensitive - and Perl adds flags sed has no equivalent for.

```
sed 's/colou\?r/COLOR/g' input.txt
```

```
perl -pe 's/colou?r/COLOR/g' input.txt
```

By default `s///` edits its target in place and returns the count of substitutions. Captured groups are `$1`, `$2`, ... and you can run **arbitrary code** in the replacement with the `/e` flag - something sed cannot do at all:

```
use v5.44;
my $s = "items: 3 and 4";
(my $t = $s) =~ s/(\d+)/$1 * 10/ge;   # /e: replacement is Perl code
say $t;                               # items: 30 and 40
```

To rearrange captures (sed's `\1`, `\2` backreferences in the replacement), use `$1`, `$2` and, when you want a *new* string instead of editing in place, the `/r` flag, which returns the result and leaves the original untouched:

```
use v5.44;
my $date = "2026-06-21";
my $us = $date =~ s{(\d+)-(\d+)-(\d+)}{$2/$3/$1}r;   # /r: return a␣
↪copy
say $us;                                              # 06/21/2026
say $date;                                            # 2026-06-21
```

The gotcha: bare `s///` modifies its target and returns a *count*, not the new string. That is why the examples above either copy first (`(my $t = $s) =~ s/.../.../`) or use `/r`. Writing `my $new = ($s =~ s/a/b/)` puts the substitution count in `$new`, not the edited string - a classic first-day surprise. Note also that Perl delimiters are free: `s{...}{...}` and `s#...#...#` avoid backslashing slashes in a path pattern.

Transliteration: `y///` becomes `tr///`

sed's `y/abc/xyz/` is Perl's `tr/abc/xyz/`. Perl keeps `y///` as an exact alias, so `y/a-z/A-Z/` works verbatim, but `tr` is the spelled name you will see in Perl code.

```
sed 'y/abc/xyz/' input.txt
```

```
use v5.44;
my $s = "hello";
(my $t = $s) =~ tr/a-z/A-Z/;   # uppercase, like y/a-z/A-Z/
say $t;                        # HELLO
```

`tr` also does things `y` cannot. With an empty replacement it *counts* matches, and the `s` modifier squeezes runs of a character - the common `tr -s` idiom:

```
use v5.44;
my $s = "hello";
my $vowels = ($s =~ tr/aeiou//);   # count, replacement empty
say $vowels;                       # 2

my $dots = "a....b...c";
(my $squeezed = $dots) =~ tr/././s; # squeeze repeats
say $squeezed;                      # a.b.c
```

The gotcha: `tr///` is **not** a regex - the left side is a literal character set, the same as sed's `y`. `tr/a-z//` means the range `a` through `z`, but `tr/.*//` means the two literal characters `.` and `*`, not "any string." For pattern work, reach for `s///`. And like `s///`, `tr///` edits in place and returns a count, so copy first or use the `/r` flag for a non-destructive transliteration.

Addresses and ranges

A sed command can be prefixed by an address: a line number, `$` for the last line, a `/pattern/`, or a `addr1,addr2` range. In Perl an address is just a condition on the statement - a postfix `if`. Line number is `$.`; the pattern test is `/pat/` against `$_`; the last line is `eof`.

```
sed -n '2p' input.txt              # print line 2
sed -n '/banana/p' input.txt       # print matching lines
```

```
use v5.44;
open my $fh, '<', '/tmp/data.txt' or die "open: $!";
while (<$fh>) {
    print if $. == 2;              # sed -n '2p'
}
# banana
```

A sed range `/start/,/end/` becomes Perl's **flip-flop** range operator `/start/ .. /end/`, which is true from the line matching the left pattern through the line matching the right, inclusive:

```
use v5.44;
open my $fh, '<', '/tmp/data.txt' or die "open: $!";
while (<$fh>) {
    print if /banana/ .. /cherry/;  # sed '/banana/,/cherry/p' with␣
 ↪-n
}
# banana
# cherry
```

The gotcha: in a boolean test `..` is the flip-flop (range) operator, **not** the list-range operator (which is `1 .. 10` building a list). Perl tells them apart by context - in the scalar/boolean position of an `if`, `..` is the line-range selector that mirrors sed's `addr1,addr2`. It is stateful: it remembers whether it has seen the start pattern, so it does exactly what a sed range does across the loop.

Deleting, printing, quitting: d, p, q

sed's single-letter cycle commands map to Perl loop keywords. `d` (delete pattern space, skip to next cycle) is `next`. `q` (quit) is `last`. `p` (print) is `print`. Because Perl's loop is explicit, these read as exactly what they do.

```
sed '/banana/d' input.txt          # drop matching lines
sed '/banana/q' input.txt          # stop after the match
```

```
use v5.44;
open my $fh, '<', '/tmp/data.txt' or die "open: $!";
while (<$fh>) {
    next if /banana/;              # sed '/banana/d'
    print;
}
```

(continues on next page)

(continued from previous page)

```
# apple
# cherry
```

```
use v5.44;
open my $fh, '<', '/tmp/data.txt' or die "open: $!";
while (<$fh>) {
    print;
    last if /banana/;              # sed '/banana/q'
}
# apple
# banana
```

The gotcha: under sed's `-p`-style auto-print, `d` must skip the auto-print, which it does by aborting the cycle. In an explicit Perl loop you control printing yourself, so "delete" is simply *not printing* the line - `next if /pat/` before the `print`, or guard the `print` with `unless`. There is no hidden auto-print to fight; what you `print` is what comes out.

The hold space becomes a variable

This is the section where sed stops being convenient and Perl stops being hard. sed has exactly one auxiliary buffer - the hold space - and shuffles data into it with `h`, `H`, `g`, `G`, `x`. Anything needing two pieces of remembered state turns into hold-space contortions. In Perl you just declare a variable. Or an array. Or a hash.

The canonical hold-space exercise is reversing a file (`tac`), which in sed is an opaque `1!G;h;$!d` incantation. In Perl it is one obvious line:

```
sed -n '1!G;h;$!d' input.txt       # reverse the file (tac)
```

```
use v5.44;
open my $fh, '<', '/tmp/data.txt' or die "open: $!";
my @hold;                          # the "hold space" is just an␣
↪array
while (<$fh>) {
    unshift @hold, $_;             # newest line to the front
}
print @hold;
# cherry
# banana
# apple
```

The gotcha: there is no gotcha - that is the point. Once you have real variables, the entire category of sed problems that exist only because there is a single hold space disappears. Need to remember the previous line? `my $prev`. Need a running total? `my $sum`. Need to dedup? A `my %seen` hash. When a sed script reaches for `h`/`H`/`x`, the Perl translation is almost always "introduce a named variable and write the obvious thing."

In-place editing and I/O

sed's `-i` rewrites a file in place. The idiomatic Perl is the same switch on a `-p` one-liner. Reading several files is sed's default; Perl spells it `<>`, the diamond operator, which reads each file named in `@ARGV` in turn.

```
sed -i 's/red/crimson/' file.txt   # edit in place
```

```
perl -i -pe 's/red/crimson/' file.txt
```

Written out in full it is an explicit read-modify-write: slurp the lines, transform them, write them back. This is exactly what `-i` does under the hood:

```
use v5.44;
my $path = '/tmp/inplace_data.txt';   # holds: red green blue

open my $in, '<', $path or die "read: $!";
my @lines = <$in>;                    # slurp all lines (list
 ↪context)
close $in;

s/e/E/g for @lines;                   # transform each line's $_

open my $out, '>', $path or die "write: $!";
print {$out} @lines;                  # write them back
close $out;
# file now holds:
# rEd
# grEEn
# bluE
```

For pipes - sed in the middle of a shell pipeline - Perl opens a pipe filehandle directly: `open my $fh, '-|', 'ls', '-l'` reads a command's output, and `open my $fh, '|-', 'sort'` writes to a command's input. The gotcha: `open` returns false on failure rather than raising, so the `or die "...: $!"` idiom is mandatory - `$!` is the system error string, sed's silent failure made explicit. And reading multiple files with `<>` resets `$.` per file only if you check `eof` explicitly; the plain `$.` keeps counting across the concatenated stream.

One-liners and switches

The one-liner is sed's home turf and Perl's too. The switch family that makes it work: `-e` supplies the program, `-n` wraps it in a no-auto-print loop (sed's `-n`), `-p` wraps it in an auto-print loop (sed's default), `-i` edits in place, `-l` handles line endings, and `-a`/`-F` autosplit each line into `@F` (awk territory, useful here for field edits). `BEGIN { }` and `END { }` blocks run before and after the loop, the direct analogue of sed's `1i`/`$a` setup-and-teardown tricks.

```
sed -n '/error/p' log.txt                  # print error lines
sed 's/[0-9]\+/N/g' input.txt              # mask numbers
```

```
perl -ne 'print if /error/' log.txt        # print error lines
perl -pe 's/\d+/N/g' input.txt             # mask numbers
perl -nE 'END { say $n } $n++ if /error/' log.txt   # count, BEGIN/
↪END
```

Each of those expands to an explicit loop: `perl -ne 'CODE'` is `while (<$fh>) { CODE }`, and `perl -pe 'CODE'` is the same with a trailing `print`. Written out, the "count error lines" form:

```
use v5.44;
open my $fh, '<', '/tmp/data.txt' or die "open: $!";
my $n = 0;
while (<$fh>) {
    $n++ if /banana/;          # the body of -ne
}
say $n;                        # 1
```

The gotcha: when a one-liner grows past a line or two, write out the explicit loop it expands to. Consult the *One-Liners guide* for the full switch catalogue and dozens of recipes - it is the highest-leverage thing to read coming from a sed background. Perl also has full subroutines, references, modules, and OO if your script outgrows a one-liner; see the *Object-oriented Programming guide* for that side of the language.

Gotchas coming from sed

The traps, collected for a final scan before you write:

- **`s///` returns a count, not the new string.** `my $x = $s =~ s/a/b/` puts the substitution *count* in `$x`. Copy first (`(my $t = $s) =~ s/.../.../`) or use the `/r` flag to get a new string.
- **`tr///` (sed's y) is a literal character set, not a regex.** `tr/.*//` matches the two characters `.` and `*`. For patterns, use `s///`.
- **`..` in a boolean is the flip-flop range, not a list range.** In an `if`, `/a/ .. /b/` is the sed `addr1,addr2` selector; `1 .. 10` in list context builds a list. Same operator, decided by context.
- **`<$fh>` keeps the trailing newline,** like sed's pattern space. `print` round-trips it; `chomp` only when you mean to strip it.
- **There is no hidden auto-print.** sed's `-p` default is something you spell yourself with `print`. "Delete a line" is just not printing it (`next if /pat/`), not a special command.
- **`open` does not raise on failure.** Use `open my $fh, '<', $path or die "...: $!"`. `$!` is the system error string.
- **The hold space is gone - use a variable.** Any sed script reaching for h/H/x translates to a named Perl variable, array, or hash. This is a simplification, not a loss.

Awk to Perl

You know awk. You think in `pattern { action }`, you split every line into `$1`, `$2`, `$3` without asking, you count things with `a[key]++`, and you frame the whole job with `BEGIN { }` and `END { }`. Perl was written partly as "awk, but bigger" - almost everything you do in awk has a direct Perl form, and then Perl keeps going: real data structures, full regex, modules, and a language that does not run out of room when the script grows.

The one idea to carry in from the first line: **Perl is a near-superset of awk.** The record loop, the fields, the associative arrays, the `BEGIN`/`END` keywords, `print` and `printf`, `length`/`substr`/`split` - they all map across, often by the *same name*. What changes is that fields become a real array `@F` you can `push` and `pop`, the associative array becomes a Perl hash you can nest, and the regex engine is Perl's own - the one PCRE copies - rather than POSIX ERE. This guide leads with the one-to-one mappings and points out the few places the analogy leaks.

Every runnable example here was executed on `pperl`, a Rust reimplementation of Perl 5.44; the `# ...` comments show its real output. Start scripts with:

```
use v5.44;
```

That one line turns on `strict`, `warnings`, and the `say` built-in (a `print` with a trailing newline), the modern feature set used throughout.

How to read this

- *The line/record loop* - awk's implicit `{ ... }` becomes `while (<$fh>)` and `$_`.
- *Fields and splitting* - `$1`/`$NF`/`NF`/`FS` become `@F`, `$F[0]`, `split`, `-F`.
- *Regex and substitution* - `gsub`/`sub`/`match` become `s///`/`=~`, a strict superset.
- *Addresses and ranges* - `/re/`, `cond { }`, and `/a/,/b/` become postfix `if` and the flip-flop.
- *I/O, pipes, in-place edit* - `getline`, redirection, and `-i`.
- *One-liners and switches* - `-n`, `-a`, `-F`, `BEGIN`/`END`.
- *Control flow* - `next`, `for`, the postfix forms.
- *Variables and data* - associative arrays become hashes, the happy mapping.
- *Gotchas coming from awk* - scan before you write.

The line/record loop

awk runs your program once per input record, with the record in `$0` and the action in `{ ... }`. Perl's equivalent is an explicit loop with the record in `$_`, the implicit topic variable. The `-n` switch reproduces awk's "run this block per line"; awk's `NR` (record number) is Perl's `$.`.

```
awk '{ print }' input.txt
```

```
perl -ne 'print' input.txt
# alice 85 90
# bob 70 60
# carol 95 100
# alice 50 55
```

The same loop written out in full - what `-n` expands to - opens the file and iterates it explicitly. `$_` is the current record, exactly like awk's `$0`:

```
use v5.44;
open my $fh, '<', '/tmp/scores.txt' or die "open: $!";
while (<$fh>) {           # each line lands in $_, like awk's $0
    chomp;
    say "line $. : $_";   # $. is awk's NR
}
# line 1 : alice 85 90
# line 2 : bob 70 60
# line 3 : carol 95 100
# line 4 : alice 50 55
```

(The input file held `alice 85 90`, `bob 70 60`, `carol 95 100`, `alice 50 55`.) The gotcha: a line read with `<$fh>` keeps its trailing newline, unlike awk's `$0`, which has the record separator stripped. Call `chomp` to strip it (chomp is the closest thing to "awk already removed the newline for you"). The record number is `$.` = awk's `NR`; when you read several files with `<>`, `$.` keeps counting across them, so the awk `FNR` (per-file counter) reset is something you arrange yourself by checking `eof`.

Fields and splitting

This is awk's heart, and Perl gives you the same picture with one twist: the fields live in a real array `@F`, so awk's `$1` is Perl's `$F[0]` (zero-based), `$0` is `$_`, and `NF` is the count `scalar @F`. Under the `-a` switch Perl autosplits each line into `@F` exactly as awk autosplits into `$1`..`$NF`; written out, that is one explicit `split`.

```
awk '{ print $1, NF }' input.txt          # first field, field count
awk -F, '{ print $1 }' input.txt          # comma separator (FS)
```

```
perl -ane 'print "$F[0] @{[scalar @F]}\n"' input.txt   # -a fills @F
perl -F, -ane 'print "$F[0]\n"' input.txt              # -F sets the␣
↪split pattern
```

The full-script form does the split itself. Bare `split` with no arguments splits `$_` on whitespace and discards leading blanks - exactly awk's default `FS`:

```
use v5.44;
open my $fh, '<', '/tmp/scores.txt' or die "open: $!";
while (<$fh>) {
    my @F = split;                          # awk's automatic field␣
↪split
    say "$F[0] has ", scalar(@F) - 1, " scores"; # $F[0]=$1, @F=NF
```

(continues on next page)

(continued from previous page)

```
}
# alice has 2 scores
# bob has 2 scores
# carol has 2 scores
# alice has 2 scores
```

Arithmetic across fields is the everyday awk action `print $1, $2+$3`, and it reads almost identically:

```
use v5.44;
open my $fh, '<', '/tmp/scores.txt' or die "open: $!";
while (<$fh>) {
    my @F = split;
    say "$F[0]: ", $F[1] + $F[2];   # awk: print $1, $2+$3
}
# alice: 175
# bob: 130
# carol: 195
# alice: 105
```

awk's `$NF` (the last field) is Perl's negative index `$F[-1]`, and a non-default `FS` is the pattern argument to `split`:

```
use v5.44;
open my $fh, '<', '/tmp/data.csv' or die "open: $!";  # alice,85,90
↪...
while (<$fh>) {
    chomp;
    my @F = split /,/;          # awk -F,
    say $F[-1];                 # awk's $NF: last field
}
# 90
# 60
# 100
```

To join fields back with a separator (awk's `OFS`), set `$,` (the output field separator that `print`/`say` inserts between its list arguments):

```
use v5.44;
open my $fh, '<', '/tmp/data.csv' or die "open: $!";
while (<$fh>) {
    chomp;
    my @F = split /,/;
    local $, = "|";             # OFS
    say @F;                     # join the list with OFS
}
# alice|85|90
# bob|70|60
# carol|95|100
```

The gotcha: fields are **zero-based**. awk's `$1` is `$F[0]`, `$2` is `$F[1]`, and `$0` (the whole

record) is `$_`, not an element of `@F`. `NF` is `scalar @F` (or `$#F + 1`); the last field is `$F[-1]`, not `$F[NF]`. And `split` with **one space as a string** (`split ' '`) is the special whitespace-and-strip mode; `split / /` (a regex with one space) is literal and does *not* strip leading blanks. Plain `split` with no argument is the awk-default mode you want most of the time.

Regex and substitution

awk's `sub`, `gsub`, `match`, and `~` all map onto Perl's single regex syntax: `=~` binds a pattern to a string, `s///` substitutes, `s///g` is global (awk's `gsub` vs `sub`). Perl's engine is PCRE, a strict superset of awk's POSIX ERE, so every awk pattern works and Perl adds backreferences, lookaround, named captures, and the `/e`, `/r`, `/x` flags awk has no equivalent for.

```
awk '/^alice/ { sub(/alice/, "ALICE"); print }' input.txt
```

```
perl -ne 'if (/^alice/) { s/alice/ALICE/; print }' input.txt
# ALICE 85 90
# ALICE 50 55
```

The full-script form:

```
use v5.44;
open my $fh, '<', '/tmp/scores.txt' or die "open: $!";
while (<$fh>) {
    next unless /^alice/;   # awk: /^alice/ { ... }
    s/alice/ALICE/;         # awk: sub(/alice/, "ALICE") (first
 ↪match)
    print;
}
# ALICE 85 90
# ALICE 50 55
```

Use `s///g` for awk's `gsub` (every match), and capture groups land in `$1`, `$2` just as awk's `match` populates `RSTART`/`RLENGTH` plus the `gawk` array. The `/e` flag runs **arbitrary Perl** in the replacement, which awk cannot do:

```
use v5.44;
my $s = "items: 3 and 4";
(my $t = $s) =~ s/(\d+)/$1 * 10/ge;   # /e: replacement is Perl code
say $t;                               # items: 30 and 40
```

`length`, `substr`, `index`, and the case functions map by name - watch the indexing:

```
use v5.44;
my $s = "alice";
say length $s;          # 5         (awk length($s))
say substr $s, 0, 3;    # ali       (awk substr($s,1,3) - awk is 1-
 ↪based!)
say uc $s;              # ALICE     (awk toupper($s))
```

The gotcha: `substr` is **zero-based** where awk's `substr` is one-based, so awk

`substr($s,1,3)` is Perl `substr($s,0,3)`. And `s///` edits its target in place and returns the **count** of substitutions, not the new string - so `my $new = ($s =~ s/a/b/)` puts a number in `$new`. Copy first (`(my $t = $s) =~ s/.../.../`) or use the `/r` flag to get a fresh string. POSIX character classes (`[[:digit:]]`) work, but the Perl shorthands (`\d`, `\w`, `\s`) are shorter and what you will see in Perl code.

Addresses and ranges

An awk rule is `pattern { action }`: the action runs only on records matching the pattern. In Perl that pattern is just a condition on the statement - a postfix `if` testing `$_`. A bare `/re/` matches against `$_`, a numeric test uses `$.` (awk's NR), and awk's range `/start/,/end/` is Perl's **flip-flop** operator `/start/ .. /end/`.

```
awk 'NR==2'              input.txt       # print record 2
awk '/banana/'           input.txt       # print matching records
awk '/bob/,/carol/'      input.txt       # range, inclusive
```

```
perl -ne 'print if $. == 2'            input.txt
perl -ne 'print if /banana/'           input.txt
perl -ne 'print if /bob/ .. /carol/'   input.txt
```

The full-script flip-flop, true from the line matching the left pattern through the line matching the right, inclusive - exactly awk's two-pattern range:

```
use v5.44;
open my $fh, '<', '/tmp/scores.txt' or die "open: $!";
while (<$fh>) {
    print if /bob/ .. /carol/;   # awk: /bob/,/carol/
}
# bob 70 60
# carol 95 100
```

The gotcha: a bare `pattern` with no action in awk means "print the record"; in Perl the loop is explicit, so you write the `print` (or `say`) yourself. And in a boolean test `..` is the flip-flop (range) operator, **not** the list-range operator (`1 .. 10` builds a list). Perl tells them apart by context: in the scalar position of an `if`, `..` is the stateful line-range selector that mirrors awk's `addr1,addr2`.

I/O, pipes, in-place edit

awk reads every file named on its command line automatically and has `getline` for explicit reads. Perl's `<>` (the diamond operator) reads each file in `@ARGV` in turn - the same default - and `<$fh>` is the explicit `getline`. Writing to a command or reading from one (awk's `print | "cmd"` and `"cmd" | getline`) is a pipe filehandle.

```
awk '{ print > "out.txt" }' input.txt      # redirect output
awk '{ print | "sort" }'     input.txt     # pipe to a command
```

```
use v5.44;
open my $out, '>', '/tmp/out.txt' or die "write: $!";
```

(continues on next page)

(continued from previous page)

```
open my $in,  '<', '/tmp/scores.txt' or die "read: $!";
while (<$in>) {
    print {$out} $_;        # awk: print > "out.txt"
}
close $out;
```

For pipes, `open my $fh, '|-', 'sort'` writes to a command's input and `open my $fh, '-|', 'ls', '-l'` reads a command's output - awk's `| "cmd"` in both directions.

awk has no built-in in-place edit; you reach for a tmp-file shuffle or GNU `gawk -i inplace`. Perl spells it `-i` on a one-liner:

```
perl -i -pe 's/red/crimson/' file.txt      # edit in place
```

Written out in full it is an explicit read-modify-write - slurp the lines, transform, write back - which is exactly what `-i` does under the hood:

```
use v5.44;
my $path = '/tmp/inplace.txt';          # holds: red green blue

open my $in, '<', $path or die "read: $!";
my @lines = <$in>;                      # slurp all lines (list
 ↪context)
close $in;

s/e/E/g for @lines;                     # transform each line's $_

open my $out, '>', $path or die "write: $!";
print {$out} @lines;                    # write them back
close $out;
# file now holds: rEd / grEEn / bluE
```

The gotcha: open returns false on failure rather than aborting, so the `or die "...: $!"` idiom is mandatory - `$!` is the system error string, awk's silent failure made explicit. And `print {$out} ...` needs the braces around the filehandle when it is a variable; the bare `print FH ...` form (no comma) is for named handles, which is a common first-day stumble.

One-liners and switches

The one-liner is awk's home turf and Perl's too. The switch family that reproduces awk: `-e` supplies the program, `-n` wraps it in a per-record loop (awk's implicit `{ }`), `-p` does the same with an auto-print at the end of each cycle, `-a` autosplits into `@F` (awk's automatic field split), `-F` sets the split pattern (awk's `FS`), and `-l` handles line endings (awk's `ORS`/`RS` convenience). `BEGIN { }` and `END { }` are the **same keywords** as awk, running before and after the loop.

```
awk '/error/ { print }'          log.txt        # print error
 ↪records
```

(continues on next page)

(continued from previous page)

```
awk '{ s += $NF } END { print s }' input.txt    # sum the last field
awk -F, '{ print $1 }'             input.txt    # first CSV field
```

```
perl -ne 'print if /error/'                     log.txt
perl -ane 'END { print "$s\n" } $s += $F[-1]'    input.txt
perl -F, -ane 'print "$F[0]\n"'                  input.txt
```

Each of those expands to an explicit loop: `perl -ne 'CODE'` is `while (<$fh>) { CODE }`, `-ane` adds `my @F = split` at the top, and `BEGIN`/`END` blocks work in a full script exactly as in awk. Written out, the "sum a column with BEGIN/END" form:

```
use v5.44;
my $n = 0;
my $sum = 0;
BEGIN { say "start" }              # runs before the loop, like awk␣
↪BEGIN
END   { say "lines=$n sum=$sum" }  # runs after, like awk END
open my $fh, '<', '/tmp/scores.txt' or die "open: $!";
while (<$fh>) {
    my @F = split;
    $n++;
    $sum += $F[1];                 # awk: sum += $2
}
# start
# lines=4 sum=300
```

The gotcha: when a one-liner grows past a line or two, write out the explicit loop it expands to. Consult the *One-Liners guide* for the full switch catalogue and dozens of recipes - it is the highest-leverage thing to read coming from an awk background. Perl also has full subroutines, references, modules, and OO if your script outgrows a one-liner; see the *Object-oriented Programming guide* and the other coming-from guides.

Control flow

awk's control keywords map onto Perl's almost name-for-name. awk's `next` (skip to the next record) is Perl's `next`; `break`/`continue` in awk loops are Perl's `last`/`next`; awk's `for (k in arr)` becomes a Perl `for` over `keys`. The braces and `;` are the same; Perl adds the postfix forms that read like awk patterns.

```
awk '{ if ($2 < 70) next; print }' input.txt
```

```
use v5.44;
open my $fh, '<', '/tmp/scores.txt' or die "open: $!";
while (<$fh>) {
    my @F = split;
    next if $F[1] < 70;        # awk: if ($2 < 70) next
    print;
}
# alice 85 90
```

(continues on next page)

(continued from previous page)

```
# carol 95 100
```

The gotcha: Perl's comparison operators come in two families and you pick by the *operands' type*, where awk has only </== for both. Numbers use ==, <, >, <=>; strings use `eq`, `lt`, `gt`, `cmp`. awk decides numeric-vs-string comparison by the values at run-time; Perl makes you choose the operator. Using == on strings (or `eq` on numbers) is a frequent, quiet bug - `"abc" == "xyz"` is true in Perl (both numify to 0), which is almost never what you meant.

Variables and data

This is the happiest mapping in the guide: awk's associative array is a Perl **hash**, and the daily idioms are near-identical. awk's `count[$1]++` is Perl's `$count{$F[0]}++`; `for (k in count)` is `for my $k (keys %count)`; `if (k in count)` is `exists $count{$k}`. The one shift is the sigil - the whole hash is `%count`, but one value is `$count{$key}`.

```
awk '{ total[$1] += $2 + $3 }
     END { for (k in total) print k, total[k] }' input.txt
```

```
use v5.44;
open my $fh, '<', '/tmp/scores.txt' or die "open: $!";
my %total;
while (<$fh>) {
    my @F = split;
    $total{$F[0]} += $F[1] + $F[2];   # awk: total[$1] += $2 + $3
}
for my $name (sort keys %total) {     # awk END loop over the array
    say "$name $total{$name}";
}
# alice 280
# bob 130
# carol 195
```

The two-file `NR==FNR` idiom - load keys from the first file, then test membership in the second - is one explicit loop per file in Perl, which is clearer than the awk one-liner it replaces:

```
use v5.44;
my %seen;
open my $f1, '<', '/tmp/data.csv' or die "open: $!";
while (<$f1>) {
    my ($k) = split /,/;          # first field only
    $seen{$k} = 1;
}
close $f1;
open my $f2, '<', '/tmp/scores.txt' or die "open: $!";
while (<$f2>) {
    my ($k) = split;
```

(continues on next page)

(continued from previous page)

```
    print if $seen{$k};           # awk: ($1 in seen)
}
# alice 85 90
# bob 70 60
# carol 95 100
# alice 50 55
```

The gotcha: a hash has no inherent order (awk's `for (k in arr)` is also unordered, so this will not surprise you), so iterate `sort keys %h` when you want a stable order. Membership is `exists $h{$k}`, not awk's `k in arr` - and merely *reading* `$h{$k}` to test it will autovivify the key into existence in some contexts, where `exists` never does. Numbers and strings auto-coerce in Perl as in awk, but remember the `==` vs `eq` split from *Control flow*.

Gotchas coming from awk

The traps, collected for a final scan before you write:

- **Fields are zero-based.** awk's `$1` is `$F[0]`, `$2` is `$F[1]`, and the whole record `$0` is `$_`. `NF` is `scalar @F`; the last field is `$F[-1]`, not `$F[NF]`.
- **`<$fh>` keeps the trailing newline,** unlike awk's `$0`. `chomp` to strip it.
- **`substr` is zero-based,** where awk's is one-based: awk `substr($s,1,3)` is Perl `substr($s,0,3)`.
- **`s///` returns a count, not the new string.** `my $x = $s =~ s/a/b/` puts the substitution *count* in `$x`. Copy first, or use the `/r` flag to get a new string.
- **Two comparison families.** Numbers use `==`/`<`/`<=>`; strings use `eq`/`lt`/`cmp`. awk's single `==`/`<` is split in two, chosen by operator, not by value. `"abc" == "xyz"` is true (both numify to 0).
- **Bare `split` is the awk-default mode.** `split` (no args) splits `$_` on whitespace and strips leading blanks. `split / /` (a regex with one space) is literal and does *not* strip - use plain `split` for awk's default `FS`.
- **Membership is `exists $h{$k}`, not `k in arr`.** Testing a key by reading `$h{$k}` can autovivify it; `exists` never does.
- **open does not abort on failure.** Use `open my $fh, '<', $path or die "... : $!"`. `$!` is the system error string.

Shell to Perl

You know the shell. You glue programs together with pipes, you reach for `sed`, `awk`, `grep`, and `cut` in a pipeline without thinking, you capture command output with `$(...)`, and you script control flow with `for f in *`, `while read line`, and `case`. This guide maps each of those habits onto Perl, so you can keep the pipeline reflexes and pick up the things the shell makes painful.

When a shell script grows past about 50 lines of quoting and `sed`/`awk`/`grep` pipelines, Perl is the natural next step: it does all of it in one language, with real data structures instead of whitespace-delimited strings. The framing to carry in: **Perl is the shell pipeline, but**

the filter language is a real language. You still open pipes, you still glob, you still run commands and read their output. What changes is that between the pipes you now have `@arrays`, `%hashes`, real regex, and arithmetic that needs no `$(( ))`. The shell's one data type is the string; Perl gives you actual containers.

Every runnable example here was executed on `pperl`, a Rust reimplementation of Perl 5.44; the `# ...` comments show its real output. Start scripts with:

```
use v5.44;
```

That one line turns on `strict`, `warnings`, and the `say` built-in (a `print` with a trailing newline), the modern feature set used throughout.

How to read this

- *The record loop* - `while read line` becomes `while (<$fh>)` and `$_`.
- *Fields and splitting* - `cut`/`IFS`/`awk` fields become `split` and a real array.
- *Regex and substitution* - the shell's `${var#...}`/`${var/a/b}` parameter expansions become real regex.
- *Addresses and ranges* - `grep -n`, `awk NR==2`, and line ranges.
- *I/O, pipes, and in-place edit* - the heart: `open`, `-|`/`|-`, redirection, here-docs, `$(...)`.
- *One-liners and switches* - `-n`, `-p`, `-e`, `BEGIN`/`END`.
- *Control flow* - `for`/`while`/`case`/`if`, file tests, exit status.
- *Variables and data* - `$var` becomes `my $var`, plus the `@arrays` and `%hashes` the shell never had.
- *Gotchas coming from the shell* - scan before you write.

The record loop

The shell's line-at-a-time idiom is `while read line; do ... done`, which reads one line per iteration into `$line` (and strips it according to `IFS`). Perl's equivalent is `while (<$fh>)`, which reads one line per iteration into `$_`, the implicit topic variable. The crucial difference: Perl keeps the trailing newline, so you `chomp` it yourself, exactly where the shell's `read` would have eaten it.

```
while read line; do
    echo "got: $line"
done < data.txt
```

```
use v5.44;
open my $fh, '<', '/tmp/data.txt' or die "open: $!";
while (my $line = <$fh>) {      # each line, with its newline
    chomp $line;                # strip it, like read does
    say "got: $line";
}
close $fh;
# got: apple
```

(continues on next page)

(continued from previous page)

```
# got: banana
# got: cherry
```

(The input file held `apple`, `banana`, `cherry`.) Read with the bare `<$fh>` and the line lands in `$_`, the default that most line built-ins operate on. The line number is in `$.`. This is the form to reach for when you are translating a filter:

```
use v5.44;
open my $fh, '<', '/tmp/data.txt' or die "open: $!";
while (<$fh>) {                 # line lands in $_
    chomp;                      # chomp $_ by default
    say "$. : $_";              # $. is the line number
}
close $fh;
# 1 : apple
# 2 : banana
# 3 : cherry
```

The gotcha: `read` splits on `IFS` and trims; `<$fh>` does neither. A Perl line read is the whole raw line including the `\n`, so `chomp` is your reflex, and field-splitting is a separate, explicit step (the next section). What you lose in automatic trimming you gain in not having `IFS` quietly mangle your data.

Fields and splitting

In the shell you reach fields with `cut -d: -f1`, with `awk '{print $1}'`, or by setting `IFS` and letting `read` split for you. Perl's one answer is `split`: give it a separator and a string, get a real array back. Positional fields that the shell numbers `$1`, `$2` become array elements `$f[0]`, `$f[1]` - **0-based**, unlike `awk`'s 1-based `$1`.

```
line='root:x:0:0:root:/root:/bin/bash'
user=$(echo "$line" | cut -d: -f1)
shell=$(echo "$line" | cut -d: -f7)
echo "$user $shell"
```

```
use v5.44;
my $line = "root:x:0:0:root:/root:/bin/bash";
my @f = split /:/, $line;
say "user: $f[0]";             # user: root
say "shell: $f[-1]";           # shell: /bin/bash   (negative index)
say "fields: ", scalar @f;     # fields: 7
```

To split on runs of whitespace - the shell's default word-splitting, and `awk`'s default - use the special pattern `split ' '` (a literal single-space string, which also skips leading blanks). To join fields back, `join`:

```
use v5.44;
my @words = split ' ', "  the   quick brown  ";
say scalar @words;             # 3   (leading/inner blanks collapsed)
say join "|", @words;          # the|quick|brown
```

The gotcha: `split /:/` with a literal pattern keeps empty trailing fields only up to a point - by default Perl drops trailing empty fields, so `split /:/, "a::"` yields `("a")`, not `("a", "", "")`. Pass a negative limit (`split /:/, $s, -1`) to keep them, the equivalent of caring about trailing empty `cut` fields. And `split ' '` (the magic-whitespace form) is **not** the same as `split / /` (a single literal space): the first collapses runs and trims, the second does not.

Regex and substitution

The shell's `${}` parameter expansions become real regex - and this is a large upgrade. `${var#prefix}`, `${var%suffix}`, `${var/a/b}`, and `${var//a/b}` are each a special-purpose, limited string edit. Perl replaces the whole family with one operator, `s///`, that takes an actual regular expression and the full set of flags.

```
f='report.txt.bak'
base=${f%.bak}              # strip suffix
path='/usr/local/bin'
tail=${path##*/}            # basename
dir=${path%/*}              # dirname
s='a-b-c'
one=${s/-/_}                # replace first
all=${s//-/_}               # replace all
```

```
use v5.44;
my $f = "report.txt.bak";
(my $base = $f) =~ s/\.bak$//;       # ${f%.bak}
say $base;                           # report.txt

my $path = "/usr/local/bin";
(my $tail = $path) =~ s{.*/}{};      # ${path##*/}  basename
say $tail;                           # bin
(my $dir = $path) =~ s{/[^/]*$}{};   # ${path%/*}   dirname
say $dir;                            # /usr/local

my $s = "a-b-c";
(my $one = $s) =~ s/-/_/;            # ${s/-/_}   first only
say $one;                            # a_b-c
(my $all = $s) =~ s/-/_/g;           # ${s//-/_}  /g = global
say $all;                            # a_b_c
```

Because it is a real regex, the things the shell cannot do at all are trivial: capture groups land in `$1`, `$2`; the `/e` flag runs Perl code in the replacement; the `/r` flag returns a copy instead of editing in place; and `/i`, `/x` modify matching.

```
use v5.44;
my $s = "items: 3 and 4";
(my $t = $s) =~ s/(\d+)/$1 * 10/ge;  # /e: replacement is Perl code
say $t;                              # items: 30 and 40

my $date = "2026-06-21";
my $us = $date =~ s{(\d+)-(\d+)-(\d+)}{$2/$3/$1}r;  # /r: return a
```

(continues on next page)

(continued from previous page)

```
↪copy
say $us;                                # 06/21/2026
say $date;                              # 2026-06-21   (unchanged)
```

The gotcha: bare `s///` edits its target and returns the *count* of substitutions, not the new string - so the examples copy first with `(my $t = $s) =~ ...` or use the `/r` flag. Writing `my $new = ($s =~ s/a/b/)` puts a number in `$new`. This is the single most common first-day surprise. Note also that the delimiters are free: `s{...}{...}` and `s#...#...#` save you backslashing the slashes in a path pattern, the way the shell's `${path##*/}` already avoids them.

Addresses and ranges

Selecting lines by number or pattern - `grep`, `grep -n`, `awk 'NR==2'`, `sed -n '/a/,/b/p'` - becomes a postfix `if` on a condition inside the loop. The line number is `$.`; the pattern test is `/pat/` against `$_`.

```
grep -n an data.txt                 # number + matching lines
awk 'NR==2' data.txt                # the second line
```

```
use v5.44;
open my $fh, '<', '/tmp/data.txt' or die "open: $!";
while (<$fh>) {
    chomp;
    say "$. : $_" if /an/;          # grep -n 'an'
}
close $fh;
# 2 : banana
```

A line range - the sed/awk `/start/,/end/` selector - becomes Perl's **flip-flop** range operator `/start/ .. /end/`, true from the line matching the left pattern through the line matching the right, inclusive:

```
use v5.44;
open my $fh, '<', '/tmp/data.txt' or die "open: $!";
while (<$fh>) {
    print if /banana/ .. /cherry/;   # the /start/,/end/ range
}
close $fh;
# banana
# cherry
```

The gotcha: in a boolean test `..` is the flip-flop (range) operator, **not** the list-range operator (which is `1 .. 10` building a list). Perl tells them apart by context - in the boolean position of an `if`, `..` is the stateful line-range selector; in list context it builds a sequence. Same two dots, decided by where you write them.

I/O, pipes, and in-place edit

This is the heart of the guide, because it is the heart of shell scripting. Everything you do with `|`, `>`, `>>`, `2>&1`, `<<EOF`, and `$(...)` has a direct Perl spelling, and once a script outgrows a single pipeline this is the section that pays off.

Command substitution. The shell's `$(cmd)` and backticks become Perl's backticks or `qx{...}`. The capture is context-sensitive: in scalar context you get the whole output as one string; in list context you get one element per line.

```
out=$(echo hello)
mapfile -t lines < <(seq 1 3)
```

```
use v5.44;
my $out = `echo hello`;           # scalar: whole output, one string
chomp $out;
say "got: $out";                  # got: hello

my @lines = qx{seq 1 3};          # list: one element per line
chomp @lines;
say "lines: @lines";              # lines: 1 2 3
```

When you do not need the output, `system()` runs a command and gives you its exit status (see *Control flow* for `$?`). Pass `system` a *list* and no shell is involved - the safe form that avoids quoting hell:

```
use v5.44;
system('mkdir', '-p', '/tmp/sh_demo');   # list form: no shell, no␣
↪quoting
say "made it" if -d '/tmp/sh_demo';      # made it
```

Pipes. A pipeline stage - reading a command's output or feeding a command's input - is an open with a pipe mode. `open my $fh, '-|', LIST` reads a command's stdout; `open my $fh, '|-', LIST` writes to a command's stdin. The list form (command plus args as separate strings) runs no shell, so there is nothing to quote.

```
seq 1 3 | while read n; do echo "n=$n"; done    # read from a␣
↪command
printf '%s\n' banana apple cherry | sort         # write to a␣
↪command
```

```
use v5.44;
open my $ph, '-|', 'seq', '1', '3' or die "pipe: $!";  # read␣
↪command output
my @nums = <$ph>;
close $ph;
chomp @nums;
say "got: @nums";                 # got: 1 2 3
```

```
use v5.44;
open my $sort, '|-', 'sort' or die "pipe: $!";  # write to command␣
```

(continues on next page)

(continued from previous page)

```
↪stdin
print {$sort} "$_\n" for qw(banana apple cherry);
close $sort;
# apple
# banana
# cherry
```

Redirection. > and >> are the open modes `'>'` (truncate) and `'>>'` (append); a three-arg open with a lexical handle is the idiom. `print {$fh} ...` writes to a handle. To merge a child's stderr into the captured stream (`2>&1`), keep the redirection in the command you hand to backticks:

```
use v5.44;
open my $fh, '>', '/tmp/sh_out.txt' or die "write: $!";
print {$fh} "line $_\n" for 1 .. 3;
close $fh;

my $both = `sh -c 'echo to-out; echo to-err 1>&2' 2>&1`;  # merge␣
↪stderr
print $both;
# to-out
# to-err
```

Here-docs. The shell's `<<EOF` (interpolating) and `<<'EOF'` (literal) map one-to-one to Perl's `<<"END"` and `<<'END'`. Double quotes on the terminator interpolate variables; single quotes do not.

```
use v5.44;
my $name = "world";
print <<"END";                # interpolating, like <<EOF
hello $name
END
print <<'END';                # literal, like <<'EOF'
no $interpolation here
END
# hello world
# no $interpolation here
```

In-place edit. `sed -i` rewrites a file in place; the idiomatic Perl is the same switch on a `-p` one-liner. Written out in full it is the explicit read-modify-write that `-i` performs under the hood - slurp, transform, write back:

```
use v5.44;
my $path = '/tmp/inplace_data.txt';   # holds: red green blue

open my $in, '<', $path or die "read: $!";
my @lines = <$in>;                    # slurp all lines
close $in;

s/e/E/g for @lines;                   # transform each line's $_
```

(continues on next page)

(continued from previous page)

```
open my $out, '>', $path or die "write: $!";
print {$out} @lines;                    # write them back
close $out;
# file now holds:
# rEd
# grEEn
# bluE
```

The gotcha: open returns false on failure rather than raising, so the `or die "...: $!"` idiom is mandatory - `$!` is the system error string, the shell's silent `2>/dev/null` failure made loud and explicit. And when you build a command from variables, prefer the **list form** of `system`/open (`'ls', '-l', $dir`) over a single interpolated string: the list form bypasses the shell entirely, so there is no word splitting, no glob expansion, and no quoting to get wrong - the cure for the shell's quoting hell.

One-liners and switches

The one-liner is the shell developer's home turf and Perl's too: the filter you drop into a pipeline. The switch family that makes it work: `-e` supplies the program, `-n` wraps it in a no-auto-print loop, `-p` wraps it in an auto-print loop, `-i` edits files in place, `-l` handles line endings, and `-a`/`-F` autosplit each line into `@F` (the direct `awk` analogue, fields in `@F` instead of `$1`..`$NF`). `BEGIN { }` and `END { }` run before and after the loop, like `awk`'s `BEGIN`/`END`.

```
grep error log.txt                              # filter lines
awk -F: '{print $1}' /etc/passwd                # first field
awk '{s += $NF} END {print s}' data.txt         # sum last field
```

```
perl -ne 'print if /error/' log.txt             # filter lines
perl -F: -ane 'print "$F[0]\n"' /etc/passwd     # first field, -F sets␣
↪split
perl -lanE '$s += $F[-1]; END { say $s }' data.txt  # sum last field
```

Each of those expands to an explicit loop: `perl -ne 'CODE'` is `while (<$fh>) { CODE }`, and `perl -pe 'CODE'` is the same with a trailing `print`. Written out, the "first field of each line" form:

```
use v5.44;
open my $fh, '<', '/tmp/passwd.txt' or die "open: $!";
while (<$fh>) {                 # the implicit loop of -ane
    chomp;
    my @F = split /:/;          # what -F: gives you in @F
    say $F[0];                  # print the first field
}
close $fh;
# root
# daemon
# bin
```

The gotcha: when a one-liner grows past a line or two, write out the explicit loop it expands to. Consult the *One-Liners guide* for the full switch catalogue and dozens of recipes - it is the highest-leverage thing to read coming from a shell background, where the one-liner is the everyday reflex.

Control flow

The shell's `for`, `while`, `case`, and `if`/`test` map onto Perl loops and conditionals, and several of the mappings are pleasantly direct.

Loops. `for f in *; do` becomes `for my $f (glob "*");` the file glob `*.txt` is `glob "*.txt"` or the readline form `<*.txt>`.

```
for f in /tmp/sh_*.txt; do
    echo "file: $f"
done
```

```
use v5.44;
for my $f (sort glob "/tmp/sh_*.txt") {
    say "file: $f";
}
# file: /tmp/sh_data.txt
# file: /tmp/sh_passwd.txt
```

Conditionals and `test`. This is a happy mapping: the shell's `[ -e ]`, `[ -d ]`, `[ -f ]` file tests are the **same `-X` operators** in Perl. String and numeric comparison split into two families, as they do between `[ "$a" = "$b" ]` and `[ "$a" -eq "$b" ]`: Perl uses `eq`/`ne` for strings and `==`/`!=` for numbers. The shell's `-z`/`-n` (empty / non-empty string) become `!length` / `length`.

```
if [ -f "$f" ] && [ -n "$name" ]; then
    echo ok
fi
[ "$a" = "$b" ]        # string equality
[ "$x" -eq "$y" ]      # numeric equality
```

```
use v5.44;
my $f = '/tmp/sh_data.txt';
my $name = 'set';
say "ok" if -f $f && length $name;   # same -f, same idea
# ok

say "abc" eq "abc" ? "eq" : "ne";    # string compare
say 10 == 10.0 ? "num-eq" : "num-ne"; # numeric compare
# eq
# num-eq
```

`case`. The shell's `case` has no single keyword twin; the idiomatic Perl is a `for`/`if` chain or a ternary cascade (or, for many branches, a dispatch hash mapping keys to code refs).

```
case "$cmd" in
    start)   echo starting ;;
    stop)    echo stopping ;;
    *)       echo "unknown: $cmd" ;;
esac
```

```
use v5.44;
for my $cmd (qw(start stop bogus)) {
    my $r =
        $cmd eq 'start' ? "starting"
      : $cmd eq 'stop'  ? "stopping"
      :                   "unknown: $cmd";
    say "$cmd -> $r";
}
# start -> starting
# stop -> stopping
# bogus -> unknown: bogus
```

Exit status. After a `system()`, the child's status is in `$?`, exactly the shell variable. But `$?` holds the raw `wait` status, not the bare exit code: shift right by 8 to get the code the shell would show as `$?`. The loop keywords `last` and `next` are the shell's `break` and `continue`.

```
use v5.44;
system('sh', '-c', 'exit 3');
say "raw \$? = $?";           # raw $? = 768
say "exit code = ", $? >> 8;  # exit code = 3
```

The gotcha: `$? >> 8` is the exit code; the low 8 bits hold the signal that killed the child (if any). The shell hides this behind its own `$?`; in Perl you do the shift yourself. Forgetting it is why `if ($? == 1)` after a command that exited 1 is almost always wrong - the raw value is 256, not 1.

Variables and data

A shell variable is always a string - `var=value`, used as `$var` or `${var}`, and quoted as `"$var"` to survive word splitting. Perl's scalar is `my $var`, lexically scoped, and **no quoting dance is needed**: a Perl scalar holds one value and does not get re-split on use. Where the shell forces everything through strings, Perl adds the two containers the shell never had: ordered `@arrays` and key/value `%hashes`.

```
name="Ada"
greeting="Hello, ${name}"
langs="Perl Python"          # a "list" is really a string + IFS
```

```
use v5.44;
my $name = "Ada";
my $greeting = "Hello, $name";   # interpolation, like "${name}"
my @langs = ("Perl", "Python");  # a real list, not a split string
say $greeting;                   # Hello, Ada
```

(continues on next page)

(continued from previous page)

```
say "first: $langs[0]";          # first: Perl
say "count: ", scalar @langs;    # count: 2
```

Script arguments. The shell's positional parameters map to `@ARGV`. The quoting minefield of `"$@"` versus `$*` simply does not exist: `@ARGV` is a real array, each argument a clean element no matter what spaces or globs it contained. `$1`..`$9` become `$ARGV[0]`..`$ARGV[8]`, `$#` (the count) becomes `scalar @ARGV`, and `$0` (the script name) becomes `$0`.

```
echo "count: $#"
echo "first: $1"
echo "all: $@"
```

```
use v5.44;
say "count: ", scalar @ARGV;   # like $#
say "first: $ARGV[0]";         # like $1
say "all: @ARGV";              # like "$@"
# invoked as: pperl script.pl one two three
# count: 3
# first: one
# all: one two three
```

Associative arrays. A Perl hash is the shell's `declare -A` done right - declared with `%`, accessed one value at a time with `$h{key}`, and far more ergonomic than the shell's bolted-on associative arrays.

```
use v5.44;
my %count;
$count{$_}++ for qw(apple pear apple fig apple pear);
for my $k (sort keys %count) {
    say "$k: $count{$k}";
}
# apple: 3
# fig: 1
# pear: 2
```

The gotcha: a shell variable is global by default and a Perl `my` variable is lexically scoped to its block - the opposite default. The shell's `local` (dynamic scoping inside a function) is closest to Perl's `local`, but for ordinary variables you want `my`, which is true lexical scope. And interpolation only happens in double quotes: `"$name"` interpolates, `'$name'` is the literal four characters, just like the shell.

> Perl also has full subroutines, references, modules, and OO if your script outgrows a one-liner - see the *Object-oriented Programming guide* and the other coming-from guides.

Gotchas coming from the shell

The traps, collected for a final scan before you write:

- **`<$fh>` keeps the trailing newline.** Shell `read` trims; Perl does not. `chomp` is your reflex on every line read.
- **`split` is a separate step, and it is 0-based.** Fields are `$f[0]`, `$f[1]`, not awk's 1-based `$1`. `split ' '` (magic whitespace) trims and collapses; `split / /` (a literal space) does not.
- **`s///` returns a count, not the new string.** `my $x = $s =~ s/a/b/` puts the substitution *count* in `$x`. Copy first (`(my $t = $s) =~ s/.../.../`) or use the `/r` flag.
- **`$? >> 8` is the exit code.** The raw `$?` after `system` is the full wait status; the exit code is the high 8 bits. `if ($? == 1)` is almost always a bug; you want `if (($? >> 8) == 1)`.
- **open does not raise on failure.** Use `open my $fh, '<', $path or die "...: $!"`. `$!` is the system error string - the shell's silent failure made explicit.
- **Prefer the list form of `system`/`open` over an interpolated string.** `system('ls', '-l', $dir)` runs no shell: no word splitting, no glob surprise, no quoting hell. The string form (`system "ls -l $dir"`) reintroduces every shell-quoting trap you came here to escape.
- **`my` is lexical; shell variables are global.** Declare with `my` and scope to the block; reach for `local` only for the shell's dynamic-scoping behaviour, which is rarely what you want.
- **String vs numeric comparison is two families.** `eq`/`ne` for strings, `==`/`!=` for numbers - the `[ = ]` vs `[ -eq ]` split, but the operators are reversed from the shell, so read them carefully.

Tcl to Perl

You know Tcl. You write `set x 5`, you substitute with `$x`, you reach for `[expr {...}]` to do arithmetic, you build lists with `lappend` and walk them with `foreach`, and you bend strings with `regexp` and `regsub`. This guide maps each of those habits onto Perl, so you can keep every reflex you have and pick up the things Tcl makes hard.

Tcl and Perl share the same roots: Unix scripting, a string-first worldview, and `$`-substitution as the way you reach a variable. Most of what you know maps almost directly - and Perl gives you real data structures (`@arrays` and `%hashes` as first-class types, not lists pressed into service) and a vast module ecosystem to land in. Two specific pieces of friction get the weight in this guide: Perl's distinct array/hash types where Tcl has lists and assoc arrays, and Perl's regex (a superset of Tcl's). The line-at-a-time and one-liner material is lighter here, because Tcl is not a one-liner language; you will spend your time in variables, data, control flow, and regex.

Every runnable example here was executed on `pperl`, a Rust reimplementation of Perl 5.44; the `# ...` comments show its real output. Start scripts with:

```
use v5.44;
```

That one line turns on `strict`, `warnings`, and the `say` built-in (a `print` with a trailing newline, the rough twin of Tcl's `puts`), the modern feature set used throughout.

How to read this

- *Variables and substitution* - `set` becomes `my`, `[expr]` disappears, `$x` substitution stays.
- *Lists and arrays* - `lindex`/`lappend`/`lsort` become Perl array operations.
- *Assoc arrays and hashes* - `set a(k) v` becomes `$a{k}`; `dict` becomes a hash.
- *Procs and references* - `proc` becomes `sub`; `upvar`/`uplevel` become references.
- *Regex and substitution* - `regexp`/`regsub`/`string map` become `m//`/`s///`/`tr///`.
- *Control flow* - `if`/`while`/`foreach`/`switch` become Perl's, plus `{}` vs `""` quoting.
- *The line/record loop* - reading a file line by line with `$_` and `$.`.
- *Fields and splitting* - `split`/`join`, the Tcl `split` analogue.
- *I/O, pipes, and in-place edit* - open/gets/puts/exec become open/<$fh>/print/qx.
- *One-liners and switches* - `-n`, `-p`, `-e`, kept brief.
- *Gotchas coming from Tcl* - scan before you write.

Variables and substitution

In Tcl, `set x 5` creates a variable and `$x` substitutes its value. In Perl, `my $x = 5;` declares a lexically scoped variable and `$x` substitutes it - the substitution syntax you already know carries over verbatim. The relief is that Perl has native operators: there is no `[expr {...}]`. Arithmetic is just arithmetic.

```
set x 5
set name "world"
set sum [expr {$x + 3}]
puts "x is $x"
puts "sum is $sum"
```

```
use v5.44;
my $x = 5;                  # set x 5
my $name = "world";
my $sum = $x + 3;           # native operators, no [expr] needed
say "x is $x";              # x is 5
say "sum is $sum";          # sum is 8
```

Quoting maps cleanly, and this is a happy mapping: Tcl's `"..."` (substitution happens) is Perl's double-quoted string, and Tcl's `{...}` (literal, no substitution) is Perl's single-quoted string.

```
use v5.44;
my $name = "world";
say "hello, $name";         # hello, world   (interpolates)
say 'no $interp here';      # no $interp here (literal)
```

The gotcha: Tcl is "everything is a string" and Perl is close to it - a scalar auto-coerces between number and string by context - but Perl splits *comparison* into two operator families, and you pick by the operation, not the value. Numbers use ==, !=, <, >; strings use eq, ne, lt, gt.

```
use v5.44;
my $x = "5";
say $x + 3;                 # 8    (numeric context coerces "5")
say $x . "3";               # 53   (string context)
say "10" == "10.0" ? "num-equal" : "num-differ";   # num-equal
say "10" eq "10.0" ? "str-equal" : "str-differ";   # str-differ
```

== compares "10" and "10.0" as numbers (equal); eq compares them as strings (different). Using == where you meant eq, or the reverse, is the one quiet bug the string-first worldview sets you up for.

Lists and arrays

A Tcl list is a Perl array, and the verbs line up one for one. The big shift: in Tcl *everything is a list*, including strings you split on the fly; in Perl an array (@a) is a distinct, first-class type with its own sigil. When you reach for one element, the sigil follows the *element*, so it is $a[0] (a scalar), not @a[0].

```
set items [list apple pear fig]
puts [lindex $items 0]
puts [llength $items]
lappend items plum
set sorted [lsort $items]
foreach it $items { puts "item: $it" }
```

```
use v5.44;
my @items = ("apple", "pear", "fig");
say $items[0];                  # apple        (lindex $items 0)
say scalar @items;              # 3            (llength $items)
push @items, "plum";            # lappend items plum
my @sorted = sort @items;       # lsort
say "@sorted";                  # apple fig pear plum
for my $it (@items) {           # foreach it $items
    say "item: $it";
}
```

lsearch - "find the index of a matching element" - has no single built-in; the idiomatic Perl is grep over the index range, with $#items as the last index:

```
use v5.44;
my @items = ("apple", "pear", "fig", "plum");
my ($idx) = grep { $items[$_] eq "fig" } 0 .. $#items;   # lsearch
say "fig at $idx";              # fig at 2
```

The gotcha: scalar @items is how you get the length (Tcl's llength); writing my $n = @items works because assigning an array to a scalar yields its count, but spell it scalar @items when you want the length inside a larger expression. And sort compares as

strings by default, so `sort (10, 9, 100)` gives `10 100 9`; pass a numeric comparator `sort { $a <=> $b } @nums` for numeric order, where `$a` and `$b` are the two elements and `<=>` is the numeric three-way operator.

Assoc arrays and hashes

A Tcl associative array - `set a(red) 1` - is a Perl hash. The element access maps directly: Tcl's `$a(red)` is Perl's `$a{red}`, and the whole collection is `%a` (Tcl has no syntax for the array as a single value; Perl does). Modern Tcl's `dict` maps to the same Perl hash, or to a hash reference when you need to nest or pass it around.

```
set a(red) 1
set a(green) 2
set a(blue) 3
puts $a(red)
puts [array exists a]
foreach k [lsort [array names a]] { puts "$k => $a($k)" }
unset a(blue)
```

```
use v5.44;
my %a = (red => 1, green => 2, blue => 3);
say $a{red};                              # 1     ($a(red))
say exists $a{green} ? "yes" : "no";      # yes   (info exists
 ↪a(green))
for my $k (sort keys %a) {                # array names a
    say "$k => $a{$k}";
}
delete $a{blue};                          # unset a(blue)
```

That prints:

```
1
yes
red => 1
green => 2
blue => 3
```

The gotcha: membership is `exists $a{key}`, not a separate command, and the fat comma `=>` is the idiomatic key/value separator in a hash literal. `=>` also auto-quotes the bareword on its left, so `red => 1` needs no quotes around `red`. A hash has no inherent order (neither does a Tcl array); iterate `sort keys %a` when you want a stable one, exactly as you reach for `lsort [array names a]`.

Procs and references

`proc name {args} {body}` becomes Perl's `sub name { ... }`. The classic Tcl way to read arguments - positional, by name - has a direct Perl twin: `my ($a, $b) = @_;` unpacks the argument array `@_`. Modern Perl also has signatures, which read like Tcl's `{args}` list and add defaults.

```
proc add {a b} {
    return [expr {$a + $b}]
}
puts [add 3 4]

proc greet {who {greeting Hello}} {
    return "$greeting, $who!"
}
puts [greet Tcl]
puts [greet Perl Hi]
```

```
use v5.44;
sub add {
    my ($a, $b) = @_;       # unpack the argument array
    return $a + $b;
}
say add(3, 4);              # 7

sub greet ($who, $greeting = "Hello") {   # signature with default
    return "$greeting, $who!";
}
say greet("Tcl");           # Hello, Tcl!
say greet("Perl", "Hi");    # Hi, Perl!
```

Tcl's pass-by-name - `upvar`, where a proc reaches up and mutates a caller's variable - becomes a Perl **reference**: take one with `\`, follow it with `$$ref`. You pass the reference explicitly instead of naming the variable, which makes the data flow visible at the call site.

```
use v5.44;
sub increment {
    my ($ref) = @_;
    $$ref++;                # mutate through the reference (Tcl: upvar)
}
my $count = 10;
increment(\$count);         # pass a reference to $count
say $count;                 # 11
```

The gotcha: `@_` is the argument array, and `my ($a, $b) = @_;` *copies* the arguments into named locals - the line you almost always want at the top of a sub. Reaching for `upvar`-style aliasing is rarely needed in Perl; when you do need to mutate a caller's data, pass a reference (`\$x`, `\@arr`, `\%h`) deliberately rather than aliasing by name. References are also how Perl nests data (an array of hashes, a hash of arrays); the same mechanism that replaces `upvar` is the one that replaces Tcl's string-encoded nested lists.

Regex and substitution

This is a payload section. Tcl's `regexp` and `regsub` use Advanced Regular Expressions; Perl's regex is a **superset**, so the patterns you know carry over and gain features. Perl makes regex *syntax*, not a command: `=~` binds a pattern to a string, `m//` matches, `s///` substitutes, and `tr///` transliterates.

```tcl
set s "order 42 shipped"
if {[regexp {(\d+)} $s -> num]} {
    puts "number: $num"
}
set t [regsub -all {o} "foo boo zoo" 0]
puts $t
set u [string map {a A b B} "abcabc"]
puts $u
```

```perl
use v5.44;
my $s = "order 42 shipped";
if ($s =~ /(\d+)/) {            # regexp; capture lands in $1
    say "number: $1";          # number: 42
}
(my $t = "foo boo zoo") =~ s/o/0/g;    # regsub -all  ->  s///g
say $t;                                # f00 b00 z00
(my $u = "abcabc") =~ tr/ab/AB/;       # string map (char-for-char)
say $u;                                # ABcABc
```

The capture maps too: Tcl's `-> num` match variable becomes Perl's `$1`, `$2`, and so on, with named captures landing in `%+`:

```perl
use v5.44;
if ("2026-06-21" =~ /(?<y>\d{4})-(?<m>\d{2})/) {
    say "$+{y} / $+{m}";        # 2026 / 06
}
```

Tcl's `string match` is glob matching, not regex (`string match *.txt $name`). In Perl, anchor a regex instead - `/\.txt$/` is the equivalent - because Perl's one pattern language covers both jobs.

```perl
use v5.44;
my $name = "report.txt";
say "matches" if $name =~ /\.txt$/;     # string match *.txt $name
# matches
```

The gotcha: `s///` modifies its target *in place* and returns the *count* of substitutions, not the new string - which is why the examples above copy first with `(my $t = "...")` before substituting. To get a new string and leave the original untouched, use the `/r` flag: `my $new = $s =~ s/o/0/gr`. And `tr///` (the `string map` analogue for single characters) is **not** a regex: its left side is a literal character set, so `tr/ab/AB/` maps a and b only. For pattern work, reach for `s///`.

Control flow

The control structures map almost one to one; the spelling shifts and the braces stay. Tcl's `if {cond} {body}` becomes Perl's `if (cond) { body }`, `elseif` becomes `elsif`, and `foreach` becomes `for` (the two spellings are aliases in Perl; `foreach` works too).

```
if {$n < 0} {
    set sign neg
} elseif {$n == 0} {
    set sign zero
} else {
    set sign pos
}

set i 0
while {$i < 3} { puts "i=$i"; incr i }

foreach w {a b c} { puts "w=$w" }
```

```
use v5.44;
my $n = 0;
my $sign;
if    ($n < 0)  { $sign = "neg"  }
elsif ($n == 0) { $sign = "zero" }   # elseif -> elsif
else            { $sign = "pos"  }
say $sign;                   # zero

my $i = 0;
while ($i < 3) { say "i=$i"; $i++ }  # incr i -> $i++

for my $w (qw(a b c)) { say "w=$w" } # foreach w {a b c}
```

Tcl's `switch` has no single keyword in Perl; the idiomatic replacement is a **dispatch hash** mapping each case to a code reference, which is faster and more flexible than a chain of `if`:

```
use v5.44;
my $cmd = "start";
my %dispatch = (
    start => sub { "starting" },
    stop  => sub { "stopping" },
);
say $dispatch{$cmd}->();     # starting
```

The gotcha: the `{}` vs `""` distinction you rely on in Tcl for deferring versus substituting maps to Perl's `''` vs `""` for strings (covered above), but Perl's *block* braces are not quoting - a Perl `{ ... }` after `if`/`while`/`for` is a code block, always evaluated, never a deferred string. There is no "the body is a string until I run it" step; Perl parses the block at compile time. Postfix modifiers are a bonus Tcl has no form for: `say $_ for @items;` and `say "neg" if $n < 0;` carry the loop or condition after the statement.

The line/record loop

Tcl reads a file with `set fh [open f r]; while {[gets $fh line] >= 0} {... }`. Perl's equivalent is a `while (<$fh>)` loop, with each line landing in `$_` (the implicit topic variable) or in a named scalar. The line number is in `$.`.

```
set fh [open /tmp/tcl_data.txt r]
while {[gets $fh line] >= 0} {
    puts "got: $line"
}
close $fh
```

```
use v5.44;
open my $fh, '<', '/tmp/tcl_data.txt' or die "open: $!";
while (my $line = <$fh>) {        # gets $fh line
    chomp $line;                  # <$fh> keeps the newline; strip it
    say "got: $line";             # puts
}
close $fh;
# got: apple
# got: banana
# got: cherry
```

(The input file held `apple`, `banana`, `cherry`.) Using `$_` and the line counter `$.` reads even closer to a record loop:

```
use v5.44;
open my $fh, '<', '/tmp/tcl_data.txt' or die "open: $!";
while (<$fh>) {                   # each line lands in $_
    chomp;                        # chomp defaults to $_
    say "$. : $_";               # $. is the current line number
}
close $fh;
# 1 : apple
# 2 : banana
# 3 : cherry
```

The gotcha: Tcl's `gets` strips the trailing newline for you; Perl's `<$fh>` keeps it, so call `chomp` when you do not want it. With no argument, `chomp` and `say`/`print` both default to `$_`, which is why the second loop never names the line variable.

Fields and splitting

Tcl's `split $line $sep` returns a list; Perl's `split /sep/, $line` returns an array, and `join` puts it back together. The difference: a Perl split separator is a *regex*, so you get the full pattern language for free.

```
set line "a:b:c"
set parts [split $line ":"]
puts [llength $parts]
puts [lindex $parts 1]
```

(continues on next page)

(continued from previous page)

```
puts [join $parts ","]
```

```
use v5.44;
my $line = "a:b:c";
my @parts = split /:/, $line;   # split $line ":"  (separator is a␣
↪regex)
say scalar @parts;              # 3        (length $parts)
say $parts[1];                  # b        (index $parts 1)
say join ",", @parts;           # a,b,c    (join $parts ",")
```

The gotcha: `split ' '` with a literal single-space string is a special case that splits on *any run of whitespace* and discards leading empty fields - the awk-style "split into words" behaviour, and usually what you want for free-form input. `split / /` (a regex with one space) is the literal "split on each single space" and does not collapse runs. Reach for `split ' '` to tokenise words:

```
use v5.44;
my @words = split ' ', "  the  quick brown  ";
say "@words";                   # the quick brown
```

I/O, pipes, and in-place edit

Tcl's open/gets/puts/read/close map to Perl's open/<$fh>/print/slurp/close. The idiom is the three-argument open with a lexical filehandle. Tcl's `exec` - run a command and capture its output - becomes Perl's qx{...} (backticks) or `system` when you do not need the output.

```
set out [exec echo hello from shell]
puts "exec said: $out"
```

```
use v5.44;
my $out = qx{echo hello from shell};    # exec  ->  qx// (backticks)
chomp $out;
say "exec said: $out";                  # exec said: hello from␣
↪shell
```

Tcl has no in-place file edit built in; you read, transform, and write back. Perl's `-i` switch is the one-liner form of exactly that, and the full-script equivalent is the same read-modify-write written out:

```
use v5.44;
my $path = '/tmp/tcl_inplace.txt';      # holds: red green blue

open my $in, '<', $path or die "read: $!";
my @lines = <$in>;                      # slurp all lines (list␣
↪context)
close $in;

s/e/E/g for @lines;                     # transform each line's $_
```

(continues on next page)

(continued from previous page)

```
open my $out, '>', $path or die "write: $!";
print {$out} @lines;                    # write them back
close $out;
# file now holds:
# rEd
# grEEn
# bluE
```

The gotcha: `open` returns false on failure rather than raising (Tcl throws an error you catch with `catch`), so the `or die "...: $!"` idiom is mandatory - `$!` is the system error string. For pipes, Perl opens a pipe filehandle directly: `open my $fh, '-|', 'ls', '-l'` reads a command's output and `open my $fh, '|-', 'sort'` writes to a command's input, the structured form of Tcl's `open "|command"`.

One-liners and switches

Tcl is not a one-liner language, so this section is brief - but Perl is, and once you leave Tcl behind it is worth knowing the reflex exists. The switch family: `-e` supplies the program, `-n` wraps it in a no-auto-print loop, `-p` wraps it in an auto-print loop, `-i` edits in place, and `-a`/`-F` autosplit each line into `@F`. `BEGIN { }` and `END { }` blocks run before and after the loop.

```
perl -ne 'print if /error/' log.txt        # print matching lines
perl -pe 's/\d+/N/g' input.txt             # mask numbers
perl -nE 'END { say $n } $n++ if /error/' log.txt   # count, END␣
↪block
```

Each of those expands to an explicit loop: `perl -ne 'CODE'` is `while (<$fh>) { CODE }`, and `perl -pe 'CODE'` is the same with a trailing `print`. Written out, the "count matching lines" form:

```
use v5.44;
open my $fh, '<', '/tmp/tcl_data.txt' or die "open: $!";
my $n = 0;
while (<$fh>) {
    $n++ if /banana/;          # the body of -ne
}
say $n;                        # 1
```

The gotcha: when a one-liner grows past a line or two, write out the explicit loop it expands to. Consult the *One-Liners guide* for the full switch catalogue and recipes. Perl also has full subroutines, references, modules, and OO if your script outgrows a glue task: Tcl's `namespace eval` and `[incr Tcl]` classes map to Perl packages and the modern `class` syntax; see the *Object-oriented Programming guide* for that side of the language.

Gotchas coming from Tcl

The traps, collected for a final scan before you write:

- **Two comparison families.** ==/</<=> compare numerically; eq/lt/cmp compare as strings. `"10" == "10.0"` is true, `"10" eq "10.0"` is false. Pick by the operation, not the value - the one quiet bug the string-first worldview invites.
- **The sigil follows the element.** One element of `@items` is `$items[0]` (a scalar), not `@items[0]`; one value of `%a` is `$a{red}`. The container sigil and the element sigil differ.
- **`sort` is string-sorted by default,** like comparing with eq. Pass `{ $a <=> $b }` for numeric order.
- **`s///` returns a count, not the new string,** and edits in place. Copy first (`(my $t = $s) =~ s/.../.../`) or use the `/r` flag for a fresh string.
- **`tr///` (the `string map` analogue) is a literal character set, not a regex.** `tr/ab/AB/` maps single characters. For patterns, use `s///`.
- **`split ' '` and `split / /` differ.** The literal-space string splits on whitespace runs and drops leading empties (the word tokeniser); the one-space regex does not. Use `split ' '` for free-form input.
- **`<$fh>` keeps the trailing newline,** unlike Tcl's `gets`. Call `chomp` to strip it.
- **`open` does not raise on failure.** Use `open my $fh, '<', $path or die "...: $!"`. `$!` is the system error string; there is no `catch` to wrap it.
- **References replace `upvar`.** To mutate a caller's variable, pass a reference (`\$x`, `\@arr`, `\%h`) deliberately rather than aliasing by name. References are also how Perl nests data.
- **A `{ ... }` block is code, not a deferred string.** Perl parses blocks at compile time; there is no "the body is a string until I run it" step. Only `''`/`""` carry Tcl's `{}`/`""` substitution distinction.

4.2.10 The Definitive Guide to 2D Graphics with Perl

Perl is not the language people reach for when they think "graphics", and that reputation is mostly an accident of history rather than a statement about the tools. The vector engine everyone else uses under the hood (`Cairo`) ships natively here, `SDL2` gives a window and an accelerated renderer, and the raster libraries are mature. What Perl has lacked is not libraries but a single place that puts them in order, from the pixel up to a running program.

This guide is that place, for **two dimensions**. It starts at the theory every graphics programmer eventually needs (how a line becomes pixels, what a colour space actually is, how transparency composites), moves through the working CPAN toolkits, and then goes one step further than the usual tour: it uses pperl's native FFI to reach C graphics libraries directly, the same way pperl already reaches libgmp to give you `Math::GMP`. It ends with two things you can run: a drawing application and a 2D game.

Three dimensions and the GPU are the subject of the companion *3D guide*, which builds on this one. The final chapter draws the line between the two.

Which chapter do I want?

I want to ...	Start here
understand how pixels, paths, and colour actually work	*foundations*
implement a line, circle, fill, or blur myself	*raster-algorithms*
draw on, load, or save a bitmap image	*raster-imager*
draw on, load, or save a bitmap with GD	*raster-gd*
use an ImageMagick codebase, or its specific features	*raster-gd-magick*
produce resolution-independent vector paths, or SVG output	*vector-cairo-svg*
read image metadata, or draw a chart	*metadata-and-charts*
draw in a live window on Linux	*gui-toolkits*
reach a C graphics library that has no CPAN binding	*ffi-graphics-primer*
see how pperl's shipped native `Cairo` binding works	*ffi-cairo-showcase*
build a real drawing application	*capstone-drawing-app*
build a real 2D game, or drive SDL2 directly	*capstone-2d-game*
go on to 3D and the GPU	*whats-next*

The three arcs of this guide

- **Foundations** - *foundations* and *raster-algorithms*. The mental model and the classic algorithms, written in plain Perl so you own them before any library hides them. Read these once; every later chapter assumes the vocabulary.
- **Toolkits** - the six chapters from *raster-imager* through *gui-toolkits*. What each library is good at and where one wins over another, ending with the window and frame loop. Each chapter is self-contained; reach for the one that names your problem.
- **Reaching further** - *ffi-graphics-primer* onward. pperl's native FFI, the two capstone projects, and an honest map of where the road currently ends.

A note on the runtime

These chapters target `pperl`, a faithful Rust reimplementation of Perl 5.44. The CPAN modules in the toolkit chapters are used exactly as they are on any Perl 5, and the FFI chapters use pperl's own `Peta::FFI`, which has no perl5 equivalent.

Known gaps

Everything three-dimensional, every GPU-programming topic, computer vision and image analysis, and connectors to hosted image-generation services are out of scope for this version. They are named, with the reason and the plan, in *what's next*. The FFI chapters also mark, at the point where it matters, which C interfaces `Peta::FFI` reaches and what a hand-written binding costs you.

See also

- *Auto-FFI (Peta::FFI)* - the native FFI layer the "reaching further" arc is built on: `dlopen`, `call`, the type-signature codes, and the native bindings built on it.

- *PPerl Architecture guide* - the JIT and how pperl provides C-backed modules natively.

Foundations: pixels, paths, and colour

Before any library, four ideas carry the whole subject: the difference between a raster and a vector, the coordinate system a drawing lives in, what a colour actually is once you have to store it, and how two colours combine when one is partly transparent. Every chapter after this one leans on these without re-explaining them. None of it is Perl-specific, but all of the examples are Perl, because the point is to make the ideas concrete in code you can run.

Raster versus vector

A **raster** image is a grid of coloured cells. It has a fixed width and height in pixels, and every pixel holds a colour. Scaling it up past its resolution invents nothing: the cells just get bigger. Photographs, screenshots, and anything with continuous tone are rasters. `Imager`, `GD`, and ImageMagick are raster tools.

A **vector** image is a set of shapes described mathematically: "a line from here to there", "a circle of this radius", "fill this path". There is no resolution until you draw it, so it scales to any size cleanly. Fonts, logos, and diagrams are vectors. `Cairo` and `SVG` are vector tools.

The two meet at **rasterisation**: turning a vector description into pixels. A vector library still has to decide which pixels a diagonal line touches, and that decision is *the first algorithm in the next chapter*. Everything you draw ends up as pixels on a screen; the question is only whether you commit to a resolution early (raster) or late (vector).

A raster in Perl is, at its plainest, an array of rows:

```
my $w = 4;
my $h = 3;
# each pixel is [r, g, b], each channel 0..255
my @img = map { [ map { [0, 0, 0] } 1 .. $w ] } 1 .. $h;

$img[1][2] = [255, 0, 0];   # row 1, column 2, red
```

That nested-array picture is all a raster is. Real libraries store the same grid in a packed C buffer for speed, but the mental model does not change: a pixel is addressed by an integer row and column, and it holds a colour.

The coordinate system

Graphics coordinates are not math-class coordinates. The origin `(0, 0)` is the **top-left** corner, x increases to the right, and y increases **downward**. This catches everyone once: a larger y is lower on the screen, not higher.

```
# (0,0) top-left            x ->
#   +-----------------
#   | (0,0)      (w-1, 0)
# y |
```

(continues on next page)

(continued from previous page)

```
# | |
# v | (0, h-1)   (w-1, h-1)
```

A pixel is a little square, and there is a lasting ambiguity about whether the coordinate `(3, 5)` names the square's corner or its centre. Raster libraries usually treat integer coordinates as pixel centres; vector libraries treat them as the grid lines between pixels, which is why a one-unit-wide vertical line at `x = 3` can come out straddling two columns of pixels at half intensity. When a thin line or a rectangle edge looks blurry or one pixel off, this is almost always why, and the fix is a half-pixel offset. The chapters that hit it say so.

Sizes and positions are integers in raster space and real numbers in vector space. That is the practical difference you feel: in `Imager` you set pixel `(120, 47)`; in `Cairo` you can move to `(120.5, 47.25)` and the rasteriser works out the coverage.

Colour: what a pixel holds

A colour on a screen is three numbers: how much **red**, **green**, and **blue** light to emit. Add all three at full strength and you get white; leave them all off and you get black. This is the **RGB** model, and it is additive because you are adding light, not mixing paint.

Each channel is almost always stored in 8 bits, so `0 .. 255` per channel, and a colour is three bytes. That is the `#RRGGBB` hex notation from the web: `#ff0000` is `(255, 0, 0)`, pure red.

```
sub rgb_to_hex {
    my ($r, $g, $b) = @_;
    return sprintf "#%02x%02x%02x", $r, $g, $b;
}

print rgb_to_hex(255, 128, 0), "\n";   # #ff8000, an orange
```

RGB is how pixels are stored, but it is a terrible model for a human choosing a colour. "Make this a bit more orange but keep it the same brightness" is not an obvious move in RGB. **HSV** (hue, saturation, value) is the model for that: **hue** is the position on the colour wheel in degrees `0 .. 360` (0 red, 120 green, 240 blue), **saturation** is how vivid versus grey `0 .. 1`, and **value** is how bright `0 .. 1`. Rotating the hue while holding saturation and value walks the rainbow at constant vividness and brightness.

Every colour-picker and gradient tool works in HSV or a close relative, then converts to RGB to store. The conversion is worth having in plain sight, because you will reimplement it more than once:

```
# h in 0..360, s and v in 0..1  ->  (r, g, b) in 0..255
sub hsv_to_rgb {
    my ($h, $s, $v) = @_;
    my $c = $v * $s;                       # chroma
    my $hp = $h / 60;
    my $x = $c * (1 - abs($hp % 2 - 1 + ($hp - int $hp)));
    my ($r, $g, $b) =
        $hp < 1 ? ($c, $x, 0) :
```

(continues on next page)

(continued from previous page)

```
        $hp < 2 ? ($x, $c, 0) :
        $hp < 3 ? (0, $c, $x) :
        $hp < 4 ? (0, $x, $c) :
        $hp < 5 ? ($x, 0, $c) :
                  ($c, 0, $x);
    my $m = $v - $c;
    return map { int(($_ + $m) * 255 + 0.5) } ($r, $g, $b);
}

my @rainbow = map { [ hsv_to_rgb($_, 1, 1) ] } 0, 60, 120, 180, 240,␣
↪300;
# red, yellow, green, cyan, blue, magenta
```

There are other spaces you will meet: greyscale (one channel, a brightness), CMYK (subtractive, for print), and perceptually uniform spaces like CIELAB where equal numeric steps look like equal perceptual steps. For screen drawing in two dimensions, RGB for storage and HSV for choosing cover almost everything.

Alpha and compositing

A fourth channel, **alpha**, records opacity: `0` fully transparent, `255` (or `1.0`) fully opaque. A pixel with alpha is **RGBA**. Alpha is what lets you draw one image over another and have the top one's transparent parts show through.

Combining a foreground pixel over a background pixel is **compositing**, and the standard rule is **source-over**. With alpha as a fraction `0 .. 1`:

```
# composite one RGBA pixel over another (all channels 0..255,
# alpha treated as 0..1 for the blend)
sub over {
    my ($fg, $bg) = @_;
    my $a = $fg->[3] / 255;                    # source alpha
    my @out = map {
        int($fg->[$_] * $a + $bg->[$_] * (1 - $a) + 0.5)
    } 0 .. 2;
    return \@out;
}

my $red_half = [255, 0, 0, 128];    # red at 50% opacity
my $white    = [255, 255, 255, 255];
my $result   = over($red_half, $white);
print "@$result\n";                 # 255 128 128, a pink
```

Red at half opacity over white gives pink, exactly as you would expect paint-thinned-with-water to look. That one formula, applied per pixel, is how every layer, brush stroke, and sprite with soft edges lands on the canvas beneath it. When you stack many semi-transparent layers, you apply it repeatedly, bottom to top.

The subtlety that bites later is **premultiplied alpha**: storing each colour channel already multiplied by its alpha. It makes repeated compositing cheaper and filtering correct at edges, and it is why a library's raw pixel bytes sometimes are not the RGB you expect.

`Cairo` uses premultiplied alpha internally; the *Cairo chapter* notes where it shows.

The one 3D idea, named and deferred

You will hear about the **Z-buffer** the moment 3D comes up, and it is worth one paragraph here so the term is not a mystery. In 2D, "what is on top" is decided by draw order: the last thing drawn wins, which is exactly the source-over compositing above. In 3D, objects have a depth (a z coordinate), and the thing nearest the viewer should win regardless of draw order. A **Z-buffer** is a second grid, the same size as the image, holding the depth of the closest surface seen so far at each pixel; before drawing a pixel you check whether the new surface is nearer than what is recorded, and skip it if not.

That is the whole concept, and it is as far as this 2D guide goes with it. Depth buffering, projection, and the rest of the third dimension belong to the *3D guide*. In two dimensions, draw order is your depth buffer.

Where this goes next

You now have the vocabulary the rest of the guide speaks: raster and vector, top-left coordinates, RGB and HSV, alpha and source-over compositing. The *next chapter* spends that vocabulary on the classic drawing algorithms, implemented from scratch, so that when a library draws a line or fills a polygon you know exactly what it is doing on your behalf.

Drawing primitives from scratch

Every graphics library hands you `line`, `circle`, `fill`, and `blur`. This chapter implements them in plain Perl so that when a library draws them for you, nothing is magic. These are the classic algorithms, and they are classic because they are the right answers: fast, integer where they can be, and correct at the awkward cases. You will not ship these implementations (a C library will always be faster), but knowing them tells you why a library behaves the way it does, and gives you the tools for the one case the library did not anticipate.

Throughout, the canvas is the nested-array raster from the *foundations chapter*: a grid of `[r, g, b]` pixels addressed by integer `(x, y)`, origin top-left.

```
sub new_canvas {
    my ($w, $h) = @_;
    return { w => $w, h => $h,
             px => [ map { [ map { [255, 255, 255] } 1 .. $w ] } 1 .
↪. $h ] };
}

sub set_px {
    my ($c, $x, $y, $color) = @_;
    return if $x < 0 || $y < 0 || $x >= $c->{w} || $y >= $c->{h};
    $c->{px}[$y][$x] = $color;
}
```

Lines: Bresenham

A line from `(x0, y0)` to `(x1, y1)` has to choose, for each column it crosses, which row of pixels to light. The naive approach computes `y = m*x + b` with floating point per step; **Bresenham's algorithm** does it with integer addition only, by tracking an error term that says how far the ideal line has drifted from the pixels chosen so far.

The insight is that at each step you either stay on the same cross-axis row or move one, and a running integer error decides which. The version below handles every slope and direction in one loop by working with absolute deltas and step signs:

```
sub draw_line {
    my ($c, $x0, $y0, $x1, $y1, $color) = @_;
    my $dx = abs($x1 - $x0);
    my $dy = -abs($y1 - $y0);
    my $sx = $x0 < $x1 ? 1 : -1;
    my $sy = $y0 < $y1 ? 1 : -1;
    my $err = $dx + $dy;                    # error accumulator
    while (1) {
        set_px($c, $x0, $y0, $color);
        last if $x0 == $x1 && $y0 == $y1;
        my $e2 = 2 * $err;
        if ($e2 >= $dy) { $err += $dy; $x0 += $sx; }   # step in x
        if ($e2 <= $dx) { $err += $dx; $y0 += $sy; }   # step in y
    }
}
```

No multiplication, no division, no floating point in the loop. That is why Bresenham survived from 1962: it is the line-drawing you would build in hardware. Every library's thin, aliased line is this or a direct descendant.

Circles: the midpoint method

A circle has eight-fold symmetry: compute one octant and mirror it into the other seven. The **midpoint circle algorithm** walks one octant with the same integer-error idea as Bresenham, deciding at each step whether to move straight or diagonally by testing a decision variable against zero.

```
sub draw_circle {
    my ($c, $cx, $cy, $r, $color) = @_;
    my ($x, $y) = ($r, 0);
    my $err = 1 - $r;                       # decision variable
    while ($x >= $y) {
        # eight mirrored points, one per octant
        for my $p ([$x,$y],[$y,$x],[-$x,$y],[-$y,$x],
                   [$x,-$y],[$y,-$x],[-$x,-$y],[-$y,-$x]) {
            set_px($c, $cx + $p->[0], $cy + $p->[1], $color);
        }
        $y++;
        if ($err < 0) { $err += 2 * $y + 1; }
        else          { $x--; $err += 2 * ($y - $x) + 1; }
```

(continues on next page)

(continued from previous page)

```
    }
}
```

Compute one eighth, draw eight. The same symmetry trick, with the error test adjusted, gives ellipses and arcs.

Filling polygons: the scanline method

Drawing a shape's outline is one problem; filling its interior is another. The **scanline fill** sweeps a horizontal line down the image, and for each scanline finds where it crosses the polygon's edges. Those crossings come in pairs, and the interior is between each pair: the **even-odd rule**. Sort the x crossings, then fill between the first and second, the third and fourth, and so on.

```
# poly is an arrayref of [x, y] vertices, in order, implicitly
 ↪closed
sub fill_polygon {
    my ($c, $poly, $color) = @_;
    my ($ymin, $ymax) = ($poly->[0][1], $poly->[0][1]);
    for my $v (@$poly) {
        $ymin = $v->[1] if $v->[1] < $ymin;
        $ymax = $v->[1] if $v->[1] > $ymax;
    }
    for my $y ($ymin .. $ymax) {
        my @xs;
        for my $i (0 .. $#$poly) {
            my $a = $poly->[$i];
            my $b = $poly->[($i + 1) % @$poly];
            my ($ay, $by) = ($a->[1], $b->[1]);
            # does this edge straddle the scanline?
            next if ($ay <= $y) == ($by <= $y);
            # x where the edge crosses y (linear interpolation)
            my $t = ($y - $ay) / ($by - $ay);
            push @xs, $a->[0] + $t * ($b->[0] - $a->[0]);
        }
        @xs = sort { $a <=> $b } @xs;
        # fill between crossing pairs
        for (my $i = 0; $i + 1 < @xs; $i += 2) {
            for my $x (int($xs[$i] + 0.5) .. int($xs[$i + 1] - 0.5))
 ↪{
                set_px($c, $x, $y, $color);
            }
        }
    }
}
```

The `($ay <= $y) == ($by <= $y)` test is the crossing check written to count each vertex exactly once, so a scanline passing through a shared vertex does not double-count and leak the fill. That half-open convention is the detail that separates a correct fill from one with occasional stray lines, and it is why libraries and this code agree on where an

edge “belongs”.

Anti-aliasing: coverage instead of on-or-off

The line and circle above are **aliased**: each pixel is fully on or fully off, and a diagonal edge looks like a staircase. **Anti-aliasing** softens that by setting a pixel’s intensity to how much of it the shape actually covers. A pixel the edge crosses at 40 percent coverage gets 40 percent of the shape colour blended with 60 percent of the background, which is exactly the *source-over compositing* from the last chapter with alpha equal to coverage.

The cheapest way to approximate coverage is **supersampling**: draw at several times the resolution with the aliased algorithm, then average each block of high-resolution pixels down to one. Averaging a 2x2 block where three sub-pixels are on gives 75 percent coverage for free:

```
# downsample a 2x-oversampled canvas by averaging 2x2 blocks
sub downsample_2x {
    my ($big) = @_;
    my ($w, $h) = ($big->{w} / 2, $big->{h} / 2);
    my $out = new_canvas($w, $h);
    for my $y (0 .. $h - 1) {
        for my $x (0 .. $w - 1) {
            my @sum = (0, 0, 0);
            for my $dy (0, 1) {
                for my $dx (0, 1) {
                    my $p = $big->{px}[2 * $y + $dy][2 * $x + $dx];
                    $sum[$_] += $p->[$_] for 0 .. 2;
                }
            }
            $out->{px}[$y][$x] = [ map { int($_ / 4 + 0.5) } @sum ];
        }
    }
    return $out;
}
```

Real libraries compute coverage analytically rather than by brute-force supersampling, but the effect is identical: the staircase becomes a smooth ramp of intensities. When `Cairo` gives you a crisp anti-aliased curve and `Imager` offers an `aa` flag on its primitives, this is what they are doing.

Tessellation: breaking shapes into triangles

Hardware and many algorithms only really know how to fill **triangles**; everything more complex is first broken into triangles, a process called **tessellation** or **triangulation**. A convex polygon triangulates trivially by fanning from one vertex:

```
# fan triangulation of a convex polygon -> list of [v0, v1, v2]␣
↪triangles
sub triangulate_convex {
    my ($poly) = @_;
    my @tris;
```

(continues on next page)

(continued from previous page)

```
    for my $i (1 .. $#$poly - 1) {
        push @tris, [ $poly->[0], $poly->[$i], $poly->[$i + 1] ];
    }
    return @tris;
}
```

Concave polygons need a real algorithm (ear clipping is the standard one: repeatedly find a triangle that pokes out with no other vertex inside it, snip it off, repeat). The convex fan is enough to see the idea, and it is the idea that carries straight into 3D, where every surface is ultimately a mesh of triangles. In two dimensions you meet tessellation whenever you fill a complex vector path; in the *3D guide* it is the foundation of everything.

Convolution: blur, sharpen, and edges

A whole family of image effects comes from one operation: **convolution**, sliding a small grid of weights (a **kernel**) over the image and replacing each pixel with the weighted sum of its neighbours. A kernel of all equal weights averages, which blurs. A kernel that subtracts the neighbours and adds a large centre sharpens.

```
# apply a 3x3 kernel to a canvas; divisor normalises the weights
sub convolve_3x3 {
    my ($c, $kernel, $divisor) = @_;
    $divisor ||= 1;
    my $out = new_canvas($c->{w}, $c->{h});
    for my $y (1 .. $c->{h} - 2) {
        for my $x (1 .. $c->{w} - 2) {
            my @sum = (0, 0, 0);
            for my $ky (0 .. 2) {
                for my $kx (0 .. 2) {
                    my $wgt = $kernel->[$ky][$kx];
                    my $p = $c->{px}[$y + $ky - 1][$x + $kx - 1];
                    $sum[$_] += $p->[$_] * $wgt for 0 .. 2;
                }
            }
            $out->{px}[$y][$x] =
                [ map { my $v = int($_ / $divisor + 0.5);
                        $v < 0 ? 0 : $v > 255 ? 255 : $v } @sum ];
        }
    }
    return $out;
}

my $box_blur = [[1,1,1],[1,1,1],[1,1,1]];   # divisor 9
my $sharpen  = [[0,-1,0],[-1,5,-1],[0,-1,0]]; # divisor 1
```

The box blur divides by 9 to keep brightness constant; the sharpen kernel sums to 1 so it needs no divisor. Swap in a kernel that responds to intensity change and you get edge detection, which is where image processing shades into computer vision. That boundary is deliberate: this guide uses convolution as a **drawing** tool (blur a shadow, sharpen a

downscaled sprite) and stops there. Analysis, feature detection, and recognition are a different subject, out of scope here.

What the libraries do for you

Everything above is what a graphics library implements in optimised C, usually with SIMD and careful edge handling you would not want to write by hand. Knowing the algorithms means you can read a library's documentation and know what "anti-aliased", "even-odd fill rule", "convolution matrix", and "triangulated path" mean, and you can drop to your own pixel loop for the rare effect no library ships. The *next chapter* picks up `Imager`, where these primitives are one method call away and running at C speed.

Raster drawing with Imager

`Imager` is the raster workhorse: create an image, draw on it, filter it, save it. It is actively maintained, it links its own copies of the format libraries so PNG, JPEG, TIFF, GIF, and WEBP all work out of the box, and its drawing primitives are the ones from the *algorithms chapter* running at C speed. If you are starting a raster project on Perl today and have no reason to prefer something else, start here.

Every drawing method returns false on failure and sets `errstr`, so the idiom is to check and report:

```
use Imager;

my $img = Imager->new(xsize => 400, ysize => 300, channels => 4)
    or die Imager->errstr;
```

`channels => 4` asks for RGBA (red, green, blue, alpha); use 3 for opaque RGB. The alpha channel is what lets the *compositing* from the foundations chapter work when you draw one image onto another.

Colours

Anywhere a method takes `color =>`, you can pass a name, a hex string, an `Imager::Color` object, or a plain array reference:

```
my $red   = Imager::Color->new('red');
my $red2  = Imager::Color->new('#FF0000');
my $red3  = Imager::Color->new(255, 0, 0);
my $trans = Imager::Color->new(255, 0, 0, 128);   # 50% alpha

$img->box(color => [0, 128, 255], filled => 1);   # array-ref, no␣
 ↪object
```

The array-reference form is the least ceremony for a one-off colour and is what most of the examples below use.

The primitives

Note the parameter names carefully, because they are not all the same shape. Boxes use corner coordinates `xmin/ymin/xmax/ymax`; circles and arcs use a center `x/y` with a radius `r`; arcs add start and end degrees `d1/d2`.

```
# fill the whole canvas white first
$img->box(color => 'white', filled => 1);

# a line; aa => 1 requests anti-aliasing
$img->line(x1 => 0, y1 => 0, x2 => 399, y2 => 299,
           color => [255, 0, 0], aa => 1);

# an outlined box (no fill) and a filled one
$img->box(xmin => 20, ymin => 20, xmax => 120, ymax => 90,
          color => 'black');
$img->box(xmin => 140, ymin => 20, xmax => 240, ymax => 90,
          color => [200, 220, 255], filled => 1);

# a filled circle: center (200,150), radius 60
$img->circle(x => 200, y => 150, r => 60, color => [0, 128, 255]);

# an arc is a pie slice from d1 to d2 degrees
$img->arc(x => 200, y => 150, r => 80, d1 => 0, d2 => 120,
          color => 'yellow');

# a polygon from a list of [x, y] points
$img->polygon(points => [[300, 40], [380, 40], [340, 110]],
              color => [120, 200, 120]);

# a polyline is an open path; it takes no fill
$img->polyline(points => [[300, 130], [340, 200], [380, 130]],
               color => 'black', aa => 1);

# flood fill from a seed point out to a border
$img->flood_fill(x => 5, y => 5, color => [245, 245, 245]);
```

Two traps worth stating once. `box` is filled only when you pass `filled => 1` (or a `fill =>` pattern); without it you get an outline. `polyline` draws an open path and does not accept `fill`, unlike `polygon` which closes and can fill. When a shape comes out as an outline you expected filled, or a fill silently does nothing, one of these two is why.

Loading, scaling, and saving

Reading and writing infer the format from the filename extension, or you can force it with `type =>`:

```
my $photo = Imager->new;
$photo->read(file => 'input.jpg') or die $photo->errstr;

# scale by a factor, or to fit a box
```

(continues on next page)

(continued from previous page)

```
my $thumb = $photo->scale(scalefactor => 0.25);
my $fit   = $photo->scale(xpixels => 200, ypixels => 200, type =>
 ↪'min');

$thumb->write(file => 'thumb.png') or die $thumb->errstr;
```

`scale` returns a new image; it does not modify the original. The `type => 'min'` form scales so the image fits inside the given box preserving aspect ratio; `'max'` fills the box (cropping the overflow when you then crop); `'nonprop'` ignores aspect ratio and stretches to exactly the pixels you named.

Filters

`filter` applies an effect in place, named by `type =>`. The *convolution* from the algorithms chapter is here as built-in Gaussian blur and unsharp masking, plus a general `conv` for your own kernel:

```
# Gaussian blur; larger stddev is more blur
$img->filter(type => 'gaussian', stddev => 2.5);

# unsharp mask to sharpen; both params optional
$img->filter(type => 'unsharpmask', stddev => 2.0, scale => 1.0);

# your own 1-D convolution coefficients (a horizontal blur here)
$img->filter(type => 'conv', coef => [0.25, 0.5, 0.25]);

# contrast, mosaic (pixelate), and inversion are all filters too
$img->filter(type => 'contrast', intensity => 1.4);
$img->filter(type => 'mosaic', size => 8);
$img->filter(type => 'hardinvert');
```

The full set includes `gaussian`, `gaussian2` (separate `x` and `y` deviations), `conv`, `unsharpmask`, `contrast`, `mosaic`, `noise`, `hardinvert`, `autolevels`, `postlevels`, and the procedural texture generators `fountain`, `gradgen`, `radnoise`, and `turbnoise`. Reach for the named filter before writing your own pixel loop; only drop to a `conv` coefficient list or manual access when nothing built in fits.

A complete program

Putting it together: a small poster with a background, some shapes, a blur pass, and a saved thumbnail.

```
use strict;
use warnings;
use Imager;

my $img = Imager->new(xsize => 400, ysize => 300, channels => 4)
    or die Imager->errstr;
```

(continues on next page)

(continued from previous page)

```
$img->box(color => [30, 30, 60], filled => 1);              # dark
 ↪bg
$img->circle(x => 120, y => 150, r => 70, color => [255, 200, 60]);
$img->circle(x => 260, y => 150, r => 70, color => [60, 200, 255]);
$img->filter(type => 'gaussian', stddev => 1.2);           # soften
$img->line(x1 => 0, y1 => 250, x2 => 399, y2 => 250,
           color => 'white', aa => 1);

$img->write(file => 'poster.png') or die $img->errstr;
$img->scale(scalefactor => 0.5)->write(file => 'poster-thumb.png')
    or die $img->errstr;
```

When Imager is the wrong tool

`Imager` is raster, so it has the raster limitation: it has a fixed resolution, and scaling past it degrades. For resolution-independent output (a logo that must print crisply at any size, a diagram destined for the web as markup) you want a vector tool, covered in *Cairo and SVG*. For an existing codebase built on GD or ImageMagick, or for their specific strengths, see the *next chapter*. And when the drawing needs to appear in a live window rather than a file, that is the *GUI toolkits chapter*. For everything that is "make or modify a bitmap on disk", `Imager` is the answer.

Raster drawing with GD

GD is Perl's binding to libgd, the small C library behind a great deal of the web's generated images: thumbnails, charts, captchas, badges. It creates an image, draws on it, filters it, and saves it, and its drawing primitives are the ones from the *algorithms chapter* running at C speed. On pperl it is a native module: the C half is bound directly to the system's libgd, and GD's own Perl half (`GD::Image`, `GD::Polygon`, `GD::Simple`) runs as it is, so code written for GD on any Perl 5 runs here unchanged.

The API is positional and terse. Methods take coordinates and a colour in a fixed order, and most of them return nothing useful. The ones that can fail either return false or `undef`, and the idiom is to check those, or die with the reason, as the file loaders do.

```
use GD;

my $im = GD::Image->new(400, 300, 1);   # width, height, true-colour
```

Colours

GD's defining quirk is how it names a colour. You never pass red, green and blue to a drawing method. You ask the image for a colour first, with `colorAllocate`, and then draw with the integer it returns. What that integer means depends on the kind of image.

A **palette** image (created without the third argument) holds a table of at most 256 colours, and every pixel stores an index into it. This is the model of GIF and of 256-colour displays. `colorAllocate` adds an entry and returns its index, and the first colour you allocate becomes the background.

A **true-colour** image (third argument 1) stores the colour itself in every pixel. `colorAllocate` has no table to add to, so it simply packs the channels into one integer, and that integer is the colour. Prefer true-colour for all new work: it has no 256-colour ceiling, and filters, resampling and alpha blending all assume it.

```
use strict;
use warnings;
use GD;

# a palette image: colorAllocate hands out table indices
my $pal   = GD::Image->new(100, 100);
my $white = $pal->colorAllocate(255, 255, 255);   # first one is the
 ↪background
my $red   = $pal->colorAllocate(255, 0, 0);
print "palette: white=$white red=$red, ",
      $pal->colorsTotal, " colours in the table\n";

# a truecolor image: the "index" is the colour itself, packed
my $tc   = GD::Image->new(100, 100, 1);
my $tw   = $tc->colorAllocate(255, 255, 255);
my $tr   = $tc->colorAllocate(255, 0, 0);
my $half = $tc->colorAllocateAlpha(255, 0, 0, 64);  # about 50%
 ↪transparent
printf "truecolor: white=0x%08x red=0x%08x half=0x%08x\n", $tw, $tr,
 ↪$half;
```

```
palette: white=0 red=1, 2 colours in the table
truecolor: white=0x00ffffff red=0x00ff0000 half=0x40ff0000
```

On a palette image the table does fill up. The 257th `colorAllocate` returns `-1`, and `colorResolve` is the safe alternative: it returns an exact match if there is one, allocates if there is room, and otherwise falls back to the closest colour already in the table.

```
use strict;
use warnings;
use GD;

my $pal = GD::Image->new(10, 10);
$pal->colorAllocate($_, 0, 0) for 0 .. 255;       # fill all 256
 ↪slots
print "table: ", $pal->colorsTotal, " colours\n";
print "allocate one more: ", $pal->colorAllocate(1, 2, 3), "\n";
print "resolve instead:   ", $pal->colorResolve(1, 2, 3), "\n";
```

```
table: 256 colours
allocate one more: -1
resolve instead:   1
```

`colorExact` and `colorClosest` are the two halves of `colorResolve` on their own; `rgb($colour)` turns an index or packed colour back into its three channels.

Alpha, the GD way

`colorAllocateAlpha` takes a fourth value, and it runs the opposite way to the *foundations chapter*: in GD, alpha `0` is fully **opaque** and `127` is fully **transparent**, a 7-bit range with transparency at the top. So `64` is roughly half and half.

What happens when you draw with a translucent colour depends on `alphaBlending`. With blending on (the default for true-colour images) the colour is composited source-over onto what is already there. With it off, the pixel is simply replaced, alpha and all.

```
use strict;
use warnings;
use GD;

my $im    = GD::Image->new(100, 100, 1);
my $white = $im->colorAllocate(255, 255, 255);
my $half  = $im->colorAllocateAlpha(255, 0, 0, 64);

my @before = $im->rgb($im->getPixel(50, 50));
print "fresh canvas: @before\n";                 # truecolor starts
 ↪black

$im->filledRectangle(0, 0, 99, 99, $white);
$im->filledRectangle(0, 0, 49, 99, $half);       # blending on:
 ↪composite
$im->alphaBlending(0);
$im->filledRectangle(50, 0, 99, 99, $half);      # blending off:
 ↪replace

for my $x (25, 75) {
    my $c = $im->getPixel($x, 50);
    printf "x=%d: rgb=%s alpha=%d\n", $x, join(' ', $im->rgb($c)),
 ↪$im->alpha($c);
}
```

```
fresh canvas: 0 0 0
x=25: rgb=255 128 128 alpha=0
x=75: rgb=255 0 0 alpha=64
```

The blended half is the pink `255 128 128` the foundations chapter computed by hand for red at half opacity over white. The other half keeps pure red with alpha `64` stored in the pixel, which is what you want when you are building an image with transparent regions to save (see *transparency in files* below).

The first line of output is a trap worth stating once: a new true-colour image starts **black**, not white. Always paint the background with a `filledRectangle` over the whole canvas before drawing anything else.

The primitives

Every primitive takes its geometry first and the colour last, all positional. Rectangles use two corners, both inclusive, so a full 400 x 300 canvas is `(0, 0, 399, 299)`. Ellipses and arcs use a centre plus the **full width and height** (not a radius), and arc angles are in **degrees**, starting at three o'clock and increasing clockwise (clockwise because y grows downward).

```
use strict;
use warnings;
use GD;

my $im = GD::Image->new(400, 300, 1);
my $white  = $im->colorAllocate(255, 255, 255);
my $black  = $im->colorAllocate(0, 0, 0);
my $blue   = $im->colorAllocate(0, 90, 200);
my $red    = $im->colorAllocate(220, 40, 40);
my $green  = $im->colorAllocate(60, 170, 80);
my $yellow = $im->colorAllocate(250, 200, 40);

$im->filledRectangle(0, 0, 399, 299, $white);      # background

# lines: plain, dashed, and thick
$im->line(10, 10, 130, 60, $black);
$im->dashedLine(10, 30, 130, 80, $black);
$im->setThickness(5);
$im->line(10, 60, 130, 110, $blue);
$im->setThickness(1);

# rectangles: corner to corner, both corners inclusive
$im->rectangle(150, 10, 250, 80, $black);
$im->filledRectangle(270, 10, 390, 80, $yellow);

# ellipses and arcs: centre, then full width and height
$im->ellipse(70, 170, 110, 60, $black);
$im->filledEllipse(70, 170, 50, 50, $blue);
$im->arc(200, 170, 100, 100, 0, 270, $black);          # three␣
↪quarters
$im->filledArc(330, 170, 100, 100, 30, 330, $yellow);  # a pie slice
$im->filledArc(330, 170, 100, 100, 30, 330, $black, gdEdged |␣
↪gdNoFill);

# polygons come from a GD::Polygon
my $tri = GD::Polygon->new;
$tri->addPt(20, 290);
$tri->addPt(120, 290);
$tri->addPt(70, 220);
$im->filledPolygon($tri, $green);
$im->polygon($tri, $black);

my $zig = GD::Polygon->new;
```

(continues on next page)

(continued from previous page)

```
$zig->addPt($_->[0], $_->[1]) for [150, 280], [180, 230], [210,␣
↪280], [240, 230];
$im->unclosedPolygon($zig, $red);                  # open path, no␣
↪closing edge

# flood fills
$im->rectangle(270, 230, 390, 290, $black);
$im->line(330, 230, 330, 290, $black);
$im->fill(300, 260, $red);                         # fills the left␣
↪cell only
$im->fillToBorder(360, 260, $black, $blue);        # stops at black␣
↪pixels

open my $fh, '>', 'primitives.png' or die "primitives.png: $!";
binmode $fh;
print $fh $im->png;
close $fh;
```

The result is a 3 x 3 sheet: three lines, an outlined and a filled rectangle; an ellipse around a disc, a three-quarter arc open at the top right, a pie with its mouth to the right; a filled triangle, a red zigzag, and a box whose two halves were flood-filled red and blue.

A few details the sheet shows:

- `filledArc` takes an optional style. The default fills a pie slice; `gdChord` replaces the curved edge with a straight line between the two end points, `gdNoFill` draws only the outline, and `gdEdged` adds the two radii. They combine with `|`, which is how the pie above gets its black outline on a second call.
- `polygon` (also spelled `openPolygon`) draws a closed outline; `unclosedPolygon` leaves off the edge from the last point back to the first, which is the polyline. `filledPolygon` fills using the *scanline method*.
- `fill` floods the connected region of the colour under the seed point, so it stopped at the black divider. `fillToBorder` floods until it meets one named border colour, whatever it crosses on the way.
- `setThickness` changes the pen for every later line, outline and arc, until you set it back.

Single pixels are `setPixel($x, $y, $colour)` and `getPixel($x, $y)`; the latter returns the index or packed colour, which `rgb` and `alpha` take apart.

Anti-aliasing

Everything above is aliased: each pixel is fully on or fully off, the staircase of the *algorithms chapter*. GD anti-aliases through a special colour. You name the real colour with `setAntiAliased`, then draw with the constant `gdAntiAliased` in place of a colour:

```
use strict;
use warnings;
use GD;
```

(continues on next page)

(continued from previous page)

```
my $im    = GD::Image->new(220, 60, 1);
my $white = $im->colorAllocate(255, 255, 255);
my $black = $im->colorAllocate(0, 0, 0);
$im->filledRectangle(0, 0, 219, 59, $white);

$im->line(10, 10, 100, 37, $black);                 # aliased

$im->setAntiAliased($black);
$im->line(120, 10, 210, 37, gdAntiAliased);         # anti-aliased

# the same column of each line, three pixels high
for my $x (55, 165) {
    my @grey = map { ($im->rgb($im->getPixel($x, $_)))[0] } 22 ..␣
↪24;
    print "x=$x: @grey\n";
}

open my $fh, '>', 'aa.png' or die "aa.png: $!";
binmode $fh;
print $fh $im->png;
close $fh;
```

```
x=55: 255 255 0
x=165: 255 127 128
```

At that column the ideal line passes exactly between two pixel rows. The aliased line picks one and paints it solid black; the anti-aliased line gives each row half coverage, two mid greys. That is the coverage idea from the algorithms chapter, computed for you.

`gdAntiAliased` works for lines and for polygons, outlined or filled. `filledEllipse` ignores it and keeps a hard edge. For curves that must be smooth, see *when GD is the wrong tool*.

GD has three more special colours in the same style: `gdStyled` draws with a repeating pattern of colours set by `setStyle` (a custom dash), `gdBrushed` stamps a small image set by `setBrush` along the line, and `gdTiled` fills with an image set by `setTile`.

Text

GD has two text systems. The built-in **bitmap fonts** need nothing installed: `gdTinyFont`, `gdSmallFont`, `gdMediumBoldFont`, `gdLargeFont` and `gdGiantFont`, fixed-size and ASCII-oriented, drawn with `string` (and `stringUp` for text rotated 90 degrees). The **TrueType** route, `stringFT`, renders any font file through FreeType at any size and angle, anti-aliased.

```
use strict;
use warnings;
use GD;
```

(continues on next page)

(continued from previous page)

```
my $im    = GD::Image->new(320, 150, 1);
my $white = $im->colorAllocate(255, 255, 255);
my $black = $im->colorAllocate(0, 0, 0);
my $blue  = $im->colorAllocate(0, 90, 200);
$im->filledRectangle(0, 0, 319, 149, $white);

# the built-in bitmap fonts: x, y is the top-left of the text
$im->string(gdSmallFont, 10, 10, 'gdSmallFont', $black);
$im->string(gdGiantFont, 10, 28, 'gdGiantFont', $black);
$im->stringUp(gdMediumBoldFont, 300, 140, 'stringUp', $blue);
printf "gdGiantFont cell: %dx%d\n", gdGiantFont->width, gdGiantFont-
 ↪>height;

# TrueType through FreeType: x, y is the baseline start
my $font = '/usr/share/fonts/TTF/DejaVuSans.ttf';
my @box = $im->stringFT($blue, $font, 20, 0, 10, 90, 'TrueType text
 ↪')
    or die "stringFT: $@";
print "bounding box: @box\n";

# angle is in radians, counter-clockwise
$im->stringFT($black, $font, 11, 0.3, 180, 135, 'at an angle')
    or die "stringFT: $@";

# measure without drawing: call it on the class, not an image
my @size = GD::Image->stringFT($black, $font, 20, 0, 0, 0, 'TrueType␣
 ↪text');
printf "width %d, height %d\n", $size[2] - $size[0], $size[1] -
 ↪$size[5];

# with fontconfig on, a font name works instead of a path
$im->useFontConfig(1);
$im->stringFT($black, 'DejaVu Sans:bold', 11, 0, 10, 135, 'by name')
    or die "stringFT: $@";

open my $fh, '>', 'text.png' or die "text.png: $!";
binmode $fh;
print $fh $im->png;
close $fh;
```

```
gdGiantFont cell: 9x15
bounding box: 9 95 188 95 188 70 9 70
width 178, height 24
```

The font path is a system detail; on your machine `fc-list` shows the installed fonts and their files, or turn on `useFontConfig` and name the font as the last call does.

Three things differ between the two systems, and all three catch people. The **position**: `string` places the top-left corner of the text, `stringFT` places the start of the baseline,

so the same y puts the two at different heights. The **argument order**: `string` takes the font first and the colour last, `stringFT` takes the colour first. And the **angle**: `stringFT` wants radians, counter-clockwise, while `arc` wants degrees, clockwise.

`stringFT` returns the four corners of the text's bounding box as eight numbers (lower-left, lower-right, upper-right, upper-left, each as x and y), and an empty list on failure with the reason in `$@`, so with a wrong font path the example above dies with `stringFT: Could not find/open font`. Called on the class instead of an image it measures without drawing, which is how you centre or right-align a caption.

Saving and loading

Output is one method per format, each returning the encoded bytes; you write them to a file opened in binary mode.

```
use strict;
use warnings;
use GD;

sub save {
    my ($file, $bytes) = @_;
    defined $bytes or die "$file: this libgd cannot write that␣
 ↪format\n";
    open my $fh, '>', $file or die "$file: $!";
    binmode $fh;
    print $fh $bytes;
    close $fh;
}

my $im    = GD::Image->new(200, 100, 1);
my $white = $im->colorAllocate(255, 255, 255);
my $red   = $im->colorAllocate(200, 40, 40);
$im->filledRectangle(0, 0, 199, 99, $white);
$im->filledEllipse(100, 50, 160, 80, $red);

save('shape.png',  $im->png);          # optional 0..9 compression␣
 ↪level
save('shape.jpg',  $im->jpeg(85));     # quality 0..100
save('shape.webp', $im->webp(80));     # quality 0..100
save('shape.gif',  $im->gif);          # palette format: colours are␣
 ↪reduced
save('shape.bmp',  $im->bmp);

my @loaded = (
    [ 'shape.png',  GD::Image->newFromPng('shape.png', 1) ],   # 1:␣
 ↪true-colour
    [ 'shape.jpg',  GD::Image->newFromJpeg('shape.jpg', 1) ],
    [ 'shape.webp', GD::Image->newFromWebp('shape.webp') ],
    [ 'shape.gif',  GD::Image->newFromGif('shape.gif') ],
    [ 'shape.bmp',  GD::Image->newFromBmp('shape.bmp') ],
);
```

(continues on next page)

(continued from previous page)

```
for (@loaded) {
    my ($file, $back) = @$_;
    printf "%-10s %5d bytes  %dx%d  centre=%s\n", $file, -s $file,
        $back->getBounds, join(' ', $back->rgb($back->getPixel(100,␣
↪50)));
}
```

```
shape.png    765 bytes  200x100  centre=200 40 40
shape.jpg   3216 bytes  200x100  centre=200 40 40
shape.webp  1274 bytes  200x100  centre=199 40 39
shape.gif    413 bytes  200x100  centre=204 42 44
shape.bmp  60054 bytes  200x100  centre=200 40 40
```

The centre pixel tells the story of each format. PNG and BMP are lossless and give back exactly `200 40 40`. JPEG and WEBP are lossy; on a flat area like this they come back exact or within a step. GIF is a palette format, so the true-colour image was reduced to at most 256 colours on the way out, and the red moved to the nearest colour in that palette.

Loading is one constructor per format, each taking a file name or an open filehandle: `newFromPng`, `newFromJpeg`, `newFromGif`, `newFromWebp`, `newFromBmp`. Each has a `Data` variant for bytes you already hold in a scalar, such as `newFromPngData($bytes)`. A loader either returns an image or dies: a missing file with `... not found`, a file it cannot decode with the name of the libgd call that refused it. That is why the loop above checks nothing.

The second argument of `newFromPng` and `newFromJpeg` (and their `Data` variants) decides whether a true-colour file stays true-colour, and leaving it out has a cost:

```
use strict;
use warnings;
use GD;

my $pal = GD::Image->newFromPng('shape.png');       # no flag:␣
↪palette
my $tc  = GD::Image->newFromPng('shape.png', 1);    # 1: true-colour
for ([ 'no flag' => $pal ], [ 'flag 1' => $tc ]) {
    my ($how, $im) = @$_;
    printf "%-8s isTrueColor=%d  centre=%s\n", $how, $im->
↪isTrueColor,
        join(' ', $im->rgb($im->getPixel(100, 50)));
}

my $was = GD::Image->trueColor(1);                  # the program-
↪wide default
my $any = GD::Image->new('shape.png');
printf "trueColor(1), was %d: new(file) isTrueColor=%d\n", $was,
↪$any->isTrueColor;

eval { GD::Image->newFromPng('shape.jpg') };
```

(continues on next page)

(continued from previous page)

```
my ($why) = $@ =~ /^(.*?) at /;
print "wrong format: $why\n";
```

```
no flag  isTrueColor=0  centre=204 42 44
flag 1   isTrueColor=1  centre=200 40 40
trueColor(1), was 0: new(file) isTrueColor=1
wrong format: gdImageCreateFromPng error
```

Without the flag, GD converts the loaded file to a palette image, the same reduction the GIF went through, and the red moves. Pass 1 for anything you will filter, resample or blend, which is what the rest of this chapter assumes. `GD::Image->trueColor(1)` changes the default for the whole program and returns the previous one; it also makes `GD::Image->new($width, $height)` true-colour, and it is the only way to steer `GD::Image->new($file)`, which recognises PNG, JPEG, GIF and WEBP from the file's first bytes but takes no flag of its own. A palette file such as a GIF loads as a palette image either way, and `paletteToTrueColor` converts it in place.

Which formats work is decided by how the system's libgd was built, not by GD. An encoder libgd was built without returns `undef`, which is why `save` above checks. `GD::supportsFileType` answers from libgd's format table, which lists a format as present even when its codec is a stub, so the reliable test is the one `save` does: ask for the bytes and see whether you got any.

Transparency in files

Two separate mechanisms make parts of a saved image transparent, one per image kind.

```
use strict;
use warnings;
use GD;

# a PNG with a real alpha channel
my $im = GD::Image->new(100, 100, 1);
$im->alphaBlending(0);                              # write alpha,␣
 ↪do not blend
$im->saveAlpha(1);                                  # keep it in the␣
 ↪PNG
my $clear = $im->colorAllocateAlpha(0, 0, 0, 127);  # fully␣
 ↪transparent
my $glass = $im->colorAllocateAlpha(0, 90, 200, 64);
$im->filledRectangle(0, 0, 99, 99, $clear);
$im->filledEllipse(50, 50, 80, 80, $glass);

open my $fh, '>', 'glass.png' or die "glass.png: $!";
binmode $fh;
print $fh $im->png;
close $fh;

# a palette GIF with one colour marked transparent
my $gif = GD::Image->new(100, 100);
```

(continues on next page)

(continued from previous page)

```
my $bg  = $gif->colorAllocate(255, 255, 255);
my $ink = $gif->colorAllocate(0, 128, 0);
$gif->transparent($bg);
$gif->filledRectangle(25, 25, 74, 74, $ink);

open $fh, '>', 'stamp.gif' or die "stamp.gif: $!";
binmode $fh;
print $fh $gif->gif;
close $fh;

my $back = GD::Image->newFromPng('glass.png', 1);
printf "glass.png: corner alpha %d, centre alpha %d\n",
    $back->alpha($back->getPixel(0, 0)), $back->alpha($back->
↪getPixel(50, 50));
my $g = GD::Image->newFromGif('stamp.gif');
printf "stamp.gif: transparent index %d\n", $g->transparent;
```

```
glass.png: corner alpha 127, centre alpha 64
stamp.gif: transparent index 0
```

For a true-colour PNG, per-pixel alpha survives the round trip only when both switches are set: `alphaBlending(0)` so the alpha is written into the pixels rather than blended away, and `saveAlpha(1)` so the PNG encoder keeps the channel. Forget the second and the file comes out opaque. For a palette image, `transparent($index)` marks one colour of the table as "see-through", all or nothing, which is the only kind of transparency GIF has.

Scaling and copying

GD scales by copying from one image into another of a different size. You create the destination first, then copy a rectangle of the source into a rectangle of the destination. There are two copies, and the difference is the one between the aliased and anti-aliased lines. `copyResized` picks the nearest source pixel for each destination pixel. `copyResampled` averages the source pixels that land on each destination pixel, which is the supersampling downscale from the *algorithms chapter*. The example shrinks the `primitives.png` sheet saved earlier both ways:

```
use strict;
use warnings;
use GD;

my $src = GD::Image->newFromPng('primitives.png', 1);
my ($sw, $sh) = $src->getBounds;

# fit inside 160x160, keeping the aspect ratio
my $scale = 160 / ($sw > $sh ? $sw : $sh);
my ($dw, $dh) = (int($sw * $scale + 0.5), int($sh * $scale + 0.5));

my $fast   = GD::Image->new($dw, $dh, 1);
```

(continues on next page)

(continued from previous page)

```
my $smooth = GD::Image->new($dw, $dh, 1);
#                   src   dstX dstY srcX srcY dstW dstH srcW srcH
$fast->copyResized($src,     0,   0,   0,   0, $dw, $dh, $sw, $sh);
$smooth->copyResampled($src, 0,   0,   0,   0, $dw, $dh, $sw, $sh);

for ([nearest => $fast], [resampled => $smooth]) {
    my ($name, $im) = @$_;
    my %colours;
    for my $y (0 .. $dh - 1) {
        $colours{ $im->getPixel($_, $y) }++ for 0 .. $dw - 1;
    }
    printf "%-9s %dx%d, %d distinct colours\n", $name, $dw, $dh,␣
↪scalar keys %colours;
    open my $fh, '>', "thumb-$name.png" or die "thumb-$name.png: $!
↪";
    binmode $fh;
    print $fh $im->png;
    close $fh;
}
```

```
nearest   160x120, 6 distinct colours
resampled 160x120, 133 distinct colours
```

The nearest-neighbour thumbnail keeps only the six colours it was drawn with, and pays for it: one-pixel lines fall between the sampled pixels and vanish, so the rectangle outline and the arc from the primitives sheet are simply gone. The resampled thumbnail blends them into faint but present lines, which is where its 133 in-between colours come from. Use `copyResampled` for anything a person will look at, and `copyResized` for pixel art you want to stay blocky when enlarged.

The same copy-a-rectangle shape does compositing:

```
use strict;
use warnings;
use GD;

my $canvas = GD::Image->new(100, 100, 1);
my $blue   = $canvas->colorAllocate(0, 0, 255);
$canvas->filledRectangle(0, 0, 99, 99, $blue);

my $patch = GD::Image->new(40, 40, 1);
my $red   = $patch->colorAllocate(200, 40, 40);
$patch->filledRectangle(0, 0, 39, 39, $red);

#                  src     dstX dstY srcX srcY  w   h
$canvas->copy($patch,        10,  10,   0,   0, 40, 40);       #␣
↪stamp it
$canvas->copyMerge($patch,   50,  50,   0,   0, 40, 40, 50);   # 50%␣
↪blend
```

(continues on next page)

(continued from previous page)

```
my $backup = $canvas->clone;                        # an independent␣
↪copy

printf "copy:      %s\n", join ' ', $canvas->rgb($canvas->
↪getPixel(30, 30));
printf "copyMerge: %s\n", join ' ', $canvas->rgb($canvas->
↪getPixel(70, 70));
printf "clone:     %s\n", join ' ', $backup->rgb($backup->
↪getPixel(70, 70));
```

```
copy:      200 40 40
copyMerge: 100 20 147
clone:     100 20 147
```

`copy` stamps the source unchanged. `copyMerge` takes a last argument from 0 to 100 and mixes that percentage of the source into the destination: half of `200 40 40` plus half of `0 0 255` is `100 20 147`. `clone` returns a new image with the same pixels, for when you want to keep the original before filtering it. Storable's `dclone` is no substitute: GD's Storable hooks hand it an empty object with no image behind it, and the first method called on that object dies.

Rotating, flipping and cropping

The quarter turns and mirror images are exact pixel moves, with no resampling and nothing lost. The `copy` forms return a new image and leave the source alone; `flipHorizontal` and `flipVertical` also come in place. `crop` returns a new image holding one rectangle of the source, given as an array reference of x, y, width and height. The example marks two corners of a card so the output can say where they went:

```
use strict;
use warnings;
use GD;

# a card that shows its orientation: red block top-left, blue block␣
↪top-right
my $card  = GD::Image->new(60, 40, 1);
my $white = $card->colorAllocate(255, 255, 255);
my $red   = $card->colorAllocate(200, 40, 40);
my $blue  = $card->colorAllocate(40, 90, 220);
$card->filledRectangle(0, 0, 59, 39, $white);
$card->filledRectangle(0, 0, 14, 14, $red);
$card->filledRectangle(50, 0, 59, 9, $blue);

# which corner pixel holds which block

print "flipHorizontal      ", corners($mirror), "\n";

my $piece = $card->crop([0, 0, 30, 20]);            # [x, y, width,
↪height]
print "crop                ", corners($piece), "\n";

# trim a border: every edge row and column within 0.5% of white goes
my $trimmed = $card->cropThreshold($white, 0.5);
print "cropThreshold       ", corners($trimmed), "\n";

# a contact sheet of the card and its three rotations
my $sheet = GD::Image->new(250, 70, 1);
$sheet->filledRectangle(0, 0, 249, 69, $sheet->colorAllocate(200,
↪200, 200));
my $x = 5;
for my $im ($card, $card->copyRotate90, $card->copyRotate180, $card-
↪>copyRotate270) {
    my ($w, $h) = $im->getBounds;
    $sheet->copy($im, $x, 5, 0, 0, $w, $h);
    $x += $w + 5;
}
open my $fh, '>', 'rotations.png' or die "rotations.png: $!";
binmode $fh;
print $fh $sheet->png;
close $fh;
```

```
original            60x40  red top-left     blue top-right
copyRotate90        40x60  red top-right    blue bottom-right
copyRotate180       60x40  red bottom-right blue bottom-left
```

(continues on next page)

(continued from previous page)

```
copyRotate270       40x60  red bottom-left  blue top-left
copyFlipHorizontal  60x40  red top-right    blue top-left
copyFlipVertical    60x40  red bottom-left  blue bottom-right
flipHorizontal      60x40  red top-right    blue top-left
crop                30x20  red top-left     blue -
cropThreshold       60x15  red bottom-left  blue top-right
```

`copyRotate90` turns the image a quarter **clockwise** as it appears on screen, the red corner moving from top-left to top-right, and swaps width and height; `copyRotate270` is the quarter turn the other way. The contact sheet `rotations.png` shows the card and its three turns side by side. A flip is a mirror, not a turn: after `copyFlipHorizontal` the blue block is on the left, but both blocks are still at the top, which no rotation achieves.

`cropThreshold` strips a uniform border instead of taking a rectangle you name. It removes rows and columns from each edge for as long as every pixel in them lies within the threshold of the colour you pass, the threshold being a percentage of the largest possible colour distance, measured squared. On the card only the bottom goes: the top row, the left column and the right column each touch a coloured block, so the white below the red block's 15 rows is all it can take. A threshold of `0` matches nothing, so a small positive value is the usual choice even for an exact colour.

Filters

libgd ships a set of whole-image filters. Each works in place and returns true on success. Most of them are fixed 3 x 3 *convolutions*, the operation the algorithms chapter wrote by hand, which the example below makes visible by reading one pixel on the edge of a red square and one inside it:

```
use strict;
use warnings;
use GD;

# a test card: a red square on white, so edges show what a filter
↪does
sub card {
    my $im = GD::Image->new(40, 40, 1);
    my $white = $im->colorAllocate(255, 255, 255);
    my $red   = $im->colorAllocate(200, 40, 40);
    $im->filledRectangle(0, 0, 39, 39, $white);
    $im->filledRectangle(10, 10, 29, 29, $red);
    return $im;
}

my @filters = (
    [ gaussianBlur    => [] ],
    [ meanRemoval     => [] ],     # sharpen
    [ emboss          => [] ],
    [ edgeDetectQuick => [] ],
    [ negate          => [] ],
    [ grayscale       => [] ],
```

(continues on next page)

(continued from previous page)

```
    [ brightness      => [40] ],   # -255 .. 255
    [ contrast        => [50] ],   # positive lowers contrast,␣
↪negative raises it
    [ smooth          => [1] ],    # weight of the centre pixel
    [ pixelate        => [8, 0] ], # block size, mode
);

for my $f (@filters) {
    my ($method, $args) = @$f;
    my $im = card();
    $im->$method(@$args) or die "$method failed\n";
    printf "%-16s edge=%-12s inside=%s\n", $method,
        join('/', $im->rgb($im->getPixel(10, 20))),
        join('/', $im->rgb($im->getPixel(20, 20)));
}
```

```
gaussianBlur     edge=213/93/93    inside=200/40/40
meanRemoval      edge=35/0/0       inside=200/40/40
emboss           edge=209/255/255  inside=127/127/127
edgeDetectQuick  edge=17/0/0       inside=127/127/127
negate           edge=55/215/215   inside=55/215/215
grayscale        edge=87/87/87     inside=87/87/87
brightness       edge=240/80/80    inside=240/80/80
contrast         edge=145/105/105  inside=145/105/105
smooth           edge=218/111/111  inside=200/40/40
pixelate         edge=255/255/255  inside=200/40/40
```

Reading the table:

- **`gaussianBlur`** changes only the edge. Its kernel is the 3 x 3 `1 2 1 / 2 4 2 / 1 2 1`, divided by 16; at the edge pixel the left column (weight 4 of 16) is white, so red becomes `(4 x 255 + 12 x 200) / 16 = 213`. One pass is a small blur; call it several times for more.
- **`meanRemoval`** is the sharpen kernel: nine times the centre minus the eight neighbours. Flat areas are untouched and the edge is pushed away from its neighbours, down to `35/0/0`.
- **`emboss`** and **`edgeDetectQuick`** respond only to change, and add a mid-grey offset of 127 so that "no change" is grey rather than black. That is why the flat inside reads `127/127/127`.
- **`negate`**, **`grayscale`** and **`brightness`** are per-pixel, not convolutions, so edge and inside change alike. `grayscale` uses the luma weights (`0.299 R + 0.587 G + 0.114 B`), giving 87 for this red.
- **`contrast`** is per-pixel too, and runs the way its name does not suggest: a positive value **lowers** the contrast. Every channel's distance from mid-grey (127.5) is scaled by `((100 - c) / 100)` squared, so `50` keeps a quarter of it and red's `200` becomes `127.5 + 72.5 / 4 = 145`. A negative value pushes channels apart instead, and `-50` already drives this red to pure `255/0/0`.
- **`smooth`** is a convolution with a centre weight you choose and weight 1 on the eight

neighbours. With `1` all nine are equal, the plain box blur: three white pixels of nine give `(3 x 255 + 6 x 200) / 9 = 218`. A larger weight keeps more of the original pixel, so the blur gets weaker. Both `smooth` and `contrast` take fractional values, such as `smooth(0.5)` or `contrast(12.5)`.

- **`pixelate`** replaces each block with one colour; mode `0` takes the block's top-left pixel, mode `1` its average. The edge pixel sits in a block whose top-left corner is white.

Also available is `selectiveBlur`, which smooths regions while leaving strong edges alone (on the test card it leaves the edge exactly as it was).

GD::Simple

`GD::Simple` ships with GD and wraps an image in a friendlier API: named colours (190 of them), a pen with a current position, and separate fill (`bgcolor`) and outline (`fgcolor`) colours, so one call draws a filled shape with a border.

```
use strict;
use warnings;
use GD::Simple;

my $img = GD::Simple->new(220, 120);     # cleared to white

$img->bgcolor('yellow');                 # fill colour
$img->fgcolor('blue');                   # outline colour
$img->rectangle(10, 10, 90, 60);

$img->bgcolor('orange');
$img->fgcolor('red');
$img->moveTo(150, 40);                   # shapes draw at the pen
 ↪position
$img->ellipse(80, 50);

$img->fgcolor('black');
$img->penSize(3, 3);
$img->moveTo(10, 100);
$img->angle(0);                          # heading: 0 points right
$img->line(100);                         # turtle-style: 100 px
 ↪ahead

$img->moveTo(130, 105);
$img->font(gdMediumBoldFont);
$img->string('GD::Simple');

open my $fh, '>', 'simple.png' or die "simple.png: $!";
binmode $fh;
print $fh $img->png;
close $fh;

printf "%d colour names\n", scalar(my @names = $img->color_names);
```

```
190 colour names
```

The result is a yellow box with a blue border, an orange ellipse with a red border, a thick black line and a caption. Any method `GD::Simple` does not define is passed through to the `GD::Image` inside it, so the filters, `copyResampled` and the rest of this chapter all work on a `GD::Simple` object, and `$img->gd` returns the image itself. It is a good fit for charts, diagrams and quick sketches; for anything that needs exact control of colours and alpha, the plain `GD::Image` API is more direct.

A complete program

Putting it together: a poster with a gradient background, two translucent discs whose overlap blends, a blur pass, an anti-aliased line and a TrueType caption drawn crisp on top, saved as a PNG plus a resampled JPEG thumbnail.

```
use strict;
use warnings;
use GD;

my ($W, $H) = (400, 300);
my $img = GD::Image->new($W, $H, 1);

# background: a vertical ramp from dark blue to near black
for my $y (0 .. $H - 1) {
    my $t = $y / ($H - 1);
    my $c = $img->colorAllocate(int(30 * (1 - $t)), int(40 * (1 -
↪$t)), int(90 - 70 * $t));
    $img->line(0, $y, $W - 1, $y, $c);
}

# two translucent discs; alpha blending composites the overlap
my $sun = $img->colorAllocateAlpha(255, 200, 60, 40);
my $sea = $img->colorAllocateAlpha(60, 200, 255, 40);
$img->filledEllipse(150, 140, 160, 160, $sun);
$img->filledEllipse(250, 140, 160, 160, $sea);

# soften: each gaussianBlur pass is one 3x3 kernel, so repeat for␣
↪more
$img->gaussianBlur for 1 .. 3;

# a crisp anti-aliased horizon and a caption, drawn after the blur
$img->setAntiAliased($img->colorAllocate(255, 255, 255));
$img->line(20, 250, 380, 244, gdAntiAliased);

my $font = '/usr/share/fonts/TTF/DejaVuSans.ttf';
my $ink  = $img->colorAllocate(240, 240, 240);
$img->stringFT($ink, $font, 16, 0, 20, 285, 'Perl, drawn with GD')
    or die "stringFT: $@";

sub save {
```

(continues on next page)

(continued from previous page)

```
    my ($file, $bytes) = @_;
    open my $fh, '>', $file or die "$file: $!";
    binmode $fh;
    print $fh $bytes;
    close $fh;
}
save('poster.png', $img->png);

# a half-size thumbnail
my $thumb = GD::Image->new($W / 2, $H / 2, 1);
$thumb->copyResampled($img, 0, 0, 0, 0, $W / 2, $H / 2, $W, $H);
save('poster-thumb.jpg', $thumb->jpeg(85));
```

Note that the background allocates 300 colours in a loop. On a true-colour image that costs nothing, because `colorAllocate` only packs the channels; on a palette image the table would be full after 256 lines. Order matters too: the blur runs before the line and the caption, so the discs are soft and the text is sharp.

When GD is the wrong tool

GD is raster, so it has the raster limitation: it works at a fixed resolution, and scaling past it degrades. Its anti-aliasing covers lines and polygons only, and its coordinates are integers. For smooth curves, sub-pixel positioning, gradients and output that must stay crisp at any size (a logo, a diagram destined for print or the web), use a vector engine: *Cairo and SVG* covers both routes, and pperl's native `Cairo` binding is shown in *the Cairo showcase*.

When the job is a per-pixel algorithm no filter covers (a custom kernel, a colour transform, a generated texture), write it over the pixels yourself. For small images the plain-Perl loops of the *algorithms chapter* are enough, and `setPixel` and `getPixel` move the result in and out of GD; for large images, PDL does the same arithmetic on whole arrays at once.

When the drawing needs to appear in a live window rather than a file, that is the *GUI toolkits chapter*. For everything that is "make or modify a bitmap on disk", GD is a small, fast and complete answer.

GD and ImageMagick when you need them

`Imager` is the default, but two other raster libraries are worth knowing. GD is older, smaller, and everywhere: a great deal of existing Perl draws with it, and its colour-index model is worth understanding even if you never choose it new. ImageMagick, through `Image::Magick`, is the heavyweight: the widest format support and the deepest bag of transformations, at the cost of a large dependency. This chapter shows ImageMagick, points to the chapter on GD, and says when each beats `Imager`.

GD

GD has a chapter of its own: *raster drawing with GD* covers its colour model, the primitives, text, file formats, scaling and filters, and ends with a complete program.

When GD wins: you are maintaining code that already uses it (a large amount of older Perl does), you want the smallest dependency that still draws, or you specifically need libgd behaviour to match another tool in a pipeline that also uses libgd. For new drawing work with no such constraint, Imager's named-colour and hash-argument API is friendlier and its filter set is richer.

ImageMagick (Image::Magick)

Image::Magick, also called PerlMagick, ships with ImageMagick itself and exposes its full engine. Its strengths are **format breadth** (it reads and writes formats nothing else on CPAN touches) and **transformations** (hundreds of operations from Resize and Blur through Distort, Morphology, and format-specific tricks). Its weakness is the dependency: you need a matching ImageMagick library installed, and it is large.

The API is verb-oriented: you create an object, Read or size it, then call named operations, each returning an error string that is empty on success.

```
use Image::Magick;

my $im = Image::Magick->new;
$im->Set(size => '200x200');
$im->ReadImage('canvas:white');            # a blank white canvas

# drawing is one Draw call per primitive, SVG-path-like
$im->Draw(primitive => 'line',    points => '0,0 199,199',
          stroke => 'blue');
$im->Draw(primitive => 'circle',  points => '100,100 100,40',
          stroke => 'red', fill => 'none');
$im->Draw(primitive => 'polygon', points => '50,10 150,10 100,90',
          fill => 'skyblue');

# transformations are named methods
$im->Blur(radius => 0, sigma => 1.5);
$im->Resize(geometry => '100x100');

my $err = $im->Write('out.png');
warn "$err" if $err;
```

The circle primitive takes the center followed by any point on the perimeter (so 100,100 100,40 is center (100,100) with radius 60), which is ImageMagick's convention rather than a radius. Every geometry argument is ImageMagick's string mini-language ('200x200', '100x100+10+10'), so it is worth a glance at ImageMagick's own geometry documentation for the details.

When ImageMagick wins: you need a format nothing else reads, you are doing heavy batch transformation (thumbnailing thousands of files, format conversion pipelines), or you want one of its many operations that would be a project to reimplement. For interactive drawing or a tight dependency footprint, it is more machine than you need,

and `Imager` or `GD` fit better.

Choosing

You want ...	Reach for
New raster drawing, friendly API, good filters	`Imager`
Smallest dependency, or an existing GD codebase	`GD`
Widest formats, heavy batch transforms	`Image::Magick`

All three are raster and share the raster ceiling: fixed resolution, degradation on upscaling. When you need output that scales cleanly, the *next chapter* moves to vector graphics with `Cairo` and `SVG`.

Vector graphics: Cairo and SVG

Raster tools commit to a resolution; vector tools describe shapes and decide the pixels later, or never. `Cairo` is a full anti-aliased 2D engine that rasterises paths to a pixel surface (or to PDF and SVG): you draw with real-number coordinates and it works out the coverage. `SVG` generates SVG markup, a text description of shapes that a browser or renderer draws later at whatever size it likes. Use `Cairo` when you need pixels now with the quality of a proper rasteriser; use `SVG` when you want resolution-independent output as a file that other tools consume.

`Cairo` also returns in *chapter 9*: pperl ships a native reimplementation of it, so the same code runs with no CPAN Cairo installed, and that chapter shows how the native binding works. Here it is the ordinary CPAN module.

Cairo: paths and the drawing model

`Cairo`'s model is a **path** built up from segments, then either **stroked** (the outline drawn) or **filled** (the interior painted). You set a source colour, build a path with `move_to` and `line_to` and curves, and commit it. Colours are floats in `0 .. 1`, not `0 .. 255`.

```
use Cairo;

# an ARGB surface is a pixel buffer with alpha
my $surface = Cairo::ImageSurface->create('argb32', 200, 200);
my $cr = Cairo::Context->create($surface);

# paint a white background: set source, then paint fills everything
$cr->set_source_rgb(1, 1, 1);
$cr->paint;

# a stroked path
$cr->set_source_rgb(0, 0, 0);
$cr->set_line_width(3);
$cr->move_to(20, 20);
$cr->line_to(180, 20);
```

(continues on next page)

(continued from previous page)

```
$cr->curve_to(180, 100, 20, 100, 20, 180);   # a bezier curve
$cr->stroke;

# a filled, semi-transparent circle (arc angles are in radians)
$cr->arc(100, 100, 40, 0, 6.28318);          # full circle = 2*pi
$cr->set_source_rgba(1, 0, 0, 0.5);           # red at 50% alpha
$cr->fill;

$surface->write_to_png('output.png');
```

Three things to internalise. Coordinates are real numbers, so `move_to(100.5, 47.25)` is meaningful and the *half-pixel offset* from the foundations chapter is how you get crisp thin lines. Arc angles are in **radians**, not degrees, so a full circle is `2 * pi`. And `set_source_rgba`'s alpha gives you the *compositing* for free: fill or stroke with alpha below 1 and Cairo blends over what is already there.

`stroke` and `fill` consume the current path. If you want to both fill and stroke the same shape, use `fill_preserve` (or `stroke_preserve`), which keeps the path for a second operation:

```
$cr->arc(100, 100, 40, 0, 6.28318);
$cr->set_source_rgb(0.4, 0.8, 1);
$cr->fill_preserve;                  # fill, but keep the path
$cr->set_source_rgb(0, 0, 0);
$cr->set_line_width(2);
$cr->stroke;                         # now outline the same circle
```

Premultiplied alpha

The `argb32` surface stores pixels with *premultiplied alpha*: each colour channel is already multiplied by its alpha. This is invisible when you draw through Cairo's API, but it matters the moment you read raw pixel bytes off the surface or feed Cairo's buffer to another library, because the bytes are not the straight RGBA you might assume. When you cross that boundary, un-multiply first. Within Cairo's own drawing it never comes up.

SVG: markup, not pixels

SVG is pure Perl and does something different: it builds an XML document describing shapes, and produces text. Nothing is rasterised; the consumer (a browser, Inkscape, a PDF converter) draws it. That makes it perfect for output that must stay sharp at any zoom, or that other tools will process further.

```
use SVG;

my $svg = SVG->new(width => 200, height => 200);

# a group carries shared style; children inherit it
my $g = $svg->group(id => 'shapes',
```

(continues on next page)

(continued from previous page)

```
                    style => { stroke => 'black', fill => 'none' });

$g->line(x1 => 0, y1 => 0, x2 => 200, y2 => 200);
$g->circle(cx => 100, cy => 100, r => 50, style => { fill =>
 ↪'skyblue' });
$g->rect(x => 10, y => 10, width => 40, height => 40);
$g->path(d => 'M10 190 L100 100 L190 190 Z');   # a triangle via␣
 ↪path data

$svg->text(x => 60, y => 110)->cdata('Hello');

print $svg->xmlify;
```

The style hash maps to SVG's presentation attributes: `stroke`, `fill`, `stroke-width`, `opacity`, and the rest. A `group` (aliased `g`) with a style is how you avoid repeating attributes on every element; children inherit and can override. Text is attached with a chained `cdata` because the character content is a child node, not an attribute.

For a polygon from computed points, `get_path` assembles the points string for you:

```
my @x = (50, 150, 100);
my @y = (10, 10, 90);
my $points = $svg->get_path(x => \@x, y => \@y, -type => 'polygon');
$g->polygon(%$points, style => { fill => 'coral' });
```

`xmlify` (also spelled `to_xml` or `render`) returns the finished document as a string. Write it to a `.svg` file and it opens in any browser; hand it to a converter for PDF or PNG.

Cairo or SVG?

You want ...	Reach for
Pixels now, anti-aliased, from real-number coordinates	`Cairo`
Vector output as a file for browsers or other tools	`SVG`
To render the same drawing to PNG, PDF, and SVG from one API	`Cairo`
No compiled dependency at all (pure Perl)	`SVG`

The two also compose: generate structure as SVG markup, then render it to pixels with a rasteriser when you need a bitmap. For applied vector output in the specific shape of charts and graphs, and for reading the metadata already inside image files, the *next chapter* covers the pragmatic bookends of raster and vector work.

Image metadata and applied 2D charting

Two pragmatic corners of 2D work round out the toolkit arc. First, reading the data already inside image files: dimensions, format, and the EXIF block a camera writes. Second, the most common reason people draw at all, which is turning numbers into a chart. Neither is glamorous, and both come up constantly.

Reading metadata: Image::Info

Before you draw on or resize an image, you often just need to know about it: how big is it, what format, what did the camera record. `Image::Info` is pure Perl, reads the headers without decoding the whole image, and returns a plain hash reference.

```
use Image::Info qw(image_info dim);

my $info = image_info('photo.jpg');
die $info->{error} if $info->{error};

my ($w, $h) = dim($info);
print "format: $info->{file_media_type}\n";     # image/jpeg
print "size:   ${w}x${h}\n";
print "created: $info->{DateTime}\n" if $info->{DateTime};
```

`dim` is a convenience that pulls width and height out of the hash. The rest of the keys depend on the format and on what the file carries: resolution, colour type, and the common EXIF fields for photographs. For a quick "what is this file" it is all you need, and it costs almost nothing because it never decodes the pixels.

Reading and writing metadata: Image::ExifTool

When you need the full metadata surface, and especially when you need to **write** it, `Image::ExifTool` is the definitive tool. It handles the metadata of essentially every image and media format, reads thousands of tags, and can edit them in place without touching the image data.

```
use Image::ExifTool qw(:Public);

my $et = Image::ExifTool->new;
$et->ExtractInfo('photo.jpg');

my $model = $et->GetValue('Model');             # camera model
my $when  = $et->GetValue('DateTimeOriginal');
print "shot on $model at $when\n" if $model;

# rewrite a tag and save
$et->SetNewValue('Artist' => 'Jane Doe');
$et->WriteInfo('photo.jpg');                     # edits metadata
 ↪only
```

`Image::Info` answers "how big, what format" cheaply; `Image::ExifTool` is the one to reach for when the metadata itself is the job (stripping location tags for privacy, batch-tagging a photo library, reading maker-note fields). Both leave the pixels alone.

Charting: the honest state of the art

Charting is applied 2D drawing: axes, bars, lines, and labels composed from the primitives you already know. The Perl charting landscape is thinner than it once was. Several once-popular modules are now unmaintained, so this section leads with what still works and names the rest plainly.

GD::Graph for quick raster charts

`GD::Graph` builds on `GD` and is still maintained. It is the shortest path to a bar, line, or pie chart as a PNG. You give it data as a set of parallel arrays (the first is the x labels, the rest are data series) and it renders.

```
use GD::Graph::bars;

my @data = (
    ['Jan', 'Feb', 'Mar', 'Apr'],       # x-axis labels
    [  12,    19,    8,     23    ],     # one data series
);

my $chart = GD::Graph::bars->new(400, 300);
$chart->set(
    title       => 'Widgets shipped',
    y_max_value => 25,
    dclrs       => ['blue'],
) or die $chart->error;

my $gd = $chart->plot(\@data) or die $chart->error;

open my $fh, '>', 'chart.png' or die $!;
binmode $fh;
print $fh $gd->png;                     # plot() returns a␣
↪GD::Image
close $fh;
```

`GD::Graph::bars`, `::lines`, `::pie`, and `::points` are the workhorses. `plot` returns a `GD::Image`, so everything from the *GD chapter* about output applies. This is the pragmatic default for a chart on disk.

SVG for vector charts

When the chart must stay sharp at any size, or live in a web page as markup, build it as *SVG* directly. There is no chart abstraction to learn: you compute the bar rectangles and axis lines yourself and emit them. That is more code than `GD::Graph`, but it is resolution-independent and needs no compiled dependency.

```
use SVG;

my @values = (12, 19, 8, 23);
my $svg = SVG->new(width => 400, height => 300);
my $base = 260;                         # baseline y
my $bw   = 60;                          # bar width

for my $i (0 .. $#values) {
    my $h = $values[$i] * 8;            # scale to pixels
    my $x = 40 + $i * ($bw + 20);
    $svg->rect(x => $x, y => $base - $h, width => $bw, height => $h,
               style => { fill => 'steelblue' });
```

(continues on next page)

(continued from previous page)

```
}
$svg->line(x1 => 30, y1 => $base, x2 => 380, y2 => $base,
           style => { stroke => 'black' });

print $svg->xmlify;
```

For anything beyond a simple bar or line chart the hand-rolled SVG grows quickly, but for exactly the common cases it is clean and dependency-free.

The legacy options, named

Two charting modules you will find referenced online are effectively unmaintained and are noted here only so their state is not a surprise. **`Chart::Clicker`** produces attractive Cairo-rendered charts but has not seen a release in years and carries a large dependency tree (including Moose); if you already run it, it works, but it is not a choice for new code. **`Chart::Gnuplot`** drives an external `gnuplot` binary and is likewise dormant; if you have `gnuplot` installed and want its plotting power, calling it directly (or through a thin wrapper of your own) is more maintainable than depending on the abandoned module. For scientific plotting specifically, the PDL ecosystem's own graphics modules are the better-supported path and belong with PDL rather than here.

Where this leaves the toolkit arc

You can now create, load, draw on, filter, save, vectorise, inspect, and chart 2D images entirely on disk. The one thing missing is a **screen**: getting a drawing into a live, interactive window. That is the *next chapter*, and it is also the bridge to the two capstone projects, which both need a window to run in.

2D on a screen: windows and the frame loop

Everything so far drew to a file. This chapter draws to a **window**: a surface that repaints, responds to the mouse and keyboard, and can animate.

On pperl that means the native `SDL2` binding, which supplies a window, a hardware-accelerated 2D renderer, an event queue and timing. The CPAN GUI toolkits are covered at the end, briefly, because they cannot run here and the reason is worth stating once.

A window and a renderer

```
use SDL2 qw(:all);

SDL_Init(SDL_INIT_VIDEO) == 0 or die "SDL_Init: ", SDL_GetError(),
 ↪"\n";

my $win = SDL2::Window->new(title => 'pperl', w => 640, h => 480);
my $ren = $win->renderer(vsync => 1) or die "renderer: ", SDL_
 ↪GetError(), "\n";
```

The explicit `SDL_Init` is optional: `SDL2::Window->new` initialises the video subsystem for you if it is not already up. The window closes when the last reference to `$win` goes away. A **renderer** draws into that window, using the GPU where one is available and falling back to software where it is not.

`vsync => 1` ties frame presentation to the display refresh, which paces a loop without a sleep and avoids tearing. `software => 1` forces the software path, which is what a headless test wants.

The frame loop

Every interactive program has the same shape: drain the event queue, update state, draw, present.

```
my $running = 1;
while ($running) {
    while (my $ev = SDL_PollEvent()) {
        $running = 0 if $ev->{type} == SDL_QUIT;
    }
    $ren->set_draw_color(30, 30, 40);
    $ren->clear;
    $ren->set_draw_color(240, 180, 60);
    $ren->fill_rect([ 200, 150, 240, 180 ]);
    $ren->present;
}
```

This is **immediate mode**: the screen is a function of your state, recomputed every frame. Nothing is retained between frames, so there is no object to update when something moves; you just draw it in its new place.

Drain the queue with a `while`, not an `if`. Handling one event per frame falls progressively behind during fast mouse movement, and the symptom is input lagging seconds behind the user.

Drawing

The renderer's primitives are deliberately few:

- `$ren->clear` fills the target with the draw colour.
- `$ren->set_draw_color($r, $g, $b, $a)`, alpha defaulting to 255.
- `$ren->draw_point`, `$ren->draw_line`.
- `$ren->draw_rect($rect)` outlines, `$ren->fill_rect($rect)` fills.
- `$ren->copy($texture, $src, $dst)` blits a texture.
- `$ren->read_pixels($rect)` returns raw RGBA bytes.

A rectangle is `[$x, $y, $w, $h]`, or `undef` meaning the whole target.

There is **no circle, no polygon, no thick line and no text**. That is not an omission to work around casually: SDL's renderer is a blitting engine, and anything richer is either a texture you prepared earlier or pixels you computed yourself with the *algorithms chapter*.

Textures, and drawing offscreen

A texture is an image in the renderer's memory. Created with `SDL_TEXTUREACCESS_TARGET` it can also be drawn **into**, which is how you keep an offscreen image that survives redraws:

```
my $canvas = SDL2::Texture->new($ren, w => 320, h => 240,
                                access => SDL_TEXTUREACCESS_TARGET);

$ren->set_target($canvas);                # draw into the texture
$ren->set_draw_color(255, 255, 255);
$ren->clear;
$ren->set_target(undef);                 # undef: back to the window
$ren->copy($canvas, undef, [0, 0, 320, 240]);
```

`set_target` points the renderer at the texture, and `undef` points it back at the window. The direct function layer's `SDL_SetRenderTarget` does the same and accepts the same objects. The *drawing app* is built on exactly this.

Input

Events arrive as plain hash references with a `type` and whatever keys that type carries. A keyboard event has `scancode`, `sym`, `mod` and `key_name`; a mouse button event has `x`, `y`, `button` and `clicks`.

For continuous movement, ask the keyboard state rather than the queue:

```
SDL_PumpEvents();
$x -= 4 if SDL2::key_pressed(SDL_SCANCODE_LEFT);
```

Events report transitions, so moving per `SDL_KEYDOWN` inherits the operating system's key-repeat delay and stutters. `key_pressed` answers "is it down right now", which is what smooth movement needs. The *game capstone* covers the scancode and keysym distinction that goes with it.

What SDL2 is not

It is not a widget toolkit. There are no buttons, no text fields, no layout, no focus handling, no accessibility. A control is a rectangle you draw and a coordinate test you write, which is fine for four colour swatches and is not fine for a settings dialogue.

If an application needs real widgets, SDL2 is the wrong layer and there is currently no right one on pperl. That is a genuine gap, stated rather than papered over.

The CPAN toolkits

`Prima`, `Perl/Tk`, `Gtk3` and `Wx` are the toolkits a search will find, and they are the right answer on perl5. **None of them runs on pperl**, for one structural reason: each is an XS module, and pperl cannot load a compiled extension, because XS binds to perl5's C-level ABI and pperl has no such ABI to bind to. `Prima.pm` calls `bootstrap Prima` unconditionally at load time, so `use Prima` fails before any of your code runs.

The natural next question is why they are not reached through `Peta::FFI` the way `Cairo` and `SDL2` are. The answer differs per toolkit, and for Prima it is decisive: **there is no library to reach.** Cairo binds `libcairo`, and SDL2 binds `libSDL2`. Prima is not a binding to anything; it *is* the implementation, with its own graphics engine and its own X11 widget layer. Prima 1.77 is roughly 117,000 lines of C and header alongside 95,000 lines of Perl module code. There is no `.so` on the far side of an FFI call, so a native Prima would mean reimplementing a windowing toolkit, not wrapping one.

`Gtk3` and `Wx` do wrap real libraries and are therefore reachable in principle, at the cost of a large binding each. Both are also in poor health upstream: `Wx` and its `Alien::wxWidgets` dependency have not had a release in years, and `Gtk3` is in slow maintenance.

For this guide they are mention-only. If you are writing for perl5 and want widgets, they remain good answers; on pperl the working answer for drawing to a screen is SDL2.

Choosing

You want ...	Reach for
A window, drawing and input on pperl	`SDL2`
Per-frame animation, a game loop	`SDL2`
An offscreen surface that survives redraws	`SDL2` target texture
Vector output to a file rather than a screen	`Cairo`
Real widgets on pperl	nothing today

With a window and a frame loop, the toolkit arc is complete. The *next arc* goes under it: pperl's native FFI, how the bindings this chapter used are built, and two projects that put the whole guide together.

Reaching further: Peta::FFI for graphics

The toolkit chapters covered what CPAN already wraps. This chapter, and the rest of the guide, goes further: reaching a C graphics library that has no CPAN binding at all, using pperl's native FFI. This is a pperl-exclusive capability. Binding a C library the traditional way means writing a C shim, compiling it, and shipping a build toolchain with your code; pperl calls the C library directly, the same mechanism that already gives you `Math::GMP` with no compiled binding to build at all.

`Peta::FFI` is built into the runtime, and so are the native bindings built on its binding layer: they are Rust modules, not Perl-side declarations. (pperl's built-in `FFI::Platypus` is a layer over Peta::FFI's engine, for code written for CPAN's FFI::Platypus.) This matters for graphics because a real graphics binding needs to manage C-allocated objects (a surface, a context) across many calls, and pperl's model handles that the way the C library itself does.

The authoritative reference for the FFI layer is the *Auto-FFI page*; this chapter applies it to graphics specifically.

The two levels

`Peta::FFI` is best understood as two levels: raw calls you write yourself, and native bindings someone has written for you.

Raw calls. You name a library, a function, and a type-signature string, and pperl dispatches the call through `libffi`. Nothing is generated ahead of time; any signature you can spell works.

```
use Peta::FFI qw(dlopen call dlclose);

my $lib = dlopen("libm.so.6");
my $r = call($lib, "sqrt", "(d)d", 2.0);     # sqrt(2) = 1.4142...
dlclose($lib);
```

The signature `"(args)ret"` uses one letter per type: `v` void, `i` int, `l` long, `L` unsigned long or size_t, `d` double, `f` float, `p` a C string in, `P` a mutable output buffer, and `o` an opaque pointer carried as a plain integer. Around those codes sit two more sets of primitives, and they are what make the rest of a graphics API reachable, beyond the functions that take plain scalars: `alloc`, `free`, `peek`, `peek_cstr`, `poke`, `pack_ptr` and `unpack_ptr` for memory you own, and `closure` and `closure_free` for handing a Perl coderef to C as a function pointer.

Native bindings. The other level is a hand-written native binding, built on Peta::FFI's binding layer: a module that opens the library once, resolves every symbol it needs, and presents a clean Perl API, managing the C-allocated objects behind Perl values. It is the faster and more comfortable form of the same reach. `Math::GMP` is exactly this: `use Math::GMP` and you get arbitrary-precision integers with operator overloading, and nowhere did you touch `dlopen` or a signature string. The *next chapter* takes one of these that pperl already ships for a graphics library, `Cairo`, and shows how it works.

What raw calls can and cannot reach

Most of a C graphics API is reachable right now, because most of it is scalars, handles, and memory the caller owns:

- Functions that take and return **numbers** (set a line width, a radius, a colour component) map straight onto `i`, `d`, `f`, and friends.
- Functions that take a **C string** (load a font by name, open a file) use `p`.
- Functions that fill a **caller-provided buffer** (read pixels into memory you own) use `P`, or `alloc` plus `o` when you want to keep the buffer across several calls.
- An **opaque handle** returned by the library (a surface pointer, a context pointer) is an address, and `o` is its type code. Declared with `handle_type`, it becomes an object of a class of your own that frees itself, as a `<Class>` type in the signature. The native pattern in the next chapter stores these object handles the same way: as an integer inside a blessed Perl reference.
- A **struct**, passed or returned by value (a `Color { r, g, b, a }`, a `Rectangle`) or through a pointer (a rectangle out-parameter), is reachable. `record` declares it member by member, Peta::FFI lays it out as the C compiler does, and the signature names it as `{Color}` by value or `*{Color}` by pointer.

- A **union** (an event record) is reachable too, by pointer: `union` declares it as `record` declares a struct, every member at offset 0, and the signature passes it as `*{Event}` for the library to fill in. A union cannot be passed by value.
- **Arrays and out-parameters** take a Perl reference: `\@points` for a `T[]`, `\my $count` for a `*T`, `\$buf` for a `P` buffer C fills.
- A **callback** is reachable. `closure` wraps a coderef as a genuine C function pointer, so a library that calls into your code (a comparator, a progress handler, an event or draw callback) gets one.

Where raw calls stop: **anything derived from a header.** Nothing reads the library's `.h` files for you. You write the signature from the C prototype yourself and declare each record's and union's members yourself. Getting those right is your responsibility. A signature that disagrees with the real prototype is undefined behaviour rather than an error you get told about.

The practical shape of that: the *mechanism* for a graphics library is in place, and what a hand-written binding costs you now is the careful work of transcribing prototypes and declarations correctly. This guide's value is telling you which side of the line a given task falls on, so you neither avoid what works nor promise what does not.

Why a native binding, not raw calls, for real work

You could drive a graphics library entirely through raw `call`s, and for a quick experiment that is fine. For anything real, a native binding is the right unit, for three reasons.

First, **object lifetime**. A graphics context is allocated by the library and must be freed exactly once. A native binding ties that lifetime to a Perl value's `DESTROY`, so the C object is released when the Perl object goes away, with no manual bookkeeping. With raw calls you declare that yourself, with `handle_type` for each C object type, or keep track of every `o` pointer by hand.

Second, **ergonomics**. `$surface->fill` reads better and is harder to get wrong than a `call` with a hand-written signature at every use site.

Third, **the signature is written once**. In a native binding each C function's exact type is declared once, in one Rust module, and the compiler checks every argument against it; every caller just uses the method. Scattering raw signatures through application code is how you get a mismatch that corrupts the stack.

The *Cairo showcase* makes all three concrete with the `Cairo` binding pperl ships, a real vector library whose API is almost entirely scalars and one opaque handle, which is precisely the shape that reaches cleanly today.

The shape of what follows

The next chapter opens up the native Cairo binding pperl ships, built the way `Math::GMP` is, so you can see a graphics library brought up on pperl end to end. Then the two capstones build a drawing application and a 2D game you can run, both on the native `SDL2` binding, with the raw layer shown where it clarifies what the binding removes. The *final chapter* draws the map of what is left.

A native Cairo binding, shipped

The *vector chapter* drew with `Cairo` as an ordinary CPAN module. This chapter shows the other side of that same code: pperl ships a **native reimplementation of `Cairo`**, so `use Cairo` works on pperl with no CPAN Cairo distribution installed and no C compiler involved. The Perl you write is identical; what backs it is pperl's own FFI reaching `libcairo` directly. Cairo makes the ideal worked example because its C API is almost entirely scalars and one opaque handle, which is precisely the shape that reaches cleanly today.

This is a real, shipped binding, not a sketch. Reading it tells you what a native graphics binding is, how the pieces fit, and how to recognise (or ask for) the same treatment for another library. Building such a binding is a runtime task; what you write as a user is the Perl on the far side of it, and that Perl is just the `Cairo` *API* you already saw.

The Perl API: exactly the CPAN one

The native binding exposes the **real `Cairo` package names and methods**: `Cairo::ImageSurface`, `Cairo::Context`, `Cairo::PdfSurface`, and the rest, with the upstream method signatures. Code written for CPAN `Cairo` runs unchanged; ported Cairo test suites pass against it. The program from the vector chapter is the program here:

```
use Cairo;

my $surface = Cairo::ImageSurface->create('argb32', 200, 200);
my $cr      = Cairo::Context->create($surface);

$cr->set_source_rgb(1, 1, 1);
$cr->paint;                                  # white background
$cr->set_source_rgb(0, 0, 0);
$cr->set_line_width(3);
$cr->move_to(20, 20);
$cr->line_to(180, 20);
$cr->stroke;
$cr->arc(100, 100, 40, 0, 6.28318);
$cr->set_source_rgba(1, 0, 0, 0.5);
$cr->fill;

$surface->write_to_png('out.png');
# the surface and context free their C objects when they go out of␣
 ↪scope
```

Nothing in that program hints at how it is implemented. There is no `dlopen`, no signature string, no binding object: just `Cairo`. The rest of this chapter is what makes `use Cairo` do that on pperl, and the pattern is the same one behind `Math::GMP`.

Step 1: open the library once, resolve the symbols

The binding opens `libcairo.so.2` a single time, when the module loads, and resolves each C function it needs into a table of function pointers held for the life of the process. Opening the library, the symbol table and the class each C pointer type is wrapped in come from Peta::FFI's binding layer, which every native library binding in pperl is built

on. This is the same shape as the `Math::GMP` binding, which opens `libgmp` once and resolves its `mpz_*` symbols. For Cairo the resolved symbols are the ones behind the methods above:

```
open libcairo.so.2 once when the module loads
resolve and store, as function pointers:
    cairo_image_surface_create(format, width, height) -> surface*
    cairo_create(surface*)                             -> context*
    cairo_move_to(context*, x, y)
    cairo_line_to(context*, x, y)
    cairo_arc(context*, xc, yc, radius, a1, a2)
    cairo_set_source_rgb(context*, r, g, b)
    cairo_set_source_rgba(context*, r, g, b, a)
    cairo_set_line_width(context*, w)
    cairo_stroke(context*)  cairo_fill(context*)  cairo_
↪paint(context*)
    cairo_surface_write_to_png(surface*, path) -> status
    cairo_destroy(context*)  cairo_surface_destroy(surface*)
```

If `libcairo` is not installed on the system, `use Cairo` still succeeds, and the first call that needs the library dies with a message saying how to install it. If the installed `libcairo` is too old to have one of these functions, only the method that calls it dies, naming the C function; you can catch that with `eval` like any other error. Every one of those C functions has a signature the FFI's type codes already express: the arguments are the opaque handle (an address, so an integer), doubles, and a string path. There is no by-value struct in the core drawing API, which is why Cairo is the clean example.

Cairo is a large library, so the real binding is organised by package: `Cairo::Surface`, `Cairo::Context`, `Cairo::Path`, `Cairo::Pattern`, `Cairo::Matrix`, `Cairo::Font`, and `Cairo::Region` each resolve the symbols they need. That is an implementation convenience; the user sees one `Cairo`. Each of those packages has its own reference page under `Cairo`, with the methods it carries and what each returns. When you want to look a method up rather than understand the pattern, that reference is the place to go, not this chapter.

Step 2: the opaque handle as a blessed integer

Cairo hands back a `cairo_surface_t*` and a `cairo_t*`: pointers to C structs whose insides you never touch. The binding does not need to understand their layout, only to hold the pointer and pass it back on every call. pperl represents such a handle the same way `Math::GMP` holds its `mpz_t` pointer: as an **integer inside a blessed reference**.

```
Cairo::ImageSurface object  =  bless(\ (surface_ptr as integer),
↪'Cairo::ImageSurface')
Cairo::Context object       =  bless(\ (context_ptr as integer),
↪'Cairo::Context')
```

When a method is called, the binding reads the integer back out of the blessed reference, casts it to the C pointer, and calls the function. The blessing gives you method dispatch (`$cr->stroke`), inheritance (every concrete surface class is a `Cairo::Surface` subclass), and, crucially, a `DESTROY` hook. The only difference from `Math::GMP` is that the opaque thing is a drawing surface instead of a big integer.

Step 3: lifetime tied to DESTROY

A C graphics object must be freed exactly once. Leak it and every drawing costs you memory you never get back; free it twice and you corrupt the memory the C allocator is managing, which crashes the program later, somewhere unrelated and hard to trace. The binding ties the C object's life to the Perl object's: when the blessed reference goes out of scope, Perl calls `DESTROY`, and the binding calls the matching C destructor, respecting cairo's reference counting.

```
Cairo::Context DESTROY  ->  cairo_destroy(context_ptr)
Cairo::Surface DESTROY  ->  cairo_surface_destroy(surface_ptr)
```

`Math::GMP` does precisely this: its destructor calls `mpz_clear` and frees the `mpz_t`. You, the user, never call a free function; the drawing objects clean up when the Perl variables holding them go away. The binding enforces the ordering cairo requires, releasing a context before the surface it draws to.

Step 4: the methods

Each Perl method is a small native function that reads the handle, reads the scalar arguments, and makes one C call. `Cairo::Context::move_to` reads the context pointer and the two coordinates and calls `cairo_move_to`; `Cairo::Context::set_source_rgba` reads the pointer and the four colour components and calls `cairo_set_source_rgba`; `Cairo::Surface::write_to_png` reads the pointer and a path string. The mapping is one method to one C call:

```
Cairo::Context::move_to($cr, $x, $y)
    -> read context ptr from $cr; call cairo_move_to(ptr, x, y)

Cairo::Context::set_source_rgba($cr, $r, $g, $b, $a)
    -> call cairo_set_source_rgba(ptr, r, g, b, a)

Cairo::Surface::write_to_png($surface, $path)
    -> call cairo_surface_write_to_png(ptr, path)
```

The C-level signatures live in the binding and are settled there once. A user calling `$cr->set_source_rgba(1, 0, 0, 0.5)` never writes a signature and cannot get one wrong. That single point of truth for the C calls is the third of the *three reasons* a native binding beats scattered raw calls: object lifetime, ergonomics, and the signature written down once.

What this reaches, and what it does not

With those four pieces (open once, handle as a blessed integer, `DESTROY` frees, methods over the resolved function table) pperl delivers a real, memory-safe `Cairo` with no CPAN distribution installed, no C compiler, and no build step. The full *vector chapter* drawing model is available, and the objects manage themselves.

Cairo's core drawing API is scalars plus one opaque handle throughout, which is why Cairo was the first graphics library brought up this way: the four pieces above are the whole job. A library with a busier C interface needs more of the toolbox but not a different pattern. Structs are declared records, passed by value or by pointer; union-typed

event records are declared unions the library fills in through a pointer; a library that **calls back** into your code gets a real function pointer from `closure`. What stays out of reach is the *primer's* hard line: any prototype or declaration you would want derived from a header rather than written out by hand. The *2D game capstone* works through a library on the busier end of that range.

The takeaway

A graphics library whose C API is scalars plus opaque handles can be brought up on pperl as a native binding, and `Cairo` is the first one shipped: open the library once, hold each C object as a blessed integer, free it in `DESTROY`, and back each method with its C call settled in one place. The result is the upstream `Cairo` API, running natively. The *next chapter* stops describing and starts building: a drawing application on the native `SDL2` binding, assembling the whole guide into something that runs.

Capstone: a drawing application

A small paint program you can run: drag to paint, pick a colour, and save a PNG. It is built entirely on the native `SDL2` binding pperl ships, which supplies the window, the input, an accelerated 2D renderer and image output.

The design is the one every paint program uses. An **offscreen canvas** holds the painting; the window merely displays it. The mouse draws onto the canvas, and the frame loop copies the canvas to the window. Keeping the two separate means the painting survives resizes and occlusion for free, and saving is reading back something that already exists.

The canvas is a target texture

SDL renders into a window by default. Give it a texture created with `SDL_TEXTUREACCESS_TARGET` and it will render into that instead, which is this program's offscreen image.

```
use SDL2 qw(:all);

my ($W, $H) = (320, 240);
my $STRIP   = 40;                       # button strip along the bottom

SDL_Init(SDL_INIT_VIDEO) == 0 or die "SDL_Init: ", SDL_GetError(), "\n";

my $win = SDL2::Window->new(title => 'pperl paint', w => $W, h => $H + $STRIP);
my $ren = $win->renderer or die "renderer: ", SDL_GetError(), "\n";

my $canvas = SDL2::Texture->new($ren, w => $W, h => $H,
                                access => SDL_TEXTUREACCESS_TARGET);

sub with_canvas {
    my ($code) = @_;
    $ren->set_target($canvas);
```

(continues on next page)

(continued from previous page)

```
    $code->();
    $ren->set_target(undef);            # undef means the window
↪again
}

with_canvas(sub {                       # start from a white sheet
    $ren->set_draw_color(255, 255, 255);
    $ren->clear;
});
```

A new target texture holds transparent black, so the canvas is cleared to white once, before anything is painted on it. Everything drawn inside `with_canvas` lands on the painting; everything outside it lands on the window and is replaced next frame. Getting that backwards is the one structural mistake available here, and its symptom is a painting that vanishes the moment the window redraws.

The brush

A stroke is a line from the previous mouse position to the current one, so a fast drag stays connected rather than dotting.

```
my @palette = ([0,0,0], [220,40,40], [40,160,60], [40,90,220]);
my $brush   = $palette[0];

sub stroke {
    my ($from, $to) = @_;
    with_canvas(sub {
        $ren->set_draw_color(@$brush);
        # A 3px nib: draw the segment three times, offset. Cheaper
↪than
        # a real thick-line routine and adequate for a brush.
        for my $d (-1, 0, 1) {
            $ren->draw_line($from->[0] + $d, $from->[1],
                            $to->[0]   + $d, $to->[1]);
            $ren->draw_line($from->[0], $from->[1] + $d,
                            $to->[0],   $to->[1]   + $d);
        }
    });
}
```

SDL's `draw_line` is one pixel wide with no thickness parameter, hence the offset draw passes. A proper brush would rasterise a disc along the segment, which is the *algorithms chapter* circle routine applied per step.

Controls, without widgets

SDL2 has no widget toolkit. There is no button object, no layout, no event routing by widget. A control is a rectangle you draw and a coordinate test you write. For four swatches that is less code than configuring a widget would be, and for a real application it is the point at which you would want a toolkit instead.

```
sub button_rect { my ($i) = @_; return [ 8 + $i * 44, $H + 6, 36, 28
↪] }

sub draw_frame {
    $ren->set_draw_color(60, 60, 60);
    $ren->clear;
    $ren->copy($canvas, undef, [0, 0, $W, $H]);
    for my $i (0 .. $#palette) {
        $ren->set_draw_color(@{ $palette[$i] });
        $ren->fill_rect(button_rect($i));
    }
    $ren->set_draw_color(200, 200, 200);
    $ren->draw_rect(button_rect($_)) for 0 .. $#palette;
    $ren->present;
}
```

copy blits the canvas texture into the top of the window, the swatches are filled rectangles below it, and `present` shows the frame.

Input

Events arrive as plain hash references. A press below the canvas picks a colour; a press above it starts a stroke.

```
my $last;
sub handle {
    my ($ev) = @_;
    if ($ev->{type} == SDL_MOUSEBUTTONDOWN) {
        if ($ev->{y} >= $H) {
            for my $i (0 .. $#palette) {
                my $r = button_rect($i);
                $brush = $palette[$i]
                    if $ev->{x} >= $r->[0] && $ev->{x} < $r->[0] +
↪$r->[2]
                    && $ev->{y} >= $r->[1] && $ev->{y} < $r->[1] +
↪$r->[3];
            }
        } else { $last = [ $ev->{x}, $ev->{y} ] }
    }
    elsif ($ev->{type} == SDL_MOUSEMOTION && $last) {
        my $p = [ $ev->{x}, $ev->{y} ];
        stroke($last, $p);
        $last = $p;
    }
    elsif ($ev->{type} == SDL_MOUSEBUTTONUP) { $last = undef }
}

my $running = 1;
while ($running) {
    while (my $ev = SDL_PollEvent()) {
```

(continues on next page)

(continued from previous page)

```
        $running = 0 if $ev->{type} == SDL_QUIT;
        handle($ev);
    }
    draw_frame();
    SDL_Delay(16);
}
```

`SDL_MOUSEMOTION` fires only while the pointer moves, and `$last` is what makes it a drag rather than a paint-on-hover: it is set on press and cleared on release.

Saving

The renderer writes its current target straight out, so saving is pointing it at the canvas and asking. The file takes the target's size: pointed at the canvas it is the 320 x 240 painting, without the button strip, whatever size the window has.

```
sub save_png {
    my ($path) = @_;
    with_canvas(sub { $ren->save_png($path) });
}
```

save_png croaks on failure and returns the renderer on success. Errors therefore arrive as exceptions, so call it plainly and wrap it in `eval` only if you want to catch the failure. The habitual `or die "save failed"` does no harm, but it can never fire.

`save_jpg` and `save_bmp` sit beside it with the same contract.

Running the drawing app

Assemble the pieces into one file and run it with `pperl`. Drag to paint, click a swatch to change colour, and call `save_png` to write the result.

The whole program has been checked with a click and a drag pushed onto SDL's event queue, both in a window and headless (`SDL_VIDEODRIVER=dummy`): the canvas starts white, a swatch click selects red, the drag paints red at the midpoint of the stroke and leaves a pixel 50 rows below untouched. In both cases `save_png` writes a 320 x 240 RGBA PNG holding exactly the painting: a white sheet crossed by the red stroke, with no button strip.

Where the FFI thread would enter

This capstone needs no raw FFI: one shipped binding covers all of it. The *FFI thread* enters when you outgrow it: a pressure-sensitive tablet, or a C brush engine with no Perl binding. That is reached exactly as the *Cairo showcase* described, and the *next capstone* shows the raw layer in use where it earns its place.

Capstone: a 2D game

A complete small game: a paddle, a ball, a score, keyboard control and a loop that runs at a steady frame rate. It is built on the native SDL2 binding, which gives a window, an accelerated renderer, an event queue and timing in one module.

A game is a loop: read input, update the world, draw the world, wait for the next frame, repeat. Everything else is detail.

The world is plain data

```
use SDL2 qw(:all);

my ($W, $H) = (480, 360);

my %game = (
    ball   => { x => 240, y => 180, dx => 3, dy => 3, r => 8 },
    paddle => { x => 200, w => 80, h => 12, y => $H - 30 },
    score  => 0,
    over   => 0,
);
```

Deliberately a plain hash. The update step is ordinary arithmetic on ordinary data and the draw step reads the same data; nothing about either is graphics-specific until the last moment.

Update

Advance the ball, bounce it off three walls and the paddle, end the game if it passes below.

```
sub update {
    return if $game{over};
    my $b = $game{ball};
    $b->{x} += $b->{dx};
    $b->{y} += $b->{dy};

    # Clamp AND reverse. Reversing alone lets a fast ball that
    # overshoots the wall reverse again next frame and stick in it.
    if ($b->{x} - $b->{r} < 0)  { $b->{x} = $b->{r};      $b->{dx} =
↪-$b->{dx} }
    if ($b->{x} + $b->{r} > $W) { $b->{x} = $W - $b->{r}; $b->{dx} =
↪-$b->{dx} }
    if ($b->{y} - $b->{r} < 0)  { $b->{y} = $b->{r};      $b->{dy} =
↪-$b->{dy} }

    my $p = $game{paddle};
    if ($b->{y} + $b->{r} >= $p->{y}
        && $b->{x} >= $p->{x} && $b->{x} <= $p->{x} + $p->{w}
        && $b->{dy} > 0) {                  # only when moving
↪downward
```

(continues on next page)

(continued from previous page)

```
        $b->{y}  = $p->{y} - $b->{r};
        $b->{dy} = -$b->{dy};
        $game{score}++;
    }
    $game{over} = 1 if $b->{y} - $b->{r} > $H;
}
```

Two conditions in there are load-bearing and both guard against the same class of bug. The `$b->{dy} > 0` test stops the ball scoring repeatedly while it is still overlapping the paddle on its way out. The clamps stop a ball that overshoots a wall from reversing again on the next frame and vibrating inside it. **Symptom: the ball sticks to a surface and shudders.** Cause: reversing velocity without correcting position.

Draw

The frame is a function of the world state, recomputed from scratch each time.

```
sub draw {
    my ($ren) = @_;
    $ren->set_draw_color(20, 20, 30);
    $ren->clear;

    my $p = $game{paddle};
    $ren->set_draw_color(230, 230, 230);
    $ren->fill_rect([ $p->{x}, $p->{y}, $p->{w}, $p->{h} ]);

    my $b = $game{ball};
    $ren->set_draw_color(250, 210, 60);
    $ren->fill_rect([ $b->{x} - $b->{r}, $b->{y} - $b->{r},
                      $b->{r} * 2, $b->{r} * 2 ]);
    $ren->present;
}
```

Clearing and redrawing everything is the immediate-mode style: simple to reason about, and fast enough that a game this size never needs anything cleverer. The ball is a square here because SDL's renderer has no circle primitive; a real one would use a texture, or the midpoint circle from the *algorithms chapter*.

Input: events tell you about changes, not state

This is the distinction that decides whether movement feels right.

The event queue reports **transitions**: this key went down, that one came up. Polling it and moving the paddle per `SDL_KEYDOWN` gives movement governed by the operating system's key-repeat delay, which stutters: one step, a pause, then a stream.

To know whether a key is held right now, ask the keyboard state instead.

```
sub input {
    my $p = $game{paddle};
```

(continues on next page)

(continued from previous page)

```
    SDL_PumpEvents();
    $p->{x} -= 6 if SDL2::key_pressed(SDL_SCANCODE_LEFT);
    $p->{x} += 6 if SDL2::key_pressed(SDL_SCANCODE_RIGHT);
    $p->{x} = 0            if $p->{x} < 0;
    $p->{x} = $W - $p->{w} if $p->{x} > $W - $p->{w};
}
```

`key_pressed` reads SDL's live key array, so it is a state query rather than an event, and it moves the paddle a fixed amount every frame for as long as the key is down. `SDL_PumpEvents` is what refreshes that array, and omitting it leaves the state frozen.

Note `SDL_SCANCODE_LEFT` rather than `SDLK_LEFT`. A **scancode** is a physical key position and a **keysym** is what that key means under the current layout. Arrow keys are the same either way, but WASD is not: on an AZERTY keyboard the keysyms are ZQSD while the scancodes stay where the fingers are. Movement wants scancodes; text and shortcuts want keysyms.

The loop

```
SDL_Init(SDL_INIT_VIDEO) == 0 or die "SDL_Init: ", SDL_GetError(),
 ↪"\n";
my $win = SDL2::Window->new(title => 'pperl bounce', w => $W, h =>
 ↪$H);
my $ren = $win->renderer(vsync => 1) or die "renderer: ", SDL_
 ↪GetError(), "\n";

my $running = 1;
while ($running) {
    while (my $ev = SDL_PollEvent()) {
        $running = 0 if $ev->{type} == SDL_QUIT;
    }
    input();
    update();
    draw($ren);
}
```

`vsync => 1` ties `present` to the display refresh, which paces the loop without a sleep and avoids tearing. Without it, add `SDL_Delay(16)` or the loop spins as fast as the CPU allows.

Draining the event queue **completely** each frame matters: a `while` rather than an `if`. A single-event-per-frame loop falls progressively further behind whenever events arrive faster than frames are drawn, and the symptom is input that lags seconds behind the user.

Running the game

Assemble the pieces into one file and run it with `pperl`. Arrow keys move the paddle, each hit with the paddle scores, and missing ends the game.

The whole program has been checked over a run of frames, both in a window and headless (`SDL_VIDEODRIVER=dummy`): the ball advances by its velocity, bounces off the left wall and is pushed back inside to `x=8`, scores and reverses on paddle contact, and ends the game when it passes the bottom. The drawn frame really does contain the ball's colour `(250, 210, 60)` at the ball's centre, the paddle's colour on the paddle, and the background colour everywhere else. With `vsync => 1` the loop runs at the display refresh: at 60 Hz, sixty frames take one second.

Under the hood: what the binding is doing

`use SDL2` is a native binding built on `Peta::FFI`, the same pattern as the *Cairo showcase*: the library is opened once, each handle is an integer inside a blessed reference, and `DESTROY` frees it.

The raw layer is still reachable, and worth seeing once because it shows what the binding removes. Polling an event without it means declaring `SDL_Event`, a C union, and the structs inside it, then passing one by pointer for `SDL_PollEvent` to fill in:

```
use Peta::FFI;
my $sdl = Peta::FFI::dlopen("libSDL2-2.0.so.0");

Peta::FFI::record("Keysym", scancode => "i32", sym => "i32", mod =>
 ↪"u16", unused => "u32");
Peta::FFI::record("KeyEvent", type => "u32", timestamp => "u32",␣
 ↪windowID => "u32",
                  state => "u8", repeat => "u8", pad => "u8[2]",␣
 ↪keysym => "{Keysym}");
Peta::FFI::union("Event", type => "u32", key => "{KeyEvent}",␣
 ↪padding => "u8[56]");

my $ev = Event->new;                              # one SDL_Event
while (Peta::FFI::call($sdl, "SDL_PollEvent", "(*{Event})i", $ev)) {
    next unless $ev->type == 0x300;               # SDL_KEYDOWN
    my $sym = $ev->key->keysym->sym;
}
```

`union` works as `record` does, except that every member starts at offset 0, so the union is as large as its largest member. A union is always passed by pointer, as `*{Event}`; a signature that passes one by value croaks, because a C call cannot pass it that way reliably.

That works, and every member in it was transcribed by hand from SDL's headers: the types and their order, the `0x300`, the 56 bytes of padding that make the union as large as SDL's. The signature `"(*{Event})i"` was written by hand too, from the C prototype. Peta::FFI computes the offsets, but a declaration that disagrees with the header is undefined behaviour rather than an error. The binding pays that cost once, in one place, checked once, which is the argument for a native binding over scattered raw calls.

Where the guide ends

You have built two programs that run: a drawing application and a game, both on bindings pperl ships, with the raw FFI layer shown where it clarifies rather than where it is needed. The *final chapter* draws the boundary of this guide; this game's sequel is the *3D game* at the end of the 3D guide.

Where this guide ends, and what's next

This guide covers two dimensions and stops there on purpose. This closing chapter draws the boundary explicitly: where the third dimension continues, what belongs in separate guides, and where the FFI line runs. Naming these keeps you from hunting for coverage that is not here.

The third dimension

Everything three-dimensional lives in the companion *3D guide*. The *foundations chapter* named the one concept that carries across (the Z-buffer, which decides what is nearest the viewer), and the *algorithms chapter* noted that tessellation into triangles is the bridge into 3D. The 3D guide picks both up and goes the whole way:

- **The mathematics and the pipeline**: vectors, matrices, projection, and a software rasteriser with a real depth buffer, written in plain Perl so every stage is visible.
- **Geometry**: meshes, the OBJ, STL, PLY and glTF file formats, modelling operations, and scene graphs with a camera and picking.
- **The GPU**, through pperl's native `Peta::WebGPU` binding: a window and a frame loop, shaders and buffers, and a lit 3D scene with depth, culling and instancing, plus GPU compute.
- **Three capstones**: a world generator, an interactive modeller, and a 3D game, the sequel to this guide's *2D game*.

Deliberately out of scope

Two areas are excluded on purpose and would each be a separate guide, not a chapter here or in the 3D guide:

- **Computer vision and image analysis.** This guide used *convolution* as a drawing tool (blur, sharpen) and stopped precisely at the line where the same maths becomes detection and recognition. Feature detection, segmentation, and recognition are analysis, not drawing, and belong elsewhere.
- **Hosted image-generation services.** Connectors to external image-generation APIs are network and service-integration work, not graphics programming, and are out of scope regardless of dimension.

Where the FFI line runs

The *reaching-further arc* was candid at each step about what pperl's native FFI reaches. Collected here, the line runs like this.

Raw `Peta::FFI` calls handle scalars, strings, buffers and opaque handles, which is all of a library like *Cairo*. Beyond those, a **struct** is a declared record, passed by value or by pointer, a **union** is declared the same way and passed by pointer, and arrays and out-parameters take a Perl reference. A **callback** is a real function pointer from `closure`. The *game capstone* shows SDL2's event records, a union, declared that way, so a struct-heavy realtime library is reachable rather than blocked.

All of it is reachable, at a price: **nothing is derived from a header.** You write each signature from the C prototype and each record's and union's members by hand, and a mistake is undefined behaviour rather than a reported error. That is the real cost of a hand-rolled binding, and the reason a native binding is the right unit for anything you intend to keep: it pays the transcription once, in one place, checked once. `SDL2` is the worked example. It was written on exactly that pattern and pperl ships it, which is why the capstones call `SDL2::Window->new` instead of counting struct offsets.

What you can do

Set against that line, the ground covered is broad. With this guide you can, on pperl:

- Draw raster images with primitives and filters, and read, scale, and save them (*Imager*, *GD*, *ImageMagick*).
- Produce resolution-independent vector output, as pixels through Cairo or as markup through SVG (*Cairo and SVG*).
- Read and write image metadata, and draw charts (*metadata and charts*).
- Open a window, respond to the mouse and keyboard, and animate (*windows and the frame loop*).
- Reach a C graphics library through a native binding, with no C compiler and no build step (*Cairo showcase*).
- Call a C library through raw FFI, reading its structs back through pointers and handing it callbacks (*FFI primer*, and the raw layer of the *2D game*).
- Build and run real programs: a *drawing application* and a *2D game*.

That is a complete 2D graphics capability in Perl, from the pixel to a running program. The road out is the *3D guide*.

4.2.11 The Definitive Guide to 3D Graphics with Perl

The *2D guide* ended by naming the third dimension as the road out, and this is that road. It covers the same ground for 3D that the first book covered for 2D: the theory you eventually need, the geometry and the file formats, the way a triangle actually reaches the screen, and how Perl talks to the hardware and to the engines everyone else uses. It ends with three programs you can run.

3D has a reputation for being gatekept by C++ and by engines, and the reputation is mostly about tooling rather than about the subject. The mathematics is a handful of ideas that fit on one page. The rendering pipeline is a sequence you can implement yourself before you ever hand it to a graphics card. Perl can drive that graphics card, and this guide shows exactly how.

What this guide runs on

Worth stating plainly at the top, because it shapes every chapter. pperl cannot load a compiled extension: XS binds to perl5's C-level ABI and pperl has no such ABI to bind to. That rules out the historical Perl 3D bindings, which are all XS. What it leaves is better than it sounds, and it is what this guide is built on:

- **Plain Perl**, for the mathematics, the meshes, the file formats and a software renderer you write yourself. Every example in the first two arcs runs with nothing installed.
- **The native SDL2 binding**, which pperl ships, for a window, the event loop and timing.
- **`PDL`**, for arithmetic over a whole grid at once without a Perl loop.
- **`Peta::WebGPU`**, the GPU binding, for drawing and for compute work. The *GPU arc* puts the earlier chapters' geometry on the screen through the graphics card, and the *world generator* writes its terrain stages in plain Perl, PDL and GPU compute and measures what each costs.

Which chapter do I want?

I want to ...	Start here
understand the maths and the transform pipeline	*foundations*
fill a triangle, or know what a depth buffer is for	*software-rasteriser*
light a surface, or paint a texture onto it	*shading*
store geometry, or diagnose a broken model	*meshes*
read or write OBJ, STL, PLY or glTF	*model-formats*
extrude, revolve, subdivide, or combine solids	*modelling-operations*
arrange a scene, steer a camera, or click on an object	*scene-graphs*
open a window, reach the GPU, or run a frame loop	*gpu-device-and-window*
draw a first triangle with shaders and buffers	*gpu-pipeline*
render a lit 3D scene with depth on the GPU	*gpu-3d-scene*
generate a landscape, or compare Perl, PDL and GPU compute	*capstone-world-generator*
build an interactive modeller	*capstone-modeller*
build a small 3D game	*capstone-3d-game*

A note on the second dimension

This guide assumes the *2D guide's foundations*: the difference between raster and vector, the top-left screen coordinate system, RGB and alpha, and source-over compositing. It does not repeat them. Where a 2D idea returns in a new form, the chapter says so and links back rather than re-explaining.

The one place the earlier book deliberately stopped short was the Z-buffer. It named the idea, said that in two dimensions draw order is your depth buffer, and left it there. This guide picks it up properly.

Foundations: vectors, matrices, and the transform pipeline

The screen is flat, so something must decide where a point in space lands on it. That is the **transform pipeline**: vectors, one 4x4 matrix, and the order operations compose in. Built here in plain Perl, because every later chapter uses the vocabulary.

Handedness

Point your right thumb along x and index finger along y; your middle finger points along z. That is a **right-handed** system, used by OpenGL and by most mathematics: with x right and y up, **z comes out of the screen**, so things in front of the camera have *negative* z. DirectX and Unity are left-handed, with z going into the screen.

Both appear in files you load. Getting it wrong renders a scene inside out or mirrors a model; it does not produce an error.

The cross product encodes the handedness, so it is where to check:

```
my $x = [1, 0, 0];
my $y = [0, 1, 0];
print join ", ", @{ v_cross($x, $y) };    # 0, 0, 1
```

x cross y gives +z. `0, 0, -1` means a left-handed convention has crept in somewhere.

Vectors

Three numbers, as an array reference. Either a **position** or a **direction** depending on context; the two behave differently under translation, so it is worth tracking which you have.

```
sub v_add   { my ($a, $b) = @_; return [ map { $a->[$_] + $b->[$_] }␣
↪0 .. 2 ] }
sub v_sub   { my ($a, $b) = @_; return [ map { $a->[$_] - $b->[$_] }␣
↪0 .. 2 ] }
sub v_scale { my ($a, $s) = @_; return [ map { $_ * $s } @$a ] }

sub v_dot {
    my ($a, $b) = @_;
    return $a->[0]*$b->[0] + $a->[1]*$b->[1] + $a->[2]*$b->[2];
}

sub v_cross {
    my ($a, $b) = @_;
    return [ $a->[1]*$b->[2] - $a->[2]*$b->[1],
             $a->[2]*$b->[0] - $a->[0]*$b->[2],
             $a->[0]*$b->[1] - $a->[1]*$b->[0] ];
}

sub v_len  { my ($a) = @_; return sqrt(v_dot($a, $a)) }

sub v_norm {
    my ($a) = @_;
```

(continues on next page)

(continued from previous page)

```
    my $l = v_len($a);
    return $l == 0 ? [0, 0, 0] : v_scale($a, 1 / $l);
}
```

Two of these carry meaning; the rest is bookkeeping.

Dot product: alignment. Zero when perpendicular, positive when aligned, negative when opposed. Divided by both lengths it is the cosine of the angle. Every lighting calculation in this guide is one dot product.

```
print v_dot([1,0,0], [0,1,0]);            # 0, so perpendicular
print v_len([3, 4, 0]);                   # 5
print join ", ", @{ v_norm([3, 4, 0]) };  # 0.6, 0.8, 0
```

Cross product: a vector perpendicular to both inputs. Gives a triangle's *normal* from two of its edges, and a camera's axes from a view direction. It does not commute; swapping the arguments flips the sign.

Normalising scales to length 1. Formulas that take directions assume it, and an unnormalised one scales the result silently rather than failing.

The 4x4 matrix

Rotation and scale fit a 3x3 matrix. Translation does not, because moving a point is an addition. Add a fourth component `w`, set it to 1 for positions, and use a 4x4: translation occupies the last column and one multiply does all three. Coordinates carrying that component are **homogeneous**. `w` is used again at the perspective divide below.

Storage is **column-major**, the layout OpenGL expects: element `m[col * 4 + row]`, putting translation in elements 12, 13, 14.

```
sub m_identity { return [1,0,0,0, 0,1,0,0, 0,0,1,0, 0,0,0,1] }

sub m_mul {                                   # returns a * b
    my ($a, $b) = @_;
    my @out = (0) x 16;
    for my $c (0 .. 3) {
        for my $r (0 .. 3) {
            my $s = 0;
            $s += $a->[$_ * 4 + $r] * $b->[$c * 4 + $_] for 0 .. 3;
            $out[$c * 4 + $r] = $s;
        }
    }
    return \@out;
}

sub m_translate {
    my ($tx, $ty, $tz) = @_;
    my $m = m_identity();
    @$m[12, 13, 14] = ($tx, $ty, $tz);
    return $m;
```

(continues on next page)

(continued from previous page)

```
}

sub m_scale {
    my ($sx, $sy, $sz) = @_;
    my $m = m_identity();
    @$m[0, 5, 10] = ($sx, $sy, $sz);
    return $m;
}

sub m_rotate_y {
    my ($rad) = @_;
    my ($c, $s) = (cos $rad, sin $rad);
    return [ $c,0,-$s,0,  0,1,0,0,  $s,0,$c,0,  0,0,0,1 ];
}
```

Applying one to a point, with `w` carried along:

```
sub xform {
    my ($m, $p) = @_;                          # $p is [x, y, z, w]
    my @o;
    for my $r (0 .. 3) {
        $o[$r] = $m->[$r] * $p->[0] + $m->[4 + $r] * $p->[1]
               + $m->[8 + $r] * $p->[2] + $m->[12 + $r] * $p->[3];
    }
    return \@o;
}

my $t = m_translate(5, 0, 0);
print join ", ", @{ xform($t, [1, 2, 3, 1]) };     # 6, 2, 3, 1
```

Order

Matrix multiplication does not commute. A translate and a scale give two different transforms depending on which side each sits:

```
my $ts = m_mul(m_translate(5,0,0), m_scale(2,2,2));
print join ", ", @{ xform($ts, [1, 2, 3, 1]) };    # 7, 4, 6, 1

my $st = m_mul(m_scale(2,2,2), m_translate(5,0,0));
print join ", ", @{ xform($st, [1, 2, 3, 1]) };    # 12, 4, 6, 1
```

Read a chain **right to left**. In `m_mul($translate, $scale)` the scale runs first: `(1,2,3)` scales to `(2,4,6)`, then moves 5 along x, giving `(7,4,6)`. The other order scales the translation too, putting x at 12. An object that orbits the origin instead of spinning in place has this backwards.

The pipeline: five spaces

A vertex starts in a model file and ends as a pixel position, through a fixed sequence.

1. **Model space.** Coordinates as authored, relative to the object's own origin.
2. **World space**, after the *model matrix*: where the object sits in the scene.
3. **View space**, after the *view matrix*: the scene re-expressed with the camera at the origin looking down -z. The camera never moves; the world moves the opposite way around it.
4. **Clip space**, after the *projection matrix*. Perspective applied but not divided out; `w` holds the depth the divide will use.
5. **Normalised device coordinates**, after dividing by `w`. Everything visible lies in a cube from -1 to +1. A scale maps that to pixels.

The camera

`m_look_at` builds the view matrix from an eye position, a target, and an up hint, by constructing the camera's axes with cross products.

```
sub m_look_at {
    # $up must NOT be parallel to ($target - $eye): the cross
↪product
    # below then has no perpendicular to find and the matrix
↪degenerates.
    my ($eye, $target, $up) = @_;
    my $f = v_norm(v_sub($target, $eye));     # forward
    my $s = v_norm(v_cross($f, $up));         # right
    my $u = v_cross($s, $f);                  # true up, re-squared
    return [ $s->[0], $u->[0], -$f->[0], 0,
             $s->[1], $u->[1], -$f->[1], 0,
             $s->[2], $u->[2], -$f->[2], 0,
             -v_dot($s, $eye), -v_dot($u, $eye), v_dot($f, $eye), 1
↪];
}

my $view = m_look_at([0, 0, 5], [0, 0, 0], [0, 1, 0]);
print join ", ", @{ xform($view, [0, 0, 0, 1]) };   # 0, 0, -5, 1
```

The camera sits 5 along z; the world origin lands at `z = -5`, five units in front of a camera looking down -z. `up` is only a hint, which is why `$u` is recomputed from the other two axes. An `up` parallel to the view direction breaks it: the cross product has no perpendicular to find.

Projection

The projection matrix puts view-space depth into `w`, so the divide that follows shrinks distant things.

```
sub m_perspective {
    my ($fovy_deg, $aspect, $near, $far) = @_;
    my $pi = 4 * atan2(1, 1);
    my $half = $fovy_deg * $pi / 360;
    my $f = cos($half) / sin($half);          # cot(fovy / 2)
    return [ $f / $aspect, 0, 0, 0,
             0, $f, 0, 0,
             0, 0, ($far + $near) / ($near - $far), -1,
             0, 0, 2 * $far * $near / ($near - $far), 0 ];
}
```

The `-1` in the third column is the mechanism: it copies view-space z into the output `w`. The rest scales to the field of view and squeezes depth into the cube.

One point, all the way through:

```
my $proj = m_perspective(60, 4/3, 0.1, 100);
my $clip = xform($proj, xform($view, [0, 0, 0, 1]));
# clip = 0.000, 0.000, 4.810, 5.000      <- w is 5, the distance

my @ndc = map { $_ / $clip->[3] } @{$clip}[0 .. 2];
# ndc = 0.000, 0.000, 0.962

my ($W, $H) = (800, 600);
my $sx = ($ndc[0] * 0.5 + 0.5) * $W;
my $sy = (1 - ($ndc[1] * 0.5 + 0.5)) * $H;
# screen = (400.0, 300.0)
```

Dead centre of an 800x600 window. The `1 -` in the y line is the flip between NDC, where y goes up, and the screen's *top-left origin*, where it goes down. That one line is where the two conventions meet.

Foreshortening

Nothing above special-cases distance, yet distant things shrink, because `w` grows with depth and everything is divided by it:

```
for my $z (1, 2, 4, 8) {
    my $c = xform($proj, xform($view, [1, 0, -$z, 1]));
    printf "z=%-2d  ndc.x = %.3f   w = %.2f\n", -$z, $c->[0] / $c->
↪[3], $c->[3];
}
# z=-1   ndc.x = 0.217   w = 6.00
# z=-2   ndc.x = 0.186   w = 7.00
# z=-4   ndc.x = 0.144   w = 9.00
# z=-8   ndc.x = 0.100   w = 13.00
```

The same point, one unit off the axis, drifts toward the centre as it recedes. Perspective is a division, not an effect applied on top.

Rotations

Euler angles: three numbers, one per axis. Readable, so this is what a user interface should show. Two failures: **gimbal lock**, where at certain orientations two axes align and a degree of freedom is lost, and poor interpolation, taking curved paths between orientations.

Quaternions: four numbers encoding an axis and angle together. No gimbal lock, compose by multiplication, interpolate smoothly. Not readable by inspection.

Store quaternions, expose Euler angles, convert at the edges.

Next

The *rasteriser* turns these screen positions into pixels: which triangles face away, and what to do when two land on the same pixel.

Rasterisation: triangles, depth, and draw order

Foundations produced screen positions. This chapter fills the space between them.

Three things differ from the 2D *scanline polygon fill*: everything is a triangle, each pixel carries a depth as well as a colour, and values varying across the surface cannot be interpolated linearly once perspective is involved.

Canvases here are small enough to print, so every figure is what the code produced.

Why triangles

Three points always lie in one plane, and a triangle is always convex. Neither holds for a general polygon: four points can be non-planar, and a concave outline needs the crossing-pair logic the 2D scanline fill carried. So geometry is tessellated into triangles first, and a triangle is the only primitive from here on.

The render target

A colour buffer and a depth buffer of the same size, the latter holding the distance to the nearest surface written so far, starting further than anything.

```
sub new_target {
    my ($w, $h) = @_;
    return { w => $w, h => $h,
             px    => [ map { [ ('.') x $w ] } 1 .. $h ],
             depth => [ map { [ (9e9) x $w ] } 1 .. $h ] };
}
```

Characters stand in for colours so the results print directly.

The inside test

One function carries the rasteriser. Given three points it returns twice the signed area of the triangle they form:

```
sub edge {
    my ($a, $b, $c) = @_;
    return ($b->[0] - $a->[0]) * ($c->[1] - $a->[1])
         - ($b->[1] - $a->[1]) * ($c->[0] - $a->[0]);
}
```

With a and b fixed as a line, the sign says which side c is on: positive one side, negative the other, zero exactly on it.

A point is inside the triangle when it is on the same side of all three edges, so run edge once per edge and check the signs agree.

```
my $w0 = edge($v1, $v2, $p);
my $w1 = edge($v2, $v0, $p);
my $w2 = edge($v0, $v1, $p);
next unless ($w0 >= 0 && $w1 >= 0 && $w2 >= 0)
         || ($w0 <= 0 && $w1 <= 0 && $w2 <= 0);
```

Accepting both sign conventions takes a triangle wound either way. Sampling at the pixel centre `($x + 0.5, $y + 0.5)` is the 2D guide's *half-pixel offset*: an integer coordinate names a corner, so coverage is decided at the middle.

Loop over the triangle's bounding box. A 20 by 10 target:

```
....................
.########...........
..##############....
...############......
...#########........
....#######.........
.....####...........
......#.............
....................
....................
```

54 pixels. No scanlines, edge lists or sorting: the same three comparisons at every candidate pixel, independent of each other, which is why hardware uses this formulation.

Winding and culling

edge on the triangle's own vertices gives its signed area, and the sign says which way it winds on screen:

```
print edge([1,1], [17,2], [6,8]);    # 107
print edge([1,1], [6,8], [17,2]);    # -107
```

Same points, opposite order, opposite sign. That sign distinguishes the front of a surface from the back.

A closed object is built so every triangle winds the same way seen from outside; rotate it and the ones now facing away flip sign. Those are invisible, so they can be discarded before any pixel work. That is **back-face culling**:

```
my $area = edge($v0, $v1, $v2);
return 0 if $opt{cull} && $area <= 0;
```

Both windings with culling on: 54 pixels front-facing, 0 reversed. On a closed mesh this discards roughly half the triangles for one sign test. It is also why a model with inconsistent winding renders with holes; each hole is a triangle culled that should not have been.

Barycentric interpolation

Divided by the total area, the three edge results are the **barycentric coordinates** of the point: weights summing to 1 giving each vertex's contribution.

```
my ($b0, $b1, $b2) = ($w0 / $area, $w1 / $area, $w2 / $area);
my $z = $b0 * $v0->[2] + $b1 * $v1->[2] + $b2 * $v2->[2];
```

At a vertex its own weight is 1 and the others 0; at the centre they are equal. Any per-vertex value interpolates this way: depth here, equally a colour, a normal or a texture coordinate.

The depth buffer

Two triangles overlap on screen. Which does the viewer see?

The 2D answer was draw order, last one wins: the **painter's algorithm**. It fails as soon as draw order does not match depth order. A is near (`z = 2`), B is far (`z = 8`).

Drawing B then A gives the right image, but only because that order happened to match the depth order:

```
..................
..AAAAAAAAAA.......
..AAAAAAAABBBBBBB..
..AAAAAAAABBBBBBB..
..AAAAAA..BBBBBBB..
..AAAA......BBBBB..
..AAA.........BBB..
..A............BB..
................B..
..................
```

Reversed, A then B, the same code produces a **wrong** image. The figure below is the bug, not the goal:

```
..................
..AAAAAAAAAA.......
..AAAAABBBBBBBBBB..
..AAAAAABBBBBBBB..
```

(continues on next page)

(continued from previous page)

```
..AAAAAA..BBBBBBBB..
..AAAA......BBBBBB..
..AAA.........BBBB..
..A............BBB..
................B..
....................
```

The far triangle has painted over the near one. The geometry is fine; the algorithm has no idea which is nearer.

Sorting back to front does not fix it: two long triangles can each be partly in front of the other, and three can form a cycle with no valid order. The answer must work per pixel:

```
next if $z >= $t->{depth}[$y][$x];    # something nearer is already
↪here
$t->{depth}[$y][$x] = $z;
$t->{px}[$y][$x] = $ch;
```

Keep the nearest depth per pixel, skip anything further. Both draw orders now produce the same image, confirmed pixel by pixel in the harness. Triangles can arrive in any sequence.

That is the **Z-buffer**, named and deferred in the *2D guide's foundations*. It costs one screen-sized buffer and one compare per pixel.

Perspective-correct interpolation

Linear interpolation in screen space is wrong for everything except depth. A receding surface covers less screen per unit of surface, so equal steps across the screen are not equal steps across the surface. A naively interpolated texture slides and warps, most visibly on a floor.

Interpolate the value divided by `w`, interpolate `1/w` alongside it, and divide at the end. An edge from `z = 1` to `z = 5` carrying a coordinate from 0 to 1:

```
t      screen-linear  perspective
0.00   0.000          0.000
0.25   0.250          0.062
0.50   0.500          0.167
0.75   0.750          0.375
1.00   1.000          1.000
```

Halfway across the screen is 17 percent along the surface, not 50. The two agree at the endpoints and diverge between, so the bug looks like a texture correct at the corners and wrong in the middle.

Depth needs no correction: `1/w` is what the depth buffer should store, and that interpolates linearly in screen space already.

Near-plane clipping

A vertex behind the camera has `w <= 0`, and dividing by it produces garbage. Such vertices must go before the divide. The test is `w > near`, and a segment crossing it is cut:

```
sub clip_near {
    my ($a, $b) = @_;                  # each [x, y, z, w]
    my ($da, $db) = ($a->[3] - $near, $b->[3] - $near);
    return ($a, $b) if $da >= 0 && $db >= 0;      # wholly in front
    return ()       if $da <  0 && $db <  0;      # wholly behind
    my $t = $da / ($da - $db);                    # where it crosses
    my $m = [ map { $a->[$_] + ($b->[$_] - $a->[$_]) * $t } 0 .. 3
↪];
    return $da >= 0 ? ($a, $m) : ($m, $b);
}
```

A segment from `w = 4` to `w = -2` cuts at `[5.20, 0.00, 0.00, 0.10]`, exactly on the near plane; both ends behind returns nothing. Clipping a triangle runs this against each edge, which can leave four vertices, so the result is re-triangulated before rasterising.

The far plane works the same way. The other four sides need no clipping here, because the bounding box is already clamped to the screen.

In hardware

All of the above is fixed-function silicon on a graphics card: edge functions, barycentric weights, depth compare, perspective divide, run per triangle in parallel. What you supply is the vertex positions going in and the colour decision coming out.

That is why the *GPU scene chapter* reads as familiar vocabulary: a depth test you enable, a cull-face mode you pick a winding for, and interpolated values that arrive perspective-correct.

The *next chapter* decides what colour a covered pixel is.

Shading: normals, light, and texture

The *rasteriser* decided which pixels a triangle covers; **shading** decides their colour. It rests entirely on the *dot product*: a surface is bright in proportion to how much it faces the light, and that is one dot product. The rest is refinement.

Normals

A **normal** is a unit vector pointing out of a surface. For a triangle it is the cross product of two edges:

```
my $n = v_norm(v_cross(v_sub($v1, $v0), v_sub($v2, $v0)));
# [0, 0, 1] for a triangle lying in the xy plane
```

Direction depends on winding, as with back-face culling: reversing the vertex order gives `[0, 0, -1]`. A mesh with inconsistent winding has some normals pointing inward, and those triangles render black.

One normal per triangle lights a flat surface. For curved objects, store a normal per **vertex** instead, averaging the normals of the faces meeting there. The geometry stays faceted, the lighting does not, which is why a sphere of 200 triangles can look round.

Lambert

Brightness is the cosine of the angle between the normal and the direction to the light, which for unit vectors is their dot product.

```
# Both must be unit vectors, and $light_dir points FROM the surface
# TOWARD the light, not the direction the light travels.
my $i = v_dot($normal, $light_dir);
$i = 0 if $i < 0;
```

The clamp matters: a negative value means the light is behind the surface, and without it light shines through solid objects.

```
light direction              intensity
straight on  [0,0,1]         1.000
30 deg off   [0.5,0,0.87]    0.866
60 deg off   [0.87,0,0.5]    0.500
edge on      [1,0,0]         0.000
from behind  [0,0,-1]        0.000
```

This models a **matte** surface: chalk, paper, unfinished wood. It looks identical from every viewing angle, because the formula never mentions the viewer.

Alone it leaves anything facing away from the light pure black, which no real scene is, because light bounces. The cheap fix is an **ambient** term:

```
my $i = 0.1 + 0.9 * $lambert;      # never fully black
```

Not physically justified: a stand-in for the bounced light the model does not simulate, which keeps shadowed areas readable.

Specular

Shiny surfaces have a highlight that moves with the viewer, which Lambert cannot produce. **Blinn-Phong** adds one using the **halfway vector**, the direction midway between light and viewer:

```
# $view_dir points FROM the surface TOWARD the viewer, matching
# $light_dir's convention. Clamp the dot product before the power:
# a negative base with a fractional exponent is a domain error.
my $H = v_norm(v_add($light_dir, $view_dir));
my $nh = v_dot($normal, $H);
$nh = 0 if $nh < 0;
my $spec = $nh ** $shininess;
```

When the normal aligns with the halfway vector the surface bounces light straight at the viewer and the highlight peaks. The exponent controls how tight it is:

```
shininess    specular
1            0.9659
8            0.7578
32           0.3298
128          0.0118
```

Same geometry throughout, only the exponent changes. Low values give a broad sheen, high values a small bright spot: roughly 8 for polished wood, 32 for plastic, 128 and up for glass or wet metal.

The three terms combined:

```
my $colour = $ambient + $diffuse * $lambert + $specular * $spec;
```

How often you evaluate it

The formulas are the same wherever they run. How often they run changes the result enormously.

Flat shading: one intensity per triangle, applied to every pixel. Cheap, and the faceting shows:

```
 +++++++
  +++++++++++++++++++
   ++++++++++++++++++++++++
   ++++++++++++++++++++
    ++++++++++++++++++
     +++++++++++++++
      ++++++++++++
      ++++++++
       +++++
        +
```

Gouraud shading: an intensity per vertex, interpolated with the same barycentric weights the rasteriser already computes for depth:

```
my $i = $b0 * $inten[0] + $b1 * $inten[1] + $b2 * $inten[2];
```

```
@%%%%##
 %%%####****++++===-
  %%###****++++====---::::
  %####***++++====---::
   ###***++++====----
    #****++++====--
     ***++++===-
     **++++==
      ++++=
       +
```

Three lighting calculations rather than one per pixel, and the flat region becomes a gradient. The approximation is interpolating the **result**, which shows on specular highlights:

a highlight landing mid triangle with all three vertices dim vanishes, because there is nothing at the vertices to interpolate.

Per-pixel shading, confusingly called Phong shading, interpolates the **normal** instead and runs the lighting at every pixel. More expensive, and correct. This is what a fragment shader does.

The rule that carries forward: interpolate the inputs, not the answer.

Texture mapping

Same interpolation again. Each vertex carries a **UV coordinate**, a position in an image, both axes 0 to 1 regardless of pixel size. Interpolate UVs across the triangle and look up the image at the result:

```
# $b0..$b2 must be PERSPECTIVE-CORRECT barycentric weights. Screen-
 ↪linear
# weights slide the texture across the surface; see the rasteriser␣
 ↪chapter.
my $u = $b0 * $uv[0][0] + $b1 * $uv[1][0] + $b2 * $uv[2][0];
my $v = $b0 * $uv[0][1] + $b1 * $uv[1][1] + $b2 * $uv[2][1];
my $texel = sample($image, $u, $v);
```

A checker pattern sampled that way, over the same triangle:

```
 ####...
  ......####...###...
   ...###...####......###..
   ####...###......####.
    ...####......###..
     ###......####.
       ......###..
       ...####.
        ###..
          .
```

Assigning UVs is **unwrapping**, a modelling task rather than a rendering one: deciding how the surface is cut and flattened, like the net of a paper model.

Two practical details. UVs are the value that slides visibly without **perspective-correct** interpolation. And a UV outside 0 to 1 needs a rule, repeat or clamp, which is a per-texture setting in every graphics API.

The same lookup carries more than colour: per-pixel normals (a **normal map**, bumps without geometry), shininess, or how much light a point blocks. Only the meaning of the number changes.

Physically based rendering

The model above uses numbers chosen by eye. **PBR** replaces them with quantities that conserve energy, so a surface never reflects more light than it receives, and describes materials by measurable properties: roughness, and whether the surface is metal.

The practical consequence: PBR materials hold up under any lighting, where Blinn-Phong parameters are tuned per scene and break in the next one. The pipeline shape is unchanged, with a dot product still at the centre.

Blinn-Phong is still worth implementing first; every PBR treatment assumes it.

Next

You can light a surface and texture it, but have nothing to shade yet. The next arc covers *meshes*, the file formats carrying them, the operations that construct new shapes, and the scene graph arranging them in a world.

Meshes: vertices, indices, and the invariants that matter

A **mesh** is the geometry an object is made of. In practice that means two arrays, plus a set of invariants which, when violated, produce the rendering faults this chapter names.

The indexed triangle mesh

A vertex array holds each distinct position once. An index array names three vertices per triangle. A cube of side 2:

```
# Winding is counter-clockwise seen from OUTSIDE, OpenGL's GL_CCW
# default. Every triangle in the mesh must agree on this.
my @vert = (
    [-1,-1,-1], [ 1,-1,-1], [ 1, 1,-1], [-1, 1,-1],   # 0..3  back
 ↪(z=-1)
    [-1,-1, 1], [ 1,-1, 1], [ 1, 1, 1], [-1, 1, 1],   # 4..7  front
 ↪(z=+1)
);
my @idx = (
    4,5,6,  4,6,7,      # front  (+z)
    1,0,3,  1,3,2,      # back   (-z)
    0,4,7,  0,7,3,      # left   (-x)
    5,1,2,  5,2,6,      # right  (+x)
    3,7,6,  3,6,2,      # top    (+y)
    0,1,5,  0,5,4,      # bottom (-y)
);
```

```
vertices stored: 8
triangles:       12
indices:         36
expanded (no index buffer) would store 36 vertices
position data: 60 floats indexed, 108 floats expanded
```

Indexing is not only about size. A shared vertex is shared: move it once and every triangle using it follows, which is what makes editing tractable. It also lets the GPU cache transformed vertices instead of transforming the same corner five times.

CCW-from-outside is consistent with the *rasteriser*: a counter-clockwise triangle in a right-handed space projects to a clockwise triangle on a y-down screen, which is the positive edge area that chapter treated as front-facing.

Invariant 1: consistent winding

Every triangle must wind the same way seen from outside. The check is the **signed volume**, which for a closed mesh is the sum over triangles of one sixth of `dot(a, cross(b, c))`:

```
sub signed_volume {
    # Requires a CLOSED mesh. On an open surface the result is
    # meaningless rather than merely wrong.
    my ($v, $i) = @_;
    my $vol = 0;
    for (my $k = 0; $k < @$i; $k += 3) {
        my ($a, $b, $c) = @{$v}[ @{$i}[$k, $k+1, $k+2] ];
        $vol += v_dot($a, v_cross($b, $c)) / 6;
    }
    return $vol;
}
```

```
signed volume = 8.0      side 2 cube, so 8 means every face is␣
↪outward
one triangle reversed: 6.6667
```

A side-2 cube has volume 8, and the test returns exactly that. Reverse one triangle and it returns 6.6667: that triangle now subtracts its contribution instead of adding it. A negative total means the whole mesh is inside out.

Symptom: a model renders with holes in it, and the holes move as the camera orbits. Cause: inconsistent winding. The holes are triangles being back-face culled that should not have been.

Invariant 2: the mesh is manifold

In a closed mesh, every **undirected** edge is shared by exactly two triangles, and every **directed** edge occurs exactly once. The second half is the winding check again, expressed combinatorially: two adjacent triangles traverse their shared edge in opposite directions, so a directed edge appearing twice means two neighbours disagree.

```
undirected edges: 18, each shared by exactly 2 faces: yes
directed edges occurring twice (a winding error): 0
same test on the mesh with one triangle reversed: 3 duplicate␣
↪directed edges
```

Both faults are worth testing for on any mesh you load or generate:

- An undirected edge used **once** means the surface has a hole.
- Used **more than twice** means it is non-manifold, and operations like boolean subtraction and subdivision have no defined answer there.
- A duplicated **directed** edge means inconsistent winding, exactly the three the reversed triangle produced above.

Normals, and the trap in averaging them

A face normal is the cross product of two edges. Per-vertex normals come from averaging the normals of the faces meeting at that vertex, which is what makes a faceted surface shade smoothly.

The naive average is weighted by **triangle count**, and that is rarely what you want:

```
vertex 6 at [1, 1, 1] -> normal [0.333, 0.667, 0.667]
```

The corner of a cube should point equally along all three axes, at `[0.577, 0.577, 0.577]`. It does not, because the six quads were each split into two triangles and that split is not symmetric about the corner: two triangles of the front face touch vertex 6, two of the top face, but only one of the right face. The average comes out `[1, 2, 2]` normalised.

Fixes, in increasing order of correctness: weight each face normal by its **area**, or by the **angle** the face subtends at that vertex. Angle weighting is the one that survives retriangulation, because the angles at a corner do not change when you split a quad differently.

Symptom: a smooth-shaded model has a subtle lighting seam along an edge where nothing else is wrong. Cause: unweighted normal averaging across a region that was triangulated asymmetrically.

When one position needs several vertices

Averaging normals is right for a curved surface and wrong for a cube. A cube should look faceted, which means each corner needs a **different** normal per face it belongs to. A vertex is not a position; it is a position **plus its attributes**, and two triangles can share a position while disagreeing about the normal there.

So a smooth-shaded cube has 8 vertices, and a correctly faceted one has 24: each of the 8 corners duplicated once per adjoining face. The same applies to UV coordinates. A **UV seam**, where the texture is cut to be unwrapped flat, forces duplicated positions along the cut, because one position needs two different UVs.

Symptom: an exported model has far more vertices than its corners suggest. Usually not a bug: hard edges and UV seams both split vertices, and a cube legitimately arrives as 24.

Bounding volumes

Cheap approximations used to reject work early: a ray that misses the box cannot hit any triangle in it.

```
AABB min [-1, -1, -1] max [ 1,  1,  1]
sphere centre [ 0,  0,  0] radius 1.7321
```

An **axis-aligned bounding box** is two corners, trivially computed, and tests fast. A **bounding sphere** is a centre and a radius, invariant under rotation, so it does not need recomputing when the object turns. The cube's radius is the half-diagonal, `sqrt(3)`.

Both are used by the culling and ray tests later in this guide, and they are the leaves of the BVH the scene-graph chapter builds.

Welding

Geometry from a file or a generator often repeats positions that should be shared. Welding collapses them by exact or tolerance match:

```
# Exact match on a rounded key. A tolerance-based weld needs a␣
 ↪spatial
# hash, not a string key, or it is quadratic.
my $key = join ",", map { sprintf "%.6f", $_ } @$v;
```

```
raw vertices 6 -> welded 4, indices [0,1,2,1,3,2]
```

Two triangles authored as six independent vertices become four vertices and an index list. Weld before running the manifold check: unwelded geometry reports every edge as used once, because no two triangles share a vertex index even where they visually share an edge.

Half-edge, for editing

The two arrays answer "what are this triangle's vertices" in constant time and "which faces touch this vertex" only by scanning everything. Editing operations need the second question constantly.

A **half-edge** structure stores each edge twice, once per direction, with each half knowing its face, its next half-edge, and its opposite. Walking the opposites around a vertex enumerates its neighbours without a scan. It is what a modelling tool holds in memory; a renderer converts back to vertex and index arrays before drawing. The modelling-operations chapter builds on it.

Next

The mesh here was written as Perl literals. Real geometry comes from files, and the *next chapter* covers the formats that carry it.

Model formats: OBJ, STL, PLY, glTF

No mesh-format module ships with pperl, and there is no maintained CPAN one to fall back on. That is less of a problem than it sounds: OBJ and STL are small enough to parse directly, and this chapter gives working readers and writers for both.

What the four differ on

	Geometry	Materials	Scene tree	Animation	Encoding	Indexed
OBJ	yes	via `.mtl`	no	no	text	yes
STL	yes	no	no	no	text + binary	no
PLY	yes	vertex colour	no	no	text + binary	yes
glTF	yes	PBR	yes	yes	JSON + binary	yes

OBJ for interchange of static geometry, STL for 3D printing, PLY for scanned point and vertex data, glTF for anything with a scene, materials or animation.

OBJ

Line-oriented text. `v` a position, `vt` a texture coordinate, `vn` a normal, `f` a face referring to them.

```
sub write_obj {
    my ($path, $v, $i) = @_;
    open my $fh, '>', $path or die "$path: $!";
    print $fh "# cube, side 2\n";
    printf $fh "v %g %g %g\n", @$_ for @$v;
    for (my $k = 0; $k < @$i; $k += 3) {
        # OBJ indices are 1-BASED
        printf $fh "f %d %d %d\n", map { $_ + 1 } @{$i}[$k, $k+1,
↪$k+2];
    }
    close $fh;
}
```

The cube becomes 21 lines: a comment, 8 positions, 12 faces.

```
# cube, side 2
v -1 -1 -1
v 1 -1 -1
v 1 1 -1
...
f 1 6 5
```

Reading is where the traps are, and there are four:

```
sub read_obj {
    my ($path) = @_;
    open my $fh, '<', $path or die "$path: $!";
    my (@v, @f);
    while (my $line = <$fh>) {
        next if $line =~ /^\s*(#|$)/;
        my @tok = split ' ', $line;
        my $kw = shift @tok;
        if ($kw eq 'v') { push @v, [ @tok[0..2] ] }
        elsif ($kw eq 'f') {
            # A face may have MORE than three vertices. Fan-
↪triangulate.
            # Each token may be v, v/vt, v//vn or v/vt/vn: take the␣
↪first.
            my @vi = map { my ($n) = split m{/}, $_; $n } @tok;
            # Indices are 1-based; a NEGATIVE index counts back from␣
↪the
            # current end of the vertex list.
            @vi = map { $_ < 0 ? @v + $_ : $_ - 1 } @vi;
            push @f, [ $vi[0], $vi[$_], $vi[$_ + 1] ] for 1 .. $#vi␣
↪- 1;
        }
```

(continues on next page)

(continued from previous page)

```
    }
    close $fh;
    return (\@v, \@f);
}
```

1. **Indices are 1-based.** Off-by-one here is the most common OBJ bug.
2. **A negative index is relative**, counting back from the vertices read so far, which is how generators emit streaming output.
3. **A face can have any number of vertices.** Quads are common and n-gons occur; both need triangulating. Fan triangulation is correct for convex faces only, which in practice OBJ faces are.
4. **A face token has up to three slots**, `v/vt/vn`, and `vt` may be empty as `v//vn`. Splitting on `/` and taking the first field is enough when only positions are wanted.

Round-tripping the cube reads back 8 vertices and 12 triangles, and a single 4-vertex face fans correctly:

```
read 8 vertices, 12 triangles
one 4-vertex face -> 2 triangles: [0 1 2] [0 2 3]
```

Symptom: a loaded model is missing every second triangle, or shows stray triangles connecting distant parts. Cause: n-gon faces triangulated as if they were triangles, or the 1-based offset applied twice.

Materials live in a sibling `.mtl` file named by a `mtllib` line, with `usemtl` switching material between faces. Colours, texture map filenames and shininess go there; geometry never does.

STL

The 3D-printing format. Binary STL is a fixed-size record layout, which makes it the clearest `pack` exercise in this guide:

```
sub write_stl {
    my ($path, $v, $i) = @_;
    open my $fh, '>', $path or die "$path: $!";
    binmode $fh;                                # REQUIRED: binary␣
↪format
    print $fh "\0" x 80;                        # 80-byte header,␣
↪ignored
    print $fh pack "V", @$i / 3;                # uint32 triangle␣
↪count
    for (my $k = 0; $k < @$i; $k += 3) {
        my ($a, $b, $c) = @{$v}[ @{$i}[$k, $k+1, $k+2] ];
        my $n = v_norm(v_cross(v_sub($b,$a), v_sub($c,$a)));
        # 12 little-endian floats then a uint16: 50 bytes per␣
↪triangle.
        print $fh pack "f<12 v", @$n, @$a, @$b, @$c, 0;
    }
```

(continues on next page)

(continued from previous page)

```
    close $fh;
}
```

The size is completely determined: 80 header bytes, 4 count bytes, then 50 per triangle.

```
file size: 684 bytes (84 + 50 * 12 = 684)
```

Reading is the same layout in reverse, and the result shows STL's defining property:

```
read 12 triangles
vertex records: 36, distinct positions: 8
```

STL has no index buffer. Every triangle carries its three positions in full, so a cube's 8 corners arrive as 36 vertex records. Weld them (the *meshes chapter* has the code) before doing anything that needs adjacency, or the manifold check will report every edge as used once.

Four more facts worth having:

- The format is **little-endian** regardless of host.
- The per-triangle **normal is frequently zero or wrong**. Recompute it from the winding rather than trusting it.
- The trailing **uint16 is nominally an attribute byte count** and is normally 0. Some tools abuse it to store colour; there is no standard.
- An **ASCII variant** exists (`solid`/`facet normal`/`outer loop`), equivalent in content and larger on disk. How much larger depends entirely on coordinate precision: this cube, whose coordinates are single digits, comes out 1471 bytes against 684, a factor of 2.2, while a scanned model with six significant figures per axis runs far higher. Detect the variant by checking whether the file begins with `solid` **and** its size does not match `84 + 50 *` n; testing the first five bytes alone is not enough, because a binary file's 80-byte header can begin with them too.

PLY

Header-driven: the header declares the elements and their properties, and the body follows that declaration.

```
ply
format ascii 1.0
element vertex 8
property float x
property float y
property float z
element face 12
property list uchar int vertex_indices
end_header
```

The parser reads the header, builds a record description from it, then reads that many records. That indirection is the point: PLY carries arbitrary per-vertex properties, so

scanner output with confidence values, colours and normals per point needs no format extension. Both ASCII and binary bodies are declared by the `format` line.

glTF

The modern interchange format, and the one to target for anything with structure. A `.gltf` is JSON describing nodes, meshes, materials, cameras and animations, referring to binary buffers for the bulk data; a `.glb` packs the same JSON and buffers into one file.

Reading it fully is a project rather than a page, but the shape is worth knowing because it explains the design: `accessors` describe typed views into `bufferViews`, which are ranges of `buffers`. Vertex positions, indices and animation keyframes are all accessors over the same byte range mechanism, so a loader implements the accessor logic once.

glTF is where PBR material parameters, a scene hierarchy and skinned animation actually live. OBJ and STL carry none of those, and no amount of convention makes them.

Choosing

- Writing geometry for another tool to read: **OBJ**, unless it needs materials or a hierarchy.
- Sending a solid to a printer or a slicer: **STL**, welded on the way back in.
- Point clouds or per-vertex measured data: **PLY**.
- A scene, materials, or animation: **glTF**, and nothing else.

Next

Geometry can now be stored and loaded. The *next chapter* constructs it: extrude, revolve, subdivision and boolean operations.

Modelling operations: extrude, revolve, subdivide, combine

Four operations build most geometry that is not scanned or sculpted. Each takes a mesh or a profile and produces a mesh, and each has an analytic answer you can check it against, which is what this chapter does throughout.

Checking a modelling operation

Before the operations themselves: a modelling operation that produces a closed solid can be verified. The `signed_volume` from the *meshes chapter* returns the enclosed volume, and most primitive shapes have a known one. A wrong answer means wrong winding, a hole, or wrong geometry, and the three are distinguishable.

Treat it as the unit test for every operation below. It catches the faults that are invisible in a render until you rotate the camera.

Extrude

Take a closed polygon, sweep it along a direction, cap both ends. This is the push/pull of a direct-modelling tool and the single most useful operation in the set.

```
# $poly is a closed polygon in the xy plane, counter-clockwise seen
# from +z. Extrudes along +z by $h. Returns ($verts, $indices).
sub extrude {
    my ($poly, $h) = @_;
    my $n = @$poly;
    # The outer parens are load-bearing: `my @v = (A), (B)` parses
↪as
    # `(my @v = A), B` and silently stores only the first list.
    my @v = ( (map { [ $_->[0], $_->[1], 0  ] } @$poly),
              (map { [ $_->[0], $_->[1], $h ] } @$poly) );
    my @i;
    # top cap: fan over the upper ring, already CCW seen from +z
    push @i, ($n, $n + $_, $n + $_ + 1) for 1 .. $n - 2;
    # bottom cap: same fan reversed, so it faces -z
    push @i, (0, $_ + 1, $_) for 1 .. $n - 2;
    # sides: one quad per edge, wound outward
    for my $e (0 .. $n - 1) {
        my $f = ($e + 1) % $n;
        push @i, ($e, $f, $n + $f), ($e, $n + $f, $n + $e);
    }
    return (\@v, \@i);
}
```

An n-gon extrudes to 2n vertices and 4n - 4 triangles: n - 2 per cap and two per side quad.

```
unit square extruded by 2: 8 vertices, 12 triangles
signed volume = 2.0000  (analytic: area 1 * height 2 = 2)
unit hexagon extruded by 1: 20 triangles, volume 2.5981 (analytic 2.
↪5981)
```

Extruding a unit square produces exactly the cube from the meshes chapter: 8 vertices, 12 triangles. The hexagon lands on `3*sqrt(3)/2` to four decimal places.

Fan-capping is only valid for a **convex** polygon. A concave outline needs ear clipping, and a polygon with holes needs a real triangulator; both produce caps that self-overlap if fanned.

Symptom: an extruded shape looks right from outside but its volume test returns a small or negative number. Cause: cap winding, usually the bottom cap not reversed.

Revolve

Sweep a profile around an axis. The profile is a list of `[radius, y]` points; each is rotated into `seg` positions around the Y axis and consecutive rings are joined.

```
for my $k (0 .. $p - 2) {
    my ($q0, $q1) = ($s * $p + $k,     $t * $p + $k);
    my ($q2, $q3) = ($t * $p + $k + 1, $s * $p + $k + 1);
    # wound so the normal points away from the axis
    push @i, ($q0, $q3, $q2), ($q0, $q2, $q1);
}
```

Unlike extrude, revolve only **approximates** its analytic shape, and the segment count is the knob. A cylinder of radius 1 and height 2:

```
cylinder r=1 h=2, analytic volume 6.2832
    8 segments:   32 triangles, volume 5.6569
   16 segments:   64 triangles, volume 6.1229
   32 segments:  128 triangles, volume 6.2429
   64 segments:  256 triangles, volume 6.2731
  256 segments: 1024 triangles, volume 6.2826
```

The volume approaches `pi * r^2 * h` from **below**, because an inscribed prism is contained by the cylinder it approximates. Every doubling of segments cuts the error by roughly four, so accuracy is cheap in geometry: halving the error takes only about 41 percent more segments. 32 segments is within 0.7 percent and is the usual default in modelling tools for a reason.

A profile that reaches the axis (`radius = 0`) needs no cap at that end, and joining a full ring to a single axis point there produces degenerate zero-area triangles unless it is special-cased.

Subdivision

Split each triangle into four by its edge midpoints. On its own this adds geometry without adding shape; the operation becomes useful when the new vertices are **moved**, which is what a subdivision surface does. Projecting them onto a sphere is the clearest case:

```
my $ab = $midpoint->($a, $b);
my $bc = $midpoint->($b, $c);
my $ca = $midpoint->($c, $a);
push @ni, ($a,$ab,$ca), ($ab,$b,$bc), ($ca,$bc,$c), ($ab,$bc,$ca);
```

The midpoint helper must **cache by edge**, or the two triangles sharing an edge each create their own copy of the midpoint and the mesh comes apart into unwelded fragments.

Starting from an octahedron and normalising every new vertex:

```
unit sphere, analytic volume 4.18879
  level 0:    8 triangles,    6 vertices, volume 1.33333
  level 1:   32 triangles,   18 vertices, volume 2.94281
  level 2:  128 triangles,   66 vertices, volume 3.81773
  level 3:  512 triangles,  258 vertices, volume 4.09160
  level 4: 2048 triangles, 1026 vertices, volume 4.16420
```

Triangles multiply by four per level. Vertices do not: each level yields `4V - 6`, which the table confirms at every step (18, 66, 258, 1026), because the midpoints on shared edges

are created once and used twice. The volume converges from below again, and level 4 is within 0.6 percent at 2048 triangles.

This is the simplest subdivision scheme. **Catmull-Clark**, the one modelling tools use, works on quads, weights each new vertex by its neighbours instead of projecting onto a known surface, and converges to a smooth limit surface with no target shape needed. The mechanism here is the same: insert vertices, then move them.

Boolean operations

Union, difference and intersection of two solids. This is the operation users reach for most and the one that is hardest to implement, so the honest position matters: **this chapter does not implement it.** A correct constructive solid geometry (CSG) implementation is a project, not a page.

The reason is that it is not really a geometry problem, it is a robustness problem. The algorithm is:

1. Split every triangle of A against the planes of B, and the reverse.
2. Classify each resulting fragment as inside, outside, or on the boundary of the other solid.
3. Keep the fragments the operation calls for, and flip the winding of B's kept fragments for a difference.

Step 1 in floating point is where implementations fail. A vertex landing exactly on a plane, two coplanar faces, a nearly-degenerate sliver triangle: each needs an explicit decision, and getting one wrong yields a mesh with a hole rather than an error.

The classification in step 2 rests on one primitive that **is** worth having on its own, since picking and collision need it too: is a point inside a closed mesh? Cast a ray and count crossings. Odd means inside.

```
# FRAGMENT: the ray/triangle body is elided. Requires a CLOSED,␣
 ↪manifold
# mesh. The ray direction is nudged off axis because a ray hitting␣
 ↪an
# edge or vertex exactly is counted twice or not at all, and nudging␣
 ↪is
# cheaper than special-casing every degenerate hit.
sub point_inside {
    my ($v, $i, $p) = @_;
    my $hits = 0;
    my $dir = v_norm([1, 0.0001, 0.0002]);
    for (my $k = 0; $k < @$i; $k += 3) {
        # ... Möller-Trumbore ray/triangle test, yielding $t ...
        $hits++ if $t > 1e-9;          # count forward hits only
    }
    return $hits % 2;
}
```

```
  [0,0,0         ] inside
  [0.9,0.9,0.9   ] inside
```

(continues on next page)

(continued from previous page)

```
  [1.1,0,0       ] outside
  [2,2,2         ] outside
  [-0.5,0.5,0    ] inside
```

The Möller-Trumbore test in the loop returns the barycentric coordinates as a side effect of solving for the intersection, which is why the same routine serves picking in the scene-graph chapter.

For real boolean work, model as a **tree of operations** rather than committing to a result mesh: keep the primitives and the operations that combine them, and evaluate to triangles only for display or export. That is what CAD tools store, and it keeps the operations reversible.

Next

Objects can now be built. The *next chapter* arranges them: transform hierarchies, cameras, picking, and the spatial structures that keep scenes fast.

Scene graphs: hierarchy, cameras, picking

A scene is more than a pile of meshes. Objects are attached to other objects, a camera has to be steered, the user clicks on something and expects the right thing selected, and none of it may cost a pass over every triangle. This chapter covers those four.

The hierarchy

Each node holds a **local** transform, relative to its parent, and a list of children. Its **world** transform is the parent's world times its own local, which means one top-down walk computes the whole scene.

```
sub walk {
    # $parent_world is the identity at the root. Multiplication
↪order
    # is parent * local: the local transform applies FIRST, then the
    # parent's, which is the right-to-left rule from foundations.
    my ($node, $parent_world, $out) = @_;
    my $world = m_mul($parent_world, $node->{local});
    $out->{ $node->{name} } = $world;
    walk($_, $world, $out) for @{ $node->{children} };
    return $out;
}
```

A turntable yawed 90 degrees, an arm translated 4 along its own x, and a hand raised 2 above the arm:

```
turntable  origin at [ 0.00,  0.00,  0.00]
arm        origin at [ 0.00,  0.00, -4.00]
hand       origin at [ 0.00,  2.00, -4.00]
```

The arm was placed 4 along **its own** x, and the turntable's yaw put it on world -z. The hand rose 2 in y, which the yaw leaves alone. That is the entire value of a hierarchy: the arm's author never thinks about the turntable's angle.

Symptom: rotating a parent makes a child orbit when it should spin in place, or vice versa. Cause: the multiplication order at this line. It is the *foundations* order rule appearing where it costs the most.

Recomputing the whole tree every frame is normal and cheap. Caching world transforms is an optimisation that needs invalidation on every parent change, and getting that wrong is a much worse bug than the recompute is a cost.

The orbit camera

Two angles and a distance. This is the camera every modelling tool uses, and the one the *modeller capstone* needs.

```
sub orbit_eye {
    # $yaw and $pitch in radians, $dist from the target. Clamp pitch
    # short of +/- 90 degrees: at exactly vertical the view␣
↪direction
    # is parallel to `up` and look_at degenerates.
    my ($target, $yaw, $pitch, $dist) = @_;
    return [ $target->[0] + $dist * cos($pitch) * sin($yaw),
             $target->[1] + $dist * sin($pitch),
             $target->[2] + $dist * cos($pitch) * cos($yaw) ];
}
```

The camera has an invariant worth testing against, because it holds at every angle: the target must land on the view-space -z axis at exactly the orbit distance.

```
yaw   0: eye [ 0.00,  3.42,  9.40]  target in view space [ 0.00,  0.
↪00, -10.00]
yaw  45: eye [ 6.64,  3.42,  6.64]  target in view space [ 0.00, -0.
↪00, -10.00]
yaw  90: eye [ 9.40,  3.42,  0.00]  target in view space [ 0.00,  0.
↪00, -10.00]
```

The eye swings around, the target stays put. Any camera bug shows up here immediately as a target that drifts off the axis or changes depth.

A **fly camera** is the other common kind: position plus a forward direction, moved with the keyboard and turned with the mouse. It stores orientation rather than deriving it, which is where the *quaternion* advice applies, since accumulating Euler angles across thousands of frames drifts and eventually gimbal-locks.

Picking

The user clicks a pixel and means an object. Turning the first into the second is a **ray** through that pixel, then an intersection test.

The ray could be built by inverting the view-projection matrix, but for a camera it is cheaper to construct it directly from the camera axes: the pixel's normalised device coordinates scale the right and up vectors, and forward supplies the rest.

```
sub pick_ray {
    my ($eye, $target, $up, $fovy, $aspect, $sx, $sy, $W, $H) = @_;
    my $f = v_norm(v_sub($target, $eye));
    my $s = v_norm(v_cross($f, $up));
    my $u = v_cross($s, $f);
    my $ndc_x = 2 * ($sx + 0.5) / $W - 1;
    my $ndc_y = 1 - 2 * ($sy + 0.5) / $H;        # screen y is down
    my $th = tan_half($fovy);
    my @d = map {
        $f->[$_] + $s->[$_] * $ndc_x * $th * $aspect + $u->[$_] *
↪$ndc_y * $th
    } 0..2;
    return ($eye, v_norm(\@d));
}
```

The `+ 0.5` samples the pixel centre and the `1 -` flips screen y, both for the same reasons as in the *rasteriser*. The aspect multiplies x because the field of view argument is vertical.

```
centre pixel ray dir [ 0.00, -0.00, -1.00]
right-of-centre  dir [ 0.50, -0.00, -0.87]
unit sphere at origin: hit at t=9.000 (eye is 10 away, r=1)
same sphere from the off-centre ray: miss
```

The centre pixel gives exactly `-z`, and a unit sphere at the origin is hit at `t = 9` from an eye 10 away. Both are checkable by hand, which is what makes them useful tests.

Test against **bounding volumes first**, and only then against triangles. A sphere test is a handful of operations:

```
sub ray_sphere {
    # Returns the near intersection distance, or undef. $d MUST be
    # normalised or $t is in units of $d's length rather than␣
↪distance.
    my ($o, $d, $c, $r) = @_;
    my $oc = v_sub($o, $c);
    my $b = 2 * v_dot($oc, $d);
    my $cc = v_dot($oc, $oc) - $r * $r;
    my $disc = $b*$b - 4*$cc;
    return undef if $disc < 0;
    my $t = (-$b - sqrt($disc)) / 2;
    return $t > 0 ? $t : undef;
}
```

The `$t > 0` check rejects hits behind the eye. Without it, clicking empty space selects whatever is behind the camera.

The bounding volume hierarchy

Testing every object per ray is fine for ten objects and hopeless for ten thousand. A **BVH** is a binary tree of nested boxes: if the ray misses a node's box, nothing inside it needs testing.

Building it is a recursive median split along the widest axis:

```
sub build_bvh {
    my ($items) = @_;
    my ($lo, $hi) = bounds($items);
    return { lo => $lo, hi => $hi, items => $items } if @$items <=
 ↪4;
    my $ax = 0;
    my $best = $hi->[0] - $lo->[0];
    for my $a (1, 2) {
        my $e = $hi->[$a] - $lo->[$a];
        if ($e > $best) { $best = $e; $ax = $a }
    }
    my @sorted = sort { $a->{c}[$ax] <=> $b->{c}[$ax] } @$items;
    my $mid = int(@sorted / 2);
    return { lo => $lo, hi => $hi,
             left  => build_bvh([ @sorted[0 .. $mid-1] ]),
             right => build_bvh([ @sorted[$mid .. $#sorted] ]) };
}
```

Splitting the **widest** axis is what keeps the boxes compact; always splitting x produces long thin nodes that overlap and defeat the pruning. The leaf size of 4 is a tuning constant: smaller leaves prune better and cost more nodes to traverse.

The ray/box test is the slab method, intersecting the ray with each pair of parallel planes and keeping the overlap:

```
my $inv = 1 / $d->[$ax];
my ($t1, $t2) = (($lo->[$ax]-$o->[$ax])*$inv, ($hi->[$ax]-$o->[
 ↪$ax])*$inv);
($t1, $t2) = ($t2, $t1) if $t1 > $t2;
$tmin = $t1 if $t1 > $tmin;
$tmax = $t2 if $t2 < $tmax;
return 0 if $tmin > $tmax;
```

A zero component in the direction needs handling before the division, or the reciprocal is an infinity and the comparisons stop meaning what they should.

Over 512 objects on a grid, with one ray:

```
512 objects, 255 BVH nodes
BVH:    hit object 0 at t=9.00, 39 nodes visited
linear: hit object 0 at t=9.00, 512 objects tested
same answer: yes
```

Thirty-nine node visits against 512 object tests, for the same answer. The 255 nodes are 128 leaves of four objects each plus 127 internal nodes, which is where the memory goes.

The same structure serves collision detection and ray tracing. In a renderer its sibling is **frustum culling**: test each node's box against the six planes of the view volume and skip whole subtrees that fall outside, which is the same pruning with a different predicate.

Next

This closes the geometry half of the guide. Everything so far has been plain Perl, computing pixels or coordinates in software.

The *next arc* hands the work to the graphics card, through `Peta::WebGPU`.

The GPU: a device, a window, and the frame loop

Everything so far computed pixels in Perl. From here the graphics card computes them. pperl's GPU binding is `Peta::WebGPU`: WebGPU as implemented by the wgpu library, which drives Vulkan, Metal, Direct3D 12 or OpenGL underneath, whichever the machine has. The programs that run on the card are written in WGSL, WebGPU's shading language. The *world generator* used the binding's compute half; this arc uses the half that draws.

The window, the events and the clock come from the native `SDL2` binding, as in the *2D guide's toolkit chapter*. The two meet at exactly one point: wgpu builds its surface on the handles of the SDL2 window. There is no context to create and no swap call. This chapter covers what takes their place.

Is there a GPU at all?

Two different things can be missing, and they fail differently.

The pperl binary may be built without the GPU option. Loading the module then dies, naming the fix:

```
Peta::WebGPU requires the 'webgpu' capability, which this pperl␣
 ↪binary
was built without. Rebuild with: cargo build --features webgpu
```

Or the build has it and the machine has no usable adapter, as in a container with no GPU driver. `have_gpu` answers that without dying, so one line covers both cases and a program can fall back to the *software rasteriser*:

```
my $gpu_ok = eval { require Peta::WebGPU; 1 } && Peta::WebGPU::have_
 ↪gpu();
```

`adapters` lists what the machine offers:

```
for my $a (Peta::WebGPU::adapters()) {
    printf "%-8s %-14s %s\n", $a->{backend}, $a->{device_type}, $a->
 ↪{name};
}
```

```
Vulkan   IntegratedGpu  Intel(R) HD Graphics P530 (SKL GT2)
Vulkan   DiscreteGpu    Quadro M2000M
Gl       Other          Quadro M2000M/PCIe/SSE2
```

One card appears twice, once per backend that can reach it. The list is for reporting; `Peta::WebGPU::Device->new` makes the choice, steered by its `power` option. On this

machine `low-power` opens the Intel chip and `high-performance` opens the Quadro. `$gpu->info` says which one you got, with the same keys.

Drawing without a window

Start with the render target that needs no display at all, because it is how every example in this arc is checked, and how you check yours.

```
use strict;
use warnings;
use Peta::WebGPU;

my $gpu = Peta::WebGPU::Device->new;           # no window
my ($W, $H) = (320, 240);

my $img = $gpu->texture(width => $W, height => $H);
$gpu->render_pass($img, clear => [0.2, 0.4, 0.6, 1])->end;

my $rgba = $img->read;                         # $W * $H * 4 bytes
sub pixel {
    my ($x, $y) = @_;
    return unpack 'C4', substr($rgba, ($y * $W + $x) * 4, 4);
}
printf "%d bytes, centre pixel %s\n", length $rgba, join ' ', pixel(
 ↪$W / 2, $H / 2);
# 307200 bytes, centre pixel 51 102 153 255
```

`texture` makes an image on the card; its format defaults to `rgba8unorm`, four bytes per pixel. `render_pass` starts recording into it, clearing to the given colour, components from 0 to 1. **Nothing happens until end**: a pass records, and end hands the recording to the card. `read` waits for the card to finish and copies the image back, rows top first, bytes in R, G, B, A order: `0.2, 0.4, 0.6` arrive as `51 102 153`.

Reading crosses the bus and waits, so it belongs at the end of a job, not inside a loop.

The same program run with `DISPLAY` and `WAYLAND_DISPLAY` removed from the environment prints the same line. It needs no display server, no window manager and no compositor, so it runs on a server or in a test suite.

To look at the result, write it out as a PNG through `GD`, which the *2D guide* covers:

```
use GD;

sub save_png {
    my ($file, $rgba, $w, $h) = @_;
    my $im = GD::Image->new($w, $h, 1);        # truecolor
    for my $y (0 .. $h - 1) {
        for my $x (0 .. $w - 1) {
            my ($r, $g, $b) = unpack 'C3', substr($rgba, ($y * $w +
 ↪$x) * 4, 3);
            $im->setPixel($x, $y, $im->colorAllocate($r, $g, $b));
        }
```

(continues on next page)

(continued from previous page)

```
    }
    open my $fh, '>', $file or die "$file: $!\n";
    binmode $fh;
    print $fh $im->png;
    close $fh;
}

save_png('clear.png', $rgba, $W, $H);
```

A loop over every pixel is slow in Perl, but this is a checking tool, run once, and it keeps the picture exactly as the card produced it.

A window, and a device opened for it

```
use strict;
use warnings;
use SDL2 qw(:all);
use Peta::WebGPU;

my $win  = SDL2::Window->new(title => 'pperl gpu', w => 800, h =>␣
↪600, resizable => 1);
my $gpu  = Peta::WebGPU::Device->new(window => $win);
my $surf = $gpu->surface;
```

The window goes to `Device->new`, not to a later call. The adapter has to be one that can present to that window, and wgpu can only answer that question for a real surface, so the device is chosen with the window in hand. A machine with two cards could otherwise open the one that does not drive the screen.

`Peta::WebGPU` opens no windows itself. It asks the window object two questions, `$win->wm_info` for the window system's own handles and `$win->size`, and draws on anything that answers them. `SDL2::Window` does; under X11 its `wm_info` carries `driver`, `display` and `window`, under Wayland `display` and `surface`. Those two window systems are the ones a surface can be made on.

`$gpu->surface` is the window's chain of images to draw into, configured at the window's size. On the machine these examples were checked on:

```
print $surf->format, ' ', join('x', $surf->size), "\n";
# bgra8unorm-srgb 800x600
```

The format is the compositor's preference. `surface(format => ...)` can ask for another the window offers, and one it does not offer is refused with the list of those it does. Whichever it is, anything that draws into the window has to be built for it, which the *next chapter* returns to.

The import trap

This one costs an afternoon, and it produces a wrong result rather than an error.

```
use SDL2;                       # no import list
SDL2->import(qw(:all));         # WRONG: runs at runtime

my $win = SDL2::Window->new(title => 'trap', w => 160, h => 120);
SDL_PushEvent({ type => SDL_QUIT() });   # parentheses: resolved at␣
↪runtime

my $quit = 0;
while (my $ev = SDL_PollEvent()) {
    $quit = 1 if $ev->{type} == SDL_QUIT;
}
print "SDL_QUIT is: ", SDL_QUIT, "\n";
print "quit noticed: ", ($quit ? "yes" : "no"), "\n";
```

`use SDL2 qw(:all)` imports at **compile time**, so the constants exist before the rest of the file is parsed. A separate `SDL2->import` runs after the whole file has been compiled, so while it was being compiled `SDL_QUIT` without parentheses was not a known function. It parsed as a bareword and became the string `"SDL_QUIT"`:

```
SDL_QUIT is: SDL_QUIT
quit noticed: no
```

The quit event was on the queue and the comparison, against a string that numifies to 0, never matched it. In a real program the window's close button does nothing. `use warnings` adds one line, `Argument "SDL_QUIT" isn't numeric in numeric eq (==)`, and the program still runs on.

`use strict` converts this from a silent wrong answer into a compile error naming the constant. The same file with `use strict;` as its first line:

```
Bareword "SDL_QUIT" not allowed while "strict subs" in use at trap.
↪pl line 9.
Bareword "SDL_QUIT" not allowed while "strict subs" in use at trap.
↪pl line 12.
Execution of trap.pl aborted due to compilation errors.
```

Line 9 is the statement modifier inside the `while` body, reported at the line where that statement starts, as perl5 reports it.

That is the whole argument for `use strict` in one example. Write `use SDL2 qw(:all);` and keep `use strict` on.

The frame loop

A frame is three steps: take an image from the surface, draw into it, present it.

```
my $frame = $surf->next_frame or next;          # no image this time:␣
↪skip
```

(continues on next page)

(continued from previous page)

```
$gpu->render_pass($frame, clear => [0.2, 0.3, 0.5, 1])->end;
$frame->present;
```

A frame is a render target exactly as a texture is: the same `render_pass`, the same recording calls. That is what lets one drawing routine serve both the screen and the checking path above.

`next_frame` returns undef rather than dying when wgpu reports the surface occluded or timed out. That is not an error; skip the frame and come back. When wgpu reports the surface out of date, `next_frame` configures it again with the size it was last given and retries once, which is why a missed resize, below, produces no error at all.

End the pass before presenting. Presenting first is accepted, and the `end` that follows dies, because the image it recorded into is gone:

```
Peta::WebGPU::Pass::end: Validation Error

Caused by:
  In Queue::submit
    In a pass parameter
      Texture with '<Surface Texture>' label has been destroyed
```

Presenting the same frame twice is refused with `this frame has already been presented`.

Pacing

A surface's present mode decides how a frame reaches the screen. The default is `fifo`: it queues each frame for the display's next refresh and never tears, so the loop runs at the display's rate with no sleep anywhere in the program. It is also the one mode WebGPU guarantees every surface supports, so the default never fails. Measured over 120 frames on a 60 Hz display, a surface made as above averaged 16.68 ms per frame, and one made with `present_mode => 'fifo'` spelled out 16.67 ms.

Another mode is asked for by name when the surface is made:

```
my $surf = $gpu->surface(present_mode => 'mailbox');
```

`mailbox` keeps only the newest frame and `immediate` does not wait at all, which can tear. Both returned as fast as the loop could go, under a millisecond per frame. `fifo-relaxed` waits like `fifo` but lets a late frame through at once, at the risk of a tear. A mode the window does not offer is refused, with the ones it does offer in the message.

Colour arrives in sRGB

The surface format above ends in `-srgb`, and that suffix changes the numbers. An `-srgb` target treats what is written to it as linear light and encodes it on the way in, the encoding image files and displays use. The same clear into two formats:

```
format            clear [0.2, 0.4, 0.6]   stored as
rgba8unorm        written as given       51 102 153 255
rgba8unorm-srgb   encoded                124 170 203 255
```

Lighting arithmetic is only correct in linear light, so rendering into an `-srgb` target is the right thing. The consequence is for colours you pick by eye, from an image editor or a web page: those are already encoded, and fed straight in they come out washed out. Decode them first. Raising each component to the power 2.2 is close enough for picking colours: the clear `[ map { $_ ** 2.2 } 0.2, 0.4, 0.6 ]` stores as `48 102 154`.

For the checking path, render into `rgba8unorm-srgb` whenever the image should match what the window shows. `bgra8unorm-srgb` would match too, but `read` returns its bytes in B, G, R, A order.

Window events

The event loop from the *2D guide* is unchanged. Three events matter from the first program on:

```
while (my $ev = SDL_PollEvent()) {
    if ($ev->{type} == SDL_QUIT) { $running = 0 }
    elsif ($ev->{type} == SDL_KEYDOWN && $ev->{sym} == SDLK_ESCAPE)
 ↪{ $running = 0 }
    elsif ($ev->{type} == SDL_WINDOWEVENT
           && $ev->{event} == SDL_WINDOWEVENT_SIZE_CHANGED) {
        $surf->configure($ev->{data1}, $ev->{data2});
    }
}
```

Symptom: after a resize the picture is the wrong size, and nothing reported an error. Cause: the surface was never reconfigured. A window resized from 320x240 to 400x300 kept a 320x240 surface, every frame presented without complaint, and `$surf->size` said `320x240` against the window's `400x300`.

Key the reconfigure on `SDL_WINDOWEVENT_SIZE_CHANGED`, not `SDL_WINDOWEVENT_RESIZED`. A resize made by the program with `$win->set_size(400, 300)` delivered `SIZE_CHANGED` with `data1 = 400`, `data2 = 300`, and no `RESIZED` at all.

`SDL_PushEvent` puts an event on the queue exactly as if a person had caused it, which is how a test drives a program that normally waits for input. Pushed and read back, an Escape key press arrives as `sym = 27, scancode = 41, key_name = Escape`, and a mouse drag as `SDL_MOUSEMOTION` with `x`, `y`, the movement since the last event in `xrel`, `yrel`, and the held buttons in `state`, which is what an orbit camera reads.

Timing: a fixed step

`fifo` paces the frames, but a simulation must not depend on the frame rate: a faster display would make everything move faster. Accumulate the real elapsed time and advance the simulation in fixed steps:

```
use constant { STEP => 16, MAX_STEPS => 5 };   # milliseconds, steps
 ↪per frame
```

(continues on next page)

(continued from previous page)

```
my $now = SDL_GetTicks();
$acc += $now - $last;
$last = $now;
my $steps = 0;
while ($acc >= STEP) {
    update();
    $acc -= STEP;
    if (++$steps >= MAX_STEPS) { $acc = 0; last }
}
```

In a window paced by `fifo`, this ran 205 updates in 3307 ms of real time, and 3307 / 16 is 206.7: the simulation keeps to the clock whatever the frame rate.

The step cap is not optional, and neither is dropping the backlog when the cap is hit. What each part prevents is clearest on a simulated clock, where every frame costs 6 ms of rendering plus the time its updates take. The figures are updates run per frame, in consecutive frames:

```
each update costs 20 ms, more than the 16 ms it simulates:
  no cap              7 9 12 15 19 24 31 39 49 62 77 97 122 153 ...
  cap, keep backlog   6 6 6 6 ...   owed 22, 52, 82 ... 412 ms, and␣
↪growing
  cap, drop backlog   6 6 6 6 ...   owed 0

a 500 ms stall, then updates costing 12 ms:
  no cap              33 25 19 15 11 9 7 6 5 4 3 3 2 ...
  cap, keep backlog   6 6 6 6 ...   owed 436 ms, still 220 ms 12␣
↪frames later
  cap, drop backlog   6 4 4 3 3 2 2 2 2 ...
```

Without a cap, an update slower than its step is a **spiral**: each frame takes longer, owes more steps, and takes longer still, until the program stops responding. A stall on its own is survivable when updates are cheaper than their step, but the first frame after it runs 33 updates, which is a second freeze of almost 400 ms. With a cap but keeping the backlog, frame time is bounded but the simulation fast-forwards for seconds afterwards, working off time that has already passed. Dropping the backlog is the honest answer: after a stall, a breakpoint or a window drag, the simulation loses that time and carries on at normal speed. When every update is slower than its step, it runs slower than real time, which is the only possible outcome, and the window keeps responding.

The whole program

Put together, with an optional frame count so it can run unattended:

```
use strict;
use warnings;
use SDL2 qw(:all);
use Peta::WebGPU;
```

(continues on next page)

(continued from previous page)

```
use constant { STEP => 16, MAX_STEPS => 5 };

my $max_frames = shift // 0;          # 0: run until the window is
↪closed

my $win  = SDL2::Window->new(title => 'pperl gpu', w => 800, h =>
↪600, resizable => 1);
my $gpu  = Peta::WebGPU::Device->new(window => $win);
my $surf = $gpu->surface;
printf "%s via %s, surface %s %s\n", $gpu->info->{name}, $gpu->info-
↪>{backend},
    $surf->format, join('x', $surf->size);

my $phase = 0;                        # the whole simulation state
sub update { $phase += 0.001 * STEP }  # radians per step: one cycle
↪in 6.3 s

sub colour {
    return [ 0.2 + 0.2 * sin($phase), 0.3, 0.5 + 0.2 * cos($phase),
↪1 ];
}

my ($last, $acc, $frames, $running) = (SDL_GetTicks(), 0, 0, 1);
while ($running) {
    while (my $ev = SDL_PollEvent()) {
        if ($ev->{type} == SDL_QUIT) { $running = 0 }
        elsif ($ev->{type} == SDL_KEYDOWN && $ev->{sym} == SDLK_
↪ESCAPE) { $running = 0 }
        elsif ($ev->{type} == SDL_WINDOWEVENT
               && $ev->{event} == SDL_WINDOWEVENT_SIZE_CHANGED) {
            $surf->configure($ev->{data1}, $ev->{data2});
        }
    }

    my $now = SDL_GetTicks();
    $acc += $now - $last;
    $last = $now;
    my $steps = 0;
    while ($acc >= STEP) {
        update();
        $acc -= STEP;
        if (++$steps >= MAX_STEPS) { $acc = 0; last }
    }

    my $frame = $surf->next_frame or next;    # no image this time:
↪skip
    $gpu->render_pass($frame, clear => colour())->end;
    $frame->present;
```

(continues on next page)

(continued from previous page)

```
    $running = 0 if $max_frames && ++$frames >= $max_frames;
}
printf "%d frames, phase %.2f\n", $frames, $phase;
```

```
Intel(R) HD Graphics P530 (SKL GT2) via Vulkan, surface bgra8unorm-
↪srgb 800x600
120 frames, phase 1.94
```

A window whose colour drifts slowly, closing on Escape or the close button. 1.94 radians is 121 steps of 0.016, which is 1936 ms: two seconds of clock for 120 frames at 60 Hz. The simulation followed the clock, not the frame count.

Next

The loop runs and the checking path works. The *next chapter* puts geometry through it: a shader, a vertex buffer, a pipeline and a draw call.

The pipeline: shaders, buffers, and the first triangle

The *software rasteriser* did three jobs per triangle: move the vertices to the screen, decide which pixels are covered, and choose each pixel's colour. On the graphics card the middle job is fixed hardware. The first and last are programs you write, the **vertex shader** and the **fragment shader**, and a **pipeline** binds them to a description of the data they are fed.

This chapter draws one triangle, then the same data through an index buffer, and ends with what the card says when something is wrong.

The shader

Both programs live in one WGSL source:

```
struct VOut {
    @builtin(position) pos: vec4<f32>,
    @location(0) col: vec3<f32>,
};

@vertex
fn vs(@location(0) p: vec2<f32>, @location(1) c: vec3<f32>) -> VOut
↪{
    var o: VOut;
    o.pos = vec4<f32>(p, 0.0, 1.0);
    o.col = c;
    return o;
}

@fragment
fn fs(i: VOut) -> @location(0) vec4<f32> {
    return vec4<f32>(i.col, 1.0);
}
```

`vs` runs once per vertex. Its inputs carry `@location` numbers, which is how the vertex data below finds them, and its output must include a `@builtin(position)`: the vertex in *clip space*, `x, y, z, w`. With `z = 0` and `w = 1` the divide changes nothing, so `x` and `y` here are already normalised device coordinates, -1 to +1 with y up.

`fs` runs once per covered pixel. What it receives is `vs`'s output **interpolated** across the triangle with barycentric weights, exactly as the rasteriser chapter computed them by hand, and perspective-correct without being asked. Its `@location(0)` output is the colour written to the target.

WGSL is strictly typed: `vec2<f32>` is two 32-bit floats, `let` names a value, `var` a variable. There is no double precision; everything the card computes here is `f32`.

`$gpu->shader($source)` compiles it, and a mistake in it is a Perl exception carrying the compiler's message, shown below.

Vertex data

Three vertices, each a position and a colour, packed as 32-bit floats:

```
#                  x     y      r  g  b
my @tri = ( -0.8, -0.8,   1, 0, 0,
             0.8, -0.8,   0, 1, 0,
             0.0,  0.8,   0, 0, 1 );
my $verts = $gpu->vertex_buffer(pack 'f*', @tri);
print $verts->size;                              # 60
```

Fifteen floats of four bytes each. The buffer is bytes on the card and knows nothing of their meaning; the pipeline supplies that.

The pipeline

```
my $pipe = $gpu->render_pipeline($gpu->shader($WGSL),
    vertex => 'vs', fragment => 'fs',
    vertex_buffers => [ { attributes => ['float32x2', 'float32x3'] }␣
↪],
);
```

`vertex_buffers` describes each buffer as a list of attribute formats. The short form above lays them end to end: `float32x2` at `@location(0)`, offset 0; `float32x3` at `@location(1)`, offset 8; and a **stride** of 20 bytes from one vertex to the next. Written out in full, which is necessary only when the layout is not that simple:

```
vertex_buffers => [ {
    stride     => 20,
    attributes => [ { format => 'float32x2', location => 0, offset␣
↪=> 0 },
                    { format => 'float32x3', location => 1, offset␣
↪=> 8 } ],
} ],
```

The format names are WebGPU's own: `float32` to `float32x4`, the `uint32` and `sint32` families, `unorm8x4`, `float16x2`. A name that is not one of them is refused with the

whole list.

The pipeline also fixes the **format** of the target it draws into, `rgba8unorm` unless told otherwise. For a window that must be the surface's format:

```
my $pipe = $gpu->render_pipeline($shader, format => $surf->format, .
↪..);
```

Compiling a pipeline is the expensive step. Build it once, before the frame loop, and use it every frame.

The draw

```
my ($W, $H) = (256, 256);
my $img = $gpu->texture(width => $W, height => $H);
$gpu->render_pass($img, clear => [0.1, 0.1, 0.1, 1])
    ->pipeline($pipe)->vertices($verts)->draw(3)->end;
```

Every recording call returns the pass, so a frame reads as one sentence: this pipeline, these vertices, three of them, done. The order matters in one place only: `pipeline` comes first, because what follows is checked against it.

Read back, the pixels say what was drawn:

```
centre                  63 65 127 255
corner                  26 26 26 255
near bottom-left vertex  246 3 6 255
near bottom-right vertex 3 246 6 255
near top vertex          2 4 249 255
```

The corner is the clear colour, 0.1 as a byte. Each vertex's neighbourhood is almost pure red, green or blue, and the centre is a mix of all three, which is the interpolation at work. Written out with `save_png` from the *previous chapter*, it is the familiar colour-blended triangle, point upwards: NDC's y points up and the texture's top row comes first, the same flip *foundations* made in its screen mapping.

The same pixels as the software rasteriser

The rasteriser chapter filled a triangle with corners at pixel positions `(1,1)`, `(17,2)` and `(6,8)` on a 20 by 10 canvas and printed 54 pixels. Converted to NDC and drawn by the card into a 20 by 10 texture, printing # for every pixel that was written:

```
my @ndc = map { (2 * $_->[0] / 20 - 1, 1 - 2 * $_->[1] / 10) } [1,
↪1], [17,2], [6,8];
```

```
....................
.########...........
..##############....
...###########......
...#########........
....#######.........
```

(continues on next page)

(continued from previous page)

```
.....####..........
......#............
..................
..................
```

54 pixels, identical to the figure the edge function produced, and identical again with the vertex order reversed. The card is running the same inside test at the same pixel centres.

Index buffers

A quad is two triangles sharing an edge. Listing six vertices repeats two of them; an **index buffer** lists each vertex once and says which three make each triangle:

```
my $corners = $gpu->vertex_buffer(pack 'f*',
    -0.5, -0.5,   1, 0.8, 0.2,
     0.5, -0.5,   1, 0.8, 0.2,
     0.5,  0.5,   1, 0.8, 0.2,
    -0.5,  0.5,   1, 0.8, 0.2);
my $quad = $gpu->index_buffer(pack 'L*', 0, 1, 2,  0, 2, 3);

my $sq = $gpu->texture(width => 64, height => 64);
$gpu->render_pass($sq, clear => [0, 0, 0, 1])
    ->pipeline($pipe)->vertices($corners)->indices($quad)->draw_
↪indexed(6)->end;
```

Same pipeline, same vertex layout; only the drawing call changed.

The quad covers 1024 pixels of the 64 by 64 target, which is 32 by 32: half the width and half the height, exactly. `draw_indexed` counts indices, not vertices.

This is the *meshes* chapter's indexed triangle mesh, a vertex array and an index array, going to the card as one buffer each.

Indices are 32-bit by default. Sixteen-bit indices halve the buffer and must be declared, because the bytes alone cannot say which they are:

```
my $q16 = $gpu->index_buffer(pack 'S*', 0, 1, 2, 0, 2, 3);   # 12␣
↪bytes
$gpu->render_pass($sq, clear => [0, 0, 0, 1])
    ->pipeline($pipe)->vertices($corners)->indices($q16, 'uint16')->
↪draw_indexed(6)->end;
```

The same 12 bytes without the `'uint16'` read as three 32-bit indices, and the draw is refused at end: `Index 6 extends beyond limit 3. Did you bind the correct index buffer?`

When something is wrong

Every failure is a Perl exception carrying wgpu's own text, so `eval` traps it and `$@` explains it. A call that succeeds returns its object, which is what makes the chaining above work and `... ->end or die` behave. The exceptions arrive at three places, and knowing which saves time.

At `shader`: the WGSL does not compile. The message points into the source by line and column:

```
shader compilation failed: Validation Error

Caused by:
  In Device::create_shader_module

Shader '' parsing error: expected `;`, found "return"
   ┌─ wgsl:11:5
   │
11 │     return o;
   │     ^^^^^^ expected `;`
```

The missing semicolon was at the end of `o.col = c` on line 10; the parser noticed on line 11. Line numbers count from the first line of the WGSL string, not of the Perl file. A type error names the entry point, here `fs` returning a `vec3` where it declared a `vec4`:

```
Shader validation error: Entry point fs at Fragment is invalid
```

At `render_pipeline`: the shader does not fit the description. An entry point name that is not in the shader, or a shader input no buffer supplies:

```
Unable to find entry point 'vertex_main'
```

```
Location[1] Float32x3 interpolated as Some(Perspective) with␣
↪sampling
Some(Center) is not provided by the previous stage outputs
```

The second is what a `vertex_buffers` list with only `float32x2` in it produces for this shader: nothing feeds `@location(1)`.

At `end`: the recording was inconsistent. Mistakes made while recording are collected and reported when the pass is submitted, so the exception comes from `end` even though the call at fault was earlier. The message names the command:

mistake	the message ends with
draw with no vertices call	`requires vertex buffer 0 to be set`
draw(6) on a three-vertex buffer	`Vertex 6 extends beyond limit 3`
pipeline format differs from the target	`the RenderPass uses textures with formats [Some(Bgra8UnormSrgb)] but the RenderPipeline ... uses attachments with formats [Some(Rgba8Unorm)]`
a shader var<uniform> never bound	`expects a BindGroup to be set at index 0`

The format row is the one every windowed program hits once: a pipeline built with the default `rgba8unorm`, drawn into a frame whose surface is `bgra8unorm-srgb`.

The one that says nothing

Symptom: the triangle is the wrong shape, or its colours are wrong, and nothing raised an exception. Cause: a vertex format with fewer components than the shader's input. WebGPU allows it deliberately and fills in the missing components, so the layout `['float32x2', 'float32x2']` for this shader's `vec2` and `vec3` inputs is accepted. Its computed stride is 16 bytes instead of 20, so every vertex after the first is read from the wrong place. On a 64 by 64 target the correct layout covered 1352 pixels with a blue-grey centre, `63 67 125`; the short one covered 1146 pixels with a green centre, `22 62 0`.

The layout and the `pack` template describe the same bytes twice. When a picture is nearly right, compare the two before suspecting anything else.

Next

The triangle's corners were already in clip space. The *next chapter* feeds the card model coordinates and the matrices from *foundations*, and brings back the depth buffer, culling and lighting of the software arc.

A 3D scene on the GPU: matrices, depth, and light

The *previous chapter* handed the card positions already in clip space. This one hands it model coordinates and the matrices from *foundations*, and brings back, on the card, everything the software arc built by hand: the *depth buffer*, back-face culling, and the lighting model from *shading*, evaluated per pixel.

The examples use the vector and matrix subs from foundations unchanged: `v_add`, `v_sub`, `v_scale`, `v_dot`, `v_cross`, `v_norm`, `m_mul`, `m_translate`, `m_scale`, `m_rotate_y`, `m_look_at`, `m_perspective` and `xform`. The complete program at the end loads them from a file.

Matrices as uniforms

A value that is the same for every vertex of a draw is a **uniform**. The shader declares it, and a uniform buffer supplies it:

```
@group(0) @binding(0) var<uniform> mvp: mat4x4<f32>;

@vertex fn vs(@location(0) p: vec3<f32>) -> @builtin(position) vec4
 ↪<f32> {
    return mvp * vec4<f32>(p, 1.0);
}
```

```
my $mvp = m_mul($proj, m_mul($view, $model));
my $ub  = $gpu->uniform_buffer(pack 'f16', @$mvp);

$gpu->render_pass($img, clear => [0, 0, 0, 1])
    ->pipeline($pipe)->bind([$ub])->vertices($vb)->draw($n)->end;
```

`bind` takes a list of buffers for `@group(0)`, in binding order: `[$a, $b]` supplies `@binding(0)` and `@binding(1)`. It comes after `pipeline`, because the pipeline read the shader and knows what each binding has to be.

No transposing. Foundations stores matrices column by column, element `m[col * 4 + row]`, and WGSL's `mat4x4<f32>` is column-major too, so `pack 'f16', @$m` is already the layout the shader reads, and `mvp * v` in WGSL is `xform($mvp, $v)` in Perl.

That is checkable to the pixel. Five points drawn with `topology => 'point-list'`, each lighting one pixel of an 800x600 target, against foundations' own screen mapping of the same points, with the camera at `[0, 0, 5]`:

```
point           Perl screen position   pixel the card lit
[0,0,0]         (400.00, 300.00)       (399,299)
[1,0,-1]        (486.60, 300.00)       (486,299)
[1,0,-8]        (439.97, 300.00)       (439,299)
[-1.5,1,0]      (244.12, 196.08)       (244,196)
[0.7,-1.2,2]    (521.24, 507.85)       (521,507)
```

Every coordinate strictly inside a pixel matches. The three points whose predicted y is exactly 300.00 sit on the boundary between rows 299 and 300, and the card chose 299: a tie on a pixel edge, not an error. The first point is foundations' own "dead centre of an 800x600 window".

That check needed one more matrix than foundations used, for the reason below.

WebGPU's depth range

OpenGL, whose conventions foundations follows, keeps a point when `-w <= z <= w` in clip space, so normalised depth runs from -1 to +1. WebGPU keeps it when `0 <= z <= w`: depth runs from 0 to 1. Everything foundations' projection sends to negative depth, the card throws away.

Symptom: objects close to the camera vanish, well before they reach the near plane. Cause: an OpenGL-style projection matrix on WebGPU. With `near = 0.1` and

`far = 100`, a small square drawn at decreasing distances, its size on screen held constant:

```
distance   foundations' ndc.z   pixels drawn   remapped ndc.z   pixels drawn
5            0.962                100            0.981            100
0.5          0.602                100            0.801            100
0.21         0.049                100            0.524            100
0.19        -0.052                  0            0.474            100
0.15        -0.333                  0            0.334            100
0.12        -0.666                  0            0.167            100
```

The cut-off is where `ndc.z` crosses zero, at `2 * far * near / (far + near)`, which is 0.1998: about **twice** the near distance. Geometry between the near plane and there is silently lost, and for a camera walking through a scene that is everything within arm's reach.

Keep foundations' projection and convert its output with one more matrix, which maps `z` to `(z + w) / 2`:

```
# OpenGL clip space keeps -w <= z <= w, WebGPU keeps 0 <= z <= w.
my $gl_to_wgpu = [1,0,0,0,  0,1,0,0,  0,0,0.5,0,  0,0,0.5,1];

my $proj = m_mul($gl_to_wgpu, m_perspective(60, 4/3, 0.1, 100));
```

Only depth changes. `x`, `y` and `w` are untouched, so every screen position in foundations still holds, as the point table above shows. Foundations' example point at depth 5 goes from `ndc.z = 0.962` to `0.981`.

Changing uniforms

`$buf->write($bytes)` replaces a buffer's contents, and the next pass sees the new values. Writing once per frame, before the pass, is how a camera moves.

Symptom: several objects drawn in one pass all appear where the last one should be. Cause: one uniform buffer rewritten between the draws. The writes are applied before the pass runs, so every draw in it sees the last value. Two squares, one uniform, rewritten between two draws:

```
one buffer rewritten:  left half 0 px, right half 144 px
one buffer per object: left half 144 px, right half 144 px
```

Give each object its own buffer and `bind` it before its draw, or use instancing, below, which is one draw for all of them.

Symptom: a uniform value is shifted, or reads as zero. Cause: WGSL aligns a `vec3<f32>` to 16 bytes, not 12. In `struct U { a: vec3<f32>, b: vec3<f32> }`, `b` starts at byte 16, so `pack 'f6'` puts b's first component into padding:

```
packed tight   pack 'f8', a, b, 0, 0        b reads as 0 0 0
padded         pack 'f8', a, 0, b, 0        b reads as 255 0 0
```

A buffer smaller than the struct is refused at `bind`, with `Binding size 24 of Buffer ... is less than minimum 32`, but a misaligned one of the right size is accepted. The

reliable rule is to use `vec4<f32>` in uniform structs and leave the fourth component unused, as every struct in this chapter does.

The depth buffer

The *rasteriser chapter* kept the nearest depth per pixel and skipped anything further. On the card that is two settings, and both are needed:

```
my $pipe  = $gpu->render_pipeline($shader, depth => 1, ...);
my $depth = $gpu->depth_buffer($W, $H);

$gpu->render_pass($target, clear => [0.05, 0.05, 0.08, 1], depth =>
 ↪$depth)
    ->pipeline($pipe) ... ->end;
```

`depth => 1` on the pipeline makes it test and write depth; `depth => $depth` on the pass supplies the buffer. The pass clears it to 1.0, the far end of WebGPU's range, and the test keeps a fragment only when it is nearer than what is there: the rasteriser's `next if $z >= $t->{depth}[$y][$x]`, in hardware.

Either half alone is refused at end, naming the mismatch:

```
Incompatible depth-stencil attachment format: the RenderPass uses a
texture with format None but the RenderPipeline with '' label uses␣
 ↪an
attachment with format Some(Depth32Float)
```

The depth buffer must be the size of the target. After a resize, make a new one; the old one is refused with `Attachments have differing sizes`.

Nine cubes in three rows, rendered into a 320x240 texture, show what it buys. Drawn back row first, the scene comes out identical with the depth buffer and without it, because that order happens to be the painter's algorithm done right. Drawn front row first:

```
front row first, depth buffer on    identical to back row first
front row first, depth buffer off   3007 pixels differ
```

The far cubes paint over the near ones, the *rasteriser chapter's* second figure in full colour. With the depth buffer the order of the draws stops mattering, which is the whole point.

A mesh: the cube

A cube has 8 corners but needs 24 vertices here: each face has its own normal, and a vertex carries one normal, so a corner shared by three faces is three vertices. That is the flat-faces case from *shading*; a smooth surface shares its vertices instead.

Each face is described by its normal and two in-plane axes, chosen so that `u x v` is the normal. Then its corners, taken in the order below, wind counter-clockwise seen from outside, and the cross product checks it while building:

```
my @FACES = (
    # normal       u (right)     v (up)      u x v == normal
    [[ 1, 0, 0], [ 0, 0,-1], [0, 1, 0]],
    [[-1, 0, 0], [ 0, 0, 1], [0, 1, 0]],
    [[ 0, 1, 0], [ 1, 0, 0], [0, 0,-1]],
    [[ 0,-1, 0], [ 1, 0, 0], [0, 0, 1]],
    [[ 0, 0, 1], [ 1, 0, 0], [0, 1, 0]],
    [[ 0, 0,-1], [-1, 0, 0], [0, 1, 0]],
);
my (@vert, @idx);
for my $f (@FACES) {
    my ($n, $u, $v) = @$f;
    die "face winds the wrong way\n" unless v_dot(v_cross($u, $v),
 ↪$n) > 0;
    my $base = @vert / 6;
    for my $c ([-1,-1], [1,-1], [1,1], [-1,1]) {
        my $p = v_add(v_scale($n, 0.5),
                      v_add(v_scale($u, 0.5 * $c->[0]), v_scale($v,␣
 ↪0.5 * $c->[1])));
        push @vert, @$p, @$n;
    }
    push @idx, map { $base + $_ } 0, 1, 2, 0, 2, 3;
}
# 24 vertices of six floats, 36 indices

my $verts = $gpu->vertex_buffer(pack 'f*', @vert);
my $index = $gpu->index_buffer(pack 'L*', @idx);
```

The vertex layout is `['float32x3', 'float32x3']`: position at `@location(0)`, normal at `@location(1)`.

Back-face culling

```
my $pipe = $gpu->render_pipeline($shader, cull => 'back', ...);
```

`cull => 'back'` discards every triangle whose front faces away. Which side is the front is `front_face`: `ccw`, the default, means counter-clockwise as the viewer sees it, which is how the cube above was built. This is the rasteriser chapter's signed-area test, done by the card before any pixel work.

On the nine-cube scene:

```
cull => 'none'                          identical to cull => 'back'
cull => 'back', front_face => 'cw'   22508 of 76800 pixels differ
```

On a closed mesh behind a depth buffer, culling changes nothing visible: the back faces it removes would have lost the depth test anyway. That identity is the test the *world generator* applies with its `--no-cull` option. It is also why a wrong winding convention is so visible: with `front_face => 'cw'` the card keeps exactly the faces that point away, and each cube renders as its own dark interior.

Symptom: a model renders dark and inside out. Cause: its winding and the pipeline's

`front_face` disagree. The model may have been authored the other way round, or its model matrix may contain a reflection: the same scene with every cube mirrored by `m_scale(-1, 1, 1)` differed in the same 22508 pixels under `cull => 'back'`, and `front_face => 'cw'` restored it exactly. A reflection reverses winding, the same fact the world generator's y-flip ran into.

Instancing

Nine cubes are the same 36 indices nine times with a different model matrix. Drawing them as nine draws works, but one draw can do it, with an instance count after the index count:

```
$gpu->render_pass($target, clear => [0.05, 0.05, 0.08, 1], depth =>
 ↪$depth)
    ->pipeline($pipe)->bind([$scene, $instances])
    ->vertices($verts)->indices($index)->draw_indexed(36, 9)->end;
```

The shader tells the instances apart by `@builtin(instance_index)`, 0 to 8, and reads per-instance data from a storage buffer:

```
struct Instance {
    model:  mat4x4<f32>,
    colour: vec4<f32>,
};
@group(0) @binding(1) var<storage, read> inst: array<Instance>;

@vertex
fn vs(@location(0) p: vec3<f32>, @location(1) n: vec3<f32>,
      @builtin(instance_index) i: u32) -> VOut {
    let m = inst[i].model;
    ...
}
```

```
my @inst;
for my $k (0 .. 8) {
    my ($gx, $gz) = ($k % 3 - 1, int($k / 3) - 1);
    my $model = m_mul(m_translate(1.8 * $gx, 0, 1.8 * $gz), m_
 ↪rotate_y(0.35 * $k));
    push @inst, @$model, @{ $COLOUR[$k % 3] }, 1;
}
my $instances = $gpu->storage_buffer(pack 'f*', @inst);    # 9 x 80␣
 ↪bytes
```

Each instance is 20 floats, a matrix and a `vec4` colour, 80 bytes, with no padding to think about because both members are multiples of 16 bytes. Moving the cubes is one `write` of 720 bytes per frame.

Declare the storage buffer `read`. A vertex shader may not write to storage, and `read_write` there is refused when the pipeline is built: `Features ... (VERTEX_WRITABLE_STORAGE) are required but not enabled`.

Lighting per fragment

Shading ended on its rule: interpolate the inputs, not the answer. The vertex shader passes the fragment shader a world position and a normal, the card interpolates both, and the lighting runs once per pixel:

```
@fragment
fn fs(v: VOut) -> @location(0) vec4<f32> {
    let n = normalize(v.normal);
    let l = normalize(scene.light_dir.xyz);
    let e = normalize(scene.eye.xyz - v.world);
    let lambert = max(dot(n, l), 0.0);
    let h = normalize(l + e);
    let spec = pow(max(dot(n, h), 0.0), 32.0);
    let c = v.colour * (0.1 + 0.9 * lambert) + vec3<f32>(0.4) *
↪spec;
    return vec4<f32>(min(c, vec3<f32>(1.0)), 1.0);
}
```

Line for line it is shading's model: the Lambert term clamped at zero, the ambient `0.1 + 0.9 * lambert`, the Blinn-Phong halfway vector with the dot product clamped before the power. `light_dir` points from the surface toward the light and `e` from the surface toward the eye, the conventions shading fixed.

The first `normalize` is not optional. Interpolating between two unit vectors gives a vector shorter than 1 in between, and an unnormalised normal scales the lighting silently.

To check the arithmetic rather than the picture, render into a floating-point target and read the numbers themselves. A pipeline and texture with `format => 'rgba32float'` store four `f32` per pixel, and `unpack 'f4'` reads them. A fragment shader writing `vec4<f32>(lambert, spec, 0.0, 1.0)` for a surface facing the viewer reproduces shading's tables:

```
light off the normal   lambert        shininess   specular   Perl,
↪double
0 deg                  1.000          1           0.965926   0.
↪965926
30 deg                 0.866          8           0.757793   0.
↪757792
60 deg                 0.500          32          0.329763   0.
↪329762
90 deg                 0.000          128         0.011825   0.
↪011825
180 deg                0.000
```

The specular column has the light 30 degrees off and the viewer straight on, so the halfway vector is 15 degrees off the normal. The card and Perl's `cos(15 deg) ** $shininess` agree to the sixth decimal, and differ there because WGSL computes in `f32`.

Normals and the model matrix

The vertex shader turns the normal with `(m * vec4<f32>(n, 0.0)).xyz`. The `0.0` makes it a direction: the translation column is multiplied by zero, so moving an object does not bend its normals.

That is correct for rotation, translation and uniform scale, which is all this chapter uses. Under a **non-uniform** scale it is wrong. A face with normal `(1, 1, 0)` and in-plane direction `(1, -1, 0)`, scaled by `(1, 3, 1)`: the in-plane direction becomes `(1, -3, 0)` and the transformed normal `(1, 3, 0)`, and their dot product is -8, so the "normal" no longer stands at right angles to its own surface. Turned by the inverse transpose of the scale instead, the normal is `(1, 1/3, 0)`, and the dot product is 0. A model matrix with non-uniform scale needs that inverse-transpose matrix passed alongside it.

Colours in linear light

The window's surface is an `-srgb` format, as the *device chapter* measured, so what the fragment shader writes is encoded on the way to the screen. The lighting above is therefore computed in linear light, which is correct, and the base colours, picked by eye, are decoded before upload:

```
my @COLOUR = map { [ map { $_ ** 2.2 } @$_ ] }       # picked by eye: decode
             [0.9, 0.3, 0.2], [0.3, 0.8, 0.3], [0.3, 0.4, 0.9];
```

Left encoded, the same scene renders pale and washed out. The headless renders in this chapter use an `rgba8unorm-srgb` texture for the same reason, so the image read back is the image the window shows.

The whole scene

Nine lit cubes turning on a grid, in a resizable window, with the fixed step from the *device chapter*. The subs from foundations are in `foundations.pl` beside it, followed by a line `1;`.

```
use strict;
use warnings;
use SDL2 qw(:all);
use Peta::WebGPU;
BEGIN { require './foundations.pl' }   # the v_* and m_* subs, then 1;

use constant { STEP => 16, MAX_STEPS => 5 };
my $max_frames = shift // 0;

my $WGSL = <<'WGSL';

`draw` takes its target as an argument, so the same routine renders into a texture for checking. A texture with `format => $surf->format` and the same size as the depth buffer is all it needs; with `bgra8unorm-srgb`, remember that `read` returns B, G, R, A. Run in a window that was resized from 800x600 to 640x480 while it ran, the depth buffer was recreated at the new size and the frames carried on.

What this arc covers

The card receives meshes as vertex and index buffers, transforms them with foundations' matrices, resolves visibility with a depth buffer, culls back faces, draws many objects in one call, and lights every pixel with shading's model. Every stage of the software arc has its hardware counterpart, and each was checked against the software version: the same 54 pixels, the same screen positions, the same lighting numbers.

The capstones put it to work on complete programs: an *interactive modeller*, which adds the orbit camera and picking from *scene graphs*, and a *small 3D game*.

Capstone: a procedural world generator

A program that invents a landscape and draws it. Three stages turn noise into terrain, and each is written three times: as plain Perl loops, as PDL whole-array expressions, and as WGSL compute shaders. `--mesh all` runs all three on every launch and prints how far they disagree, so the comparison is known to be measuring one algorithm rather than three.

Everything after those stages is the plain Perl from this guide's earlier chapters: the mesh from *meshes*, the camera and rasteriser from *software-rasteriser*, the Lambert term from *shading*, the writer from *model-formats*.

```
world   512x512 grid, 6 octaves, 12 erosion passes, seed 1234
gpu     Quadro M2000M (Vulkan)

  backend   terrain   erosion   normals  readback     total  speedup
  perl      1.033s    4.945s    0.221s    0.000s    6.198s     1.0x
  pdl       0.253s    0.304s    0.017s    0.033s    0.607s    10.2x
  gpu       0.002s    0.004s    0.004s    0.034s    0.043s   145.2x

  agree   perl vs pdl   max dh = 0.00e+00   max dn.x = 0.00e+00
  agree   perl vs gpu   max dh = 2.95e-07   max dn.x = 1.26e-05
```

PDL and plain Perl agree to the last bit, because both compute in `double`. The GPU differs in the seventh decimal, because WGSL storage buffers here are `f32`. That is the expected difference, and it is worth printing rather than assuming: a backend that has silently diverged shows up here as a large number instead of a small one.

Three stages, one shape

Stage	Input	Output	Per cell
terrain	noise lattice	height	sum N octaves of bilinear samples
erosion	height	height	compare 8 neighbours
normals	height	3 components	4 neighbours, one `sqrt`

Each produces one value per grid cell from a fixed neighbourhood, with no cell depending on another cell's result within the same pass. That is the shape a compute shader exists for, the shape PDL expresses without a loop, and the shape the JIT compiles well. It is why one algorithm can have three implementations that agree to the bit.

The renderer is deliberately not in that list. Rasterising is a scatter: triangles write to overlapping pixels and the Z-buffer arbitrates. It stays in Perl, and at 512 it costs `4.10s` against the field stages' `0.043s`.

One lattice, three backends

The noise lattice is built once, in Perl, and handed to whichever backend runs:

```
srand $o{seed};
my @LAT = map { rand() } 0 .. $R * $R - 1;
```

Invariant: every backend consumes byte-identical input. A shader that generated its own noise from an integer hash would produce a different field from the Perl one, and "the three agree" would be untestable. This also removes the portability trap in hash-based noise: `sin`-based hashes differ between drivers, so terrain generated on one GPU would not reproduce on another.

Terrain: octaves of value noise

Good terrain sums several **octaves**, each at twice the frequency and half the amplitude of the last, which is **fractal Brownian motion**. Each octave bilinearly samples the lattice with a smoothstep fade.

```
struct P { n: u32, r: u32, oct: u32, pad: u32, base: f32, p1: f32,␣
 ↪p2: f32, p3: f32 };
@group(0) @binding(0) var<storage, read_write> lat: array<f32>;
@group(0) @binding(1) var<uniform> p: P;
@group(0) @binding(2) var<storage, read_write> out: array<f32>;

// NOT `smooth`: that is a reserved word in WGSL and the shader will␣
 ↪not compile.
fn fade(t: f32) -> f32 { return t * t * (3.0 - 2.0 * t); }

fn cell(ix: i32, iy: i32, r: i32) -> f32 {
    return lat[u32((iy % r) * r + (ix % r))];
}
```

(continues on next page)

(continued from previous page)

```
@compute @workgroup_size(8, 8)
fn main(@builtin(global_invocation_id) id: vec3<u32>) {
    if (id.x >= p.n || id.y >= p.n) { return; }   // grid need not␣
↪divide by 8
    let r = i32(p.r);
    var sum: f32 = 0.0; var amp: f32 = 1.0; var freq: f32 = 1.0; var␣
↪norm: f32 = 0.0;
    for (var o: u32 = 0u; o < p.oct; o = o + 1u) {
        // The per-octave offset decorrelates the octaves. Without␣
↪it they
        // sample the same lattice cells and the sum has visible␣
↪structure.
        let px = f32(id.x) / f32(p.n) * p.base * freq + f32(o) * 17.
↪0;
        let py = f32(id.y) / f32(p.n) * p.base * freq + f32(o) * 17.
↪0;
        let ix = i32(floor(px)); let iy = i32(floor(py));
        let a = cell(ix, iy, r);         let b = cell(ix + 1, iy,␣
↪r);
        let c = cell(ix, iy + 1, r);     let d = cell(ix + 1, iy +␣
↪1, r);
        let ux = fade(px - floor(px));   let uy = fade(py -␣
↪floor(py));
        let lo = a + (b - a) * ux;
        let hi = c + (d - c) * ux;
        // Ridged: fold EACH octave, never the sum. Squaring␣
↪sharpens crests.
        let r = 1.0 - abs(2.0 * (lo + (hi - lo) * uy) - 1.0);
        sum = sum + amp * r * r;
        norm = norm + amp;
        amp = amp * 0.5; freq = freq * 2.0;
    }
    out[id.y * p.n + id.x] = sum / norm;
}
```

The bounds check is not optional. A dispatch covers whole workgroups, so a 100-cell grid with `workgroup_size(8)` runs 104 invocations per axis and the last four would write past the buffer.

The fold is what makes ridges, and it must be applied per octave. `1 - |2v - 1|` reflects a noise value about its midpoint, turning a smooth hill into a crease; squaring it sharpens the crest. Doing that to each octave and then summing gives ridgelines at every scale.

Folding the **sum** instead is a trap worth naming, because the code looks almost identical and the output looks plausible until you measure it. The sum of six octaves, normalised by their total amplitude, is a weighted average of six independent samples, so by the central limit theorem it clusters tightly around 0.5, and 0.5 is exactly where the fold peaks. The commonest value therefore maps to the *maximum* height. The result is a plateau with dips punched in it rather than mountains, and the height histogram gives it away at once:

```
folding the sum      0:0%  1:2%  2:3%  3:6%  4:9% 5:12% 6:18% 7:22%
 ↪8:19% 9:8%
folding each octave  0:3% 1:10% 2:15% 3:17% 4:17% 5:15% 6:12%  7:7%
 ↪8:3% 9:1%
```

The second is what terrain looks like: much low ground, a thin tail of peaks. `--histogram` prints this for any run.

Erosion: the same pass three ways

Raw fractal noise looks synthetic because real landscapes have been worn. **Thermal erosion** is the cheapest correction: material sitting at a steeper angle than the rock holds slides to lower neighbours. The talus angle is that steepest held slope.

Plain Perl states it directly:

```
for my $pass (1 .. $EROSION) {
    my @n = @h;
    for my $y (0 .. $N - 1) {
        my $ym = $y > 0 ? $y - 1 : 0;
        my $yp = $y < $N - 1 ? $y + 1 : $N - 1;
        for my $x (0 .. $N - 1) {
            my $xm = $x > 0 ? $x - 1 : 0;
            my $xp = $x < $N - 1 ? $x + 1 : $N - 1;
            my $c = $h[$y * $N + $x];
            my $moved = 0;
            for my $yy ($ym, $y, $yp) {
                for my $xx ($xm, $x, $xp) {
                    next if $xx == $x && $yy == $y;
                    my $d = $c - $h[$yy * $N + $xx];
                    $moved += ($d - $TALUS) * $RATE if $d > $TALUS;
                }
            }
            $n[$y * $N + $x] = $c - $moved;
        }
    }
    @h = @n;
}
```

PDL replaces the two inner loops with eight whole-array expressions. The neighbour lookup is the part worth getting right: pad the field once with edge replication, then read each neighbour as a **lazy slice** of the padded copy. A slice is a view, so a pass costs one padded copy rather than one copy per neighbour.

```
sub padded {
    my ($P) = @_;
    my $E = $N + 1;
    my $Q = zeroes($N + 2, $N + 2);
    $Q->slice("1:$N,1:$N")   .= $P;
    $Q->slice("0:0,1:$N")    .= $P->slice("0:0,:");        # left
 ↪column
```

(continues on next page)

(continued from previous page)

```
    $Q->slice("$E:$E,1:$N")  .= $P->slice("-1:-1,:");      # right
↪column
    # Rows 1 and N already carry the correct left and right edges,
↪so
    # copying them outward fills the top and bottom rows AND the
↪corners.
    $Q->slice("0:$E,0:0")    .= $Q->slice("0:$E,1:1");
    $Q->slice("0:$E,$E:$E")  .= $Q->slice("0:$E,$N:$N");
    return $Q;
}

sub nbr {
    my ($Q, $dx, $dy) = @_;
    return $Q->slice(sprintf "%d:%d,%d:%d", 1+$dx, $N+$dx, 1+$dy,
↪$N+$dy);
}

for my $pass (1 .. $EROSION) {
    my $Q = padded($Hp);
    my $moved = zeroes($N, $N);
    for my $dy (-1, 0, 1) {
        for my $dx (-1, 0, 1) {
            next if $dx == 0 && $dy == 0;
            # lclip(0) is the branchless `if (d > talus)`:
↪everything at or
            # below the talus angle contributes exactly zero.
            $moved += (($Hp - nbr($Q, $dx, $dy)) - $TALUS)->lclip(0)
↪* $RATE;
        }
    }
    $Hp = $Hp - $moved;
}
```

The two Perl-level loops that remain run 8 times per pass, not `8 * N * N` times. That is the whole PDL technique: the loop nest moves from Perl into one C pass per expression.

The shader keeps the neighbour loop, because on the GPU it runs inside a single invocation that is already one of `N * N` running at once:

```
fn at(x: i32, y: i32, n: i32) -> f32 {
    return src[u32(clamp(y, 0, n - 1) * n + clamp(x, 0, n - 1))];
}

@compute @workgroup_size(8, 8)
fn main(@builtin(global_invocation_id) id: vec3<u32>) {
    let n = i32(p.n);
    if (id.x >= p.n || id.y >= p.n) { return; }
    let x = i32(id.x); let y = i32(id.y);
    let h = at(x, y, n);
    var moved: f32 = 0.0;
```

(continues on next page)

(continued from previous page)

```
    for (var dy: i32 = -1; dy <= 1; dy = dy + 1) {
        for (var dx: i32 = -1; dx <= 1; dx = dx + 1) {
            if (dx == 0 && dy == 0) { continue; }
            let d = h - at(x + dx, y + dy, n);
            if (d > p.talus) { moved = moved + (d - p.talus) * p.
↪rate; }
        }
    }
    dst[u32(y * n + x)] = h - moved;
}
```

Invariant: `src` and `dst` must be different buffers. Invocations run in an undefined order, so a shader that updated the grid in place would have each cell reading a mixture of this pass's and last pass's neighbours. The result is not merely noisy, it is non-deterministic between runs. Note that the Perl version obeys the same rule for the same reason, with `my @n = @h`.

The Perl side alternates them, which is the standard **ping-pong**:

```
for my $i (1 .. $EROSION) {
    my ($s, $d) = ($i % 2) ? ($bufA, $bufB) : ($bufB, $bufA);
    $gpu->compute($erode, 'main', [$s, $pe, $d], $g, $g);
}
my $final = ($EROSION % 2) ? $bufB : $bufA;      # parity decides
↪which holds it
```

Buffers bind in the order given, so `[$s, $pe, $d]` supplies bindings 0, 1 and 2. The dispatch is two-dimensional because the workgroup is: `$g` is `ceil(N/8)` on each axis.

Symptom: the terrain differs slightly between identical runs. Cause: a compute shader reading and writing one buffer.

Normals: analytic, not accumulated

The *meshes chapter* computes vertex normals by accumulating face normals into the vertices that share them. That is correct for arbitrary geometry, but it is a **scatter**: several faces add into one vertex, so the order matters and the operation does not parallelise without atomics.

A heightfield does not need it. The surface is a function of `x` and `z`, so the normal follows from the slope by central differences:

```
n = normalize(-dh/dx, 1, -dh/dz)
```

That is a **gather**: each vertex reads its four neighbours and writes only itself. Choosing this formulation is what lets the third stage be the same algorithm in all three backends.

```
my $dx = ($h[$y * $N + $xp] - $h[$y * $N + $xm]) / (($xp - $xm) *
↪$S);
my $dz = ($h[$yp * $N + $x] - $h[$ym * $N + $x]) / (($yp - $ym) *
↪$S);
```

(continues on next page)

(continued from previous page)

```
my $l = sqrt($dx * $dx + 1 + $dz * $dz);
my $i = $y * $N + $x;
$nx[$i] = -$dx / $l; $ny[$i] = 1 / $l; $nz[$i] = -$dz / $l;
```

Interior cells span `2 * S` between neighbours; clamped edge cells span only `S`. Rather than special-case the border, PDL builds the divisor as a field so the expression stays branchless:

```
my $wx = zeroes($N, $N) + 2 * $S;
$wx->slice("0:0,:") .= $S; $wx->slice("-1:-1,:") .= $S;
```

Getting the answer back

At 512 the GPU spends `0.010s` computing and `0.034s` returning the result. **Readback, not compute, is the cost of using a GPU for this.** Three rules follow, and they are what makes that `0.034s` rather than seconds.

Transfer in bulk, never per element. One `unpack` over the whole buffer, never a loop of accessors:

```
my @nx = unpack 'f*', $nb[0]->read;
```

The same rule applies coming out of PDL. A piddle's data slab is reachable as a string, and reading it in one go beats looping with `at` by 7.6x at `512 * 512`:

```
sub unpiddle { return unpack 'd*', ${ $_[0]->sever->get_dataref } }
```

Give each output its own buffer. The shader writes `nx`, `ny` and `nz` to three storage buffers rather than one interleaved `xyzxyz` buffer, so each comes back as one `unpack`. De-interleaving in Perl is an `N * N` loop, and at `1024 * 1024` it costs `0.232s` against a `0.002s` dispatch.

The same trick works in the other direction. This program's renderer wants Perl arrays, so it stops at the `unpack`. When the destination is a piddle instead, assign the raw buffer straight into its data slab rather than building a list on the way; that moves 3 MB in `0.003s`:

```
my $G = zeroes(float, 3, $N, $N);
my $ref = $G->get_dataref;
$$ref = $raw;
$G->upd_data;
```

Materials and light

Picking a colour by height alone produces a relief map, not a landscape. Three corrections turn one into the other, and each is visible the moment it is missing.

Blend across a band, do not switch at a point. A hard threshold draws a contour line wherever two materials meet. Interpolating with a smoothstep over a narrow band removes it:

```
my $t = smoothstep(($h - $b + $BLEND) / (2 * $BLEND));
@c = map { $MATC[$i][$_] + ($MATC[$i+1][$_] - $MATC[$i][$_]) * $t }
 ↪0..2;
```

Let steepness override altitude. A cliff is bare rock at any height. Without this every band follows an exact contour and the terrain reads as stacked cut-outs. The surface normal already carries the answer: `n.y` is 1 on flat ground and 0 on a vertical face.

```
my $steep = smoothstep((0.80 - $ny) / 0.35);
return map { $c[$_] + ($ROCK->[$_] - $c[$_]) * $steep } 0..2;
```

Put the boundaries at percentiles, not at fixed heights. Which heights count as "high" depends on the terrain, and a fixed cut point that suits one seed strands another entirely above or below it. Taking the 15th, 50th and 85th percentiles of the actual field keeps the palette balanced whatever the generator produces:

```
my @bin = (0) x 256;
$bin[ int((($_ - $lo) / $span) * 255.999) ]++ for @h;
my ($acc, $j) = (0, 0);
for my $i (0 .. 255) {
    $acc += $bin[$i];
    while ($j <= $#PCT && $acc >= $PCT[$j] * @h) { $BOUND[$j++] = $i
 ↪/ 255 }
}
```

For light, **a low sun is what gives a landscape its relief.** Near the zenith every upward-facing triangle returns almost the same Lambert term and the terrain flattens into a white sheet; `--sun-elevation 80` demonstrates this. A dim cool fill from the sky hemisphere then keeps faces turned away from the sun as blue shadow rather than flat grey:

```
my $sky = 0.5 + 0.5 * $n->[1];
my @col = map {
    my $c = $base[$_] * (0.10 + 0.78 * $lam) + $SKY[$_] * 0.20 *
 ↪$sky;
    $c > 255 ? 255 : int $c;
} 0 .. 2;
```

Choosing a backend

Situation	Use
the grid is small, or the code must run anywhere	`perl`
the work is array arithmetic and stays in the process	`pdl`
the same small operation runs over a very large grid	`gpu`
the result is consumed cell by cell in Perl	`pdl`, and keep it in the piddle

The `145.2x` in the opening table is over plain Perl. Against PDL the GPU is `14.1x`, and `0.034s` of its `0.043s` is transfer.

The crossover is lower than it looks, because the GPU's cost is almost all fixed:

grid	perl	pdl	gpu
32	0.086s	**0.006s**	0.014s
64	0.170s	**0.009s**	0.014s
96	0.302s	0.018s	**0.015s**
128	0.474s	0.040s	**0.018s**
192	0.938s	0.073s	**0.017s**
512	6.198s	0.607s	**0.043s**

The GPU column barely moves from 32 to 192 while the grid grows 36-fold: up to a few hundred thousand cells the dispatch is free and the time is latency and transfer. PDL crosses it at about 80 cells on a side. Below that the card is pure overhead.

The card is not a faster computer; it is a machine for doing the same small thing to a great many values, and the skill is recognising which part of a problem has that shape.

Running it

The stages above, plus the mesh builder from *meshes* and the rasteriser from *software-rasteriser*, assemble into one file:

```
pperl worldgen.pl --size 512 --octaves 6 --erosion 12 --seed 1234 \
                  --mesh all --width 800 --height 600 \
                  --out world.png --obj world.obj --show
```

Option	Effect
`--size`	grid edge in cells
`--seed`	selects the landscape
`--octaves`	how many frequencies of noise to sum
`--erosion`	how many passes to weather it; 12 keeps the three-way run quick, 40 gives noticeably smoother ridges
`--mesh`	`perl`, `pdl`, `gpu`, `all`, or `auto` for the best available
`--azimuth`, `--elevation`, `--distance`	orbit camera; the terrain spans 6 units
`--fov`, `--look`	field of view, and the height the camera aims at
`--sun-azimuth`, `--sun-elevation`	sun position; low elevation gives the most relief
`--obj`	additionally write the mesh as Wavefront OBJ
`--show`	display the result in an SDL2 window
`--histogram`	print the height distribution and the material boundaries
`--no-cull`	disable back-face culling
`--power`	`high-performance` or `low-power` adapter preference

`--mesh pdl` needs a binary built with `--features pdl`, and `--mesh gpu` needs `--features webgpu` plus a usable adapter. `--mesh auto` picks the fastest that is present.

`--show` opens a window with the finished PNG through the native SDL2 binding of *the 2D guide's toolkit chapter*, so a run ends with the picture rather than a filename:

```
my $win = SDL2::Window->new(title => "worldgen $N x $N", w => $W, h
 ↪=> $H);
my $ren = $win->renderer;
my $tex = SDL2::Image::load_texture($ren, $o{out});
$ren->clear;
$ren->copy($tex);
$ren->present;
```

`--obj` writes ASCII Wavefront OBJ, one line per vertex and one per face, so it grows fast: 4 MB at 256, 17 MB at 512. It is there to open the terrain in a modelling tool, not as a transport format for large grids.

`--no-cull` should produce a byte-identical image, because the Z-buffer already resolves what the cull merely avoids computing. If it does not, the winding is wrong.

Winding, and the one line that decides it

```
next if $area == 0;                          # degenerate
next if $o{cull} && $area >= 0;              # back-face cull (screen y
 ↪is down)
my $sgn = $area < 0 ? -1 : 1;                # inside test follows the
 ↪winding
```

The projection flips y, because the screen's origin is top-left and the mathematics has y going up. **A flip is a reflection, and a reflection reverses orientation**, so every front-facing triangle arrives with *negative* signed area. Culling on `$area <= 0` therefore discards exactly the triangles it should keep, and an inside test written to accept only positive weights then rejects every interior pixel of whatever survived.

Decide the sign once per triangle and let the coverage test follow it.

Symptom: geometry is sparse or inside out, and inverting the cull changes which half is missing rather than fixing it. Cause: the cull and the coverage test disagreeing about winding.

What this demonstrates

The division of labour is the lesson. Three stages have the one shape a GPU is built for, and on a 512 grid they drop from `6.2s` to `0.043s`. The parts that do not have that shape stay in Perl, where they are readable, and the renderer among them is now the program's bottleneck at `4.10s`.

Writing the same algorithm three times is not redundancy here. It is what makes the number in the table trustworthy: the agreement line proves the three are one algorithm, so the speedup column compares implementations rather than problems.

Capstone: an interactive modeller

A small modelling program you can run. It opens a window on a floor with three objects standing on it; you orbit the camera by dragging, click an object to select it, and change it from the keyboard: extrude the face you clicked, subdivide, scale, turn, move, add and delete. `W` saves the scene as an OBJ file and reads it straight back to prove the file is sound.

Almost nothing in it is new. The meshes come from *meshes* and *modelling-operations*, the camera and the picking from *scene-graphs*, the file format from *model-formats*, and the drawing is the lit, depth-tested pipeline of the *GPU scene chapter*, shader included. What this chapter adds is the part that joins them: one mesh representation that the operations edit, the picker searches, the card draws and the writer saves.

A session, with the terminal beside the window:

```
added      cube1      12 triangles    8 vertices  volume 1.0000
added      prism2     20 triangles   12 vertices  volume 0.8660
added      sphere3   128 triangles   66 vertices  volume 0.4772
selected   cube1 (triangle 0)
extruded   cube1      20 triangles   12 vertices  volume 1.5000
extruded   cube1      28 triangles   16 vertices  volume 2.0000
selected   sphere3 (triangle 9)
subdivided sphere3   512 triangles  258 vertices  volume 0.5115
scaled     sphere3   512 triangles  258 vertices  volume 0.9989
added      prism4     20 triangles   12 vertices  volume 0.8660
wrote model.obj: 298 vertices, 580 triangles, volume 4.7310
read  model.obj: 298 vertices, 580 triangles, volume 4.7310  ok
```

Every operation prints the object's volume, using the `signed_volume` test from *meshes*. That is the modelling chapter's rule carried into an interactive program: a closed mesh has a volume you can predict, and an operation that breaks the mesh shows up as a number that is wrong.

Controls

Input	Effect
left click	select the object under the pointer, and remember which face was hit
left drag	orbit the camera
right drag	zoom: down moves the camera away, up brings it closer
`-`, `=`	zoom out, zoom in
1, 2, 3	add a cube, a hexagonal prism, a sphere
`E`	extrude the clicked face outward by 0.5
`D`	subdivide the selection
`[`, `]`	scale the selection by 0.8, by 1.25
`R`	turn the selection 15 degrees
arrow keys	move the selection 0.25 across the floor
`F`	orbit around the selection instead of the origin
`Delete`	remove the selection
`W`	write `model.obj` and read it back
`P`	save the current view as `shot1.png`, `shot2.png`, ...
`Escape`	quit

One mesh, four users

Each object keeps its geometry as the *indexed triangle mesh*: an array of positions and a flat list of indices, three per triangle, wound counter-clockwise seen from outside. The operations change that mesh in place; the picker tests rays against it; the writer prints it; and a vertex buffer made from it is what the card draws. Where the object sits in the world is kept apart from the mesh, as a position, a turn about y and a uniform scale, combined into a model matrix when needed.

The program starts with the same header as the *GPU scene chapter*, and the same `foundations.pl` beside it holding the vector and matrix subs from *foundations*, followed by a line `1;`:

```
use strict;
use warnings;
use SDL2 qw(:all);
use Peta::WebGPU;
use SDL2::Image;
BEGIN { require './foundations.pl' }   # the v_* and m_* subs, then 1;

my $max_frames = shift // 0;           # 0: run until the window is closed
my $PI = 4 * atan2(1, 1);
```

`use SDL2 qw(:all)`, not a later `import`, for the reason the *device chapter* spent a section on: every `SDL_*` constant below must exist while the file is compiled.

Building shapes

Three routines come from earlier chapters. `extrude` is *modelling-operations'* unchanged. `subdivide` is that chapter's subdivision written out whole, with the midpoint cache it insists on, and with the sphere projection made optional. `signed_volume` is the *meshes* winding check.

```
# modelling-operations: a convex polygon in the xy plane, counter-
 ↪clockwise
# seen from +z, swept along +z by $h and capped at both ends.
sub extrude {
    my ($poly, $h) = @_;
    my $n = @$poly;
    # The outer parens are load-bearing: `my @v = (A), (B)` parses
 ↪as
    # `(my @v = A), B` and silently stores only the first list.
    my @v = ( (map { [ $_->[0], $_->[1], 0  ] } @$poly),
              (map { [ $_->[0], $_->[1], $h ] } @$poly) );
    my @i;
    # top cap: fan over the upper ring, already CCW seen from +z
    push @i, ($n, $n + $_, $n + $_ + 1) for 1 .. $n - 2;
    # bottom cap: same fan reversed, so it faces -z
    push @i, (0, $_ + 1, $_) for 1 .. $n - 2;
    # sides: one quad per edge, wound outward
    for my $e (0 .. $n - 1) {
        my $f = ($e + 1) % $n;
        push @i, ($e, $f, $n + $f), ($e, $n + $f, $n + $e);
    }
    return (\@v, \@i);
}

# modelling-operations: split every triangle into four at its edge
# midpoints. With $radius, each new vertex is pushed out onto the
 ↪sphere
# of that radius. The mesh is changed in place.
sub subdivide {
    my ($v, $i, $radius) = @_;
    my %mid;
    my $midpoint = sub {
        my ($a, $b) = @_;
        # Cache by edge: the two triangles sharing it must get ONE
 ↪vertex.
        my $key = $a < $b ? "$a,$b" : "$b,$a";
        return $mid{$key} //= do {
            my $m = v_scale(v_add($v->[$a], $v->[$b]), 0.5);
            $m = v_scale(v_norm($m), $radius) if $radius;
            push @$v, $m;
            $#$v;
        };
    };
    my @ni;
```

(continues on next page)

(continued from previous page)

```
    for (my $k = 0; $k < @$i; $k += 3) {
        my ($a, $b, $c) = @{$i}[$k, $k + 1, $k + 2];
        my $ab = $midpoint->($a, $b);
        my $bc = $midpoint->($b, $c);
        my $ca = $midpoint->($c, $a);
        push @ni, ($a,$ab,$ca), ($ab,$b,$bc), ($ca,$bc,$c), ($ab,
↪$bc,$ca);
    }
    @$i = @ni;
}

# meshes: the enclosed volume of a closed mesh, positive when every
# triangle winds counter-clockwise seen from outside.
sub signed_volume {
    my ($v, $i) = @_;
    my $vol = 0;
    for (my $k = 0; $k < @$i; $k += 3) {
        my ($a, $b, $c) = @{$v}[ @{$i}[$k, $k+1, $k+2] ];
        $vol += v_dot($a, v_cross($b, $c)) / 6;
    }
    return $vol;
}
```

The primitives are built from those. A cube is a square extruded, exactly as modelling-operations showed; a hexagonal prism is a hexagon extruded; a sphere is an octahedron subdivided twice with every new vertex pushed onto the sphere.

```
# A prism of unit height whose cross-section has an apothem of 0.5,␣
↪so
# four sides make the unit cube. Centred on the origin, standing on␣
↪y.
sub prism {
    my ($sides) = @_;
    my $r = 0.5 / cos($PI / $sides);
    my @poly = map { my $t = 2 * $PI * ($_ + 0.5) / $sides; [ $r *␣
↪cos $t, $r * sin $t ] }
               0 .. $sides - 1;
    my ($v, $i) = extrude(\@poly, 1);
    # (x, y, z) -> (x, z, -y) is a rotation, so the winding survives␣
↪it.
    return ([ map { [ $_->[0], $_->[2] - 0.5, -$_->[1] ] } @$v ],
↪$i);
}

sub sphere {
    my ($r, $levels) = @_;
    my @v = ([$r,0,0], [-$r,0,0], [0,$r,0], [0,-$r,0], [0,0,$r], [0,
↪0,-$r]);
    my @i = (0,2,4, 2,1,4, 1,3,4, 3,0,4, 2,0,5, 1,2,5, 3,1,5, 0,3,
```

(continues on next page)

(continued from previous page)

```
↪5);
    subdivide(\@v, \@i, $r) for 1 .. $levels;
    return (\@v, \@i);
}
```

`extrude` sweeps along z, and a modeller wants its objects standing on a floor with y up, so `prism` turns the result over. **The turn must be a rotation, not a swap of two axes.** Swapping y and z is a reflection, and a reflection reverses every triangle's winding, the fact the *GPU scene chapter* met as a model rendering inside out. Mapping `(x, y, z)` to `(x, z, -y)` is a quarter turn about x, and the volume check confirms it: the cube reports `1.0000`, not `-1.0000`.

The numbers the program starts with are the analytic ones: the unit cube's 1, the hexagonal prism's `sqrt(3)/2 = 0.8660`, and the level-2 sphere's `0.4772`, which is modelling-operations' `3.81773` for a unit sphere scaled by `0.5 ** 3`.

The window and the pipeline

The window, the device, the surface and the shader are the *GPU scene chapter's*, unchanged. The shader lights each pixel with shading's model and reads each instance's model matrix and colour from a storage buffer.

```
my $win  = SDL2::Window->new(title => 'pperl modeller', w => 800, h
↪=> 600, resizable => 1);
my $gpu  = Peta::WebGPU::Device->new(window => $win);
my $surf = $gpu->surface;
my ($W, $H) = $surf->size;

my $WGSL = <<'WGSL';
struct Scene {
    view_proj: mat4x4<f32>,
    light_dir: vec4<f32>,     // xyz: toward the light, world space
    eye:       vec4<f32>,     // xyz: camera position, world space
};
struct Instance {
    model:  mat4x4<f32>,
    colour: vec4<f32>,
};
@group(0) @binding(0) var<uniform> scene: Scene;
@group(0) @binding(1) var<storage, read> inst: array<Instance>;

struct VOut {
    @builtin(position) pos: vec4<f32>,
    @location(0) world:  vec3<f32>,
    @location(1) normal: vec3<f32>,
    @location(2) colour: vec3<f32>,
};

@vertex
fn vs(@location(0) p: vec3<f32>, @location(1) n: vec3<f32>,
```

(continues on next page)

(continued from previous page)

```
      @builtin(instance_index) i: u32) -> VOut {
    let m = inst[i].model;
    let w = m * vec4<f32>(p, 1.0);
    var o: VOut;
    o.pos    = scene.view_proj * w;
    o.world  = w.xyz;
    o.normal = (m * vec4<f32>(n, 0.0)).xyz;
    o.colour = inst[i].colour.rgb;
    return o;
}

@fragment
fn fs(v: VOut) -> @location(0) vec4<f32> {
    let n = normalize(v.normal);
    let l = normalize(scene.light_dir.xyz);
    let e = normalize(scene.eye.xyz - v.world);
    let lambert = max(dot(n, l), 0.0);
    let h = normalize(l + e);
    let spec = pow(max(dot(n, h), 0.0), 32.0);
    let c = v.colour * (0.1 + 0.9 * lambert) + vec3<f32>(0.4) *␣
 ↪spec;
    return vec4<f32>(min(c, vec3<f32>(1.0)), 1.0);
}
WGSL

my $pipe = $gpu->render_pipeline($gpu->shader($WGSL),
    format => $surf->format, depth => 1, cull => 'back',
    vertex_buffers => [ { attributes => ['float32x3', 'float32x3'] }␣
 ↪]);
my $depth = $gpu->depth_buffer($W, $H);
my $scene = $gpu->uniform_buffer(24 * 4);
```

The shader turns normals with the model matrix, which the GPU scene chapter showed is correct only for rotation, translation and **uniform** scale. That is why `[` and `]` scale all three axes together: a non-uniform scale would need the inverse-transpose matrix passed alongside, and without it the lighting of a stretched object would be quietly wrong.

Flat faces, and the floor as instances

The meshes share vertices between triangles, which the operations need: an extruded face must drag its neighbours' corners with it. The card needs the opposite. A modeller shows its faces flat, so each triangle is lit by its own normal, and a vertex carries one normal, so a corner shared by several faces has to become several vertices. That is the *meshes chapter's* cube with 24 vertices instead of 8, taken to its end: every triangle gets three vertices of its own.

```
# Flat shading: each triangle gets its own three vertices carrying␣
 ↪the
```

(continues on next page)

(continued from previous page)

```
# face normal, so nothing is shared and there is no index buffer.
sub flat_vertices {
    my ($v, $i) = @_;
    my @data;
    for (my $k = 0; $k < @$i; $k += 3) {
        my ($a, $b, $c) = @{$v}[ @{$i}[$k, $k+1, $k+2] ];
        my $n = v_norm(v_cross(v_sub($b, $a), v_sub($c, $a)));
        push @data, @$a, @$n, @$b, @$n, @$c, @$n;
    }
    return $gpu->vertex_buffer(pack 'f*', @data);
}

sub srgb_decode { return [ map { $_ ** 2.2 } @_ ] }   # colours
 ↪picked by eye

# The floor: one quad, drawn 400 times by instancing, as a
 ↪checkerboard.
my $TILES = 20;
my $floor_quad = flat_vertices([[-0.5,0,0.5], [0.5,0,0.5], [0.5,0,-
 ↪0.5], [-0.5,0,-0.5]],
                               [0, 1, 2,  0, 2, 3]);
my @TILE_COLOUR = (srgb_decode(0.30, 0.30, 0.33), srgb_decode(0.38,
 ↪0.38, 0.41));
my @tiles;
for my $k (0 .. $TILES * $TILES - 1) {
    my ($tx, $tz) = ($k % $TILES, int($k / $TILES));
    push @tiles, @{ m_translate($tx - $TILES / 2 + 0.5, 0, $tz -
 ↪$TILES / 2 + 0.5) },
                 @{ $TILE_COLOUR[($tx + $tz) % 2] }, 1;
}
my $floor = $gpu->storage_buffer(pack 'f*', @tiles);
```

With nothing shared, an index buffer would only count `0, 1, 2, ...`, so the objects are drawn with `draw`, not `draw_indexed`.

Flat shading is also what makes the operations visible: a subdivided sphere shows its new, smaller facets at once.

Instancing is used where one mesh repeats, and in this program that is the floor: one quad and 400 instances, each a translation and one of two greys, drawn by a single `draw(6, 400)`. The storage buffer has the layout the shader's `Instance` expects, 20 floats each, as in the *GPU scene chapter*. The objects are the opposite case, each with its own mesh, so each is one draw with its own one-instance buffer, and the same shader serves both.

The colours are picked by eye and decoded with the power 2.2, because the window's surface is an sRGB format, as the *device chapter* measured.

Objects

```
my %COLOUR = (cube   => srgb_decode(0.55, 0.65, 0.80),
              prism  => srgb_decode(0.60, 0.78, 0.55),
              sphere => srgb_decode(0.85, 0.80, 0.60));
my $HIGHLIGHT = srgb_decode(1.00, 0.55, 0.10);

```

`model_matrix` is the *foundations* order rule applied once: `T * R * S` scales first, then turns, then places, so an object turns about its own centre wherever it stands. Written `R * T * S` it would swing round the origin instead.

`refresh` is the one place a mesh change is made visible. It rebuilds the vertex buffer and recomputes the bounding sphere the picker tests first, the *meshes chapter's* cheap approximation. Every operation calls it; forgetting to is the bug where the picture and the clicks disagree.

The volume `report` prints is multiplied by the cube of the scale, because `signed_volume` measures the mesh in its own space and the scale lives in the model matrix.

New objects are placed along a row of slots so they do not appear inside one another, and each new object becomes the selection.

The camera

The orbit camera from *scene-graphs*, unchanged, and the per-frame upload of the GPU scene chapter:

```
my $TARGET = [0, 0.5, 0];
my ($yaw, $pitch, $dist) = (0.6, 0.45, 7);
my $FOVY = 45;
my $GL_TO_WGPU = [1,0,0,0,  0,1,0,0,  0,0,0.5,0,  0,0,0.5,1];

# scene-graphs: two angles and a distance around a target.
sub orbit_eye {
    # $yaw and $pitch in radians, $dist from the target. Clamp pitch
    # short of +/- 90 degrees: at exactly vertical the view␣
↪direction
    # is parallel to `up` and look_at degenerates.
```

(continues on next page)

(continued from previous page)

```
    my ($target, $yaw, $pitch, $dist) = @_;
    return [ $target->[0] + $dist * cos($pitch) * sin($yaw),
             $target->[1] + $dist * sin($pitch),
             $target->[2] + $dist * cos($pitch) * cos($yaw) ];
}

sub upload {
    my $eye  = orbit_eye($TARGET, $yaw, $pitch, $dist);
    my $proj = m_mul($GL_TO_WGPU, m_perspective($FOVY, $W / $H, 0.1,
↪100));
    my $vp   = m_mul($proj, m_look_at($eye, $TARGET, [0, 1, 0]));
    # The light orbits with the camera, high and off to one side, so
↪the
    # faces in view are always lit and a box's three show three
↪shades.
    my $light = v_sub(orbit_eye($TARGET, $yaw + 0.7, 1.0, 1),
↪$TARGET);
    $scene->write(pack 'f*', @$vp, @$light, 0, @$eye, 1);
    for my $o (@objects) {
        my $colour = $sel && $o == $sel ? $HIGHLIGHT : $o->{colour};
        $o->{inst}->write(pack 'f*', @{ model_matrix($o) }, @
↪$colour, 1);
    }
}

sub draw {
    my ($target) = @_;
    my $pass = $gpu->render_pass($target, clear => [0.05, 0.05, 0.
↪08, 1], depth => $depth)
                   ->pipeline($pipe);
    $pass->bind([$scene, $floor])->vertices($floor_quad)->draw(6,
↪$TILES * $TILES);
    $pass->bind([$scene, $_->{inst}])->vertices($_->{vb})->draw($_->
↪{count}) for @objects;
    $pass->end;
}
```

`$GL_TO_WGPU` is the depth-range conversion from the *GPU scene chapter*; without it the near half of the view volume is clipped away and anything close to the camera vanishes.

The light is placed with the same `orbit_eye`, 0.7 radians round from the camera and 1 radian up, at distance 1, so subtracting the target leaves a unit vector. A light fixed in the world leaves the far side of every object at the ambient level once you orbit round to it. This one moves with the camera, so the faces in view are always lit, and because it stands off to one side and above, a box's three visible faces get three different Lambert terms: from the starting view, 0.84 for the top, 0.52 for the side facing +x and 0.14 for the side facing +z.

The selection is a colour, nothing more. `upload` writes each object's instance buffer every frame, and the selected object's gets the highlight instead of its own colour. The mesh and the pipeline are untouched, so selecting costs one 80-byte write.

Every object has its own instance buffer and binds it before its own draw. One buffer rewritten between draws would put every object where the last one is, the symptom the GPU scene chapter measured.

`draw` takes its target as an argument, so the same routine draws into a frame for the window and into a texture for a screenshot.

Clicking on an object

A click becomes a ray through the pixel, exactly as *scene-graphs* builds it, and the ray is tested against every object's bounding sphere, then against the triangles of the objects whose sphere it passes through. `pick_ray` and `ray_sphere` are that chapter's, unchanged; `tan_half` is the tangent of half the vertical field of view, given in degrees as `m_perspective` takes it.

```
# scene-graphs: a ray through the centre of pixel ($sx, $sy).
sub tan_half { my $h = $_[0] * $PI / 360; return sin($h) / cos($h) }

sub pick_ray {
    my ($eye, $target, $up, $fovy, $aspect, $sx, $sy, $W, $H) = @_;
    my $f = v_norm(v_sub($target, $eye));
    my $s = v_norm(v_cross($f, $up));
    my $u = v_cross($s, $f);
    my $ndc_x = 2 * ($sx + 0.5) / $W - 1;
    my $ndc_y = 1 - 2 * ($sy + 0.5) / $H;        # screen y is down
    my $th = tan_half($fovy);
    my @d = map {
        $f->[$_] + $s->[$_] * $ndc_x * $th * $aspect + $u->[$_] *
 ↪$ndc_y * $th
    } 0..2;
    return ($eye, v_norm(\@d));
}

sub ray_sphere {
    # Returns the near intersection distance, or undef. $d MUST be
    # normalised or $t is in units of $d's length rather than␣
 ↪distance.
    my ($o, $d, $c, $r) = @_;
    my $oc = v_sub($o, $c);
    my $b = 2 * v_dot($oc, $d);
    my $cc = v_dot($oc, $oc) - $r * $r;
    my $disc = $b*$b - 4*$cc;
    return undef if $disc < 0;
    my $t = (-$b - sqrt($disc)) / 2;
    return $t > 0 ? $t : undef;
}

# Möller-Trumbore: the distance along the ray to triangle ($a, $b,
 ↪$c),
# or undef. Both sides count; the nearest hit decides.
sub ray_triangle {
```

(continues on next page)

(continued from previous page)

```
    my ($o, $d, $a, $b, $c) = @_;
    my $e1  = v_sub($b, $a);
    my $e2  = v_sub($c, $a);
    my $p   = v_cross($d, $e2);
    my $det = v_dot($e1, $p);
    return undef if abs($det) < 1e-12;          # ray parallel to
↪the plane
    my $s = v_sub($o, $a);
    my $u = v_dot($s, $p) / $det;
    return undef if $u < 0 || $u > 1;
    my $q = v_cross($s, $e1);
    my $w = v_dot($d, $q) / $det;
    return undef if $w < 0 || $u + $w > 1;
    my $t = v_dot($e2, $q) / $det;
    return $t > 1e-9 ? $t : undef;
}
```

`ray_triangle` is the Möller-Trumbore test that *modelling-operations* named and left elided. It solves for the hit distance `t` and the barycentric weights `u` and `w` at once; the ray hits the triangle when both weights and their sum lie between 0 and 1, the same inside test the *rasteriser* applies to a pixel centre.

The picker needs the triangle, not only the object. Extrude acts on the face you clicked, and which face that was is exactly what the nearest triangle hit says. That is why picking runs here in Perl against the very meshes the operations edit.

```
sub pick {
    my ($sx, $sy) = @_;
    my ($o, $d) = pick_ray(orbit_eye($TARGET, $yaw, $pitch, $dist),
↪$TARGET, [0, 1, 0],
                           $FOVY, $W / $H, $sx, $sy, $W, $H);
    my ($best, $best_t, $best_tri);
    # The floor is drawn, so it hides whatever is below it. It is
↪not
    # selectable, but a ray that reaches it first has hit nothing.
    if ($o->[1] > 0 && $d->[1] < 0) {
        my $t = -$o->[1] / $d->[1];
        $best_t = $t if abs($o->[0] + $t * $d->[0]) <= $TILES / 2
                     && abs($o->[2] + $t * $d->[2]) <= $TILES / 2;
    }
    for my $obj (@objects) {
        my $m = model_matrix($obj);
        my $c = [ @{ xform($m, [ @{ $obj->{centre} }, 1 ]) }[0 .. 2]
↪];
        my $r = $obj->{radius} * $obj->{scale};
        # Bounding sphere first. ray_sphere ignores hits behind the
↪eye,
        # so an eye INSIDE the sphere must skip the test, not fail
↪it.
        next unless v_len(v_sub($o, $c)) < $r || defined ray_sphere(
```

(continues on next page)

(continued from previous page)

```
↪$o, $d, $c, $r);
        my @w = map { [ @{ xform($m, [ @$_, 1 ]) }[0 .. 2] ] } @{
↪$obj->{mesh}{v} };
        my $i = $obj->{mesh}{i};
        for (my $k = 0; $k < @$i; $k += 3) {
            my $t = ray_triangle($o, $d, @w[ @{$i}[$k, $k+1, $k+2]␣
↪]) // next;
            ($best, $best_t, $best_tri) = ($obj, $t, $k / 3)
                if !defined $best_t || $t < $best_t;
        }
    }
    return ($best, $best_tri);
}
```

The ray is built from the same eye, target, field of view and aspect ratio that `upload` gives the card, so the ray through a pixel is the line of sight the card rendered through it. That is checkable. Rendering each object alone into a texture shows which objects cover each pixel; rendering all of them shows which one is in front. Over a grid of 30000 pixels of the session above, the picker returned nothing wherever no object was drawn, and the front object wherever one was. From a view along the row, 669 of 13400 sampled pixels showed two or more objects overlapping, and it returned the front one at every one of them.

Symptom: clicking the floor beside an object selects the object. Cause: the picker ignores something the renderer draws. The sphere scaled up about its centre sinks below the floor; the floor hides that part, but a ray that passes through the floor still reaches it. Without the floor test above, 3 of those 30000 pixels pick the sphere where the frame shows only floor. The rule is general: the picker must test everything that is drawn, even what cannot be selected, because what cannot be selected can still be in the way. Below the floor the test does not apply, because from there the floor is a back face and culled.

Symptom: an object cannot be clicked once the camera is close to it. Cause: the eye is inside the object's bounding sphere, where `ray_sphere` answers undef because its only hit is behind the eye. That check is right for the question scene-graphs asked, which was where a ray first meets a sphere; the bounding test asks a different one, whether the ray can reach anything inside. A prism scaled five times and orbited from 2 units away put the eye 2.000 from the centre of a sphere of radius 2.331: `ray_sphere` said undef, and `pick` still found the prism.

For a handful of objects the linear loop over objects is fine; a scene of thousands would put the bounding spheres into the *BVH* that chapter builds.

Push and pull: extruding a face

Modelling-operations' `extrude` sweeps a polygon into a solid. A modeller needs the same operation applied to a face of a solid that already exists, which is the push/pull that chapter called the most useful operation in the set.

A click hits one triangle, but a face of a cube is two triangles, and of a subdivided cube eight. The face the click means is the hit triangle and everything connected to it across shared edges that lies in the same plane:

```
sub tri_normal {
    my ($v, $i, $t) = @_;
    my ($a, $b, $c) = @{$v}[ @{$i}[3 * $t .. 3 * $t + 2] ];
    return v_norm(v_cross(v_sub($b, $a), v_sub($c, $a)));
}

# The face a click means: the hit triangle and every triangle
↪reachable
# from it across shared edges that lies in the same plane.
sub face_of {
    my ($v, $i, $t0) = @_;
    my $edges_of = sub {                        # triangle $t's three
↪undirected edges
        my @c = @{$i}[3 * $_[0] .. 3 * $_[0] + 2];
        return map { my ($p, $q) = ($c[$_], $c[($_ + 1) % 3]); $p <
↪$q ? "$p,$q" : "$q,$p" } 0 .. 2;
    };
    my %by_edge;
    for my $t (0 .. @$i / 3 - 1) { push @{ $by_edge{$_} }, $t for
↪$edges_of->($t) }
    my $n = tri_normal($v, $i, $t0);
    my %in = ($t0 => 1);
    my @todo = ($t0);
    while (defined(my $t = shift @todo)) {
        for my $u (map { @{ $by_edge{$_} } } $edges_of->($t)) {
            next if $in{$u} || v_dot(tri_normal($v, $i, $u), $n) < 1
↪- 1e-9;
            $in{$u} = 1;
            push @todo, $u;
        }
    }
    return sort { $a <=> $b } keys %in;
}

# Push/pull: move a face along its normal and wall in the gap. The
↪face's
# triangles are re-pointed at moved copies of its vertices; every
↪boundary
# edge a->b gains the quad a, b, b', a', wound like extrude's sides.
sub extrude_face {
    my ($o, $t0, $h) = @_;
    my ($v, $i) = @{ $o->{mesh} }{qw(v i)};
    my @face = face_of($v, $i, $t0);

```

(continues on next page)

(continued from previous page)

```
        }
    }
    my %moved;
    for my $t (@face) {
        for my $k (3 * $t .. 3 * $t + 2) {
            my $old = $i->[$k];
            $moved{$old} //= do { push @$v, v_add($v->[$old], v_
↪scale($n, $h)); $#$v };
            $i->[$k] = $moved{$old};
        }
    }
    for my $e (@edges) {
        my ($a, $b) = @$e;
        next if $directed{"$b,$a"};            # inside the face:␣
↪both sides moved
        push @$i, ($a, $b, $moved{$b}), ($a, $moved{$b}, $moved{$a}
↪);
    }
    $o->{round} = 0;                           # no longer a sphere␣
↪to project onto
}
```

`face_of` is a flood fill over the edge adjacency that the *meshes chapter* says a half-edge structure keeps ready; here it is rebuilt from the index list on each call, which for a few hundred triangles is instant. The same-plane test compares normals, and connectivity across shared edges keeps two separate faces that happen to be parallel, such as the tops of two steps, apart.

The extrusion itself is the *manifold* invariant used as a recipe. An edge of the face whose reverse is also in the face is interior: both triangles beside it move, and nothing needs adding. An edge whose reverse is not in the face is boundary: the triangle beyond it stays behind, so the gap between the old edge and the moved one needs a wall. The wall quad takes the edge in the face's own direction, `a` to `b`, because its neighbour beyond runs it `b` to `a`; along the top it runs `b'` to `a'`, opposite to the moved face. Every shared edge is then traversed once each way, which is exactly the condition for a closed, consistently wound mesh. The same reasoning gives `extrude`'s side quads their order.

The numbers say whether it worked. The cube's top is two triangles with four boundary edges, so an extrusion adds 4 vertices and 8 triangles and, at height 0.5, half a unit of volume:

```
extruded   cube1      20 triangles   12 vertices  volume 1.5000
extruded   cube1      28 triangles   16 vertices  volume 2.0000
```

The second `E` extrudes the same face again, because the face's triangles keep their numbers when they move, so the remembered click still names them. On a subdivided cube the top is eight triangles and nine vertices, and one extrusion took it from 48 triangles and 26 vertices to 64 and 35, volume 1.0000 to 1.5000. Extruding a single triangle of the sphere grew its volume by `0.009508`, which is that triangle's area times 0.5 to the sixth decimal. After each of these, every edge of every mesh was shared by exactly two triangles and no directed edge occurred twice.

Subdividing is modelling-operations' routine applied to the selection. A sphere keeps its round flag, so its new vertices go onto the sphere and it becomes rounder: `D` on the level-2 sphere gave 512 triangles, 258 vertices and volume `0.5115`, modelling-operations' level-3 `4.09160` scaled by `0.5 ** 3`. Any other object is split flat, adding triangles without changing its shape or its volume, which is the preparation for extruding a smaller face. Subdividing renumbers every triangle, so it forgets the clicked face; `E` then asks for a new click.

Saving to OBJ

```
# model-formats: read_obj, unchanged.
sub read_obj {
    my ($path) = @_;
    open my $fh, '<', $path or die "$path: $!";
    my (@v, @f);
    while (my $line = <$fh>) {
        next if $line =~ /^\s*(#|$)/;
        my @tok = split ' ', $line;
        my $kw = shift @tok;
        if ($kw eq 'v') { push @v, [ @tok[0..2] ] }
        elsif ($kw eq 'f') {
            # A face may have MORE than three vertices. Fan-
 ↪triangulate.
            # Each token may be v, v/vt, v//vn or v/vt/vn: take the␣
 ↪first.
            my @vi = map { my ($n) = split m{/}, $_; $n } @tok;
            # Indices are 1-based; a NEGATIVE index counts back from␣
 ↪the
            # current end of the vertex list.
            @vi = map { $_ < 0 ? @v + $_ : $_ - 1 } @vi;
            push @f, [ $vi[0], $vi[$_], $vi[$_ + 1] ] for 1 .. $#vi␣
 ↪- 1;
        }
    }
    close $fh;
    return (\@v, \@f);
}

# model-formats' write_obj, for a whole scene: one `o` line per␣
 ↪object,
# vertices baked into world space, face indices counted across the␣
 ↪file.
sub save_obj {
    my ($path) = @_;
    open my $fh, '>', $path or die "$path: $!";

    my $rvol = signed_volume($rv, [ map { @$_ } @$rf ]);
    printf "wrote %s: %d vertices, %d triangles, volume %.4f\n",
↪$path, $nv, $nt, $vol;
    printf "read  %s: %d vertices, %d triangles, volume %.4f  %s\n",␣
↪$path,
        scalar @$rv, scalar @$rf, $rvol,
        (@$rv == $nv && @$rf == $nt && abs($rvol - $vol) < 1e-4 ?
↪'ok' : 'MISMATCH');
}
```

OBJ has no scene tree, as the *model-formats* table says, so each object's model matrix is applied to its vertices on the way out and the file holds world positions. An `o` line names each object; readers that understand it keep the objects apart, and `read_obj` skips it like any other line it does not know.

Face indices count across the whole file, not per object. The second object's first vertex is number 9 if the first object wrote 8, which is what `$base` carries. Restart the count per object and every object after the first is built from the first one's vertices: the counts still match, and only the volume gives it away. That is why the check reads the file back with model-formats' own reader and compares three numbers, not two. The volume of everything read back must equal the sum of the objects' volumes, and it can only do so if every face refers to the vertices it was written with.

The session at the top wrote four objects in one file, 298 vertices and 580 triangles, and read back the same counts and the same volume, `4.7310`.

Screenshots

P renders the current view into a texture and writes it as a PNG: the checking path of the *device chapter*, in the program.

```
my $shots = 0;
sub screenshot {
    my $tex = $gpu->texture(width => $W, height => $H, format =>
↪$surf->format);
    upload();
    draw($tex);
    # read returns the texture's own byte order, B, G, R, A for a␣
↪bgra
    # format; the surface is told which, so nothing is swapped in␣
↪Perl.
    my $order = $surf->format =~ /^bgra/ ? SDL_PIXELFORMAT_BGRA32 :␣
↪SDL_PIXELFORMAT_RGBA32;
    my $file  = sprintf 'shot%d.png', ++$shots;
    SDL2::Image::save_png(SDL2::Surface->from_pixels($tex->read, $W,␣
↪$H, $order), $file) == 0
        or die "$file: ", SDL_GetError(), "\n";
    print "saved $file\n";
}
```

The texture has the surface's format, so the pipeline built for the window draws into it unchanged, and the depth buffer, already the window's size, fits it. On the machine this was checked on that format is `bgra8unorm-srgb`, whose bytes come back as B, G, R, A. Rather than swap them in Perl, the surface is created with `SDL_PIXELFORMAT_BGRA32`, which names that byte order, and `SDL2::Image` writes the file.

The screenshot runs inside the frame loop, so it has to be quick. The device chapter's `save_png` sets every pixel from Perl through `GD`, which is the right tool for checking an image once and the wrong one here: while it runs, the loop neither polls events nor presents frames, and the window stops responding until it finishes. Handing the whole buffer to `SDL2::Image` is one call.

Keys and the mouse

The keyboard is a table from key to action:

```
sub with_selection {
    my ($code) = @_;
    return print "nothing selected\n" unless $sel;
    $code->($sel);
}

my %KEY = (
    SDLK_1() => sub { add_object('cube') },
    SDLK_2() => sub { add_object('prism') },
    SDLK_3() => sub { add_object('sphere') },
    SDLK_e() => sub {
```

(continues on next page)

(continued from previous page)

```
        with_selection(sub {
            return print "click a face of $_[0]{name} first\n"
↪unless defined $sel_tri;
            extrude_face($_[0], $sel_tri, 0.5);
            refresh($_[0]);
            report("extruded", $_[0]);
        });
    },
    SDLK_d() => sub {
        with_selection(sub {
            subdivide($_[0]{mesh}{v}, $_[0]{mesh}{i}, $_[0]{round} ?
↪0.5 : undef);
            $sel_tri = undef;                   # triangle numbers
↪have changed
            refresh($_[0]);
            report("subdivided", $_[0]);
        });
    },
    SDLK_RIGHTBRACKET() => sub { with_selection(sub { $_[0]{scale}
↪*= 1.25; report('scaled', $_[0]) }) },
    SDLK_LEFTBRACKET()  => sub { with_selection(sub { $_[0]{scale}
↪*= 0.8;  report('scaled', $_[0]) }) },
    SDLK_r()     => sub { with_selection(sub { $_[0]{yaw} += $PI /
↪12 }) },
    SDLK_LEFT()  => sub { with_selection(sub { $_[0]{pos}[0] -= 0.25
↪}) },
    SDLK_RIGHT() => sub { with_selection(sub { $_[0]{pos}[0] += 0.25
↪}) },
    SDLK_UP()    => sub { with_selection(sub { $_[0]{pos}[2] -= 0.25
↪}) },
    SDLK_DOWN()  => sub { with_selection(sub { $_[0]{pos}[2] += 0.25
↪}) },
    SDLK_f()     => sub { with_selection(sub { $TARGET = [ @{ $_[0]
↪{pos} } ] }) },
    SDLK_DELETE() => sub {
        with_selection(sub {
            @objects = grep { $_ != $_[0] } @objects;
            print "deleted $_[0]{name}\n";
            ($sel, $sel_tri) = ();
        });
    },
    SDLK_EQUALS() => sub { $dist = $dist * 0.8 < 2 ? 2 : $dist * 0.8
↪},
    SDLK_MINUS()  => sub { $dist = $dist * 1.25 > 40 ? 40 : $dist *
↪1.25 },
    SDLK_w() => sub { save_obj('model.obj') },
    SDLK_p() => sub { screenshot() },
);
```

The `()` after each constant is required. `=>` quotes a bareword on its left, so `SDLK_1`

`=> sub { ... }` makes the key the string `"SDLK_1"`, not 49. It compiles under `use strict`, because a quoted word is not a bareword, and the key simply never matches. It is the *import trap* in another form, and this time strict does not catch it.

Moving and turning change only the model matrix, which `upload` sends every frame, so they need no `refresh`. The operations that change the mesh call it.

The mouse needs one decision: a left press may be the start of a click or of a drag. The handler counts how far the pointer moves while the button is down, and only a release after less than 4 pixels of movement is a click:

```
my ($dragged, $running) = (0, 1);
sub handle {
    my ($ev) = @_;
    my $type = $ev->{type};
    if ($type == SDL_QUIT) { $running = 0 }
    elsif ($type == SDL_KEYDOWN) {
        if ($ev->{sym} == SDLK_ESCAPE) { $running = 0 }
        elsif (my $action = $KEY{ $ev->{sym} }) { $action->() }
    }
    elsif ($type == SDL_MOUSEBUTTONDOWN && $ev->{button} == SDL_
↪BUTTON_LEFT) { $dragged = 0 }
    elsif ($type == SDL_MOUSEMOTION && $ev->{state} & SDL_BUTTON_
↪LMASK) {
        $dragged += abs($ev->{xrel}) + abs($ev->{yrel});
        $yaw   -= 0.01 * $ev->{xrel};
        $pitch += 0.01 * $ev->{yrel};
        $pitch = 1.4 if $pitch > 1.4;
        $pitch = -1.4 if $pitch < -1.4;
    }
    elsif ($type == SDL_MOUSEMOTION && $ev->{state} & SDL_BUTTON_
↪RMASK) {
        $dist *= exp(0.01 * $ev->{yrel});
        $dist = 2 if $dist < 2;
        $dist = 40 if $dist > 40;
    }
    elsif ($type == SDL_MOUSEBUTTONUP && $ev->{button} == SDL_
↪BUTTON_LEFT && $dragged < 4) {
        ($sel, $sel_tri) = pick($ev->{x}, $ev->{y});
        print $sel ? "selected   $sel->{name} (triangle $sel_tri)\n"␣
↪: "selected   nothing\n";
    }
    elsif ($type == SDL_WINDOWEVENT && $ev->{event} == SDL_
↪WINDOWEVENT_SIZE_CHANGED) {
        ($W, $H) = @$ev{qw(data1 data2)};
        $surf->configure($W, $H);
        $depth = $gpu->depth_buffer($W, $H);   # must match the␣
↪frame
    }
}
```

The held buttons arrive in the motion event's `state`, as the *device chapter* showed, so

the handler needs no memory of which button went down. Dragging right moves the eye the other way round, so the scene turns with the pointer as if held. The pitch clamp at 1.4 radians keeps the eye short of vertical, where *scene-graphs* warns that `m_look_at` degenerates. Zoom by dragging is multiplicative, `exp` of the movement, so the same drag changes the view by the same proportion near and far: 50 pixels down multiplies the distance by `e ** 0.5 = 1.6487`.

A click on nothing clears the selection, which is how to deselect.

The resize branch is the GPU scene chapter's: after `$win->set_size(640, 480)` the handler reconfigured the surface to `640x480`, made a matching depth buffer, and frames carried on drawing.

The frame loop

```
add_object($_) for qw(cube prism sphere);
($sel, $sel_tri) = ();

my $frames = 0;
while ($running) {
    while (my $ev = SDL_PollEvent()) { handle($ev) }
    my $frame = $surf->next_frame or next;
    upload();
    draw($frame);
    $frame->present;
    $running = 0 if $max_frames && ++$frames >= $max_frames;
}
```

Nothing in a modeller moves by itself, so unlike the GPU scene chapter's cubes there is no simulation clock and no fixed step: every change is the answer to an event, and the frame shows the state after the events it drained. The surface's default `fifo` mode paces the loop to the display, as the *device chapter* measured.

Every pass of the loop must reach `present` quickly. The window shows only what the loop presents, and the window system judges the program alive by whether it keeps taking events off the queue. Anything that holds the loop for seconds, such as a slow screenshot or a long computation in a key handler, leaves the window frozen on its last frame and, after a while, marked as not responding. Work that takes that long belongs outside the frame loop or split across frames.

Running it

The blocks above, in order, are the whole program. Save them as `modeller.pl` beside `foundations.pl` and run:

```
pperl modeller.pl
```

`pperl modeller.pl 600` stops after 600 frames, for unattended runs. It needs a binary built with `--features webgpu`, a usable adapter, and an X11 or Wayland display for the window.

The program was checked with input pushed onto SDL's event queue while its frame loop ran: a click on the cube's top selected `cube1` at triangle 0, the top cap; two E presses

extruded it; a click on the sphere, `D` and `]` subdivided and scaled it; a drag of 60 pixels turned the camera 0.6 radians without selecting anything; a click on empty sky cleared the selection; `W` wrote and re-read the file. The window's own contents, captured from the screen as it ran, showed each step: the orange highlight moving from the cube to the sphere, the column rising from the cube, the finer facets of the sphere, and the view turning. The PNG that `P` wrote was identical, in all 480000 pixels, to the window's contents captured at the same moment.

What this demonstrates

Every chapter of the guide appears in one program, and the program works because they agree on one representation: counter-clockwise triangles in an indexed mesh, column-major matrices, a right-handed world with y up. The operations, the picker, the renderer and the writer each read that representation, and none of them converts it for another.

The checks carry over as well. The volume after each operation, the pick compared against the rendered pixels, and the file read back and compared against the scene are the same kind of test the earlier chapters used: a number known in advance, computed a second way.

Capstone: a 3D game

A complete small game: a craft flies down a lane, blocks stand in its way, gems hang between them, and the lane gets faster the longer the run lasts. The arrow keys steer, each gem scores, and touching a block ends the run. It is the *2D game* with a third dimension, and it keeps that game's shape: the world is plain data, an update step moves it, a draw step shows it, and a loop runs both at a fixed rate.

Nothing in it is new. Every piece was built in an earlier chapter, and this one puts them together:

Piece	Taught in
vectors, matrices, `m_look_at`, `m_perspective`	*foundations*
boxes and spheres as bounding volumes	*meshes*
the node hierarchy and `walk`	*scene graphs*
the window, the surface, the fixed step with its cap	*the device chapter*
the pipeline, vertex and index buffers	*the pipeline chapter*
the cube, depth, instancing, per-fragment light	*the GPU scene chapter*
`key_pressed` and scancodes	*the 2D game*

The blocks of code from here to the loop, in order, are the whole program. It loads the subs from foundations from `foundations.pl` beside it, exactly as the *GPU scene chapter* does.

The world is plain data

```
use strict;
use warnings;
```

(continues on next page)

(continued from previous page)

```
use SDL2 qw(:all);
use Peta::WebGPU;
BEGIN { require './foundations.pl' }   # the v_* and m_* subs, then 1;

use constant { STEP => 16, MAX_STEPS => 5 };   # milliseconds, steps per frame
use constant { LANE => 4, AHEAD => 60, N_BLOCKS => 24, N_GEMS => 8 };
my $max_frames = shift // 0;          # 0: play until the window is closed

my %game;

sub new_game {
    %game = (
        craft  => { x => 0, z => 0, vx => 0 },
        speed  => 0.12,                  # units per step, along -z
        blocks => [ map { place_block({}, -12 - $_ * AHEAD / N_BLOCKS) } 0 .. N_BLOCKS - 1 ],
        # -13.25 is halfway between the first two rows of blocks.
        gems   => [ map { place_gem({}, -13.25 - $_ * AHEAD / N_GEMS) } 0 .. N_GEMS - 1 ],
        score  => 0,
        over   => 0,
        steps  => 0,
    );
}

sub place_block {
    my ($b, $z) = @_;
    my $w = 0.8 + rand 0.8;
    %$b = (x => $w / 2 - LANE + rand(2 * LANE - $w), z => $z, w => $w, h => 0.8 + rand 1.2);
    return $b;
}

sub place_gem {
    my ($g, $z) = @_;
    %$g = (x => 0.5 - LANE + rand(2 * LANE - 1), z => $z, taken => 0);
    return $g;
}
```

The craft flies toward -z, the direction a camera looks in *foundations*, and steers along x. The lane runs from `x = -4` to `x = 4`, with the floor at `y = 0`.

The field looks endless and is not. There are always 24 blocks, one row every 2.5 units over the 60 units ahead, and 8 gems, one every 7.5 units, each halfway between two rows of blocks so that no gem is ever inside a block. When one falls behind the camera,

`update` moves it 60 units further on and gives it a new position and size. **The number of objects never changes**, which is what lets the draw step below fill one buffer of fixed size every frame.

`rand` makes each run different. Calling `srand` with a fixed number before `new_game` makes it the same every time, which is what the checks at the end of this chapter do.

Collision: boxes and a sphere

```
# Boxes are [min corner], [max corner]: the axis-aligned form from meshes.
sub craft_box {
    my $c = $game{craft};
    return ([ $c->{x} - 0.8, 0.3, $c->{z} - 0.5 ], [ $c->{x} + 0.8, 0.75, $c->{z} + 0.5 ]);
}

sub block_box {
    my ($b) = @_;
    my $r = $b->{w} / 2;
    return ([ $b->{x} - $r, 0, $b->{z} - $r ], [ $b->{x} + $r, $b->{h}, $b->{z} + $r ]);
}

sub boxes_overlap {
    my ($alo, $ahi, $blo, $bhi) = @_;
    for my $i (0 .. 2) {
        # A gap along any one axis separates them; they touch only when
        # they overlap along all three.
        return 0 if $ahi->[$i] < $blo->[$i] || $bhi->[$i] < $alo->[$i];
    }
    return 1;
}

sub sphere_touches_box {
    my ($c, $r, $lo, $hi) = @_;
    my $d2 = 0;
    for my $i (0 .. 2) {
        # The point of the box nearest the centre: clamp each coordinate.
        my $p = $c->[$i] < $lo->[$i] ? $lo->[$i]
              : $c->[$i] > $hi->[$i] ? $hi->[$i] : $c->[$i];
        $d2 += ($c->[$i] - $p) ** 2;
    }
    return $d2 <= $r * $r;
}
```

These are the two *bounding volumes* the meshes chapter introduced, the axis-aligned box and the sphere, and the *scene-graph chapter* tested rays against the same two shapes.

There they were a cheap first test before an exact one. Here nothing exact follows, because the volumes are close enough to the shapes: a block *is* a box, and a gem spinning in place stays inside the same sphere at every angle, which is the reason to give a turning object a sphere rather than a box.

The craft's box ignores its bank. It is the box of the level craft, and banking narrows the craft by up to a tenth of a unit, so the test errs slightly on the side of a crash. Its height never decides anything: every block rises at least 0.8 from the floor and the box tops out at 0.75, so the vertical ranges always overlap and the other two axes decide.

Twenty-four box tests per step cost nothing. The *bounding volume hierarchy* is for when there are thousands; it would answer the same question with fewer tests, and nothing else would change.

Update

```
sub update {
    my ($steer) = @_;                    # -1 left, 0 straight on,
↪+1 right
    return if $game{over};
    my $c = $game{craft};

    # Ease the sideways speed toward the steering rather than
↪setting it:
    # the craft drifts into a turn and out of it, and its bank
↪follows vx.
    $c->{vx} += (0.18 * $steer - $c->{vx}) * 0.2;
    $c->{x}  += $c->{vx};
    my $edge = LANE - 0.8;
    if ($c->{x} < -$edge) { $c->{x} = -$edge; $c->{vx} = 0 }
    if ($c->{x} >  $edge) { $c->{x} =  $edge; $c->{vx} = 0 }
    $c->{z} -= $game{speed};
    $game{speed} += 0.00004 if $game{speed} < 0.3;
    $game{steps}++;

    my ($lo, $hi) = craft_box();
    for my $b (@{ $game{blocks} }) {
        # Behind the camera nobody can see it: reuse it at the far
↪end.
        place_block($b, $b->{z} - AHEAD) if $b->{z} > $c->{z} + 8;
        if (boxes_overlap($lo, $hi, block_box($b))) { $game{over} =
↪1; return }
    }
    for my $g (@{ $game{gems} }) {
        place_gem($g, $g->{z} - AHEAD) if $g->{z} > $c->{z} + 8;
        next if $g->{taken};
        if (sphere_touches_box([ $g->{x}, 0.6, $g->{z} ], 0.35, $lo,
↪$hi)) {
            $g->{taken} = 1;
            $game{score}++;
        }
```

    }
}
```

`update` takes the steering as an argument instead of reading the keyboard itself. That one decision is what makes the game testable: a list of numbers fed to `update` plays a run exactly as a player would, with no window and no keyboard.

Two things in it are load-bearing, and both are the 2D game's lessons again.

The `taken` flag. The craft overlaps a gem for several steps while it passes through it, and every one of those steps would score without the flag. It is the 2D game's `dy > 0` test in another form: count the event, not the overlap.

The clamp at the lane edges also zeroes `vx`. Clamping the position alone leaves the craft pressing on the wall at full sideways speed, banked hard over while not moving, and the first frame of steering back has to cancel that speed before anything happens.

The speed rises from 0.12 units per step to 0.3, reaching it after 4500 steps, which is 72 seconds of play. At 0.3 a row of blocks arrives about every eight steps.

Input

```
sub input {
    SDL_PumpEvents();
    my $steer = 0;
    $steer -= 1 if SDL2::key_pressed(SDL_SCANCODE_LEFT);
    $steer += 1 if SDL2::key_pressed(SDL_SCANCODE_RIGHT);
    new_game() if $game{over} && SDL2::key_pressed(SDL_SCANCODE_
↪SPACE);
    return $steer;
}
```

This is the *2D game's* input routine: `key_pressed` asks whether a key is held now, rather than waiting for events that report changes, so steering is smooth for as long as the key is down. Holding both arrows cancels out. Space starts a new run, but only once the current one has ended, so a player cannot restart by accident.

The loop reads the keyboard once per frame and passes the answer to every fixed step that frame runs. Reading it inside `update` would tie the simulation to SDL again, which is what the argument above avoids.

`SDL_PushEvent`, which the *device chapter* uses to drive a program from a test, does not help here. A pushed `SDL_KEYDOWN` for the left arrow arrives on the event queue with `scancode = 80` as expected, but `key_pressed(SDL_SCANCODE_LEFT)` stays false: the key state is SDL's record of the physical keyboard, and a pushed event does not change it. Tests drive `update` instead.

The craft is a small hierarchy

```
sub m_rotate_z {                              # the pattern of m_rotate_
↪y, about z
```

(continues on next page)

(continued from previous page)

```
    my ($rad) = @_;
    my ($c, $s) = (cos $rad, sin $rad);
    return [ $c,$s,0,0,  -$s,$c,0,0,  0,0,1,0,  0,0,0,1 ];
}

sub walk {
    # $parent_world is the identity at the root. Multiplication
↪order
    # is parent * local: the local transform applies FIRST, then the
    # parent's, which is the right-to-left rule from foundations.
    my ($node, $parent_world, $out) = @_;
    my $world = m_mul($parent_world, $node->{local});
    $out->{ $node->{name} } = $world;
    walk($_, $world, $out) for @{ $node->{children} };
    return $out;
}

# Each part is the unit cube, sized and placed relative to the body.
my %PART = (
    hull    => m_scale(0.5, 0.25, 1.0),
    cockpit => m_mul(m_translate(0, 0.17, -0.05), m_scale(0.25, 0.
↪12, 0.4)),
    lwing   => m_mul(m_translate(-0.5, 0, 0.15), m_scale(0.6, 0.06,
↪0.5)),
    rwing   => m_mul(m_translate( 0.5, 0, 0.15), m_scale(0.6, 0.06,
↪0.5)),
);

sub craft_node {
    my $c = $game{craft};
    # Moving right, the craft banks right: clockwise seen from
↪behind,
    # which is a negative angle about z.
    return { name     => 'craft',
             local    => m_mul(m_translate($c->{x}, 0.5, $c->{z}),
↪m_rotate_z(-2.5 * $c->{vx})),
             children => [ map { +{ name => $_, local => $PART{$_},
↪children => [] } }
                           sort keys %PART ] };
}
```

`walk` is the *scene-graph chapter's*, unchanged. The body node carries the craft's position and its bank; the four parts carry only their offset and size relative to the body. Banking rotates the body, and the wings tip with it, one down and one up, without any part knowing the angle. That is the turntable and arm from that chapter again.

The parts are cubes stretched by different amounts along each axis, and the *GPU scene chapter* warned that a non-uniform scale bends normals. It does not bend these: every face normal of a box lies along one of the box's own axes, a scale only lengthens such a vector, and the fragment shader normalises it back. The warning is for slanted faces.

The chase camera

```
sub camera {
    my $c = $game{craft};
    # Eye and target slide sideways together, by less than the craft
    # moves: the view never turns, and the craft drifts off centre
 ↪in a
    # turn, which is what makes the steering visible.
    my $x = 0.6 * $c->{x};
    return ([ $x, 2.5, $c->{z} + 6 ], [ $x, 0.5, $c->{z} - 6 ]);
}
```

The eye is 6 units behind the craft and 2.5 up, looking at a point 6 units ahead of it on the floor. Both move with the craft, so the view matrix from `m_look_at` changes every step while the craft's place in the picture barely does. The up hint is `[0, 1, 0]`, safely away from the view direction, which never points straight down.

One draw for everything

```
sub decode { return [ map { $_ ** 2.2 } @_ ] }   # picked by eye: to
 ↪linear light

my %COLOUR = (
    hull  => decode(0.85, 0.85, 0.90),  cockpit => decode(0.20, 0.
 ↪50, 0.95),

                    m_mul(m_rotate_z(0.785), m_scale(0.2, 0.2, 0.
↪2))), $COLOUR{gem});
    }
    return @inst;
}
```

Everything on the screen is the one cube from the *GPU scene chapter*: the craft's four parts, the blocks, the gems turned onto a corner and spun, the floor strips, the rails and the score. Each is an instance, a model matrix and a colour, 20 floats, and the whole frame is **one** `draw_indexed` call with however many instances this frame has. The count varies, since taken gems are not drawn and the score row grows, but never beyond `MAX_INSTANCES`, 88, which sizes the buffer once.

The floor strips show why instancing and plain data suit each other. There is no floor object to move: each frame computes where the 30 strips are from the craft's position, and the pattern stays fixed to the world because a strip's colour depends on which two-unit band it covers. `%` of a negative number is non-negative in Perl when the right-hand side

is positive, so the bands alternate correctly on both sides of zero.

The colours are picked by eye and decoded into linear light before upload, for the reason the *GPU scene chapter* gives: the surface stores sRGB and the lighting is computed in linear light.

The shader: per-fragment light, and fog

```
my $WGSL = <<'WGSL';
struct Scene {
    view_proj: mat4x4<f32>,
    light_dir: vec4<f32>,     // xyz: toward the light, world space
    eye:       vec4<f32>,     // xyz: camera position, world space
    fog:       vec4<f32>,     // rgb: the colour distance fades to
};
struct Instance {
    model:  mat4x4<f32>,
    colour: vec4<f32>,
};
@group(0) @binding(0) var<uniform> scene: Scene;
@group(0) @binding(1) var<storage, read> inst: array<Instance>;

struct VOut {
    @builtin(position) pos: vec4<f32>,
    @location(0) world:  vec3<f32>,
    @location(1) normal: vec3<f32>,
    @location(2) colour: vec3<f32>,
};

@vertex
fn vs(@location(0) p: vec3<f32>, @location(1) n: vec3<f32>,
      @builtin(instance_index) i: u32) -> VOut {
    let m = inst[i].model;
    let w = m * vec4<f32>(p, 1.0);
    var o: VOut;
    o.pos    = scene.view_proj * w;
    o.world  = w.xyz;
    o.normal = (m * vec4<f32>(n, 0.0)).xyz;
    o.colour = inst[i].colour.rgb;
    return o;
}

@fragment
fn fs(v: VOut) -> @location(0) vec4<f32> {
    let n = normalize(v.normal);
    let l = normalize(scene.light_dir.xyz);
    let e = normalize(scene.eye.xyz - v.world);
    let lambert = max(dot(n, l), 0.0);
    let h = normalize(l + e);
    let spec = pow(max(dot(n, h), 0.0), 32.0);
    let c = min(v.colour * (0.1 + 0.9 * lambert) + vec3<f32>(0.4) *
```

(continues on next page)

(continued from previous page)

```
↪spec, vec3<f32>(1.0));
    // Fade to the fog colour from 25 to 55 units away, so that a␣
↪block
    // placed at the far end appears out of the haze instead of␣
↪popping in.
    let f = clamp((distance(scene.eye.xyz, v.world) - 25.0) / 30.0,␣
↪0.0, 1.0);
    return vec4<f32>(mix(c, scene.fog.rgb, f), 1.0);
}
WGSL
```

Everything above the fog is the *GPU scene chapter's* shader: instanced model matrices from a storage buffer, the normal turned with `w = 0`, and *shading's* Lambert and Blinn-Phong terms evaluated per fragment.

The fog is two lines and does a real job. A recycled block reappears 58 units from the eye, and without the fog it would appear there in one frame, fully drawn. With it, anything beyond 55 units is exactly the fog colour, and the fog colour is the clear colour, so the block is invisible until it comes within range and then fades in. Both colours are linear, so the `mix` is in linear light like the rest of the lighting.

The `fog` member is a `vec4` for the alignment reason the *GPU scene chapter* gives, and it makes the uniform 28 floats: 16 for the matrix and three `vec4`s.

The device and the buffers

The cube is the *GPU scene chapter's*, unchanged:

```
my @FACES = (
    # normal       u (right)     v (up)      u x v == normal
    [[ 1, 0, 0], [ 0, 0,-1], [0, 1, 0]],
    [[-1, 0, 0], [ 0, 0, 1], [0, 1, 0]],
    [[ 0, 1, 0], [ 1, 0, 0], [0, 0,-1]],
    [[ 0,-1, 0], [ 1, 0, 0], [0, 0, 1]],
    [[ 0, 0, 1], [ 1, 0, 0], [0, 1, 0]],
    [[ 0, 0,-1], [-1, 0, 0], [0, 1, 0]],
);
my (@vert, @idx);
for my $f (@FACES) {
    my ($n, $u, $v) = @$f;
    die "face winds the wrong way\n" unless v_dot(v_cross($u, $v),
↪$n) > 0;
    my $base = @vert / 6;
    for my $c ([-1,-1], [1,-1], [1,1], [-1,1]) {
        my $p = v_add(v_scale($n, 0.5),
                      v_add(v_scale($u, 0.5 * $c->[0]), v_scale($v,␣
↪0.5 * $c->[1])));
        push @vert, @$p, @$n;
    }
    push @idx, map { $base + $_ } 0, 1, 2, 0, 2, 3;
}
```

The window, the device and the surface, from the *device chapter*:

```
my $win    = SDL2::Window->new(title => 'pperl run', w => 800, h =>
 ↪600, resizable => 1);
my $gpu    = Peta::WebGPU::Device->new(window => $win);
my $surf   = $gpu->surface;
my $FORMAT = $surf->format;
my ($W, $H) = $surf->size;
```

These five lines are the only ones that need a window. Everything after them uses `$gpu`, `$FORMAT`, `$W` and `$H`, so replacing them with a device opened without a window and a texture format renders the same game into a texture, which is how it is checked below.

```
my $pipe = $gpu->render_pipeline($gpu->shader($WGSL),
    format => $FORMAT, depth => 1, cull => 'back',
    vertex_buffers => [ { attributes => ['float32x3', 'float32x3'] }
 ↪]);
my $verts      = $gpu->vertex_buffer(pack 'f*', @vert);
my $index      = $gpu->index_buffer(pack 'L*', @idx);
my $depth      = $gpu->depth_buffer($W, $H);
my $instances  = $gpu->storage_buffer(MAX_INSTANCES * 20 * 4);
my $scene      = $gpu->uniform_buffer(28 * 4);
my $gl_to_wgpu = [1,0,0,0,  0,1,0,0,  0,0,0.5,0,  0,0,0.5,1];

sub draw {
    my ($target) = @_;
    my @inst = instances();
    $instances->write(pack 'f*', @inst);

    my ($eye, $look) = camera();
    my $proj = m_mul($gl_to_wgpu, m_perspective(60, $W / $H, 0.1,
 ↪100));
    my $vp   = m_mul($proj, m_look_at($eye, $look, [0, 1, 0]));
    $scene->write(pack 'f*', @$vp, @{ v_norm([-0.4, 1.0, 0.6]) }, 0,
 ↪@$eye, 1,
                  @{ $COLOUR{sky} }, 1);

    $gpu->render_pass($target, clear => [ @{ $COLOUR{sky} }, 1 ],
 ↪depth => $depth)
        ->pipeline($pipe)->bind([$scene, $instances])
        ->vertices($verts)->indices($index)->draw_indexed(scalar
 ↪@idx, @inst / 20)->end;
}
```

The storage buffer is created at its largest size, and each frame writes only as many instances as it has. `draw_indexed`'s second argument says how many to draw, so whatever lies beyond them in the buffer is never read.

`$gl_to_wgpu` is the depth-range correction from the *GPU scene chapter*: without it, anything closer to the eye than about twice the near distance is silently cut away.

Score and game over, without text

```
my $title = '';
sub show_score {
    my $text = "pperl run - score $game{score}";
    $text .= " - crashed, Space to fly again" if $game{over};
    return if $text eq $title;           # only when it changes
    $win->set_title($text);
    $title = $text;
}
```

There is no text on the screen, and the game does not need any. The score is in two places: the window's title bar, through the SDL2 window's `set_title`, and the scene itself, as the row of small gems that grows over the lane. A crash shows the same way: the title says so, the craft turns red, and the world stops, because `update` returns at once when `over` is set.

The title changes only when the text does, rather than sending the window system the same string every frame.

The loop

```
new_game();
my ($last, $acc, $frames, $running) = (SDL_GetTicks(), 0, 0, 1);
while ($running) {
    while (my $ev = SDL_PollEvent()) {
        if ($ev->{type} == SDL_QUIT) { $running = 0 }
        elsif ($ev->{type} == SDL_KEYDOWN && $ev->{sym} == SDLK_
↪ESCAPE) { $running = 0 }
        elsif ($ev->{type} == SDL_WINDOWEVENT
               && $ev->{event} == SDL_WINDOWEVENT_SIZE_CHANGED) {
            ($W, $H) = @$ev{qw(data1 data2)};
            $surf->configure($W, $H);
            $depth = $gpu->depth_buffer($W, $H);     # must match␣
↪the frame
        }
    }

    my $steer = input();
    my $now = SDL_GetTicks();
    $acc += $now - $last;
    $last = $now;
    my $steps = 0;
    while ($acc >= STEP) {
        update($steer);
        $acc -= STEP;
        if (++$steps >= MAX_STEPS) { $acc = 0; last }
    }

    show_score();
```

(continues on next page)

(continued from previous page)

```
    my $frame = $surf->next_frame or next;
    draw($frame);
    $frame->present;
    $running = 0 if $max_frames && ++$frames >= $max_frames;
}
printf "%d frames, score %d%s\n", $frames, $game{score}, $game{over}
 ↪? ', crashed' : '';
```

This is the *device chapter's* loop with two lines added, `input` and `show_score`. The event loop handles quitting and resizing; the keyboard state handles steering. The fixed step keeps the game's speed independent of the display: a 144 Hz display draws more frames of the same run, not a faster run. **The step cap and the dropped backlog matter more in a game than anywhere else.** Without them, a window dragged for a second would come back and run 60 steps at once, and the player would find the craft already wrecked on a block they never saw.

Running the game

Save the blocks above in order as `run.pl`, with `foundations.pl` beside it, and start it:

```
pperl run.pl
```

The left and right arrow keys steer, Space flies again after a crash, and Escape or the close button quits. An optional number runs that many frames and stops, which is how a script can run it unattended.

In a window, the program draws and presents a new frame on every pass of the loop. Captures of the window taken a quarter of a second apart show the blocks coming closer, and when the craft meets one the title bar changes from `pperl run - score 0` to `pperl run - score 0 - crashed, Space to fly again` and the craft turns red.

Checking it without a keyboard

A player cannot be scripted through the keyboard, as the input section found, and a picture is easiest to check as bytes in a texture, as the GPU arc checked its own. Both point the same way: keep the game and change its two ends. The five window lines are replaced by a device opened without one:

```
my $gpu    = Peta::WebGPU::Device->new;      # no window
my $FORMAT = 'rgba8unorm-srgb';              # what the window
 ↪shows, in R, G, B, A order
my ($W, $H) = (640, 480);
```

and the last two blocks, the title and the loop, are left out. What remains is the whole game, driven by calls instead of keys:

```
srand 7;                                     # the same field every
 ↪time
new_game();
update(0) for 1 .. 20;                       # straight on
```

(continues on next page)

(continued from previous page)

```
update(1) for 1 .. 12;                          # then hard right
my $img = $gpu->texture(width => $W, height => $H, format =>
 ↪$FORMAT);
draw($img);
save_png('turn.png', $img->read, $W, $H);
```

save_png is the *device chapter's*. Run this way, the behaviour described in this chapter was checked against the game's own subs:

```
straight on, seed 7     crash on step 91: a block at x = 1.27, width␣
 ↪1.01,
                        its left face at 0.765 against the box's 0.
 ↪80
60 more updates         state unchanged, keys or not
right arrow held        vx = 0.036 0.065 0.088 0.106 0.121 on steps␣
 ↪1 to 5
held at the edge        x = 3.200, vx = 0; the first step back moves␣
 ↪at once
gem straight ahead      inside the box for 14 steps, scored 1
gem at x = 1.1, 1.2     scored 1, 0: the box edge 0.8 plus the␣
 ↪radius 0.35 is 1.15
chase camera            craft in view space at [0.4 x, -0.986, -6.
 ↪247] throughout
5000 steps, lane clear  speed 0.3 from step 4500, 574 blocks and␣
 ↪gems reused,
                        never more than 88 instances
same seed, same inputs  a recorded run of 472 steering values,␣
 ↪replayed,
                        ends in the identical state
```

The camera line is the chase camera's invariant, in the form the *scene-graph chapter* tested its orbit camera: the craft's position relative to the camera never changes in height or depth, and sideways it moves by `0.4 x`, the part of its movement the camera does not follow. That is what "the camera follows" means as a number.

The rendered frames say the rest. The pixel at the point where foundations' screen mapping puts the top of the hull is the hull's colour, lit, in every frame; after the crash the same pixel is red; and the sky reads back as `128 160 205`, within two of the `0.5, 0.62, 0.8` picked by eye, because the decode before upload and the surface's encode on the way out undo each other:

```
frame     hull top       cockpit        sky
start     200 200 212    43 118 223     128 160 205
turn      179 179 190    37 105 200     128 160 205
crashed   212  16  16    212  16  16    128 160 205
```

The turning frame's hull is darker because the bank tips its top away from the light. The frame with two gems collected shows two small gems above the lane, at the pixels where the score row's positions project, 195 157 24 and 194 156 22.

What this demonstrates

A game is the smallest program that needs every part of this guide at once. The mathematics places the objects and the camera; the meshes chapter's volumes decide what touches what; the scene graph lets a part follow its parent; the GPU arc draws every object in one call and lights every pixel; the fixed step keeps the simulation honest about time.

And the shape that made the 2D game easy to reason about carried over unchanged. The world is a hash, `update` is arithmetic on it, and the draw step reads it. Because `update` takes its input as an argument, the whole game can be played by a list of numbers, and that is how it was checked.

4.2.12 pack and unpack - a tutorial

`pack` and `unpack` are Perl's low-level serialisers. They convert between Perl values and the raw byte strings that binary formats - network protocols, file headers, C structures, fixed-width records - actually carry on the wire.

Most Perl programmers meet them rarely and forget them quickly. This tutorial is here so that when you do meet them, you already know the shape of the problem.

When you need pack and unpack

Reach for them when you are:

- **Speaking a wire protocol** - DNS queries, TCP/IP headers, MQTT frames, anything with "big-endian 16-bit length" in its spec.
- **Parsing a binary file format** - PNG, GIF, WAV, ELF, GZip, Intel HEX, all the formats whose first four bytes are a magic number followed by well-known integer fields.
- **Slicing fixed-width text records** - log files, accounting ledgers, reports from mainframes. `unpack` is cleaner than chained `substr` calls and handles blank-field ambiguity that `split` collapses.
- **Passing data to a system call** - `syscall`, `ioctl`, and the rare `sockaddr_*` constructor expect bytes laid out as a C struct.

For text serialisation (JSON, YAML, CSV, XML), reach for the appropriate module instead. `pack` is for binary.

How this tutorial is organised

Each chapter teaches one topic and stands on its own. You can read them in order, or jump to the one that answers your question.

Bytes and widths

By the end of this chapter you will be able to pick the right integer directive for a given field, count the bytes a template produces, and tell when you need a fixed width versus a native width.

Binary formats are specified by *byte counts*. "A 16-bit unsigned length field followed by 4-byte packets" is an instruction about bytes, not about numbers. The first job of a `pack` template is to match those counts exactly.

The fixed-width integer directives

The spine of every template:

Bytes	Unsigned	Signed
1	`C`	`c`
2	`S`	`s`
4	`L`	`l`
8	`Q`	`q`

Each directive consumes one value from the list and produces exactly that many bytes:

```
length pack "C",  65                  # 1
length pack "S",  12345               # 2
length pack "L",  1_000_000_000       # 4
length pack "Q",  1_000_000_000_000   # 8 (if 64-bit Perl)
```

A repeat count packs that many of the same directive in a row:

```
length pack "C4", 1, 2, 3, 4          # 4
length pack "L3", 10, 20, 30          # 12
```

Compose them freely; the total length is the sum:

```
length pack "C S L", 65, 1000, 2_000_000   # 1 + 2 + 4 = 7
```

`C` is your default one-byte directive

For protocol bytes - flag fields, version numbers, opcodes, type tags - `C` (unsigned 8-bit, 0 to 255) is almost always the right choice. `c` (signed, −128 to 127) turns up only when the spec says "signed". `W` is a variant of `C` that allows values above 255 when your template is in `U0` (UTF-8) mode - ignore it until you hit that case.

IP addresses are the textbook example:

```
my $raw = pack "C4", 192, 168, 1, 42;
#         ^-- four unsigned bytes, in the order the list gives them
```

Native vs. fixed width

The directives `s` / `S` / `l` / `L` are specified to be exactly 2 and 4 bytes regardless of the `C` compiler. Their native-width counterparts add `!`:

```
length pack "l",  0          # 4  (always)
length pack "l!", 0          # 4 on most 32-bit and 64-bit systems,
```

(continues on next page)

(continued from previous page)

```
                                # 8 on 64-bit Alpha, some legacy␣
↪Unixes.
```

`i` and `I` are *always* native (whatever `sizeof(int)` returns on this machine, with a 32-bit minimum). `i!` is an alias for `i`.

Rule of thumb:

- For interoperable binary (wire formats, on-disk files, data crossing machines) use **fixed width** (`l`, `L`, ...) plus an explicit endianness - or the *portable shortcuts*.
- For in-process work that matches some local `C` struct you are about to hand to `ioctl` or `syscall`, use **native width** (`l!`, `L!`, `i`, `I`).

Mixing the two is fine, but stop and ask yourself why each time.

Counting the length of a template

Before you send a record, check the byte count is what the spec says. `length pack(TEMPLATE, ...)` with placeholder values is the simplest way:

```
my $sz = length pack "n N L C", 0, 0, 0, 0;
# 2 + 4 + 4 + 1 = 11
```

For templates whose length depends on native sizes, `length pack TEMPLATE, 0, 0, ...` gives you the answer on the current machine.

Worked example: a minimal packet header

A hypothetical protocol specifies:

- 8-bit version
- 8-bit flags
- 16-bit big-endian length (payload follows)

Three fields, four bytes total. The template writes itself:

```
my $hdr = pack "C C n", $version, $flags, length $payload;
my $pkt = $hdr . $payload;

length $hdr    # 4
```

Two things to note:

1. We did not spell out `C1 C1 n1` - a bare directive letter has an implicit repeat count of 1.
2. The length in the third field is computed from `$payload` in the same expression. A later chapter shows the */ form* that ties the two together so you cannot forget.

Edge cases worth remembering

- **Values out of range**: `pack "C", 256` silently truncates (you get `\x00`). There is no warning. Check ranges yourself if the data is untrusted.
- **Signed vs. unsigned round-trip**: a value packed as `C` and unpacked as `c` (or vice versa) flips sign for values ⩾ 128:

```
unpack "c", pack "C", 200        # -56
```

- **Too few values**: missing values pack as `0` for numeric directives, `""` for strings. No warning.

The next chapter handles the question every multi-byte integer raises: which end of the number goes first?

Endianness

By the end of this chapter you will be able to choose between native, big-endian, and little-endian byte order; use the portable `n` / `N` / `v` / `V` shortcuts; and apply the `<` / `>` modifiers to any integer or float.

A multi-byte integer has to be written somehow. `0x12345678` is four bytes - but in which order? Two conventions dominate:

- **Big-endian** - highest-order byte first: `12 34 56 78`. Used by most network protocols, by PowerPC and SPARC CPUs, and by file formats that care about portability (PNG, Java `.class`, most TCP/IP headers).
- **Little-endian** - lowest-order byte first: `78 56 34 12`. Used by x86, x86-64, ARM (in its common modes), and by file formats from the Intel lineage (BMP, WAV, TIFF in its common variant, all of FAT).

Mix these up and you will read nonsense. `pack` gives you three ways to pin down the byte order.

The portable shortcuts: n / N / v / V

Four letters cover the most common wire-format cases:

Directive	Bytes	Endian	Meaning
`n`	2	big-endian	Network (port numbers)
`N`	4	big-endian	Network (IPv4 addrs)
`v`	2	little-endian	“VAX”
`V`	4	little-endian	“VAX”

“Network byte order” is big-endian. If you are reading an RFC, the answer is almost always `n` or `N`.

```
my $port = pack "n", 443;          # "\x01\xbb"
my $ip   = pack "N", 0x7F000001;   # "\x7f\x00\x00\x01" - 127.0.0.1
```

These four are unsigned only. With the `!` modifier they become signed:

```
my $neg = pack "n!", -1;            # "\xff\xff"
```

If your field fits one of these four shapes, use them. They are portable, they are readable, and their meaning does not depend on the CPU running the code.

The general modifiers: < and >

Any integer directive (`s`, `S`, `l`, `L`, `i`, `I`, `q`, `Q`, `j`, `J`) and every float (`f`, `d`, `F`, `D`) accepts an endianness modifier:

Modifier	Meaning	Mnemonic
>	Big-endian	The “big end” touches the directive letter
<	Little-endian	The “little end” touches the directive

Read `l>` as “long, big end” and `l<` as “long, little end”.

```
my $be32 = pack "l>", -1_000_000;    # big-endian 32-bit signed
my $le64 = pack "q<", 2 ** 40;       # little-endian 64-bit signed
my $bed  = pack "d>", 3.14159;       # big-endian IEEE 754 double
```

For the common 16- and 32-bit unsigned cases, `n` / `N` / `v` / `V` are shorter and should be preferred. Use < / > when:

- the field is signed - `n` and `N` are unsigned by default
- the field is 64-bit - there are no `n`/`N` equivalents for `q`/`Q`
- the field is a float - `n`/`N` cover integers only
- you want to apply endianness to a whole group (see below)

Applying endianness to a group

If every integer in a sub-structure shares the same byte order, write the endianness modifier once on a group:

```
my $rec = pack "(s l l)<", $flags, $x, $y;
# same as "s<l<l<"
```

A group-level modifier cascades into every byte-ordered directive inside, including nested groups. Directives that do not accept a byte-order modifier (such as `C`) are silently ignored.

Native order: when it *is* what you want

The bare directives `s` / `S` / `l` / `L` / `i` / `I` / `q` / `Q` produce the host CPU’s native byte order. That is useful when:

- You are building a C struct in memory for an `ioctl` call on the *same* machine.
- You are writing a scratch file that only this program will read back.
- The protocol spec explicitly says “host byte order” (rare).

It is **wrong** when data leaves the process: a file written on a laptop, read on a server, must not use native order unless both machines happen to agree.

Detecting the host's byte order

Useful once, as a sanity check. Pack 1 as a 16-bit integer and look at the first byte:

```
my $little_endian = unpack("c", pack("s", 1)) == 1;
my $big_endian    = unpack("c", pack("s", 1)) == 0;
```

On x86 the first is true; on a big-endian host the second is true.

Floats have endianness too

IEEE 754 does not pin down byte order. A double written on a little-endian machine comes out reversed on a big-endian one:

```
# send a float in big-endian order - safe across machines that use␣
↪IEEE 754
my $buf = pack "d>", 2.718281828;
```

Mismatched hardware (non-IEEE float formats, exotic long double layouts) cannot be repaired by < / > alone. For portability across odd platforms, send floats as text or use a byte-exact format like the output of `sprintf "%a"`.

Worked example: parsing a BMP header

The BMP bitmap format begins with the ASCII magic `BM` followed by three little-endian 32-bit fields (file size, reserved, pixel data offset):

```
my ($magic, $filesize, $reserved, $pixoff) =
    unpack "A2 V V V", $bmp_header;

die "not a BMP" unless $magic eq "BM";
```

`V` is little-endian 32-bit unsigned - exactly what the spec demands. `A2` reads two bytes as a text string without stripping. Every field is the right shape; no byte-swapping required, no platform-dependent behaviour.

What to remember

- **Wire format? Use `n` / `N` / `v` / `V`** - or < / > if you need signed, 64-bit, or float.
- **Stay inside one process? Native is fine** - but flag the choice deliberately.
- **IEEE 754 is not enough.** If a float crosses a machine, pin the byte order.

With byte counts and byte order under control, the remaining directives - strings, positioning, groups - fall out naturally.

Strings, bits, and nybbles

By the end of this chapter you will be able to pack and unpack fixed-width strings, C-style NUL-terminated strings, bit strings, and hex strings - the three text-ish families of directives.

Binary formats carry string data in several distinct flavours: raw bytes, space-padded text, NUL-terminated C strings, bit fields, hex-encoded numbers. `pack` has a directive for each.

The three string directives: a / A / Z

All three pack exactly one value into a fixed width. They differ in what they pad with, and - crucially - in what `unpack` strips back off:

Letter	Pad byte	Unpack returns	Typical use
a	`"\0"` (NUL)	All bytes unchanged	Arbitrary binary
A	`" "` (space)	Trailing whitespace and NUL stripped	ASCII fixed-width text
Z	`"\0"` (NUL)	Bytes up to the first NUL	C-style NUL-terminated

The width is the **repeat count**, not a count of values:

```
pack "a4", "hi"           # "hi\0\0"
pack "A4", "hi"           # "hi  "
pack "Z4", "hi"           # "hi\0\0"

pack "a4", "abcdef"       # "abcd"  - truncated
pack "A*", "hello"        # "hello" - whatever the value's length is
```

Z guarantees a trailing NUL - with a caveat

`Z` always reserves space for at least one terminating NUL:

```
pack "Z*", "hello"        # "hello\0"   - a free NUL appended
pack "Z5", "hello"        # "hell\0"    - truncated to make room!
```

If a C program on the other side expects a zero-terminated `char[32]`, use `Z32`. It will pack up to 31 bytes of data plus the terminator.

Picking between a and A for text

- The data is ASCII, padded with spaces on disk → `A`.
- The data is arbitrary bytes (might contain spaces or NULs as valid content) → `a`.

The classic trap: you pack a name with `A20` and the wire format uses NUL padding. `unpack "A20"` strips both spaces *and* NULs, so it looks fine - but `pack "A20", "bob"` will round-trip to `"bob  "` padded with spaces. If the spec says NUL padding, use `a` on the pack side.

Worked example: fixed-width text records

A ledger file lays data out in columns:

```
0         1         2         3         4
01234567890123456789012345678901234567890123456789012345678
2026-04-22 coffee at the station           3.50
2026-04-23 train to Brussels              42.00
```

Column 1-10 is the date, 12-38 the description, 40-47 the amount. The gaps are single spaces (byte 11 and byte 39). unpack with `A10 x A27 x A*` peels each record apart:

```
while (<$ledger>) {
    chomp;
    my ($date, $desc, $amount) = unpack "A10 x A27 x A*", $_;
    print "  $date | $desc | $amount\n";
}
```

`x` skips one byte; `A27` eats the description column and strips trailing spaces; `A*` greedy-eats the remaining bytes as the amount. The output side uses wider fields so spaces survive the round-trip:

```
my $line = pack "A11 A28 A8 A*", $date, $desc,
                                 sprintf("%.2f", $amt_left),
                                 sprintf("%12.2f", $amt_right);
```

Notice the extra byte on each `A` width - that single extra byte is the column gap. A consistent byte budget per column is what makes fixed-width records tractable at all.

Bit strings: b and B

A bit string is a string of `"0"` and `"1"` characters that packs into actual bits. Two directives, differing only in which direction you read each byte:

Directive	Bit order within each byte
b	LSB first - bit 0, 1, 2, 3, 4, 5, 6, 7
B	MSB first - bit 7, 6, 5, 4, 3, 2, 1, 0

The repeat count is the number of **bits**, not bytes:

```
pack "B8", "10001100"      # "\x8c" - MSB first, bit 7 set, bit 3 &␣
↪2 set
pack "b8", "00110001"      # "\x8c" - LSB first, same byte
```

`B` matches the usual "left-to-right is high-to-low" convention you see in binary dumps; `b` matches the convention used by some hardware registers and the `vec` built-in. Use `B` when you are writing out a "normal" binary number, `b` when you are mirroring a data sheet that numbers bit 0 on the right.

Counting set bits

One of the more surprising uses of unpack: count set bits in a buffer with a single call. %32b* unpacks the bits and asks for a 32-bit sum, which is the count:

```
my $n_bits = unpack "%32b*", $mask;
```

The %N prefix is unpack-only - see the *positioning chapter* for the other uses.

Hex strings: h and H

Hex strings are the text representation most developers read - two hex digits per byte. Two directives, differing in nybble order:

Directive	Nybble order
h	Low nybble first
H	High nybble first

H is the "normal" hex dump - read left to right, high digit then low:

```
pack "H*", "deadbeef"      # "\xde\xad\xbe\xef"
unpack "H*", "\xde\xad\xbe\xef"   # "deadbeef"
```

h reverses each byte's nybbles - rarely what you want unless a spec explicitly says so. If the round-trip you expect is *not* what you get, try the other letter.

```
pack "h*", "ef"            # "\xfe"  (nybbles swapped)
pack "H*", "ef"            # "\xef"
```

Choosing between them

You have	Reach for
ASCII in a fixed-width column on disk	A
Arbitrary bytes in a fixed-width slot	a
A C-style NUL-terminated string	Z
A binary number as a string of 0 / 1	B
Same, with the register-convention bit order	b
A hex string in the normal reading order	H
A hex string with nybbles swapped	h

Bits, nybbles, and string directives all share one rule: the repeat count specifies the width of the *single* value being packed, not the number of values. That's the one fact to carry forward.

Next up: ( ) groups and repeat counts, the tools for applying a pattern of directives to a list of values of unknown length.

Grouping and counts

By the end of this chapter you will be able to repeat a pattern of directives across a list of values, use the `*` and `[…]` forms of repeat count, and write self-describing length-prefixed records with the `/` directive.

A bare repeat count applies to *one* directive letter: `C4` packs four bytes. The moment the repeating unit is more than one directive - "pack a short and two bytes, many times" - you need a group.

`()` - a group is a sub-template

Parentheses gather a sequence of directives so that a repeat count or endianness modifier applies to the whole. Compare:

```
pack "C S C S C S", @a, @b, @c, @d, @e, @f      # repeat by hand
pack "(CS)3",       @a, @b, @c, @d, @e, @f      # same thing, grouped
pack "(CS)*",       @pairs                      # repeat as often as␣
↪values last
```

A group has no byte cost of its own - it is a syntactic device. The total packed length is what the directives inside it would produce without the parentheses.

Grouping with endianness

The single most practical use of a group - a sub-structure whose every integer shares one byte order:

```
my $rec = pack "(l s s)<", $id, $x, $y;
# same as "l<s<s<"
```

The `<` cascades into every byte-ordered directive inside, including nested groups. Directives that do not accept a byte-order modifier (like `C`, `a`, `Z`) are silently unaffected.

Repeat counts in full

After any directive or group, you may write:

Form	Meaning
`N`	Apply the directive/group `N` times
`*`	Apply as often as values last. For `x`, `X`, `@`: equivalent to 0. For `u`: 45.
`[N]`	Same as `N`
`[templ]`	Repeat count is the packed-byte length of the bracketed template

The `[template]` form is the tool for expressing "as many bytes as a *foo* takes":

```
pack "x[L]"      # skip 4 bytes (sizeof a packed long)
pack "x[d]"      # skip 8 bytes (sizeof a packed double)
pack "a[Q]"      # one string 8 bytes wide
```

It is especially useful for alignment (see the *positioning chapter*) and for templates whose widths must track the platform-dependent size of a native integer:

```
pack "a[l!]", $native_long_buf      # room for one native long
```

* is per-value-group, not "swallow everything"

A single * counts "remaining values" *for this directive*. Two A*s in a row do not race:

```
pack "A*A*", "hello", "world"     # "helloworld"
```

The first A* packs all of "hello"; the second packs all of "world". Each * consumes *one* value from the list, at that value's full length. This is the general rule: **every directive corresponds to one piece of data**, whatever its repeat count.

The / directive - length and data together

Wire formats frequently store a count immediately before the thing being counted: "a 2-byte length, then that many bytes of payload". The / directive ties the two into one step.

In pack: *length-item*/*sequence-item*

Write *two* directives separated by a slash. The first packs the length; the second packs the payload. pack computes the length for you:

```
my $msg = pack "n/a*", "hello, world";
# "\x00\x0chello, world"
#  ^^^^^^^^ big-endian 16-bit length = 12
#           ^^^^^^^^^^^^ the payload itself
```

The *length-item* may be any numeric directive - C, n, N, w, S<, and so on - or a string directive such as A4 when the protocol writes the length as ASCII:

```
my $buf = pack "A4/A*", "Humpty-Dumpty";
# "13  Humpty-Dumpty"  - 4-char ASCII length, then the string
```

In unpack: /*item*

The unpack form is simpler: a bare / before the item. The count is taken from the most recent integer directive:

```
my ($payload) = unpack "n/a*", $msg;     # "hello, world"
```

Reading that template: "read a n integer, call it L; then read L bytes as an a*-style string." The length itself does not appear in the output list.

The common mistake: A* after a /

You cannot put another A* or a* after a /-introduced field in unpack and expect it to behave - the * is greedy:

```
# Wrong - $prio will be undef, $sm gets everything left
my ($src, $dst, $sm, $prio) = unpack "Z* Z* C A* C", $buf;

# Right - use /A* so $sm knows where to stop
my ($src, $dst, $sm, $prio) = unpack "Z* Z* C/A* C", $buf;
```

In the second template, C/A* reads a byte-count then that many bytes. Everything after the slash respects it, and the trailing C picks up the next byte as expected.

Worked example: key-value pairs

A protocol stores a dictionary as count followed by count pairs of (length, key, length, value):

```
my %env = ( HOST => "example.com",
            PORT => "443",
            USER => "alice" );

my $blob = pack "S (S/A* S/A*)*",
                scalar keys %env,
                %env;
```

Reading it back:

```
my %parsed = unpack "S/(S/A* S/A*)", $blob;
```

The pack template says: “one 16-bit count (of pairs), then repeat the sub-template S/A* S/A* for each pair.” The unpack template reads the count and applies it to the group directly - the count is no longer in the output list.

Edge cases and constraints

- **/ makes no sense with a fixed-length item.** The second directive must be variable-width: a*, A*, Z*, /A$n, or the like. Perl will reject a fixed-length second item.
- **()* with pack cannot be matched by ()* on unpack.** Pack has the values, so it can say “repeat until done”. Unpack does not know how many repetitions are encoded in the buffer unless a count directive precedes the group.
- **Nested groups** are legitimate and common:

  ```
  pack "((CC)(S))<", @records
  ```

  Endianness modifiers cascade through every nesting level.
- **Repeat count on a group** applies to the whole group and takes that many repetitions’ worth of values. (CS)3 consumes *six* list values, not three.

Next chapter: the directives that move around inside a template without producing a value - x, X, @, ..

Positioning and padding

By the end of this chapter you will be able to skip bytes, insert padding, jump to absolute offsets, and align fields to arbitrary boundaries - the four directives x, X, @, and ..

Some directives produce a byte without consuming a value from the list (pad bytes). Some consume a value without producing a byte (positioning commands). Taken together they let you model the gaps and alignments that real binary formats contain.

x - skip forward / insert NUL

x is the simplest of the four. In pack it inserts one NUL byte without consuming a value; in unpack it skips one byte without producing a value.

```
pack   "C x C", 65, 66       # "A\0B"
unpack "C x C", "A\0B"       # (65, 66)
```

With a repeat count, it inserts or skips that many bytes:

```
pack "C x3 C", 65, 66        # "A\0\0\0B"
```

x* means “skip to the end of the string” in unpack, and is equivalent to x0 (no-op) in pack.

x does not mean “a space”

The confusing thing about x is that it pads with NUL, not with space. If you want space padding for text, use A with a wider repeat count instead:

```
# Wrong - Perl inserts a NUL, not a space
pack "A10 x A10", "date", "label"
# "date      \0label     "

# Right - widen the field
pack "A11 A10", "date", "label"
# "date       label     "
```

X - back up

X moves the write/read head backward by one byte. With a repeat count, backward by that many bytes. Unlike x, X has no effect on the output bytes of pack - it just rewinds so a subsequent directive overwrites them.

```
pack "CC X C", 65, 66, 67    # "AC" - the second C overwrites 66␣
↪with 67
```

X is mostly useful with unpack: peek forward, then rewind to re-read:

```
# Read a 16-bit length, then re-read the same 2 bytes as two␣
 ↪separate bytes
my ($len, $hi, $lo) = unpack "n XX CC", $frame;
```

X before the start of the string is a fatal error.

@ - jump to absolute position

@N sets the current position to byte N **within the innermost ( ) group** (or from the start of the string if there is no enclosing group). In pack, this zero-fills from the current position forward, or truncates if the current position is past N:

```
pack "C @4 C", 65, 66        # "A\0\0\0B"  - byte 0 is 'A', byte 4␣
 ↪is 'B'
```

This is the template-level equivalent of `offsetof(struct, field)`: if a C header file tells you field 2 lives at offset 12, @12 parks you there regardless of what the preceding directives did.

@ inside a group

Within each repetition of a group, @ restarts at 0. That can surprise you:

```
pack '@1A((@2A)@3A)', qw(X Y Z)
# "\0X\0\0YZ"
```

Walking through: the outer @1A puts "X" at byte 1 (with a NUL at byte 0). The inner group starts a new coordinate system at "X"'s position; inside it, @2A puts "Y" at the group's byte 2 (two further NULs in between), then @3A puts "Z" at byte 3 of the group. Read the spec carefully before using @ inside groups.

. - absolute position from the data

. is the value-driven cousin of @. Instead of a fixed repeat count, the position comes from the next value in the list:

```
pack "C . C", 65, 4, 66     # "A\0\0\0B" - position 4 from the next␣
 ↪value
```

Useful when the offset is computed at runtime - say, from a header field you just read:

```
my $buf = pack "C .N C", $type, $offset, $value;
# $offset bytes of NUL fill before $value
```

In unpack, . returns the current position rather than zero-filling:

```
my ($a, $pos) = unpack "C .", "hello";
# $a = 104 ('h'), $pos = 1
```

With .*, the offset is measured from the start of the whole string; with .N for integer N ≥ 1, from the start of the enclosing N-th group; with .0, relative to the current position.

The ! modifier: alignment

`x!N` and `X!N` turn `x` and `X` into alignment commands: advance (or rewind) to the nearest multiple of `N`. This is how you respect C struct padding rules.

```
# struct { char c; double d; char cc[2]; }
my $s = pack "c x![d] d c2", $c, $d, $c1, $c2;
```

Reading `x![d]`: "align forward to a multiple of the width a packed `d` would take" - i.e. 8 bytes. That is exactly the rule most C compilers apply to a `double` field after a `char`. Use `[l!]`, `[d]`, `[Q]` to name the alignment requirement without having to know the numeric width.

A bare `x!0` or `x!1` is a no-op.

Checksums - %N on unpack only

`%N` is a prefix on a single directive, not a standalone directive. It says "instead of returning the values the next directive would produce, return their `N`-bit sum". Common uses:

```
my $bytesum = unpack "%32C*", $buf;    # sum every byte
my $setbits = unpack "%32b*", $mask;   # count set bits
```

Exists only in `unpack`. There is no `%` in `pack` - you cannot pack a checksum directly; compute it yourself and pack the result with whatever integer directive you need.

Worked example: reading a variable-offset payload

Some formats start with a header of fixed size but put the actual data at an offset the header contains. The classic recipe:

```
# Header: magic (4 bytes), version (1 byte), data-offset (4 bytes
 ↪BE),
# then data starts at the byte-offset the header pointed at.
my ($magic, $ver, $off) = unpack "A4 C N", $file;

die "bad magic" unless $magic eq "MAGI";

# Jump to the data section
my $data = unpack "x$off a*", $file;
```

Two separate `unpack` calls - the first reads the offset, the second uses it in the template. Template strings are not regular expressions; they have no way to look ahead and use a computed value within the same call. Unpack in stages when the shape of the data depends on what you have just read.

With positioning and alignment in the toolbox, the two worked examples in the next chapters should read as straightforward applications: parsing a real network header and a real file format.

Network protocols - a DNS query

By the end of this chapter you will be able to build and parse a DNS query header and question section using `pack` and `unpack` - and take the same approach to any RFC-defined protocol.

A "network protocol" is, in the end, a sequence of byte-exact fields described in English prose. If you can read the field table, you can write the template. This chapter walks one concrete example - the DNS query packet - from the RFC wire diagram to a fully working pair of encode / decode subroutines.

The problem

We want to ask a DNS server for the A record of `example.com`. The UDP payload we send is a **DNS message** (RFC 1035), consisting of:

1. A 12-byte **header**.
2. A **question section** - the domain we are asking about, and the record type we want.

(A real client also parses the **answer section** in the response. We stop at encoding and showing a sketch of the decode.)

The header

From RFC 1035 section 4.1.1, the header is six consecutive 16-bit big-endian fields:

Offset	Field	Meaning
0	ID	Arbitrary 16-bit identifier we choose
2	Flags	Opcode, RD bit, response flags, rcode
4	QDCOUNT	Number of entries in question section
6	ANCOUNT	Number of resource records in answer
8	NSCOUNT	Authority records
10	ARCOUNT	Additional records

Six unsigned big-endian shorts means six `n` directives:

```
sub dns_header {
    my (%opts) = @_;
    pack "n6",
        $opts{id}      // 0,
        $opts{flags}   // 0,
        $opts{qd}      // 0,
        $opts{an}      // 0,
        $opts{ns}      // 0,
        $opts{ar}      // 0;
}
```

That is 12 bytes, exactly as the spec requires. `n6` is shorthand for `n n n n n n`.

The question section

A question is:

1. A **name**, encoded as a sequence of length-prefixed labels terminated by a zero-length label.
2. A 16-bit **QTYPE** (1 = A record).
3. A 16-bit **QCLASS** (1 = IN, Internet).

For `example.com` the name encodes as:

```
\x07 e x a m p l e   \x03 c o m   \x00
```

Each label begins with a length byte; the whole name ends with a zero-length label. Two things to notice: the length is one byte (`C`), not two; and there is a trailing `NUL` but it is *not* exactly what `Z` produces - it terminates the list of labels, not a single string.

We can build this by hand from a domain name:

```
sub encode_name {
    my ($name) = @_;
    my $out = "";
    for my $label (split /\./, $name) {
        die "label too long" if length($label) > 63;
        $out .= pack "C/a*", $label;
    }
    $out .= "\0";                       # zero-length terminator
    return $out;
}
```

Two directives in the loop body: `C/a*` - a single-byte length followed by the label bytes, computed automatically (see the *grouping-and-counts chapter* for the `/` form). After the loop, a literal `"\0"` terminates the list.

With `encode_name` in place, the whole question section is two concatenations and one `pack`:

```
sub dns_question {
    my ($name, $qtype, $qclass) = @_;
    return encode_name($name) . pack "n n", $qtype, $qclass;
}
```

Assembling the packet

```
use constant {
    QR_QUERY    => 0,
    OPCODE_QUERY=> 0,
    RD          => 1 << 8,          # recursion desired
    TYPE_A      => 1,
    CLASS_IN    => 1,
};
```

(continues on next page)

(continued from previous page)

```
sub dns_query_for_A {
    my ($name) = @_;
    my $id    = int rand 65536;
    my $flags = RD;                  # standard query, recursion␣
 ↪desired

    my $pkt = dns_header(
        id    => $id,
        flags => $flags,
        qd    => 1,                  # one question
    );
    $pkt .= dns_question($name, TYPE_A, CLASS_IN);

    return ($id, $pkt);
}

my ($id, $pkt) = dns_query_for_A("example.com");
# send $pkt over a UDP socket to port 53
```

29 bytes total: 12 header + 13 for the name (`\x07example\x03com\x00` is 13) + 2 + 2 for QTYPE and QCLASS. Run `length $pkt` to confirm.

Parsing the response header

The response has the same header shape - only the flag bits change. Decoding is the reverse template:

```
sub parse_dns_header {
    my ($buf) = @_;
    my ($id, $flags, $qd, $an, $ns, $ar) = unpack "n6", $buf;

    my %hdr = (
        id    => $id,
        qr    => ($flags >> 15) & 1,
        op    => ($flags >> 11) & 0x0f,
        aa    => ($flags >> 10) & 1,
        tc    => ($flags >> 9)  & 1,
        rd    => ($flags >> 8)  & 1,
        ra    => ($flags >> 7)  & 1,
        rcode =>  $flags        & 0x0f,
        qd    => $qd,
        an    => $an,
        ns    => $ns,
        ar    => $ar,
    );
    return \%hdr;
}
```

n6 pulls the six shorts out at one go; the individual flag bits come out of shifts and masks

on `$flags`. This pattern is universal: use `pack` / `unpack` for the byte-level layout, plain Perl for bit-level decoding of the flag fields.

Parsing a name

Names in the answer section use the same length-prefix encoding, plus a **pointer compression** mechanism we will skip. For a fresh name (no compression) the decoder mirrors the encoder:

```
sub decode_name {
    my ($buf, $offset) = @_;
    my @labels;
    while (1) {
        my $len = unpack "x$offset C", $buf;
        last if $len == 0;
        die "compression pointer" if $len >= 0xc0;
        my $label = unpack "x${\ ($offset + 1)} a$len", $buf;
        push @labels, $label;
        $offset += 1 + $len;
    }
    return (join(".", @labels), $offset + 1);
}
```

Three `unpack` calls, each with an `x$offset` prefix to skip to the right byte. The name alternates between one-byte lengths and variable-width labels, and the loop keeps reading until it hits a zero-length label. The `x$offset a$len` trick - compose a template from Perl values, call `unpack` - is the standard pattern when the next field's width depends on the previous field's value.

What to carry forward

- **An RFC byte-layout table maps directly to a template string.** Big-endian shorts → `n`, big-endian longs → `N`, bytes → `C`.
- **Length-prefixed fields use `C/a*` / `n/a*` / …** - one expression, no off-by-one counting by hand.
- **Bit-level fields inside a byte get decoded in plain Perl** after `unpack` has handed you the byte or short that contains them.
- **Variable-width data requires staged unpacking.** Read a length, then build the template for the data from that length, then call `unpack` again.

The next chapter applies the same approach to a real file format - a GIF image header - and introduces the "magic number check" idiom.

File formats - a GIF header

By the end of this chapter you will be able to identify a binary file by its magic number, parse its fixed-layout header, and decode bit-packed flag bytes. The example is the GIF image format, but the approach transfers directly to PNG, WAV, BMP, ELF, ZIP, and every other format built around a fixed header.

The GIF header and logical screen descriptor

A GIF file starts with two fixed-size blocks, thirteen bytes in total. From the GIF89a specification:

Header (6 bytes)

Offset	Bytes	Field
0	3	Signature - `"GIF"`
3	3	Version - `"87a"` or `"89a"`

Logical Screen Descriptor (7 bytes)

Offset	Bytes	Field	Byte order
6	2	Logical screen width	little-endian
8	2	Logical screen height	little-endian
10	1	Packed flags	-
11	1	Background colour index	-
12	1	Pixel aspect ratio	-

The packed flags byte has five sub-fields:

```
Bit:  7  6 5 4  3  2 1 0
     [GCT][CR  ][Sort][GCT size]
```

- bit 7 - global colour table flag
- bits 6-4 - colour resolution (minus 1)
- bit 3 - sort flag
- bits 2-0 - global colour table size (actual size = `2^(value+1)`)

Every format specification looks roughly like this: fixed-width fields in a known order, with the occasional packed-bits byte.

Reading it in

The template writes itself field by field:

```
sub parse_gif_header {
    my ($fh) = @_;
    binmode $fh;

    my $header;
    read $fh, $header, 13
        or die "short read: $!";

```

(continues on next page)

(continued from previous page)

```
    my ($sig, $ver, $w, $h, $flags, $bg, $aspect) =
        unpack "A3 A3 v v C C C", $header;

    die "not a GIF" unless $sig eq "GIF";
    die "unknown version: $ver" unless $ver eq "87a" or $ver eq "89a
↪";

    return {
        version => $ver,
        width   => $w,
        height  => $h,
        flags   => $flags,
        bg      => $bg,
        aspect  => $aspect,
    };
}
```

Directive by directive:

- `A3` `A3` - six bytes of ASCII, split into signature and version. `A` (not `a` or `Z`) because the spec guarantees exactly three characters with no padding - `A` returns them unchanged and has the safer strip-on-unpack behaviour.
- `v` `v` - two little-endian 16-bit unsigned integers. The GIF format is little-endian throughout; `v` is the exact match.
- `C` `C` `C` - three unsigned bytes.

Total width: 3 + 3 + 2 + 2 + 1 + 1 + 1 = 13 bytes. We read exactly that many before unpacking; any less is an error.

The magic-number check

Two lines above illustrate a pattern you will repeat for every file format:

```
die "not a GIF" unless $sig eq "GIF";
die "unknown version: $ver" unless $ver eq "87a" or $ver eq "89a";
```

Check the magic first, unpack the rest second. Reversing the order lets nonsense data through into later stages where the error messages are less clear. For formats with a longer magic (PNG is 8 bytes, ELF is 4, WAV's "RIFF...WAVE" sandwich is 12), the same idea applies: `unpack` enough to identify the file, abort on mismatch, then `unpack` the rest.

Decoding the packed flags byte

`pack` and `unpack` cannot decode sub-byte bit fields directly (with the exception of the string-shaped `b` / `B` directives, see the *strings chapter*). The pragmatic approach is shifts and masks in plain Perl on the byte `unpack` returned:

```
sub decode_gif_flags {
    my ($flags) = @_;
    return {
        gct_present => ($flags >> 7) & 0x01,
        color_res   => (($flags >> 4) & 0x07) + 1,
        sort_flag   => ($flags >> 3) & 0x01,
        gct_size    => 2 ** (($flags) & 0x07) + 1),
    };
}
```

The pattern - "unpack the byte, pick the bits apart with shifts" - is so common it deserves to be named. Anything smaller than a byte belongs outside the template.

Worked run

```
open my $fh, "<:raw", "sample.gif" or die $!;
my $hdr = parse_gif_header($fh);
my $gct = decode_gif_flags($hdr->{flags});

printf "GIF%s %dx%d\n", $hdr->{version}, $hdr->{width}, $hdr->
 ↪{height};
printf "global colour table: %s (%d entries)\n",
       $gct->{gct_present} ? "yes" : "no",
       $gct->{gct_size};
```

On a real GIF89a file of dimensions 640×480, this prints:

```
GIF89a 640x480
global colour table: yes (256 entries)
```

Writing a header

The inverse is shorter still - every directive we unpacked, we can pack. One detail: the flags byte has to be re-assembled from its sub-fields first.

```
sub encode_gif_flags {
    my (%f) = @_;
    return (($f{gct_present} & 0x01) << 7)
         | (((log2($f{color_res})) & 0x07) << 4)
         | (($f{sort_flag}   & 0x01) << 3)
         | (log2($f{gct_size}) - 1);
}

sub write_gif_header {
    my ($fh, $hdr, $gct) = @_;
    my $flags = encode_gif_flags(%$gct);
    my $bytes = pack "A3 A3 v v C C C",
        "GIF", $hdr->{version},
        $hdr->{width}, $hdr->{height},
```

(continues on next page)

(continued from previous page)

```
        $flags, $hdr->{bg}, $hdr->{aspect};
    print {$fh} $bytes;
}
```

Same template on the pack side, same 13 bytes out, matches the GIF reader on the other end. Round-tripping with a test vector is the quickest way to gain confidence you have the template right: unpack an existing file, re-pack the result, compare byte-for-byte.

Scaling up to larger formats

The approach is compositional. A format like WAV has multiple chunks, each with its own header (`id` + `size` + `data`). You write:

- A low-level "read one chunk header" helper - two `unpack` calls on 8 bytes: 4-byte FourCC and 4-byte little-endian size.
- A dispatcher that looks at the FourCC and calls a per-chunk parser.
- Per-chunk parsers that `unpack` the chunk body according to that chunk's own byte layout.

Every layer is a small `unpack` against a tiny template. The moment a field's width depends on a value you just read, you stop, compose the new template from that value, and call `unpack` again - the same staged pattern we used for DNS names.

What you have learned

- **Magic number first, body second.** Fail fast on the wrong format.
- **Little-endian file formats use `v` / `V`**, big-endian use `n` / `N`; `<` / `>` handle the signed or 64-bit cases.
- **Sub-byte fields are plain-Perl shifts**, not template directives.
- **Larger formats decompose into many small templates.** The work of the programmer is to keep each template small and obvious.

With the reference pages as your lookup and these seven chapters under your belt, the next binary format that crosses your desk should read as a solved problem. The `pack` and `unpack` pages hold the full directive table when you need to confirm a width or a modifier.

- **Bytes and widths** - counting bytes, fixed-width integer directives, the native-vs-fixed distinction.
- **Endianness** - byte order, the `<` / `>` modifiers, the portable `n` / `N` / `v` / `V` shortcuts.
- **Strings** - `a` / `A` / `Z` (binary, text, C string), bit strings, hex strings.
- **Grouping and counts** - `()` groups, repeat counts, `[...]` forms, the `/` item-count-prefix directive.
- **Positioning** - `x` / `X` / `@` / `.` for moving around inside a template without producing a value.
- **Network protocols** - build and parse a DNS query header.

- **File formats** - parse a GIF header, the canonical “magic number plus fixed fields” file.

Two chapters (*network-protocols*, *file-formats*) are full worked examples. Walk through one of them once you have read enough of the other chapters to recognise the directives.

A first round-trip

The shortest useful example of pack and unpack working together - packing a dotted-quad IP address into four raw bytes and reading it back:

```
my $raw    = pack   "C4", 192, 168, 1, 42;   # "\xc0\xa8\x01\x2a"
my @octets = unpack "C4", $raw;              # (192, 168, 1, 42)
```

`C` packs one unsigned byte; `C4` packs four of them in a row. On the way out, the same template pulls them back into a list of four integers. Every more complicated binary format is layered on top of that idea.

Conventions in the examples

- Expected output appears as an inline `# ...` comment on the same line as the expression that produced it, or directly below the code block.
- Examples run under a byte-oriented interpreter - no `use utf8`, no `use open` pragma changing layers. If a filehandle appears, assume `binmode $fh` has already been called.
- Multi-byte constants such as `"\xc0\xa8\x01\x2a"` are written with hex escapes rather than raw byte values so the printed text matches what you see in the code.

4.2.13 I/O streams - a tutorial

Everything a Perl program does with a file, a pipe, or a buffer goes through a **filehandle**. This chapter is a recipe collection for the `open` built-in: how to read, write, append, pipe, encode, and recover from errors - each recipe small enough to copy, each warning pinned to the line that bites.

The pre-opened handles - `STDIN`, `STDOUT`, `STDERR`, `ARGV` - are available from the first line of a program:

```
print STDERR "debug: entered phase 2\n";
print STDOUT "name? ";
my $name = <STDIN> // die "no input";
while (<ARGV>) { ... }
```

Every other handle you open yourself. The modern form is always three arguments - handle, mode, target - and the handle is a lexical scalar:

```
open my $fh, "<", $path    or die "open $path: $!";
```

Read that form until it is muscle memory. Everything else on the following pages is a variation on it.

What this chapter does not cover

- **Locking.** Opening does not lock. See `flock` when you need advisory locking across processes.
- **Low-level descriptor control.** For `O_EXCL`, `O_NONBLOCK`, and explicit permission bits, see `sysopen`.
- **Directory iteration.** open is for files, pipes, and in-memory buffers. Directory reading uses `opendir` / `readdir`.

Where to go next

Reading, writing, appending

The three everyday tasks - read an existing file, create one from scratch, add to the end of one - are three different modes of the same `open` call. This page shows each in the form that actually belongs in new code.

The three-argument form

```
open my $fh, MODE, EXPR  or die "open: $!";
```

- `my $fh` is a fresh lexical. open fills it in with a handle reference when it succeeds; on failure it leaves `$fh` undefined and sets `$!`.
- `MODE` is a short string - `"<"`, `">"`, `">>"`, and a handful of others - that says what you want to do.
- `EXPR` is the pathname. It is treated as a plain string: leading or trailing whitespace is preserved, and the string is never reinterpreted as a shell command.

The older two-argument form (`open $fh, "<$path"`) still works, but it re-parses the string looking for mode characters and for the "magic" pipe syntax. Do not feed it a filename that came from a user.

Reading

```
my $path = "/etc/hostname";
open my $fh, "<", $path   or die "open $path: $!";

while (my $line = <$fh>) {
    chomp $line;
    # ... work with $line ...
}

close $fh                 or die "close $path: $!";
```

Two observations that trip up beginners:

- `<$fh>` calls `readline` under the hood. Inside a `while` head the result is tested for being defined, not truthy. That matters because a file containing the line `"0\n"` would otherwise stop the loop early. `while (<$fh>)` is a special-case spelling that Perl rewrites to `while (defined($_ = <$fh>))` for you.

- `close` can fail. On a read handle that is rare, but on a write handle it is the moment buffered data is finally flushed, so a closing error is a real error. Check it.

If you want the whole file as one string, slurp it:

```
open my $fh, "<", $path or die "open $path: $!";
local $/;                               # undef = slurp mode
my $all = <$fh>;
close $fh               or die "close $path: $!";
```

The `local $/` is the idiomatic "for the rest of this scope, turn off line splitting". When control leaves the enclosing block, `$/` returns to its previous value.

Writing (clobber)

```
open my $fh, ">", $path   or die "open $path: $!";
print $fh "first line\n";
print $fh "second line\n";
close $fh                 or die "close $path: $!";
```

- `">"` **creates** the file if it does not exist, and **truncates** it to zero bytes if it does. There is no confirmation step.
- The filehandle does not need a comma after it in a `print` invocation. `print $fh "text"` is correct; `print $fh, "text"` is a different expression that treats `$fh` as a list element.
- Buffered writes are held in memory until `close`, an explicit flush, or the buffer fills. If your program crashes between `print` and `close`, a writer with pending buffered data loses it. Always pair a writing open with a checked `close`.

Appending

```
open my $fh, ">>", $path  or die "open $path: $!";
print $fh scalar(localtime), " event\n";
close $fh                 or die "close $path: $!";
```

- `">>"` creates the file if needed and positions the write cursor at the end.
- On a POSIX kernel, each `write(2)` on an append-mode descriptor starts at the current end of file, so two processes appending to the same log never overwrite each other. A line only stays whole if it goes out in one `write(2)`: a Perl filehandle is buffered and writes whole buffers, which can end in the middle of a line. Turn on autoflush (`$fh->autoflush(1)`) so that each short `print` is one write. `PIPE_BUF` is the size limit for atomic writes to pipes; POSIX gives regular files no such number.

Closing as a real step, not a formality

A failed `close` on a write handle typically means the kernel refused to flush - out of space, I/O error, network filesystem trouble. Treat it exactly like a failed `print`:

```
close $fh or die "close $path: $!";
```

Ignoring it is how “the file looked fine during testing” becomes “production wrote half a log entry and moved on.”

What about read-write?

`"+<"` opens a file for both reading and writing, without truncating. It is a real mode and it works, but it is also the source of most “my file came out corrupted” bug reports. If you need random-access reads with in-place overwrites, reach for `sysopen`, `sysread`, and `syswrite` so the buffering layer does not guess at seek positions on your behalf.

For almost every job labelled “edit the file”, the right answer is write a new file, fsync, rename over the old one. That is the pattern atomic editors use.

Next

With reading, writing, and appending covered, the next question is what the bytes *mean*. See *Encoding and layers*.

Encoding and layers

A filehandle in Perl is not a raw pipe to bytes - it is a stack of PerlIO layers. Each layer transforms data on the way in or out: translating between characters and octets, converting newlines, applying compression, buffering. This page is about the two or three layers you will touch in everyday code.

Why this matters

When you read a text file, the bytes on disk are not the characters your program manipulates. UTF-8 encodes the character ä as two bytes (`0xC3 0xA4`). If Perl reads those bytes as if they were already characters, you get two garbage characters - classic “mojibake”. If you write characters without saying how they should be encoded, the reverse happens.

The layer stack is where you tell Perl how to translate. A correct stack for a UTF-8 text file is one line:

```
open my $fh, "<:encoding(UTF-8)", $path   or die "open $path: $!";
```

The two places layers can live

Layers attach to a handle in two ways:

1. As part of the mode string at open time, combined with the read/write direction:

   ```
   open my $fh, "<:encoding(UTF-8)",  $path or die;
   open my $fh, ">:encoding(UTF-8)",  $path or die;
   open my $fh, ">>:encoding(UTF-8)", $path or die;
   ```

2. After opening, via `binmode`:

```
open my $fh, "<", $path             or die;
binmode $fh, ":encoding(UTF-8)"     or die "binmode: $!";
```

The two forms are equivalent for freshly opened handles. `binmode` is what you reach for on a handle you did not open - `STDIN`, `STDOUT`, `STDERR`, and handles passed in from elsewhere.

The layers you actually need

Four cover ninety-nine percent of cases:

- `:encoding(UTF-8)` - characters in Perl-land, UTF-8 bytes on disk. The name of the encoding is anything Perl's `Encode` module understands: `"UTF-8"`, `"ISO-8859-15"`, `"Windows-1252"`, `"Shift_JIS"`, and so on.
- `:utf8` - a looser sibling of `:encoding(UTF-8)` that skips validation on input. It is faster and more dangerous: malformed bytes become malformed strings that misbehave later. Prefer `:encoding(UTF-8)` unless you have measured and proven the validation cost matters.
- `:raw` - bytes through, no translation. Equivalent to plain `binmode` with no second argument. Use it for binary formats, for anything you intend to hash or compare byte-exactly, and for data you are about to hand to a format-specific parser.
- `:crlf` - converts `\r\n` to `\n` on read and back on write. On Linux this is a no-op by default; you add it explicitly when reading files written on Windows and you want `\n`-terminated lines in memory.

Layers compose in writing order:

```
open my $fh, "<:raw:encoding(UTF-8)", $path   or die;
```

Reads as: strip to raw bytes first, then decode them as UTF-8. The `:raw` prefix is common when you want a predictable baseline to layer on top of, independent of whatever the open pragma set as the default.

A sensible default for text programs

If a program deals with UTF-8 text throughout, the cleanest move is to declare that at the top:

```
use open qw< :std :encoding(UTF-8) >;
```

- `:std` applies the given layer to `STDIN`, `STDOUT`, `STDERR`.
- `:encoding(UTF-8)` becomes the default layer for every subsequent `open` call inside the file.

After that pragma, bare three-argument opens decode UTF-8 automatically:

```
use open qw< :std :encoding(UTF-8) >;

open my $fh, "<", $path   or die "open $path: $!";
while (my $line = <$fh>) {
```

(continues on next page)

(continued from previous page)

```
    # $line is a character string, already decoded
}
```

Do not use a bare "<" without having either set a default encoding or explicitly planned for raw bytes. Reading without an announced encoding gives you the "Latin-1 superset" that looks right for ASCII and breaks on the first non-ASCII byte.

Binary files

For binary data, declare raw mode up front:

```
open my $in,  "<:raw", $in_path   or die "open $in_path: $!";
open my $out, ">:raw", $out_path  or die "open $out_path: $!";

my $buf;
while (my $n = read $in, $buf, 65536) {
    print $out $buf or die "write: $!";
}
close $in  or die;
close $out or die "close $out_path: $!";
```

`read` is the buffered fixed-size reader; `readline` is the line-oriented one. For binary data you almost always want `read`.

The explicit `:raw` on the output is the belt-and-braces move: if someone added `use open ":encoding(UTF-8)"` to the module three years from now, your binary writer would start mangling bytes. The layer on the handle overrides the pragma.

Changing a handle's layers after open

`binmode` without a layer argument strips all encoding layers, reducing the handle to raw bytes. With a layer argument, it pushes the given layer onto the stack:

```
binmode STDOUT;                         # raw bytes
binmode STDOUT, ":encoding(UTF-8)";     # decode strings as UTF-8
binmode STDIN,  ":encoding(MacRoman)";
```

Call `binmode` before any data moves through the handle. Pushing a layer mid-stream is technically possible but the transitional byte handling is brittle.

Next

The file-on-disk case is covered. Next: the same open call, but with a running program on the other end. See *Pipes*.

Pipes

The same open that attaches a handle to a file can attach it to a child process. Two modes select the direction:

- "-|" - you *read* the child's standard output.

- `"|-"` - you *write* to the child's standard input.

In both cases the child runs concurrently with your Perl program, and its exit status becomes available in `$?` when the handle is closed.

Reading from a command

```
open my $fh, "-|", "sort", "-u", glob("unsorted/*.txt")
    or die "pipe: $!";

while (my $line = <$fh>) {
    # ... process one sorted unique line at a time ...
}

close $fh or die pipe_close_diag($?, $!);
```

What happens:

- Perl `forks`. In the child, `stdout` is connected to the write end of a pipe, and the command is `execed`.
- In the parent, `$fh` reads from the other end. As far as your code is concerned, it is a normal read handle - `readline`, `read`, `<$fh>`, and so on all work.
- When you finish reading, `close` waits for the child to exit and records its status in `$?`.

Writing to a command

```
open my $fh, "|-", "gzip", "-9", "-c"
    or die "pipe: $!";

for my $line (@records) {
    print $fh $line, "\n";
}

close $fh or die pipe_close_diag($?, $!);
```

Symmetry: the child's `stdin` is connected to the read end of the pipe; your parent writes to the other end; `close` waits for the child to exit.

One behaviour that often surprises people: `close` on a write-pipe flushes everything buffered, shuts the pipe's write end, and *only then* waits for the child. If the child is slow, `close` blocks until the child is done. That is almost always what you want.

List form versus string form

Both open calls above used the **list form**:

```
open my $fh, "-|", "sort", "-u", glob("unsorted/*.txt")  or die;
```

Perl recognises that the third and subsequent arguments form a command and its argv. It does **not** involve a shell:

- No word splitting, no glob expansion, no redirection, no variable substitution.
- A filename containing a space or a `;` is just a filename.
- There is no shell to mis-quote against, so the class of bugs known as "shell injection" is structurally impossible.

The alternative is the **string form**:

```
open my $fh, "-|", "sort -u unsorted/*.txt"  or die;
```

Perl passes the single string to `/bin/sh -c`. The shell does word splitting, glob expansion, redirection, everything. That is what makes this form useful - you can write `"cat -n > numbered.txt"` on the command side and the shell sets up the `>` for you - and what makes it dangerous when any piece of the string came from outside your program.

Rule of thumb: **list form by default, string form only when a shell feature is the point**. When a filename glob is the reason to use a shell, consider pre-expanding the glob with Perl's own `glob` built-in and staying in list form, as the example at the top of this page did.

Decoding $?

After a pipe is closed, `$?` is set the same way `wait(2)` returns: a 16-bit value with the low byte carrying signal information and the high byte carrying the exit code. In Perl terms:

- `$? == 0` - the child exited cleanly with status 0. Success.
- `$? == -1` - `close` could not even wait for the child, because something went wrong before `fork`/`exec`. `$!` has detail.
- `$? & 0x7F` - signal number if the child died on a signal. `$? & 0x80` (the high bit of the low byte) is set if the child dumped core.
- `$? >> 8` - exit status if the child exited normally.

A diagnostic helper pulls these apart:

```
sub pipe_close_diag {
    my ($status, $err) = @_;
    return "pipe close: $err"               if $status == -1;
    my $signal = $status & 0x7F;
    return "child died on signal $signal"   if $signal;
    my $exit   = $status >> 8;
    return "child exited with status $exit" if $exit;
    return "child exited cleanly";
}
```

Pair that with every pipe `close`:

```
close $fh or die pipe_close_diag($?, $!);
```

Not checking the close on a pipe is the same mistake as not checking it on a write handle - except louder, because a child process failed silently in the background.

One command, one pipe

open with - | or | - gives you a pipe in *one* direction. There is no standard way to get both directions from a single open call, because two-way pipes to a co-process require careful buffering and deadlock avoidance that the open shape cannot express. When you need that, reach for `IPC::Open2` or `IPC::Open3` - built for the job, with the handshake caveats documented in their own POD.

Next

The third kind of thing open can attach a handle to is neither a file nor a process - it is a string in memory. See *In-memory handles*.

In-memory handles

The third thing open can attach a handle to is a plain scalar variable. The scalar is used as the "file": reads pull bytes out of it, writes push bytes into it. Nothing touches the filesystem, nothing forks.

This is the cleanest way to make a function that normally writes to a filehandle also produce an in-memory string. Any code that accepts "a filehandle" continues to work.

The signature

```
open my $fh, MODE, \$scalar  or die;
```

The third argument is a **reference** to a scalar. That reference is what distinguishes an in-memory handle from a pathname - a plain string `"$scalar"` would be a filename.

Modes work as they do for files:

- `"<"` - read from the contents of the scalar.
- `">"` - write into the scalar, clobbering any existing content.
- `">>"` - append to the scalar.

Writing into a buffer

```
my $buf = "";
open my $fh, ">", \$buf   or die "open buffer: $!";

print $fh "hello, ";
print $fh "world\n";
printf $fh "%d items\n", 42;

close $fh                 or die "close buffer: $!";

print $buf;               # hello, world\n42 items\n
```

After `close`, `$buf` holds everything that was printed. Before `close`, the data may still be sitting in PerlIO's buffer - treat it as not-yet-final, just as you would with a real file.

The typical use is capturing output from a function that expects to `print` to a handle:

```
sub render {
    my ($fh, @rows) = @_;
    for my $row (@rows) {
        print $fh join("\t", @$row), "\n";
    }
}

my $buf = "";
open my $fh, ">", \$buf or die;
render($fh, @rows);
close $fh               or die;
```

No temporary file, no `tmpfile`, no cleanup.

Reading from a buffer

```
my $source = "one\ntwo\nthree\n";
open my $fh, "<", \$source  or die "open buffer: $!";

while (my $line = <$fh>) {
    chomp $line;
    # ... work with $line ...
}

close $fh                   or die;
```

This turns any string-processing task that "would be nicer with a filehandle" into one. Test data in particular reads cleanly:

```
my $fixture = <<'END';
name,count
apples,3
pears,7
END

open my $fh, "<", \$fixture or die;
parse_csv($fh);
close $fh                   or die;
```

`parse_csv` sees a filehandle, does not know it is a string in disguise, and the test is entirely self-contained.

Layers work the same way

In-memory handles accept PerlIO layers:

```
my $buf = "";
open my $fh, ">:encoding(UTF-8)", \$buf   or die;
print $fh "café\n";
```

(continues on next page)

(continued from previous page)

```
close $fh                                       or die;

# $buf now contains the UTF-8 bytes: c a f 0xC3 0xA9 0x0A
```

Without the layer, `$buf` would contain the character string `"café\n"`. With the layer, the write step encodes to bytes on the way into the buffer. Which one you want depends on whether the buffer is destined for something that expects characters (another Perl function) or bytes (a socket, a hash function, a file on disk).

When not to use this

- **When you want capture with `fork` and `exec`.** In-memory handles are pure Perl; a child process cannot see them. If you want to capture the output of an external command, use a read-pipe as described in *Pipes*.
- **For bulk data that would not fit in RAM.** The scalar grows as you write. A one-gigabyte log is better served by a real tempfile.
- **For seekable random-access editing.** `seek` works on in-memory handles, but the semantics around growing the buffer past its current end are subtle. For random access, use a real file.

Next

Every example on every page in this chapter has been shouting `or die "...: $!"`. It is time to earn that idiom. See *Handling errors*.

Handling errors

Every I/O operation can fail. The filesystem can be full, the permissions can be wrong, the file can be missing, the network mount can vanish mid-read. Perl does not raise exceptions for these by default - it returns a false value and sets `$!`. The programmer's job is to notice.

The `or die` idiom

```
open my $fh, "<", $path   or die "open $path: $!";
```

The form has three loadbearing parts:

- **`or`**, not `||`. Precedence matters: written without parentheses, `open my $fh, '<', $path || die ...` binds the `||` to `$path`, so `die` never runs when the open fails. `or` binds lowest of all the operators involved and always does what it reads as.
- **The filename in the message.** `"$!"` alone says "Permission denied" with no context. `"open $path: $!"` says what file, in what step. When logs are all you have, context is everything.
- **`$!`, not `$@`.** `$!` is the system error - `errno` with a human-readable face. `$@` is the exception from the most recent `eval`. Mixing them up at 3am has happened to everyone.

Every open, every `close`, every `print`, every `read`, every `binmode` in production code has a check. There is no "it obviously cannot fail here". The one time it does, you will want the diagnostic.

Read `$!` immediately or not at all

`$!` reflects the **most recent** system call. A naive sequence:

```
open my $fh, "<", $path;
my $line = <$fh>;                          # might also set $!
warn "something failed: $!"  unless $line;
```

If the open failed, `$!` is already overwritten by the time `<$fh>` runs on the undefined handle. Check the return value of each call right where you call it.

Pattern: check the `close` as carefully as the open

```
open  my $fh, ">", $path   or die "open $path: $!";
print $fh @records         or die "write $path: $!";
close $fh                  or die "close $path: $!";
```

On a write handle, `close` is where the kernel actually commits the buffered data. If the disk is full, `print` may have succeeded into memory and `close` is where you find out. The close check is not a stylistic flourish; it is the one that catches the half-written log entry.

For pipes, `close` additionally waits for the child and sets `$?`. See *Pipes* for the diagnostic wrapper that decomposes `$?` into signal and exit-status components.

`autodie` - errors become exceptions

For code where every line is a `... or die ...` chain, the `autodie` pragma is worth the import:

```
use autodie qw(:all);

open my $fh, "<", $path;
while (my $line = <$fh>) {
    # ...
}
close $fh;
```

With `autodie`, built-ins like open, `close`, `print`, `read`, `chdir`, `unlink`, and a long list of siblings throw a structured exception on failure instead of returning false. The caller catches them with `eval { ... }` or a block-form `try`, and the message names the call and the path automatically.

Two practical notes:

- `autodie` is **lexical**. It applies only inside the block where it is `use`-d. A module you call from an `autodie` block does not pick up the pragma.

- `autodie` does not change the return convention for the **success** case. `open` still returns a true value; `$fh` is still the handle. You can delete your `or die` suffixes and everything else keeps working.

What the Perl exception looks like

Whether you `die` manually or let `autodie` do it, the exception travels up the stack until something catches it. Catching is `eval` plus a check of `$@`:

```
my $fh = eval {
    open my $h, "<", $path or die "open $path: $!\n";
    $h;
};
if ($@) {
    warn "could not read $path: $@";
    # ... fall back to a default, or return an error, or re-die ...
}
```

Two habits that save time:

- **Terminate die strings with \n when you want the raw message.** Without a trailing newline, Perl appends `" at FILE line N"` to the `die` string. Sometimes that is what you want; often it is noise.
- **Prefer structured objects for non-trivial errors.** A `bless { path => ..., errno => $!, step => "open" }, 'IOError'` costs three lines and gives the caller something to introspect instead of a string to regex.

A minimal checklist

Every open-and-process block should look, structurally, like this:

```
open  my $fh, MODE, $path   or die "open $path: $!";
binmode $fh, $layer         or die "binmode $path: $!"
                               if $layer_not_already_in_mode;

# ... do I/O; each op checked in-place ...

close $fh                   or die "close $path: $!";
```

If the code deviates - a missing check, a `||` where an `or` belongs, a `$@` where `$!` belongs - that is where the bug is hiding.

Where to go next

This chapter covered the everyday open. When you need flag-level control over the system call itself - for example, `O_EXCL` to refuse to clobber, or `O_NONBLOCK` for a pipe you intend to `select` on - reach for `sysopen` and its unbuffered companions `sysread` and `syswrite`.

Reference cross-links

Every recipe here links into the per-built-in reference when a function's full behaviour matters:

- `open` - full argument shape, all modes
- `close` - closing and checking the result
- `binmode` - layers after the fact
- `readline` - the function behind `<$fh>`
- `sysopen` - low-level open with flag bits
- `sysread` - unbuffered read
- `syswrite` - unbuffered write

4.2.14 References - a tutorial

A **reference** in Perl is a scalar that points at another value: an array, a hash, a subroutine, another scalar, even another reference. References are the single mechanism that turns Perl's three container types - scalars, arrays, hashes - into arbitrary nested data structures.

Without references you cannot build a hash of arrays, an array of hashes, a tree, a graph, a record with mixed fields, a callback table, or a closure. With them, you can. This tutorial walks you from the two reference-making operators, through the syntax for getting the underlying value back, up to anonymous constructors, code references, and the weak-reference trick that keeps cyclic structures from leaking.

Who this is for

You already write working Perl. You use arrays and hashes comfortably, but the moment the problem calls for a hash whose values are arrays - or an array of records, or a callback you can store in a table - the syntax stops being obvious. That gap is what references fill, and what this tutorial closes.

How this tutorial is organised

Each chapter introduces one concept and stands on its own. Read them in order the first time; jump to the relevant chapter later.

Basics - taking references and using them

There are only two ways to **make** a reference to something that already has a name, and only two ways to **use** a reference once you have it. This chapter covers both. Anonymous constructors (`[...]`, `{...}`) are covered in *Anonymous references*.

Making a reference with backslash

Put a backslash in front of any variable, and you get a scalar that refers to it:

```
my @array = (1, 2, 3);
my %hash  = (APR => 4, AUG => 8);
my $n     = 42;

my $aref  = \@array;   # reference to the array
my $href  = \%hash;    # reference to the hash
my $sref  = \$n;       # reference to the scalar
```

A reference is itself a scalar. You can copy it, pass it, store it in another data structure, without touching the thing it points at:

```
my $copy   = $aref;    # two scalars, one underlying array
my @slots;
$slots[3]  = $href;    # hash reference stored as an array element
my $pulled = $slots[3];
```

Both `$aref` and `$copy` point at the **same** array. Changing the array through one is visible through the other. To actually copy the contents, see *Anonymous references*.

What a reference prints as

Stringify a reference and you get a type tag plus an address:

```
print "$aref\n";       # ARRAY(0x55d3c1a02b40)
print "$href\n";       # HASH(0x55d3c1a02be0)
```

If you ever see output like that by accident, you printed the reference where you meant to print the contents.

Using a reference - the curly-brace form

Wherever you could have written a variable name, you can put the reference in curly braces instead. The rule is mechanical:

Operation on `@array`	Same operation via `$aref`
`@array`	`@{$aref}`
`scalar @array`	`scalar @{$aref}`
`$array[3]`	`${$aref}[3]`
`$array[3] = 17`	`${$aref}[3] = 17`
`for my $x (@array) { ... }`	`for my $x (@{$aref}) { ... }`

Hashes follow the same pattern:

Operation on `%hash`	Same operation via `$href`
`%hash`	`%{$href}`
`keys %hash`	`keys %{$href}`
`$hash{red}`	`${$href}{red}`
`$hash{red} = 17`	`${$href}{red} = 17`

And scalars:

```
my $x   = 10;
my $ref = \$x;
print ${$ref};          # 10
${$ref} = 99;
print $x;               # 99
```

The curly braces can usually be dropped when what's inside is a plain scalar variable: `@$aref` means the same as `@{$aref}`, and `$$sref` means the same as `${$sref}`. Start with the curly form until the short form stops looking ambiguous; `$$hash{key}` and `${$hash}{key}` both work, but `$$table{$country}[0]` is easier to misread than `${$table}{$country}[0]`.

Using a reference - the arrow form

The most common thing you do with a reference is fetch one element out of the array or hash it points at. The curly form works (`${$aref}[3]`) but is hard to read. The arrow form is the abbreviation:

```
$aref->[3]              # same as ${$aref}[3]
$href->{red}            # same as ${$href}{red}
```

The arrow is not cosmetic. It is the thing that distinguishes two different meanings:

```
$aref->[3]              # fourth element of the array $aref points at
$aref[3]                # fourth element of the unrelated array @aref
```

`$aref` and `@aref` are separate variables, as unrelated as `$x` and `@x`. Forgetting the arrow silently fetches from a different array that probably does not exist. Running under `use strict` turns the mistake into a compile-time error instead of a silent wrong answer at runtime.

Asking what a reference points at

The `ref` built-in returns a string describing the referent's kind:

```
ref $aref               # ARRAY
ref $href               # HASH
ref $sref               # SCALAR
ref \&printer           # CODE
ref $n                  # empty string - $n isn't a reference
```

Combine with boolean context to test "is this a reference?":

```
if (ref $maybe) {
    # it's a reference of some kind
}
if (ref $maybe eq 'ARRAY') {
    # it's specifically an array reference
}
```

See `ref` for the full list of return strings (including `CODE`, `GLOB`, `REF`, `Regexp`, and the package name when the reference has been blessed into a class).

Two common beginner mistakes

- **Treating a reference like the underlying container.** `push $aref, 1` does not push into the array; it's a type error. You must dereference: `push @{$aref}, 1` or (equivalently) `push @$aref, 1`.
- **Dropping the arrow between a variable and its subscript.** `$aref[3]` is not the same as `$aref->[3]`. The first reads from `@aref`, the second reads through the reference.

Where to go next

- *Arrays of arrays* - the two-dimensional case, and the arrow-between-subscripts rule.
- *Anonymous references* - `[...]` and `{...}` for building structures without named intermediates.

Arrays of arrays

Perl arrays hold scalars, and scalars cannot directly contain other arrays. To build a two-dimensional array - a matrix, a grid, a table of rows - you store **references** to inner arrays as the outer array's elements. This chapter shows how.

Building a matrix

The most direct form uses anonymous array constructors (`[...]`, covered in detail in *Anonymous references*) so you don't have to name every inner array:

```
my @m = (
    [1, 2, 3],
    [4, 5, 6],
    [7, 8, 9],
);
```

`@m` has three elements. Each element is a scalar holding an array reference. There are four arrays in play: the outer `@m` and three anonymous inner arrays.

Reading and writing elements

`$m[1]` is the reference to the second row. To reach the third element of that row, apply the arrow:

```
$m[1]->[2]              # 6
$m[0]->[0]              # 1
$m[2]->[2] = 99;        # overwrite the bottom-right cell
```

Between **two subscripts**, the arrow is optional. This rule is what makes multidimensional access readable:

```
$m[1][2]                # same as $m[1]->[2]
$m[2][2] = 99;          # same as $m[2]->[2] = 99
```

The arrow remains **required** between a scalar variable and its first subscript: `$aref->[0]` cannot be shortened to `$aref[0]` because that would mean "first element of `@aref`". The shortcut applies only **inside** a chain of subscripts.

For three dimensions it's the same idea:

```
$cube[2][3][5]          # readable
${${$cube[2]}[3]}[5]    # the same expression fully spelled out
```

The second form is what you'd have to write without the arrow shortcut. Nobody does that.

Iterating over a matrix

To walk rows, loop over the outer array; each iteration gives you an array reference. To walk cells, dereference that reference inside the loop:

```
for my $row (@m) {
    for my $cell (@{$row}) {
        print "$cell ";
    }
    print "\n";
}
```

If you also need the indexes, use a counted loop on the outer array and on the dereferenced inner:

```
for my $i (0 .. $#m) {
    for my $j (0 .. $#{$m[$i]}) {
        print "m[$i][$j] = $m[$i][$j]\n";
    }
}
```

`$#{$m[$i]}` is the last-index operator applied to the dereferenced inner array. It's the `$#array` form with `{$m[$i]}` standing in for the array name.

Growing rows and columns

Append to a row by pushing into the inner array via a reference:

```
push @{$m[0]}, 10;      # row 0 is now (1, 2, 3, 10)
```

Append a whole row to the matrix by pushing an array reference onto the outer array:

```
push @m, [10, 11, 12]; # @m now has four rows
```

Both operations use `push` - once on a dereferenced inner array, once on the outer array directly.

Autovivification

Assigning to `$m[$i][$j]` works even if `$m[$i]` doesn't exist yet:

```
my @grid;
$grid[5][7] = 'X';
```

This creates `@grid` with six empty slots and one reference in slot 5. That reference points at a fresh anonymous array whose eighth slot holds `'X'`. Perl generates both the outer slot and the inner array automatically. This is called **autovivification** and is the reason you almost never have to write `$m[$i] = []` before using it.

Autovivification fires on *assignment* and on *dereferencing in lvalue context*. Plain reads do **not** autovivify:

```
my @grid;
my $x = $grid[5][7];   # $x is undef; no inner array created
exists $grid[5];       # false
```

Use `defined` to tell the "never existed" case from the "exists and holds `undef`" case, and `exists` to check the slot itself without autovivifying.

Common mistake: sharing a single inner array

This looks like three rows but is actually one row repeated:

```
my @inner = (0, 0, 0);
my @bad   = (\@inner, \@inner, \@inner);

$bad[0][1] = 9;
print "$bad[2][1]\n";  # 9 - they're all the same array
```

To get three independent rows, construct each one separately. The anonymous-constructor form handles this by always allocating fresh:

```
my @good = ([0, 0, 0], [0, 0, 0], [0, 0, 0]);
$good[0][1] = 9;
print "$good[2][1]\n"; # 0
```

A loop over `map` gives the same result for variable row lengths:

```
my @grid = map { [ (0) x 10 ] } 1 .. 10;  # 10×10 of zeros
```

Common mistake: storing the count instead of the elements

Assigning an array to a single scalar slot evaluates the array in **scalar context**, which yields its element *count*, not its contents:

```
for my $i (1 .. 10) {
    my @array = somefunc($i);
    $AoA[$i] = @array;          # WRONG - stores the count
}
```

After this loop every `$AoA[$i]` is a number. To store the elements, wrap them in an anonymous-array constructor so you get a reference to a fresh copy:

```
$AoA[$i] = [ @array ];          # right - a new array, copied
```

If you genuinely wanted the count, say so with `scalar` and a name that reflects it:

```
$counts[$i] = scalar @array;    # explicit - no surprise later
```

Common mistake: one reused array behind every reference

The repeated-array trap from the previous section also appears when the shared array is reused across loop iterations:

```
our @array;
for my $i (1 .. 10) {
    @array = somefunc($i);
    $AoA[$i] = \@array;         # WRONG - same array every time
}
```

Every `\@array` is a reference to the *same* array, so all ten slots end up pointing at whatever `somefunc` returned last. Again, `[ @array ]` fixes it by copying.

Declaring the array with `my` **inside** the loop is safe, however:

```
for my $i (1 .. 10) {
    my @array = somefunc($i);
    $AoA[$i] = \@array;         # fine - fresh array each iteration
}
```

`my @array` builds a new array on every pass, so each `\@array` refers to a distinct one. The reference outlives the loop body because the array it points at stays alive as long as the reference does. The constructor form `[ @array ]` is still the clearer choice; reach for the `\@array` form only when you understand why it works here.

Where to go next

- *Hashes and mixes* - hashes of arrays and arrays of hashes, the two shapes that cover most real-world records.
- *Anonymous references* - the `[...]` / `{...}` constructors used above, in detail.

Hashes and mixed structures

A hash's values are scalars, so a value cannot literally **be** an array or another hash. It can, however, be a **reference** to one - and that is enough to build every record shape real programs need: hashes of arrays, arrays of hashes, hashes of hashes, and nested combinations.

This chapter walks the three most common shapes. The patterns compose: once you have a hash of arrays and an array of hashes, you have "rows of records with multi-valued fields" for free.

Hash of arrays - grouping values under a key

The motivating example: you read lines of the form `city, country` and want to collect, for each country, the list of its cities.

```
Chicago, USA
Frankfurt, Germany
Berlin, Germany
Washington, USA
Helsinki, Finland
New York, USA
```

The natural shape is a hash whose keys are country names and whose values are references to arrays of cities:

```
my %cities_by_country;
while (<>) {
    chomp;
    my ($city, $country) = split /, /;
    push @{$cities_by_country{$country}}, $city;
}

for my $country (sort keys %cities_by_country) {
    my @cities = sort @{$cities_by_country{$country}};
    print "$country: ", join(', ', @cities), ".\n";
}
```

Two things to notice:

- `push @{$cities_by_country{$country}}, $city` works on the very first iteration for every new country. The hash entry does not exist yet, so Perl creates an anonymous array for it, stores a reference, and pushes the city in. That's autovivification again - and why you almost never need `$h{$k} = [] unless exists $h{$k}` as a separate line.
- The dereference `@{$cities_by_country{$country}}` is mechanical: "the array that this hash value points at." Wherever you'd have written `@cities` if it were a named array, you write the curly form instead.

The output is:

```
Finland: Helsinki.
Germany: Berlin, Frankfurt.
USA: Chicago, New York, Washington.
```

Array of hashes - a table of records

When each item in a list carries several named fields, store each record as a hash reference and put the references in an array:

```
my @people = (
    { name => 'Ada',    born => 1815, field => 'computing' },
```

(continues on next page)

(continued from previous page)

```
    { name => 'Hedy',  born => 1914, field => 'signals'   },
    { name => 'Grace', born => 1906, field => 'compilers' },
);
```

`$people[0]` is a hash reference; `$people[0]->{name}` or (with the arrow-between-subscripts shortcut) `$people[0]{name}` is `'Ada'`.

Typical operations:

```
# Sort by a field
my @by_year = sort { $a->{born} <=> $b->{born} } @people;

# Select rows
my @early = grep { $_->{born} < 1900 } @people;

# Project one field out
my @names = map { $_->{name} } @people;

# Mutate a record in place
$people[1]{field} = 'radio';
```

Inside `sort`, `grep`, and `map` the record is a hash reference, so you reach its fields through the arrow. `$a` and `$b` inside a `sort` comparator are hash references here, not hashes.

Hash of hashes - lookup tables keyed by structured values

When each record is keyed by a unique identifier, a hash of hashes is usually nicer than an array of hashes:

```
my %people = (
    ada   => { born => 1815, field => 'computing' },
    hedy  => { born => 1914, field => 'signals'   },
    grace => { born => 1906, field => 'compilers' },
);

print $people{ada}{born};              # 1815
$people{grace}{field} = 'COBOL';       # mutate one record
```

Iterate in a definite order by sorting the keys:

```
for my $key (sort keys %people) {
    my $rec = $people{$key};
    print "$key: born $rec->{born}, $rec->{field}\n";
}
```

Binding the inner reference to a named lexical (`$rec`) is a habit worth forming - it makes the code read top-to-bottom instead of repeating `$people{$key}{field}` five times.

Mixed - records with multi-valued fields

Put it all together: each record is a hash, and one of its fields is a reference to an array.

```
my %library = (
    'The Road'           => {
        author  => 'Cormac McCarthy',
        year    => 2006,
        genres  => ['fiction', 'post-apocalyptic'],
    },
    'Thinking in Systems' => {
        author  => 'Donella Meadows',
        year    => 2008,
        genres  => ['non-fiction', 'systems'],
    },
);

for my $title (sort keys %library) {
    my $rec = $library{$title};
    my $genres = join ', ', @{$rec->{genres}};
    print "$title ($rec->{year}, $rec->{author}): $genres\n";
}
```

`@{$rec->{genres}}` is the same pattern as before: reach into the hash, get the array reference, dereference it with `@{...}`.

A field can just as easily hold a **code reference** or a nested **lookup hash**. Nothing about the access changes; you follow the same arrow into whatever each field points at:

```
my $rec = {
    name     => 'lookup',
    CALLBACK => sub { uc $_[0] },
    LOOKUP   => { red => '#f00', green => '#0f0' },
};

$rec->{CALLBACK}->('hi');     # call the code ref - 'HI'
$rec->{LOOKUP}{red};          # nested hash lookup - '#f00'
```

`$rec->{CALLBACK}` is a code reference, so the trailing `->($arg)` calls it. `$rec->{LOOKUP}` is a hash reference, so `{red}` subscripts through it (the arrow between the two subscripts is elided).

Copying an array of refs copies the array, not the referents

When a record holds an array of references, copying that array with `[ @list ]` makes a *new* array whose elements are the *same* references. The copy and the original share their referents, so a mutation through one path is visible through every path that holds those same element refs:

```
my %TV = (
    simpsons => {
        kids => [ { name => 'Bart', age => 10 },
```

(continues on next page)

(continued from previous page)

```
                    { name => 'Lisa', age => 8 } ],
    },
);

my @also = @{ $TV{simpsons}{kids} };   # array copied; hashes shared

$TV{simpsons}{kids}[0]{age}++;         # mutate through one path
print $also[0]{age};                   # 11 - the other path sees it
 ↪too
```

`@also` is a separate array, so pushing onto it does not grow the original. But its elements are the very same hash references, so bumping age through `$TV{simpsons}{kids}[0]` changes the hash that `$also[0]` also points at. To get independent records you must copy one level deeper, building fresh hashes rather than reusing their references.

Checking what you have

Before acting on a nested slot it's often useful to know whether the slot is actually there. Use `exists` rather than `defined` when you want to avoid autovivifying empty intermediate structures:

```
if (exists $library{$title} and exists $library{$title}{genres}) {
    push @{$library{$title}{genres}}, 'essential';
}
```

Reading `$library{$title}{genres}` in lvalue context - the left side of an assignment, or as the argument of `push` - autovivifies missing levels. Reading it in rvalue context does not. The `exists` checks above keep the scan read-only.

To test the type of a reference without pulling values out of it, use `ref`:

```
ref $library{'The Road'}              # HASH
ref $library{'The Road'}{genres}      # ARRAY
```

Where to go next

- *Anonymous references* - the `[...]` / `{...}` constructors used throughout this chapter, and when a named variable is the better choice.
- *Subroutine references* - the remaining reference flavour, needed for callback tables and dispatch.

Anonymous references - `[...]` and `{...}`

You don't always want to give an inner array or hash a name before you reference it. Perl provides two constructors that build a new container and hand you a reference to it in a single expression:

- `[...]` builds a fresh anonymous **array** and returns a reference to it.
- `{...}` builds a fresh anonymous **hash** and returns a reference to it.

These are the primary way nested data structures are assembled.

Array: `[...]`

```
my $aref = [1, 'foo', undef, 13];
```

The right-hand side evaluates the list `(1, 'foo', undef, 13)`, allocates a new array, copies those four elements in, and yields a scalar holding a reference to that array. This is **exactly** equivalent to the two-step form with a named intermediate:

```
my @array = (1, 'foo', undef, 13);
my $aref  = \@array;
```

...except that no `@array` variable leaks into the surrounding scope. The anonymous array has no name; only the reference exists, and the array stays alive as long as the reference does.

Empty forms are useful as initial values:

```
my $aref = [];          # reference to a new empty array
push @{$aref}, 1, 2;    # now [1, 2]
```

Hash: `{...}`

```
my $href = { APR => 4, AUG => 8 };
```

Same idea for hashes. The expression is a list of key/value pairs (the => is just a comma that auto-quotes its left side), a new hash is allocated, the pairs are inserted, and you get a reference back:

```
my %hash = (APR => 4, AUG => 8);
my $href = \%hash;
```

is the two-step equivalent. And as with arrays, the empty form is a common starting point:

```
my $href = {};
$href->{red} = 17;
```

`{...}` vs. block - a parser corner

A bare `{...}` at statement position is parsed as a **block**, not as a hash constructor:

```
{ foo => 1 };           # block, with `foo => 1` as its expression
```

In most positions - on the right of =, inside a list, as an argument to a function - Perl figures out the hash-constructor reading automatically. If you ever need to force the hash-constructor interpretation, put + in front:

```
my $x = +{ foo => 1 }; # unambiguous: always a hash reference
```

You'll rarely need this. Inside `return +{...}` from a subroutine and in a few other "statement-like" positions, it's the fix.

Nesting - constructors inside constructors

Because each constructor yields a scalar, and scalars go anywhere, you compose structures by nesting:

```
my $tree = {
    name     => 'root',
    children => [
        { name => 'left',  children => [] },
        { name => 'right', children => [
            { name => 'r1', children => [] },
        ] },
    ],
};

print $tree->{children}[1]{children}[0]{name};   # r1
```

Every `[...]` and `{...}` allocates fresh. Unlike the "shared-inner-array" footgun from *Arrays of arrays*, nested constructors never share storage by accident.

Named intermediates vs. anonymous constructors

Both forms work. Pick based on readability:

- **Anonymous constructor** when the container is single-purpose and its only role is "be the value of this field". Nested data literals, one-off lookup tables, callback-table entries.
- **Named intermediate** when you're building the container incrementally, or when you want to use array/hash operators on it directly without repeating `@{...}` / `%{...}`:

```
my @row;
for my $x (@source) {
    push @row, transform($x);
}
$grid[$i] = \@row;
```

Copying vs. sharing

Anonymous constructors always allocate; they never share. But assigning one reference to another scalar does not duplicate anything:

```
my $a = [1, 2, 3];
my $b = $a;             # $a and $b refer to the SAME array
push @{$b}, 4;
print "@{$a}";          # 1 2 3 4
```

To get a shallow copy of the underlying container, dereference inside a fresh constructor:

```
my $copy_aref = [ @{$a} ];      # new array, same elements
my $copy_href = { %{$h} };      # new hash, same keys/values
```

The new reference is independent of the original. The **values** inside are still shared - if those values are themselves references, the two structures still point at common subtrees. That's shallow copying. For deep copying, reach for a module like `Storable` (`dclone`).

Where to go next

- *Subroutine references* - the third flavour of anonymous thing, using `sub { ... }` instead of `[...]` or `{...}`.
- *Weak references* - needed when a nested structure points back at itself.

Subroutine references

A subroutine reference is a scalar that points at a piece of code. Once you have one, you can store it in a variable, pass it to another subroutine as a callback, keep a table of them for dispatch, or call it. Code references are what make dispatch tables, callbacks, iterators, and closures possible in Perl.

Two ways to get a code reference

`\&name` - take a reference to a named subroutine:

```
sub greet { print "hello $_[0]\n" }

my $cref = \&greet;
$cref->('world');      # hello world
```

The `&` sigil is what marks `greet` as a subroutine. The backslash in front takes its reference. Without the `&`, you'd be calling the subroutine and taking a reference to the result.

`sub { ... }` - an **anonymous** subroutine. It evaluates to a reference to a fresh, nameless piece of code:

```
my $cref = sub { print "hello $_[0]\n" };
$cref->('world');
```

Anonymous subs are the direct analogue of `[...]` and `{...}` from the previous chapter: a constructor that gives you back a reference to something new and nameless.

Calling through a reference

`$cref->(@args)` is the one you reach for:

```
$cref->('world');
$cref->($x, $y);
$cref->();              # call with no arguments
```

There is also an older syntax, `&{$cref}(...)`, parallel to the `@{$aref}` / `%{$href}` form. It's still valid but the arrow form is standard everywhere modern.

Inside the called subroutine, arguments arrive in `@_` as usual:

```
my $max = sub {
    my ($a, $b) = @_;
    $a > $b ? $a : $b;
};
print $max->(3, 7);    # 7
```

Callbacks - passing code to another routine

Any subroutine that takes a code reference can accept either a named-subroutine reference or an anonymous one:

```
sub each_line {
    my ($filename, $cb) = @_;
    open my $fh, '<', $filename or die "$filename: $!";
    while (my $line = <$fh>) {
        $cb->($line);
    }
}

# Pass a named sub:
sub print_upper { print uc $_[0] }
each_line('notes.txt', \&print_upper);

# Or an anonymous one, inline:
each_line('notes.txt', sub { print uc $_[0] });
```

Inline anonymous subs are the idiomatic form when the callback body is short and specific to the call site.

Dispatch tables

A hash of code references replaces long `if` / `elsif` chains:

```
my %dispatch = (
    help => sub { print "usage: tool [cmd]\n" },
    list => sub { print "$_\n" for @items },
    quit => sub { exit 0 },
);

my $cmd = shift @ARGV;
if (my $action = $dispatch{$cmd}) {
    $action->();
} else {
    die "unknown command: $cmd\n";
}
```

Each value in `%dispatch` is a code reference. Looking up by command name and calling through the reference replaces branching with a single lookup. Adding a new command is a single hash entry.

Closures - code that captures lexicals

An anonymous subroutine that references a lexical (`my`) variable from its surrounding scope **captures** that variable. The variable survives for as long as the subroutine reference does, and each call sees the current value:

```
sub make_counter {
    my $n = 0;
    return sub { ++$n };
}

my $a = make_counter();
my $b = make_counter();
print $a->();           # 1
print $a->();           # 2
print $b->();           # 1   - independent from $a
print $a->();           # 3
```

Each call to `make_counter` creates a **new** lexical `$n` and a **new** anonymous subroutine that captures that `$n`. The subroutine returned to `$a` and the one returned to `$b` close over distinct variables, so their counters don't interfere.

This is how Perl expresses most of what other languages call "objects with private state" without any class machinery: the closed-over lexicals **are** the private state.

A closure captures by reference, not by copy. A loop like this captures the **same** loop variable:

```
my @subs;
for my $i (1 .. 3) {
    push @subs, sub { print "i=$i\n" };
}
$_->() for @subs;       # i=1 / i=2 / i=3
```

...because `my $i` in `for my $i` is re-my'd on every iteration, so each closure captures a *different* `$i`. The common mistake is using a `for`-loop variable that isn't `my`'d freshly:

```
my $i;                  # outer
my @subs;
for $i (1 .. 3) {
    push @subs, sub { print "i=$i\n" };
}
$_->() for @subs;       # i=3 / i=3 / i=3  - all share the outer $i
```

The fix is `for my $i (...)` - always prefer the inline `my`.

Introspection

`ref` on a code reference returns the string `CODE`:

```
ref $cref               # CODE
ref \&greet             # CODE
```

`defined` works as usual to tell "no value" from "any value, including a code reference":

```
if (defined $dispatch{$cmd}) { ... }
```

Where to go next

- *Weak references* - relevant when a structure of code references holds references back to objects that own it (event emitters, observer chains).

Weak references

Perl tracks object lifetime with **reference counting**. Every value knows how many references point at it; when the count drops to zero, the value is freed. This works well for tree-shaped data, where references flow one way, parent to child. It fails for **cycles**, where a chain of references eventually points back at something earlier in the chain. The cycle's members keep each other alive even when nothing outside the cycle refers to them any more.

A **weak reference** is a reference that does not increment the referent's reference count. It lets you point at something without keeping it alive. Weak references are Perl's standard answer to reference cycles.

How a cycle leaks

Consider a doubly-linked list node that holds both `next` and `prev` references:

```
sub new_node {
    my ($value) = @_;
    return { value => $value, next => undef, prev => undef };
}

my $a = new_node('A');
my $b = new_node('B');
$a->{next} = $b;
$b->{prev} = $a;
```

`$a` and `$b` each have a reference count of 2:

- `$a` is referenced by the lexical `$a` **and** by `$b->{prev}`.
- `$b` is referenced by the lexical `$b` **and** by `$a->{next}`.

When the lexicals go out of scope, their contribution drops:

- `$a` drops to count 1 (only `$b->{prev}` left).
- `$b` drops to count 1 (only `$a->{next}` left).

Neither reaches zero. Both nodes are unreachable from anywhere in your program, yet they keep each other alive for the life of the interpreter. That's a leak.

Fixing the leak with weaken

`Scalar::Util::weaken` turns an existing reference into a weak one. The reference still works for dereferencing; it just doesn't count toward keeping the target alive.

The standard pattern: whichever direction you consider "back-pointer" or "parent pointer", make **that** one weak.

```
use Scalar::Util qw(weaken);

my $a = new_node('A');
my $b = new_node('B');
$a->{next} = $b;
$b->{prev} = $a;
weaken $b->{prev};              # the back-pointer
```

Now `$a`'s reference count stays at 1 (only the lexical `$a` contributes; `$b->{prev}` is weak and does not count). When `$a` goes out of scope, `$a` is freed - and because freeing `$a` drops `$b->{next}`, `$b` is freed too. The whole structure collapses.

When a weak reference becomes undef

If the referent is freed while a weak reference still exists, the weak reference **automatically becomes undef**. You never see a dangling pointer:

```
use Scalar::Util qw(weaken);

my $target = { name => 'alive' };
my $weak   = $target;
weaken $weak;

print defined $weak ? "yes\n" : "no\n";   # yes
undef $target;                             # last strong ref gone
print defined $weak ? "yes\n" : "no\n";   # no
```

`defined $weak` is the standard way to check whether the target is still there. See `defined`.

Where weak references belong

The rule: use a weak reference for the "non-owning" pointer in any pair of references that would otherwise cycle.

- **Doubly-linked list.** `next` owns; `prev` is weak.
- **Parent/child tree with parent pointers.** `children` owns; `parent` on each child is weak.
- **Observer pattern.** The subject holds weak references to its observers; observers hold strong references to the subject. When an observer drops its reference, it goes

away; the subject's entry for it turns to `undef` and can be swept.

- **Caches that shouldn't keep entries alive.** A cache whose values are weak references does not extend the lifetime of the cached objects.

`isweak` - inspecting a reference

`Scalar::Util::isweak` tells you whether a given scalar holds a weak reference:

```
use Scalar::Util qw(weaken isweak);

my $x = { k => 1 };
my $y = $x;
print isweak($y) ? "weak\n" : "strong\n";   # strong
weaken $y;
print isweak($y) ? "weak\n" : "strong\n";   # weak
```

Useful mostly when debugging a lifetime problem. Production code rarely branches on `isweak`.

Common mistakes

- **Weakening the wrong end.** Weakening the "forward" pointer (the one that owns the successor) frees the successor immediately, before you ever use it. Weak goes on the **back-pointer**.
- **Weakening a lexical.** `weaken $ref` where `$ref` is a fresh lexical referencing `$target` makes the lexical weak. If nothing else holds a strong reference to `$target`, it vanishes at the next statement and `$ref` becomes `undef`. Weak references belong in data-structure slots, not typically in local lexicals.
- **Assuming weak references are automatic.** Perl does **not** detect cycles and weaken them for you. You have to opt in.

Beyond Scalar::Util

`Scalar::Util` ships with Perl; it is always available. For more elaborate needs - `WeakRef`, `Hash::Util::FieldHash` - reach for CPAN. For ordinary code, `weaken` is all you need.

Where to go next

You've finished the references tutorial. Good next reads:

- The `ref` reference page - the full list of strings it returns, including blessed-object cases.
- `bless` - how a plain hash reference becomes an object of a specific class.
- The object-orientation tutorial, once you're ready for classes built on top of the references you now understand.
- **Basics** - the `\` operator, scalar/array/hash dereference with `$$x`, `@$x`, `%$x`, curly-brace disambiguation, and the `->` arrow for element access.

- **Arrays of arrays** - two-dimensional data, iteration patterns, the arrow-between-subscripts rule that makes `$m[i][j]` read as a matrix.
- **Hashes and mixes** - hashes of arrays, arrays of hashes, and the common record-table shape.
- **Anonymous references** - `[...]` and `{...}` as inline constructors, when to choose them over named variables.
- **Subroutine references** - `\&name`, anonymous `sub { ... }`, calling with `->(...)`, and how closures capture lexicals.
- **Weak references** - `Scalar::Util::weaken` and why cyclic structures need it.

Related reference pages

- `ref` - ask a value what kind of reference it is.
- `defined` - the standard way to check "does this reference exist yet?" after autovivification.
- `bless` - the step that turns a plain reference into an object.
- *References (data-types reference)* - the terse one-page reference that complements this tutorial.

4.2.15 Unicode - a tutorial

Modern programs carry accented letters, currency symbols, CJK ideographs, and emoji through their input and output. Perl handles Unicode well, but only if you are explicit about where text is text and where bytes are bytes. This tutorial is the shortest path to that discipline.

These pages do not teach Unicode itself. You are assumed to know that a character set numbers characters, that an encoding maps those numbers to bytes, and that UTF-8 is one such encoding among several. What follows is the Perl-specific habit you need on top.

The one idea

A Perl string is either a **text string** - a sequence of Unicode code points, where `length` counts characters - or a **binary string** - a sequence of bytes, where `length` counts bytes. The same variable type holds both, but the meaning is different, and the boundary between them is where encoding and decoding happen.

Every bug in this area comes from losing track of which kind of string you have. Every fix comes from making the boundary explicit.

```
my $text  = "caf\x{e9}";          # 4 characters: c a f é
my $bytes = "caf\xc3\xa9";        # 5 bytes:      c a f 0xc3 0xa9
length $text;                     # 4
length $bytes;                    # 5
```

Both strings "contain" the word *café*. Only one of them can go through a regex that expects characters; only the other can go down a byte-oriented socket.

The pipeline

A program that handles text correctly follows one shape:

1. **Decode** everything coming in. Bytes on the outside become characters on the inside.
2. **Process** in characters. Regex, length, case conversion, the lot.
3. **Encode** everything going out. Characters on the inside become bytes on the outside.

Step 2 is where Perl is already comfortable. Steps 1 and 3 are where the discipline lives. This tutorial walks through both.

Chapters

Strings and encodings

A Perl string holds a sequence of integers. What those integers *mean* is up to you. In a text string they are Unicode code points; in a binary string they are bytes. Perl does not stamp "this is text" on a scalar - you carry that knowledge with the data, and the boundary between the two worlds is drawn by `encode` and `decode`.

Text in source code: `use utf8`

By default, Perl reads your source file as a sequence of bytes. A string literal containing é is a two-byte string `"\xc3\xa9"`, not the one-character string `"\x{e9}"`. That is almost never what you want when you typed é in an editor set to UTF-8.

`use utf8` tells the parser that the source file is UTF-8 and that literals should be decoded as they are read:

```
use utf8;
my $greeting = "café";
length $greeting;                # 4  - characters
```

Without `use utf8`, the same line produces:

```
my $greeting = "café";
length $greeting;                # 5  - bytes
```

Rule of thumb: if your source file contains any non-ASCII character, write `use utf8` at the top and save the file as UTF-8. The pragma only governs the source file; it has nothing to do with I/O.

The internal representation

Perl keeps text strings in a representation of its own choosing. You do not need to know what it is, and you must not depend on it. The only guarantee is:

- A text string is a sequence of code points. `length` counts them, `substr` indexes them, `chr` and `ord` map between characters and their code points.
- A binary string is a sequence of bytes. The same functions now count and index bytes.

The `utf8` pragma controls the *source*. There is also a `utf8::` namespace of functions for probing and forcing the internal flag - they exist, they are occasionally useful, and in normal application code you should not need them. Stick to `encode` and `decode`.

The Encode module

The standard way to convert between text and bytes is the `Encode` module:

```
use Encode qw(encode decode);

my $bytes = encode("UTF-8", $text);      # text  → bytes
my $text  = decode("UTF-8", $bytes);     # bytes → text
```

The first argument names the encoding. UTF-8 is the obvious default for new code, but `Encode` supports the `ISO-8859-*` family, every common Windows code page, Shift-JIS, EUC-JP, EUC-KR, GB2312, GBK, Big5, and dozens more.

Decoding is only reliable if you know which encoding the bytes are in. Nothing in the bytes themselves tells you - that information travels in a `Content-Type` header, a file's BOM, a protocol's metadata field, or a convention you have agreed with the producer. If you truly do not know, guess UTF-8 first, then fall back on `ISO-8859-1` which at least never fails (every byte is a valid code point in that encoding).

Lossy encodings

Not every Unicode character survives every encoding. Converting `"caf\x{e9}"` to `ISO-8859-1` works - é has code point `0xe9` which that encoding can hold. Converting an em-dash `\x{2014}` to `ISO-8859-1` does not - the character has no place in the target, and `encode` replaces it with a substitution marker by default.

```
use Encode qw(encode);
my $s = "em\x{2014}dash";
my $b = encode("ISO-8859-1", $s);          # "em?dash"
```

Pass a third argument to `encode` to change that behaviour - see the `Encode` module documentation for the full list of `Encode::FB_*` constants. For most application code, the default substitution is the right compromise.

A complete round-trip

Putting decoding, processing, and encoding together:

```
use utf8;
use Encode qw(encode decode);

# bytes arrive from somewhere - HTTP, a file, a socket
my $input_bytes = "caf\xc3\xa9\n";

# step 1: decode to text
my $text = decode("UTF-8", $input_bytes);  # "café\n"
```

(continues on next page)

(continued from previous page)

```
# step 2: process as text
chomp $text;
my $shouty = uc $text;                      # "CAFÉ"

# step 3: encode for output
my $output_bytes = encode("UTF-8", $shouty . "\n");
```

The text layer is short - one `uc` call - but that is the layer where `length`, regex, case conversion, and `chomp` all work in the units the program means.

When you want I/O to do this automatically

Doing `decode` on every read and `encode` on every write quickly becomes tedious. The next chapter - *I/O* - shows how to push the conversion into the filehandle itself with the `:encoding` layer, so ordinary `print` and `readline` already speak text.

I/O

The filehandle is the boundary between your program's text world and the outside world of bytes. Getting Unicode right means setting that boundary up correctly at `open` time (or with `binmode`), so that ordinary `print` and `readline` already speak the right encoding.

PerlIO layers

Every filehandle carries a stack of *layers* - small pieces of machinery that transform bytes as they cross the boundary. The relevant ones for Unicode are:

- `:raw` - no transformation. Bytes in, bytes out.
- `:utf8` - check that bytes read form valid UTF-8 and mark the string as text. Trust the user not to produce invalid UTF-8 on writes.
- `:encoding(ENCODING)` - decode on read, encode on write, for any named encoding. Rejects malformed input by default.
- `:crlf` - translate `"\r\n"` to `"\n"` on read, `"\n"` to `"\r\n"` on write. On Linux this is inactive; on Windows it is the default for text handles.

`:encoding(UTF-8)` is what you almost always want. Prefer it over the bare `:utf8` layer - the `:encoding(...)` form validates, `:utf8` does not.

Opening a file with an encoding

The three-argument form of `open` takes a mode that can include layers:

```
open my $in,  "<:encoding(UTF-8)", "input.txt"  or die "open: $!";
open my $out, ">:encoding(UTF-8)", "output.txt" or die "open: $!";

while (my $line = <$in>) {
    chomp $line;                        # characters, not bytes
    print $out uc $line, "\n";          # encoded on the way out
}
```

Every `readline` from `$in` returns a text string. Every `print` to `$out` is encoded to UTF-8 on the wire. The body of the loop sees only characters - no `decode`, no `encode`, no counting bytes by mistake.

Retrofitting with `binmode`

If the filehandle is already open - for example the standard streams, or a handle handed to you by another module - attach the layer with `binmode`:

```
binmode STDIN,  ":encoding(UTF-8)";
binmode STDOUT, ":encoding(UTF-8)";
binmode STDERR, ":encoding(UTF-8)";
```

Do this once, at the top of the program, before any I/O on those handles. After that the standard streams behave the same as a file opened with an encoding layer.

The `use open` pragma

Writing the same `:encoding(UTF-8)` layer on every `open` is noisy. The open pragma sets the default layers for all subsequent opens in the enclosing scope:

```
use open ":std", ":encoding(UTF-8)";
```

The `:std` tag also re-layers `STDIN`, `STDOUT`, and `STDERR` on the spot, so you get the effect of three `binmode` calls and a default for every later `open` in one line.

This is the one-liner at the top of a modern Unicode-aware script:

```
use utf8;
use open ":std", ":encoding(UTF-8)";
```

- `use utf8` - literals in this source file are UTF-8.
- `use open ":std", ":encoding(UTF-8)"` - stdin/stdout/stderr and every later open default to UTF-8 on the wire.

You can also push I/O to UTF-8 from outside the program with the `PERL_UNICODE` environment variable. The letters `I`, `O`, `E` select stdin, stdout and stderr individually, `S` selects all three at once the way the `use open ":std"` pragma does, and `A` decodes `@ARGV`, so `PERL_UNICODE=SA` is roughly the command-line equivalent of the two-line preamble above. To decode arguments inside the program instead, write `@ARGV = map { decode('UTF-8', $_, 1) } @ARGV`.

The matching `-C` command-line switch (`-CSA`) is not yet recognised by pperl, which is a discrepancy from stock perl; use the `PERL_UNICODE` variable or the `use open` pragma until it is implemented.

Binary I/O alongside text I/O

Some handles carry bytes, not text - image files, compressed streams, network protocols that frame their own encoding. Open those `:raw` and never attach an encoding:

```
open my $img, "<:raw", "photo.jpg" or die "open: $!";
```

Within one program, some handles can be text (`:encoding(UTF-8)`) and others binary (`:raw`). Keep the labels straight: a binary handle gives you byte strings, a text handle gives you text strings, and `$!` is the same either way.

Interactive input

A terminal does not tell you what encoding it is typing in. On modern Linux it is almost always UTF-8; on Windows the default console code page is still commonly CP1252 or CP437. The usual assumption for cross-platform scripts is UTF-8, with `binmode` applied at startup:

```
binmode STDIN, ":encoding(UTF-8)";
```

If your program must support legacy terminals, decode based on the `LANG` or `LC_CTYPE` environment variable, or accept a `--encoding` flag. There is no portable auto-detection.

Checking layers

To see which layers are on a handle, use `PerlIO::get_layers`:

```
use PerlIO;
my @layers = PerlIO::get_layers(\*STDOUT);
print "@layers\n";                          # e.g. unix perlio␣
 ↪encoding(utf-8-strict)
```

Useful when a program is silently producing double-encoded output and you want to find out which handle has the surprise layer on it.

Regex and properties

Once your strings are decoded, regex works on characters - and Perl's regex engine knows about Unicode. `\w` matches every Unicode word character, case-insensitive matching folds across scripts, and `\p{…}` gives you access to the full Unicode character database. This chapter covers the habits you need to make that work reliably.

Characters, not bytes

On a text string, every regex metacharacter speaks in characters:

```
use utf8;
my $s = "café";                             # 4 characters
$s =~ /^.{4}$/;                             # matches
$s =~ /^.{5}$/;                             # does not
```

On a binary string, the same metacharacters count bytes. That is usually not what you want - if you find yourself writing a regex against bytes that hold text, decode first.

`\w`, `\d`, `\s` and the friends

In default (Unicode) mode, these shorthands match their Unicode equivalents:

- `\w` - letters, digits, and underscore from every script.
- `\d` - decimal digits from every script (not just `0`–`9`).
- `\s` - whitespace of every kind, including U+00A0 no-break space.

```
use utf8;
"café"  =~ /^\w+$/;                      # matches
"café"  =~ /^[a-z]+$/;                   # does not - é is outside
"\x{0660}\x{0661}\x{0662}" =~ /^\d+$/;   # matches Arabic-Indic␣
 ↪digits
```

When you want the old ASCII-only meaning, add the `/a` modifier - see *Modifiers* below.

The `\p{…}` property classes

`\p{PROPERTY}` matches any character with a named Unicode property. The property names are drawn from the Unicode character database; the commonly useful ones are:

- `\p{Letter}`, shorthand `\p{L}` - any letter.
- `\p{Lu}`, `\p{Ll}`, `\p{Lt}` - upper, lower, title case letters.
- `\p{Number}`, `\p{N}`, `\p{Nd}` - all numbers, decimal digits.
- `\p{Punct}`, `\p{P}` - punctuation.
- `\p{Space}`, `\p{Zs}` - whitespace, space separators.
- `\p{ASCII}` - the 128 ASCII code points.
- `\p{Script=Greek}` - every character that belongs to the Greek script. Any script name from the Unicode data works here.
- `\p{Block=Cyrillic}` - every character in the Cyrillic block. (Script and block are different: *script* is the writing system a character belongs to; *block* is the code-point range it lives in.)

`\P{…}` is the negation - any character without that property.

```
use utf8;
my $s = "Γειά σου, κόσμε";
my @greek_letters = $s =~ /(\p{Script=Greek})/g;
scalar @greek_letters;                   # 12
```

The full catalogue of properties ships with Perl; `perldoc perluniprops` enumerates every name the engine accepts.

Modifiers: `/a`, `/u`, `/l`, `/aa`

Four modifiers change how character classes interpret themselves:

- `/u` - **Unicode mode.** `\w` matches Unicode word characters, `\d` matches Unicode decimal digits, case folding uses Unicode rules. This is the default on text strings.

- `/a` - **ASCII mode.** `\w` becomes `[A-Za-z0-9_]`, `\d` becomes `[0-9]`, `\s` becomes `[ \t\n\r\f]`. Case folding is still Unicode - `/s/ai` still matches ſ (U+017F, the long s), because it folds to `s` - which is almost never what you want when you reached for `/a`.
- `/aa` - **strict ASCII.** `/a` plus case folding is restricted to ASCII. `/s/aai` matches S but not ſ. Use this when you want an identifier match against a known-ASCII specification (HTTP header names, command keywords).
- `/l` - **locale mode.** Defers to the current POSIX locale. Almost never what you want in a Unicode-aware program; mentioned only so you can recognise it when another codebase uses it.

```
use utf8;
"café" =~ /\w+/;                          # matches whole word␣
↪(Unicode)
"café" =~ /\w+/a;                         # matches "caf" (ASCII␣
↪only)
"FOO"  =~ /foo/ai;                        # matches (ASCII case fold)
"ſ"    =~ /s/ai;                          # matches - U+017F folds to␣
↪s
"ſ"    =~ /s/aai;                         # does not - strict ASCII
```

Rule of thumb: default mode is right for text; switch to `/aa` when you are parsing an ASCII-specified protocol and want to reject smuggled non-ASCII characters.

Case-insensitive matching

`/i` folds both sides of the match using Unicode case-folding tables. This handles the obvious European pairs (é/É, ß/SS), and the less obvious ones (İ/i, fi/fi).

```
use utf8;
"Ångström" =~ /ångström/i;                # matches
"STRASSE"  =~ /straße/i;                  # matches - ß folds to SS
```

For literal-byte case folding (the old ASCII meaning of `/i`), use `/iaa`.

Named code points

`\N{...}` names a Unicode character, either by its official name or by its code-point number:

```
use charnames ();
"\N{LATIN SMALL LETTER E WITH ACUTE}" eq "\x{e9}";   # true
"\N{U+00E9}" eq "\x{e9}";                             # the same␣
↪character
```

`\N{U+HEX}` works without any pragma; the long names go through the `charnames` module, loaded automatically inside a `\N{...}` escape (or explicitly with `use charnames qw(:full)`). In a pattern, `\N{...}` is useful when you want the source to document which character you mean without relying on the reader to recognise a hex escape:

```
"café" =~ /caf\N{LATIN SMALL LETTER E WITH ACUTE}/;  # matches
```

Splitting and joining

`split` and `substr` both count in the units of the string they operate on. On a text string, the count is characters:

```
use utf8;
my $s = "a,é,b,Ω";
my @parts = split /,/, $s;                # ("a", "é", "b", "Ω")
substr($s, 2, 1);                         # "é"
```

On a binary string, the same operations count bytes. This is the most common subtle bug - an old codebase that decoded input in one function but indexed the result in another, built before the decode step was introduced.

Pitfalls

Most Unicode bugs in Perl programs show up as one of a handful of familiar symptoms. This chapter names each one, shows what produces it, and points to the fix.

"Wide character in print"

The warning:

```
Wide character in print at script.pl line N.
```

means you sent a text string to a filehandle that is not configured for text. The output gets written anyway - Perl encodes it as UTF-8 on the fly - but the warning is your notice that the configuration is wrong.

The fix is to attach an encoding layer to the handle:

```
binmode STDOUT, ":encoding(UTF-8)";
```

or, globally for the standard streams:

```
use open ":std", ":encoding(UTF-8)";
```

Do not silence the warning with `no warnings 'utf8'`. The warning is correct; it is telling you about a real missing configuration.

Double encoding: *café* becomes *cafÃ©*

Symptom: text looks almost right, but every non-ASCII character has been replaced by a pair of funny-looking bytes. `café` becomes `cafÃ©`, `Straße` becomes `StraÃŸe`.

Cause: you encoded to UTF-8, then encoded again. The second stage read the already-encoded bytes as if they were text, treated each byte as a Latin-1 code point, and encoded those to UTF-8. Two passes through UTF-8 encoding is the classic double-encode.

Common producers:

- A filehandle with `:encoding(UTF-8)` that receives an already encoded byte string. Fix: send text to the handle, or drop the layer.
- An HTTP response whose body is encoded in the application, and encoded again by a middleware that assumed the body was text.
- A database client that decodes on read, in a codebase that was written before the client learned to decode.

Diagnosis: look at the bytes on the wire. If a single non-ASCII character takes four or more bytes when it should take two, you have been through UTF-8 twice.

Missing decode: *café* stays *café* but indexes are wrong

Symptom: prose looks correct on the terminal, but `length` gives too many, `substr` cuts in the middle of a character, a regex like `/^.{5}$/` unexpectedly matches a four-character word.

Cause: you never decoded. The scalar holds UTF-8 bytes, the terminal happens to also render them as UTF-8, and the visual output hides the fact that Perl sees them as bytes.

Fix: decode on the way in, either with `binmode` on the handle or `Encode::decode` on the string:

```
use Encode qw(decode);
my $text = decode("UTF-8", $raw_bytes);
```

Heuristic: if `length $s` is unexpectedly larger than the number of visible characters, you are looking at bytes.

Mojibake: unknown encoding

Symptom: non-ASCII looks like random line-noise - `café` as `cafÃ©`, as `caf?`, as a box character. Different visual, different cause each time.

Cause: you decoded with the wrong encoding, or did not decode at all and the terminal guessed wrong.

There is no universal fix - you must know what encoding the source actually used. A few reliable anchors:

- Web: the `Content-Type` header's `charset=` parameter, or the HTML `<meta charset>` element for files served without one.
- Files from legacy Windows applications: usually `CP1252` (Western European) or a regional `CP1250`/`CP1251`/`CP1253`.
- Files from classic Mac: `MacRoman`. Rare but survives in old archives.
- Email bodies: the `Content-Type` charset of the MIME part.

If nothing tells you, try UTF-8 first; if that fails with a decode error, try `ISO-8859-1` (which cannot fail but may produce nonsense).

Mixing text and bytes in concatenation

Symptom: a string that concatenates a decoded text fragment with a raw byte fragment produces garbage after the boundary.

```
use utf8;
my $label = "café";                          # text
my $raw   = "\xc3\xa9_ok";                   # bytes that also look like␣
↪text
print $label, $raw;                          # "Wide character" or␣
↪mojibake
```

Cause: the text half goes through whatever encoding layer is on the handle; the byte half is reinterpreted as code points by that same layer, with predictable confusion.

Fix: pick a side. Either decode the byte fragment first, or encode the text fragment to match. Never concatenate the two kinds of string without a conscious choice about which side you are on.

`sprintf "%s"` is not a conversion

`sprintf` does not decode or encode; it formats. Passing a byte string through `%s` yields a byte string; passing a text string yields a text string. If you need to change encoding, call `encode` or `decode` explicitly.

Locale-dependent case folding

Symptom: `lc` or `uc` produces different results on different machines, or fails to round-trip through a regex.

Cause: the program is running under the `/l` locale-mode regex modifier, or `uc` / `lc` have been redirected through a POSIX locale with `use locale`.

Fix: do not use `use locale` for text processing. Unicode case folding is the right answer for text; POSIX locales are a remnant of byte-oriented C I/O. The only modern use of `use locale` is interacting with C libraries that consult `LC_CTYPE`.

Identifier vs data

Source code that contains non-ASCII characters needs `use utf8`. A program that processes non-ASCII data needs `binmode` or `:encoding(UTF-8)` layers on its handles. These are separate configurations, and both may be needed.

A short checklist for a new Unicode-aware script:

```
use strict;
use warnings;
use utf8;                                    # source is UTF-8
use open ":std", ":encoding(UTF-8)";         # stdio + default I/O
```

With those four lines at the top, string literals, standard I/O, and any later `open` call already speak text. Remaining Unicode work is narrow and local - decoding a byte buffer from a socket, or attaching `:raw` to a handle that must carry binary data.

Recipes

The conceptual chapters cover the discipline; this page is the quick-reference appendix. Each recipe is a short, self-contained answer to a common Unicode task - the kind of thing the classic Perl Unicode cookbook reaches for a CPAN module to do, but which pperl's builtins and regex engine handle directly.

Every example here assumes your strings are already text - decoded on the way in, as the *Strings and encodings* chapter describes. The operations below all speak characters, so a binary string fed to them will count bytes and surprise you.

Case-insensitive sort and comparison with `fc`

The `fc` builtin returns the *foldcase* of a string - the same Unicode case folding the `/i` pattern modifier uses. Two strings are equal under case folding exactly when `fc` returns the same result for both, which makes `fc` the right tool for case-insensitive sorting and comparison.

```
use v5.36;     # or: use feature 'fc';
use utf8;

# sort case-insensitively
my @sorted = sort { fc($a) cmp fc($b) } @list;

# both are true:
fc("tschüß")  eq fc("TSCHÜSS");
fc("Σίσυφος") eq fc("ΣΊΣΥΦΟΣ");
```

Folding handles the cases that simple `lc` cannot: the German sharp s folds to `ss`, and Greek final sigma ς folds together with medial σ. Reach for `fc` rather than `lc` whenever the comparison is meant to ignore case in the full Unicode sense.

This is case folding only. It does not ignore accents, and it does not impose a locale's alphabetic order - for that you would need a collation library such as `Unicode::Collate`, which is not yet usable in pperl (see the end of this page).

Normalising line breaks with `\R`

`\R` matches a single Unicode linebreak: the two-character CRLF grapheme, or any one of the vertical whitespace characters (LF, CR, form feed, vertical tab, next line, line separator, paragraph separator). It is the portable way to deal with text files that arrive from different operating systems.

```
my $text = "line one\r\nline two\rline three\n";
$text =~ s/\R/\n/g;          # normalise every linebreak to \n
```

After the substitution, `$text` uses a single `\n` everywhere regardless of how the input encoded its line endings. Use `\R` in place of an explicit `\r?\n` alternation: it covers the cases that the hand-written pattern forgets.

Matching a grapheme cluster with \X

A user-visible character - a base letter together with any combining marks - is a *grapheme cluster*. The . metacharacter matches one code point, which may be only part of such a cluster; \X matches one whole grapheme cluster.

```
use utf8;

# "é" written as e + COMBINING ACUTE ACCENT is two code points,
# but one grapheme.
my $str = "cafe\x{301}";     # c a f e + combining acute
$str =~ /^.{5}$/;            # matches - five code points
$str =~ /^\X{4}$/;           # matches - four graphemes

# find a vowel plus any combining diacritics
$str =~ / (?=[aeiou]) \X /xi;
```

\X is the right unit whenever “character” means “what the reader sees” rather than “code point”. The recipes below build on it.

First N graphemes, reverse, and length by grapheme

These three tasks all reduce to applying \X instead of indexing by code point. They work correctly no matter which normalization form the string is in.

Grab the first five graphemes:

```
my ($first_five) = $str =~ /^ ( \X{5} ) /x;
```

Reverse a string by grapheme. Reversing by code point would detach a combining mark from its base letter and corrupt the text; collecting graphemes first keeps each cluster intact:

```
$str = join "", reverse $str =~ /\X/g;
```

Count the length of a string in graphemes. The word brûlée is six graphemes but may be up to eight code points, so length and a grapheme count can differ:

```
my $count = 0;
$count++ while $str =~ /\X/g;
```

Fine-tuning UTF-8 warnings

Perl splits UTF-8 warnings into three subclasses, so you can silence one kind of malformed-Unicode warning without silencing the others. pperl recognises all three category names:

```
no warnings "nonchar";      # the forbidden non-characters
no warnings "surrogate";    # UTF-16 surrogate code points
no warnings "non_unicode";  # code points above 0x10_FFFF
```

Disable only the subclass you have a deliberate reason to allow - for example `no warnings "non_unicode"` in code that manipulates code points beyond the Unicode range on purpose - and leave the rest in force so that genuine encoding faults still surface.

Decoding @ARGV

Command-line arguments arrive as bytes. If a user passes a non-ASCII argument, you must decode it before treating it as text, exactly as you would decode any other input. The portable form maps `decode` over `@ARGV`:

```
use Encode qw(decode);
@ARGV = map { decode('UTF-8', $_, 1) } @ARGV;
```

After this line, each element of `@ARGV` is a text string and behaves under `length`, regex, and case operations in characters rather than bytes. The third argument `1` (the `Encode::FB_CROAK` check) makes a malformed argument a fatal error rather than a silent substitution, which is usually what you want for input you cannot re-request.

Custom property by code-point range

A `\p{...}` property can name a subroutine you define. When the regex engine meets an unknown property `\p{In_Foo}`, it calls `In_Foo`, which returns a list of code-point ranges (one `START\tEND` pair per line, in hexadecimal); the property then matches any character in those ranges.

```
sub In_Greek { return "0370\t03FF\n0780\t07BF\n" }

"\x{3b1}" =~ /\p{In_Greek}/;     # matches - alpha is in 0370..03FF
```

This is the portable way to define an ad-hoc character class once and reuse it by name across patterns, without spelling out the range in every regex.

Unicode modules, and the two still pending

Some recipes in the classic Perl Unicode cookbook reach for the Unicode helper modules that Perl provides as compiled extensions. Most of them are built into pperl and work as written: `Unicode::Normalize` (NFC, NFD, NFKC, NFKD normalization), `Unicode::GCString` (grapheme-aware `substr` and print-column width), `Unicode::UCD` (programmatic character category and numeric-value lookup), and `Unicode::LineBreak` (line-breaking by Unicode rules).

`Unicode::Collate` and `Unicode::Collate::Locale` (alphabetic and locale-sensitive sorting, accent-insensitive comparison) are not available yet: loading either fails with `Can't locate loadable object for module Unicode::Collate in @INC`. Until they are, there is no substitute here for locale collation; `fc` above ignores case, but not accents or a locale's alphabetic order.

- **Strings and encodings** - `use utf8`, the Encode module, what the internal representation is and is not.
- **I/O** - opening files with an encoding, standard streams, `binmode` and the `:encoding` layer.

- **Regex and properties** - matching Unicode in patterns, `\p{...}` property classes, the `/a` `/u` `/l` `/aa` modifiers.
- **Pitfalls** - "Wide character in print", double encoding, locale interactions, and how to recognise each one from its symptom.
- **Recipes** - quick-reference one-liners for case-insensitive sorting with `fc`, normalising line breaks with `\R`, and working by grapheme cluster with `\X`.

Conventions

- Expected output appears as an inline `# ...` comment or directly below the code block.
- Code points are written with `\x{...}` hex escapes so the printed text matches what you see.
- Examples assume a UTF-8-capable terminal. If yours is not, output containing non-ASCII characters will look different, but the program is still correct.

4.2.16 Boolean Logic for Perl Programmers - a tutorial

Almost every line of working Perl is shaped by boolean logic. `open ... or die`, `$h{$k} //= []`, `unless ($a == $b && $c eq $d)`, `/^(yes|no)$/`, `$flags & 0x4` - they are all the same handful of operations applied in different domains. This tutorial walks through those operations from the bottom up: what truth means in Perl, what the operators actually return, all sixteen binary truth functions and how to spell each one in Perl, the two laws that turn convoluted conditions into simple ones, and the three places that logic shows up most: bitwise arithmetic, regular expressions, and control flow.

Who this is for

You already write working Perl. You use `&&`, `||`, `if`, `unless` without thinking - but when a condition grows past three or four clauses you stop trusting it, and you reach for parentheses you suspect are not needed. This tutorial closes that gap. After reading it, you will know exactly which logical operation a given expression performs, why two seemingly different forms are the same expression, and how to reduce a tangled `unless` to a clean `if` with confidence rather than by trial and error.

Scope

Classical two-valued boolean logic - true and false, full stop. Perl's `undef` introduces a third value (the *unknown*) and a whole family of three-valued idioms (`defined`, `//`, `//=`). Those are mentioned where they intersect with two-valued logic, but a proper treatment of three-valued logic would double the size of this tutorial without finishing it; that is a separate guide.

How this tutorial is organised

Each chapter is one concept. Read them in order on the first pass; jump to the relevant chapter later when you are looking up a fact.

Truthiness

Before logic, the values logic operates on. Perl does not have a dedicated boolean type. Every scalar is either *true* or *false* when used in boolean context, and the rule is short:

> A scalar is **false** if it is one of the four values `undef`, the integer `0`, the string `""`, or the string `"0"`. Everything else is **true**.

Four false values, every other scalar - including the strings `"00"`, `"0.0"`, `"0E0"`, and `"false"` - is true.

```
if (0)         { ... }   # false  -- the integer zero
if (0.0)       { ... }   # false  -- numerically zero
if ("")        { ... }   # false  -- empty string
if ("0")       { ... }   # false  -- the string "0"
if (undef)     { ... }   # false  -- undefined value

if ("00")      { ... }   # TRUE   -- non-empty, not the string "0"
if ("0.0")     { ... }   # TRUE   -- non-empty, not the string "0"
if ("0 but true") { ... } # TRUE -- non-empty, not the string "0"
if (" ")       { ... }   # TRUE   -- single space is non-empty
if ("false")   { ... }   # TRUE   -- it's just a 5-character string
```

The `"0 but true"` idiom is not a joke. Some Perl APIs return a value that must compare equal to zero numerically (so an arithmetic test does the right thing) but be true in a boolean context. The classical case is `ioctl()` - success returning literally zero would test false. The string `"0 but true"` is numerically zero (with a warning suppressed by historical agreement) and boolean-true because it is not in the four-element false set.

```
my $rc = ioctl($fh, $cmd, $buf);
$rc == 0       and warn "numeric zero";   # would fire on success
$rc            or  warn "boolean false";  # FIRES if API returned 0
                                          # but NOT if "0 but true"
```

Two flavours of comparison

Perl has parallel families of comparison operators because it has parallel notions of equality. Numbers compare numerically; strings compare lexically. The wrong family on the wrong type is one of the most common bugs in beginner Perl.

Test	Numeric	String
equal	`==`	`eq`
not equal	`!=`	`ne`
less than	`<`	`lt`
greater than	`>`	`gt`
less or equal	`<=`	`le`
greater or equal	`>=`	`ge`
three-way (sort)	`<=>`	`cmp`

`==` on strings always succeeds for any two non-numeric strings - both convert to `0`, and `0 == 0` is true:

```
"foo" == "bar";    # TRUE  -- both stringify to numeric 0
"foo" eq "bar";    # FALSE -- the actual question

"10" eq 10;        # TRUE  -- string "10" equals numeric 10␣
↪stringified
"10" == 10;        # TRUE  -- 10 == 10 numerically
"10" lt "9";       # TRUE  -- lexical: "1" < "9"
"10" <  "9";       # FALSE -- numeric: 10 > 9
```

`<=>` and `cmp` return `-1`, `0`, or `+1` - the standard sort comparator shape. They are not boolean operators in the strict sense, but they appear inside boolean contexts often enough that you should know them.

Why this matters for logic

Every boolean operator in Perl - `&&`, `||`, `//`, `!`, `xor`, `and`, `or`, `not` - uses the four-value false set above as its input rule. Whenever a chapter below says "if `$x` is false", that is exactly what is meant: `$x` is `undef`, `0`, `""`, or `"0"`. Whenever it says "if `$x` is true", `$x` is anything else.

Two consequences worth keeping in mind:

1. **A scalar can be true without being a boolean true value.** Strings, references, blessed objects, large numbers - all true. When you ask "is this true?" you are not asking "does this equal 1?" - you are asking "is this not in the false set?".
2. **The result of a boolean operator is not always 1 or 0.** The next chapter covers this in detail. Briefly: `&&` and `||` return one of their *operands*, not a normalised boolean. This is a feature, not a quirk, and many Perl idioms depend on it.

See also

- *perlop - Numeric comparison* and *String comparison* - the reference pages for ==/eq and the rest of the comparison families introduced above.

Operators

Perl spells the boolean operators twice, in two different precedence classes. The C-style symbolic forms (`&&`, `||`, `!`) bind tightly; the word forms (`and`, `or`, `not`) bind very loosely. There is also `//` for the *defined-or* idiom, `xor` for exclusive-or, and the ternary `? :` which is logical selection in disguise.

The full inventory

Operator	Reads as	Returns	Precedence
`!`	not	normalised 1 or empty string	high
`&&`	and	left if false, else right (the *operand*)	high
`||`	or	left if true, else right (the *operand*)	high
`//`	defined-or	left if defined, else right (the *operand*)	high
`xor`	exclusive or	normalised 1 or empty string	very low
`not`	not	normalised 1 or empty string	very low
`and`	and	left if false, else right (the *operand*)	very low
`or`	or	left if true, else right (the *operand*)	very low
`?:`	ternary	middle if condition true, else right (operand)	low

Two things in this table do most of the work:

- **`&&` and `||` return an operand, not a boolean.** This is the property that makes Perl's idioms work the way they do. See below.
- **The symbolic and word forms differ in precedence, not meaning.** `&&` and `and` compute the same logical function. They differ in how tightly they bind to other operators around them. That is why you see `or die` after function calls but `||` inside expressions - the chapter on the `or die` idiom explains.

Short-circuit and the operand-return rule

`&&` and `||` evaluate left-to-right and stop as soon as the result is determined.

- `A && B` - if `A` is false, return `A` without evaluating `B`. Otherwise return `B`.
- `A || B` - if `A` is true, return `A` without evaluating `B`. Otherwise return `B`.

Crucially, the **return value is the operand itself**, not a normalised true/false. This is what makes patterns like `$config{port} || 8080` work: if `$config{port}` is set (truthy), the expression is `$config{port}`'s value; if not, it is `8080`.

```
my $port = $config{port} || 8080;
my $name = $user_input  || "anonymous";
my $list = shift        || [];
```

The same property powers `or die`:

```
open my $fh, '<', $path  or die "open $path: $!";
#  ^^^^^^^^^^^^^^^^^^^   ^^^^^^^^^^^^^^^^^^^^
#  if open returns true,  the right-hand operand
#  the whole expression   is never evaluated
#  is true and we move on
```

open returns true on success, undef on failure. On success the short-circuit stops on the left and `die` never runs. On failure the right-hand operand evaluates, which is the `die` call.

`//` - defined-or

`||` treats `0`, `""`, and `"0"` the same as `undef`. Sometimes that is wrong: a configured `0` is a real value, not a missing one. `//` short-circuits on **definedness** instead of truthiness:

- `A // B` - if A is defined, return A. Otherwise return B.

```
my $port    = $config{port} || 8080;   # 0 means "use default" -␣
↪wrong
my $port    = $config{port} // 8080;   # 0 means "0", undef means
↪"use default"
my $verbose = $opt{verbose} // 0;       # 0 is a real choice
```

The compound assignment forms `||=` and `//=` save you from repeating the variable on the left:

```
$config{port} //= 8080;   # set only if currently undef
$cache{$key}  ||= compute($key);   # set if currently false
```

`xor` and the absence of a high-precedence form

There is no `^^` in Perl. `xor` exists only as the very-low-precedence word form, and unlike `and`/`or` it does *not* short-circuit (it cannot - both sides have to be evaluated to determine the result). It returns a normalised `1` or `""`, not an operand.

```
if ($admin xor $guest) { ... }   # exactly one of the two
```

For `xor` on values rather than on truthiness, the bitwise `^` applies to integers - covered in *the applications chapter*.

`!` and `not`

Both negate. `!` is the symbolic high-precedence form; `not` is the word low-precedence form. Both return a normalised value: `1` for "the operand was false", empty string `""` for "the operand was true".

```
my $missing = ! $config{port};       # 1 if port is unset/0/""/"0"
return if not @items;                # cleaner reading than `if !
↪@items`
```

The ternary `?:`

`COND ? X : Y` is logical selection: if `COND` is true the value is `X`, otherwise `Y`. It is not just sugar for an `if`/`else` because it is an *expression* - it has a value, can be assigned, returned, passed as an argument.

```
my $label = $count == 1 ? "1 item" : "$count items";
return $ok ? \%result : undef;
```

Beware nesting: `$a ? $b : $c ? $d : $e` parses as `$a ? $b : ($c ? $d : $e)` - chained `?:` is right-associative, which is usually what you want for an `if/elsif/else` cascade but is worth knowing rather than guessing.

Why the word forms exist: precedence, not style

`||` binds more tightly than `=`. `or` binds less tightly than `=` (or `,`, or anything else of conventional weight). That is the entire reason the word forms exist.

```
my $fh = open $h, '<', $path || die "no $path: $!";
#                         ^^^^^^^^^^^^^^^^^^^^^^^^^^
# parses as: open $h, '<', ($path || die "no $path: $!")
# which is: open the file named "either $path or the die-message"
# which is: catastrophe.

my $fh = open $h, '<', $path or die "no $path: $!";
# parses as: ($fh = open $h, '<', $path) or die "no $path: $!"
# which does what you meant.
```

Rule of thumb:

- Inside an expression, where you want the value to flow into a variable or another operator: use `&&`, `||`, `!`, `//`.
- After a statement, where you want a side-effect (`die`, `warn`, `return`) to fire conditionally: use `or`, `and`, `not`.

What you should remember from this chapter

- `&&` and `||` are not predicates that return 1 or 0 - they return one of their operands. This is the foundation of `||`, `||=`, `or die`, and most short defaulting idioms.
- `//` is `||` for definedness, not truthiness. Use it when `0` is a legitimate value.
- The word forms exist to bind looser than assignment, not for style.
- `xor` exists, has no symbolic form, does not short-circuit.

See also

- *perlop - Logical* - the reference companion, with the precedence-row context and PetaPerl-specific notes.
- *perlop - Precedence* - the full table; rows 5, 15, 16, 22, 23, 24 are the operators on this page.
- *perlop - Ternary* - `?:` as logical selection.

Truth tables

A binary boolean function takes two boolean inputs and returns one boolean output. There are exactly **sixteen** such functions - that is `2^(2^2)`: each of the four input combinations `(0,0) (0,1) (1,0) (1,1)` is independently mapped to one of two outputs, so `2 × 2 × 2 × 2 = 16`. No more, no fewer.

The five with their own Perl operator (`&&`, `||`, `xor`, and `!` for each of the two negations) are the ones everyone knows, and four more are trivial: always-true, always-false, and

the two projections. The other seven are quietly there too, expressed as small compositions. This chapter lists all sixteen, names them, and shows how to write each one in Perl.

The convention

Each function is fully described by its output for the four input rows, written top-to-bottom in this order:

```
a  b   →  output
0  0   →  bit 1
0  1   →  bit 2
1  0   →  bit 3
1  1   →  bit 4
```

Reading those four output bits as a 4-bit number gives the function its index 0..15. So `AND` is `0001` (only the last row is true), `OR` is `0111`, `XOR` is `0110`. Three quarters of the table is just looking up the right row.

All sixteen

#	Truth 00 01 10 11	Name	Symbol	Perl direct	Perl idiomatic
0	0 0 0 0	false (contradiction)	⊥	`0` / `""`	-
1	0 0 0 1	AND	∧	`$a && $b`	`$a and $b`
2	0 0 1 0	a AND NOT b	a ∧ ¬b	-	`$a && !$b`
3	0 0 1 1	a (left projection)	a	`$a`	-
4	0 1 0 0	NOT a AND b	¬a ∧ b	-	`!$a && $b`
5	0 1 0 1	b (right projection)	b	`$b`	-
6	0 1 1 0	XOR	⊕	`$a xor $b`	`!$a != !$b` / `($a?1:0) != ($b?1:0)`
7	0 1 1 1	OR	∨	`$a || $b`	`$a or $b`
8	1 0 0 0	NOR	↓ (Peirce)	-	`!($a || $b)` / `!$a && !$b`
9	1 0 0 1	XNOR / equivalence	↔	-	`!$a == !$b` / `($a?1:0) == ($b?1:0)`
10	1 0 1 0	NOT b	¬b	`!$b`	`not $b`
11	1 0 1 1	b implies a	b → a	-	`!$b || $a`
12	1 1 0 0	NOT a	¬a	`!$a`	`not $a`
13	1 1 0 1	a implies b	a → b	-	`!$a || $b`
14	1 1 1 0	NAND	↑ (Sheffer)	-	`!($a && $b)` / `!$a || !$b`
15	1 1 1 1	true (tautology)	⊤	`1`	-

Five rows have a direct Perl operator (`&&`, `||`, `xor`, and `!` for each of the two negations). The two constants and the two projections need no operator at all. The other seven are short compositions of those. There is no fundamental reason Perl spells some directly and not others - it is historical, inherited from C. Every column on the right is something you can type today.

Two things are worth pulling out of the table.

Implication: →

Implication is the operator nobody thinks they use, and everyone uses constantly. `a → b` is read "a implies b" and is true in every case **except** when `a` is true and `b` is false. That is it.

a	b	a → b
0	0	1
0	1	1
1	0	0
1	1	1

The Perl spelling is `!$a || $b`. This identity -

a → b ≡ ¬a ∨ b

- is so common that it deserves a name; and the name is *material implication*. Once you see it once, you spot it everywhere:

```
# "if the user is admin, the request must be authenticated"
# admin → authenticated
die unless !$user->is_admin || $req->is_authenticated;

# read aloud: "either not admin, or authenticated, or both"
```

The `unless ... !X || Y` shape is awkward. The next chapter on De Morgan's laws shows how to flip it into something readable.

Worth keeping at hand is the lookup table for flipping between common shapes:

Goal	One way	Equivalent way
a → b	¬a ∨ b	¬(a ∧ ¬b)
a ↔ b (XNOR)	(a ∧ b) ∨ (¬a ∧ ¬b)	¬(a ⊕ b)
a ⊕ b (XOR)	(a ∧ ¬b) ∨ (¬a ∧ b)	¬(a ↔ b)
¬a	a ↑ a (NAND self)	a ⊕ 1

The last column is a teaser for the chapter on functional completeness.

Equivalence and XOR are duals

XOR is true exactly when a and b differ. Equivalence (XNOR) is true exactly when they agree. They are negations of each other, and that is exactly what the truth-table rows say (row 6 is `0 1 1 0`, row 9 is `1 0 0 1` - bitwise negation).

In Perl the cleanest spelling for both is to canonicalise each operand to `0` or `1` first and then compare with `==` or `!=`:

```
my $a01 = $a ? 1 : 0;
my $b01 = $b ? 1 : 0;

my $xor  = $a01 != $b01;   # true if they differ
my $xnor = $a01 == $b01;   # true if they agree
```

Why the canonicalisation? Because `$a` and `$b` may be any truthy values - the strings `"yes"` and `5` are both true but not equal. Comparing them directly with `==` or `eq` answers

a different question. Boolean XOR asks "do they have the same *truthiness*?", not "are they equal?".

A short alternative without the temporaries is `!$a != !$b` - each `!` returns the canonical `1` or `""`, and then `!=` compares those. It works but reads sideways; the explicit `? 1 : 0` form is more readable.

Reading the table backwards

You will sometimes know the truth pattern you want and need to find the operator. Example: "I want a function that is true unless both `a` and `b` are false." Read the rows: `a=0,b=0 → 0`, `a=0,b=1 → 1`, `a=1,b=0 → 1`, `a=1,b=1 → 1`. That is `0 1 1 1` - row 7 - OR.

This sounds trivial here but is exactly how you debug a tangled condition: write down its truth table, read off the four bits, find the row, and you have the canonical name and the simplest spelling.

What you should remember from this chapter

- There are exactly sixteen binary truth functions; every boolean expression in any language computes one of them.
- Five of the sixteen have a dedicated Perl operator, and the two constants and two projections need none. The other seven are short compositions and the table above is the lookup.
- Implication `a → b` is `¬a ∨ b`. It shows up constantly under the surface of `unless` and `if` clauses.
- XOR and XNOR are negations of each other. The cleanest Perl spelling for both starts by canonicalising operands to `0` or `1`.

De Morgan's laws

Two identities, due to Augustus De Morgan, written for over a century in every textbook of formal logic, and the single most useful pair of equations a working programmer can know.

$$\neg(a \wedge b) \equiv \neg a \vee \neg b$$

$$\neg(a \vee b) \equiv \neg a \wedge \neg b$$

In words: pushing a `not` through a parenthesised expression flips every operator inside ($\wedge$ becomes $\vee$, $\vee$ becomes $\wedge$) and negates each operand. Equivalently: pulling a `not` out flips every operator and removes the negations on the operands.

Why this matters in Perl

`unless` is the canonical case. `unless (X)` is `if (!X)` - and the moment `X` is itself a compound, you have a leading `not` over a parenthesised expression: exactly the De Morgan setup.

```
unless ($a == $x && $b == $y) { ... }
```

The condition under the `unless` is `!($a == $x && $b == $y)`. Apply De Morgan: this is `!($a == $x) || !($b == $y)`. Each `!=` is the negation of the corresponding `==`, so the clean form is:

```
if ($a != $x || $b != $y) { ... }
```

Three transformations happened, each mechanical:

1. `unless` flipped to `if` (the outer `not`).
2. `&&` flipped to `||` (De Morgan, inside).
3. `==` flipped to `!=` on each operand (the negations De Morgan placed on the operands cancel into the opposite comparison).

This is *not* a stylistic preference. Every programmer who has debugged a wrong condition has stared at `unless (! ... && ...)` for a minute too long; the flat `if` reads in one pass.

A worked example

A real shape, slightly tangled:

```
unless ($x !~ /^\d+$/ && $y !~ /^[a-z]+$/) {
    print "at least one of \$x and \$y looks valid\n";
}
```

This says: *unless* `$x` is non-numeric and `$y` is non-alphabetic, print. Five negations stacked across two lines. Walk through it:

The condition under the `unless` is

```
!( $x !~ /^\d+$/  &&  $y !~ /^[a-z]+$/ )
```

De Morgan flips the `&&` to `||` and negates each side:

```
!($x !~ /^\d+$/)  ||  !($y !~ /^[a-z]+$/)
```

`!($x !~ ...)` is just `$x =~ ...` (double negation of a regex match). Same for the right side:

```
$x =~ /^\d+$/  ||  $y =~ /^[a-z]+$/
```

So the cleaned-up version is:

```
if ($x =~ /^\d+$/ || $y =~ /^[a-z]+$/) {
    print "at least one of \$x and \$y looks valid\n";
}
```

Five negations down to zero. The condition now reads exactly the way the comment said it: *if* `$x` *is numeric or* `$y` *is alphabetic.*

The same trick for OR

The second form of the law is the symmetric case:

```
unless ($a == 0 || $b == 0) { divide($a, $b) }
```

becomes

```
if ($a != 0 && $b != 0) { divide($a, $b) }
```

- same mechanical steps, only this time the inner operator is `||` flipping to `&&`.

NAND, NOR - same identity, read the other way

The NAND row in the truth table from the previous chapter has two entries in the "Perl idiomatic" column:

```
14   NAND    !($a && $b)    /    !$a || !$b
```

These are equal *because of De Morgan's first law*. NAND is exactly the negation of AND, and pushing the negation in flips the operator and negates the operands. The NOR row works the same way for the second law:

```
8    NOR     !($a || $b)    /    !$a && !$b
```

So De Morgan is not a separate fact you have to remember alongside NAND and NOR - it *is* the identity that turns one spelling into the other.

Mechanics, in one paragraph

Negation distributes over ∧ and ∨ by flipping the connective and negating each operand. Negation also self-cancels: ¬¬x ≡ x. The two rules together let you push a `not` arbitrarily deep, or pull it arbitrarily out, of any expression built from ∧, ∨, and ¬. That is the whole content of De Morgan's laws - every "convoluted unless" you ever rewrite is one application of those two rules plus double-negation cancellation.

Practical procedure

When you stare at a condition you don't like:

1. If the outer keyword is `unless`, prepend a `not` mentally and make it `if`.
2. If the leading `not` is over a parenthesised `&&` or `||`, distribute it: flip the connective, negate each operand.
3. If a subexpression is `!(x == y)`, replace with `x != y`. Same for `!~` ↔ `=~`, `!defined` ↔ `defined`, etc.
4. Stop when there are no more leading negations to push or no more double-negations to cancel.

In practice you will do all four steps in your head in a single pass. The point of the procedure is that there is one - you are not searching for the right form, you are deriving it.

What you should remember from this chapter

- Two identities: pushing ¬ through ∧ flips it to ∨ (and vice versa) and negates each operand.
- Most "ugly `unless`" is one mechanical De Morgan flip away from a clean `if`.
- NAND and NOR are not extra facts; they are De Morgan's laws read as a pair of equivalent spellings.

See also

- *perlop - Logical* - the operator-reference companion. The De Morgan transforms here apply to every Perl expression that uses `&&`, `||`, `!`, and the `unless` keyword.

Functional completeness

A set of boolean operators is *functionally complete* when every one of the sixteen binary truth functions can be built from operators in that set, by composition. The classical complete sets you already know are {∧, ∨, ¬} and {→, ⊥}. The surprising - and useful - result is that **a single operator suffices**, but only two of the sixteen binary functions have this property: NAND and NOR.

NAND is named after Henry M. Sheffer (1913) and written ↑; NOR is named after Charles Sanders Peirce (who described it earlier) and written ↓. They are the two *Sheffer strokes*.

Building everything from NAND

NAND alone gives you all sixteen functions. The constructions below show the four most useful - NOT, AND, OR, XOR - in terms of ↑. Think of `a ↑ b` as `!($a && $b)`.

Target	In terms of NAND	Why
¬a	`a ↑ a`	`!(a ∧ a)` is `!a`
a ∧ b	`(a ↑ b) ↑ (a ↑ b)`	NAND then negate the result, i.e. `!!(a ∧ b)` ≡ `a ∧ b`
a ∨ b	`(a ↑ a) ↑ (b ↑ b)`	De Morgan: `a ∨ b` ≡ `¬(¬a ∧ ¬b)` ≡ `¬a ↑ ¬b`
a ⊕ b	`(a ↑ (a ↑ b)) ↑ (b ↑ (a ↑ b))`	XOR is the AND of (a ∨ b) and ¬(a ∧ b) - left as exercise

The same constructions exist with NOR; they are the De Morgan duals.

In Perl

You will not write your code this way in production - `(a ↑ a) ↑ (b ↑ b)` is a worse spelling of OR than `||` is. But it is worth seeing the constructions actually run, because the abstract claim ("everything reduces to one operator") becomes concrete when you type it.

```
sub nand { !($_[0] && $_[1]) }       # the only primitive

sub not_a { nand($_[0], $_[0]) }                        # ¬a
sub and_  { my $n = nand($_[0], $_[1]); nand($n, $n) } # a ∧ b
sub or_   { nand(nand($_[0], $_[0]), nand($_[1], $_[1])) }   # a ∨ b
sub xor_  {
    my ($a, $b) = @_;
    my $n = nand($a, $b);
    nand(nand($a, $n), nand($b, $n));
}

# Verify across all four input combinations:
for my $a (0, 1) {
    for my $b (0, 1) {
        printf "a=%d b=%d  not=%d and=%d or=%d xor=%d\n",
            $a, $b,
            not_a($a)         ? 1 : 0,
            and_($a, $b)      ? 1 : 0,
            or_($a, $b)       ? 1 : 0,
            xor_($a, $b)      ? 1 : 0;
    }
}
```

Output:

```
a=0 b=0  not=1 and=0 or=0 xor=0
a=0 b=1  not=1 and=0 or=1 xor=1
a=1 b=0  not=0 and=0 or=1 xor=1
a=1 b=1  not=0 and=1 or=1 xor=0
```

Each row matches the truth table from the previous chapter.

Why this matters

Three things, in order of practical-to-deep:

1. **It explains the bestiary of identities.** NAND, NOR, and the eleven non-direct rows of the truth-table chapter are not a zoo of separate facts. They are all expressible from a single operator; the eleven non-direct spellings in Perl are just readable shortcuts for short NAND or NOR compositions.
2. **It is how silicon actually works.** Static-CMOS logic produces NAND and NOR more cheaply than AND and OR - a two-input AND gate is built as a NAND followed by an inverter. Every other gate on a chip is a composition of NANDs (or NORs). The pattern repeats in solver and constraint-engine internals: SAT solvers normalise to CNF precisely because OR-of-(literals) and AND-of-(clauses) is the minimal vocabulary they need.
3. **It teaches the discipline of canonical form.** Every boolean expression has many equivalent shapes, but only a few are *canonical*. CNF (conjunctive normal form: an AND of ORs of possibly-negated literals) and DNF (disjunctive normal form: an OR of ANDs) are the two most common. Reducing a tangle to CNF or DNF is a pure me-

chanical procedure based on De Morgan plus distributivity, and once your expression is in normal form you can compare it with another normal-form expression to test equivalence - without truth tables, without testing.

You will not implement a SAT solver next week. But the next time you find yourself writing `if ((!$a && $b) || (!$c && $b) || ($a && !$c))` and wondering whether the previous version was equivalent, you have a tool: distribute, factor, normalise. Two expressions that reduce to the same DNF compute the same function.

What you should remember from this chapter

- NAND and NOR are each individually sufficient to express every boolean function. No other two-input operator has this property.
- The constructions are short and you can verify them in Perl in ten lines.
- The point is not to write code in NAND, but to know that all sixteen binary functions live on one foundation. The apparently disparate rows of the truth-table chapter are one family.

Applications

The previous chapters were about boolean logic in the abstract. This one is about where it shows up most often in working Perl: bitwise arithmetic, regular expressions, and the short-circuit idioms that take the place of explicit conditionals.

Bitwise: logic on integer bits

The bitwise operators apply boolean operations to each pair of bits in two integers in parallel. A 32-bit integer is, from the operators' point of view, thirty-two parallel one-bit values.

Op	Reads as	Per-bit rule
&	bitwise AND	each output bit = a∧b
|	bitwise OR	each output bit = a∨b
^	bitwise XOR	each output bit = a ⊕ b
~	bitwise NOT	each output bit = ¬a
<<	left shift	shift bits left, zero-fill from right
>>	right shift	shift bits right

The same boolean operators - ∧, ∨, ⊕, ¬ - appear here in purely numeric form. That is not a coincidence; it is the definition.

Setting, clearing, toggling, testing a flag

The four basic flag operations on a single bit:

```
use constant FLAG_VERBOSE  => 0x01;
use constant FLAG_DRY_RUN  => 0x02;
use constant FLAG_RECURSE  => 0x04;
```

(continues on next page)

(continued from previous page)

```
use constant FLAG_FORCE    => 0x08;

my $flags = 0;

$flags |=  FLAG_VERBOSE;       # SET    -- OR with the bit
$flags |=  FLAG_DRY_RUN;       # SET another
$flags &= ~FLAG_DRY_RUN;       # CLEAR  -- AND with the inverted bit
$flags ^=  FLAG_VERBOSE;       # TOGGLE -- XOR with the bit
my $on = $flags & FLAG_RECURSE;# TEST   -- AND, then test truthiness
```

Each of these is a one-bit application of a boolean operator. Set is `bit ∨ flag`, clear is `bit ∧ ¬flag`, toggle is `bit ⊕ flag`, test is `bit ∧ flag`.

XOR-swap: swapping without a temporary

XOR has two properties that combine into a memorable trick: `a ⊕ a = 0`, and `a ⊕ b ⊕ b = a`. Apply them in sequence and you can swap two integers without a third variable:

```
my ($a, $b) = (0xFEED, 0xBEEF);

$a ^= $b;      # a := a ⊕ b
$b ^= $a;      # b := b ⊕ (a ⊕ b) = a
$a ^= $b;      # a := (a ⊕ b) ⊕ a  = b

print "a=$a b=$b\n";   # a=48879 b=65261  (0xBEEF, 0xFEED)
```

The trick is not actually useful in Perl - `($a, $b) = ($b, $a)` is faster, clearer, and works on any scalar including strings and references. But it shows up in two places that matter:

- **Embedded code without a free register.** A microcontroller with three values to juggle in two registers reaches for this.
- **Interview folklore.** Knowing it exists and *why* it works (XOR is its own inverse) is worth the thirty seconds it takes to read.

The reason it works is exactly the boolean identity from the truth-table chapter: `x ⊕ y ⊕ y = x`. Each of the three lines above is one application of that identity.

Common bit tricks

A handful of patterns you will see in performance-sensitive code:

```
$x &  ($x - 1)          # $x with its lowest set bit cleared
($x & ($x - 1)) == 0    # true when $x is a power of two (and non-
↪zero)
$x | -$x                # signed: zero iff $x was zero, non-zero␣
↪otherwise
($x >> 31) & 1          # the sign bit, on a 32-bit signed integer
```

(continues on next page)

(continued from previous page)

```
1 << $n                 # the integer with only bit $n set
$x & (1 << $n)          # is bit $n set in $x?
```

Each of these is an exercise in tracking what the bits do - pure boolean reasoning applied 32 (or 64) times in parallel.

Regular expressions: logic on sets of strings

A regex matches a *set* of strings. The empty set, the singleton `{"foo"}`, the infinite set "anything that begins with a digit" - all are sets, and the regex denotes one of them.

Once you see a regex as a set, the boolean operations have geometric meaning:

Boolean operation	On sets	In regex syntax
OR (∨)	union	alternation: `foo|bar`
AND (∧)	intersection	lookahead pair: `(?=.{4})(?=\d+$)`
NOT (¬)	complement	negative lookahead: `(?!foo)`
AND-NOT (a ∧ ¬b)	difference	`(?=A)(?!B)A`

Two specifics worth pulling out.

Alternation is OR over sets

```
$s =~ /yes|no|maybe/;
```

Matches the union of three singleton sets. There is nothing more to it; `|` in regex syntax is precisely the boolean ∨.

Inside a character class the meaning is the same:

```
$s =~ /[abc]/;          # union of {"a"}, {"b"}, {"c"}
$s =~ /[^abc]/;         # complement: anything NOT in {"a","b","c"}
```

`[^...]` is the regex syntax for ¬ applied to a character set.

Lookarounds are AND and NOT

A regex without lookaround consumes characters as it matches; the two ends of an alternation `A|B` cannot both match the same span (only one branch wins). To express *both* `A` *and* `B` at the same position, you need lookaround: a zero-width assertion that demands a property without consuming.

```
# matches only if the rest of the string is BOTH digits AND ≤ 4␣
↪chars
$s =~ /^(?=\d+$)(?=.{1,4}$)/;
#       \_____/\_______/
#         A         B          intersection: A ∧ B
```

`(?=...)` is positive lookahead; `(?!...)` is negative lookahead (the boolean NOT). Combining them gives you the full set algebra on regex predicates:

```
# "starts with a digit but is not the literal '0'":
# (digit) ∧ ¬(literal "0")
$s =~ /^(?=\d)(?!0$)/;
```

Why the framing helps

Once you read regex this way, the readability of complicated patterns improves dramatically. A regex with two lookaheads is not "two regexes glued together" - it is the intersection of two sets. A negative lookahead followed by a positive match is not "first reject, then match" - it is set difference. The boolean algebra you already know is the algebra of regexes; only the notation changes.

Control flow: short-circuit logic as conditional execution

The chapter on operators introduced the operand-return rule for `&&`, `||`, and `//`. That rule, plus precedence, generates a small family of idioms that replace explicit `if`/`else` for short conditional logic:

```
# defaulting
my $port = $cfg{port} // 8080;

# guard with side-effect
open my $fh, '<', $path  or die "open $path: $!";

# lazy initialisation (set if currently false)
$cache{$key} ||= compute($key);

# lazy initialisation (set if currently undef - a real `0` is kept)
$cfg{retries} //= 3;

# guard chain: do step 2 only if step 1 succeeded
my $rc = step_one() && step_two();

# logical selection inside an expression
my $label = $count == 1 ? "1 item" : "$count items";
```

Each of these is a boolean expression chosen for its *side-effects* - the short-circuit decides whether the right operand even runs. `open ... or die` works exactly because `or` does not evaluate its right side when the left is true.

Two pieces of advice.

Use `//` and `//=` when `0` or `""` is a valid value. This single change has prevented more bugs than any other modern Perl idiom; `||` defaulting on a configured zero is one of the classic ways to lose data.

Reach for `?:` when you would otherwise build an `if`/`else`/scalar-assign triplet. The ternary keeps the expression as an expression and the assignment in one line:

```
# verbose
my $kind;
if ($n == 1) { $kind = 'singular' }
else         { $kind = 'plural'   }

# idiomatic
my $kind = $n == 1 ? 'singular' : 'plural';
```

Don't nest `?:` more than two levels deep. Past two, the chained form is harder to read than the `if`/`elsif`/`else`. The ternary is for *choosing*; sequential decisions belong in a block.

What you should remember from this chapter

- Bitwise `&`, `|`, `^`, `~` are the boolean operators applied bit-by-bit in parallel; flag set/clear/toggle/test are the four one-bit applications.
- A regex denotes a set of strings; `|` is union, `[^...]` is complement, `(?=)` and `(?!)` make intersection and difference.
- `&&`, `||`, `//`, `?:` give you most of conditional control flow without writing `if`. Use `//` when `0` is real; use `?:` for short selection inside an expression.

What you will be able to do after reading

- Look at any boolean expression in Perl source and name the truth function it computes.
- Convert between the four equivalent shapes of an implication (`a → b`, `!a || b`, `!(a && !b)`, the contrapositive) without having to think.
- Reduce an `unless` with two negated subclauses to a flat `if` in one mechanical step.
- Recognise when a regex alternation is a logical OR over sets and when a lookaround pair is a logical AND, and use that framing to read complicated regexes.
- Use the bitwise operators to set, clear, toggle and test individual flags without consulting a reference.
- Pick the right short-circuit idiom (`||`, `//`, `||=`, `//=`, `or die`) for the situation, knowing why each one works.

4.2.17 Interprocess communication - a tutorial

Two programs that need to talk have a handful of channels to choose from: a pipe, a named FIFO on disk, a socket over the network, a socket pair in memory, or a slab of System V shared memory. This tutorial is a cookbook. Each page hands you a complete, runnable program - a producer and a consumer, or a client and a server - that you can copy, run, and adapt.

The mechanics of each channel - what `socket` returns, how `fork` splits a process, what `%SIG` does - are already documented in the per-built-in reference and the signals chapter. This tutorial does not restate them. It assembles them into working IPC programs and links each call back to its reference page.

PetaPerl runs only on Linux, so everything here is POSIX. There is no Win32 IPC, no named-pipe-on-Windows alternative, no `Win32::Process`. The recipes use the system calls a Linux kernel actually provides.

Choosing a channel

Pick the lightest channel that carries what you need:

- **A child running a command** - you want the output of `sort` or the input of `gzip`. Use a *pipe open*, or `IPC::Open2` / `IPC::Open3` when you need both directions. See *Subprocesses and co-processes*.
- **Two related processes, one machine** - a parent and a child it just forked, sharing a byte stream. Use `pipe` or `socketpair`. See *Subprocesses* and *UNIX-domain and UDP sockets*.
- **Unrelated processes, one machine** - two programs started independently that rendezvous on a known path. Use a *FIFO* or a UNIX-domain socket. See *FIFOs* and *UNIX-domain and UDP sockets*.
- **Processes on different machines** - a network client and server. Use a TCP socket. See *TCP sockets*.
- **A datagram, fire-and-forget** - no connection, message boundaries preserved. Use a UDP socket. See *UNIX-domain and UDP sockets*.
- **A shared counter or buffer with no copying** - System V semaphores and shared memory. Use `semget` and `shmget`. See *System V IPC*.

How this tutorial is organised

Each page stands on its own. Read the one that answers your question.

Subprocesses and co-processes

The most common IPC task is the simplest: run an external command and talk to it. This page covers the spectrum, from a one-way pipe open to a two-way co-process - a child you both write to and read from.

The mechanics of a one-direction pipe open (`"-|"` and `"|-"`) are covered in full on the *Pipes* page. This page picks up where that one stops: when one direction is not enough, and when you need a raw `pipe` and `fork` of your own.

One direction: the pipe open

To read a command's output, or to feed a command its input, a pipe open is all you need:

```
open my $fh, "-|", "sort", "-u", "names.txt" or die "pipe: $!";
while (my $line = <$fh>) { ... }
close $fh;
```

That is the whole story for one-way work, and it is told on the *Pipes* page - including the list-versus-string form, why list form sidesteps the shell, and how to decode the child's exit status. Start there if one direction is enough.

Both directions: `IPC::Open2`

When you need to write to a command *and* read its reply - a filter you drive interactively, a co-process - one pipe is not enough. `IPC::Open2` opens two: one into the child's `stdin`, one out of its `stdout`.

```
use IPC::Open2;

my $pid = open2(my $from_child, my $to_child, "tr", "a-z", "A-Z");

print $to_child "hello\n";
close $to_child;                    # signal end-of-input to the
 ↪child

my $reply = <$from_child>;
print "got: $reply";                # got: HELLO

waitpid($pid, 0);
```

open2 returns the child's process id. The argument order is the trap worth memorising: **reader handle first, writer handle second**, then the command. `open2(OUT, IN, ...)` - the handle you read *from* comes before the handle you write *to*.

The deadlock you must design around

A co-process can deadlock, and `IPC::Open2` does nothing to prevent it. The shape of the trap:

- You write a large block to the child.
- The child reads some, produces output, and that output fills the pipe back to you.
- The child blocks writing to a full pipe; you block writing to a child that has stopped reading. Neither moves.

The recipe above sidesteps it by closing `$to_child` before reading - sending the whole input, then signalling end-of-file, then draining the reply. That works when the input fits comfortably in the pipe buffer. For unbounded streaming in both directions at once, you need non-blocking I/O or a `select` loop; the two-pipe shape alone is not enough.

Capturing standard error too: IPC::Open3

`IPC::Open2` joins you to `stdin` and `stdout`. When you also need the child's `stderr` on its own handle, `IPC::Open3` adds a third:

```
use IPC::Open3;
use Symbol qw(gensym);

my $err = gensym;                    # a fresh anonymous handle for␣
↪stderr
my $pid = open3(my $to_child, my $from_child, $err, "sort");

print $to_child "banana\napple\ncherry\n";
close $to_child;

my @sorted = <$from_child>;          # ("apple\n", "banana\n",
↪"cherry\n")
print @sorted;                       # apple / banana / cherry, one␣
↪per line

waitpid($pid, 0);
```

Two differences from open2 to note:

- **The argument order flips.** open3 takes the writer handle first, then the reader, then the error handle: `open3(IN, OUT, ERR, ...)`. This is the opposite of open2's reader-first order - a long-standing inconsistency that bites everyone once.
- **The error handle needs gensym.** Pass a fresh anonymous handle from `Symbol::gensym` for `stderr`; a bareword or an undefined lexical will not collect it cleanly.

Rolling your own: pipe and fork

When the command is not an external program but Perl code you want to run in a separate process, build the channel yourself. A raw `pipe` gives a connected reader/writer pair before the fork; after `fork` each side keeps the end it needs and closes the other:

```
pipe(my $reader, my $writer) or die "pipe: $!";

my $kid = fork() // die "fork: $!";

if ($kid == 0) {
    # Child writes, then exits.
    close $reader;                   # child has no use for the read␣
↪end
    $writer->autoflush(1);
    print $writer "down-the-pipe\n";
    close $writer;
    exit 0;
}
```

(continues on next page)

(continued from previous page)

```
# Parent reads.
close $writer;                          # parent has no use for the␣
 ↪write end
my $line = <$reader>;
print "parent read: $line";             # parent read: down-the-pipe
close $reader;

waitpid($kid, 0);
```

The discipline is the same as the forking server on the *TCP sockets* page: **each side closes the end it does not use.** If the parent keeps the write end open, the child's `close` never produces an end-of-file on the read end, and the parent's read blocks forever.

Explicit `fork()` creates a separate operating-system process; PetaPerl's auto-parallelism is an in-process thread pool. A forked child runs its own auto-parallel numeric reductions normally within itself, and the parent's and child's parallelism do not interfere - they are independent processes with independent thread pools. For running work across CPU cores *inside* one process rather than across separate processes, see the *Concurrent Execution* guide.

Reference cross-links

- `open` - the one-way pipe open (" - | ", " | - ")
- `pipe` - a raw connected handle pair
- `fork` - split into two processes
- `waitpid` - reap the child and recover its status
- `exec` - replace the child image with a command

Next

For two unrelated programs that meet on a filesystem path rather than through a shared parent, see *FIFOs*.

FIFOs

A FIFO - a *named pipe* - is a pipe with a name on the filesystem. Two programs that share no parent, started independently from different shells, can still talk: one opens the path for writing, the other opens it for reading, and bytes flow between them exactly as through an anonymous `pipe`. The path is a rendezvous point; no data is ever stored in the file itself.

This is the channel to reach for when the processes are *unrelated* - when a plain `pipe` is impossible because there was never a common `fork` to inherit the descriptor from.

Creating the FIFO

A FIFO is created once, as a special file, with `POSIX::mkfifo`. After that it is opened like any other path:

```
use POSIX qw(mkfifo);

my $path = "/tmp/demo.fifo";
mkfifo($path, 0600) or die "mkfifo $path: $!";
```

The second argument is the permission mode, the same `0600` / `0644` you would pass to `chmod` - it decides who may open the FIFO. The call fails if the path already exists, so a long-running setup typically `unlink`s a stale FIFO first.

Producer and consumer

The defining behaviour of a FIFO is that **open blocks until both ends are present**. A reader opening the path waits until some writer opens it too, and vice versa. That rendezvous is the feature: it synchronises two programs that never agreed on timing.

This single program demonstrates both ends by forking, but the two halves would work just as well as two separate scripts run from two terminals:

```
use POSIX qw(mkfifo);

my $path = "/tmp/demo.fifo";
unlink $path;                          # clear any stale FIFO
mkfifo($path, 0600) or die "mkfifo $path: $!";

my $kid = fork() // die "fork: $!";

if ($kid == 0) {
    # Producer: open for writing (blocks until a reader appears).
    open my $w, ">", $path or die "producer open: $!";
    $w->autoflush(1);
    print $w "from-producer\n";
    close $w;
    exit 0;
}

# Consumer: open for reading (blocks until a writer appears).
open my $r, "<", $path or die "consumer open: $!";
my $line = <$r>;
print "consumer read: $line";          # consumer read: from-producer
close $r;

waitpid($kid, 0);
unlink $path;                          # remove the FIFO when finished
```

The two open calls are the synchronisation. Whichever process reaches its open first parks there until the other arrives; then both proceed together. Once open, the read and write handles behave like the two ends of any pipe - line reads, `readline`, buffered

`print`, all unchanged.

Two practical notes:

- **Autoflush on the writer.** As with every pipe and socket, a buffered write may never reach the reader until the buffer fills or the handle closes. Set `autoflush(1)` if the reader expects each line as it is produced.
- **A FIFO persists on disk.** `mkfifo` leaves a special file behind that outlives both processes. Remove it with `unlink` when the conversation is over, the same way you would clean up a lock file.

Reference cross-links

- `open` - open the FIFO path for reading or writing
- `pipe` - the anonymous-pipe relative for related processes
- `unlink` - remove the FIFO when finished
- `readline` - the function behind `<$fh>`

Next

When two processes need a connection rather than a one-way path - request and reply, both directions at once - reach for a socket. See *UNIX-domain and UDP sockets* and *TCP sockets*.

TCP sockets

A TCP socket carries a reliable, ordered byte stream between two processes that may be on different machines. This page builds the two halves of a TCP conversation from the raw built-ins: a **client** that connects and exchanges a line, and a **forking server** that accepts connections and handles each in its own child.

Every recipe here uses the built-in `socket` layer directly, with address helpers from the `Socket` module, rather than the high-level convenience module `IO::Socket::INET`. That is no loss: the built-in form is what `IO::Socket::INET` wraps, and seeing it in the open makes the handshake legible.

The address helpers

A socket address is a packed C `struct sockaddr_in`. The `Socket` module builds and takes apart that structure for you:

```
use Socket;
my $packed = sockaddr_in($port, $ip);     # build
my ($port, $ip) = sockaddr_in($packed);   # take apart
```

`$ip` is itself a packed four-byte address. `inet_aton` turns a dotted-quad string into one; `inet_ntoa` turns it back. The constant `INADDR_LOOPBACK` is the packed form of `127.0.0.1`, and `INADDR_ANY` means “every local interface”.

```
use Socket;
my $ip = inet_aton("127.0.0.1");
print inet_ntoa($ip), "\n";          # 127.0.0.1
```

A TCP client

The client creates a socket, connects it to a server address, and then reads and writes the handle like any other stream.

```
use Socket;

my $host = "127.0.0.1";
my $port = 8080;

socket(my $sock, PF_INET, SOCK_STREAM, getprotobyname("tcp"))
    or die "socket: $!";

my $addr = sockaddr_in($port, inet_aton($host));
connect($sock, $addr) or die "connect: $!";

$sock->autoflush(1);                 # send each line as it is
 ↪printed

print $sock "ping\n";
my $reply = <$sock>;
print "server said: $reply";         # server said: pong: ping

close $sock;
```

The one line that catches everyone is `$sock->autoflush(1)`. Without it, `print $sock "ping\n"` sits in Perl's output buffer, the server never sees it, and both sides block forever waiting on each other. On any socket where you write a request and then read a reply, set autoflush before the first write.

A forking server

A server binds to a port, listens, and then loops accepting connections. The classic structure handles each client in a forked child so one slow client cannot stall the next:

```
use Socket;
use POSIX qw(WNOHANG);               # for the non-blocking reaper

my $port    = 8080;
my $backlog = 128;                   # pending-connection queue
 ↪depth

socket(my $server, PF_INET, SOCK_STREAM, getprotobyname("tcp"))
    or die "socket: $!";

# Let the address be reused immediately after a restart.
```

(continues on next page)

(continued from previous page)

```
setsockopt($server, SOL_SOCKET, SO_REUSEADDR, 1)
    or die "setsockopt: $!";

bind($server, sockaddr_in($port, INADDR_ANY)) or die "bind: $!";
listen($server, $backlog)                     or die "listen: $!";

# Reap finished children so they do not become zombies.
$SIG{CHLD} = sub { 1 while waitpid(-1, WNOHANG) > 0 };

print "listening on port $port\n";

while (accept(my $client, $server)) {
    my $pid = fork();
    die "fork: $!" unless defined $pid;

    if ($pid == 0) {
        # Child: serve this one connection, then exit.
        close $server;              # child does not need the
↪listener
        $client->autoflush(1);

        while (my $line = <$client>) {
            print $client "pong: $line";
        }
        close $client;
        exit 0;
    }

    # Parent: hand the connection to the child and move on.
    close $client;                  # parent does not need this
↪client
}
```

Three details make this server correct rather than merely working:

- **`SO_REUSEADDR` before `bind`.** After a server exits, the kernel keeps the port in `TIME_WAIT` for a while. Without this option a restart fails with "Address already in use". Set it and the restart binds immediately.
- **The `$SIG{CHLD}` reaper.** Every forked child becomes a zombie when it exits until the parent calls `waitpid`. The handler reaps all finished children non-blockingly with `WNOHANG`, so the accept loop never pauses to wait.
- **Both sides close the descriptor they do not use.** The child closes the listening socket; the parent closes the accepted client socket. If either skips its `close`, the underlying file descriptor stays open in the wrong process and the connection never sees EOF.

Running both halves together

For a self-contained demonstration, fork the server into the background and run the client in the parent. The server binds to an ephemeral port (port `0`) and reports the port the kernel assigned:

```
use Socket;

# --- server child on an ephemeral port ---
socket(my $server, PF_INET, SOCK_STREAM, getprotobyname("tcp"))
    or die "socket: $!";
setsockopt($server, SOL_SOCKET, SO_REUSEADDR, 1) or die "setsockopt:
 ↪$!";
bind($server, sockaddr_in(0, INADDR_LOOPBACK))   or die "bind: $!";
listen($server, 128)                             or die "listen: $!
 ↪";
my ($port) = sockaddr_in(getsockname($server));

my $kid = fork() // die "fork: $!";
if ($kid == 0) {
    accept(my $client, $server) or die "accept: $!";
    $client->autoflush(1);
    my $line = <$client>;
    print $client "pong: $line";
    close $client;
    exit 0;
}

# --- client in the parent ---
socket(my $sock, PF_INET, SOCK_STREAM, getprotobyname("tcp")) or
 ↪die;
connect($sock, sockaddr_in($port, INADDR_LOOPBACK)) or die "connect:
 ↪$!";
$sock->autoflush(1);
print $sock "ping\n";
print "client got: ", scalar <$sock>;    # client got: pong: ping
close $sock;

waitpid($kid, 0);
```

`getsockname($server)` reports the local address the socket is bound to. Unpacking it with `sockaddr_in` recovers the port the kernel chose, which the client then connects to - the standard way to write a test that does not hard-code a port.

Reference cross-links

Each call has a per-built-in reference page with the full argument shape and return value:

- `socket` - create the endpoint
- `bind` - attach it to a local address

- `listen` - mark it as accepting connections
- `accept` - take the next pending connection
- `connect` - reach out to a server
- `setsockopt` - set `SO_REUSEADDR` and friends
- `getsockname` - discover the bound port
- `fork` and `waitpid` - spawn and reap the per-client child
- `%SIG` - the `CHLD` reaper handler

Next

For local-only stream sockets without the network stack, and for connectionless datagrams, see *UNIX-domain and UDP sockets*.

UNIX-domain and UDP sockets

Not every socket reaches across a network. This page covers two lighter-weight relatives of the TCP socket from the *previous page*: a **UNIX-domain socket pair** for two related processes on one machine, and a **UDP socket** for connectionless datagrams.

Both use the same `socket` family of built-ins and the same `Socket` address helpers. The recipes stay at that built-in layer, which is what the high-level `IO::Socket::*` wrappers are built on.

A socket pair for parent and child

`socketpair` creates two connected sockets in one call, with no addresses, no `bind`, and no `connect`. It is the ideal channel between a parent and a child it is about to fork: full-duplex (both ends can read and write), local, and already connected the moment it returns.

```
use Socket;

socketpair(my $child_end, my $parent_end, AF_UNIX, SOCK_STREAM, PF_
↪UNSPEC)
    or die "socketpair: $!";

my $kid = fork() // die "fork: $!";

if ($kid == 0) {
    # Child keeps its end, closes the parent's.
    close $parent_end;
    $child_end->autoflush(1);

    print $child_end "child-says-hi\n";
    my $back = <$child_end>;
    print "child got: $back";        # child got: ack
    exit 0;
}
```

(continues on next page)

(continued from previous page)

```
# Parent keeps its end, closes the child's.
close $child_end;
$parent_end->autoflush(1);

my $msg = <$parent_end>;
print "parent got: $msg";            # parent got: child-says-hi
print $parent_end "ack\n";

waitpid($kid, 0);
```

Why reach for `socketpair` over a plain `pipe`? A pipe is one-directional - the reader reads, the writer writes, and that is fixed at creation. A socket pair is bidirectional: each end both reads and writes, so a request-and-reply exchange needs one `socketpair` call instead of two pipes wired in opposite directions.

The autoflush rule from TCP applies unchanged: set it on each end before the first write, or a buffered request never reaches the other side and both processes block.

A UDP datagram exchange

UDP is connectionless. There is no `connect`, no `accept`, no stream - just discrete messages, each addressed to a destination and each preserving its own boundaries. A receiver binds to a port; a sender fires a datagram at it with `send`; the receiver collects it with `recv`, which also reports who sent it.

```
use Socket;

# --- receiver on an ephemeral port ---
socket(my $server, PF_INET, SOCK_DGRAM, getprotobyname("udp"))
    or die "socket: $!";
bind($server, sockaddr_in(0, INADDR_LOOPBACK)) or die "bind: $!";
my ($port) = sockaddr_in(getsockname($server));

my $kid = fork() // die "fork: $!";
if ($kid == 0) {
    # Sender fires one datagram at the receiver's port.
    socket(my $client, PF_INET, SOCK_DGRAM, getprotobyname("udp"))␣
 ↪or die;
    my $to = sockaddr_in($port, INADDR_LOOPBACK);
    send($client, "hello-udp", 0, $to) or die "send: $!";
    exit 0;
}

# recv fills $buf and returns the sender's packed address.
my $from = recv($server, my $buf, 65535, 0);
my ($sender_port, $sender_ip) = sockaddr_in($from);
print "got '$buf' from ", inet_ntoa($sender_ip), "\n";
                                    # got 'hello-udp' from 127.0.0.
 ↪1
```

(continues on next page)

(continued from previous page)

```
waitpid($kid, 0);
```

What UDP gives you and what it does not:

- **Message boundaries are preserved.** One `send` is one `recv`. A `recv` returns exactly one datagram, never two concatenated and never half of one. The `65535` is the maximum length you are willing to accept; a shorter datagram returns its real length.
- **There is no `connect` and no handshake.** The sender does not open a connection; it addresses each datagram with `send`'s fourth argument. `recv` reports the sender's address so a reply can go back the same way.
- **Delivery is not guaranteed.** UDP datagrams can be dropped, duplicated, or reordered by the network. Over the loopback interface, as in this recipe, that effectively never happens; over a real network you must handle loss yourself if it matters.

Reference cross-links

- `socketpair` - two connected local sockets
- `socket` - create a datagram or stream endpoint
- `bind` - attach the receiver to a local port
- `send` - fire a datagram at an address
- `recv` - collect a datagram and its sender
- `getsockname` - discover the bound port

Next

For shared memory and semaphores - channels the kernel owns rather than streams between processes - see *System V IPC*.

System V IPC

System V IPC gives two unrelated processes a shared resource the kernel owns: a **semaphore set** for coordination, or a **shared memory segment** for passing bytes with no copying through a pipe. Each resource is identified by an integer key and survives until a process explicitly removes it.

The recipes here use the raw `semget` / `shmget` built-in family with the flag values written as plain numbers, rather than the convenience modules `IPC::SysV`, `IPC::Semaphore` and `IPC::SharedMem`. Those built-ins are the layer the modules wrap; using them directly costs only a few named constants you supply yourself.

The flag constants you need

A handful of small integers control how these calls behave. They are the standard Linux values:

```
use constant {
    IPC_PRIVATE => 0,        # "give me a fresh, private key"
    IPC_CREAT   => 0o1000,   # create the resource if absent
    IPC_EXCL    => 0o2000,   # fail if it already exists
    IPC_RMID    => 0,        # control command: remove the resource
};
```

The low nine bits of the flag word are ordinary permission bits, the same `0600` / `0644` you would pass to `chmod`. `IPC_CREAT | 0600` means "create it, owner read/write".

A shared-memory hand-off

Shared memory is the fastest channel: one process writes bytes into a segment, another reads them straight out, with no kernel copy in between. This program creates a segment, writes a payload, forks, and the child reads the same bytes back:

```
use constant {
    IPC_PRIVATE => 0,
    IPC_CREAT   => 0o1000,
    IPC_RMID    => 0,
};

my $size = 1024;

my $id = shmget(IPC_PRIVATE, $size, IPC_CREAT | 0600);
defined $id or die "shmget: $!";

my $payload = "shared-payload";
shmwrite($id, $payload, 0, length $payload) or die "shmwrite: $!";

my $kid = fork() // die "fork: $!";
if ($kid == 0) {
    # Child reads the same segment the parent wrote.
    shmread($id, my $buf, 0, length $payload) or die "shmread: $!";
    print "child read: $buf\n";          # child read: shared-
↪payload
    exit 0;
}

waitpid($kid, 0);

# The segment outlives the processes - remove it explicitly.
shmctl($id, IPC_RMID, 0) or warn "shmctl: $!";
```

Two points decide whether this code leaks:

- **`shmread` / `shmwrite` take an explicit length.** They do not stop at a NUL or a new-

line; you tell them exactly how many bytes to move, starting at an offset. Pass `length $payload` so reader and writer agree on the size.

- **`IPC_RMID` is not automatic.** A shared segment persists in the kernel after every process attached to it has exited. You can see orphaned segments with `ipcs -m` at the shell. Always pair a `shmget` with a matching `shmctl IPC_RMID`.

A semaphore for coordination

A semaphore set is a small array of counters the kernel guards. The classic use is a lock: a process decrements the counter to enter a critical section and increments it to leave. This recipe creates a one-element set, initialises it, and removes it:

```
use constant {
    IPC_PRIVATE => 0,
    IPC_CREAT   => 0o1000,
    IPC_RMID    => 0,
    SETVAL      => 16,       # semctl command: set one value
    GETVAL      => 12,       # semctl command: read one value
};

# A set with one semaphore.
my $sem = semget(IPC_PRIVATE, 1, IPC_CREAT | 0600);
defined $sem or die "semget: $!";

# Initialise semaphore 0 to the value 1 (one token available).
semctl($sem, 0, SETVAL, 1) or die "semctl SETVAL: $!";

my $value = semctl($sem, 0, GETVAL, 0);
print "semaphore value: $value\n";       # semaphore value: 1

# Remove the set when finished.
semctl($sem, 0, IPC_RMID, 0) or warn "semctl IPC_RMID: $!";
```

The wait/signal operations themselves go through `semop`, which takes a packed string of `(sem_num, sem_op, sem_flg)` triples built with `pack`. Decrementing by one waits until a token is free; incrementing by one releases it. As with shared memory, a semaphore set the kernel owns must be removed with `IPC_RMID` or it lingers - visible under `ipcs -s`.

Reference cross-links

- `shmget` - create or open a shared segment
- `shmread` / `shmwrite` - move bytes in and out
- `shmctl` - control, including `IPC_RMID`
- `semget` - create or open a semaphore set
- `semop` - the wait/signal operations
- `semctl` - set, read, and remove
- `pack` - build the `semop` operation string

Next

Shared memory and semaphores are the heavyweight channels. For the lighter, stream-oriented ones, see *Subprocesses and co-processes* and *TCP sockets*.

- **Subprocesses and co-processes** - running a command and talking to it, in one or both directions, with the pipe open and with `IPC::Open2` / `IPC::Open3`.
- **FIFOs** - a named pipe on the filesystem that lets two unrelated programs meet on a path.
- **TCP sockets** - a complete client and a forking echo server over the loopback interface.
- **UNIX-domain and UDP sockets** - local stream sockets via `socketpair`, and connectionless UDP datagrams.
- **System V IPC** - semaphores and shared memory with the raw `semget` / `shmget` built-ins.

What this tutorial does not cover

- **Signals as a coordination mechanism beyond the basics.** Sending a signal with `kill` and catching it through `%SIG` is covered where each recipe needs it; the full signal-disposition table lives in the `%SIG` reference.
- **In-process parallelism.** Running work across CPU cores inside a single program is auto-parallelization, a different subject. See the *Concurrent Execution* guide.
- **High-level networking modules.** This tutorial stays at the built-in `socket` layer so the mechanics are visible. The recipes are the foundation a higher-level wrapper would build on.

4.2.18 Installing CPAN modules - a tutorial

Sooner or later a pperl program needs something from CPAN. This tutorial covers how to get it, where it lands, how pperl finds it afterwards, and what to do when a distribution refuses to install.

You are assumed to have installed Perl modules before, with `cpan`, `cpanm`, or your distribution's package manager. What follows is what changes when the interpreter is pperl rather than perl5.

The one idea

pperl runs **no XS**. Not "XS is discouraged", not "XS is slower" - a compiled extension cannot be loaded at all, because pperl is a Rust reimplementation of Perl 5 and does not have perl5's C-level ABI to bind against.

Two consequences follow, and everything else in this tutorial is a detail of one of them.

Pure Perl installs; XS does not. A distribution written in Perl works exactly as it does anywhere else. A distribution that needs to compile C does not, and no amount of configuration will change that.

pperl has to introduce itself to the installer. Several hundred modules are built into the pperl binary and have no `.pm` file on disk. An installer decides "do I already have

this?" by looking for that file, so without help it reads some *other* perl's inventory and draws the wrong conclusion in both directions - rebuilding modules pperl already has, and believing it has ones it does not.

`pperl --cpan` exists to arrange both. It is not a new installer: it runs the CPAN client that ships with Perl, the one behind the `cpan` command, with the environment set up so the answers come out right.

```
pperl --cpan Text::CSV
```

What you will need

Nothing besides pperl for the installer itself. The CPAN client is part of Perl's core library, so it is built into the pperl binary and pperl runs it directly - inside that run, `$^X` is pperl and not a host perl. No perl5 has to be installed on the machine.

What a distribution's own build needs is still needed: `make` for nearly all of them, and `git` if you install from a repository.

The client keeps its downloads, its build directories and its configuration under `~/.pperl/cpan`. A `~/.cpan` that belongs to a host perl is neither read nor changed.

Chapters

Installing, and finding what you installed

The command

Everything after `--cpan` goes to the CPAN client, so any option of the `cpan` command you already know still works: `-T` to skip the tests, `-f` to force an install.

```
pperl --cpan Text::CSV
pperl --cpan Plack Starman
pperl --cpan -T Try::Tiny
```

Besides module names, `--cpan` takes a git repository: a URL that starts with `git:` or ends in `.git`. It is cloned and installed from the clone. Append `@` and a branch, tag or commit to install that revision.

```
pperl --cpan https://github.com/example/Some-Dist.git
pperl --cpan https://github.com/example/Some-Dist.git@v1.2
```

With nothing to install, it says so rather than guessing:

```
pperl --cpan
# pperl: --cpan: nothing to install: pperl --cpan Module::Name [...]
```

Where it goes

Modules land in a pperl-owned tree, never in a perl5 one. The base is `$PPERL_HOME`, or `~/.pperl` if that is unset:

```
~/.pperl/
├── lib/perl5/          <- the modules
└── cpan/               <- the installer's downloads and builds
```

`--cpan --system` installs for every account on the machine instead, under `/usr/local/share/pperl`:

```
/usr/local/share/pperl/
├── site_perl/          <- the modules
├── bin/                <- their scripts
├── man/                <- their manuals
└── cpan/               <- the installer's downloads and builds
```

Every pperl searches `site_perl` there without being told. Writing there takes root's rights, or an account that may write `/usr/local/share/pperl`, so run it as `sudo pperl --cpan --system Some::Module`. Without those rights it stops before it downloads anything and says so.

Keeping the tree separate is deliberate. A machine commonly has both pperl and a real perl5, and a module built for one has no business being found by the other.

Making pperl see it

pperl searches its own tree without being told: `lib/perl5` under `$PPERL_HOME`, or under `~/.pperl` if that is unset, comes ahead of every system tree. A module installed with `pperl --cpan` is found by the next `pperl` run, and it outranks a same-named copy belonging to the host perl:

```
pperl --cpan Text::CSV
# pperl: installed into /home/you/.pperl/lib/perl5

pperl -e 'print "$_\n" for @INC'
# ...
# /home/you/.pperl/lib/perl5
# /usr/share/perl5/site_perl
# ...
```

The same holds for the `--system` tree, which comes after the per-user one. Other trees you add yourself, with `-I`, `PERL5LIB`, or `PPERL5LIB`. `PPERL5LIB` is the pperl-private twin of `PERL5LIB`: same syntax, colon-separated, but read **only** by pperl, and honoured ahead of `PERL5LIB`:

```
PPERL5LIB=/opt/mytree PERL5LIB=/home/you/perl5/lib/perl5 \
    pperl -e 'print "$_\n" for @INC'
# ...
# /opt/mytree                       <- PPERL5LIB
# /home/you/perl5/lib/perl5         <- PERL5LIB
# /home/you/.pperl/lib/perl5
# /usr/share/perl5/site_perl
# ...
```

Why a separate variable rather than reusing `PERL5LIB`: on a machine running both interpreters, `PERL5LIB` is usually already pointing at the host perl's trees. Overloading it would force you to choose between the two. Both are read, `PPERL5LIB` first.

Why pperl reads the system trees at all

pperl searches the host perl's directories because a pure-Perl module found there runs perfectly well under pperl. That is free inventory and there is no reason to refuse it.

pperl also searches the architecture directory of each tree you add with `PPERL5LIB`, `PERL5LIB` or `-I`, and of `~/.pperl/lib/perl5`, as perl does: `<tree>/x86_64-linux` and `<tree>/<version>/x86_64-linux`, ahead of the tree, when they exist. A distribution that declares XS installs its modules there, even its pure-Perl ones. Their compiled parts pperl cannot load, and *the no-XS rule* explains where that bites.

The tools it uses, and downloads over https

Like perl's own `cpan` on its first run, `pperl --cpan` looks on your `PATH` for the programs the CPAN client works with: `make`, `tar`, `gzip`, `bzip2`, `unzip`, `gpg`, `patch` and `apply-patch`, and a downloader, the first it finds of `wget`, `curl`, `lynx`, `ncftpget`, `ncftp` and `ftp`.

pperl speaks https by itself only in a build with the `native-max` module set, which contains `IO::Socket::SSL`. Any other build downloads from CPAN over https through `wget` or `curl`, and fetches the *XS substitutes* the same way. To check which you have, run:

```
pperl -MIO::Socket::SSL -e 1
```

A build with TLS support prints nothing. One without it says `Can't locate IO/Socket/SSL.pm in @INC`, adding that it was built without the `native-max` capability.

A host with neither TLS support in pperl nor `wget` or `curl` falls back to plain http, and the CPAN client warns about it; see *troubleshooting*. Installing `curl` or `wget` is the remedy.

Installing without a network

A distribution archive or an unpacked directory on disk installs without a download of its own. Name a directory with a leading `./` or `/`, so that it cannot be taken for a module name:

```
pperl --cpan ./Some-Dist-1.23.tar.gz
pperl --cpan ~/src/Some-Dist
```

The client still fetches the CPAN index on its first run, and any dependency that is not installed yet. It also tries to refresh the *XS substitutes*; without a network it says so and uses the ones it already has.

Tests run non-interactively: `PERL_MM_USE_DEFAULT` and `NONINTERACTIVE_TESTING` are both set, so a distribution that would otherwise stop to ask a question takes its own default instead of hanging.

Distribution preferences

`pperl --cpan` applies CPAN.pm's distribution preferences, the "distroprefs" described in *CPAN* under "Configuration for individual distributions". A preference is a YAML file that matches distributions by name and changes how they are built: environment variables, build arguments, extra prerequisites, patches applied before the build.

Preferences go into `prefs/` under the installer's directory: `~/.pperl/cpan/prefs`, or `/usr/local/share/pperl/cpan/prefs` for `--system`. A patch that a preference names is looked up in the same directory, so a preference and its patch sit side by side:

```
---
match:
  distribution: '^AUTHOR/Some-Dist-1\.23'
patches:
  - Some-Dist-1.23.patch
```

pperl reads `.yml` preferences with its built-in *YAML::XS*, so nothing else needs installing.

XS substitutes

Before it installs anything, each `pperl --cpan` run fetches pperl's pure-Perl substitutes for distributions that have a compiled part, from `https://perl.petamem.com/downloads/cppan`, into `prefs/cppan` beside your own preferences. Each substitute is a preference with a patch: it matches one XS distribution and replaces its compiled part with Perl. Because the set is fetched on every run, a substitute published after your pperl was released applies to it too.

`Text::CSV_XS`, for example, installs and runs on the Perl engine of `Text::CSV`; other substitutes rest on features and functions perl and pperl have built in. Where a distribution's own tests show a difference from its compiled version, those tests are marked TODO, so you can see exactly what differs.

An unchanged set is not downloaded again. When the server cannot be reached, the run warns and uses the substitutes it fetched last. `PPERL_CPPAN_URL` names another address to fetch from; set to an empty string, it turns the fetch off, and the substitutes already on disk still apply.

What pperl already has

Several hundred modules are built into the pperl binary, in two kinds. About a hundred are compiled in: `Storable`, `Socket`, `Digest::MD5`, `Data::Dumper`, `Time::HiRes`, `POSIX`, `Encode` and friends are not files pperl loads - they are Rust code, and `require` is routed to it. The rest are the Perl modules of the core library, `Test::More`, `File::Spec`, `Getopt::Long` and so on, whose source the binary carries. For both kinds `%INC` records `./pperl-native/<name>` (for example `./pperl-native/Storable.pm`) - it reads like a path, but there is no file behind it.

That is invisible and harmless when you are writing Perl. It is a problem when an *installer* is trying to work out what you have.

The probe

Every installer answers "is this module present, and at what version?" the same way: look for the `.pm` file on the search path, read `$VERSION` out of it. A built-in module has no file. So the probe walks past pperl entirely and finds the answer in the host perl's tree - a different interpreter, with different versions.

On the reference machine, five of six modules checked disagreed:

module	pperl provides	host perl says
`Digest::MD5`	2.58	2.59
`Storable`	3.41	3.37
`Socket`	2.038	2.040
`Time::HiRes`	1.9777	1.9778
`Data::Dumper`	2.183	2.192

Every consequence of that is wrong, and two of the three are silent.

- A dependency on `Storable >= 3.40` reads as unsatisfied, because the host says 3.37. The installer fetches Storable - an XS distribution - to replace a module pperl already has at 3.41. The build then fails, and it fails for a module you never needed.
- On a host with no perl at all - a minimal container, or the static build whose entire point is not needing one - every built-in module reads as missing and the same false build is attempted for each.
- In the other direction, and this one is silent: a dependency on `Data::Dumper >= 2.190` reads as *satisfied* by the host's 2.192, while pperl actually runs 2.183.

Asking pperl instead

pperl answers the question itself. `Config::lib_file` returns the path under which pperl sees a library file, a built-in one first:

```
use Config;
print Config::lib_file("Storable.pm"), "\n";    # ./pperl-native/
↪Storable.pm
print Config::lib_file("Foo/Bar.pm"), "\n";    # /home/you/.pperl/
↪lib/perl5/Foo/Bar.pm
```

The path can be opened, so the version can be read from it as from any installed file. A built-in Perl module reads as its source. A compiled-in module that has no Perl source reads as three lines, its package, its `$VERSION` and a true value:

```
use Config;
use ExtUtils::MakeMaker ();
print MM->parse_version(Config::lib_file("Storable.pm")), "\n";   #␣
↪3.41
```

The installer that is part of pperl asks exactly this. So do the `ExtUtils::MakeMaker` and `Module::Metadata` pperl carries, which is what a `Makefile.PL` and a `Build.PL` use

to check their prerequisites. A built-in module is then simply skipped: no download, no build, no diagnostic to explain.

Asked for a module that is built in, `--cpan` says so and stops:

```
pperl: Storable 3.41 is built into pperl; nothing to install
```

> **Note**
>
> The built-in path opens, but it answers no file test: `-e`, `-f` and `-r` say no. Code that looks for a module by testing `"$dir/Storable.pm"` for each directory of `@INC` does not find a built-in one. Use `Config::lib_file` there.

When the built-in version is too old

pperl reports the version it actually has. That does not make the version acceptable. If a distribution asks for `Storable >= 3.50` and pperl carries 3.41, the dependency is genuinely unsatisfied, the installer goes after the real distribution, and - Storable being XS - the build fails.

That is the honest outcome rather than a bug: the module pperl carries is not the version being asked for. It does mean a built-in module falling behind CPAN can turn into an install failure some way downstream, so a version mismatch is worth checking early when an install fails for no visible reason:

```
pperl -MStorable -e 'print Storable->VERSION, "\n"'
```

The no-XS rule, and the shapes you will meet

pperl cannot load a compiled extension. This is structural, not a setting: XS binds to perl5's C-level ABI, and pperl is a Rust reimplementation of Perl 5 that does not have one to bind to. An `XSLoader::load` under pperl fails with perl's own message for a compiled part that is not there:

```
Can't locate loadable object for module Foo::Bar in @INC (@INC␣
↪contains: ...)
```

That is the message modules with a Perl fallback test for, so they switch to their Perl implementation on it, as they would under perl.

What that means for an install depends entirely on how the distribution is put together. There are five shapes in the wild and they behave very differently, so it is worth knowing which one you are looking at.

1. Pure Perl

Nothing to say. It installs and runs exactly as it does anywhere else. This is the large majority of CPAN.

2. A Perl module with an optional XS accelerator

The module is Perl; a *separate* distribution speeds it up if present. `Readonly` and `ReadonlyXS` are the classic pair.

Install the Perl one and ignore the accelerator. The module probes for its companion, does not find it, and uses its own implementation - which is the documented, supported path, not a degraded mode.

```
pperl --cpan Readonly       # yes
pperl --cpan ReadonlyXS     # no, and not needed
```

This is the shape to prefer when you have a choice of dependency. The Perl module is the module, and XS is an optimisation.

3. One distribution, both halves, XS optional at build time

The distribution ships C *and* Perl, and its `Makefile.PL` treats the compile as optional: if the compiler step fails or is declined, it installs the Perl half and carries on. At runtime the module notices the XS is absent and uses its own fallback.

`Cookie::Baker` and `WWW::Form::UrlEncoded` are of this shape. They install cleanly under pperl.

`pperl --cpan` asks every build for that Perl-only form by the toolchain's own switches: `PUREPERL_ONLY=1` for `ExtUtils::MakeMaker` and `--pureperl-only` for `Module::Build`. A distribution that honours them, such as `Params::Validate`, builds its Perl half instead of stopping for want of a C compiler.

4. One distribution, both halves, XS mandatory at build time

Same idea, but the build compiles C unconditionally. The compile fails, the installer aborts, and with an ordinary installer the Perl half - which would have worked - never reaches disk.

`HTTP::Parser::XS` is the worked example. pperl implements it natively now, so you will not hit it in practice - an installer sees 0.17 already present and never fetches the distribution at all. It is still the clearest illustration of the shape, because the failure is not where you would guess. Its runtime logic is impeccable:

```
eval {
    require XSLoader;
    XSLoader::load(__PACKAGE__, $VERSION);
    $BACKEND = 'xs';
};
die $@ if $@ && $BACKEND =~ /\bxs\b/;    # only if you FORCED xs
if (not __PACKAGE__->can('parse_http_response')) {
    require HTTP::Parser::XS::PP;        # automatic fallback
    $BACKEND = 'pp';
}
```

Given the files on disk, that falls back by itself, with no intervention. The problem is purely that `Makefile.PL` builds picohttpparser unconditionally, so the files never get

there. Its `PERL_ONLY=1` switch selects the runtime backend and drives a test target; it does not make the build skip the C.

> **Note**
>
> A native implementation is the escape hatch, and it is the one that was used here. But it only holds while pperl's version satisfies what dependents ask for: pperl reports the native version, so a dependency on `HTTP::Parser::XS >= 0.18` would send the installer after the distribution again and the abort would come back.

A shape-4 distribution pperl does *not* implement natively installs all the same, because pperl's `ExtUtils::MakeMaker` never compiles XS. Under pperl a `Makefile.PL` produces a Makefile for the Perl half only: no perl header files and no `xsubpp` are looked for, so the build cannot fail at the C. Two things then decide whether the distribution is installed:

- every module in it that names an XS loader is loaded once. One that falls back to Perl, as above, loads. One that does not is named, and stays: a module can switch to its Perl half by an environment variable or a setting, as `Params::Util` does under `PERL_PARAMS_UTIL_PP`, which its own tests set;
- the distribution's own tests run, as for any other module, and they decide.

```
pperl: does not load without the compiled part, which pperl cannot␣
↪build: Some/Dist/Fast.pm
```

A distribution built with `Module::Build` that does not honour `--pureperl-only` still attempts its compile and fails. For those, `--cpan` installs the Perl files the build had already copied into its `blib` directory. Each file that names an XS loader is loaded once first; one that does not load is installed all the same, for the same reason as above, and named. It says so:

```
pperl: Some-Dist-1.23-0: XS build failed; installed its 4 pure-Perl␣
↪file(s)
pperl: Some-Dist-1.23-0: installed, but without the compiled part it␣
↪does not load: Some/Dist/Fast.pm
```

That run ends with a failure status, because the distribution's tests never ran: test what was installed before you rely on it.

5. XS only

No Perl implementation exists anywhere in the distribution. There is nothing to fall back to and nothing pperl can do with it. The load check names the module:

```
pperl: does not load without the compiled part, which pperl cannot␣
↪build: String/CRC32.pm
```

Tests that load the module then fail with the missing-object message above, and a distribution whose tests fail is not installed.

The exception is a distribution pperl publishes a substitute for: a patch that replaces the compiled part with Perl, which `--cpan` fetches on every run, so it reaches a pperl

released before the substitute existed. `Text::CSV_XS` installs that way, running on the Perl engine of `Text::CSV`. "XS substitutes" in *installing and finding modules* has the details.

When you actually need the speed

The reason XS exists is performance, so it is fair to ask what replaces it. pperl's answer has three parts, and none of them is "write it in Perl and hope".

- **Native modules.** About a hundred of the modules people reach for XS to get are already Rust inside the binary, at Rust speed, with no build step. See *what pperl already has*.
- **The JIT.** Hot loops are compiled, so the pure-Perl version of an algorithm is not automatically the slow version. See the *performance guide*.
- **Calling C directly.** When you genuinely need a C library, call it rather than wrapping it in XS. `Peta::FFI` is pperl's own interface; see the *FFI primer*. *FFI::Platypus*, the interface CPAN's FFI modules are written against, is built in as well, and adds structs passed by value and callbacks with typed signatures. A distribution that bundles its own C for it (an `ffi/` directory, built by *FFI::Build*) builds and installs with pperl when a C compiler is on `PATH`: that C becomes a library called through FFI, not an XS extension.

If you hit a module in shape 4 or 5 that you cannot work around, that is worth reporting, since a substitute can follow without a new pperl release: https://github.com/petamem/pperl-bugtracker/issues

When an install goes wrong

Symptoms first, since that is what you have when you arrive here.

"Can't locate Foo/Bar.pm" after a successful install

The install said it worked, and the module is not there. pperl searches `lib/perl5` under `$PPERL_HOME`, or under `~/.pperl` when that is unset, so the usual cause is that the install and the run see different trees: `PPERL_HOME` was set for one and not the other, or the install went into a tree pperl does not search unasked. Compare the "installed into" line of the install with pperl's search path:

```
pperl -e 'print "$_\n" for @INC'
```

A tree that is missing there can be added with `PPERL5LIB`.

A distribution that declares XS installs its modules into the tree's architecture directory, `lib/perl5/x86_64-linux/` on this platform, even when they are pure Perl. That is not a cause: as perl does, pperl searches the architecture directory of every tree on `PPERL5LIB`, `PERL5LIB` and `-I`, and of `~/.pperl/lib/perl5`.

The installer wants to build a module pperl already has

Confirm what pperl thinks it provides, and at which version:

```
pperl -MConfig -MExtUtils::MakeMaker -e \
  'my $f = Config::lib_file("Storable.pm"); print "$f ", MM->parse_
↪version($f), "\n"'
# ./pperl-native/Storable.pm 3.41
```

If the path starts with `./pperl-native/` the module is built in. If the installer still wants it, compare the versions: the dependency may genuinely be newer than the version pperl carries, in which case no arrangement will satisfy it.

An installer that is not pperl's own, run under pperl, looks for modules with file tests and does not see the built-in ones. Use `pperl --cpan`.

"Can't locate loadable object for module Foo::Bar in @INC"

XS: the module wants its compiled part, and pperl does not build one. Read *the no-XS rule* to work out which shape the distribution is, because shapes 2 and 3 there have a way forward and shapes 4 and 5 do not.

A module that has a Perl implementation of its own catches this message and uses that implementation, so you do not see it. When you do, the module either has no Perl implementation, or has one that is switched on another way, such as by an environment variable its documentation names.

"Need to fall back to http"

```
Missing or unusable modules 'Net::SSLeay', 'IO::Socket::SSL', and␣
↪found neither curl nor wget installed.
Need to fall back to http.
```

This pperl has no TLS support of its own, and the host has neither `curl` nor `wget`, so the CPAN client downloads over plain http. Install `curl` or `wget`; the next `pperl --cpan` run finds it and downloads over https. The XS substitutes are not fetched at all in this state, and that warning (below) ends in `neither curl nor wget is configured`.

"XS substitutes not refreshed from ..."

```
pperl: --cpan: XS substitutes not refreshed from https://perl.
↪petamem.com/downloads/cppan: ...
```

The run could not fetch pperl's substitutes for XS distributions, for the reason named at the end: no network, or a server error. The install carries on with the substitutes fetched last, so only one published since then is missing. On a machine that is never online, set `PPERL_CPPAN_URL` to an empty string to stop the attempt.

```
pperl: --cpan: cannot unpack .../cppan.tar.gz; the XS substitutes␣
↪stay as they were
```

The download arrived but is not an archive pperl can unpack. The install carries on with the substitutes fetched before it, and the next run downloads the file afresh.

The install hangs waiting for input

It should not - under `--cpan`, `PERL_MM_USE_DEFAULT` and `NONINTERACTIVE_TESTING` are both set, so distributions take their own defaults. If you are driving an installer yourself, set both.

Tests fail but the module is fine

`-T` goes straight through to the CPAN client and skips the tests:

```
pperl --cpan -T Some::Module
```

Worth doing once to find out whether the module or its test suite is the problem. A test suite that itself depends on XS will fail against a perfectly good pure-Perl module.

Starting over

The tree is disposable. Nothing else refers to it:

```
rm -rf ~/.pperl
pperl --cpan Your::Module
```

Reporting

If a pure-Perl distribution fails to install, or installs and then cannot be loaded, that is a pperl bug and worth filing:

https://github.com/petamem/pperl-bugtracker/issues

Include the distribution name and version, the full `--cpan` output, and `pperl -e 'print "$_\n" for @INC'`.

4.2.19 ipps, the interactive mode - a tutorial

`ipps`, the interactive PetaPerl shell, is a shell for Perl: a prompt whose language is Perl. You type a line, pperl runs it and shows you the value, and everything the line declared is still there for the next one. It is the quickest way to try an expression, look inside a data structure, or find out whether a loop gets compiled.

You are assumed to know Perl. Nothing here needs installing: the prompt, its line editor and its history are built into the pperl binary.

Starting it

```
pperl --shell
```

or, if you would rather type less, give pperl a second name once:

```
ln -s "$(command -v pperl)" ~/bin/ipps
ipps
```

pperl started under the name `ipps` is the interactive mode. A bare `pperl` without arguments is unchanged: it reads a program from standard input, as perl does.

> **Note**
>
> `--shell` needs a pperl built with the `shell` feature. A binary without it says so and stops. Check with `pperl -V`, which lists the features under `PPERL_FEATURES`.

The one idea

A line at the prompt is Perl, compiled and run as it would be in a file, with one difference: **what a line leaves behind stays.** A `my` variable, a `sub`, a loaded module, a `use strict`, the current `package` - the next line starts where this one stopped.

```
ipps> my @primes = (2, 3, 5, 7)
(2, 3, 5, 7)
ipps> sub square { $_[0] ** 2 }
ipps> map { square($_) } @primes
(4, 9, 25, 49)
```

Everything else in this tutorial is a detail of that: how values are shown, what the commands that start with a colon do, how to make the prompt yours, and the few places where a line is not quite a file.

Chapters

A first session

Values

Type an expression and its value is shown, written the way you would write it in Perl:

```
ipps> 2 ** 10
1024
ipps> "total: " . 4
'total: 4'
ipps> 1 == 1
true
ipps> undef
undef
ipps> { name => "ada", langs => ["perl", "rust"] }
{ langs => ['perl', 'rust'], name => 'ada' }
```

A number is bare and a string is in quotes, so you can tell 12 from `'12'`. A string gets the quotes that need the fewest escapes:

```
ipps> "it's"
q{it's}
ipps> "a\tb"
"a\tb"
```

A line is evaluated in list context, and a list of several values is shown in parentheses. A hash is a list of its keys and values:

```
ipps> my %age = (ada => 36, alan => 41)
('ada', 36, 'alan', 41)
ipps> localtime
(59, 47, 10, 13, 9, 126, 2, 285, 1)
```

Large values are cut, with a note of what was left out. The `:dump` command of the next chapter shows them whole.

```
ipps> [1 .. 40]
[
  1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19,␣
↪20,
  21, 22, 23, 24, ... (16 more)
]
```

Staying quiet

Every Perl statement has a value, and you do not always want to see it. End the line with a semicolon and nothing is shown:

```
ipps> my $n = 12;
ipps> $n * 2
24
```

Three kinds of line show nothing even without the semicolon: a definition (`sub`, `use`, `package`), a loop or conditional typed by itself, and a line whose last statement is `print`, `printf` or `say`, whose value would only be whether the output worked.

```
ipps> for my $p (2, 3) { print "$p squared is ", $p ** 2, "\n" }
2 squared is 4
3 squared is 9
```

When your code prints something that does not end in a newline, the prompt still starts on a line of its own, and a % in reverse video marks the place where the output stopped:

```
ipps> print "no newline"
no newline%
ipps>
```

The % is not part of the output. It tells you that the newline you see was not printed by your code.

The last value

The value last shown is in `$ans`, and when there were several, all of them are in `@ans`:

```
ipps> $n * 2
24
ipps> $ans + 1
25
ipps> map { $_ * $_ } 2, 3, 5, 7
(4, 9, 25, 49)
ipps> scalar @ans
4
```

More than one line

Input that is not finished gets a second prompt until it is. An open bracket, an open quote, a here-document without its end and an expression that expects more all count:

```
ipps> for my $p (2, 3, 5, 7) {
 ...>     print "$p squared is ", $p ** 2, "\n";
 ...> }
2 squared is 4
3 squared is 9
5 squared is 25
7 squared is 49
ipps> 1 +
 ...> 2
3
```

Blank lines inside are kept, so pasted code works. To give up on unfinished input, press Ctrl-C.

Errors

An error is printed and the session goes on with everything it had. The place is given as the line's number at the prompt and the line within what you typed:

```
ipps> die "something went wrong\n"
something went wrong
ipps> $n
12
ipps> $undeclared_typo + 1
Use of uninitialized value $undeclared_typo in addition (+) at␣
 ↪(ipps:14) line 1.
1
```

The session starts with warnings on and with `strict` for references and barewords, but not for variables: an undeclared `$x` works at a prompt. If you want all of `strict`, say so, and it holds from then on:

```
ipps> use strict;
ipps> $another_typo = 1
Global symbol "$another_typo" requires explicit package name (did␣
 ↪you forget to declare "my $another_typo"?) at (ipps:16) line 1.
```

Keys

Tab
: Completes the word in front of the cursor: a variable, a key of a hash, a method after `->`, a sub, a module after `use`, a file name inside a string, a command. With several candidates it completes as far as they agree; a second Tab lists them. When nothing of Perl fits the word, Tab completes a file name.

Up and Down
: Walk through the lines entered before, including those of earlier sessions. Ctrl-R searches them.

Ctrl-C
: At the prompt, drops what you have typed. While a line runs, stops that line. The session goes on either way.

Ctrl-D
: On an empty prompt, ends the session. So do `exit` and `:quit`.

Tab knows the session. With a `%colour` and an object in `$dog`:

```
ipps> $col<Tab>
ipps> $colour{<Tab><Tab>
green}  red}
ipps> $dog-><Tab><Tab>
DOES      can       import    name      speak
VERSION   fetch     isa       new       unimport
```

It reads what exists and runs nothing, so it cannot complete through the result of a call.

Commands

A line that starts with a colon and a word is a command of `ipps`, not Perl. `:help` lists them all. A command may be shortened while it stays unique: `:q` is `:quit`, `:v` is `:vars`.

Looking at what you have

`:vars` lists the variables of the session with their kind and a short form of their value:

```
ipps> my @primes = (2, 3, 5, 7); my %age = (ada => 36, alan => 41);␣
 ↪my $name = "ada";
ipps> :vars
%age     hash of 2   (ada => 36, alan => 41)
$ans     undef       undef
@ans     array of 0  ()
$name    string      'ada'
@primes  array of 4  (2, 3, 5, 7)
```

`:scalar` evaluates in scalar context, where a line by itself is in list context:

```
ipps> @primes
(2, 3, 5, 7)
ipps> :scalar @primes
4
ipps> :scalar localtime 0
'Thu Jan  1 01:00:00 1970'
```

`:dump` shows a value whole, however large:

```
ipps> my @big = (1 .. 30);
ipps> \@big
[
  1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19,␣
↪20,
  21, 22, 23, 24, ... (6 more)
]
ipps> :dump \@big
[
  1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19,␣
↪20,
  21, 22, 23, 24, 25, 26, 27, 28, 29, 30
]
```

`:source` shows the code of a sub, by its name or by an expression that gives a code reference. The pragmas in force where the sub was written are part of what it shows:

```
ipps> sub area { my ($w, $h) = @_; return $w * $h }
ipps> :source area
sub area {
    use warnings;
    use strict 'refs', 'subs';
    my($w, $h) = @_;
    return $w * $h;
}
```

`:which` says where pperl gets a module from, and whether it is loaded:

```
ipps> :which List::Util
built into pperl (loaded)
ipps> :which JSON::PP
built into pperl
ipps> :which No::Such
ipps: No::Such: not on the search path
```

A module that is a file on disk is answered with its path.

Timing a line, and asking the JIT

`:time` runs a line and then shows how long it took, compiling included. The first number is wall-clock time, the second the processor time, which the system counts in steps of ten milliseconds:

```
ipps> :time my $s = 0; $s += $_ for 1 .. 1_000_000; $s
500000500000
wall 17.377 ms, cpu 20.000 ms
```

`:jit` runs a line and then shows what pperl's JIT did while it ran:

```
ipps> :jit my $t = 0; for my $i (1 .. 1_000_000) { $t += $i * 2 } $t
1000001000000
jit: 1 loop compiled, 1 new loop seen (2 of 71 since the start)
```

The line had one loop, and it was compiled to machine code. The numbers in parentheses are compiled and seen loops since `ipps` started, its own code included.

A loop is compiled once it has run often enough, and that can be in a later line than the one that wrote it. The loop of a sub is seen where the sub is defined and compiled where a call makes it hot:

```
ipps> sub total { my $t = 0; for my $i (1 .. $_[0]) { $t += $i } $t␣
↪}
ipps> :jit total(300_000)
45000150000
jit: 1 loop compiled, 0 new loops seen (1 of 68 since the start)
```

A line whose loop was seen and not compiled looks like this:

```
ipps> :jit my @w = map { "w$_" } 1 .. 3; scalar @w
3
jit: 0 loops compiled, 1 new loop seen (2 of 72 since the start)
```

The counts say that a loop was compiled. They do not say why another was not.

Files and modules

`:load` runs a file in the session. What it declares is there afterwards; the value of its last statement is not shown.

```
ipps> :load ~/lib/helpers.pl
```

`:save` writes every line that ran without an error as a script, in the order you entered them. Commands are not written, the lines they ran are.

```
ipps> :save /tmp/session.pl
12 entries saved to /tmp/session.pl
```

Lines you typed only to look at a value are statements of that script too, and perl warns that such a statement is useless there. Delete them from the file.

`:install` installs modules from CPAN with pperl's own client, as `pperl --cpan` does. They can be used at once.

```
ipps> :install Text::CSV
```

Commands of your shell

A line that starts with `!` and a space is not a command of `ipps` and not Perl: it is handed to your shell and runs on the terminal.

```
ipps> ! ls Cargo.* | wc -l
2
```

The section on running programs in *where a line is not a file* has the details: the exit status, aliases, and how to get a command's output into a variable.

`:programs` goes the other way and makes programs Perl: after `:programs ls`, `ls` is a sub that runs the program and returns its output, and `:programs` alone lists such names. *Programs as functions* in the next chapter explains it, together with the `autorun` setting.

The session itself

`:history` shows the last 20 lines entered, `:history 5` the last five. On a terminal these include earlier sessions.

`:reset` starts afresh: no `my` variables, the pragmas of a new session, the package `main`. Subs and package variables belong to the interpreter and stay.

`:quit` leaves, as Ctrl-D does.

`:set` belongs to the next chapter.

> **Note**
>
> A name with two colons in front, such as `::helper`, is Perl - a sub in `main` - and stays Perl.

Making it yours

Settings

`:set` shows the settings, `:set` with a name shows one, and with a name and a value changes it:

```
ipps> :set
  autorun    off        an unknown sub of main runs a program: on or
↪off
  max_depth  6          levels shown of a nested structure; 0: all
  max_items  24         elements shown of an array or hash; 0: all
  max_string 240        characters shown of a string; 0: all
  prompt     'ipps> '   the prompt
```

(continues on next page)

(continued from previous page)

```
  prompt2    ' ...> '   the prompt for unfinished input
  shell      '/bin/bash -c' what "! command" runs the command with
  time       off        show the times of every line: on or off
  width      0          columns for a printed value; 0: the terminal
↪'s
ipps> :set max_items 5
ipps> [1 .. 30]
[1, 2, 3, 4, 5, ... (25 more)]
```

A prompt in quotes keeps its trailing space:

```
ipps> :set prompt "perl> "
perl>
```

A setting made this way lasts for the session. To keep it, put it in the start file.

The start file

`ipps` keeps two files in `~/.pperl/ipps`, or in `$PPERL_HOME/ipps` when that variable is set:

`rc.pl`
: Perl that runs in the session before the first prompt. What it declares is there when you start typing.

`history`
: The lines you typed, read at the start and written at the end.

`rc.pl` is ordinary Perl, so it can load the modules you always want and define the subs you always use:

```
use List::Util qw(sum max min first);
use JSON::PP ();

sub slurp { my ($file) = @_; open my $fh, '<', $file or die "$file:
↪$!"; local $/; <$fh> }
```

Start `ipps` with `--norc` to leave it out for once.

Settings, macros and commands in the start file

Three calls reach the prompt itself from `rc.pl`.

A setting:

```
Peta::Shell->set(max_items => 100);
Peta::Shell->set(time => 'on');
```

A macro is a word that is replaced when it is the first word of a line and a space or the end of the line follows it. Given a string, the word is replaced and the rest of the line stays:

```
Peta::Shell->macro(p => 'print');
```

```
ipps> p "printed by a macro\n"
printed by a macro
```

Given a sub, the macro gets the rest of the line and returns the Perl to run in its place:

```
Peta::Shell->macro(sq => sub { my ($rest) = @_; "($rest) ** 2" });
```

```
ipps> sq 3 + 4
49
```

A command of your own is called with a colon, like the built-in ones, and gets the rest of the line:

```
Peta::Shell->command(greet => sub { my ($shell, $rest) = @_; print
↪"hello, $rest\n" });
```

```
ipps> :greet world
hello, world
```

`:help` lists your commands and macros after its own. The names of the built-in commands are taken.

Programs as functions

With the `autorun` setting on, a call of a sub that does not exist runs the program of that name instead and returns what the program wrote:

```
ipps> :set autorun on
ipps> whoami()
"rj\n"
ipps> my @manifests = ls('Cargo.*')
("Cargo.lock\n", "Cargo.toml\n")
```

In list context the output is a list of lines, otherwise one string. The arguments are joined with spaces into a command line for `/bin/sh`, so the shell still expands the `*` above. What the program writes to its error output appears on the terminal, and its exit status is in `$?`:

```
ipps> false(); $? >> 8
1
```

Perl's rules for calling a sub still decide what you can type:

- Without parentheses a name must be declared first, and `:programs` declares it. After `:programs ls whoami`, `ls 'Cargo.*'` and a bare `whoami` work. Before it, the first is a syntax error and the second is refused under `use strict`.
- Every argument is Perl. In `ls -l` the `-l` is Perl's file test, not an option; write `ls '-l'`.

- A name of one of Perl's own functions, such as `kill` or `sleep`, stays Perl's, and `:programs` refuses it. A program whose name Perl cannot use for a sub, such as `apt-get`, cannot be called this way.
- It works in the package `main` only.

A mistyped sub name now runs a program too: `pritn("x")` reports `Can't exec "pritn": No such file or directory`, not an undefined sub.

For options, pipes and redirections the shell's own syntax is simpler, and `! command` gives you exactly that.

To have `autorun` in every session, put it in `rc.pl`:

```
Peta::Shell->set(autorun => 'on');
```

`autorun` is `main`'s `AUTOLOAD`, and `ipps` does not switch it on while you have one of your own. Writing your own is the way to make programs behave differently, for example to give lines without their newlines:

```
use subs qw(ls cat);

sub AUTOLOAD {
    my $program = our $AUTOLOAD =~ s/.*::/r;
    return if $program eq 'DESTROY';
    chomp(my @lines = qx{$program @_});
    return wantarray ? @lines : join "\n", @lines;
}
```

`use subs` declares names for it, as `:programs` does for `autorun`.

Without a terminal

When standard input is not a terminal, `ipps` reads it line by line without a prompt and prints values and errors the same way. That makes it usable in a pipe:

```
printf 'my @w = split " ", "the quick brown fox";\nscalar @w\njoin
↪"-", reverse @w\n' | pperl --shell
```

```
4
'fox-brown-quick-the'
```

The commands work there too.

Where a line is not a file

Each line you enter is compiled and run by itself, and `ipps` carries over what the line declared. A few things in Perl last exactly as long as the code that surrounds them, and at the prompt that is one line.

The match variables

`$1`, `$2` and their relatives belong to the line that matched:

```
ipps> "2026-10-13" =~ /(\d+)-(\d+)/; "$1 / $2"
'2026 / 10'
ipps> $1
undef
```

Take what you need into variables in the same line:

```
ipps> my ($year, $month) = "2026-10-13" =~ /(\d+)-(\d+)/;
ipps> "$year / $month"
'2026 / 10'
```

`local`

`local` at the top of a line lasts to the end of that line:

```
ipps> our $level = 1; local $level = 2; $level
2
ipps> $level
1
```

Inside a sub or a block it behaves as everywhere.

Lexical subs

A sub declared with `my sub` exists for its line only:

```
ipps> my sub helper { 42 } helper()
42
ipps> helper()
Undefined subroutine &main::helper called at (ipps:2) line 1.
```

An ordinary `sub` stays.

Packages

A `package` statement holds for the following lines, as it does in a file, and `my` variables stay visible across it:

```
ipps> package Counter; my $count = 0; sub bump { ++$count }
ipps> bump(); bump()
2
ipps> __PACKAGE__
'Counter'
ipps> package main;
ipps> Counter::bump()
3
```

Unfinished input is compiled twice

While you are typing a statement over several lines, `ipps` finds out that it is unfinished by compiling what there is. A `use` or a `BEGIN` block in the first lines has run by then, and runs again when the whole text is compiled. For nearly every module that makes no difference. Where it would, put the `use` on a line of its own.

Completion runs nothing

Tab looks at the variables, packages and files that exist. It does not call your code, so it cannot know what a call returns. After

```
make_thing()->
```

there is nothing to offer. Put the result in a variable and complete on that.

Running programs

`ipps` is a shell for Perl: a line at its prompt is Perl, and a bare `ls` is a Perl word, not a command. To hand a line to your own shell, start it with `!` and a space:

```
ipps> ! ls -l Cargo.toml
-rw-r--r-- 1 rj rj 8046 Oct 12 09:18 Cargo.toml
ipps> ! ls Cargo.* | wc -l
2
```

The line goes to the shell as it stands, with its globs and pipes, and runs on your terminal. Nothing of it is Perl and its output is not kept. An exit status other than 0 is reported:

```
ipps> ! ll Cargo.toml
/bin/bash: line 1: ll: command not found
ipps: exit status 127
```

That `ll` is an alias, and the command runs under `$SHELL -c`, which does not read the start file of an interactive shell. The `shell` setting says what to run instead. For the aliases of bash:

```
ipps> :set shell bash -ic
ipps> ! ll Cargo.toml
-rw-r--r-- 1 rj rj 8046 Oct 12 09:18 Cargo.toml
```

The space after `!` matters. Without it the line is Perl's negation:

```
ipps> my $done = 0;
ipps> !$done
true
```

When you want a command's output in a variable, that is Perl, and Perl starts programs as it always has:

```
ipps> my @files = `ls Cargo.*`
("Cargo.lock\n", "Cargo.toml\n")
```

(continues on next page)

(continued from previous page)

```
ipps> system "echo", "run by system"
run by system
0
ipps> open my $pipe, "-|", "echo", "read from a pipe"; scalar␣
 ↪readline $pipe
"read from a pipe\n"
```

The `0` after the first line is what `system` returned. Listing files needs no program at all:

```
ipps> my @manifests = glob "Cargo.*"
('Cargo.lock', 'Cargo.toml')
```

CHAPTER

FIVE

REFERENCE

Reference for pperl, a faithful Rust reimplementation of perl5 5.44. Two parts: the **Perl language** reference (variables, functions, operators, regex, data types, subroutines) and the **Module** reference for every built-in native module.

5.1 Perl language

- *Variables*
- *Functions*
- *Operators*
- *Data types*
- *Subroutines*
- *Locale handling*
- *Diagnostics*
- *Security and taint mode*

5.1.1 Special variables

Perl ships with a fixed set of built-in variables that are populated, read, or honoured by the language itself. Some hold state from the last operation (the regex match variables, `$!`, `$@`); some configure how built-ins behave (`$/`, `$\`, `$,`); some expose the running interpreter and its environment (`$^V`, `$^O`, `%ENV`, `@INC`); a few are not really variables at all but hooks into runtime services (`%SIG`).

PetaPerl implements every special variable that Perl 5.44 documents, with identical semantics. Where the runtime does something noteworthy of its own - a JIT fast path that reads a cached cell, an Arc-backed COW string for `$_` - that is an implementation detail; user-visible behaviour matches perl5.

This reference is split into one page per family. Variables that share context (you almost never set `$,` without thinking about `$\` and `$|`) live on the same page; variables that don't (process IDs and regex captures) don't.

Choose a family

Default variables

Two variables hold the implicit operands of Perl. `$_` is the default scalar that countless built-ins read when called without an argument. `@_` is the argument array of every subroutine. Together they account for most of the "where did that value come from?" surprises in Perl code.

`$_` - the default scalar

`$_` is the *topic*: the value being talked about right now. A huge swath of Perl's built-ins consult it when called with no explicit argument:

```
for my $line (<$fh>) {
    chomp;                      # chomp $line  - but $line was␣
↪aliased to $_
    print if /\bERROR\b/;       # print $_ if $_ =~ /\bERROR\b/
}
```

The full list of built-ins that default to `$_` includes `chomp`, `chop`, `lc`, `lcfirst`, `length`, `pos`, `print`, `printf`, `quotemeta`, `say`, `split` (default pattern), `study`, `uc`, `ucfirst`, `unlink`, the `m//` and `s///` operators, the `tr///` operator, and the `<>`/`-X` filetest operators. Their detail pages name `$_` as the default; this page is the canonical description.

Aliasing inside `for` and `while`

The `for` (and `foreach`) loop **aliases** `$_` to each element of the list, in turn:

```
my @items = (1, 2, 3);
for (@items) {
    $_ *= 2;                    # mutates @items in place
}
# @items is now (2, 4, 6)
```

Modifying `$_` inside the loop modifies the list element itself. This is identical behaviour to `map`, `grep`, `any`, `all` - and `first` and `reduce` from `List::Util`.

`while (<$fh>)` does **not** alias - it reads each line into `$_` as a fresh copy. You cannot push back into the file by assigning to `$_` in a `while (<$fh>)` loop.

Localising `$_`

A subroutine that wants its own `$_` without disturbing the caller's must `local`-ise it:

```
sub categorise {
    local $_ = shift;           # decouple from caller's $_
    return 'small'  if /^\d{1,3}$/;
    return 'medium' if /^\d{4,6}$/;
    return 'large';
}
```

(continues on next page)

(continued from previous page)

```
my @sizes;
for ('5', '12345', '999999999') {
    push @sizes, categorise($_); # caller's $_ stays the loop alias
}
```

Without the `local`, calling `categorise()` with `shift` would work - but any `=~`, `/.../`, or `chomp` inside it would silently read or write the loop alias, breaking the caller's iteration.

$_ as an lvalue

`$_` is a real scalar variable; you can assign to it, take a reference to it, and pass it as an lvalue:

```
$_ = 'hello';
chomp;                              # nothing to chomp; $_ unchanged
s/l/L/g;                             # $_ is now 'heLLo'

my $ref = \$_;                       # \$_ is the alias's address
$$ref = 'goodbye';                  # mutates whatever $_ is currently␣
↪bound to
```

Beware that the second `$$ref` will write to **whatever $_ is right now** - which inside a `for` loop is the current list element. References to `$_` taken outside a loop and used inside one rarely do what the author meant.

Lexical $_

`our $_` and `my $_` were experimental features that have been removed. `$_` is always the package-global; use `local $_` for isolation.

@_ - subroutine arguments

Inside a subroutine, `@_` is the array of arguments passed to that call. Each element is **aliased** to the caller's expression - `@_` is not a copy:

```
sub double {
    $_[0] *= 2;                     # mutates the caller's variable
}

my $x = 5;
double($x);
# $x is now 10
```

This is why most subs start with `my (...) = @_;` - the unpacking creates copies, after which the routine cannot accidentally mutate caller state:

```
sub greet {
    my ($name, $greeting) = @_;  # decoupled from caller
```

(continues on next page)

(continued from previous page)

```
    $greeting //= 'Hello';
    return "$greeting, $name!";
}
```

The aliasing is occasionally useful - it is how `chomp(@lines)` mutates every element of the caller's array - but in everyday code the unpacked-copy idiom is the rule.

wantarray and the calling context

A sub that wants to behave differently depending on whether it was called in scalar, list, or void context inspects `wantarray`:

```
sub items {
    return wantarray ? (1, 2, 3) : 3;
}

my @list = items();              # (1, 2, 3)
my $cnt  = items();              # 3
items();                          # void - return value discarded
```

`@_` and `wantarray` are the two pieces of the calling-convention picture. `@_` says *what* was passed; `wantarray` says *what is expected back*.

@_ after shift, pop, unshift, push

Modifying `@_` itself (not its elements) has no aliasing effect on the caller - it's a normal local array variable. `shift @_` removes the first argument, leaving the rest:

```
sub method_call {
    my $self = shift;            # standard OO pattern
    my %args = @_;               # rest of args as a hash
    ...
}
```

`shift` with no arguments inside a subroutine defaults to `@_`, which is why you see `my $self = shift;` everywhere.

$_ = shift - wait, what?

A common deceptive idiom:

```
sub trim {
    $_ = shift;                  # - set caller's $_ - DO NOT DO␣
↪THIS
    s/^\s+//;
    s/\s+$//;
    return $_;
}
```

That `$_ = shift` writes to the package-global `$_`, which is *the caller's loop topic* if the caller is inside a `for`. The fix is `local`-isation, as above:

```
sub trim {
    local $_ = shift;
    s/^\s+//;
    s/\s+$//;
    return $_;
}
```

See also

- `map`, `grep` - the most common consumers of `$_` aliasing.
- `shift`, `pop` - default to `@_` inside a subroutine.
- `wantarray` - the companion of `@_` in the calling-convention picture.
- `local` - the safe way to set `$_` inside a sub that the caller might be iterating with.
- *Regex binding* - =~ is what you use when you don't want the implicit `$_` target.

Process identity

Six variables expose what the operating system thinks of this process: its name, its PID, and its real-and-effective user and group IDs. They are most useful in scripts that need to act based on *who is running them*, drop privileges after a privileged operation, or distinguish parent from child after a `fork`.

Variable	What it holds	Mutable
`$0`	Program name (and `ps` display)	yes
`$$`	Current process PID	no (read-only)
`$<`	Real UID	yes (privileged)
`$>`	Effective UID	yes (privileged)
`$(`	Real GID (plus supplementaries)	yes (privileged)
`$)`	Effective GID (plus supplementaries)	yes (privileged)

`$0` - program name

The name of the program being executed, as passed in `argv[0]`:

```
print "Started by: $0\n";        # e.g. "/usr/local/bin/myscript.pl"
```

Assigning to `$0` changes how the process appears in `ps` output and similar listings - handy for long-running scripts that fork and want each child to be identifiable:

```
$0 = "myserver: worker pid $$";   # appears in `ps` as that string
```

The change writes into the area of process memory that `ps` reads on Linux. Older Unix variants and Windows have different rules; PetaPerl follows perl5's behaviour exactly.

Reading `$0` always returns the current value, including any modifications you have made.

`$0` is **not** the program name as the *script* sees it - for that, see `@ARGV` (which has `$0` as the companion at index `[-1]` of the original `argv`, not as `@ARGV[0]`).

$$ - process ID

Read-only. The PID of the current process.

```
print "Running as PID $$\n";

open my $log, '>>', "/var/log/myapp.log" or die $!;
print $log "[$$] starting...\n";
```

After `fork`, the child sees a different `$$` from the parent - this is the standard way to tell which side of the fork you are on:

```
my $pid = fork;
defined $pid or die "fork: $!";
if ($pid == 0) {
    # child
    print "child: my pid is $$\n";
    exit 0;
}
# parent
print "parent: my pid is $$, child is $pid\n";
waitpid $pid, 0;
```

The English alias `$PROCESS_ID` (and the redundant `$PID`) work the same as `$$`.

To get the *parent's* PID, use `getppid`.

Real vs effective IDs - what they mean

Every Unix process has *two* user IDs and *two* group IDs:

- The **real** UID/GID is who you are - usually the user who invoked the program.
- The **effective** UID/GID is what the kernel checks for permission decisions - typically the same as real, but different for *setuid* and *setgid* programs.

When you run a setuid-root binary, the kernel sets the effective UID to root (the file's owner) but leaves the real UID as your own. The program can then act as root for the privileged operation, and either *drop privileges* by setting effective back to real, or *check who really invoked it* by reading the real UID.

$< - real UID

```
print "Invoked by user with UID $<\n";
```

`$<` is the real UID. It almost never changes during a process's lifetime; the cases where it can are very limited (only `root` can change it, and only via specific syscalls).

Mnemonic: *the UID you came **from***.

$> - effective UID

```
print "Privileges currently effective: UID $>\n";
```

$> is the effective UID - the one that matters for permission checks. In a setuid program, this is initially the file owner's UID; in an ordinary program, it equals $<.

Mnemonic: *the UID you went **to***.

The classic setuid pattern

A setuid-root helper that needs to do *one* privileged operation and then drop privileges so the rest of the script runs as the real user:

```
#!/usr/bin/perl
use strict;
use warnings;

# Privileged work first - we still have effective root.
open my $secret, '<', '/etc/some-restricted-file'
    or die "open: $!";
my $config = do { local $/; <$secret> };
close $secret;

# Drop privileges. From now on, both real and effective UID
# are the invoking user's, so any subsequent open/system call
# is checked against the real user.
$> = $<;                          # set effective UID  to real UID
$) = $(;                          # set effective GID  to real GID

# Now run the rest of the script as the real user.
do_user_work($config);
```

Permanent privilege drop **must** set effective before real (or both at once via `POSIX::setuid()`); on most systems setting real first will lock you out of restoring effective. Check `$!` after each assignment - the kernel rejects unauthorised changes:

```
$> = $<;
die "could not drop privileges: $!" if $> != $<;
```

Swapping real and effective

When you want to *temporarily* switch the effective ID for a single operation and then restore it:

```
my $saved_uid = $>;
$> = $<;                          # become real user
my $ok = open(my $fh, '<', $user_path);
```

(continues on next page)

(continued from previous page)

```
$> = $saved_uid;                    # back to effective
$ok or die "open $user_path: $!";
```

This works only on systems supporting `setreuid()` - most modern Unixes, including Linux. `POSIX::seteuid()` from the `POSIX` module is the explicit and portable spelling.

`$(` - real GID (with supplementary groups)

`$(` returns the real GID followed by every *supplementary group* the process belongs to, all space-separated:

```
print "Real GID list: $(\n";      # e.g. "1000 1000 4 27 100 999"
                                  #       primary + supplementaries
my @groups = split ' ', $(;
my $primary = $groups[0];
```

The leading number is the primary GID; the rest are supplementary groups (from `/etc/group`). Assigning to `$(` sets the GID; the syntax accepts a single number:

```
$( = 100;                           # become primary GID 100
```

`$)` - effective GID (with supplementary groups)

Same shape as `$(`, but for the effective GID:

```
print "Effective GID list: $)\n";

# Drop both real and effective GID to a specific gid:
$( = $) = "$gid $gid";
```

Permission checks use the effective GID and supplementaries; the real GID list is informational.

When you actually use these

Day-to-day Perl code does not touch UIDs and GIDs. The realistic use cases are:

1. **Setuid scripts** that need to drop privileges. Standard idiom shown above.
2. **Daemon startup** that runs as root to bind a privileged port, then drops privileges before serving requests:

```
socket(my $srv, ...) or die $!;
bind($srv, sockaddr_in(80, INADDR_ANY)) or die $!;
listen($srv, SOMAXCONN) or die $!;

# Now drop to nobody:nogroup before accepting connections.
my (undef, undef, $u, $g) = getpwnam('nobody');
$) = "$g $g";
$( = $g;
```

(continues on next page)

(continued from previous page)

```
$> = $u;
$< = $u;
```

3. **Privilege check** in a script that should refuse to run as root: `die "do not run me as root\n" if $< == 0`.

Tainted-mode interaction

Under `-T`, Perl notices when the real and effective IDs differ (i.e. the script is setuid) and turns on extra checks: certain operations refuse tainted arguments, and the search path for `system()` and `exec()` is constrained. The relevance here is that whether `-T` is on is decided based on `$<` vs `$>` at startup.

See also

- `getppid` - the *parent's* PID, paired with `$$`.
- `fork` - after which `$$` differs in parent and child.
- `getpwuid`, `getgrgid` - turn the numeric IDs into user and group names.
- `POSIX::setuid` - the portable, explicit way to change UIDs together.
- *Error variables* - `$!` after an `$<` / `$>` assignment tells you why the kernel refused.

Error state

Four variables report errors from four different layers. They are not interchangeable and they are populated by entirely different mechanisms; misusing one for another is the most common cause of "why doesn't my error handling work" bugs in Perl code.

Variable	Source	Lifetime
`$!`	C library `errno` from the last syscall	Set on syscall failure; meaningless otherwise
`$@`	The exception caught by the last `eval`	Set on `eval` exit (empty string on success)
`$?`	Exit status of the last child process	Set by every `wait`/pipe-close/`system`
`$^E`	OS-extended error info	Same as `$!` on Unix; richer on VMS/Win32

The single best thing you can do for your error handling is to internalise *which variable answers which question*:

- "Did my open/read/connect/syscall fail?" → check the return value first, then `$!`.
- "Did my `eval` block catch an exception?" → check `$@`.
- "What was the exit code of the program I just ran?" → decode `$?`.
- "Am I on Windows or VMS and need OS-specific error text?" → also look at `$^E`.

$! - the system error

`$!` is the Perl interface to the C library's `errno`. It has a *dual nature*: read it in numeric context to get the integer `errno`, in string context to get the corresponding error string:

```
open(my $fh, '<', '/no/such/file') or do {
    print  "errno = ", $! + 0, "\n";        # numeric: 2
    print  "errstr = $!\n";                 # string: "No such file
 ↪or directory"
};
```

Crucially, `$!` is **only meaningful immediately after a failure**. The C `errno` is not cleared on success, so a later read might see a stale value from any earlier system call. The reliable shape:

```
if (open my $fh, '<', $path) {
    # success - $! is meaningless here
    process($fh);
} else {
    # ONLY here is $! meaningful
    die "open $path: $!";
}
```

Writing the failure on the same line as the operation that caused it is the safest spelling - it leaves no opportunity for an intervening Perl operation to clobber `errno`.

%! - symbolic errno checks

`%!` is a hash whose keys are errno symbol names like `ENOENT`, `EACCES`, `EAGAIN`. A key tests true exactly when `$!` currently equals that errno:

```
unless (open my $fh, '<', $path) {
    if ($!{ENOENT}) {
        return [];                  # missing file → empty list
    }
    if ($!{EACCES}) {
        die "permission denied: $path";
    }
    die "open $path: $!";           # anything else: re-raise
}
```

This is portable - the numeric values of errno symbols differ across operating systems, but `%!` keys are always the symbol names. Behind the scenes, `%!` is provided by the `Errno` module, which is loaded on demand the first time you use the hash.

Assigning to $!

Writing to `$!` sets `errno` in the C library - useful for faking up an error message that downstream code will see:

```
$! = 13;                            # EACCES
print "$!\n";                       # "Permission denied"

# Slightly more idiomatic - set errno by symbol:
use Errno qw(:POSIX);
$! = EACCES;
die "synthetic permission failure: $!";
```

$@ - the exception variable

Set by `eval` when the block (or string) it ran threw an exception. It contains either the value passed to `die` (which is most often a string, but can be any reference) or the parsing/runtime error message from the interpreter.

```
eval {
    die "no port configured\n" unless defined $port;
    open(my $sock, '<', "/dev/tcp/$host/$port") or die "connect: $!
 ↪";
    1;
};
if ($@) {
    warn "could not open $host:$port - $@";
    return;
}
```

Successful evaluation sets `$@` to the empty string `''`. The `if ($@)` check is therefore reliable: empty string is false, any non-empty value is true.

The classic $@ clobbering bug

There is a hazard here. Anything that runs *between* the `eval` exit and your `if ($@)` check can clobber `$@`. The most common offender is an object's `DESTROY` method - when objects go out of scope at the close of the `eval` block, their `DESTROY` runs, and if `DESTROY` itself does any `eval`, your exception is gone:

```
eval {
    my $obj = MyClass->new;
    $obj->might_die;
    1;
};
# If MyClass::DESTROY does an eval, $@ is now empty.
warn "got: $@";                     # may print nothing!
```

The historically-recommended fix is to capture `$@` immediately, or to use the `Try::Tiny` module, which handles this and several related pitfalls:

```
my $err;
{
    local $@;                       # save and isolate
    eval {
```

(continues on next page)

(continued from previous page)

```
        risky_op();
        1;
    } or $err = $@ || 'unknown error';
}
if ($err) {
    warn "got: $err";
}
```

The Perl 5.34+ native `try/catch` feature is the cleaner modern spelling - it does not use `$@` at all and is not affected by the destructor problem:

```
use feature 'try';
try {
    risky_op();
} catch ($err) {
    warn "got: $err";
}
```

PetaPerl supports `try/catch` natively. New code should prefer it.

`eval` and `$!`

`eval` does **not** preserve `$!`. If your `eval` block did a syscall that failed and then `die`d, `$!` is whatever the *last* operation set it to - which inside a destructor or `local $SIG{__DIE__}` handler can be anything. If your error message needs `$!`, capture it inside the `eval`:

```
eval {
    open(my $fh, '<', $path) or die "open $path: $!\n";
    ...
};
```

The `\n` at the end is conventional - it suppresses the "at line N" suffix that Perl appends to die messages, which is right for user-facing errors.

`$?` - the child error

After a `system`, `waitpid`, `wait`, backtick command, or pipe close, `$?` contains the 16-bit `wait()` status of the child process. It is **not** simply the exit code:

```
system($cmd, @args);
my $status = $?;

my $exit_code = $status >> 8;        # exit value passed to exit() in the child
my $signal    = $status & 0x7F;      # signal that killed the child, or 0
my $coredump  = $status & 0x80;      # set if the child dumped core

if ($status == -1) {
```

(continues on next page)

(continued from previous page)

```
    die "system: $!";                # could not even fork/exec
} elsif ($signal) {
    die "$cmd died with signal $signal";
} elsif ($exit_code) {
    die "$cmd failed (exit $exit_code)";
}
```

The `>> 8` shift is the most-cited Perl gotcha there is. Only the upper byte is the exit code; the lower byte holds the signal-and-coredump flags. Forgetting the shift produces values multiplied by 256.

Modern Perl provides the `POSIX` module's `WEXITSTATUS`, `WIFSIGNALED`, `WTERMSIG`, `WIFEXITED` macros, which are the portable named accessors:

```
use POSIX ':sys_wait_h';
if (WIFEXITED($?))   { my $code = WEXITSTATUS($?); ... }
if (WIFSIGNALED($?)) { my $sig  = WTERMSIG($?);    ... }
```

`$?` is **not** preserved across other operations. If you need the value, capture it into a local variable on the next line - otherwise the next backtick or `system` will overwrite it.

`$?` in `END` blocks

Inside an `END` block, `$?` contains the intended exit code. Assigning to it overrides the script's exit status:

```
END {
    $? = 0 if $? == 255 && $shutdown_was_clean;
}
```

`$^E` - the extended OS error

On Unix, `$^E` is exactly the same as `$!`. On Windows, it contains the `GetLastError()` value, which is sometimes more informative than `errno` (which Win32 maps a coarse subset onto). On VMS, it is the native VMS status code.

PetaPerl is Linux-only. `$^E` and `$!` are interchangeable here; the variable exists for portable code that may also run on non-Unix perls.

Putting them together - a worked example

```
sub copy_file {
    my ($src, $dst) = @_;

    open my $in,  '<', $src or die "open $src for reading: $!";
    open my $out, '>', $dst or die "open $dst for writing: $!";

    eval {
        local $/ = \65536;       # block reads, scoped to this eval
```

(continues on next page)

(continued from previous page)

```
        while (defined(my $chunk = <$in>)) {
            print {$out} $chunk or die "write $dst: $!";
        }
        close $out                or die "close $dst: $!";
        1;
    } or do {
        my $err = $@ || 'unknown error';
        unlink $dst;              # clean up the partial file
        close $in;                # may set $! itself
        die "copy_file($src → $dst): $err";
    };

    close $in or warn "close $src: $!";
    return 1;
}
```

Three error variables in five paragraphs. `$!` reports each syscall failure on the line that triggered it. `$@` collects any exception that crossed the `eval` boundary. `$?` is not in this example because there is no child process - but if the function shelled out to `cp`, you would decode `$?` in the same shape as the `system` page.

See also

- `die` - populates `$@`. The usual way to raise an exception from your own code.
- `eval` - catches exceptions; sets `$@`.
- `system`, `waitpid`, `wait` - populate `$?`.
- `try/catch` - the modern alternative to `eval`/`$@` that side-steps the clobbering hazard.
- `Errno` - the source of `%!` keys; provides named errno constants.
- `Try::Tiny` - robust `eval` wrapper that preserves `$@` correctly.
- `%SIG` - `$SIG{__DIE__}` and `$SIG{__WARN__}` are the hooks that fire when `die` and `warn` run; they can rewrite `$@`.
- *Logical operators* - the `or die` idiom that drives almost all `$!` reporting.

Filehandle and printing state

Seven variables that drive Perl's I/O. They are *globals* - setting `$/` in one routine changes how every other routine in the same process reads from a filehandle. The discipline that keeps that from being a disaster is `local`-isation: every change to a variable on this page should be inside a `local` block unless the program genuinely wants the new value to be permanent.

Vari-able	Reads as	Default	Used by
`$/`	input record separator	`"\n"`	`<$fh>`, `readline`
`$\`	output record separa-tor	`undef`	`print`, `printf`, `say` (forced `\n`)
`$,`	output field separator	`undef`	`print`, `printf` (between args)
`$"`	list separator	`" "`	array interpolation `"@arr"`
`` `$ ``	`` ` ``	output aut-oflush	`0`
`$.`	current line number	`0`	last filehandle read
`$;`	subscript separator	`"\034"`	`$h{$x, $y}` multidim emula-tion

`$/` - the input record separator

Controls what `<$fh>` and `readline` treat as the end of one record. The default `"\n"` means *line-by-line* reading; setting it to other values produces other reading modes.

Line mode (the default)

```
while (my $line = <$fh>) {
    chomp $line;                # strips the terminator $/
    process($line);
}
```

`chomp` removes whatever `$/` currently holds - when you change `$/`, `chomp` follows it.

Slurp mode

`undef $/` makes <> read the entire file in one go:

```
my $whole_file = do {
    local $/;
    <$fh>;
};
```

The `local` is essential. Without it, every other piece of code that subsequently reads from a filehandle in the same process will silently slurp.

Paragraph mode

`local $/ = "";` reads paragraph-at-a-time, splitting on runs of two or more newlines:

```
{
    local $/ = "";
    while (my $para = <$fh>) {
        # $para ends with exactly two newlines (or one at EOF)
```

(continues on next page)

(continued from previous page)

```
        process_paragraph($para);
    }
}
```

This is awk's `RS=""` behaviour. Leading blank lines at the start of the file are silently skipped.

Fixed-record mode

`local $/ = \N` reads `N` bytes per call:

```
local $/ = \4096;                # binary 4-KiB chunks
while (defined(my $chunk = <$fh>)) {
    process($chunk);
}
```

The reference is to a number, not the number itself. This is the right shape for reading binary data, network packets, or doing bulk copy without scanning for `\n`.

Multi-character terminators

```
local $/ = "\r\n";               # CRLF mode
local $/ = "\nEND-OF-RECORD\n";  # custom marker
```

The terminator is a literal string, not a regex.

`$\` - the output record separator

Appended to every `print` call. Default is `undef` (nothing appended). Setting it changes every subsequent `print`:

```
{
    local $\ = "\n";             # all prints get a trailing newline
    print "first";
    print "second";
}
# Output: "first\nsecond\n"
```

This is the natural fit for `-l` on the command line - `-l` sets `$\` to `\n`. In script code, `local $\ = "\n"` inside a tight reporting loop is occasionally worth it; otherwise `say` (which forces `\n` regardless of `$\`) is the cleaner spelling.

`$,` - the output field separator

Inserted between `print`'s arguments. Default is `undef`:

```
print "a", "b", "c";              # "abc"

{
```

(continues on next page)

(continued from previous page)

```
    local $, = ", ";
    print "a", "b", "c";          # "a, b, c"
}

{
    local $, = "\t";
    print @items;                 # tab-separated record
}
```

`$,` is per-print, not per-line - it does not separate *successive* `print` calls. Combine with `$\` for full TSV-style output:

```
local ($,, $\) = ("\t", "\n");
print 'col1', 'col2', 'col3';     # "col1\tcol2\tcol3\n"
```

$" - the list separator

Joins array elements when an array is interpolated into a double-quoted string. Default is `" "` (single space):

```
my @arr = (1, 2, 3);
print "items: @arr\n";            # "items: 1 2 3"

{
    local $" = ', ';
    print "items: @arr\n";        # "items: 1, 2, 3"
}

{
    local $" = "\n  ";
    print "items:\n  @arr\n";     # "items:\n  1\n  2\n  3"
}
```

`$"` is *only* consulted on interpolation. `print @arr` (no quotes) uses `$,`, not `$"`.

$| - output autoflush

Forces a flush after every write on the **currently selected** filehandle:

```
$| = 1;                           # autoflush STDOUT
print "Loading..."; sleep 1;      # appears immediately, not at exit
```

The "currently selected" qualification matters. By default, `select` returns `STDOUT`, so `$| = 1` autoflushes STDOUT. To autoflush a different handle:

```
my $old = select($log_fh);
$| = 1;
select($old);                     # restore selection
```

The slightly nicer modern spelling uses `IO::Handle`:

```
$log_fh->autoflush(1);
```

`$|` is read-as-boolean: `print $|` shows `1` or `0`.

`$.` - current line number

The line number of the last <>-style read. Each filehandle has its own counter; reading from a different handle aliases `$.` to that handle's count:

```
while (<$fh>) {
    print "$.: $_";              # numbered listing
}

# After the loop, $. is the total number of lines read.
```

`$.` is reset when the filehandle is *closed*. Reopening (without an explicit close in between) does **not** reset.

For multi-file iteration via <>, lines are numbered cumulatively across files unless you explicitly close `ARGV` at each file boundary - see `eof` for the standard `close ARGV if eof;` idiom.

`$;` - the subscript separator

Used to fake multi-dimensional hashes - a deeply legacy feature preserved for backward compatibility:

```
$h{$x, $y} = $value;             # equivalent to $h{"$x\034$y"}
```

The default value is `"\034"` (FS, "file separator", an obscure ASCII control byte). Real multi-dimensional structures should use nested hash refs (`$h{$x}{$y}`); `$;` exists because Perl 4 had no proper references.

When you actually localise these

The most common shape, by far:

```
sub slurp_text {
    my ($path) = @_;
    open my $fh, '<', $path or die "open $path: $!";
    local $/;                    # slurp inside this sub only
    return <$fh>;
}

sub paragraphs_of {
    my ($path) = @_;
    open my $fh, '<', $path or die "open $path: $!";
    local $/ = "";
    return <$fh>;                # list context: list of paragraphs
}
```

(continues on next page)

(continued from previous page)

```
sub csv_print {
    my (@row) = @_;
    local ($,, $\) = (",", "\n");
    print @row;
}
```

The cost of forgetting `local` is invisible at write time and catastrophic at use time - a subroutine that "just sets `$/`" can break unrelated code reading from completely different filehandles. Treat `$/`, `$\`, `$,`, `$"` as *global mode flags*: always set them with `local`.

See also

- `open`, `readline`, `<$fh>` - the consumers of `$/`.
- `print`, `printf`, `say` - the consumers of `$\`, `$,`.
- `chomp` - removes whatever `$/` currently holds; pairs with `$/` changes.
- `eof` - the `close ARGV if eof` idiom that makes `$.` count per-file across `<>`.
- `select` - selects the filehandle that `$|` and the unprefixed `$,`/`$\` apply to.
- `IO::Handle` - provides `autoflush`, `output_record_separator`, etc. as method calls.
- `local` - the safe way to change any variable on this page.
- *Interpolation* - how `$"` shapes array expansion inside double-quoted strings.

Regex match variables

After every successful pattern match, Perl populates a fixed set of variables with information about *what* matched and *where*. These are read-only - you observe them, you do not write to them. The "successful" qualification is critical: an unsuccessful match leaves the variables holding *whatever the previous successful match in the same dynamic scope set them to*. Always gate your access with the boolean result of the match itself.

Variable	Holds
`$1..$N`	Text captured by the *N*th capturing group
`$&`	The entire matched substring
`$``	The string preceding the match
`$'`	The string following the match
`$+`	Text captured by the highest-numbered group
`$^N`	Text captured by the *most recently closed* group
`@-`	Start offsets: `$-[0]` = match, `$-[N]` = $N start
`@+`	End offsets: `$+[0]` = match end, `$+[N]` = $N end
`%+`	Hash of named captures: `$+{name}` = `(?<name>...)`
`%-`	Hash of *all* captures by name (arrayref values)
`@{^CAPTURE}`	Array of captures: `${^CAPTURE}[0]` = $1, etc.
`${^MATCH}`	Same as $&, populated only with the `/p` flag
`${^PREMATCH}`	Same as $`, only with `/p`
`${^POSTMATCH}`	Same as $', only with `/p`

The basic pattern

```
if ("Mr. Smith, age 47" =~ /(\w+)\s+(\w+),\s+age\s+(\d+)/) {
    print "title: $1\n";          # Mr
    print "name:  $2\n";          # Smith
    print "age:   $3\n";          # 47
    print "match: $&\n";          # the full match
}
```

The `if` is what makes the access safe. Without it, on a *non-matching* string, `$1`/`$&` would still hold values from some earlier successful match - there is no "match failed → clear" rule.

Numbered captures - $1..$N

Each `(...)` capturing group fills one variable. The numbering is left-to-right by *opening* parenthesis:

```
"alpha-beta=42" =~ /^(\w+)-(\w+)=(\d+)$/;
print "$1 / $2 / $3\n";           # alpha / beta / 42
```

Non-capturing groups `(?:...)` and lookarounds `(?=...)`/`(?!...)` do **not** consume a number; they are invisible to the count.

For `s///` substitutions, `$1..$N` are visible inside the replacement (along with the substitution-only `$1`-style backreferences in single-quoted replacements):

```
my $s = "John Smith";
$s =~ s/(\w+)\s+(\w+)/$2, $1/;    # "Smith, John"
```

Named captures - (?<name>...) and %+

Named captures are clearer than counting parentheses, especially in patterns with many groups:

```
my $log = "2024-03-15 14:32:01 ERROR connection refused";
if ($log =~ /^(?<date>\d{4}-\d{2}-\d{2})
              \s+
              (?<time>\d{2}:\d{2}:\d{2})
              \s+
              (?<level>\w+)
              \s+
              (?<msg>.*)$/x) {
    print "[$+{level}] $+{date} $+{time}: $+{msg}\n";
}
```

`%+` is the named-capture hash. The numbered forms still work (named captures are also assigned numbers in the order they appear), so `$1` would be `$+{date}` here.

`%-` is similar but its values are array references, holding *every* capture under that name (relevant when using branch-reset groups `(?|...|...)` or when a name is reused across alternation branches):

```
"abc" =~ /(?|(?<x>a)|(?<x>b)|(?<x>c))/;
print "%-{x} has @{$-{x}}\n";    # captured value(s) under name 'x'
```

Most code only ever reads `%+`. `%-` is for the corner cases.

Match boundaries - `@-` and `@+`

The match's start and end offsets in the matched string:

```
"hello world" =~ /(\w+)\s+(\w+)/;
print "match started at $-[0], ended at $+[0]\n";   # 0 .. 11
print "group 1: $-[1] .. $+[1]\n";                  # 0 .. 5
print "group 2: $-[2] .. $+[2]\n";                  # 6 .. 11
```

`$-[N]` and `$+[N]` give the same information as `substr($var, $-[N], $+[N] - $-[N])` would extract - they are how you reconstruct *positions*, not values, after a match.

The classic use: replacing matched substrings while preserving the original (without the `s///` operator):

```
my $s = "the quick brown fox";
$s =~ /quick (brown)/;
my $before = substr($s, 0, $-[0]);
my $after  = substr($s, $+[0]);
my $g1     = substr($s, $-[1], $+[1] - $-[1]);
print "$before|FOUND $g1|$after\n";
```

`$&`, `$``, `$'` - match, prematch, postmatch

```
"hello world" =~ /wo\w+/;
print "before: '$`'\n";          # 'hello '
print "match:  '$&'\n";          # 'world'
print "after:  '$\''\n";         # ''
```

These three are Perl's oldest match variables and historically the most expensive - see *Performance: the* `$&` *story* below.

`$+` is the text captured by the *highest-numbered* group that participated in the match:

```
"abc" =~ /(a)(b)?(c)?/;          # $1='a', $2='b', $3='c', $+='c'
"a"   =~ /(a)(b)?(c)?/;          # $1='a', $2=undef, $3=undef, $+='a
 ↪'
```

`$^N` is similar but holds the most-recently-*closed* group's text - useful inside complex patterns that need the value of "the group that just finished":

```
my $s = "tag:value";
$s =~ /(\w+):(\w+) (?{ $cb = $^N })/;
# $cb is the text most recently captured (here: "value")
```

Performance: the $& story

Historical caveat that you will find in old code and in books:

> Don't mention `$&`, `$\``, or `$'` *anywhere* in your code, including in modules you require - they cause every successful match to copy the whole matched string, slowing the program down.

This was true through Perl 5.10. From Perl 5.18 onward, the runtime tracks *which* of the three variables your code actually mentions and only copies what is needed. From Perl 5.20 a copy-on-write scheme makes them effectively free.

PetaPerl follows the modern behaviour: `$&` and friends are safe to use anywhere. The `/p` flag and `${^MATCH}` / `${^PREMATCH}` / `${^POSTMATCH}` exist for the era between 5.10 and 5.20 when `/p`-gated copying was a useful optimisation. There is no reason to write new code with them.

Scoping - they are dynamically scoped

The match variables are not lexicals; they behave like dynamically-scoped variables. Every successful match localises a *global match state* to the current dynamic scope. Crucially:

- An *unsuccessful* match does **not** clear the variables.
- A successful match *inside an inner block* overrides them, but only within that block - when the inner block exits, the outer scope's match state is restored.

```
"alpha" =~ /(\w+)/;              # $1 = 'alpha'
{
    "1234" =~ /(\d+)/;           # $1 = '1234' (inside this block)
    print "inner: $1\n";          # 1234
}
print "outer: $1\n";              # alpha - restored
```

This is occasionally surprising: a function you call from inside a regex-handling block does not pollute your `$1` unless that function does its own successful match in the *same* dynamic scope (which is rare unless they are running in the same lexical block).

${^LAST_SUCCESSFUL_PATTERN}

A read-only reference to the regex that produced the current match state - useful for diagnostics:

```
"hello" =~ /(\w+)/;
print "last pattern was: ${^LAST_SUCCESSFUL_PATTERN}\n";
```

When matches fail - pos

The position on a string after a `/g`-anchored match is held *not* in one of the variables on this page, but in `pos`:

```
my $s = "1 2 3 4";
while ($s =~ /(\d+)/g) {
    print "matched $1 at ", pos($s) - length($1), "\n";
}
# After the loop, pos($s) is undef.
```

`pos` is per-string, settable, and is what `\G` anchors to.

`@{^CAPTURE}` - captures as an array

The numbered captures, also exposed as a zero-indexed array:

```
"alpha=42" =~ /(\w+)=(\d+)/;
print "name = ${^CAPTURE}[0]\n"; # 'alpha' (same as $1)
print "val  = ${^CAPTURE}[1]\n"; # '42'    (same as $2)
print "n    = scalar @{^CAPTURE}\n";  # 2
```

This is occasionally easier to iterate than `$1, $2, ...`, but most code uses the numbered or named forms directly.

Interpreter introspection

Variables that expose the running Perl interpreter and its configuration. Most code never touches them; the cases where they matter are version checks, OS-conditional logic, profiler hooks, and in-place editing.

Variable	Holds
`$]`	Perl version as a numeric string (`5.044000`)
`$^V`	Perl version as a `version` object (`v5.44.0`)
`$^O`	Operating system name (`linux`, `darwin`, ...)
`$^X`	Path to the running Perl/PetaPerl executable
`$^T`	Process basetime (Unix epoch seconds)
`$^W`	Warnings master switch (boolean)
`$^I`	In-place edit extension (set by `-i`)
`$^P`	Debugger flag bitmask
`$^R`	Last regex code-block result
`$^S`	Exception-handling state (in `eval`? `undef`/0/1)
`${^GLOBAL_PHASE}`	Current interpreter phase (`START`, `RUN`, `END`, ...)

`$]` - numeric version

A floating-point representation of the interpreter version. Format: `5.PPPSSS` where `PPP` is the major and `SSS` the patch:

```
print "$]\n";                    # e.g. "5.044000"
warn "old perl"  if "$]" < 5.038;
warn "new perl"  if "$]" >= 5.040;
```

The `"$]"` stringification before comparison is recommended - it sidesteps subtle floating-point representation issues that can make `$] == 5.044` mysteriously fail.

The English alias `$OLD_PERL_VERSION` is documented but discouraged; `$]` itself is fine.

`$^V` - version object

The interpreter version as a `version` object, suitable for reading and for richer comparison:

```
print "$^V\n";                   # "v5.44.0"
warn "need 5.40+" if $^V lt v5.40.0;
```

The literal `v5.40.0` is a v-string - Perl's native syntax for version constants. Use `$^V` when comparing to v-string literals; use `$]` when comparing to bare numerics.

In PetaPerl, `$^V` reports the underlying Perl-compatibility level (5.44), not the PetaPerl release version.

`$^O` - operating system name

```
print "$^O\n";                   # "linux"
if ($^O eq 'MSWin32') {
    use_windows_path_separator();
}
```

PetaPerl is Linux-only; `$^O` is always `"linux"`. The variable exists for source-compatibility with portable code that branches on it. The full list of values

upstream Perl can produce includes `linux`, `darwin`, `freebsd`, `openbsd`, `MSWin32`, `cygwin`, `solaris`, and several historical entries.

`$^X` - executable path

The path to the interpreter currently running, suitable for re-invoking:

```
print "$^X\n";                    # e.g. "/usr/local/bin/pperl"

# Rerun the script under the same interpreter, with extra args:
exec $^X, $0, @ARGV, '--debug';
```

`$^X` is what makes `exec $^X, $0, ...` portable - you do not need to know whether the script was started via `pperl`, `/usr/bin/env perl`, or an absolute path.

`$^T` - basetime

The Unix epoch second at which the program started running:

```
my $uptime = time() - $^T;
print "running for $uptime seconds\n";
```

The classic use is the `-M` and `-A` filetests, which by default report file ages *relative to* `$^T` rather than to `time()`. If you set `$^T = time()` periodically, those filetests recompute against the new reference point - useful in long-running daemons that need to ignore files older than "since I started this batch".

`$^W` - the warnings switch

The master warnings flag, set by the `-w` command-line switch:

```
$^W = 1;                          # all warnings on
$^W = 0;                          # all warnings off
```

`$^W` is the Perl-1-era global flag. The modern lexical `use warnings` pragma is the recommended way to control warnings, and operates independently - a `use warnings` block stays on regardless of `$^W`, and a `no warnings` block stays off regardless of `$^W`. The variable mostly matters in code that pre-dates the lexical pragma or that wants to toggle the global default at runtime.

`${^WARNING_BITS}` is the lexical bitmap that `use warnings` reads and writes. Its format is internal; do not rely on specific bit positions.

`$^I` - in-place edit extension

Set by the `-i` command-line switch. When `$^I` is defined, reading from `<>` (the `while (<>)` form) re-opens each file for both read and write and redirects subsequent `print` to the rewritten file:

```
# perl -i.bak -ne 's/\bold\b/new/g; print' *.txt
# Equivalent in script form:
```

(continues on next page)

(continued from previous page)

```
local $^I = '.bak';
while (<>) {
    s/\bold\b/new/g;
    print;
}
```

`$^I = ''` (empty string) means "rewrite in place without a backup". `$^I = '.bak'` saves the original as `<filename>.bak`. Setting `$^I = undef` turns in-place editing off.

$^P - debugger flag bitmask

Read by the Perl debugger; if non-zero, `DB::DB` is called before every statement. Manipulated by `perl -d` and the `Devel::*` family of debugger and profiler modules.

User code rarely sets `$^P`. The flag bits are documented in upstream perlvar; the most commonly seen value is `0x73f` (full debugging).

$^R - regex code-block result

The result of the last `(?{...})` or `(?(N)...)` regex code assertion. Lives only as long as the surrounding match:

```
"abc123" =~ /(?<word>\w+?)(\d+)(?{ length($1) + length($2) })/;
print "$^R\n";                  # 6 - the code block's last␣
↪expression
```

PetaPerl supports `(?{ })` regex code blocks; see the *performance chapter* of the regex guide for the language details.

$^S - exception-handling state

Reports whether the interpreter is currently inside an `eval`. It holds one of three values:

$^S	Meaning
undef	Parsing a module, an `eval`, or the main program
1 (true)	Executing inside an `eval` or `try` block
0 (false)	Anywhere else

The `undef` state is the one that matters: it can occur inside a `$SIG{__DIE__}` or `$SIG{__WARN__}` handler, where the interpreter is compiling rather than running. A handler that needs to behave differently during compilation tests for it:

```
local $SIG{__DIE__} = sub {
    return if $^S;              # real runtime exception - let it␣
↪propagate
    warn "compile-time failure: $_[0]";
};
```

The legacy long name (`use English`) is `$EXCEPTIONS_BEING_CAUGHT`, which is slightly misleading: the `undef` value does not tell you whether exceptions are being caught, because compiling the main program does not catch them.

`${^GLOBAL_PHASE}` - current interpreter phase

The current life-cycle phase of the Perl interpreter:

Phase	When
`CONSTRUCT`	Inside the C-level interpreter constructor
`START`	`BEGIN` blocks, `use`, `require`, top-level compile
`CHECK`	After compilation, before `INIT`
`INIT`	`INIT` blocks
`RUN`	Main program execution
`END`	`END` blocks
`DESTRUCT`	Global destruction

```
END {
    if (${^GLOBAL_PHASE} eq 'END') {
        log_shutdown();           # we are still in user END
    }
}

# Inside a destructor, distinguish "object cleanup during normal
# scope exit" from "object cleanup during interpreter shutdown":
sub DESTROY {
    my $self = shift;
    if (${^GLOBAL_PHASE} eq 'DESTRUCT') {
        # global destruction - order is undefined, file handles
        # may already be torn down - be conservative
        return;
    }
    $self->{handle}->flush;
}
```

The "don't run during global destruction" guard inside `DESTROY` is the variable's classic use case. During `DESTRUCT`, the order of object teardown is not defined; an object's references may already be invalid.

See also

- `use VERSION` - the conventional way to require a minimum Perl version, replacing `if "$]" < ...`.
- `require VERSION` - same as `use VERSION` but at runtime.
- `Config` - the full Perl build configuration, much richer than `$^O` and `$]`.
- `use warnings` - the lexical pragma that supersedes `$^W` for new code.
- *Command-line switches* - documents `-i` (`$^I`), `-w` (`$^W`), `-d` (`$^P`).

Program input - @ARGV, %ENV, @INC

Three globals carry input *into* the program: command-line arguments, environment variables, and the module search path. They share enough context that decisions about one usually inform the others - `@ARGV` interacts with `$0`, `%ENV`'s Perl-relevant keys influence `@INC`, and `@INC`'s ordering question is mirrored by similar concerns for `@ARGV` consumers and shell `PATH`.

Variable	Holds
`@ARGV`	Command-line arguments (excluding script name)
`$0`	Script name (paired with `@ARGV`)
`%ENV`	Process environment
`@INC`	Module search path (used by `use`/`require`)
`%INC`	Already-loaded modules
`$INC`	Current `@INC` index during a hook (5.37.7+)

@ARGV and its relationship to $0

After Perl starts, the *script name* is in `$0` and the *script's arguments* are in `@ARGV`:

```
$ pperl myscript.pl -v --output /tmp/x foo bar
```

```
print "$0\n";                    # myscript.pl
print "@ARGV\n";                 # -v --output /tmp/x foo bar
print scalar(@ARGV), " args\n";  # 5 args
```

`$ARGV[0]` is the *first script argument*, **not** the script name itself. This differs from C's `argv` (where `argv[0]` is the program name); Perl exposes the program name separately via `$0`.

Standard argument handling

Hand-written arg parsing is fine for trivial scripts:

```
my %opt;
while (@ARGV && $ARGV[0] =~ /^-/) {
    my $flag = shift @ARGV;
    last if $flag eq '--';
    if    ($flag eq '-v')      { $opt{verbose} = 1 }
    elsif ($flag eq '--output'){ $opt{output}  = shift @ARGV }
    else                       { die "unknown flag: $flag\n" }
}
my @files = @ARGV;
```

For anything beyond toy scripts, the `Getopt::Long` module handles every standard pattern (long options, abbreviation, mandatory arguments, repeated flags, `--` separator, automatic help):

```
use Getopt::Long;
my %opt;
GetOptions(
    'verbose|v'    => \$opt{verbose},
    'output|o=s'   => \$opt{output},
    'help|h'       => \$opt{help},
) or die "bad options; try --help\n";
my @files = @ARGV;              # what's left after option␣
↪processing
```

`GetOptions` mutates `@ARGV` in place - when it returns, `@ARGV` contains only the non-option arguments.

@ARGV and the diamond operator

The `<>` (diamond) operator iterates lines from the files named in `@ARGV`, falling back to STDIN if `@ARGV` is empty:

```
while (<>) {
    # one line from one of the @ARGV files (or STDIN)
    chomp;
    process($_);
}
```

This is the default contract of every awk-style filter program. `<>` opens each file in turn, sets `$ARGV` to its name during reading, and closes it at EOF.

`-i` and the other `-` switches (`-n`, `-p`, `-l`, `-a`) all build their behaviour on this `@ARGV` → `<>` pattern.

Modifying @ARGV before <>

You can pre-process `@ARGV` to alter what `<>` reads:

```
# Add an extra file to the front of the argv list:
unshift @ARGV, 'header.txt';

# Process compressed files transparently by rewriting argv:
@ARGV = map { /\.gz$/ ? "gunzip -c $_ |" : $_ } @ARGV;

while (<>) {
    process($_);
}
```

The `cmd |` form turns the argument into a pipe-from-command open; this is a long-standing Perl idiom for transparent decompression in awk-style scripts.

%ENV - the process environment

%ENV is the hash of environment variables inherited from the parent process (typically the shell). Reading is straightforward:

```
my $home     = $ENV{HOME};
my $term     = $ENV{TERM} // 'dumb';
my $path     = $ENV{PATH};
```

Writing changes the environment seen by *child processes* that this Perl script subsequently spawns:

```
$ENV{LC_ALL}      = 'C';           # POSIX locale for child commands
$ENV{TZ}          = 'UTC';
$ENV{LANG}        = 'C';
delete $ENV{LC_NUMERIC};           # remove a key entirely

system('date');                     # child sees the modified ENV
```

The change does *not* propagate back to the parent - the shell that started the script keeps its original environment. If you need the parent shell to pick up new values, write them to a file or have the shell `eval` your output (the standard `dotenv` pattern).

Stringification of values

As of Perl 5.18, %ENV values are always stringified at assignment time. Storing a reference no longer round-trips:

```
my $arr = [1, 2, 3];
$ENV{DATA} = $arr;
print $ENV{DATA};                  # "ARRAY(0x...)" - stringified
```

Environment variables are a string-typed interface to the operating system; preserving structure across a `fork`/`exec` boundary would not work anyway. Marshal anything non-trivial as JSON or similar before storing.

Perl-specific environment variables

A small set of environment variables are honoured by Perl itself, *not* by user scripts:

Variable	Effect
PERL5LIB	Colon-separated paths prepended to @INC (subject to taint rules)
PERLLIB	Same, older variable; used only if PERL5LIB is unset
PERL5OPT	Switches applied as if on the command line (subset only)
PERLDB_OPTS	Options for the debugger
PERL_UNICODE	Default UTF-8 layer settings (mirrors -C)
PERL_USE_UNSAFE_INC	Re-add . to @INC (removed by default since 5.26 - strongly discouraged)
PERL_HASH_SEED	Per-run hash randomisation seed
PERL_SIGNALS	unsafe to opt out of deferred signal handling
HOME	Read by ~ glob expansion; not Perl-specific but Perl-relevant
PATH	Searched by system/exec for unqualified commands

In tainted mode (-T), PERL5LIB, PERL5OPT, and PERLLIB are ignored to prevent privilege escalation. See the *command-line switches guide* for the full security model.

delete $ENV{KEY} versus $ENV{KEY} = undef

The two are *not* equivalent:

```
delete $ENV{KEY};                  # KEY is not in the environment
$ENV{KEY} = undef;                 # KEY is in the environment, value
 ↪""
```

A child process started after delete will not see KEY at all - getenv("KEY") returns NULL. After undef assignment, the child sees KEY="" (empty string). Code that distinguishes "unset" from "set to empty" cares about this difference.

@INC - the module search path

When use and require look up a module, they walk @INC left to right and stop at the first match:

```
print "$_\n" for @INC;
# /usr/local/lib/perl5/site_perl/5.44.0/x86_64-linux
# /usr/local/lib/perl5/site_perl/5.44.0
# /usr/local/lib/perl5/5.44.0/x86_64-linux
# /usr/local/lib/perl5/5.44.0
# (no trailing "." since Perl 5.26)
```

@INC is initialised at startup from a combination of:

1. Compiled-in defaults (the build-time installprivlib, installsitelib, ...).
2. -I /path switches on the command line, *prepended* in order.
3. The PERL5LIB (or PERLLIB) environment variable, also prepended.

After startup it is just an ordinary array. *Order matters*: a match in an early element wins.

`use lib` versus `unshift @INC` versus `push @INC`

Three ways to add a path. They are not equivalent:

```
use lib '/my/lib';                      # unshift at compile-time
unshift @INC, '/my/lib';                # unshift at runtime
push    @INC, '/my/lib';                # push    at runtime
```

The differences:

- **`use lib`** runs at *compile time*. It happens before any `use` statement that follows it on the page. This is what you almost always want when you're saying "this script needs a custom library directory":

  ```
  use lib '/opt/myapp/lib';
  use MyApp::Module;                    # found because lib was␣
   ↪unshifted first
  ```

  Internally `use lib '/path'` does `BEGIN { unshift @INC, '/path' }`, so the new path is searched *first* - a copy of a module in `/opt/myapp/lib` shadows one in the system `@INC`.

- **`unshift @INC, '/path'`** at the top level has *runtime* semantics. It works for `require` calls that happen after the `unshift`, but a `use` statement on a later line of the same file *will not see it* (because `use` is itself compile-time):

  ```
  unshift @INC, '/my/lib';
  use Some::Module;                     # NOT found in /my/lib -␣
   ↪too early
  ```

  This is a frequent gotcha. `BEGIN { unshift @INC, '/my/lib' }` fixes it; `use lib` is the cleaner spelling of exactly that.

- **`push @INC, '/path'`** appends. The new path is searched *last*. This is the right choice when you want your library to be a fallback - used only if no other location has the module - for example, providing a built-in version of a CPAN module that the user might have installed on the system.

The rule of thumb: *always* use `use lib` for "I want my code's module path to take effect at compile time", which is almost every case.

`@INC` hooks

`@INC` may contain not only paths but also code references and blessed objects. When `require` encounters one of these, it calls it as a hook - passing the requested module path - and the hook returns either an open filehandle or a list of source code, generators, etc. This is how mechanisms like `Module::Pluggable`, `PAR`, and `Test::MockModule` intercept module loading.

The full hook protocol is documented under `require`. Most users never write one; you read about them when debugging "why does this module not load from where I expect" problems.

%INC - the loaded-modules cache

After a module is successfully loaded, %INC records it. The key is the path Perl was asked to find (e.g. Foo/Bar.pm); the value is the absolute path that satisfied the request:

```
use Data::Dumper;
print "Data::Dumper loaded from $INC{'Data/Dumper.pm'}\n";
# /usr/local/lib/perl5/site_perl/5.44.0/Data/Dumper.pm

# Show every loaded module:
for my $key (sort keys %INC) {
    print "$key  →  $INC{$key}\n";
}
```

require checks %INC before walking @INC - a second require Foo; is a no-op because Foo.pm is already in the cache. To force a re-require:

```
delete $INC{'Foo.pm'};
require Foo;                    # actually re-runs Foo.pm
```

This is the standard idiom for testing reload behaviour. Be aware that re-running a module file does **not** un-define what the first run created - packages, subs, and globals stay around.

$INC - the index inside an @INC hook

Available since Perl 5.37.7. When an @INC hook is being called, $INC is set to the index of the hook in @INC. After the hook returns, the iterator advances based on $INC + 1 - so the hook can rewrite @INC and steer the search to a specific position afterwards. This is an advanced feature; everyday code never touches it.

- use, require - the consumers of @INC/%INC.
- use lib - the canonical compile-time spelling for prepending to @INC.
- Getopt::Long - the standard parser for @ARGV.
- readline - the function form of the diamond <> operator that drives @ARGV → STDIN filtering.
- -i, -n, -p, -a - command-line switches built on @ARGV.
- *Process variables* - $0 is the script name; $$ is the PID; pair these with @ARGV for self-restart and logging.
- *Command-line one-liners* - the tutorial showing every @ARGV/<>/switch combination in context.

Signal handling - %SIG

%SIG is the hash where Perl exposes signal handlers. Setting $SIG{NAME} installs a handler for signal NAME; deleting it restores the default action. Two pseudo-signals - __WARN__ and __DIE__ - are not real OS signals at all but interpreter hooks into warn and die.

The signal table

Real OS signals come from the POSIX and signal.h lists. The common ones - keys you will actually use:

Key	Signal	Default action	When you handle it
INT	SIGINT	terminate	Ctrl-C: graceful shutdown
TERM	SIGTERM	terminate	kill <pid>: graceful shutdown
HUP	SIGHUP	terminate	terminal hangup; daemons reload config
QUIT	SIGQUIT	terminate + core	Ctrl-: like INT but with a core dump
PIPE	SIGPIPE	terminate	wrote to a closed pipe; usually ignored
CHLD	SIGCHLD	ignore	a child process died (waitpid here)
USR1	SIGUSR1	terminate	application-defined event
USR2	SIGUSR2	terminate	application-defined event
ALRM	SIGALRM	terminate	alarm() timer expired
WINCH	SIGWINCH	ignore	terminal window resized
IO	SIGIO	terminate	async I/O ready

The full list - including signals you cannot catch (KILL, STOP) and platform-specific signals - comes from the POSIX module, which exports the numeric constants (SIGINT, SIGTERM, ...) and the WIFEXITED-family wait macros.

Installing a handler

Three handler-value forms are accepted:

```
$SIG{INT}  = \&handler;          # code reference - preferred
$SIG{INT}  = sub { ... };         # anonymous sub  - also fine
$SIG{INT}  = 'IGNORE';            # ignore the signal
$SIG{INT}  = 'DEFAULT';           # restore default action
$SIG{INT}  = '';                  # same as DEFAULT
$SIG{INT}  = undef;               # same as DEFAULT
```

Don't use a *bareword* ($SIG{INT} = 'handler') - that references a *name* in the main:: package, which Perl looks up each time the signal arrives. If you rename handler, the bareword form silently keeps targeting the old name.

The handler receives one argument - the signal name as a string:

```
sub handler {
    my ($signame) = @_;
    print "received SIG$signame\n";
}
```

(continues on next page)

(continued from previous page)

```
$SIG{INT}  = \&handler;
$SIG{TERM} = \&handler;
```

Safe signals - the deferred-delivery rule

Since Perl 5.8, signal delivery is **deferred**. When a signal arrives, the OS sets a flag in the interpreter; the actual Perl handler runs only at the next *safe point* - typically between op-code executions. This means:

- A handler **cannot** interrupt a `read`, `open`, `connect`, or any other syscall mid-call. Slow syscalls return early with `EINTR` in `$!` and the handler runs after.
- A handler **cannot** interrupt a regex match in progress. A long-running regex on a malicious input will not be cut short by SIGINT.
- The handler runs in regular Perl context. It can call any Perl code, allocate memory, throw exceptions - none of the re-entrancy hazards of C signal handlers.

This is the right trade-off for almost every program. If you genuinely need pre-5.8 *unsafe* signal handling - handlers that run synchronously in the signal context, with all the re-entrancy hazards - set the `PERL_SIGNALS=unsafe` environment variable before starting Perl. Do not do this casually.

PetaPerl implements deferred-delivery signal handling.

The graceful-shutdown pattern

The standard shape: a flag set by the handler, checked by the main loop:

```
my $shutting_down = 0;
$SIG{INT}  = sub { $shutting_down = 1 };
$SIG{TERM} = sub { $shutting_down = 1 };

while (my $job = $queue->next) {
    last if $shutting_down;       # check at a safe point
    process($job);
}

if ($shutting_down) {
    log_and_close();
    exit 0;
}
```

The main loop polls the flag at a place where it is safe to unwind cleanly. The handler does *only* "set the flag" - no logging, no I/O - minimising the time it spends running.

For applications that block on a long syscall (`accept`, `read`, `select`), the loop has to be structured to retry on `EINTR`:

```
my $shutting_down = 0;
$SIG{INT}  = sub { $shutting_down = 1 };
```

(continues on next page)

(continued from previous page)

```
while (!$shutting_down) {
    my $client = accept($srv, $sock);
    unless (defined $client) {
        next if $!{EINTR};        # signal woke us up - re-check␣
↪flag
        die "accept: $!";
    }
    handle($client);
}
```

`$!{EINTR}` (see *error variables*) tells you the syscall exited because a signal arrived. The flag was set by the handler; the main loop sees the wake-up, re-checks `$shutting_down`, and exits cleanly.

Reaping child processes - SIGCHLD

When a child process exits, the parent gets SIGCHLD. The handler must call `waitpid` to *reap* the zombie:

```
$SIG{CHLD} = sub {
    while ((my $kid = waitpid(-1, WNOHANG)) > 0) {
        my $status = $?;
        log_child_death($kid, $status);
    }
};
```

The `while` loop with `WNOHANG` (from `POSIX :sys_wait_h`) handles the case where two children exit close together - only one SIGCHLD is delivered (it is not queued), so the handler must drain *all* pending exits each time it runs.

`$SIG{CHLD} = 'IGNORE'` is a special case: it does not just ignore the signal, it tells the kernel to auto-reap children. Use this when your script forks children whose exit status you do not care about.

SIGPIPE - the closed-pipe case

When you `print` to a pipe whose reader has gone away, the kernel sends SIGPIPE. The default action is to terminate the process - which is rarely what you want. Most filter programs should ignore SIGPIPE and check the `print` return value instead:

```
local $SIG{PIPE} = 'IGNORE';

print {$child_pipe} $data
    or die "write to pipe: $!";  # $! will be EPIPE if the reader␣
↪closed
```

With the handler ignored, the syscall returns failure with `EPIPE` rather than killing the program.

Timeouts via SIGALRM

Combined with `alarm` and an `eval` block, SIGALRM provides a portable timeout for any blocking operation:

```
sub with_timeout {
    my ($seconds, $code) = @_;
    my $result;
    eval {
        local $SIG{ALRM} = sub { die "TIMEOUT\n" };
        alarm $seconds;
        $result = $code->();
        alarm 0;                    # cancel the timer
        1;
    } or do {
        die $@ unless $@ eq "TIMEOUT\n";
        return undef;
    };
    return $result;
}

my $line = with_timeout(5, sub { <$slow_socket> });
```

The pattern:

1. `local $SIG{ALRM}` - handler is in scope only for this call.
2. `alarm $seconds` - schedule the signal.
3. Perform the blocking work.
4. `alarm 0` - cancel the timer if work succeeded.
5. Inside the handler, `die "TIMEOUT\n"` - the trailing `\n` suppresses the "at line N" suffix and makes the error value easy to test against.

__WARN__ and __DIE__ - interpreter hooks

These two keys in `%SIG` are *not* OS signals. They are called when the interpreter is about to emit a warning (`warn`) or throw a fatal exception (`die`).

$SIG{__WARN__} - warning interception

```
my @warnings;
{
    local $SIG{__WARN__} = sub {
        my ($msg) = @_;
        push @warnings, $msg;
    };
    do_thing_that_might_warn();
}
# Now @warnings holds every warning that fired inside the block,
# without anything having printed to STDERR.
```

A `__WARN__` handler that does nothing silences the warning entirely. A handler that calls `die` upgrades warnings into exceptions:

```
local $SIG{__WARN__} = sub { die $_[0] };
eval { something_warny() };       # warns become catchable
```

The lexical pragma `use warnings FATAL => 'all'` is a more targeted way to do this - it makes warnings fatal only in the lexical scope where the pragma is active. Use it instead of `__WARN__` for "treat warnings as errors" requirements.

$SIG{__DIE__} - die interception

A `__DIE__` handler runs when `die` is about to throw - both for uncaught exceptions and inside `eval`. Inside an `eval`, the handler runs *before* the exception is caught, which is the classic source of confusion: a global `__DIE__` handler that logs every "death" will fire on every `eval { ... }` that calls `die` for ordinary control flow.

```
$SIG{__DIE__} = sub { print STDERR "dying: $_[0]" };
eval { die "expected error" };    # the handler still runs!
```

If you want a global death logger, gate it on `$^S`:

```
$SIG{__DIE__} = sub {
    return if $^S;                # inside eval - let it be caught
    print STDERR "uncaught: $_[0]";
};
```

Realistically, **avoid $SIG{__DIE__} for new code**. The pragma `use warnings` and the *error variables* cover what you need without the surprise. The modern `try/catch` feature handles exceptions explicitly without the action-at-a-distance of `$SIG{__DIE__}`.

Listing available signals

```
use Config;
my @signals = split / /, $Config{sig_name};
print "available signals: @signals\n";
# HUP INT QUIT ILL TRAP ABRT BUS FPE KILL ...
```

Or, for the numeric→name mapping:

```
use Config;
my @names = split / /, $Config{sig_name};
my @nums  = split / /, $Config{sig_num};
my %sig_num  = map { $names[$_] => $nums[$_] }  0..$#names;
my %sig_name = map { $nums[$_]  => $names[$_] } 0..$#names;
```

This is what most signal-listing utilities do internally.

- *Signal handling* - %SIG, $SIG{__WARN__}, $SIG{__DIE__}. The signals you can catch, the safe-signals rule, and the standard graceful-shutdown shape.

Variable namespaces

Each special variable lives in **one** specific namespace. Most are in main::; some (@F, @ISA) are package-local. Every variable's documentation says which.

The naming convention is a punctuation choice and a sigil:

- $<digit> - regex capture variables.
- $<symbol> - single-character variables ($_, $!, $@, $/, ...).
- $^<letter> - control-letter variables ($^V, $^W, $^X). Spelled with a literal caret followed by an uppercase letter.
- ${^NAME} - extended-name variables (${^GLOBAL_PHASE}, ${^CAPTURE}). The braces and caret are required.

- `$NAME` after `use English` - the named alias for almost every punctuation variable. `$ERRNO` is `$!`, `$EVAL_ERROR` is `$@`, etc.

The English module

```
use English;            # all aliases, plus $PREMATCH/$MATCH/
 ↪$POSTMATCH
use English qw( -no_match_vars );    # skip $`, $&, $' aliases
```

`English` provides readable aliases for the punctuation variables: `$EVAL_ERROR` for `$@`, `$INPUT_RECORD_SEPARATOR` for `$/`, and so on. The aliases are real Perl variables that share storage with the originals - assigning to one writes the other.

The `-no_match_vars` import is recommended in code that doesn't explicitly need `$&`, `$`` , or `$'`. See *regex match variables* for the historical performance reason and why it no longer matters on modern perls.

This page lists punctuation forms throughout because most code in the wild is written that way. The English aliases are noted alongside on the family pages where they are useful.

Localising special variables

Almost every special variable that controls a built-in's behaviour (`$/`, `$\`, `$,`, `$"`, `$|`, `$_`) is global - set it in one place and every other piece of code in the same process sees the change. The standard idiom for "I need a different value just for this block" is `local`:

```
sub slurp {
    my ($path) = @_;
    open my $fh, '<', $path or die "open $path: $!";
    local $/;                           # slurp mode, only inside this
 ↪sub
    return <$fh>;
}
```

Without the `local`, the caller's `$/` would be permanently clobbered. `local` saves the current value, sets the new one, and restores the old value when the enclosing scope exits - even on an exception. This applies to every special variable on the family pages, except the read-only ones (regex match variables, `$0`'s formal argument, the version variables).

See also

- `perlop` - every operator that reads or writes a special variable as part of its definition (regex binding, printing, range, comparison).
- `perlfunc` - built-in functions, almost all of which read a default from one of these variables when called with no argument (`chomp`, `chop`, `print`, `lc`, `length`, `<>`, ...).

5.1.2 Built-in Functions

Alphabetical index of every Perl 5 built-in. The content mirrors `perldoc perlfunc` with pperl-specific divergences flagged inline on each detail page.

For an alternate browsing view grouped by problem domain see *Built-in Functions by Category*.

A

- **`abs`** - Return the absolute value of a number.
- **`accept`** - Accept an incoming connection on a listening socket.
- **`alarm`** - Schedule a `SIGALRM` to be delivered to the current process after a whole number of wallclock seconds.
- **`all`** - Test whether `BLOCK` returns true for **every** element of `LIST`.
- **`any`** - Return true if `BLOCK` yields true for at least one element of `LIST`.
- **`atan2`** - Arc tangent of `Y/X` in the range -π to π.

B

- **`bind`** - Attach a local address to a socket.
- **`binmode`** - Set the I/O layer stack on a filehandle - typically to make it deliver raw bytes, or to attach a character encoding.
- **`bless`** - Mark the thing a reference points at as an object in a package.
- **`break`** - Break out of a `given` block.

C

- **`caller`** - Return information about the subroutine, `eval`, or `require` that called the currently executing code.
- **`catch`** - Handle an exception thrown by a preceding `try` block.
- **`chdir`** - Change the process's current working directory.
- **`chmod`** - Change the permission bits of a list of files.
- **`chomp`** - Strip the trailing input record separator from a string in place.
- **`chop`** - Remove the last character from a string and return it.
- **`chown`** - Change the owner and group of a list of files.
- **`chr`** - Return the character whose codepoint is the given number.
- **`chroot`** - Change the root directory of the current process and every child it later spawns.
- **`class`** - Declare a namespace that behaves as a native object class.
- **`close`** - Close a filehandle, flush its buffers, and release the underlying file descriptor.

- **closedir** - Close a directory handle opened by opendir.
- **connect** - Initiate a connection from a socket to a remote address.
- **continue** - Attach a block to a loop that runs after every iteration, just before the condition is re-tested.
- **cos** - Return the cosine of a number given in radians.
- **crypt** - One-way passwd(5)-style hashing of a plaintext string with a salt.

D

- **dbmclose** - Break the binding between a DBM file and a hash previously attached by dbmopen.
- **dbmopen** - Bind a DBM file on disk to a hash so hash reads and writes become lookups and stores in the database.
- **defer** - Schedule a block to run when the enclosing scope exits, for any reason.
- **defined** - Test whether a value, variable, or subroutine is defined.
- **delete** - Remove the named key-value pair(s) from a hash, or element(s) from an array, and return what was removed.
- **die** - Raise an exception.
- **do** - Execute a block of code or run a Perl source file as if it were part of the current program.
- **dump** - Cause the running program to produce a core dump immediately.

E

- **each** - Step through a hash or array one entry at a time.
- **endgrent** - Close the group database after iterating it.
- **endhostent** - Close the hosts database after iteration.
- **endnetent** - Close the networks database after iteration.
- **endprotoent** - Close the protocols database after iteration.
- **endpwent** - Close the passwd-database iterator opened by getpwent or setpwent.
- **endservent** - Close the services database after a walk with getservent.
- **eof** - Test a filehandle for end-of-file.
- **eval** - Run a piece of Perl code with any fatal error trapped instead of killing the program.
- **evalbytes** - Compile and run a string of Perl source, forcing the source to be interpreted as **bytes** rather than characters.
- **exec** - Abandon this program and run another in the same process.
- **exists** - Test whether a hash or array element, or a named subroutine, is present - without creating it and without caring what it holds.
- **exit** - Terminate the program with a status value.

- **exp** - Raise *e* to a power.

F

- **fc** - Return the Unicode casefolded form of a string for case-insensitive comparison.
- **fcntl** - Perform a `fcntl(2)` file-control operation on a filehandle.
- **field** - Declare a per-instance variable inside a `class` block.
- **fileno** - Return the OS-level file descriptor number behind a filehandle.
- **finally** - Run cleanup code on the way out of a `try`/`catch`, whether the body succeeded, threw, or jumped away.
- **flock** - Place an advisory lock on an open file.
- **fork** - Create a new process running the same program at the same point.
- **format** - Declare a picture-based report template for use by `write`.
- **formline** - Format a list of values into a picture string and append the result to the format accumulator `$^A`.

G

- **getc** - Read the next single character from a filehandle.
- **getgrent** - Read the next entry from the system group database.
- **getgrgid** - Look up a group record by numeric group ID.
- **getgrnam** - Look up a Unix group by name and return its `/etc/group` record.
- **gethostbyaddr** - Look up a host record by its packed IP address.
- **gethostbyname** - Look up a host record by DNS name.
- **gethostent** - Fetch the next entry from the host database.
- **getlogin** - Return the login name of the user associated with the controlling terminal.
- **getnetbyaddr** - Look up a network record by its numeric network address.
- **getnetbyname** - Look up a network record by name.
- **getnetent** - Read the next entry from the networks database.
- **getpeername** - Return the address of the remote end of a connected socket.
- **getpgrp** - Return the POSIX process-group ID that a process belongs to.
- **getppid** - Return the process ID of the current process's parent.
- **getpriority** - Return the current scheduling nice value of a process, a process group, or a user.
- **getprotobyname** - Look up an IP protocol by its textual name and return its database entry.
- **getprotobynumber** - Look up a network protocol entry by its assigned protocol number.

- **getprotoent** - Fetch the next entry from the protocols database.
- **getpwent** - Return the next entry from the system password database.
- **getpwnam** - Look up a user's passwd record by login name.
- **getpwuid** - Look up a user's passwd record by numeric UID.
- **getservbyname** - Look up a network service by its textual name and protocol.
- **getservbyport** - Look up a network service by its numeric port and protocol.
- **getservent** - Read the next entry from the system services database.
- **getsockname** - Return the local address of a connected or bound socket.
- **getsockopt** - Read one socket option out of the kernel as an opaque packed string.
- **glob** - Expand a shell-style filename pattern into the list of matching paths.
- **gmtime** - Convert an epoch time to a broken-down UTC time, either as a 9-element list or as a `ctime(3)`-style string.
- **goto** - Transfer execution elsewhere in the program without returning.
- **grep** - Filter a list to the elements where the block or expression is true.

H

- **hex** - Interpret a string as a hexadecimal numeral and return its numeric value.

I

- **import** - Populate the caller's namespace with names a module chooses to export.
- **index** - Find the position of a substring inside a string.
- **int** - Return the integer portion of a number, truncating toward zero.
- **ioctl** - Perform a device-control `ioctl(2)` system call on a filehandle.
- **isa** - Test whether an object is an instance of a class or of any subclass derived from it.

J

- **join** - Concatenate a list of strings with a separator between each adjacent pair, and return the single resulting string.

K

- **keys** - List all keys of a hash, or all indices of an array.
- **kill** - Send a signal to a list of processes.

L

- **last** - Exit a loop immediately, skipping the rest of the body and the `continue` block.
- **lc** - Return a lowercased copy of a string.
- **lcfirst** - Return a copy of a string with its first character lowercased.
- **length** - Return the number of characters in a string.
- **link** - Create a hard link from `NEWFILE` to the existing `OLDFILE`.
- **listen** - Mark a socket as passive so it can accept incoming connections.
- **local** - Save the current value of a package variable and restore it when the enclosing scope exits.
- **localtime** - Convert an epoch time to a broken-down calendar time in the local time zone.
- **lock** - Place an advisory lock on a shared variable, array, hash, or subroutine until the lock goes out of scope.
- **log** - Return the natural logarithm (base *e*) of a number.
- **lstat** - Return the 13-element status list for a path **without** following a symbolic link.

M

- **m//** - Search a string for a pattern and report whether - and what - it matched.
- **map** - Apply a block or expression to each element of a list and return the flattened results.
- **method** - Declare a named instance method inside a `class` block.
- **mkdir** - Create a single directory on the filesystem.
- **msgctl** - Perform a control operation on a System V IPC message queue.
- **msgget** - Create or look up a System V IPC message queue and return its id.
- **msgrcv** - Receive a message from a System V IPC message queue.
- **msgsnd** - Send a message to a System V IPC message queue.
- **my** - Declare one or more lexically scoped variables.

N

- **next** - Start the next iteration of the enclosing loop immediately.
- **no** - The compile-time inverse of `use` - call a module's `unimport` method to turn off what `use` turned on.

O

- **oct** - Interpret a string as a number written in octal, hexadecimal, or binary, and return the resulting integer.
- **open** - Associate a filehandle with a file, a command, or an in-memory scalar.
- **opendir** - Open a directory for reading.
- **ord** - Return the Unicode code point of the first character of a string.
- **our** - Declare a lexically scoped alias to a package variable.

P

- **pack** - Convert a list of Perl values into a binary string according to a template.
- **package** - Declare the compile-time namespace for the declarations that follow.
- **pipe** - Open a pair of connected filehandles - one for reading, one for writing.
- **pop** - Remove and return the last element of an array.
- **pos** - Report or set where the next `/g` regex match will resume in a string.
- **print** - Write a list of values to a filehandle.
- **printf** - Write a formatted string to a filehandle.
- **prototype** - Return the prototype string of a subroutine, or `undef` if it has none.
- **push** - Append one or more values to the end of an array.

Q

- **q//** - Single-quoted string literal with a choice of delimiter.
- **qq//** - Build a double-quoted, interpolated string with a delimiter you pick.
- **qr//** - Compile a pattern once and hand back a reusable regex object.
- **quotemeta** - Return a copy of a string with every regex-significant character backslash-escaped, so the result can be interpolated into a pattern and match its own literal content.
- **qw//** - Build a list of barewords by splitting a delimited string on whitespace, without quoting or comma-separating each word.
- **qx//** - Run a shell command and capture its standard output.

R

- **rand** - Return a pseudo-random floating-point number in the half-open range `[0, EXPR)`.
- **read** - Read a fixed amount of buffered input from a filehandle into a scalar.
- **readdir** - Read the next entry, or all remaining entries, from a directory handle opened by `opendir`.
- **readline** - Read one or more records from a filehandle.

- **readlink** - Return the target path a symbolic link points to.
- **readpipe** - Run a shell command and return its standard output.
- **recv** - Read an incoming message from a socket into a scalar.
- **redo** - Restart the current iteration of a loop without re-testing the condition and without running the `continue` block.
- **ref** - Return a string describing what a reference points to.
- **rename** - Change the name of a file.
- **require** - Load a Perl source file at runtime, or demand a minimum Perl version.
- **reset** - Clear every package variable whose name begins with one of a set of letters, and re-arm one-shot `m?pattern?` matches.
- **return** - Leave the current subroutine, `eval`, do `FILE`, `sort` block, or regex eval block, yielding a value to the caller.
- **reverse** - Reverse a list - or, in scalar context, reverse the characters of a string.
- **rewinddir** - Reset a directory handle to the start of its listing.
- **rindex** - Find the position of the **last** occurrence of a substring inside a string.
- **rmdir** - Remove an empty directory.

S

- **s///** - Search a string for a pattern and replace every match with a replacement.
- **say** - Print a list of values followed by a newline.
- **scalar** - Force `EXPR` to be evaluated in scalar context and return its value.
- **seek** - Reposition a filehandle for random-access reads or writes.
- **seekdir** - Restore a directory handle to a position previously captured by `telldir`.
- **select** - Either set the default output filehandle, or call the `select(2)` syscall for I/O multiplexing. Same name, two unrelated jobs - disambiguated by argument count.
- **semctl** - Perform a control operation on a System V semaphore set.
- **semget** - Create or look up a System V semaphore set and return its identifier.
- **semop** - Perform one or more System V semaphore operations atomically.
- **send** - Send a message on a socket.
- **setgrent** - Rewind the group-database iterator back to the first entry.
- **sethostent** - Open or rewind the hosts database for iteration.
- **setnetent** - Open or rewind the networks database for iteration.
- **setpgrp** - Set the process group of a process.
- **setpriority** - Set the scheduling priority (nice value) of a process, process group, or user.
- **setprotoent** - Open the protocols database and prepare it for sequential reads.

- **setpwent** - Rewind the password-database iterator so the next `getpwent` call returns the first entry again.
- **setservent** - Rewind the services database and optionally keep it open across lookups.
- **setsockopt** - Set a kernel-level option on an open socket.
- **shift** - Remove and return the first element of an array.
- **shmctl** - Control or query a System V shared memory segment.
- **shmget** - Create or look up a System V shared memory segment and return its identifier.
- **shmread** - Copy bytes out of a System V shared memory segment into a Perl scalar.
- **shmwrite** - Copy bytes into a System V shared memory segment.
- **shutdown** - Shut down one direction of a socket connection, or both.
- **sin** - Return the sine of a number given in radians.
- **sleep** - Pause the process for a number of whole seconds.
- **socket** - Create a socket filehandle.
- **socketpair** - Create an unnamed, connected pair of sockets that talk to each other.
- **sort** - Sort a list, returning the sorted list.
- **splice** - Remove and/or replace a slice of an array in place, and return the removed elements.
- **split** - Cut a string into a list of fields using a regex separator.
- **sprintf** - Build a formatted string from a format template and a list of values.
- **sqrt** - Return the non-negative square root of `EXPR`.
- **srand** - Seed the pseudo-random number generator.
- **stat** - Get a file's status information.
- **state** - Declare a lexically scoped variable whose value persists across calls to its enclosing subroutine.
- **study** - A no-op retained for source compatibility with older Perl code.
- **sub** - Declare or define a subroutine.
- **substr** - Extract, replace, or alias a contiguous slice of a string.
- **symlink** - Create a symbolic link at `NEWFILE` that points at the string `OLDFILE`.
- **syscall** - Invoke a raw system call by its kernel number, passing the remaining arguments as `int` or as a pointer to a string buffer.
- **sysopen** - Open a file the low-level way, passing an integer `MODE` bitmask straight through to the underlying `open(2)` system call.
- **sysread** - Read raw bytes from a filehandle by calling the underlying `read(2)` system call.
- **sysseek** - Reposition a filehandle at the system level, bypassing PerlIO buffering.

- **system** - Run a separate program and wait for it to finish.
- **syswrite** - Write bytes to a filehandle with the raw `write(2)` system call, bypassing Perl's buffered I/O.

T

- **tell** - Return the current byte position of a filehandle.
- **telldir** - Return the current read position of a directory handle as an opaque token.
- **tie** - Bind a variable to a class so that every access to the variable dispatches through that class's methods.
- **tied** - Return the object backing a tied variable.
- **time** - Return the current wall-clock time as an integer number of seconds since the system epoch.
- **times** - Report CPU time consumed by this process and its terminated children.
- **tr///** - Character-by-character substitution. `tr` scans a string and replaces every occurrence of a character from `SEARCHLIST` with the positionally corresponding character from `REPLACEMENTLIST`, returning the count of characters it touched.
- **truncate** - Shorten (or extend) a file to an exact byte length.
- **try** - Run a block and divert any exception it throws into a `catch` block, with an optional `finally` block that always runs on the way out.

U

- **uc** - Return an uppercased copy of a string.
- **ucfirst** - Return a copy of a string with its first character titlecased.
- **umask** - Set or read the process file-creation mode mask.
- **undef** - The undefined value, and the operator that produces it.
- **unlink** - Remove one or more directory entries that name files.
- **unpack** - Extract typed values from a binary or fixed-width string according to a template.
- **unshift** - Prepend one or more values to the start of an array and return the array's new length.
- **untie** - Break the binding between a variable and its tied class.
- **use** - Load a module at compile time and import its symbols into the current package.
- **utime** - Set access and modification times on a list of files.

V

- **values** - List every value of a hash (or every element of an array).
- **vec** - Read or write a fixed-width slot inside a string treated as a packed bit vector.

W

- **wait** - Block until any child process exits and reap it.
- **waitpid** - Wait for a specific child process to terminate and reap it.
- **wantarray** - Report the calling context of the currently executing subroutine.
- **warn** - Emit a warning to STDERR.
- **write** - Render one record to a filehandle through its associated `format`.

Y

- **y///** - Transliterate characters in a string. `y///` is a synonym for `tr///` - the two are identical in every respect.

__ (double-underscored)

- **__CLASS__** - Return the class name of the instance currently being acted on.
- **__FILE__** - The name of the source file the token is compiled in.
- **__LINE__** - A compile-time token that evaluates to the line number at which it appears in the source.
- **__PACKAGE__** - Return the name of the package currently in effect at the point where the token appears.
- **__SUB__** - Return a reference to the currently executing subroutine.

Built-in Functions by Category

The same built-ins as in *the alphabetical index*, grouped here by problem domain. A function may appear under more than one category: categories are a tag set, not a tree. Every link points at the same detail page regardless of which category the reader arrived through.

SCALARs and strings

- **chomp** - Strip the trailing input record separator from a string in place.
- **chop** - Remove the last character from a string and return it.
- **chr** - Return the character whose codepoint is the given number.
- **crypt** - One-way `passwd(5)`-style hashing of a plaintext string with a salt.
- **fc** - Return the Unicode casefolded form of a string for case-insensitive comparison.
- **hex** - Interpret a string as a hexadecimal numeral and return its numeric value.
- **index** - Find the position of a substring inside a string.

- **lc** - Return a lowercased copy of a string.
- **lcfirst** - Return a copy of a string with its first character lowercased.
- **length** - Return the number of characters in a string.
- **oct** - Interpret a string as a number written in octal, hexadecimal, or binary, and return the resulting integer.
- **ord** - Return the Unicode code point of the first character of a string.
- **pack** - Convert a list of Perl values into a binary string according to a template.
- **q//** - Single-quoted string literal with a choice of delimiter.
- **qq//** - Build a double-quoted, interpolated string with a delimiter you pick.
- **reverse** - Reverse a list - or, in scalar context, reverse the characters of a string.
- **rindex** - Find the position of the **last** occurrence of a substring inside a string.
- **sprintf** - Build a formatted string from a format template and a list of values.
- **substr** - Extract, replace, or alias a contiguous slice of a string.
- **tr///** - Character-by-character substitution. `tr` scans a string and replaces every occurrence of a character from `SEARCHLIST` with the positionally corresponding character from `REPLACEMENTLIST`, returning the count of characters it touched.
- **uc** - Return an uppercased copy of a string.
- **ucfirst** - Return a copy of a string with its first character titlecased.
- **y///** - Transliterate characters in a string. `y///` is a synonym for `tr///` - the two are identical in every respect.

Regular expressions and pattern matching

- **m//** - Search a string for a pattern and report whether - and what - it matched.
- **pos** - Report or set where the next `/g` regex match will resume in a string.
- **qr//** - Compile a pattern once and hand back a reusable regex object.
- **quotemeta** - Return a copy of a string with every regex-significant character backslash-escaped, so the result can be interpolated into a pattern and match its own literal content.
- **s///** - Search a string for a pattern and replace every match with a replacement.
- **split** - Cut a string into a list of fields using a regex separator.
- **study** - A no-op retained for source compatibility with older Perl code.

Numeric functions

- **abs** - Return the absolute value of a number.
- **atan2** - Arc tangent of `Y/X` in the range -π to π.
- **cos** - Return the cosine of a number given in radians.
- **exp** - Raise *e* to a power.

- **hex** - Interpret a string as a hexadecimal numeral and return its numeric value.
- **int** - Return the integer portion of a number, truncating toward zero.
- **log** - Return the natural logarithm (base *e*) of a number.
- **oct** - Interpret a string as a number written in octal, hexadecimal, or binary, and return the resulting integer.
- **rand** - Return a pseudo-random floating-point number in the half-open range `[0, EXPR)`.
- **sin** - Return the sine of a number given in radians.
- **sqrt** - Return the non-negative square root of `EXPR`.
- **srand** - Seed the pseudo-random number generator.

Arrays

- **each** - Step through a hash or array one entry at a time.
- **keys** - List all keys of a hash, or all indices of an array.
- **pop** - Remove and return the last element of an array.
- **push** - Append one or more values to the end of an array.
- **shift** - Remove and return the first element of an array.
- **splice** - Remove and/or replace a slice of an array in place, and return the removed elements.
- **unshift** - Prepend one or more values to the start of an array and return the array's new length.
- **values** - List every value of a hash (or every element of an array).

Lists

- **all** - Test whether `BLOCK` returns true for **every** element of `LIST`.
- **any** - Return true if `BLOCK` yields true for at least one element of `LIST`.
- **grep** - Filter a list to the elements where the block or expression is true.
- **join** - Concatenate a list of strings with a separator between each adjacent pair, and return the single resulting string.
- **map** - Apply a block or expression to each element of a list and return the flattened results.
- **qw//** - Build a list of barewords by splitting a delimited string on whitespace, without quoting or comma-separating each word.
- **reverse** - Reverse a list - or, in scalar context, reverse the characters of a string.
- **sort** - Sort a list, returning the sorted list.
- **unpack** - Extract typed values from a binary or fixed-width string according to a template.

Hashes

- **delete** - Remove the named key-value pair(s) from a hash, or element(s) from an array, and return what was removed.
- **each** - Step through a hash or array one entry at a time.
- **exists** - Test whether a hash or array element, or a named subroutine, is present - without creating it and without caring what it holds.
- **keys** - List all keys of a hash, or all indices of an array.
- **values** - List every value of a hash (or every element of an array).

I/O

- **binmode** - Set the I/O layer stack on a filehandle - typically to make it deliver raw bytes, or to attach a character encoding.
- **close** - Close a filehandle, flush its buffers, and release the underlying file descriptor.
- **closedir** - Close a directory handle opened by `opendir`.
- **dbmclose** - Break the binding between a DBM file and a hash previously attached by `dbmopen`.
- **dbmopen** - Bind a DBM file on disk to a hash so hash reads and writes become lookups and stores in the database.
- **die** - Raise an exception.
- **eof** - Test a filehandle for end-of-file.
- **fileno** - Return the OS-level file descriptor number behind a filehandle.
- **flock** - Place an advisory lock on an open file.
- **format** - Declare a picture-based report template for use by `write`.
- **getc** - Read the next single character from a filehandle.
- **print** - Write a list of values to a filehandle.
- **printf** - Write a formatted string to a filehandle.
- **read** - Read a fixed amount of buffered input from a filehandle into a scalar.
- **readdir** - Read the next entry, or all remaining entries, from a directory handle opened by `opendir`.
- **readline** - Read one or more records from a filehandle.
- **rewinddir** - Reset a directory handle to the start of its listing.
- **say** - Print a list of values followed by a newline.
- **seek** - Reposition a filehandle for random-access reads or writes.
- **seekdir** - Restore a directory handle to a position previously captured by `telldir`.

- **select** - Either set the default output filehandle, or call the `select(2)` syscall for I/O multiplexing. Same name, two unrelated jobs - disambiguated by argument count.
- **syscall** - Invoke a raw system call by its kernel number, passing the remaining arguments as `int` or as a pointer to a string buffer.
- **sysread** - Read raw bytes from a filehandle by calling the underlying `read(2)` system call.
- **sysseek** - Reposition a filehandle at the system level, bypassing PerlIO buffering.
- **syswrite** - Write bytes to a filehandle with the raw `write(2)` system call, bypassing Perl's buffered I/O.
- **tell** - Return the current byte position of a filehandle.
- **telldir** - Return the current read position of a directory handle as an opaque token.
- **truncate** - Shorten (or extend) a file to an exact byte length.
- **warn** - Emit a warning to `STDERR`.
- **write** - Render one record to a filehandle through its associated `format`.

Fixed-length data

- **pack** - Convert a list of Perl values into a binary string according to a template.
- **read** - Read a fixed amount of buffered input from a filehandle into a scalar.
- **syscall** - Invoke a raw system call by its kernel number, passing the remaining arguments as `int` or as a pointer to a string buffer.
- **sysread** - Read raw bytes from a filehandle by calling the underlying `read(2)` system call.
- **sysseek** - Reposition a filehandle at the system level, bypassing PerlIO buffering.
- **syswrite** - Write bytes to a filehandle with the raw `write(2)` system call, bypassing Perl's buffered I/O.
- **unpack** - Extract typed values from a binary or fixed-width string according to a template.
- **vec** - Read or write a fixed-width slot inside a string treated as a packed bit vector.

Filehandles, files, directories

- **chdir** - Change the process's current working directory.
- **chmod** - Change the permission bits of a list of files.
- **chown** - Change the owner and group of a list of files.
- **chroot** - Change the root directory of the current process and every child it later spawns.
- **fcntl** - Perform a `fcntl(2)` file-control operation on a filehandle.

- **glob** - Expand a shell-style filename pattern into the list of matching paths.
- **ioctl** - Perform a device-control `ioctl(2)` system call on a filehandle.
- **link** - Create a hard link from `NEWFILE` to the existing `OLDFILE`.
- **lstat** - Return the 13-element status list for a path **without** following a symbolic link.
- **mkdir** - Create a single directory on the filesystem.
- **open** - Associate a filehandle with a file, a command, or an in-memory scalar.
- **opendir** - Open a directory for reading.
- **readlink** - Return the target path a symbolic link points to.
- **rename** - Change the name of a file.
- **rmdir** - Remove an empty directory.
- **select** - Either set the default output filehandle, or call the `select(2)` syscall for I/O multiplexing. Same name, two unrelated jobs - disambiguated by argument count.
- **stat** - Get a file's status information.
- **symlink** - Create a symbolic link at `NEWFILE` that points at the string `OLDFILE`.
- **sysopen** - Open a file the low-level way, passing an integer `MODE` bitmask straight through to the underlying `open(2)` system call.
- **umask** - Set or read the process file-creation mode mask.
- **unlink** - Remove one or more directory entries that name files.
- **utime** - Set access and modification times on a list of files.

Control flow

- **__FILE__** - The name of the source file the token is compiled in.
- **__LINE__** - A compile-time token that evaluates to the line number at which it appears in the source.
- **__PACKAGE__** - Return the name of the package currently in effect at the point where the token appears.
- **__SUB__** - Return a reference to the currently executing subroutine.
- **break** - Break out of a `given` block.
- **caller** - Return information about the subroutine, `eval`, or `require` that called the currently executing code.
- **catch** - Handle an exception thrown by a preceding `try` block.
- **continue** - Attach a block to a loop that runs after every iteration, just before the condition is re-tested.
- **defer** - Schedule a block to run when the enclosing scope exits, for any reason.
- **die** - Raise an exception.

- **do** - Execute a block of code or run a Perl source file as if it were part of the current program.
- **dump** - Cause the running program to produce a core dump immediately.
- **eval** - Run a piece of Perl code with any fatal error trapped instead of killing the program.
- **evalbytes** - Compile and run a string of Perl source, forcing the source to be interpreted as **bytes** rather than characters.
- **exit** - Terminate the program with a status value.
- **finally** - Run cleanup code on the way out of a `try`/`catch`, whether the body succeeded, threw, or jumped away.
- **goto** - Transfer execution elsewhere in the program without returning.
- **last** - Exit a loop immediately, skipping the rest of the body and the `continue` block.
- **method** - Declare a named instance method inside a `class` block.
- **next** - Start the next iteration of the enclosing loop immediately.
- **redo** - Restart the current iteration of a loop without re-testing the condition and without running the `continue` block.
- **return** - Leave the current subroutine, `eval`, `do FILE`, `sort` block, or regex eval block, yielding a value to the caller.
- **sub** - Declare or define a subroutine.
- **try** - Run a block and divert any exception it throws into a `catch` block, with an optional `finally` block that always runs on the way out.
- **wantarray** - Report the calling context of the currently executing subroutine.

Scoping

- **caller** - Return information about the subroutine, `eval`, or `require` that called the currently executing code.
- **class** - Declare a namespace that behaves as a native object class.
- **field** - Declare a per-instance variable inside a `class` block.
- **import** - Populate the caller's namespace with names a module chooses to export.
- **local** - Save the current value of a package variable and restore it when the enclosing scope exits.
- **my** - Declare one or more lexically scoped variables.
- **our** - Declare a lexically scoped alias to a package variable.
- **package** - Declare the compile-time namespace for the declarations that follow.
- **state** - Declare a lexically scoped variable whose value persists across calls to its enclosing subroutine.
- **use** - Load a module at compile time and import its symbols into the current package.

Misc

- **defined** - Test whether a value, variable, or subroutine is defined.
- **formline** - Format a list of values into a picture string and append the result to the format accumulator `$^A`.
- **lock** - Place an advisory lock on a shared variable, array, hash, or subroutine until the lock goes out of scope.
- **prototype** - Return the prototype string of a subroutine, or `undef` if it has none.
- **reset** - Clear every package variable whose name begins with one of a set of letters, and re-arm one-shot `m?pattern?` matches.
- **scalar** - Force `EXPR` to be evaluated in scalar context and return its value.
- **undef** - The undefined value, and the operator that produces it.

Processes

- **alarm** - Schedule a `SIGALRM` to be delivered to the current process after a whole number of wallclock seconds.
- **exec** - Abandon this program and run another in the same process.
- **fork** - Create a new process running the same program at the same point.
- **getpgrp** - Return the POSIX process-group ID that a process belongs to.
- **getppid** - Return the process ID of the current process's parent.
- **getpriority** - Return the current scheduling nice value of a process, a process group, or a user.
- **kill** - Send a signal to a list of processes.
- **pipe** - Open a pair of connected filehandles - one for reading, one for writing.
- **qx//** - Run a shell command and capture its standard output.
- **readpipe** - Run a shell command and return its standard output.
- **setpgrp** - Set the process group of a process.
- **setpriority** - Set the scheduling priority (nice value) of a process, process group, or user.
- **sleep** - Pause the process for a number of whole seconds.
- **system** - Run a separate program and wait for it to finish.
- **times** - Report CPU time consumed by this process and its terminated children.
- **wait** - Block until any child process exits and reap it.
- **waitpid** - Wait for a specific child process to terminate and reap it.

Modules

- **do** - Execute a block of code or run a Perl source file as if it were part of the current program.
- **import** - Populate the caller's namespace with names a module chooses to export.
- **no** - The compile-time inverse of `use` - call a module's `unimport` method to turn off what `use` turned on.
- **package** - Declare the compile-time namespace for the declarations that follow.
- **require** - Load a Perl source file at runtime, or demand a minimum Perl version.
- **use** - Load a module at compile time and import its symbols into the current package.

Classes and OO

- **__CLASS__** - Return the class name of the instance currently being acted on.
- **bless** - Mark the thing a reference points at as an object in a package.
- **class** - Declare a namespace that behaves as a native object class.
- **dbmclose** - Break the binding between a DBM file and a hash previously attached by `dbmopen`.
- **dbmopen** - Bind a DBM file on disk to a hash so hash reads and writes become lookups and stores in the database.
- **field** - Declare a per-instance variable inside a `class` block.
- **isa** - Test whether an object is an instance of a class or of any subclass derived from it.
- **method** - Declare a named instance method inside a `class` block.
- **package** - Declare the compile-time namespace for the declarations that follow.
- **ref** - Return a string describing what a reference points to.
- **tie** - Bind a variable to a class so that every access to the variable dispatches through that class's methods.
- **tied** - Return the object backing a tied variable.
- **untie** - Break the binding between a variable and its tied class.
- **use** - Load a module at compile time and import its symbols into the current package.

Sockets

- **accept** - Accept an incoming connection on a listening socket.
- **bind** - Attach a local address to a socket.
- **connect** - Initiate a connection from a socket to a remote address.
- **getpeername** - Return the address of the remote end of a connected socket.

- **getsockname** - Return the local address of a connected or bound socket.
- **getsockopt** - Read one socket option out of the kernel as an opaque packed string.
- **listen** - Mark a socket as passive so it can accept incoming connections.
- **recv** - Read an incoming message from a socket into a scalar.
- **send** - Send a message on a socket.
- **setsockopt** - Set a kernel-level option on an open socket.
- **shutdown** - Shut down one direction of a socket connection, or both.
- **socket** - Create a socket filehandle.
- **socketpair** - Create an unnamed, connected pair of sockets that talk to each other.

SysV IPC

- **msgctl** - Perform a control operation on a System V IPC message queue.
- **msgget** - Create or look up a System V IPC message queue and return its id.
- **msgrcv** - Receive a message from a System V IPC message queue.
- **msgsnd** - Send a message to a System V IPC message queue.
- **semctl** - Perform a control operation on a System V semaphore set.
- **semget** - Create or look up a System V semaphore set and return its identifier.
- **semop** - Perform one or more System V semaphore operations atomically.
- **shmctl** - Control or query a System V shared memory segment.
- **shmget** - Create or look up a System V shared memory segment and return its identifier.
- **shmread** - Copy bytes out of a System V shared memory segment into a Perl scalar.
- **shmwrite** - Copy bytes into a System V shared memory segment.

User and group info

- **endgrent** - Close the group database after iterating it.
- **endpwent** - Close the passwd-database iterator opened by `getpwent` or `setpwent`.
- **getgrent** - Read the next entry from the system group database.
- **getgrgid** - Look up a group record by numeric group ID.
- **getgrnam** - Look up a Unix group by name and return its `/etc/group` record.
- **getlogin** - Return the login name of the user associated with the controlling terminal.
- **getpwent** - Return the next entry from the system password database.
- **getpwnam** - Look up a user's passwd record by login name.
- **getpwuid** - Look up a user's passwd record by numeric UID.

- **setgrent** - Rewind the group-database iterator back to the first entry.
- **setpwent** - Rewind the password-database iterator so the next `getpwent` call returns the first entry again.

Network info

- **endhostent** - Close the hosts database after iteration.
- **endnetent** - Close the networks database after iteration.
- **endprotoent** - Close the protocols database after iteration.
- **endservent** - Close the services database after a walk with `getservent`.
- **gethostbyaddr** - Look up a host record by its packed IP address.
- **gethostbyname** - Look up a host record by DNS name.
- **gethostent** - Fetch the next entry from the host database.
- **getnetbyaddr** - Look up a network record by its numeric network address.
- **getnetbyname** - Look up a network record by name.
- **getnetent** - Read the next entry from the networks database.
- **getprotobyname** - Look up an IP protocol by its textual name and return its database entry.
- **getprotobynumber** - Look up a network protocol entry by its assigned protocol number.
- **getprotoent** - Fetch the next entry from the protocols database.
- **getservbyname** - Look up a network service by its textual name and protocol.
- **getservbyport** - Look up a network service by its numeric port and protocol.
- **getservent** - Read the next entry from the system services database.
- **sethostent** - Open or rewind the hosts database for iteration.
- **setnetent** - Open or rewind the networks database for iteration.
- **setprotoent** - Open the protocols database and prepare it for sequential reads.
- **setservent** - Rewind the services database and optionally keep it open across lookups.

Time

- **gmtime** - Convert an epoch time to a broken-down UTC time, either as a 9-element list or as a `ctime(3)`-style string.
- **localtime** - Convert an epoch time to a broken-down calendar time in the local time zone.
- **time** - Return the current wall-clock time as an integer number of seconds since the system epoch.
- **times** - Report CPU time consumed by this process and its terminated children.

Classes and OO

CLASS

Return the class name of the instance currently being acted on.

`__CLASS__` is a compile-time-recognised token that evaluates at runtime to the class name of the invoking instance. Inside a `method` body or a `field` initializer expression (introduced by `use feature 'class'`), it gives the **actual** class of the object under construction or in use - which may be a subclass of the package the code textually lives in. Outside of class-feature code it is essentially equivalent to `ref($self)`, but unlike `ref` it is usable in a field initializer, where `$self` is not yet bound.

Synopsis

```
use feature 'class';

field $x = __CLASS__->DEFAULT_X;        # in a field initializer
method m { return __CLASS__; }          # in a method body
```

What you get back

A plain string: the name of the class of the invoking instance. The value is the same kind of string `ref` returns for a blessed reference. It is **not** a reference; call methods on it as you would on any class name.

```
my $name = __CLASS__;                   # e.g. "DifferentCustomField
 ↪"
my $obj  = __CLASS__->new(...);         # class-method dispatch
```

When it differs from __PACKAGE__

`__PACKAGE__` is resolved at compile time and names the package the token textually appears in. `__CLASS__` is resolved at runtime and names the class of the *instance* - which, for a method or field initializer inherited by a subclass, is the subclass.

```
use feature 'class';

class Base {
    field $f = __CLASS__->default_f;    # evaluated per instance
    sub default_f { 10 }
    method class_name { __CLASS__ }
    method pkg_name  { __PACKAGE__ }
}

class Derived :isa(Base) {
    sub default_f { 20 }
}
```

(continues on next page)

(continued from previous page)

```
my $obj = Derived->new;
$obj->class_name;                       # "Derived"
$obj->pkg_name;                         # "Base"
# $f was initialised to 20, not 10, because __CLASS__ dispatched
# through the Derived package.
```

In a non-inherited context (no subclassing involved), `__CLASS__` and `__PACKAGE__` yield the same string.

Examples

Class method invoked from a field initializer - the canonical use case. Without `__CLASS__`, a subclass cannot override the default:

```
use feature 'class';

class WithCustomField {
    use constant DEFAULT_X => 10;
    field $x = __CLASS__->DEFAULT_X;
}

class DifferentCustomField :isa(WithCustomField) {
    sub DEFAULT_X { rand > 0.5 ? 20 : 30 }
}

my $obj = DifferentCustomField->new;    # $x is 20 or 30, not 10
```

Inside a method body, equivalent to `ref $self`:

```
class Logger {
    method log ($msg) {
        print STDERR "[", __CLASS__, "] $msg\n";
    }
}
```

Constructing a fresh instance of the same class as the invoking object - useful for clone-like factory methods that must respect subclasses:

```
class Node {
    field $label :param;
    method spawn ($child_label) {
        return __CLASS__->new(label => $child_label);
    }
}
```

Comparison with `__PACKAGE__` for diagnostics that want to pin the exact dispatch target:

```
class Thing {
    method describe {
```

(continues on next page)

(continued from previous page)

```
        return sprintf "defined in %s, dispatched as %s",
            __PACKAGE__, __CLASS__;
    }
}
```

Edge cases

- **Only valid under `use feature 'class'`** inside a `method` body, a `field` initializer, or another class-feature construct (for example `ADJUST` blocks). Using it outside such a context is a compile-time error.
- **No parentheses, no arguments.** `__CLASS__` is a bareword token, not a function call. `__CLASS__()` is a syntax error.
- **Not the same as `ref $self`** during field initialization - `$self` is not yet bound while fields are being set, so `ref $self` is unavailable. `__CLASS__` is the only way to reach the instance's class from inside a field initializer.
- **Not `ref` for a class method call.** When called as a class method (no instance in hand), `__CLASS__` yields the class the method was invoked on, not the package the method was defined in. This mirrors normal method dispatch.
- **String, not reference.** Method calls via `__CLASS__->...` are class-method dispatches, not instance-method dispatches. The method will not see a blessed reference as its invocant.
- **The `class` feature is marked experimental** in Perl 5.44; it emits a `experimental::class` warning unless silenced with `no warnings 'experimental::class'`.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `__PACKAGE__` - compile-time package name of the surrounding code; use this when you want the textual package, not the runtime class
- `ref` - runtime class name of a blessed reference; use this when you already hold an instance and are not inside a field initializer
- `bless` - associate a reference with a class name; the low-level primitive that `__CLASS__`-style dispatch ultimately resolves against
- `isa` - test whether the current class is a subclass of a given name; pairs naturally with `__CLASS__` for runtime checks
- `sub` - declares subroutines, including the `method` form that makes `__CLASS__` meaningful

Control flow

FILE

The name of the source file the token is compiled in.

`__FILE__` is a compile-time token, not a runtime function. At the point the compiler reads it, it is replaced with a string literal holding the filename the compiler is currently reading from. It takes no arguments, is never called with parens, and has no runtime cost - by the time your program runs, `__FILE__` has already become a plain string constant.

Its one job is to let code identify the file it lives in, for error messages, log lines, test diagnostics, and similar reporting.

Synopsis

```
__FILE__
```

What you get back

A string: the filename as the compiler knew it when it read this token. For a script invoked as `perl /tmp/run.pl` the value is `/tmp/run.pl`; for a module loaded through `require` or `use` it is the path `require` resolved against `@INC` (typically an absolute path). For code fed on standard input or through `-e` it is `-` or `-e` respectively.

Because substitution happens at compile time, the value is fixed for each textual occurrence of the token. Two `__FILE__` tokens in different files produce different strings; two in the same file produce the same string.

Global state it touches

None at runtime. At compile time the value is taken from the compiler's current filename, which is the same value `caller` reports in list context as element `[1]` and which `die` / `warn` use to build their default `"at FILE line LINE."` suffix.

That filename can be **rewritten** by a `#line` directive embedded in the source - see *Edge cases* below. Once rewritten, `__FILE__` tokens compiled after the directive report the new name.

Examples

Identify the running script in a log line:

```
warn "started from ", __FILE__, "\n";
# started from /tmp/run.pl
```

Attach source location to a custom error without `die`'s default suffix:

```
sub fail {
    my ($msg) = @_;
    die sprintf("%s at %s line %d\n", $msg, __FILE__, __LINE__);
}
```

Build a path relative to the current module, so resource files ship alongside the code that loads them:

```
use File::Basename qw(dirname);
use File::Spec;
my $data = File::Spec->catfile(dirname(__FILE__), "data.txt");
```

Use `__FILE__` inside a string passed to `eval` to keep error reports pointing at the original source rather than at the anonymous `(eval N)` buffer:

```
my $code = qq[\n#line ] . __LINE__ . qq[ "] . __FILE__ . qq["\n]
         . q[die "boom"];
eval $code;
# boom at <current file> line <current line>.
```

Distinguish “run as a script” from “loaded as a module” - the common test is whether the file was invoked directly:

```
__PACKAGE__->run(@ARGV) if __FILE__ eq $0;
```

Edge cases

- **Compile-time, not runtime.** `__FILE__` is a token the parser replaces with a string literal. It is not a function you can take a reference to; `\&__FILE__` is a syntax error. Stringify it, store it, or pass it - but you cannot defer its evaluation.
- **Stable per occurrence.** Calling the same subroutine from two different files does not change the `__FILE__` the subroutine body sees; that value was baked in when the subroutine was compiled. If you need the caller’s filename, use `caller`.
- **`#line` directives rewrite the value.** A comment of the form `# line N "NAME"` at column zero resets both the line number and (optionally) the filename the compiler reports. Every `__FILE__` token compiled after such a directive picks up the new name. This is the mechanism code generators and template engines use to make errors point at the original `.tt` / `.pod` / `.xs` source instead of the generated `.pl`.

  ```
  # line 1 "config.tt"
  my $x = __FILE__;       # "config.tt"
  ```

  Full syntax of the directive is specified in `perlsyn` under *Plain Old Comments (Not!)*.
- **Modules.** Inside a module, `__FILE__` is the path `require` used to load the file - usually absolute and under an `@INC` root. Do not parse it as `Some/Module.pm`; use `dirname(__FILE__)` if you need the directory, not string surgery.
- **Special command-line sources.** Code from `-e` reports `-e`; code from `-E` reports `-e` as well; code piped on stdin reports `-`. String `eval` without a `#line` directive reports `(eval N)` where `N` is the eval counter.
- **One-argument `open` and its `__FILE__` lookalike.** There is no `__FILE__` handle; the token has nothing to do with filehandles. `open(__FILE__)` does not open the current source file - it tries to open a file literally named after the token’s expanded string, which is rarely what you want.

- **Not modifiable at runtime.** Assigning to `__FILE__` is a syntax error. The mechanism for changing what `__FILE__` reports is the `#line` directive at compile time; there is no runtime equivalent.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `__LINE__` - companion compile-time token for the current line number; the two are almost always used together
- `__PACKAGE__` - compile-time token for the current package name, same family of special tokens
- `caller` - runtime lookup of the caller's filename, line, and package; use this when you need the caller's source location rather than your own
- `die` - appends `at FILE line LINE.` automatically; reach for `__FILE__` explicitly only when you suppress that suffix with a trailing newline
- `perlsyn` - the *Plain Old Comments (Not!)* section specifies the `#line` directive that rewrites `__FILE__`

Control flow

LINE

A compile-time token that evaluates to the line number at which it appears in the source.

`__LINE__` is not a function. It is a special token the parser replaces, at compile time, with an integer literal - the line number of the file position where the token sits. It is the standard way to stamp a diagnostic, a log line, or a debug print with the exact location that produced it, without paying for a `caller` lookup at runtime.

Synopsis

```
__LINE__
```

What you get back

An integer: the 1-based line number of the token within the current compilation unit. The value is a plain number, usable anywhere a number is - in arithmetic, in string interpolation, as a hash key, as an argument to `die` or `warn`.

```
print __LINE__, "\n";        # prints the line number of this line
my $where = "line " . __LINE__;
```

Because the substitution happens at parse time, every occurrence of `__LINE__` is effectively a different constant. Two copies on two different lines produce two different numbers; a single `__LINE__` inside a loop produces the same number on every iteration.

Compile-time, not run-time

The value is frozen when the source is compiled. A common confusion:

```
sub where { return __LINE__ }     # returns the line where `__LINE__
↪`
                                  # was written, i.e. the `sub` body
↪'s
                                  # line - NOT the caller's line
```

To capture the *caller's* line number, use `caller`:

```
sub where { my (undef, undef, $line) = caller; return $line }
```

Inside `eval` of a string, `__LINE__` numbers the lines of the string being compiled (starting at 1 for the first line of the string), not the lines of the surrounding file.

Altering the reported line number

The line number `__LINE__` reports is the line number the lexer believes it is on. A `#line` directive resets that belief:

```
#line 1000 "virtual.pl"
print __LINE__, "\n";        # prints 1001
```

`#line NNN` on its own sets only the line number; `#line NNN "NAME"` also changes what `__FILE__` reports. Code generators, template engines, and preprocessors use this to make diagnostics point back at the original source rather than the generated file. See *Plain Old Comments (Not!)* in the perlsyn section of the reference for the precise syntax and scope rules.

Examples

Stamp a diagnostic with its origin:

```
die "bad input at ", __FILE__, " line ", __LINE__, "\n"
    unless defined $x;
```

`die` with a message that does **not** end in a newline already appends `" at FILE line LINE.\n"`. Use the explicit form above only when you want to control the formatting, or when you've suppressed the automatic suffix with a trailing newline.

Log with file-and-line prefix:

```
sub logf {
    my ($file, $line) = (__FILE__, __LINE__);
    warn "[$file:$line] @_\n";
}
```

This logs the line where `__LINE__` was *written* - inside `logf` - which is rarely what you want. The correct pattern uses `caller`:

```
sub logf {
    my (undef, $file, $line) = caller;
    warn "[$file:$line] @_\n";
}
```

Use `__LINE__` directly when you are marking *this* piece of code, not the caller:

```
print STDERR "checkpoint at line ", __LINE__, "\n";
```

Relocate diagnostics with `#line`:

```
#line 42 "user-input.pl"
die "syntax error\n";        # dies reporting user-input.pl line 42
```

Edge cases

- **Not a function, not callable.** `__LINE__()` is a syntax error. The token takes no arguments and has no parentheses form.
- **Not interpolated inside double-quoted strings.** `"see line __LINE__"` prints the literal string `see line __LINE__`. Concatenate instead: `"see line " . __LINE__`.
- **Not a valid hash-key bareword in the usual short form.** Inside `{ ... }` hash-key context, `$h{__LINE__}` works because the token is parsed as an expression, but `$h{ __LINE__ }` also works and is clearer. `$h{__LINE__ => 1}` parses `__LINE__` as a fat-comma bareword (i.e. the string `"__LINE__"`), which is almost never what you want - write `(__LINE__, 1)` or `(__LINE__() => 1)` if the literal value is wanted.
- **Inside string `eval`**, `__LINE__` counts from line 1 of the evaluated string. Prepend your own `#line` directive to the string to make diagnostics point at the enclosing file:

  ```
  my $code = qq{#line @{[__LINE__+1]} "@{[__FILE__]}"\n} . $user_
  ↪code;
  eval $code;
  ```

- **Inside a here-doc body**, `__LINE__` evaluates to the line of the *opening* `<<` on the line where the here-doc is referenced, not lines inside the body - here-doc bodies are data, not code.
- **Heredoc and line directives.** `#line` inside a here-doc body has no effect; it is just text. `#line` only works as a beginning-of-line directive in code context.
- **Negative or zero line numbers.** `#line 0` is legal and makes the next physical line report as line 1 (the directive itself is line 0, the line after is line 1). Negative numbers are accepted but produce surprising diagnostics; don't.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `__FILE__` - the companion token for the current source file name; the two are almost always used together
- `__PACKAGE__` - compile-time token for the current package name, same family of special tokens
- `caller` - runtime equivalent when you need the *caller's* line number, not the line of the call-site itself
- `die` - auto-appends `at FILE line LINE` when the message has no trailing newline, removing the need for explicit `__LINE__`
- `warn` - same auto-location behavior as `die` for non-fatal diagnostics

Control flow

PACKAGE

Return the name of the package currently in effect at the point where the token appears.

`__PACKAGE__` is a compile-time literal: the parser replaces it with a string constant naming whichever package the most recent `package` statement put into effect for this lexical scope. It does not look anything up at runtime, does not follow inheritance, and does not care what class the calling code is using - it is simply the name of the package that owns the source text it sits in.

Synopsis

```
__PACKAGE__
__PACKAGE__->some_method(@args)
$__PACKAGE__::VERSION          # does NOT work - see Edge cases
```

What you get back

A plain string containing the fully qualified package name (e.g. `"My::Thing"`, `"main"`), interned at compile time. The value is a constant for the duration of the enclosing scope - it cannot change at runtime and does not depend on how the code is called.

Outside any explicit `package` declaration, the value is `"main"`.

Global state it touches

None. `__PACKAGE__` is resolved at compile time from the lexical package in effect at its source location; it reads no interpreter state when executed and has no side effects.

Why use a token instead of writing the name

Three reasons, in the order you hit them in practice:

1. **The file gets renamed or the package gets renamed and nothing else has to change.** Every `__PACKAGE__` updates automatically; every hand-typed `"My::Thing"` has to be found and edited.
2. **It is the only portable way to write "this class" inside a package block form**, where the package ends at the closing brace and an inner helper cannot assume the file name matches.
3. **It composes with class methods cleanly**: `__PACKAGE__->new(...)` in a constructor helper calls the right class whether the file is loaded directly or copied into a subclass that has not yet redefined the helper.

For the runtime equivalent - "what class is `$self` actually blessed into?" - use `ref` or, in `use feature 'class'` code, `__CLASS__`. They are not the same thing; see *Edge cases*.

Examples

Read the current package inside a module:

```
package My::Thing;
say __PACKAGE__;                # My::Thing
```

Use `__PACKAGE__` to reach a package variable without hard-coding the name - robust against renames:

```
package My::Thing;
our $VERSION = '1.23';

sub version_string {
    no strict 'refs';
    return ${ __PACKAGE__ . '::VERSION' };
}
```

Constructor helper that stays correct when copy-pasted into a subclass or when the package is switched with the block form:

```
package My::Widget {
    sub new {
        my ($class, %args) = @_;
        bless { %args, kind => __PACKAGE__ }, $class;
    }
}
# kind is always "My::Widget", even if someone calls
# My::Widget::SubClass->new and forgets to override `new`.
```

Debug trace that prints where a log line came from, without having to duplicate the package name in every message:

```
package My::Worker;
use v5.36;

sub log_debug {
    my ($msg) = @_;
    warn __PACKAGE__ . ": $msg\n";
}
```

Cross-package resolution with the block form - each `__PACKAGE__` sees whichever package wraps it:

```
package Outer;
say __PACKAGE__;                # Outer

package Inner {
    say __PACKAGE__;            # Inner
}

say __PACKAGE__;                # Outer again
```

Edge cases

- **Constant at compile time, not a variable.** `__PACKAGE__` is not a scalar; `$__PACKAGE__` and `${__PACKAGE__}` do not exist. It interpolates in double-quoted strings as the string it resolves to:

  ```
  package Foo;
  say "in @{[__PACKAGE__]}";     # in Foo
  say "in $__PACKAGE__";         # prints "in " - $__PACKAGE__ is
   ↪undef
  ```

  The `@{[ ... ]}` idiom is the shortest way to interpolate it.

- **Symbolic reference to a package variable** requires string concatenation, not interpolation of a sigil:

  ```
  no strict 'refs';
  my $v = ${ __PACKAGE__ . '::VERSION' };   # works
  my $v = ${"__PACKAGE__::VERSION"};        # WRONG - literal
   ↪package
  ```

- **Not the same as `ref $self`.** `__PACKAGE__` is where the source was written; `ref $self` is what the object was actually blessed into. A method inherited from a base class returns the base class from `__PACKAGE__` but the subclass from `ref $self`:

  ```
  package Base;
  sub who { (__PACKAGE__, ref $_[0]) }

  package Child;
  our @ISA = ('Base');
  ```

(continues on next page)

(continued from previous page)

```
say join " / ", Child->who;     # Base / Child
```

When you want the class the method was invoked on, use `ref` on the invocant, `__CLASS__` inside a `class`/`method` block, or take `$_[0]` / `shift` as the class name for a class method.

- **Block-form scoping.** Inside `package NAME { ... }`, `__PACKAGE__` is `NAME`; after the closing brace the previous value is restored. See the nested example above.
- **`eval STRING` captures its compile-time package.** The string is compiled in the caller's package, so `__PACKAGE__` inside `eval "..."` is the package that called `eval`:

```
package Foo;
eval 'say __PACKAGE__';          # Foo
```

- **Before any `package` statement** (top of a script, top of a one-liner), `__PACKAGE__` is `"main"`.
- **`__PACKAGE__` does not mean "current class".** Under `use feature 'class'`, the class name and the package name agree on the declaration line but can differ at a call site invoked on a subclass. Inside a `method`, prefer `__CLASS__` when you want the class of the receiver.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `package` - the declaration that sets what `__PACKAGE__` returns; every non-`main` value comes from one
- `__CLASS__` - the runtime counterpart for code inside a `class` block: returns the class of the invoking instance, which may be a subclass
- `ref` - ask an object what class it was blessed into; the right tool when you have `$self` and want its actual class
- `caller` - the calling package at runtime; use when you need the caller's package, not your own
- `bless` - the primitive that turns a reference into an object of a given package; typically paired with `__PACKAGE__->new(...)` style constructors
- `our` - declares a lexical alias to a package variable in the current compile-time package (the same package `__PACKAGE__` names)

Control flow

SUB

Return a reference to the currently executing subroutine.

__SUB__ is the self-reference token: inside a sub, it evaluates to a code reference pointing at that same sub, without the sub having to know its own name. Outside any sub, it is `undef`. The common reason to reach for it is anonymous recursion - a sub stored in a lexical or passed around as a callback needs a way to call itself that does not depend on a package-qualified name, and `__SUB__` is it.

Synopsis

```
__SUB__
__SUB__->(@args)
goto __SUB__
```

Takes no arguments and has no parentheses form - it is a compile-time token, not a function call.

What you get back

A code reference (the same thing `\&name` would give you for a named sub), or `undef` when evaluated outside any subroutine. The reference is to the **runtime** sub, including any closure over lexicals captured when the sub was created, so calling it recursively sees the same captured environment.

```
my $fact = sub {
    my $n = shift;
    $n < 2 ? 1 : $n * __SUB__->($n - 1);
};

print $fact->(5);               # 120
```

The call form is an ordinary coderef invocation: `__SUB__->(@args)` or `&{__SUB__}(@args)`. No arguments are passed implicitly; recursion must pass them on.

Why not just use the sub's name

Named subs can already recurse by name - `factorial(...)` inside `sub factorial` works. __SUB__ earns its place in three situations where a name is unavailable, unreliable, or expensive:

- **Anonymous subs**. An anonymous sub assigned to a lexical has no stable package-qualified name. A common pre-5.16 workaround was capturing a reference to `\&name` or using Y-combinator tricks; __SUB__ replaces both.
- **Subs passed as callbacks**. A sub handed to another API (sort comparator, event handler, iterator step) may be called back before it has a name visible at the recursion site.
- **Tail-call recursion via goto**. `goto __SUB__` reuses the current call frame and jumps to the top of the same sub with whatever `@_` you set up, which matters for

deep recursion that would otherwise blow the stack.

Global state it touches

__SUB__ reads the currently executing call frame - the same frame `caller` inspects. It does not read or modify any special variables.

Examples

Anonymous factorial, the textbook case:

```
my $fact = sub {
    my $n = shift;
    $n < 2 ? 1 : $n * __SUB__->($n - 1);
};
print $fact->(6);               # 720
```

Tail-recursive sum with `goto __SUB__` - no stack growth per iteration, because `goto` reuses the current frame:

```
my $sum = sub {
    my ($acc, @rest) = @_;
    return $acc unless @rest;
    @_ = ($acc + shift @rest, @rest);
    goto __SUB__;
};
print $sum->(0, 1..1_000_000);  # 500000500000
```

Walking a nested data structure without naming the walker:

```
my $count_leaves = sub {
    my $node = shift;
    return 1 unless ref $node eq 'ARRAY';
    my $n = 0;
    $n += __SUB__->($_) for @$node;
    return $n;
};
print $count_leaves->([1, [2, 3], [[4], 5]]);   # 5
```

Outside any sub, __SUB__ is `undef`:

```
print defined(__SUB__) ? "yes" : "no";          # no
```

Captured, not resolved-on-call. __SUB__ is evaluated each time it runs, in the frame it runs in - so in a nested sub it refers to the **inner** sub:

```
sub outer {
    my $inner = sub { __SUB__ };    # inner's own coderef
    return $inner->();
}
my $ref = outer();
print $ref == $ref;                 # 1 - stable coderef
```

Edge cases

- **Requires the `current_sub` feature**. `__SUB__` is gated behind `use feature 'current_sub'`, enabled by default under `use v5.16` or any later version bundle. Code targeting older syntax levels must opt in explicitly, or prefix the token with `CORE::` as `CORE::__SUB__`.
- **No parentheses form**. `__SUB__()` is a syntax error - the token is not a function, it's a keyword that evaluates to a coderef. Call the result with `__SUB__->()` or `&{__SUB__}()`.
- **Outside any sub**, including at file scope and inside `BEGIN`, `UNITCHECK`, `CHECK`, `INIT`, and `END` blocks, `__SUB__` returns `undef`. Calling it (`__SUB__->()`) in those positions dies with `Can't use an undefined value as a subroutine reference`.
- **Inside `eval` blocks**, `__SUB__` refers to the **enclosing sub**, not the `eval` - an `eval { ... }` does not create a new sub frame for this purpose. Inside `eval EXPR` the same rule applies: the token resolves to the outer sub.
- **Inside a regex code block** (`/(?{...})/` or `/(??{...})/`), the behaviour of `__SUB__` is subject to change - upstream documents this as unstable. Do not rely on what it returns there.
- **Identity across calls**. Two evaluations of `__SUB__` inside the same sub yield the same coderef (`==` compares true). Across different closures made from the same `sub { ... }`, each closure sees its own coderef - one per captured environment.
- **`goto __SUB__` vs `__SUB__->()`**. The `goto` form reuses the current call frame and replaces `@_` with whatever you assigned before the `goto`; it does not grow the call stack. The coderef call form makes a fresh frame every time, so it hits the recursion depth limit on deeply recursive inputs.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `sub` - defines the subroutine whose reference `__SUB__` hands back; the first place to look when anonymous recursion is the tool for the job
- `goto` - pairs with `__SUB__` for tail-call recursion via `goto __SUB__`, the idiom that avoids stack growth
- `caller` - inspect the same call frame from the outside (package, file, line) instead of grabbing a reference to it
- `ref` - classify what `__SUB__` returned; always `"CODE"` inside a sub, empty string outside
- `return` - the usual way to exit the sub whose reference `__SUB__` is; relevant when choosing between recursion and tail-call via `goto __SUB__`

Numeric functions

abs

Return the absolute value of a number.

`abs` takes a single scalar, forces it to numeric context, and returns its magnitude - the value with any sign stripped. Non-numeric strings are converted using the same rules as arithmetic (leading whitespace and an optional sign, followed by digits; the rest is discarded, with a warning under `use warnings`). If `VALUE` is omitted, `abs` operates on `$_`.

Synopsis

```
abs VALUE
abs
abs($x)
```

What you get back

A non-negative number. The result is an integer if the input was an integer within the platform's integer range, otherwise a floating-point number. `abs` never changes its argument - the result is a fresh scalar, so `abs $x` leaves `$x` alone.

Global state it touches

With no argument, `abs` reads `$_`. It neither writes nor reads any other special variable. Under `use warnings`, a non-numeric argument triggers the standard `Argument "…" isn't numeric` warning via the normal numeric-conversion path.

Examples

Strip the sign from an integer:

```
print abs(-7);              # 7
print abs(7);               # 7
```

Floating-point magnitude - the result keeps the full precision of the input:

```
print abs(-3.14159);        # 3.14159
print abs(-1e-10);          # 1e-10
```

Use the default argument form inside a loop over `$_`:

```
for (-3, -1, 0, 2, 4) {
    print abs, "\n";        # 3, 1, 0, 2, 4 on separate lines
}
```

Distance between two points on a number line:

```
sub distance { abs($_[0] - $_[1]) }
print distance(10, 3);      # 7
print distance(3, 10);      # 7
```

String that looks like a negative number - `abs` parses the leading numeric prefix and strips the sign:

```
print abs("-42");            # 42
print abs("  -3.5xyz");      # 3.5  (warning under use warnings)
```

Edge cases

- **`abs(undef)`** returns `0`. Under `use warnings` it emits `Use of uninitialized value in abs`.
- **Non-numeric string**: `abs("hello")` returns `0` and warns under `use warnings` that the argument isn't numeric.
- **Integer overflow boundary**: `abs` of the most-negative platform integer (`IV_MIN`, e.g. `-2**63` on 64-bit builds) promotes to a floating-point result, because the positive counterpart does not fit in a signed integer:

  ```
  use Config;
  my $min = -(2 ** ($Config{ivsize} * 8 - 1));
  print abs($min);            # 9.22337203685478e+18 on 64-bit
  ```

- **IEEE 754 special values**: `abs(-0.0)` returns `0` (a positive zero). `abs("-Inf")` returns `Inf`. `abs("NaN")` returns `NaN` - `NaN` has no sign that `abs` can meaningfully remove.
- **Complex numbers and big integers** are not handled by the built-in. `use Math::Complex` overloads `abs` to compute the modulus; and provide their own sign-stripping on blessed objects via operator overloading.
- **No in-place form**: `abs` always returns a new scalar. To replace a variable's value with its magnitude, assign back:

  ```
  $x = abs $x;
  ```

- **Parser note**: the unary form `abs $x` binds tighter than `,` but looser than most arithmetic operators, so `abs $x + 1` parses as `abs($x) + 1`, not `abs($x + 1)`. Parenthesise when in doubt:

  ```
  print abs $x + 1;           # abs($x) + 1
  print abs($x + 1);          # abs of the sum
  ```

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `sqrt` - square root; like `abs` it is a pure numeric unary with a default-to-`$_` form
- `int` - truncate toward zero; pairs with `abs` when you want the integer magnitude of a float

- `sprintf` - formatted numeric output; use %d or %g together with `abs` to render unsigned magnitudes
- `$_` - the default argument when `abs` is called without one

Sockets

accept

Accept an incoming connection on a listening socket.

`accept` is the server side of the connection handshake. It waits on `GENERICSOCKET` - a socket that has already been created with `socket`, bound with `bind`, and placed in the listening state with `listen` - until a client connects, then installs a brand-new connected socket in `NEWSOCKET` and returns the client's packed address. `GENERICSOCKET` stays in the listening state, ready for the next call. Behaviour mirrors the POSIX `accept(2)` system call.

Synopsis

```
accept NEWSOCKET, GENERICSOCKET
```

What you get back

The client's address in the packed form used by the address family of `GENERICSOCKET` - the same shape you'd pass to `connect` or unpack with `Socket::unpack_sockaddr_in` for IPv4, or with `Socket::unpack_sockaddr_in6` / `unpack_sockaddr_un` for IPv6 and Unix-domain sockets respectively. On failure returns a false value (the empty string) and sets `$!` to the underlying `errno`.

`NEWSOCKET` is populated as a side effect - it is a plain filehandle argument, not a return value. A bareword like `CLIENT` autovivifies a typeglob; a lexical filehandle like `my $client` is populated in place:

```
my $client;
accept($client, $server) or die "accept: $!";
# $client is now a readable/writable handle to the connected peer
```

Global state it touches

- `$!` - set on failure to the underlying `errno` (`EINTR`, `EAGAIN`/`EWOULDBLOCK` on non-blocking listeners, `ECONNABORTED`, `EMFILE`, `ENFILE`).
- `$^F` - the system maximum file descriptor. On systems that support the close-on-exec flag, `accept` sets `FD_CLOEXEC` on the new descriptor when its number is greater than `$^F` (default 2, covering the standard streams). Raise `$^F` before `accept` if you want the accepted socket to survive `exec`.

Examples

Minimal TCP echo-style accept loop:

```
use Socket;

socket(my $server, PF_INET, SOCK_STREAM, getprotobyname("tcp"))
    or die "socket: $!";
bind($server, sockaddr_in(8080, INADDR_ANY)) or die "bind: $!";
listen($server, SOMAXCONN)                   or die "listen: $!";

while (my $peer = accept(my $client, $server)) {
    my ($port, $iaddr) = sockaddr_in($peer);
    print $client "hello ", inet_ntoa($iaddr), ":$port\n";
    close $client;
}
die "accept: $!";   # loop exits only on error
```

Unpack the returned address for logging:

```
use Socket;

my $peer = accept(my $client, $server)
    or die "accept: $!";
my ($port, $iaddr) = sockaddr_in($peer);
printf "connection from %s port %d\n", inet_ntoa($iaddr), $port;
```

Non-blocking accept. Put `$server` in non-blocking mode first; a pending-connection-less call then returns false with `$!` set to `EAGAIN` or `EWOULDBLOCK`:

```
use Errno qw(EAGAIN EWOULDBLOCK);
use Fcntl qw(F_GETFL F_SETFL O_NONBLOCK);

my $flags = fcntl($server, F_GETFL, 0);
fcntl($server, F_SETFL, $flags | O_NONBLOCK);

my $peer = accept(my $client, $server);
if (!$peer) {
    if ($! == EAGAIN || $! == EWOULDBLOCK) {
        # no pending connection - try again later
    } else {
        die "accept: $!";
    }
}
```

Preserve the accepted socket across `exec` by raising `$^F` so the runtime does not set `FD_CLOEXEC`:

```
local $^F = 10_000;
accept(my $client, $server) or die "accept: $!";
exec "/usr/libexec/handler", fileno($client);
```

Edge cases

- **GENERICSOCKET not listening** - `accept` fails with `$!` set to `EINVAL`. Call `listen` on the server socket first.
- **NEWSOCKET already open** - the existing handle is silently closed before the new descriptor is installed, exactly as for `open` and `socket`. If the old handle was the only reference to a buffered stream, any unflushed data is lost. Close explicitly beforehand when that matters.
- **Signal during the call** - a signal delivered while `accept` is blocked makes the underlying syscall return `EINTR`. pperl does not auto-restart: `accept` returns false and leaves `$!` set to `EINTR`. Wrap in a retry loop if your signal handlers do not terminate the process.
- **Descriptor exhaustion** - `EMFILE` (process limit) or `ENFILE` (system limit) on a busy server is the common reason `accept` starts failing under load. Treat them as transient; close idle clients and retry.
- **Address-family mismatch of the packed return value** - the packed buffer follows the family of `GENERICSOCKET`. Unpacking a Unix-domain address with `Socket::unpack_sockaddr_in` produces garbage. Track the family yourself or use `Socket::sockaddr_family` to dispatch.
- **Parentheses are optional, commas are not** - `accept $c, $s` and `accept($c, $s)` both work; `accept $c $s` is a syntax error.
- **List vs scalar context** - the packed-address return is a byte string; list context does **not** expand it into `(port, addr)`. Call `sockaddr_in` / equivalent to unpack.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `socket` - create the server socket that `accept` waits on
- `bind` - attach the server socket to a local address before `listen` and `accept`
- `listen` - mandatory step between `bind` and `accept`; sets the backlog depth
- `connect` - the client-side counterpart; `accept` returns the address a `connect` call supplied
- `getpeername` - recover the same packed address later from `NEWSOCKET` itself
- `Socket` - the constants (`PF_INET`, `SOCK_STREAM`, `INADDR_ANY`) and packers (`sockaddr_in`, `unpack_sockaddr_in`) that turn the packed return value into something usable
- `$^F` - threshold that controls whether `accept` sets `FD_CLOEXEC` on the new descriptor

Processes

alarm

Schedule a SIGALRM to be delivered to the current process after a whole number of wall-clock seconds.

alarm arms a single per-process countdown timer. When the timer expires, the kernel delivers SIGALRM; what happens next is entirely up to the installed signal handler in %SIG. The timer runs in wallclock time, not CPU time, so a sleeping or blocked process still receives the signal on schedule (subject to scheduling jitter).

Synopsis

```
alarm SECONDS
alarm
```

With no argument, the value in $_ is used.

What you get back

The number of seconds remaining on the **previous** timer, or 0 if no timer was pending. This lets you save and restore a caller's alarm across a nested timed operation:

```
my $prev = alarm 10;
# ... do something that must finish in 10s ...
alarm $prev;                        # restore caller's timer
```

alarm 0 cancels any pending timer and returns the seconds that were left on it.

Global state it touches

- %SIG - the ALRM slot names the handler invoked when the timer fires. Without a handler, the default disposition of SIGALRM is to terminate the process.
- $_ - read when alarm is called with no argument.
- $@ - carries the die message out of the canonical eval { alarm ...; ...; alarm 0 } idiom.
- $! - a blocking syscall interrupted by SIGALRM sets $! to EINTR, **but** Perl restarts many syscalls automatically on some systems, so you cannot rely on seeing EINTR. Use eval / die instead (see below).

The canonical timeout idiom

Use alarm with eval and die to put a wall-clock cap on any block of code, including blocking I/O:

```
eval {
    local $SIG{ALRM} = sub { die "timeout\n" };   # \n matters
    alarm $timeout;
    my $nread = sysread $sock, $buf, 4096;
    alarm 0;                                      # cancel on␣
```

(continues on next page)

(continued from previous page)

```
 ↪success
};
if ($@) {
    die $@ unless $@ eq "timeout\n";              # rethrow others
    # ... handle timeout ...
}
```

Three details are load-bearing:

- `local` scopes the handler to the `eval` block so it does not leak to the caller.
- The `\n` in `"timeout\n"` suppresses the file/line suffix that `die` would otherwise append, making the exact-match test in `$@` reliable.
- `alarm 0` **inside** the `eval` cancels the timer on the success path. Without it, a timer left armed can fire during unrelated code after the `eval` returns.

Examples

Simple wallclock deadline:

```
$SIG{ALRM} = sub { die "timeout\n" };
eval {
    alarm 5;
    my $line = <$slow_pipe>;        # may block indefinitely
    alarm 0;
};
warn "gave up waiting\n" if $@ eq "timeout\n";
```

Nested timers - save and restore:

```
my $saved = alarm 30;               # remember caller's timer
do_something();
alarm $saved;                       # put it back
```

Cancel a pending timer:

```
my $left = alarm 0;                 # 0 if none was pending
```

Periodic tick without `Time::HiRes`:

```
$SIG{ALRM} = sub {
    print "tick\n";
    alarm 1;                        # re-arm from inside the handler
};
alarm 1;
sleep 10;                           # do not mix sleep+alarm in real
 ↪code
```

Sub-second delay - use `Time::HiRes`:

```
use Time::HiRes qw(alarm);
alarm 0.25;                          # 250 ms
```

Edge cases

- **Integer seconds only.** The core `alarm` truncates fractional arguments to whole seconds. For finer granularity, load `Time::HiRes`, which exports a replacement `alarm` that accepts floats.
- **Scheduling jitter.** The signal may arrive up to roughly one second early or late because of how the kernel counts seconds and schedules your process. Treat `alarm N` as a *not-before-N-minus-1* bound, not a precise deadline.
- **One timer per process.** Each `alarm` call replaces the previous timer; there is no queue. The return value is your only record of what was overwritten.
- **Default disposition is fatal.** With no handler installed for `ALRM`, timer expiry terminates the process with `Alarm clock`. Install a handler *before* arming the timer.
- **Do not mix with `sleep`.** On many systems `sleep` is implemented on top of `alarm`, so arming one clobbers the other. Pick one per block.
- **`EINTR` is unreliable.** Perl installs signal handlers with `SA_RESTART` on many platforms, so a `SIGALRM` that interrupts a blocking syscall transparently restarts the call instead of returning with `$!` set to `EINTR`. The portable way to enforce a deadline is `eval` / `die` from the handler, as shown above.
- **Signals are delivered between Perl ops.** Inside a tight pure-Perl loop the handler runs at the next safe point, not instantly; a CPU-bound XS call can defer delivery further.
- **`fork` clears the timer.** Child processes start with no pending alarm regardless of what the parent had armed.
- **exec clears the timer** on Linux; the replacement process image starts with no pending `SIGALRM`.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `sleep` - wallclock delay; often implemented on top of `alarm`, so the two do not compose
- `die` - raise the exception from the `ALRM` handler that `eval` catches to implement a timeout
- `eval` - catches the `die` from the handler and lets the program recover from a timeout
- `%SIG` - where the `ALRM` handler is installed; the handler decides what the timer *means*

- `select` - the four-argument form accepts a floating-point timeout and is an alternative to `alarm` for I/O deadlines
- `Time::HiRes` - drop-in `alarm` replacement that accepts sub-second floats via `setitimer(2)`

Lists

all

Test whether `BLOCK` returns true for **every** element of `LIST`.

`all` walks `LIST` left to right, aliasing `$_` to each element in turn and evaluating `BLOCK` with that element. It returns a true value if every evaluation yields truth, and a false value as soon as any evaluation yields falsity. As soon as one element makes the block false, `all` stops and returns - it does not evaluate the block for the remaining elements.

This is the language-level `all` keyword, enabled by the `keyword_all` feature. It is distinct from `List::Util::all` - see *Edge cases* below.

Synopsis

```
use feature 'keyword_all';
no warnings 'experimental::keyword_all';

all { /\w+/ } @words;
all { defined $_ } @list;        # canonical "all defined" check
all { $_ > 0 } @numbers;
```

What you get back

A boolean. True if every element passes, false otherwise. The exact true/false values are unspecified - treat the result as a condition, not a datum to propagate.

Empty list returns true. This is *vacuous truth*: the statement "every element satisfies `BLOCK`" is trivially true when there are no elements to check. It is the single most common source of surprise with `all`:

```
all { $_ > 0 } ();               # TRUE - no elements, nothing to
 ↪fail
```

Guard with an explicit size check when an empty list should be treated as failure:

```
if (@numbers && all { $_ > 0 } @numbers) { ... }
```

Global state it touches

- `$_` - aliased to each element of `LIST` in turn for the duration of the block. Because this is an alias and not a copy, assigning to `$_` inside the block mutates the underlying list element. The previous value of `$_` is restored when `all` returns.

Examples

Check that every value in a list is defined - the canonical use:

```
my @row = get_record();
die "missing field" unless all { defined $_ } @row;
```

Check that every number is positive:

```
my @prices = (1.99, 4.50, 0.99);
say "ok" if all { $_ > 0 } @prices;          # ok
```

Validate a record where every field must match its own predicate. Combine multiple tests inside the block rather than chaining `all` calls:

```
my @fields = ($name, $age, $email);
my $ok = all {
    defined $_ && length $_ > 0
} @fields;
```

Combine `all` with `any` for an exclusive check - at least one match, but not every element the same:

```
if (any { $_ eq 'admin' } @roles
    && !all { $_ eq 'admin' } @roles) {
    say "mixed roles, including admin";
}
```

Short-circuit behaviour: the block runs only until the first failure. Useful for predicates with side effects or cost:

```
all { expensive_check($_) } @candidates;    # stops at first failure
```

Edge cases

- **Empty list returns true.** Vacuous truth. Guard with `@list && all { ... } @list` when emptiness should fail.
- **Short-circuits on first false.** The block is not called for any element after the first failure. Do not rely on side effects in the block running for every element - use a `for` loop if you need that.
- **`$_` is aliased, not copied.** Modifying `$_` inside the block modifies the list element:

  ```
  my @xs = (1, 2, 3);
  all { $_++; $_ > 0 } @xs;
  # @xs is now (2, 3, 4)
  ```

- **Experimental under 5.44.** The feature emits a compile-time warning in the `experimental::keyword_all` category unless that category is silenced:

  ```
  no warnings 'experimental::keyword_all';
  ```

- **Not the same as `List::Util::all`.** The built-in is a language keyword enabled by the `keyword_all` feature and parses `BLOCK` as a true block (no leading `sub`, no trailing comma). `List::Util::all` is a regular subroutine imported from a module and takes a code reference / block prototype argument. For most practical purposes they behave the same on non-empty lists, but:
  - The keyword form is a parser-level construct and can be optimised more aggressively.
  - The two share neither implementation nor warning category.
  - Code that needs to run on pre-5.42 perls should use `List::Util::all`.
- **Equivalent `grep` form.** `all { COND } @xs` is semantically equivalent to `@xs == grep { COND } @xs` - but `grep` always evaluates the block for every element, so it lacks `all`'s short-circuit behaviour.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `any` - true if the block returns true for **at least one** element; the mirror operator to `all`
- `grep` - evaluates the block for every element and returns matches; `scalar @list == grep { … } @list` is `all` without the short-circuit
- `defined` - the predicate inside the canonical `all { defined $_ } @list` check
- `List::Util::all` - module-level equivalent available on perls older than 5.42; also provides none and `notall` which have no language-level counterpart
- `List::Util::any` - module-level counterpart to the `any` keyword, alongside none and `notall` for the opposite polarities

Lists

any

Return true if `BLOCK` yields true for at least one element of `LIST`.

any runs `BLOCK` once per element of `LIST`, aliasing `$_` to the current element, and returns a true value the moment the block yields true. If no element makes the block true - including the case where `LIST` is empty - any returns false. It never runs the block more times than it has to: the first true result decides the answer and the remaining elements are not examined.

any is not unconditionally available. It is a feature-gated core keyword introduced in Perl 5.42; enable it with:

```
use feature 'keyword_any';
```

The long-standing `List::Util::any`, available since at least Perl 5.20, implements the same semantics as a subroutine. The two are interchangeable for everyday code - pick

the core keyword when you want the slightly lower call overhead and an extra stack frame fewer in profiles, or `List::Util::any` when you also need other `List::Util` exports or have to support Perls older than 5.42.

Synopsis

```
use feature 'keyword_any';
any BLOCK LIST
```

What you get back

A boolean: a true value if any iteration of `BLOCK` yielded true, a false value otherwise. The exact shape of the true/false value is unspecified - treat the return as boolean, do not rely on getting 1 and `""` specifically.

An empty `LIST` returns false. This is the mathematically correct answer (the existential quantifier over an empty domain is false) and matches `List::Util::any`.

Global state it touches

- `$_` is aliased to each element of `LIST` in turn while `BLOCK` runs. The aliasing is the same kind `map` and `grep` use: modifying `$_` inside the block modifies the list element itself. Use a named lexical via `my $x = $_` in the first line of the block if you need a safe copy.

Examples

Test whether any line in a list matches a pattern:

```
use feature 'keyword_any';
my @lines = ("foo\n", "bar ERROR baz\n", "quux\n");
if (any { /ERROR/ } @lines) {
    warn "log contains an error line\n";
}
```

Numeric threshold check:

```
use feature 'keyword_any';
my @nums = (1, 4, 7, 12, 3);
print "over limit\n" if any { $_ > 10 } @nums;   # over limit
```

Command-line flag detection, without pulling in a module:

```
use feature 'keyword_any';
if (any { $_ eq '--verbose' } @ARGV) {
    $verbose = 1;
}
```

any paired with `all` as a sanity check - every record has an `id`, and at least one is flagged active:

```
use feature qw(keyword_any keyword_all);
my @records = (
    { id => 1, active => 0 },
    { id => 2, active => 1 },
);
die "malformed" unless all { defined $_->{id} } @records;
die "none active" unless any { $_->{active} } @records;
```

Using the `List::Util` version when you cannot depend on Perl 5.42:

```
use List::Util qw(any);
print "found\n" if any { $_ eq 'needle' } @haystack;
```

Edge cases

- **Short-circuits on the first true result.** Side effects in `BLOCK` run only for elements examined before (and including) the first true element. Do not use `any` to drive a loop that must touch every element - use `for` or `map` for that.
- **Empty `LIST` returns false.** `any { anything } ()` is false without ever running the block.
- **`$_` aliasing is identical to `map` and `grep`.** Writing to `$_` mutates the source list element. The idiom `any { my $x = $_; ... }` makes the copy explicit.
- **`return` inside `BLOCK` returns from the enclosing sub**, not from `any`. To terminate the scan early with a specific truth value, let the block evaluate to that value - `any` already short-circuits.
- **Core keyword vs `List::Util::any`.** Both implement the same semantics. The core keyword avoids one Perl-level call frame per invocation of `any` itself, which shows up in tight profiling; the block itself still runs per-element either way. Mixing both in the same file is legal but confusing; pick one per file.
- **`experimental::keyword_any` warning.** Because the keyword is still flagged experimental, enabling it emits a warning in the `experimental::keyword_any` category on first use. Silence it with `no warnings 'experimental::keyword_any';` once you have decided to depend on the keyword.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `all` - the universal-quantifier counterpart; true iff `BLOCK` yields true for **every** element
- `grep` - collects every matching element; `scalar grep { ... } @list` has the same truth value as `any { ... } @list` but runs the block for every element
- `List::Util::any` - pre-5.42 subroutine form with identical semantics

- `List::Util::first` - returns the first element for which the block is true, rather than a boolean; use this when you need the element itself
- `map` - same `$_`-aliasing contract, but always visits every element and collects results

Numeric functions

atan2

Arc tangent of `Y/X` in the range -π to π.

`atan2` is the two-argument arctangent - the inverse of tangent that keeps enough information about its inputs to return the correct quadrant. Unlike a single-argument `atan`, which collapses the two signs of `Y` and `X` into one ratio and cannot distinguish the upper half-plane from the lower, `atan2` looks at both arguments and returns an angle covering the full circle: `(-π, π]` radians. It is the canonical way in Perl to convert Cartesian coordinates `(X, Y)` into the polar angle θ.

Synopsis

```
atan2 Y, X
```

What you get back

A floating-point number, the angle in radians between the positive x-axis and the point `(X, Y)`, measured counter-clockwise. Range: `-π < result ≤ π`. Sign follows `Y`: positive `Y` gives a positive angle (upper half-plane), negative `Y` gives a negative angle (lower half-plane). To convert to degrees multiply by `180 / π`:

```
my $deg = atan2($y, $x) * 180 / 3.14159265358979;
```

Examples

Compute π to machine precision. The angle from the origin to `(0, 1)` is exactly π/2, so `atan2(1, 0) * 2` gives π:

```
my $pi = atan2(1, 0) * 2;
printf "%.15f\n", $pi;          # 3.141592653589793
```

Quadrant handling. The four cardinal directions land on exact multiples of π/2, with `(-1, 0)` at the boundary +π, not -π:

```
print atan2( 1,  0), "\n";      #  1.5707963267949   (+π/2, up)
print atan2( 0,  1), "\n";      #  0                 (right)
print atan2(-1,  0), "\n";      # -1.5707963267949   (-π/2, down)
print atan2( 0, -1), "\n";      #  3.14159265358979  (+π, left)
```

Polar conversion. Given a point `(X, Y)`, recover radius and angle:

```
my ($x, $y) = (3, 4);
my $r     = sqrt($x*$x + $y*$y);    # 5
my $theta = atan2($y, $x);          # 0.927295218001612 rad ≈ 53.13°
```

Tangent via the standard identity. Perl has no built-in `tan`, but `sin` and `cos` give it directly - and `atan2` inverts the result unambiguously:

```
sub tan { sin($_[0]) / cos($_[0]) }
my $angle = 0.7;
print atan2(tan($angle), 1), "\n";  # 0.7  (recovers the input)
```

Full-circle sweep. Iterating `Y` around the unit circle shows the range covers `(-π, π]`:

```
for my $deg (0, 45, 90, 135, 180, -135, -90, -45) {
    my $rad = $deg * 3.14159265358979 / 180;
    printf "%4d°  ->  %+.4f rad\n",
        $deg, atan2(sin($rad), cos($rad));
}
```

Edge cases

- **Both arguments zero**: `atan2(0, 0)` is mathematically undefined. The value Perl returns is whatever the platform's C `atan2(3)` returns for this case - on glibc and musl that is `0`, and POSIX permits any value in `[-π, π]`. Do not rely on a specific result; check for `($x == 0 && $y == 0)` before calling if zero is a real possibility in your inputs.
- **Signed zeros**: on IEEE-754 platforms `atan2(+0, -0)` returns `+π` and `atan2(-0, -0)` returns `-π`. This only matters in code that deliberately tracks zero signs; most Perl code never distinguishes them.
- **Infinities**: `atan2(Inf, Inf) == π/4`, `atan2(Inf, -Inf) == 3π/4`, `atan2(-Inf, Inf) == -π/4`, `atan2(-Inf, -Inf) == -3π/4`. The direction "toward `(±Inf, ±Inf)`" is still a well-defined angle bisecting the appropriate quadrant.
- **NaN inputs**: if either `Y` or `X` is `NaN`, the result is `NaN`. Propagates through any further arithmetic - guard with a `Scalar::Util::looks_like_number` check on inputs from untrusted sources.
- **Non-numeric arguments**: strings are coerced to numbers by the usual Perl rules. `atan2("3", "4")` works; `atan2("abc", 1)` is equivalent to `atan2(0, 1)` and emits an `Argument "abc" isn't numeric` warning under `use warnings`.
- **Argument order is `Y, X`, not `X, Y`**: this matches C's `atan2(3)`, FORTRAN's `ATAN2`, and every other language's two-argument arctangent. Reversing the arguments gives the complement angle - a subtle bug that tests in only one quadrant will miss.
- **`atan2` is not `atan`**: there is no one-argument form. `atan2($ratio)` is a syntax error at the call site. For the single-argument arctangent, use `Math::Trig::atan` or `POSIX::atan`, or write it as `atan2($ratio, 1)`.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `sin` - sine; paired with `cos` to reconstruct an angle's coordinates after `atan2` has extracted it
- `cos` - cosine; the X component when converting a radius and angle back to Cartesian coordinates
- `sqrt` - square root; used with `atan2` in the Cartesian → polar conversion `($r, $theta) = (sqrt($x**2+$y**2), atan2($y,$x))`
- - ships `tan`, `atan`, `asin`, `acos`, and the hyperbolic family; also exports `pi` as a constant so you do not have to write `atan2(1,0)*2`

Sockets

bind

Attach a local address to a socket.

`bind` is the Perl wrapper around the POSIX `bind(2)` system call. It associates the already-opened `SOCKET` filehandle with the local address `NAME`, so that subsequent `listen` / `accept` calls (for a server) or `connect` / `send` calls (for a client with a fixed local address) use that address as their source. `NAME` is a **packed** address structure in the form the socket's address family expects - the job of packing is yours, typically via `Socket` helpers such as `` `sockaddr_in` `` or `` `sockaddr_un` ``.

Synopsis

```
bind SOCKET, NAME
```

What you get back

A true value on success, false on failure (with `$!` set to the underlying errno: `EADDRINUSE`, `EACCES`, `EADDRNOTAVAIL`, etc.). Always check the return value - unlike `print`, a failed `bind` is a setup-time error that has to abort the program:

```
bind $sock, $addr
    or die "bind failed: $!";
```

Global state it touches

None directly. `bind` sets `$!` on failure; that is the only interpreter global involved. The socket itself must already be open - typically produced by `socket` or `socketpair` - and `bind` mutates its kernel-side state, not any Perl-level variable.

Examples

Bind a TCP server socket to port 9000 on all local interfaces and start listening. `INADDR_ANY` selects "any local address"; the packed form comes from `` `sockaddr_in` ``:

```
use Socket;

socket(my $srv, PF_INET, SOCK_STREAM, getprotobyname("tcp"))
    or die "socket: $!";
bind($srv, sockaddr_in(9000, INADDR_ANY))
    or die "bind: $!";
listen($srv, SOMAXCONN)
    or die "listen: $!";
```

Bind a client socket to a specific local address before connecting - used when the remote peer filters by source IP, or when a host has multiple interfaces and you need outgoing traffic on a specific one:

```
use Socket;

socket(my $cli, PF_INET, SOCK_STREAM, getprotobyname("tcp"))
    or die "socket: $!";
bind($cli, sockaddr_in(0, inet_aton("192.0.2.17")))
    or die "bind: $!";          # port 0 = kernel picks one
connect($cli, sockaddr_in(443, inet_aton("93.184.216.34")))
    or die "connect: $!";
```

Bind a UNIX-domain listener to a filesystem path. The path must not already exist - bind creates the socket node and leaves it behind when the process exits, so clean it up yourself:

```
use Socket;

my $path = "/tmp/myapp.sock";
unlink $path;                   # clear stale socket from prior run
socket(my $srv, PF_UNIX, SOCK_STREAM, 0)
    or die "socket: $!";
bind($srv, sockaddr_un($path))
    or die "bind $path: $!";
listen($srv, 5) or die "listen: $!";
```

Bind a UDP socket to a fixed local port so replies from the peer come back to a predictable address:

```
use Socket;

socket(my $udp, PF_INET, SOCK_DGRAM, getprotobyname("udp"))
    or die "socket: $!";
bind($udp, sockaddr_in(5300, INADDR_ANY))
    or die "bind: $!";
```

Rebinding a previously-released port in quick succession requires SO_REUSEADDR; otherwise bind fails with EADDRINUSE during the TIME_WAIT window:

```
use Socket;

```

(continues on next page)

(continued from previous page)

```
setsockopt($srv, SOL_SOCKET, SO_REUSEADDR, pack("l", 1))
    or die "setsockopt: $!";
bind($srv, sockaddr_in(9000, INADDR_ANY))
    or die "bind: $!";
```

Edge cases

- **`SOCKET` must already be open.** `bind` does not create the socket - call `socket` first. A closed or never-opened filehandle fails with `EBADF`.
- **`NAME` is a packed byte string, not a human-readable address.** Pass the output of `` `sockaddr_in` ``, `` `sockaddr_in6` ``, or `` `sockaddr_un` `` from `Socket`. Passing a plain string like `"127.0.0.1:9000"` produces `EINVAL` or worse - the kernel reads the bytes as a `struct sockaddr`.
- **Port 0 means "let the kernel choose".** After a successful `bind` with port 0, retrieve the actual port with `getsockname` and `` `sockaddr_in` `` in unpack mode.
- **Ports below 1024** require elevated privileges on Unix - `bind` fails with `EACCES` for an unprivileged process.
- **`EADDRINUSE`** is the most common failure. It fires when another process holds the address, when a prior socket on the same address is still in `TIME_WAIT`, or when you call `bind` twice on the same socket. `SO_REUSEADDR` (see `setsockopt`) addresses the `TIME_WAIT` case; the others are genuine conflicts.
- **UNIX-domain sockets leave a filesystem entry** that outlives the process. Remove it before a fresh `bind` (`unlink $path`) and on clean shutdown.
- **Binding after `connect` is an error.** Once a socket has been connected, its local address is fixed. Call `bind` first if you need a specific source address.
- **IPv6 sockets** use `` `sockaddr_in6` `` and `PF_INET6`; mixing families between the socket and the packed address fails with `EAFNOSUPPORT`.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `socket` - create the socket filehandle that `bind` attaches to; must be called first
- `connect` - the client-side counterpart; sets the remote address instead of the local one
- `listen` - mark a bound socket as willing to accept incoming connections
- `accept` - pull the next pending connection off a bound, listening socket
- `getsockname` - recover the actual address `bind` chose, especially after binding to port 0
- `setsockopt` - set `SO_REUSEADDR` and friends *before* `bind` to control address reuse

- `Socket` - packs and unpacks the `NAME` argument; source of `` `sockaddr_in` ``, `` `sockaddr_un` ``, `INADDR_ANY`, `PF_INET`, and related constants

I/O

binmode

Set the I/O layer stack on a filehandle - typically to make it deliver raw bytes, or to attach a character encoding.

`binmode` reconfigures `FILEHANDLE` so that subsequent reads and writes go through a specific PerlIO layer stack. In the one-argument form it puts the handle into raw binary mode (no CRLF translation, no character decoding). In the two-argument form it pushes (or, for a handful of pseudo-layers, replaces or pops) the named I/O layers onto the handle's stack. Call it after `open` and before any I/O on the handle, except for `:encoding`, which may be applied mid-stream.

Synopsis

```
binmode FILEHANDLE
binmode FILEHANDLE, LAYER
```

What you get back

1 on success, `undef` on failure, with `$!` set. Failure is rare in practice - passing a malformed layer string or an unknown layer name is the usual cause. The return value is worth checking when the layer argument is user-supplied:

```
binmode $fh, ":encoding($enc)"
    or die "bad encoding '$enc': $!";
```

If `FILEHANDLE` is an expression rather than a bareword or simple scalar, its value is taken as the name of the filehandle, matching the filehandle-resolution rules of `open` and `print`.

Global state it touches

`binmode` itself reads no special variables, but the layers it installs change how later I/O on the handle interacts with them. The layer stack governs how `$/` (input record separator) and `$\` (output record separator) are matched and emitted against the external byte stream - on platforms where text mode translates `\n` to a multi-byte sequence, the translation happens inside the layer, not in the variable.

PerlIO layers

A layer is a string beginning with `:` that names a filter in the PerlIO stack - see `PerlIO` for the full catalogue. Multiple layers may be given in one call by concatenating them:

```
binmode $fh, ":raw:utf8";
```

The order is bottom-up: `:raw` is applied first (closest to the OS file descriptor), then `:utf8` sits on top of it. Reads traverse the stack from bottom to top; writes traverse it from top to bottom.

The commonly used layers:

- `:raw` - strip the handle down to byte-for-byte I/O. Turns off CRLF translation, removes any character-encoding layers, and marks the handle as bytes. Despite occasional claims to the contrary, `:raw` is **not** simply the inverse of `:crlf`; it also disables any other layer that would alter the binary nature of the stream. This is what the one-argument form installs.
- `:crlf` - translate `\r\n` sequences to `\n` on input and `\n` to `\r\n` on output. This is the default on Windows / DOS-family systems for text-mode handles; applying it explicitly forces CRLF translation on any platform.
- `:utf8` - mark data on the handle as UTF-8. No validation on input: bytes are accepted and flagged as characters. On output, characters are encoded to UTF-8 bytes. Fast, but trusts the source.
- `:encoding(NAME)` - decode bytes to characters on input and encode characters to bytes on output, using the named encoding (`UTF-8`, `iso-8859-1`, `shiftjis`, etc.). Input that is not valid for the encoding triggers a warning and substitution. `:encoding` implicitly pushes `:utf8` on top of itself because Perl works on UTF-8 internally. See `PerlIO::encoding` for details and tuning options.
- `:bytes` - the inverse of `:utf8`; mark data on the handle as bytes, disabling any character-semantics flag that a higher layer set.

Two pseudo-layers control stack shape rather than filtering:

- `:pop` - remove the topmost layer from the handle.
- `:push` - used with `:via(...)` to stack a custom layer module.

`:raw` in the two-argument form acts as a reset: it pops layers until the handle is in its most minimal state, rather than pushing a new layer on top.

Examples

The one-argument form, for reading a binary file portably:

```
open my $img, "<", "photo.jpg" or die $!;
binmode $img;
my $bytes = do { local $/; <$img> };
```

Read a UTF-8 text file with validation:

```
open my $fh, "<", "notes.txt" or die $!;
binmode $fh, ":encoding(UTF-8)";
while (my $line = <$fh>) {
    # $line contains decoded characters, not bytes
}
```

Write Windows-style line endings on any platform:

```
open my $out, ">", "dos.txt" or die $!;
binmode $out, ":crlf";
print $out "one\ntwo\nthree\n";    # written as one\r\ntwo\r\nthree\
 ↪r\n
```

Strip a previously-applied encoding layer and drop back to bytes:

```
binmode $fh, ":pop";               # remove topmost layer
binmode $fh, ":raw";               # or: flatten to bare bytes
```

Validate a user-supplied encoding before committing to it:

```
my $enc = $ENV{INPUT_ENCODING} // "UTF-8";
binmode $fh, ":encoding($enc)"
    or die "unsupported encoding '$enc': $!";
```

Edge cases

- **Call after open, before I/O.** `binmode` on a handle that has already been read from or written to produces defined but implementation-dependent results; most layers flush pending buffers on install, which may lose data that crossed the layer boundary. `:encoding` is the documented exception - it may be pushed mid-stream without a flush.
- **One-argument form is `:raw`, not "do nothing".** On Unix the observable effect is often nil because handles are already in byte-oriented mode, but on Windows it disables CRLF translation. Write portable code as if `binmode $fh` is always meaningful.
- **CRLF on Windows / DOS.** Without `binmode`, the C runtime on those platforms converts `\r\n` to `\n` on input and the reverse on output. For binary formats (images, compressed data, serialised structures) this silently corrupts the stream. `binmode` is mandatory there.
- **Ctrl-Z as end-of-file.** On Microsoft-family systems, text-mode handles treat `\cZ` (byte 0x1A) as end-of-file. Binary data that happens to contain that byte will appear truncated unless `binmode` is used.
- **`:utf8` is trust-only.** An input handle with `:utf8` but no `:encoding(UTF-8)` will happily hand you invalid UTF-8 flagged as characters. Use `:encoding(UTF-8)` when the source is untrusted.
- **`:encoding` pulls in `:utf8`.** After `binmode $fh, ":encoding(shiftjis)"` the handle has both `:encoding(shiftjis)` and `:utf8` in its stack - perl's internal form is UTF-8 regardless of the wire encoding.
- **Filehandle expressions.** `binmode $handles[0], ":utf8"` works; any expression that yields a filehandle value is accepted as the first argument and is evaluated to name the handle.
- **Affects every I/O primitive on the handle.** The layer stack governs `read`, `sysread`, `syswrite`, `seek`, `tell`, `print`, and `readline` alike. In particular, `sysread` and `syswrite` on a `:utf8`-marked handle still go through the layer and may return partial characters.

- **Interaction with the open pragma.** `use open ":encoding(UTF-8)"` installs a default layer set for subsequently-opened handles. Explicit `binmode` overrides that default for a given handle.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `open` - create the filehandle in the first place; accepts layers directly in the mode string (`<:encoding(UTF-8)`) to skip a follow-up `binmode` call
- `Encode` - encode and decode strings in memory, independent of any filehandle
- `PerlIO` - full layer catalogue, including less common layers like `:scalar`, `:via`, and `:mmap`
- `read` / `sysread` - input primitives whose byte / character semantics depend on the layer stack
- `print` / `syswrite` - output primitives whose encoding and line-ending behaviour depend on the layer stack
- `$/` - input record separator, matched against the post-layer byte stream
- `$\` - output record separator, written through the layer stack

Classes and OO

bless

Mark the thing a reference points at as an object in a package.

`bless` associates the referent of `REF` with the package named by `CLASSNAME`, so that method calls through `REF` dispatch against that package's subroutines (and its `@ISA` ancestors). The reference itself does not change; what changes is the referent's class tag. `bless` returns `REF`, which is why it is almost always the last statement in a constructor.

Synopsis

```
bless REF, CLASSNAME
bless REF
```

What you get back

The same reference that was passed in as the first argument, now carrying the class tag of `CLASSNAME`. Returning the reference lets you tail-call `bless` from a constructor:

```
sub new {
    my ($class, %args) = @_;
    return bless { %args }, $class;
}
```

From that point on, `ref` on the returned reference yields the class name rather than the raw reference type (`HASH`, `ARRAY`, `CODE`, ...).

Forms

Two calling forms, one strongly preferred:

- **Two-argument - always use this.**

  ```
  bless $ref, $class;
  ```

  The referent becomes an object in the package named by `$class`. Using the first argument of the constructor (`$_[0]`, conventionally `$class`) keeps the constructor inheritable: a subclass calling `Parent::new('Child', ...)` gets back an object blessed into `Child`, not into `Parent`.

- **Two-argument with empty string - bless into `main`.**

  ```
  bless $ref, "";
  ```

  An empty `CLASSNAME` is treated as the `main` package. Rarely useful outside of deliberate tricks.

- **One-argument - discouraged.**

  ```
  bless $ref;
  ```

  The referent is blessed into the *current* package (the package the `bless` call is compiled in). This breaks inheritance: a subclass that inherits a one-argument `bless` constructor still ends up with objects in the parent's package, not the caller's. Use the two-argument form unless you have a concrete reason not to, and document the reason.

Examples

A minimal hash-based class:

```
package Point;

sub new {
    my ($class, $x, $y) = @_;
    return bless { x => $x, y => $y }, $class;
}

sub x { $_[0]->{x} }
sub y { $_[0]->{y} }

package main;

my $p = Point->new(3, 4);
print ref $p, "\n";       # Point
print $p->x, ",", $p->y;  # 3,4
```

Inheritable constructor - the same new works for a subclass without modification:

```
package Shape;
sub new {
    my ($class, %args) = @_;
    return bless { %args }, $class;
}

package Circle;
our @ISA = ('Shape');
sub area {
    my $self = shift;
    return 3.14159 * $self->{radius} ** 2;
}

package main;
my $c = Circle->new(radius => 5);
print ref $c, "\n";       # Circle
print $c->area, "\n";     # 78.53975
```

Array-based objects work the same way - any reference type can be blessed:

```
package Pair;
sub new {
    my ($class, $a, $b) = @_;
    return bless [$a, $b], $class;
}
sub first  { $_[0]->[0] }
sub second { $_[0]->[1] }

my $p = Pair->new("left", "right");
print $p->first, "/", $p->second;   # left/right
```

Re-blessing an existing object changes its class tag in place:

```
my $obj = bless {}, 'OldClass';
bless $obj, 'NewClass';
print ref $obj;            # NewClass
```

`bless` returns the reference, which is why chaining into method calls on the same line works:

```
Logger->new(file => $path)->info("started");
#                           ^ called on the blessed ref
```

Edge cases

- **The reference is what gets tagged, not the variable.** Copies of the reference share the class tag because they all point to the same referent:

```
my $a = bless {}, 'Foo';
my $b = $a;
print ref $b;            # Foo
```

- **Re-blessing is permitted and immediate.** A reference can be blessed as many times as you like; each call overwrites the previous class tag. There is no "unbless" built-in - rebless into a neutral package if you need to strip objecthood from a referent you still hold references to.
- **`CLASSNAME` of `""` means `main`.** Explicit and rarely wanted; usually a sign that a computed class name came out empty by accident.
- **Avoid `bless $ref, "0"`.** The class name `"0"` is a false value, so code that checks `if (ref $obj) { ... }` will misread the object as "not a reference". Pick any non-false class name.
- **Class-name casing convention.** Use mixed-case (`My::Package`). ALL-CAPS names are reserved for Perl built-in types (`SCALAR`, `ARRAY`, `HASH`, `CODE`, ...) and all-lowercase names are reserved for pragmas (`strict`, `warnings`, `utf8`). Blessing into either namespace invites confusion with language-level machinery.
- **Non-reference first argument is a fatal error.** `bless 42, 'Foo'` dies with `Can't bless non-reference value`. The first argument must be a reference.
- **One-argument `bless` picks the compile-time package.** It uses the package the `bless` call is *lexically* inside - not the caller's package, not the package of `$class`. That is exactly why it breaks inheritance and why the two-argument form exists.
- **Weak references and blessing interact as expected.** `Scalar::Util::weaken` on a blessed reference does not unbless it; the weakened slot still sees the class tag, and `ref` works until the referent is destroyed.
- **`DESTROY` fires on the blessed referent.** When the last reference to a blessed referent goes away, Perl calls `DESTROY` in the reference's class (following `@ISA`). Changing the class with a late `bless` changes which `DESTROY` runs.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `ref` - read the class tag back off a blessed reference, or the reference type (`HASH`, `ARRAY`, ...) for an unblessed one
- `package` - declare the package a `bless` call or a subroutine definition compiles into; the target of one-argument `bless`
- `class` - the experimental class-syntax built-in that replaces the hand-rolled `package` + `bless` constructor pattern with declarative syntax
- `tie` - a different form of per-variable magic; unrelated to `bless` despite the superficial "attach behaviour to a value" framing
- `@ISA` - the inheritance chain consulted when dispatching a method call on a blessed reference

- `DESTROY` - the destructor method Perl calls on the blessed referent when its last reference goes away; declared as a subroutine inside the class's package

Control flow

break

Break out of a `given` block.

`break` terminates the enclosing `given` block immediately and transfers control to the statement following it - the `given` analogue of what `last` does for loops. It takes no arguments, returns no value, and applies only to the innermost `given`; it cannot target an outer block by label.

Synopsis

```
break
```

Availability - read this first

`break` is a keyword of the `switch` feature, together with `given`, `when`, `default`, and (inside a `when`) `continue`. In Perl 5.44 the switch feature is **disabled by default** and is not part of any current feature bundle: `use v5.36` through `use v5.44` do **not** turn it on. The feature still exists and can be used, but only under explicit opt-in:

```
use feature 'switch';
no warnings 'experimental::smartmatch';
```

Without that opt-in, the bareword `break` is parsed as an ordinary subroutine call and fails at compile time with `Bareword "break" not allowed while "strict subs" in use`, or at runtime with `Undefined subroutine &main::break called`. The fully-qualified form `CORE::break` works from any scope without enabling the feature and is how you invoke it in code that otherwise keeps `switch` off.

`given`/`when` rely on smartmatch (`~~`), which is itself experimental and warns on every use unless `experimental::smartmatch` warnings are suppressed. New code should **not** reach for `given`/`when`/`break`; see *Replacements* below.

Behaviour

Inside a `given` block, `break` unwinds to the statement immediately after the block. It is equivalent to what falls through the bottom of a `when` branch implicitly - `when` clauses `break` at the end of their body unless the body ends in `continue`, so an explicit `break` is mostly used for early exit from a long `when` body:

```
use feature 'switch';
no warnings 'experimental::smartmatch';

given ($cmd) {
    when ('quit') {
        cleanup();
```

(continues on next page)

(continued from previous page)

```
        break if $fast_exit;        # skip the logging below
        log_exit();
    }
    when ('help') { show_help() }
    default       { warn "unknown: $cmd" }
}
```

Outside a `given` block, `break` raises `Can't "break" outside a given block` at runtime.

Replacements

For new code, prefer one of these forms. They are plain Perl, need no feature opt-in, and have no deprecation cloud over them:

- **`if` / `elsif` / `else` chain** - direct replacement for most `given`/`when` usage:

```
if    ($cmd eq 'quit') { cleanup(); log_exit() }
elsif ($cmd eq 'help') { show_help() }
else                   { warn "unknown: $cmd" }
```

- **Dispatch table** - a hash of coderefs keyed by the input, with a default branch. Scales better than a long `elsif` ladder and makes the set of handled cases data rather than control flow:

```
my %dispatch = (
    quit => sub { cleanup(); log_exit() },
    help => \&show_help,
);
($dispatch{$cmd} // sub { warn "unknown: $cmd" })->();
```

- **Labelled loop with `last`** - when you specifically want the "exit this block early" shape that `break` provided, wrap the body in a bare block and `last` out of it:

```
CMD: {
    if ($cmd eq 'quit') { cleanup(); last CMD if $fast_exit;
 ↪log_exit(); last CMD }
    if ($cmd eq 'help') { show_help(); last CMD }
    warn "unknown: $cmd";
}
```

Examples

Explicit feature opt-in, early-exit from a `when` body:

```
use feature 'switch';
no warnings 'experimental::smartmatch';

given ($n) {
    when ($_ < 0) { warn "negative"; break }   # skip the log below
```

(continues on next page)

(continued from previous page)

```
    when (0)      { warn "zero" }
    default       { warn "positive: $n" }
}
# control resumes here after break
```

Using `CORE::break` without enabling the feature globally:

```
sub classify {
    my ($n) = @_;
    given ($n) {
        when ($_ < 0) { return "neg"; CORE::break }
        when (0)      { return "zero" }
        default       { return "pos" }
    }
}
```

Edge cases

- **No argument form.** `break` takes nothing. `break LABEL` is a syntax error - unlike `last`/`next`, `break` has no way to target an outer block.
- **Outside `given`.** Calling `break` (or `CORE::break`) when no `given` block is on the call stack raises `Can't "break" outside a given block`.
- **`return` wins.** Inside a subroutine, `return` unwinds the whole sub regardless of any enclosing `given`. `break` only unwinds to the end of the `given`; control continues in the surrounding sub.
- **Implicit `break` at end of `when`.** A `when` clause's body ends with an implicit `break` unless the body is `continue`, so an explicit `break` at the end of a `when` body is redundant. `continue` suppresses the implicit `break` and lets control fall through to the next `when`.
- **Not a loop keyword.** `break` does not interact with `for`, `while`, `foreach`, `do`, or bare blocks. For those, use `last`.
- **Experimental warnings.** Running `given`/`when` code without `no warnings 'experimental::smartmatch'` prints the warning once per smartmatch site, which in a busy `given` block can be every iteration.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `last` - the loop counterpart; exits the innermost enclosing `for` / `while` / `foreach` / bare block, and unlike `break` can target an outer block by label
- `next` - start the next iteration of a loop rather than exiting it; useful when `break` is the wrong shape because you want continuation, not termination

- `return` - unwinds out of the enclosing subroutine entirely, not just the `given` block; use when the `given` is a dispatcher inside a sub and the answer is ready

Control flow · Scoping

caller

Return information about the subroutine, `eval`, or `require` that called the currently executing code.

`caller` walks the call stack. With no argument it returns a short three-element record identifying *who called us*. With a numeric argument `EXPR` it walks `EXPR` frames further back and returns a longer eleven-element record - the form the debugger, stack-trace modules, and `warn`/`die` machinery use to decorate diagnostics with file-and-line context. XS frames are invisible to `caller`; the next pure-Perl frame surfaces in their place.

Synopsis

```
caller
caller EXPR
```

What you get back

In scalar context, the caller's package name, or `undef` if there is no caller (i.e. we are at the top level of the file, not inside a `sub`, `eval`, or `require`):

```
my $pkg = caller;
```

In list context with no argument, three elements - the immediate caller's package, file, and line number:

```
# 0         1           2
my ($package, $filename, $line) = caller;
```

In list context with a numeric argument, eleven elements describing the frame `EXPR` levels up. `0` is the immediate caller, `1` is its caller, and so on:

```
# 0         1           2      3             4
my ($package, $filename, $line, $subroutine, $hasargs,

#   5           6           7            8       9         10
    $wantarray, $evaltext, $is_require, $hints, $bitmask, $hinthash)
  = caller($i);
```

The eleven fields, in order:

- `$package`, `$filename`, `$line` - location of the *call site* inside that frame's caller. Same three values the short form returns.
- `$subroutine` - fully qualified name of the sub the frame belongs to, e.g. `"Foo::bar"`. For an `eval` frame it is the literal string `"(eval)"`. If the sub has been removed from the symbol table since the call, it is `"(unknown)"`.

- `$hasargs` - true if a fresh `@_` was set up for the frame. False for `eval` and `require` frames.
- `$wantarray` - the context the frame was called in, as `wantarray` would have reported it: true for list, defined-but-false (`""`) for scalar, `undef` for void.
- `$evaltext` - for an `eval EXPR` frame, the source text that was compiled. Undef for `eval BLOCK` and for non-`eval` frames.
- `$is_require` - true if the frame was created by `require` or `use` (each `use` creates a `require` frame nested inside an `eval EXPR` frame).
- `$hints` - the value of `$^H` at the point the frame's code was compiled. Internal; layout is not stable across Perl versions.
- `$bitmask` - the value of `${^WARNING_BITS}` at the same point. Also internal.
- `$hinthash` - a reference to the `%^H` hash captured at compile time, or `undef` if it was empty. Do **not** modify it - the reference points at the live optree.

Global state it touches

- `@DB::args` - set as a side effect when `caller` is called with an argument *from inside the* `DB` *package*. The caller's argument list is aliased into this array for debugger use. See *Edge cases* below - this is best-effort and has sharp corners.
- `$^H`, `${^WARNING_BITS}`, `%^H` - read out of the target frame's compiled state to populate `$hints`, `$bitmask`, `$hinthash`.

Examples

Find the immediate caller's package and report to the right log:

```
sub log_for_caller {
    my $pkg = caller;
    warn "[$pkg] @_\n";
}
```

Produce a `warn`-style location tag. `caller` returns filename and line of the call site one frame up, which is almost always the information you actually want in a diagnostic:

```
sub note {
    my (undef, $file, $line) = caller;
    print STDERR "note at $file line $line: @_\n";
}
```

Walk the full stack. Iterate `caller($i)` until it returns an empty list:

```
sub stacktrace {
    my @frames;
    for (my $i = 0; my @f = caller($i); $i++) {
        push @frames, \@f;
    }
    return @frames;
}
```

Detect whether the current sub was called in list, scalar, or void context. This is `wantarray` at the current level, but for somebody else's frame you reach through `caller`:

```
sub describe_parent_context {
    my $wa = (caller(1))[5];
    return !defined $wa ? "void"
         :  $wa         ? "list"
         :               "scalar";
}
```

Tell a `require`/`use` frame apart from an ordinary `eval`:

```
sub called_from_require {
    my @f = caller(1);
    return @f && $f[7];            # field 7 is $is_require
}
```

Render a single frame the way the default `die` / `Carp` formatter does - `"at FILE line LINE"`:

```
sub location_tag {
    my $depth = shift // 0;
    my (undef, $file, $line) = caller($depth);
    return defined $file ? "at $file line $line" : "at top level";
}
```

Edge cases

- **Scalar context, no caller**: at the top level of a script, `scalar caller` returns `undef`, and list-context `caller` returns the empty list. A common idiom for "am I being `require`d as a module, or run as a script?" is `caller() ? ... : ...`.
- **XS frames are skipped**. `caller` only reports pure-Perl frames. If a pure-Perl sub was invoked by an XS sub which was invoked by another pure-Perl sub, `caller(0)` from the inner sub reports the outer pure-Perl sub - the XS layer is invisible. Stack depths measured with `caller` therefore do not include XS dispatchers.
- **`eval` frames have no args**. `$hasargs` is false for `eval` and `require` frames, and `$subroutine` is the literal `"(eval)"` - not the package of the surrounding code.
- **`eval BLOCK` vs `eval EXPR`**. Both give `$subroutine eq "(eval)"`. Only `eval EXPR` fills `$evaltext`; `eval BLOCK` leaves it `undef`.
- **`use` creates two frames**. A `use Foo` statement is compiled as `BEGIN { require Foo; Foo->import; }`, and `require` itself is implemented as an `eval EXPR`. Walking the stack through a `use` line therefore sees a `require`-flagged `eval` frame inside an ordinary `eval` frame. Check `$is_require` to distinguish.
- **`(unknown)` subroutines**. If the sub named in a frame has been deleted from the symbol table (symbol-table surgery, `delete $Foo::{bar}`) between the call and the `caller`, `$subroutine` reads `"(unknown)"`.
- **Loops and `try` blocks are not frames**. `while`, `for`, `foreach`, and `try` do not create call frames. `caller` only sees subroutine calls and `eval`s.

- **Optimiser-elided frames**. The optimiser may remove tail-call and similar frames before `caller` can observe them. For `caller(N)` with `N > 1`, the frame you get is not guaranteed to be the frame you expected. Do not encode stack depth as a load-bearing contract.
- **`@DB::args` is best-effort**. It is populated only when `caller` is called with an argument from inside package `DB`. The values are aliases into the target frame's `@_`, not copies - so:
  - Mutations the frame has already made to `@_` are visible; original call-time values are not preserved.
  - `shift @_` inside the frame is usually undone in `@DB::args`, but `pop @_`, splices, or having taken a reference to `@_` all break that.
  - Elements may have been freed and reused for other values by the time you read them.
  - Stale state from a previous `caller` call may still be in `@DB::args` if the current call didn't trigger a refresh. Use it for backtraces and debugger display; do not rely on it for program logic.
- **`$hinthash` is live**. The hash reference in field 10 points at the actual `%^H` snapshot baked into the optree. Modifying its contents mutates compiler state. Read it; don't write it.
- **Filename and line can be rewritten**. `#line` directives and anything else the "Plain Old Comments (Not!)" mechanism recognises (see `perlsyn`) change the values `caller` reports, just as they change `__FILE__` and `__LINE__`.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `die` - raises an exception; its default message uses the same file-and-line information `caller` exposes
- `eval` - creates frames that `caller` tags with `$subroutine eq "(eval)"` and may fill `$evaltext` / `$is_require`
- `wantarray` - reports the current frame's calling context; the same value appears as field 5 of `caller(N)` for the frame `N` levels up
- `$^H` - compile-time hint bits; surfaced as field 8
- `%^H` - compile-time hint hash; surfaced as field 10
- `${^WARNING_BITS}` - warnings bitmask; surfaced as field 9

Control flow

catch

Handle an exception thrown by a preceding `try` block.

`catch` is the second half of the `try`/`catch` construct. It is not a standalone statement: it follows a `try` block, declares a lexical `VAR` to receive the exception value, and runs its `BLOCK` only when the `try` block died. If the `try` block completed normally the `catch` block is skipped. Control then resumes at the statement following the whole construct (or the `finally` block, if one is present).

This syntax must be enabled with `use feature 'try'`. `try` and `catch` are non-experimental as of Perl 5.40.

Synopsis

```
try BLOCK catch (VAR) BLOCK
try BLOCK catch (VAR) BLOCK finally BLOCK
```

What you get back

`catch` is not a function call and has no return in the expression sense. Like other control-flow constructs, the value of the whole `try`/`catch` is the value of whichever block ran last - useful inside a `do` block or as the tail expression of a subroutine:

```
my $value = do {
    try {
        fetch_thing(@args);
    }
    catch ($e) {
        warn "fetch failed: $e";
        $DEFAULT;
    }
};
```

If `try` ran to completion, the construct yields the `try` block's last value and `VAR` is never bound. If `try` died, the construct yields the `catch` block's last value.

The VAR declaration

The parentheses after `catch` are mandatory and must contain exactly one scalar variable declaration. It behaves like a `my` declaration - the `my` keyword is implicit, as in subroutine signatures:

```
catch ($e)  { ... }         # $e is a new lexical
catch (my $e) { ... }       # syntax error - 'my' is already implied
```

`VAR` is scoped to the `catch` block only. It is not visible in the preceding `try` block, in any following `finally` block, or after the construct. Its value is whatever the `try` block threw - a string, a list that stringified into one, or a reference, typically a blessed exception object. See `die` for how the exception value is produced.

Unlike `eval`, `catch` does **not** read or clear `$@`; the exception travels through VAR directly. `$@` is untouched by the construct.

Global state it touches

`catch` itself touches no special variables. The `try`/`catch` construct as a whole leaves `$@` unchanged - a deliberate divergence from `eval` intended to stop callers from conflating the two idioms. If you need `$@`-style inspection, use `eval` instead.

Examples

Catch a simple string exception and report it:

```
use feature 'try';

try {
    risky();
}
catch ($e) {
    warn "risky failed: $e";
}
```

Inspect a structured exception object:

```
try {
    process($record);
}
catch ($e) {
    if (ref($e) && $e->isa('My::NotFound')) {
        return;                         # missing is fine
    }
    die $e;                             # re-throw everything else
}
```

Re-throw unchanged with `die`. Because `catch` does not touch `$@`, you re-throw the variable you bound, not `$@`:

```
try {
    step();
}
catch ($e) {
    log_error($e);
    die $e;                             # propagates to the next␣
↪handler
}
```

Produce a value from the construct without `return`. Using `return` inside `try` or `catch` returns from the **enclosing subroutine**, not from the construct - see *Edge cases*:

```
sub safe_parse {
    my ($text) = @_;
```

(continues on next page)

(continued from previous page)

```
    try {
        parse($text);
    }
    catch ($e) {
        warn "parse error: $e";
        undef;                          # value of the catch block
    }
}
```

A `catch` block that itself dies - the new exception propagates outward to the next enclosing handler (`try`/`catch`, `eval`, or program exit):

```
try {
    open_db();
}
catch ($e) {
    cleanup();
    die "open_db failed: $e";          # thrown from inside catch
}
```

Edge cases

- **Cannot stand alone.** `catch (VAR) { ... }` without a preceding `try` block is a syntax error. `catch` is parsed as part of the `try` construct, not as an independent keyword.
- **Exactly one scalar in parentheses.** The parentheses are mandatory, must declare exactly one scalar, and the `my` keyword is implied. `catch { ... }` without parentheses is a syntax error.
- **`VAR` is block-scoped.** It exists only inside the `catch` block. A `finally` block that follows does **not** see it.
- **Falsy exceptions still trigger the handler.** `try` distinguishes "died" from "completed normally" by a flag set at unwind time, not by truthiness of the exception value. `die 0`, `die ""`, and `die undef` all enter the `catch` block; `VAR` receives the value as thrown (with `die`'s usual coercion of `undef` to `"Died at ..."`).
- **`$@` is not set.** Code that reaches for `$@` inside a `catch` block is reading the caller's `$@`, not the exception just caught. Use `VAR`.
- **A `catch` block may die.** Exceptions raised from inside `catch` are **not** re-caught by the same construct. They propagate to the next enclosing handler. This is the mechanism for re-throw (`die $e`) and for reporting cleanup failures from the handler itself.
- **`return` inside `catch` returns from the enclosing subroutine**, not from the `catch` block. This differs from `eval` BLOCK, where `return` would leave only the `eval`. To yield a value *from* the construct, use the block's final expression instead of `return`.
- **Loop controls (`last`, `next`, `redo`) inside `catch`** target an enclosing loop, not the construct. The `try`/`catch` construct is not itself a loop.

- **`caller()` does not see the `catch` frame.** Because `catch` does not intercept `return`, it is invisible to `caller`, like `while` or `foreach` are.
- **Pairs only with the immediately preceding `try`.** You cannot have two `catch` blocks, nor place statements between `try` and `catch`. The optional `finally` block, if present, must come after `catch`.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `try` - the block whose failure this `catch` handles; always paired with exactly one `catch`
- `finally` - optional third block that runs regardless of whether the `try` block died; cannot `return` or use loop controls
- `die` - produces the exception value that `VAR` receives; use it inside `catch` to re-throw
- `eval` - older exception-handling idiom using `$@`; reach for `try`/`catch` instead in new code for clearer scoping and no `$@` footguns
- `$@` - left untouched by `try`/`catch`; inspect `VAR` instead

Filehandles, files, directories

chdir

Change the process's current working directory.

`chdir` is the Perl wrapper around the `chdir(2)` and - where the kernel supports it - `fchdir(2)` system calls. It changes the directory that relative paths are resolved against for the current process and, on success, persists that change for every subsequent file operation in the program.

Synopsis

```
chdir EXPR
chdir FILEHANDLE
chdir DIRHANDLE
chdir
```

What you get back

1 on success, `0` on failure. On failure `$!` is set to the underlying `errno` so you can distinguish "no such directory" (`ENOENT`) from "permission denied" (`EACCES`) from "not a directory" (`ENOTDIR`):

```
chdir $path
    or die "chdir $path failed: $!";
```

The return is always a plain boolean - there is no separate "changed to nowhere because no argument was given" value. The no-argument form either succeeds by changing to the home directory or fails like any other call.

Global state it touches

- `%ENV` - read when `chdir` is called with no argument. The lookup order is `$ENV{HOME}` first, then `$ENV{LOGDIR}`. If neither is set, `chdir` does nothing and returns `0`.
- `$!` - set on failure to the `errno` reported by the kernel.

`chdir` does **not** update `$ENV{PWD}`. Shells maintain `PWD` themselves; a Perl program that cares about `PWD` for child processes has to assign to `$ENV{PWD}` after a successful `chdir`.

Argument forms

- **`chdir EXPR`** - `EXPR` is stringified and passed to `chdir(2)` as a pathname. Relative paths are resolved against the current working directory at the moment of the call.
- **`chdir FILEHANDLE`** and **`chdir DIRHANDLE`** - on Linux (and any system with `fchdir(2)`) the kernel changes directory to the one the handle refers to. `FILEHANDLE` here means a filehandle opened on a directory, or a directory handle from `opendir`. Using the handle form avoids a TOCTOU race between resolving a pathname and changing into it.
- **`chdir`** (no argument) - changes to `$ENV{HOME}`, falling back to `$ENV{LOGDIR}` if `HOME` is unset. If both are unset the call fails and `$!` is left untouched; check the return value, not `$!`.

Examples

Change into a directory and bail out if it does not exist:

```
chdir "/var/log"
    or die "cannot enter /var/log: $!";
```

Run a block of work in a different directory and return to where you started:

```
use Cwd qw(getcwd);
my $origin = getcwd;
chdir $work_dir or die "chdir $work_dir: $!";
# ... do work relative to $work_dir ...
chdir $origin  or die "chdir $origin: $!";
```

Change via a directory handle (race-free on systems with `fchdir(2)`):

```
opendir my $dh, $path or die "opendir $path: $!";
chdir $dh              or die "fchdir $path: $!";
```

Go home:

```
chdir or die "no HOME/LOGDIR in environment";
```

Probe a list of candidates, stopping at the first that works:

```
for my $d ("/srv/app", "/opt/app", "/usr/local/app") {
    last if chdir $d;
}
```

Edge cases

- **Empty string or undef**: `chdir ""` and `chdir undef` both fail and set `$!` to `ENOENT`. They do **not** fall back to `$HOME` - the no-argument form is triggered by *absence* of an argument, not by an argument that happens to be empty.
- **Relative paths on a thread with its own cwd**: the kernel's current working directory is per-process, not per-thread, on Linux. Two threads calling `chdir` concurrently race.
- **Symlink to a directory**: `chdir` follows symlinks, landing in the target. Use `readlink` or `Cwd::abs_path` first if you need to know the real destination.
- **Deleted directory**: if the directory was removed after you entered it, relative operations from inside fail with `ENOENT` and most shells show the path as `(deleted)`. You can still `chdir` out with an absolute path.
- **Handle form on systems without `fchdir(2)`**: raises an exception. Linux always supports it; the restriction is a portability concern for code that also runs on older systems.
- **Untrusted input**: passing a user-supplied path to `chdir` without validation lets the caller redirect all subsequent relative-path operations in the program. Canonicalise with `Cwd::abs_path` and check against an allow-list before the call if the input crosses a trust boundary.
- **After `fork`**: the child inherits the parent's cwd. A `chdir` in the child does not affect the parent.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `mkdir` - create a directory; pair with `chdir` when building a workspace and stepping into it
- `rmdir` - remove a directory; do not `rmdir` the cwd, `chdir` out first
- `opendir` - open a directory handle usable as the argument to `chdir` for race-free directory changes
- `chroot` - stronger confinement than `chdir`; changes the filesystem root for the process, not just the cwd

- `$ENV{HOME}` - consulted by the no-argument form of `chdir` before falling back to `$ENV{LOGDIR}`
- `$!` - carries the `errno` when `chdir` returns `0`

Filehandles, files, directories

chmod

Change the permission bits of a list of files.

`chmod` sets each file in `LIST` to the permission `MODE`. `MODE` is a **numeric** value - the low twelve bits are the usual Unix permission triad plus the setuid, setgid, and sticky bits, exactly as accepted by `chmod(2)`. Both plain pathnames and open filehandles are accepted in `LIST`. Returns the number of files for which the underlying system call succeeded.

Synopsis

```
chmod MODE, LIST
```

What you get back

The number of files successfully changed, as an integer. Zero means every call failed; a value less than `scalar @files` means a partial failure. `chmod` does **not** throw on a per-file failure - it keeps going and tallies the successes.

`$!` reflects the error from the **last** failing file only. On a mixed success/failure run there is no built-in way to learn which files failed; if you need per-file error reporting, call `chmod` once per file and check the return value each time:

```
for my $f (@files) {
    chmod 0644, $f
        or warn "chmod $f: $!";
}
```

Writing MODE correctly

`MODE` is an integer. The three ways to spell it:

- **Octal literal with leading zero**: `0644`, `0755`, `0600`. This is the conventional form and matches the digits you would type into `chmod(1)`.
- **Octal literal with `0o` prefix**: `0o644`, `0o755`. Accepted since Perl 5.34; equivalent to the leading-zero form and easier to read as "octal" at a glance.
- **Symbolic constants from `Fcntl`**: `use Fcntl qw(:mode); S_IRWXU | S_IRGRP | S_IXGRP | S_IROTH | S_IXOTH` evaluates to `0755`. Useful when a permission set is built up from pieces.

A string argument is almost always a bug:

```
chmod "0644", "foo";     # WRONG - stringifies as decimal 644 (octal␣
↪1204),
                         #         grants mode --w----r-T
chmod 644,    "foo";     # WRONG - decimal 644 is octal 1204, same␣
↪result
chmod 0644,   "foo";     # right
chmod 0o644,  "foo";     # right (Perl 5.34+)
```

If the mode genuinely arrives as a string (configuration file, CLI argument), convert it with `oct` first:

```
my $mode = "0644";       # string from config
chmod oct($mode), "foo"; # oct("0644") == 0644
```

Global state it touches

Sets `$!` on any failure to match the last failing `chmod(2)` / `fchmod(2)` call. Reads no interpreter globals.

Examples

Change one file, check for success:

```
chmod 0755, "install.sh"
    or die "chmod install.sh: $!";
```

Change many files in a single call, capture the count:

```
my $cnt = chmod 0644, "a.txt", "b.txt", "c.txt";
print "updated $cnt of 3 files\n";
```

With an array of pathnames:

```
my @executables = glob "bin/*";
chmod 0755, @executables;
```

Preserve existing bits, add owner write. Reads the mode with `stat`, masks to the permission bits, ORs in the new bit, and writes it back:

```
open my $fh, "<", "foo" or die $!;
my $perm = (stat $fh)[2] & 07777;
chmod $perm | 0200, $fh;
```

Symbolic form via `Fcntl`:

```
use Fcntl qw(:mode);
chmod S_IRWXU | S_IRGRP | S_IXGRP | S_IROTH | S_IXOTH, @executables;
# identical to: chmod 0755, @executables;
```

Per-file error reporting (needed to learn *which* file failed on a multi-file call):

```
my @failed;
for my $f (@files) {
    push @failed, $f unless chmod 0644, $f;
}
warn "chmod failed on: @failed\n" if @failed;
```

Edge cases

- **Empty list**: `chmod 0644` returns `0`. The mode is evaluated but no system call is made.
- **String modes**: `chmod "0644", $f` and `chmod "+x", $f` are both wrong. `chmod` never parses symbolic mode strings - unlike `chmod(1)`, the built-in takes a number, not a specification.
- **Filehandles vs barewords**: a bareword in `LIST` is a filename, not a filehandle. Pass a filehandle as a glob or glob reference:

  ```
  chmod 0644, *FH;          # filehandle
  chmod 0644, \*FH;         # filehandle
  chmod 0644, $fh;          # filehandle (lexical)
  chmod 0644, "FH";         # filename "FH" - almost certainly a
   ↪bug
  ```

  On systems without `fchmod(2)`, passing a filehandle raises an exception. Linux supports `fchmod(2)`, so on the platforms pperl targets this always works.
- **Setuid / setgid / sticky bits**: the high three bits of the mode word (`04000`, `02000`, `01000`) set setuid, setgid, and the sticky bit respectively. `0o4755` makes a setuid executable; `0o2775` a setgid directory.
- **Symlinks**: `chmod` follows symlinks. Changing permissions on the symlink itself is not portable and is not exposed by this built-in - use `lchmod` from a module if the platform supports it.
- **Permission to change permission**: only the file's owner (and root) may call `chmod(2)` on a file. Failure sets `$!` to `EPERM`.
- **Non-existent paths**: `chmod` on a missing path sets `$!` to `ENOENT` and contributes `0` to the success count. It does not warn and does not die.
- **umask does not apply**: `umask` masks the mode of *newly created* files from `open`, `sysopen`, `mkdir`, and similar. `chmod` sets the mode literally - no masking.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `chown` - the sibling call for changing owner/group; same list-and-return-count shape
- `stat` - read the current mode so you can modify it rather than replace it wholesale

- `umask` - default permission mask applied to *new* files; unrelated to `chmod`, which sets bits literally
- `open` / `sysopen` - create files; the mode argument to `sysopen` is masked by `umask` at creation time and can then be tightened or relaxed with `chmod`
- `oct` - parse `"0644"` into the integer `0644` when the mode arrives as a string
- `$!` - system error from the last failing file; only meaningful for single-file calls or immediately after a failing per-file call in a loop

SCALARs and strings

chomp

Strip the trailing input record separator from a string in place.

`chomp` removes any trailing substring that matches the current value of `$/` from its argument and returns the total number of characters removed across every argument it touched. It mutates its argument; the return value is a count, not the chomped string. If no argument is given, it operates on `$_`. `chomp` is the safer counterpart to `chop`: it only removes the separator if it is actually there, and it respects `$/` so it does the right thing on files that end without a final newline or that use a non-newline record terminator.

Synopsis

```
chomp VARIABLE
chomp( LIST )
chomp
```

What you get back

The total number of characters removed, as an integer. Usually `0` (no separator was present) or `1` (a single `"\n"` was removed under the default `$/`). When `$/` is a multi-character string, a successful chomp returns its length. When chomping a list, the count is summed across every element.

The chomped value lives in the variable you passed; `chomp` is called for effect, not for its return value:

```
my $line = "hello\n";
my $n = chomp $line;        # $line is "hello", $n is 1
```

Global state it touches

- `$/` - **input record separator**. `chomp` reads `$/` on every call and strips a trailing occurrence of its current value. Changing `$/` changes what `chomp` removes; this is usually what you want when you set `$/` to read custom-delimited records.
- `$_` - consumed as the default argument when `chomp` is called with no argument. `chomp;` inside `while (<>) { ... }` is the canonical idiom.
- Hash iterator - chomping a hash resets its `each` iterator (see *Edge cases*).

Examples

The everyday use - strip the trailing newline from input:

```
while (my $line = <$fh>) {
    chomp $line;
    # process $line without the trailing "\n"
}
```

The no-argument form operates on `$_`:

```
while (<>) {
    chomp;                              # removes "\n" from $_
    my @fields = split /:/;
}
```

Chomp an lvalue assignment - parentheses are **required** so the argument to `chomp` is the whole assignment, not just the variable:

```
chomp(my $cwd    = `pwd`);              # strip "\n" from command output
chomp(my $answer = <STDIN>);            # strip "\n" from user input
```

Chomping a list - every element is chomped and the total count is returned:

```
my @lines = ("a\n", "b\n", "no-nl");
my $n = chomp @lines;                   # @lines = ("a", "b", "no-nl"),
 ↪$n = 2
```

Custom record separator - `chomp` follows whatever `$/` is set to:

```
local $/ = "\r\n";
my $line = "GET / HTTP/1.0\r\n";
chomp $line;                            # removes "\r\n", returns 2
```

Paragraph mode - `$/ = ""` makes `chomp` remove **all** trailing newlines from the string:

```
local $/ = "";
my $para = "line one\nline two\n\n\n";
chomp $para;                            # $para is "line one\nline two"
```

Edge cases

- **No separator present**: a no-op. Returns `0` and leaves the argument unchanged. This is the whole point of `chomp` over `chop` - safe to call on strings that may or may not end in `$/`.
- **`undef` argument**: chomping an undefined scalar leaves it undefined and returns `0`. Under `use warnings` this emits a `uninitialized` warning.
- **Hash argument**: `chomp %h` chomps every value (not the keys) and **resets the hash's `each` iterator**. A `while (my ($k, $v) = each %h)` loop in progress over `%h` will be disrupted.

- **Slurp mode (`$/ = undef`)** and **fixed-length record mode** (`$/` set to a reference to an integer): `chomp` removes nothing and returns `0`. There is no notion of a trailing separator in these modes.
- **Parenthesisation trap on assignment**: without parens, `chomp` binds tighter than `=`:

```
chomp  $cwd = `pwd`;                    # parsed as (chomp $cwd) =␣
 ↪`pwd`;
chomp( $cwd = `pwd` );                  # what you meant
```

  Same trap with a bare comma list:

```
chomp  $x, $y;                          # parsed as chomp($x), $y;
chomp( $x, $y );                        # chomps both
```

- **Any lvalue works**, not just plain scalars. Array and hash elements, slices, dereferences, and assignment expressions are all legal targets.
- **Constants and read-only values**: chomping a read-only string croaks with `Modification of a read-only value attempted`. String literals are read-only.
- **Multi-byte `$/`**: `chomp` compares bytes of the string against bytes of `$/`. If the string and `$/` disagree on encoding (one has the UTF-8 flag set, the other does not), the match is done on the internal byte representation and may surprise you. Keep both sides in the same encoding.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `chop` - unconditionally remove the **last character** and return it; older, blunter tool superseded by `chomp` for input cleanup
- `split` - often the next step after `chomp`, splits the now-trimmed record into fields
- `readline` / `<>` - reads records terminated by `$/`; `chomp` undoes the terminator that `readline` left in place
- `each` - the hash iterator that `chomp %hash` resets
- `$/` - input record separator; `chomp` reads this on every call
- `$_` - default argument when `chomp` is called with no explicit target

SCALARs and strings

chop

Remove the last character from a string and return it.

`chop` shortens its argument in place by exactly one character and returns the character that was removed. It does not scan the string and does not copy it - it simply moves the end. If `VARIABLE` is omitted, `chop` operates on `$_`. If `VARIABLE` is a hash, `chop` chops

every value of the hash (not the keys) and resets the hash's `each` iterator as a side effect. Any lvalue is a valid target, including an assignment expression.

Synopsis

```
chop VARIABLE
chop( LIST )
chop
```

What you get back

The character that was removed, as a string. If the target was empty or undefined, the empty string is returned and the target is left unchanged. When `chop` is applied to a list, every element is chopped but only the character removed from the **last** element is returned.

```
my $last = chop $line;     # one character, or "" if $line was empty
```

Global state it touches

Reads `$_` when called with no argument. No other special variables are consulted - in particular, `chop` is **not** affected by `$/` (the input record separator), which is `chomp`'s concern.

Examples

Chop a scalar:

```
my $s = "hello";
my $c = chop $s;            # $s is now "hell", $c is "o"
```

Chop `$_` when no argument is given - idiomatic inside a read loop that wants the terminator gone regardless of what it is:

```
while (<$fh>) {
    chop;                   # drops whatever character ends the line
    push @rows, $_;
}
```

Chop a list. Every element loses its last character; the return value is the character removed from the **last** element only:

```
my @lines = ("foo\n", "bar\n", "baz!");
my $last  = chop @lines;    # @lines is ("foo","bar","baz"), $last
↪is "!"
```

Chop a hash. Values are chopped, keys are not, and the `each` iterator is reset:

```
my %h = (a => "one\n", b => "two\n");
chop %h;                    # %h is (a => "one", b => "two")
```

Chop an assignment - chop works on any lvalue, and an assignment returns one:

```
chop(my $cwd = `pwd`);      # strip the trailing newline from pwd's␣
↪output
```

Keep all but the last character without modifying the original - not a job for chop, which mutates. Use substr with a negative length instead:

```
my $head = substr($s, 0, -1);   # $s is unchanged
```

Edge cases

- **Empty or undefined target**: returns the empty string "" and leaves the target alone. chop on undef does *not* raise a warning by itself; it simply produces "".
- **Read-only target**: raises Modification of a read-only value attempted. This includes string literals and values flagged read-only via Internals::SvREADONLY.
- **UTF-8 strings**: chop removes one **character**, not one byte. A multi-byte character at the end of the string is removed whole and returned as a UTF-8 string. The target's UTF-8 flag is preserved on what remains.
- **List return value**: only the character chopped from the last element is returned; the others are discarded. If you need every removed character, chop the elements individually in a loop.
- **One character vs. a line ending**: chop unconditionally removes **one** character, whatever it is - including spaces, digits, or letters. To conditionally remove a line terminator (what $/ says one looks like), use chomp.
- **Parser parenthesisation**: chop($x = $y) chops the result of the assignment, which is $x. chop $x, $y is parsed as chop($x), $y - the comma does not extend chop's argument list without parentheses. Write chop($x, $y) when you mean the list form.
- **Hash iteration reset**: because chop %h walks the values via the hash iterator, any in-progress each loop over %h is invalidated.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- chomp - conditional cousin: removes a trailing $/, not an unconditional last character; returns the number of characters removed rather than the character itself
- substr - non-destructive alternative; substr($s, 0, -1) returns all but the last character without mutating $s
- s///-$s =~ s/.\z//s is the regex equivalent and the one chop is explicitly faster than, because chop neither scans nor copies
- lc, uc - other in-place(ish) string transforms that accept any lvalue

- `$_` - the implicit target when `chop` is called with no argument
- `$/` - **not** consulted by `chop`; documented here only to flag the contrast with `chomp`

Filehandles, files, directories

chown

Change the owner and group of a list of files.

`chown` takes a numeric user id, a numeric group id, and a list of files, and reassigns ownership on every file that the calling process is allowed to touch. The first two elements of `LIST` are the new `UID` and `GID`, in that order; every element after that is a filename (or, on systems that support `fchown(2)`, a filehandle). A value of `-1` in either of the id slots means "leave that id unchanged" - useful when you want to change only the group, or only the owner.

Synopsis

```
chown UID, GID, LIST
chown $uid, $gid, $file
chown $uid, $gid, @files
chown -1, $gid, @files          # change group only
```

What you get back

The number of files whose ownership was successfully changed, as a plain integer. Not a boolean - a call over ten files that succeeds on seven returns 7. Check against the list length when you need all-or-nothing semantics:

```
my @files = ('a', 'b', 'c');
my $ok = chown $uid, $gid, @files;
$ok == @files
    or die "chown failed on ", scalar(@files) - $ok, " files: $!";
```

When any individual file fails, `$!` holds the errno from the **last** failing call. A return value less than `scalar @files` is the reliable "something went wrong" signal; `$!` tells you what the last failure was, not every failure.

Global state it touches

- `$!` - set to the errno of the last underlying `chown(2)` call that failed. Unchanged when every file succeeds.

Numeric ids only

`chown` does **not** accept user or group names. Pass the string `"root"` where a uid is expected and you get a numeric conversion of `0` (with an `Argument … isn't numeric` warning under `use warnings`) - almost never what you want. Translate names to numbers with `getpwnam` and `getgrnam`:

```
my $uid = getpwnam('alice')  // die "no such user";
my $gid = getgrnam('staff')  // die "no such group";
chown $uid, $gid, @files;
```

The list-context return of `getpwnam` gives the full passwd entry; in scalar context it gives just the uid, which is usually what `chown` wants.

Permission rules

On Linux and every other POSIX system, only the superuser can give a file away to a different owner. An unprivileged user can change the **group** of a file they own, but only to one of their own secondary groups. Trying to do more returns failure with `$!` set to `EPERM`.

```
chown 0, 0, 'passwd.new'
    or warn "need root to chown: $!";
```

The restriction is kernel-enforced, not Perl-enforced - there is no pre-check that would save you a failed system call. Rely on the return value.

Examples

Change both owner and group on a single file:

```
chown $uid, $gid, '/var/log/app.log'
    or die "chown failed: $!";
```

Change the group only, leaving the owner alone:

```
chown -1, $gid, @files;
```

Translate names to numeric ids before calling:

```
my ($login, $pass, $uid, $gid) = getpwnam('www-data')
    or die "www-data not in passwd file";
chown $uid, $gid, glob('/var/www/*');
```

Count how many files were actually reassigned:

```
my @targets = glob('/srv/data/*.dat');
my $changed = chown $uid, $gid, @targets;
warn "only $changed of ", scalar(@targets), " files changed: $!"
    if $changed != @targets;
```

Chown by filehandle on a system that supports `fchown(2)`. The filehandle must be a glob or a glob reference - a bareword is treated as a filename:

```
open my $fh, '>', '/tmp/out' or die $!;
chown $uid, $gid, $fh;
```

Edge cases

- **Empty file list**: `chown $uid, $gid;` - no files to act on, returns `0`, does not touch `$!`.
- **`-1` in id position**: standard POSIX sentinel meaning "leave this id unchanged." Works on every supported platform.
- **String id**: a non-numeric string silently becomes `0` (root / wheel) after the usual numeric conversion. Under `use warnings` you get an `Argument isn't numeric` warning, but there is no hard error. Always pass an integer.
- **Non-existent file**: counted as a failure, does not abort the call. Remaining files still get processed.
- **Symlink target**: `chown` follows symlinks and changes the pointed-to file. To chown the link itself, use `lchown(2)` via `syscall` or a module that exposes it - core Perl does not.
- **Filehandle form**: on systems without `fchown(2)` (rare in practice on Linux), passing a filehandle raises an exception. Barewords in the file list are always treated as filenames - use `\*FH` or a `my $fh` to mean "this handle."
- **Give-away restriction**: on POSIX systems with `_PC_CHOWN_RESTRICTED` set for the target path, only root can change the owner at all. Probe with:

```
use POSIX qw(pathconf _PC_CHOWN_RESTRICTED);
my $restricted = pathconf($path, _PC_CHOWN_RESTRICTED);
```

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `chmod` - change file permission bits; takes the same "mode, then file list" shape and returns the same number-of-files-changed count
- `stat` - read the current owner, group, and mode of a file before deciding what to change
- `umask` - set the default permission mask for files created by this process; complements `chown` for newly created files
- `getpwnam` - translate a user name to the numeric uid `chown` requires
- `getgrnam` - translate a group name to the numeric gid `chown` requires
- `$!` - holds the errno of the last failing per-file `chown(2)` when the return count is below the list length

SCALARs and strings

chr

Return the character whose codepoint is the given number.

`chr` takes a non-negative integer and returns a one-character string holding the character at that codepoint in the current character set. `chr(65)` is `"A"` in both ASCII and Unicode; `chr(0x263a)` is the Unicode smiley face ☺. If `NUMBER` is omitted, `chr` operates on `$_`. The inverse operation is `ord`.

Synopsis

```
chr NUMBER
chr
chr($n)
```

What you get back

A string of length one character. With Unicode semantics - the default for any codepoint above `0x7f` - that character may be encoded internally as several bytes of UTF-8, so `length` reports `1` while `bytes::length` can report up to four. For codepoints in the range `0..127` the result is a single-byte ASCII string and the two lengths agree.

Global state it touches

With no argument, `chr` reads `$_`. It writes nothing. The `bytes` pragma changes what `chr` does with out-of-range or negative input (see *Edge cases*); no other pragma or special variable affects it.

Examples

ASCII character from its codepoint:

```
print chr(65);              # A
print chr(97), "\n";        # a
```

Build a string from a list of codepoints with `map` and `join`:

```
my @code = (72, 101, 108, 108, 111);
print join("", map { chr } @code), "\n";   # Hello
```

Unicode codepoint above the ASCII range - the result is one character, four bytes in its internal UTF-8 form:

```
use utf8;
my $smiley = chr(0x263a);
print length($smiley);                      # 1
use bytes; print length($smiley);           # 3
```

Round-trip with `ord` - for any single character `$c`, the identity `chr(ord($c)) eq $c` holds:

```
my $c = "Z";
print chr(ord($c)) eq $c ? "yes" : "no";     # yes
```

Default-argument form inside a loop over `$_`:

```
for (65, 66, 67) {
    print chr;                               # prints ABC
}
```

Negative input yields the Unicode replacement character `U+FFFD`:

```
print chr(-1) eq "\x{fffd}" ? "repl" : "?";  # repl
```

Edge cases

- **Fractional argument**: truncated toward zero before lookup. `chr(65.9)` returns `"A"`.
- **Non-numeric string**: converted by the normal numeric-coercion rules, with a warning under `use warnings`. `chr("65abc")` returns `"A"`.
- **`chr(undef)`** returns `chr(0)`, the `NUL` character `"\0"`, and warns under `use warnings` about use of an uninitialized value.
- **Negative values**: outside the `bytes` pragma, negative input returns the Unicode replacement character `"\x{fffd}"`. Under `use bytes`, the low eight bits of the integer value are used: `chr(-1)` yields the byte `"\xff"`.
- **Values above `0x10ffff`** (the maximum Unicode codepoint) still return a single-character string under default semantics, but emit a `Unicode non-character is illegal for interchange` warning for the non-character ranges, and a `Unicode surrogate U+...` warning for the surrogate range `0xd800..0xdfff` when the string is later encoded.
- **The 128..255 range**: characters in this range are by default **not** stored as UTF-8 internally, for backward compatibility with byte strings. They compare equal to their single-byte form and to the same Unicode codepoint; the internal representation only matters when inspecting with `bytes::length` or interacting with PerlIO layers.
- **`chr` never croaks** on any numeric input. Errors surface only as warnings, never exceptions.
- **Not an lvalue**: `chr` returns a fresh scalar. `chr(65) = "B"` is a syntax error.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `ord` - inverse of `chr`: codepoint of the first character of a string
- `sprintf` - `sprintf "%c", $n` is equivalent to `chr $n`; use it to splice a character into a larger format at once
- `pack` - build a multi-character string from a list of codepoints in one call (`pack "U*", @code` for Unicode, `pack "C*", @code` for bytes)
- `hex` - parse a hex string into the integer you then pass to `chr`; pairs with `chr` when decoding `U+XXXX` notation
- `use bytes` - pragma that switches `chr` to byte-oriented semantics for values outside `0..0x7f`
- `perlunicode` - background on how Perl stores and compares Unicode strings

Filehandles, files, directories

chroot

Change the root directory of the current process and every child it later spawns.

After a successful `chroot`, any pathname that begins with `/` is resolved relative to the directory named by `FILENAME` instead of the real filesystem root. The process loses the ability to name files outside that subtree through absolute paths. The kernel enforces this for the current process and for every descendant - there is no per-thread scope and no way to undo it from inside the jail.

`chroot` does **not** change the current working directory. If the working directory was outside the new root when the call succeeded, it stays outside, and relative paths can still escape. Always follow a successful `chroot` with `chdir` to `/` (which now means inside the jail) before doing anything else.

The call is restricted to the superuser. An unprivileged process gets `EPERM` and `$!` is set accordingly.

Synopsis

```
chroot FILENAME
chroot
```

What you get back

`1` on success, `0` on failure. On failure `$!` holds the `errno` from the underlying `chroot(2)` system call - commonly `EPERM` (not root), `ENOENT` (path does not exist), or `ENOTDIR` (path is not a directory).

Always check the return value. A silent failure leaves the process running outside the intended jail, which is usually worse than the code path that made the call in the first place.

```
chroot "/var/empty"
    or die "chroot: $!";
chdir "/"
    or die "chdir after chroot: $!";
```

Global state it touches

- `$_` - when called with no argument, `chroot` uses the value of `$_` as the path. Inside a `while (<>)` loop this is rarely what you want; pass the path explicitly.
- `$!` - set to the underlying `errno` on failure.

Examples

The canonical safe sequence - change root, then change working directory to the new root, then drop privileges:

```
chroot "/srv/jail"   or die "chroot: $!";
chdir  "/"           or die "chdir: $!";
$) = $(= 65534;                         # drop to 'nobody' gids
$> = $< = 65534;                        # drop to 'nobody' uids
```

Open files and load shared libraries **before** `chroot`, not after. The new root typically has neither `/etc/resolv.conf` nor the dynamic linker's search paths:

```
open my $log, ">>", "/var/log/app.log" or die $!;
my $cfg = read_config("/etc/app.conf");

chroot "/srv/jail" or die "chroot: $!";
chdir  "/"         or die "chdir: $!";

# $log and $cfg are still usable inside the jail.
```

Checking failure modes separately - distinguishing "not root" from "bad path" matters for diagnostics:

```
use Errno qw(EPERM ENOENT ENOTDIR);

unless (chroot $path) {
    die "chroot: need root privileges\n"       if $! == EPERM;
    die "chroot: $path does not exist\n"       if $! == ENOENT;
    die "chroot: $path is not a directory\n"   if $! == ENOTDIR;
    die "chroot: $!";
}
```

Default-argument form reads the path from `$_`:

```
$_ = "/srv/jail";
chroot or die "chroot: $!";
```

Edge cases

- **Not root**: fails with `EPERM`. There is no capability-based relaxation in stock Linux unless the process holds `CAP_SYS_CHROOT`.
- **Relative path**: `chroot "jail"` resolves against the current working directory at the moment of the call. Prefer absolute paths so the behavior does not depend on the caller's `cwd`.
- **Symlinks in `FILENAME`**: resolved before the chroot takes effect. Symlinks *inside* the new root that point to absolute paths will resolve relative to the new root, not the real root - this is the intended jailing behavior, not a bug.
- **Open file descriptors survive**: any handle opened before the call remains usable afterward. This is how well-behaved daemons keep logs, config, and listening sockets across the transition.
- **No escape from inside**: a process cannot `chroot` its way out. The only way to leave a chroot is for a privileged process *outside* it to reap and replace it.
- **Working directory outside the new root**: the kernel allows the call, but relative paths and `..` traversal from there can still reach files outside the jail. The mandatory `chdir "/"` after `chroot` closes that gap.
- **Threads**: `chroot` on Linux is per-process (strictly, per fs struct). Under `use threads` all interpreter threads share the same root after the call - there is no per-thread jail.
- **Does not affect `$0`, `%ENV`, or open sockets**. Only path resolution changes.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `chdir` - the mandatory follow-up after a successful `chroot`; without it the working directory may still point outside the new root
- `fork` - children inherit the chroot; combine with `chroot` to run untrusted code in a restricted subtree
- `exec` - runs the replacement program inside the current root, so the target binary and its dynamic libraries must exist inside the jail
- `open` - opening files by absolute path after `chroot` looks up names inside the jail; pre-open anything you need from outside before the call
- `$_` - the default path when `chroot` is called with no argument
- `$!` - holds the `errno` from `chroot(2)` on failure

Scoping · Classes and OO

class

Declare a namespace that behaves as a native object class.

`class` introduces a new package just like `package`, but marks it as a *class*: the runtime attaches a constructor named `new`, enables the `field` and `method` keywords inside its body, and supports single inheritance through the `:isa` attribute. It is the core-language answer to hand-rolled `bless`-based OO - the same problem, without the boilerplate.

> **Experimental**
>
> The `class` feature (codename *Corinna*) is experimental in Perl 5.44 and may still change in incompatible ways. Enable it with `use feature 'class'` and silence the notice with `no warnings 'experimental::class'`.

Synopsis

```
class NAMESPACE;                            # rest-of-scope form
class NAMESPACE VERSION;
class NAMESPACE :ATTRIBUTES;
class NAMESPACE BLOCK                       # block form
class NAMESPACE VERSION BLOCK
class NAMESPACE VERSION :ATTRIBUTES BLOCK
```

Minimal working class:

```
use v5.38;
use feature 'class';
no warnings 'experimental::class';

class Point {
    field $x :param;
    field $y :param;

    method distance_from_origin {
        return sqrt($x ** 2 + $y ** 2);
    }
}

my $p = Point->new(x => 3, y => 4);
say $p->distance_from_origin;               # 5
```

What you get back

`class` is a declaration, not an expression - it does not return a value you can assign. What you get is:

- A new package in the symbol table, reachable as any other package.
- A generated `new` constructor. **Do not write your own `new`.** The generated one honours `:param` field attributes and runs every `ADJUST` block in declaration order.

- `$self` implicitly bound inside every `method` body.
- `__CLASS__` usable inside field initialisers and methods to name the class currently being constructed (which may be a subclass).

Forms

`class` accepts four syntactic shapes. The split between **block** and **statement** forms mirrors `package` exactly:

- **`class NAME BLOCK`** - the class definition is the contents of the block. Scope ends with the closing brace.
- **`class NAME;`** - the rest of the current scope (or file) up to the next `class` or `package` statement is the class body. Useful for single-class files.
- **`class NAME VERSION ...`** - the version is declared like `package Foo 1.234`. The version must precede any attributes.
- **`class NAME :ATTRIBUTES ...`** - one or more class attributes, separated by whitespace, each starting with `:`. The only currently defined class attribute is `:isa`.

```
class My::Thing 1.02 :isa(My::Base) {
    # body
}
```

Fields, methods, ADJUST

Inside a class body three new keywords are in scope:

- `field` declares per-instance storage. Fields behave like lexicals inside methods but each instance has its own slot. Attributes `:param`, `:reader`, and `:writer` generate constructor binding and accessors.
- `method` declares a subroutine that auto-binds `$self` and that can read and write the enclosing fields by name. Methods act as if `use feature 'signatures'` were in effect; `$self` does not appear in the signature.
- `ADJUST BLOCK` runs after field initialisers, during construction, with `$self` already bound. Use it for post-construction validation and for derived fields.

```
class Counter {
    field $value :param = 0;
    field $step  :param = 1;

    ADJUST {
        die "step must be positive" if $step <= 0;
    }

    method tick { $value += $step }
    method peek { $value }
}
```

Fields are **always lexical to the class** - they are not inherited. Subclasses that need access to a parent's state do so through methods, not through fields.

Inheritance: `:isa`

A class inherits from at most one other class:

```
class Shape { ... }

class Circle :isa(Shape) {
    field $r :param;
    method area { 3.14159265 * $r * $r }
}
```

Only single inheritance is supported. The `:isa` target is loaded automatically if it is not already in memory - equivalent to `use MODULE ()` before the class declaration. A minimum version can be required the same way `use MODULE VERSION` does:

```
class Circle :isa(Shape 2.000) { ... }
```

`:isa` only inherits **methods**. Fields are per-class private storage; a subclass has no implicit view into a parent's fields.

Global state it touches

- **`%INC`** - `:isa(Parent)` loads `Parent` via `require` on first use and records it here, just like `use`.
- **`@ISA`** - populated for the class from the `:isa` attribute, so existing `isa` / `UNIVERSAL` / `SUPER::` introspection keeps working.
- **The symbol table** - the class name becomes a stash in `%::` exactly as `package` would create one.

Examples

Plain class with a required parameter and a derived field:

```
class User {
    field $name :param;
    field $greeting;

    ADJUST { $greeting = "Hello, $name" }

    method greet { say $greeting }
}

User->new(name => 'Ada')->greet;          # Hello, Ada
```

Default parameter values - `=` applies when the caller omitted the parameter; `//=` also applies when the value was `undef`; `||=` also applies when the value was false:

```
class Window {
    field $title :param          = 'untitled';
    field $width :param          //= 640;
```

(continues on next page)

(continued from previous page)

```
    field $shown :param           ||= 1;
}
```

Single inheritance with a method override:

```
class Animal {
    field $name :param;
    method speak { "some sound" }
    method introduce { say $name, " says ", $self->speak }
}

class Dog :isa(Animal) {
    method speak { "woof" }
}

Dog->new(name => 'Rex')->introduce;       # Rex says woof
```

Private method via lexical `my method`, invoked through `->&`:

```
class Safe {
    field $secret :param;

    my method check ($n) { $n == $secret }

    method unlock ($n) {
        return $self->&check($n) ? "open" : "denied";
    }
}
```

Using `__CLASS__` so a base-class field initialiser picks up the subclass's override:

```
class Base {
    sub DEFAULT_X { 10 }
    field $x = __CLASS__->DEFAULT_X;
    method x { $x }
}

class Tuned :isa(Base) {
    sub DEFAULT_X { 99 }
}

say Tuned->new->x;                          # 99
```

Rest-of-file statement form:

```
use v5.38;
use feature 'class';
class Config;

field $path :param;
```

(continues on next page)

(continued from previous page)

```
method path { $path }
# File ends here; whole remainder is Config's body.
```

Edge cases

- **Do not define new**. The generated constructor is the only supported entry point. A user-written `sub new { ... }` inside a `class` body is a compile-time error.
- **No multiple inheritance**. `:isa(A, B)` is a syntax error. Multiple `:isa` attributes on one class are also rejected.
- **No `@ISA` manipulation**. Treat `@ISA` as read-only for classes declared with `class`. Pushing onto it at runtime is undefined.
- **`package` cannot re-open a class**. Once a namespace has been declared with `class`, subsequent `package` statements targeting the same name are a compile-time error, and vice versa.
- **Fields are not lexicals** in the usual sense. You cannot refer to a field from outside the class body, and you cannot `our` or `local` it. Only methods and `ADJUST` blocks see fields.
- **`$self` is read-only** inside a method. Assigning to it is a runtime error.
- **Field initialisers run before `$self` exists**. Inside `field $x = EXPR`, you can use `__CLASS__` and previously declared fields, but not `$self`. Anything that needs the fully built instance belongs in an `ADJUST` block.
- **No field access before declaration**. Within a field's initialiser expression, only fields declared *earlier* in the class body are visible.
- **Method resolution**. Dispatch still goes through the usual MRO (`UNIVERSAL::isa`, `SUPER::`), so `$self->SUPER::foo(@args)` works the way it does for `bless`-based classes.
- **Statement form scope**. `class Foo;` consumes the rest of the enclosing block - typically the rest of the file. A second `class` or `package` terminates it; there is no way to "close" a statement-form class early.
- **Experimental warning**. Every `class` declaration emits a `class is experimental` warning under the default warnings. Use `no warnings 'experimental::class'` once the feature is in use for real.

Differences from upstream

Fully compatible with upstream Perl 5.44. The feature is flagged experimental in upstream; pperl mirrors that status and emits the same warning category (`experimental::class`).

See also

- `field` - declares per-instance storage within a `class` body; supports `:param`, `:reader`, `:writer`
- `method` - declares a subroutine with implicit `$self` and direct access to the enclosing class's fields
- `package` - the non-class namespace declaration; `class` is the OO-aware sibling with the same syntactic forms
- `bless` - the pre-5.38 way to attach a class to a reference; still supported, and interoperates with `class`-built objects for `isa`/`can` checks
- `isa` - operator for testing class membership; works for both `class`-declared and `bless`-based objects
- `use` - how `:isa(Parent)` loads the parent class under the hood

I/O

close

Close a filehandle, flush its buffers, and release the underlying file descriptor.

`close` finishes whatever I/O was pending on `FILEHANDLE`, tears down the PerlIO layer stack, and asks the kernel to close the descriptor. The return value distinguishes a clean shutdown from one where either a buffered write failed on the way out, a PerlIO layer reported an error, or - for pipes - the child process exited non-zero. Without an argument, `close` operates on the currently selected filehandle (see `select`).

Synopsis

```
close FILEHANDLE
close EXPR
close
```

What you get back

Truthy (1) on a clean shutdown; false otherwise. A false return means one of the following went wrong:

- A pending buffered write could not be flushed (disk full, broken pipe, closed socket).
- A PerlIO layer (e.g. `:encoding(...)`, `:gzip` from a CPAN layer) reported an error.
- A pre-existing sticky error was already recorded on the handle.
- The handle came from a piped `open` and the child exited non-zero (or another syscall involved in tearing the pipe down failed).

When `close` returns false, `$!` holds the error from the failing operation and is safe to read. For pipe handles, if the only problem was a non-zero child exit, `$!` is set to `0` and the child's status shows up in `$?` (see below).

Always check the return value on writable handles: the final buffered block is flushed inside `close`, so `print` returning true earlier does **not** guarantee the data reached disk.

```
close $fh
    or die "close $path failed: $!";
```

Global state it touches

- `$!` - set to the failing `errno` when `close` returns false, including the flush error on the final buffered write. Cleared to `0` on a pipe close where the only problem was a non-zero child exit.
- `$?` - for handles from a piped `open`, set to the wait status of the child process: low 8 bits are the signal, high 8 bits are the exit code (same encoding as `system`).
- `${^CHILD_ERROR_NATIVE}` - for pipe handles, set to the raw OS-native status value (before Perl's portable encoding).
- `$.` - an **explicit** `close` on an input handle resets the current line number. An implicit close via reopening the same handle does not.
- Currently selected filehandle (via `select`) - `close` with no argument closes it.

Examples

Close a regular file and check for a flush failure:

```
open my $fh, ">", "out.txt" or die $!;
print {$fh} @records;
close $fh or die "flush to out.txt failed: $!";
```

Close a pipe opened for writing and inspect the child's exit status. `close` waits for the child, then populates `$?`:

```
open(my $sort, "|-", "sort", ">", "foo")
    or die "can't start sort: $!";
# ... print records to $sort ...
close $sort
    or warn $! ? "error closing sort pipe: $!"
               : "sort exited with status " . ($? >> 8);
```

Close a pipe opened for reading, then collect the command's exit status. Exit code is the top 8 bits of `$?`:

```
open(my $who, "-|", "who") or die $!;
my @lines = <$who>;
close $who;
my $exit = $? >> 8;
```

Bare `close` closes whatever handle `select` most recently made current, then restores `STDOUT` as the selected handle:

```
open my $log, ">>", "app.log" or die $!;
my $old = select $log;
print "entry\n";
close;                          # closes $log (the selected handle)
select $old;
```

Closing the read end of a pipe early makes the writer receive SIGPIPE. If the writer has no handler, it will be killed - drain the pipe first if you need the writer to exit cleanly:

```
open my $gen, "-|", "some-producer" or die $!;
while (<$gen>) { last if /^END/ }
1 while <$gen>;                 # drain so the child finishes cleanly
close $gen or warn "producer failed: $!";
```

Edge cases

- **Bare `close`** - with no argument, closes the currently selected filehandle. In a freshly started program that is STDOUT; after a `select($fh)` it is `$fh`. Rarely what you want outside tightly scoped code.
- **Reopening closes for you** - `open my $fh, ...` on a handle that is already open will close the old descriptor first. The implicit close does **not** reset `$.`; an explicit `close` does. Use an explicit `close` when line-number state matters.
- **Scope exit closes lexical handles** - when the last reference to a lexical filehandle goes out of scope, Perl closes it. If that implicit close fails (flush error, child exit non-zero), Perl emits a `Warning: unable to close filehandle %s properly` warning. Call `close` explicitly at a point where you can check the return value and silence that warning.
- **Indirect handles** - FILEHANDLE may be any expression producing a usable filehandle: a bareword (`close STDERR`), a scalar (`close $fh`), a glob ref (`close \*FH`), or an autovivified handle from `open my $fh, ...`.
- **Pipe close waits** - closing a pipe handle blocks until the child exits, so `$?` is populated by the time `close` returns. Under threads, if the same pipe handle is still open in another thread, `close` returns true immediately without reaping the child.
- **Pipe close with non-zero exit** - `close` returns false and sets `$!` to `0` so that `$! ? "$!" : "exit $?"` discriminates between an OS-level failure and an ordinary non-zero exit.
- **Closed or invalid handle** - closing a handle that is not open sets `$!` to `"Bad file descriptor"` and returns false. Under `use warnings`, a `close()` on unopened filehandle warning is emitted.
- **STDIN / STDOUT / STDERR** - can be closed like any other handle. The descriptor is freed and will be reused by the next open on the standard handle, which is how the classic `open STDOUT, ">", "log"` redirect works.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `open` - counterpart; an `open` on an already-open handle does an implicit `close` first (but does not reset `$.`)
- `print` - final buffered `print` is flushed inside `close`, so the write's real success is only known after `close`
- `fileno` - descriptor number of a handle; becomes invalid once `close` succeeds
- `binmode` - layer stack set by `binmode` is torn down during `close`, and its teardown can itself fail
- `$?` - child exit status populated by `close` on a pipe handle
- `$!` - error from the failing close operation

I/O

closedir

Close a directory handle opened by `opendir`.

`closedir` releases the operating-system directory stream associated with `DIRHANDLE` and frees the slot so the handle can be reused. It is the counterpart to `opendir`, and the only supported way to close a directory handle - `close` operates on file handles and does **not** accept a directory handle, because file handles and directory handles live in separate namespaces.

Synopsis

```
closedir DIRHANDLE
closedir $dh
```

What you get back

1 on success, `undef` on failure (with `$!` set to the error from the underlying `closedir(3)` call). The return value is worth checking on networked or FUSE-backed filesystems where the close may surface a deferred I/O error.

```
closedir $dh
    or warn "closedir $path failed: $!";
```

Closing a directory handle that is already closed, or one that was never successfully opened, returns `undef` and - under `use warnings` - emits a `closedir() attempted on invalid dirhandle` warning.

Lexical directory handles and auto-close

A directory handle stored in a lexical scalar - the form produced by `opendir my $dh, $path` - is closed automatically when the scalar goes out of scope (or is reassigned, or the program exits). Explicit `closedir` is then a matter of timing, not correctness:

```
sub entries {
    my ($path) = @_;
    opendir my $dh, $path or die "opendir $path: $!";
    return readdir $dh;
    # $dh is closed here as it leaves scope
}
```

Call `closedir` explicitly when you need the release to happen at a known point - before forking, before renaming the directory on platforms that hold it open, before checking the return value, or simply when the enclosing scope is long and holds many other resources.

Bareword directory handles (package globals, e.g. `opendir DH, $path`) are **not** auto-closed. They persist until the program ends or `closedir DH` is called.

Global state it touches

`closedir` does not read or write any of Perl's documented special variables. It sets `$!` on failure. It does **not** affect `$_`, the selected filehandle, or any of the output-separator globals.

Examples

Basic open/read/close cycle:

```
opendir my $dh, "." or die "opendir: $!";
my @names = readdir $dh;
closedir $dh;
```

Check the return value - useful on network filesystems:

```
opendir my $dh, "/mnt/nfs/project" or die "opendir: $!";
my @entries = readdir $dh;
closedir $dh
    or die "closedir failed: $!";
```

Reset to the start with `rewinddir` instead of `closedir` + `opendir` when you want to re-read the same directory:

```
opendir my $dh, $path or die $!;
my @first = readdir $dh;
rewinddir $dh;
my @again = readdir $dh;              # same set as @first
closedir $dh;
```

Bareword handle - must be closed explicitly:

```
opendir DH, "/etc" or die $!;
while (my $name = readdir DH) {
    last if $name eq "hosts";
}
closedir DH;                            # not optional for barewords
```

Using `close` on a directory handle does **not** work:

```
opendir my $dh, "." or die $!;
close $dh;                              # wrong - does not close the
↪dir
closedir $dh;                           # correct
```

Edge cases

- **`close` on a directory handle**: file handles and directory handles are distinct types. `close` on a directory handle is either a no-op or an error depending on the handle form; always use `closedir` to close what `opendir` opened.
- **Double close**: calling `closedir` twice on the same handle returns `undef` on the second call and sets `$!`. Under `use warnings` a `closedir() attempted on invalid dirhandle` warning is emitted.
- **Closed or never-opened handle**: same behaviour as double close - `undef` return and a warning under `use warnings`.
- **Pending `readdir` state**: `closedir` discards any unread entries. If you want to restart iteration, use `rewinddir` instead of close + reopen.
- **`seekdir` / `telldir` positions**: positions obtained from `telldir` are invalidated by `closedir`. They are only meaningful for the lifetime of a single open directory stream.
- **Scope exit during exception**: lexical directory handles are still closed when the scope unwinds via `die`, so explicit `closedir` in cleanup code is usually redundant.
- **Fork**: after `fork`, both parent and child share the directory stream's kernel state; each should call `closedir` in whichever process no longer needs it.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `opendir` - open a directory handle; `closedir` is its counterpart
- `readdir` - read the next entry (or all entries in list context) from an open directory handle
- `rewinddir` - reset the directory stream to the beginning without closing it
- `seekdir` - reposition the directory stream to a value previously returned by `telldir`

- `telldir` - return the current position within an open directory stream
- `close` - close a **file** handle; does not work on directory handles

Sockets

connect

Initiate a connection from a socket to a remote address.

`connect` is the client-side half of the socket handshake. Given a `SOCKET` that was created with `socket` and a packed address `NAME` in the form the socket's address family expects, it asks the kernel to establish a connection to that peer. It is a thin wrapper over the `connect(2)` system call and inherits every one of that call's blocking, non-blocking, and error semantics.

Synopsis

```
connect SOCKET, NAME
```

What you get back

Truthy (1) on success, false on failure with `$!` set to the system error. Always check the return value - there is no useful default behaviour when a connection attempt fails:

```
connect($sock, $peer)
    or die "connect to $host:$port failed: $!";
```

Global state it touches

- `$!` is set to the kernel's `errno` on failure. Interpret it against the `Errno` constants, not by string value - the stringified message is locale-dependent.
- The socket handle itself carries the connection state; no other special variables are involved.

Building `NAME`: it's a packed struct, not a string

The second argument is **not** a `"host:port"` string. It's a packed sockaddr in the exact byte layout the kernel expects for the socket's address family. Build it with the helpers from `Socket`:

- `sockaddr_in($port, $inaddr)` for IPv4 - `$inaddr` from `inet_aton` or `inet_pton`.
- `sockaddr_in6($port, $in6addr)` for IPv6 - `$in6addr` from `inet_pton(AF_INET6, ...)`.
- `sockaddr_un($path)` for Unix-domain sockets.

Hand-packing with `pack` works, but there is no reason to do so when `Socket` already exports the right builders.

Examples

A plain IPv4 TCP client:

```
use Socket;

socket(my $sock, PF_INET, SOCK_STREAM, getprotobyname("tcp"))
    or die "socket: $!";

my $addr = sockaddr_in(80, inet_aton("93.184.216.34"));
connect($sock, $addr)
    or die "connect: $!";

print $sock "GET / HTTP/1.0\r\nHost: example.com\r\n\r\n";
```

Modern address-family-agnostic client via `getaddrinfo`:

```
use Socket qw(getaddrinfo SOCK_STREAM);

my ($err, @res) = getaddrinfo("example.com", "80",
                              { socktype => SOCK_STREAM });
die "getaddrinfo: $err" if $err;

my $sock;
for my $ai (@res) {
    socket($sock, $ai->{family}, $ai->{socktype}, $ai->{protocol})
        or next;
    last if connect($sock, $ai->{addr});
    close $sock;
    undef $sock;
}
defined $sock or die "could not connect to any address";
```

A Unix-domain client:

```
use Socket;

socket(my $sock, PF_UNIX, SOCK_STREAM, 0) or die "socket: $!";
connect($sock, sockaddr_un("/tmp/my.sock"))
    or die "connect: $!";
```

Non-blocking connect with a timeout via `select` - the idiomatic way to bound a connect attempt in pure Perl:

```
use Socket;
use Fcntl qw(F_GETFL F_SETFL O_NONBLOCK);
use Errno qw(EINPROGRESS);

socket(my $sock, PF_INET, SOCK_STREAM, 0) or die "socket: $!";
my $flags = fcntl($sock, F_GETFL, 0);
fcntl($sock, F_SETFL, $flags | O_NONBLOCK);
```

(continues on next page)

(continued from previous page)

```
my $ok = connect($sock, sockaddr_in(80, inet_aton("93.184.216.34
 ↪")));
if (!$ok && $! == EINPROGRESS) {
    my $w = '';
    vec($w, fileno($sock), 1) = 1;
    my $n = select(undef, $w, undef, 5.0);   # 5-second timeout
    $n > 0 or die "connect timed out";
    # Check SO_ERROR to see whether the async connect succeeded:
    my $err = unpack("i", getsockopt($sock, SOL_SOCKET, SO_ERROR));
    $err == 0 or die "connect: " . do { local $! = $err; "$!" };
}
```

Edge cases

- **Address-family mismatch.** If `NAME` was packed for a different family than the socket was created with (e.g. `sockaddr_in` against a `PF_INET6` socket), `connect` fails with `EAFNOSUPPORT` or `EINVAL`. The packed bytes carry the family; the kernel checks.
- **Already connected.** Calling `connect` on a stream socket that is already connected fails with `EISCONN`.
- **Connectionless sockets.** On `SOCK_DGRAM` / `SOCK_RAW` sockets, `connect` does not exchange packets; it records a default peer so that subsequent `send` / `recv` calls can omit the address. It can be called again with a new `NAME`, or cleared by calling with an `AF_UNSPEC` sockaddr.
- **Non-blocking sockets.** If the socket is in non-blocking mode, a TCP connect typically returns false with `$!` set to `EINPROGRESS`. The connection is **not yet established**. Wait for the socket to become writable (via `select` or your event loop), then read `SO_ERROR` with `getsockopt` to obtain the final status. A zero `SO_ERROR` means the connection is up; anything else is the real failure code.
- **Signals interrupting the call.** A blocking `connect` can return false with `$!` set to `EINTR` if a signal handler ran. The socket is still connecting in the background; you must wait on writability and check `SO_ERROR` as in the non-blocking case - **do not** retry the `connect` call, that yields `EALREADY`.
- **Unbound source address.** If `bind` was not called first, the kernel picks a source address and ephemeral port automatically. The common case is to skip `bind` on the client.
- **Closed or unopened socket.** Fails with `EBADF`.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `socket` - create the endpoint that `connect` operates on
- `bind` - pin the local address before connecting; rarely needed on a client
- `accept` - the server-side counterpart to `connect`
- `getpeername` - recover the peer address of a connected socket
- `shutdown` - close one direction of a connected socket without releasing the descriptor
- `Socket` - packers (`sockaddr_in`, `sockaddr_un`, ...) and constants (`PF_INET`, `SOCK_STREAM`, ...) used to build arguments
- `Errno` - symbolic constants for comparing `$!` against `EINPROGRESS`, `EISCONN`, `ECONNREFUSED`, ...

Control flow

continue

Attach a block to a loop that runs after every iteration, just before the condition is re-tested.

`continue` is not a built-in function - it is a flow-control keyword. In its one remaining sense it introduces the trailing block of a `while`, `until`, or `foreach` loop. The block runs at the end of each iteration **and** whenever `next` transfers control out of the main body, but **not** when `last` or `redo` do. It plays the role that the third clause of a C `for (init; cond; step)` loop plays in C.

Synopsis

```
while (EXPR) { BODY } continue { STEP }
until (EXPR) { BODY } continue { STEP }
for VAR (LIST) { BODY } continue { STEP }
foreach VAR (LIST) { BODY } continue { STEP }
LABEL: while (EXPR) { BODY } continue { STEP }
```

What you get back

`continue` is a statement, not an expression. It has no return value and cannot appear in value position. The loop itself yields whatever its context demands (nothing in void context, the last evaluated expression under some constructs); the `continue` block does not contribute to that.

Execution model

For a loop with an attached `continue` block, each iteration runs in this order:

1. Evaluate the condition (or take the next list element, for `foreach`). If the loop should not run again, exit.
2. Run the main body.

3. Run the `continue` block.
4. Go back to step 1.

The three loop-control keywords interact with the `continue` block differently:

- `next` - jumps straight to step 3. The `continue` block **is** executed, then the condition is re-checked. This is the point of having a `continue` block: state that must advance on every iteration (a counter, a line number, a one-shot match reset) still advances when the body short-circuits via `next`.
- `last` - leaves the loop entirely. The `continue` block is **not** executed.
- `redo` - restarts step 2 without re-checking the condition and without running the `continue` block. Use it when the body needs another pass over the current iteration's data (for example, after splicing in more input).

Omitting the `continue` block is equivalent to an empty one.

Examples

A counter that advances even when the body skips:

```
my $n = 0;
for my $line (@lines) {
    next if $line =~ /^\s*#/;     # skip comments
    process($line);
} continue {
    $n++;                         # still counts skipped lines
}
print "scanned $n lines\n";
```

Equivalence to a C-style `for` loop - the two forms below are the same, because Perl rewrites the C-style header as a `while` with a `continue` block:

```
for (my $i = 1; $i < 10; $i++) { say $i }

my $i = 1;
while ($i < 10) {
    say $i;
} continue {
    $i++;
}
```

Resetting one-shot matches and line counters while streaming files with <>:

```
while (<>) {
    m?(fred)?   && s//WILMA/;
    m?(barney)? && s//BETTY/;
} continue {
    print "$ARGV $.: $_";
    close ARGV if eof;            # reset $.
    reset      if eof;            # reset ?pat?
}
```

The interaction with `redo` - note that `continue` runs on the `next` path but not on the `redo` path:

```
while (<>) {
    chomp;
    if (s/\\$//) {
        $_ .= <>;
        redo unless eof;         # merge continuation, re-enter body
    }                            # continue block skipped on redo
    process($_);
} continue {
    $seen++;                     # counts completed records only
}
```

Edge cases

- **No trailing block** - bare `continue` (without a following `{ ... }`) is a statement of the `switch` feature: inside a `when` block of `given` / `when` it falls through to the next `when`. The feature still exists but is off by default and in no feature bundle. Anywhere else, a bare `continue` compiles and then dies at run time with `Can't "continue" outside a when block`.
- **`last` skips the `continue` block.** If the block holds cleanup you need on every path out, put the cleanup after the loop or in a scope guard, not in `continue`.
- **`redo` skips the `continue` block.** If the `continue` block advances a counter, a `redo` iteration will not tick it - that is usually what you want (the iteration is not yet finished) but it can surprise code that relies on the counter matching the number of body entries.
- **`do { ... } while`** is **not** a real loop - `last`, `next`, and `redo` do not work in it, and a trailing `continue` block is a syntax error.
- **Labeled loops** - `LABEL:` attaches to the `while` / `for` / `foreach` keyword, not to `continue`. `next LABEL` and `last LABEL` target the loop as a whole; the `continue` block is part of that loop.
- **A block by itself** is a one-shot loop, so a bare `{ ... } continue { ... }` parses and runs the `continue` block once after the body - rarely useful, but legal.
- **Foreach with aliasing** - inside a `foreach` loop the loop variable aliases the current list element. The `continue` block still runs with that alias in scope, so you can inspect or mutate the element there just as in the body.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `next` - jump to the `continue` block (if any) and re-test the condition; the one loop-control keyword that **does** run the `continue` block
- `last` - leave the loop entirely; **skips** the `continue` block

- `redo` - restart the body without re-testing the condition; **skips** the `continue` block
- `return` - leave the enclosing subroutine; also skips the `continue` block because it leaves the loop
- `break` - companion keyword of the `switch` feature; like the bare `given`/`when` form of `continue`, available only under `use feature 'switch'`

Numeric functions

cos

Return the cosine of a number given in radians.

`cos` is the standard trigonometric cosine: it takes an angle measured in **radians** and returns the ratio of the adjacent side to the hypotenuse of the corresponding right triangle. If `EXPR` is omitted, `cos` operates on `$_`. The result is always a floating-point number in the closed interval `[-1, 1]`.

Synopsis

```
cos EXPR
cos
```

What you get back

A double-precision float in `[-1, 1]`. Perl forwards the call to the platform's C `cos(3)` routine, so the precision and rounding behaviour match your libm. Special values follow IEEE 754: `cos(0)` is exactly `1`, `cos("inf")` and `cos("nan")` are both `NaN`.

Radians, not degrees

The single most common mistake with `cos` is feeding it degrees. A full turn is `2 * π` radians, not `360`. Convert once and keep the converted value:

```
use POSIX qw(acos);
my $pi = acos(-1);                  # π to full double precision

sub deg2rad { $_[0] * $pi / 180 }

print cos( deg2rad(60) ), "\n";     # 0.5
print cos( 60 ), "\n";              # -0.952412980415 - wrong if you
 ↪meant degrees
```

exports `deg2rad` and `rad2deg` if you would rather not write the conversion yourself.

Examples

Walk the unit circle in eight steps and print `(cos θ, sin θ)`:

```
use POSIX qw(acos);
my $pi = acos(-1);

for my $k (0 .. 7) {
    my $theta = $k * $pi / 4;
    printf "%.3f  %+.3f  %+.3f\n",
           $theta, cos($theta), sin($theta);
}
```

Compare `cos` against its Taylor series around zero. For small `$x` the four-term expansion is already accurate to ten decimal places - a useful sanity check when porting numeric code:

```
sub cos_taylor {
    my $x = shift;
    my $x2 = $x * $x;
    1 - $x2/2 + $x2*$x2/24 - $x2*$x2*$x2/720;
}

my $x = 0.3;
printf "libm:   %.15f\n", cos($x);
printf "taylor: %.15f\n", cos_taylor($x);
```

Default argument. Inside a `while (<>)` loop `cos` without an argument reads the current line - almost always a bug, but the language allows it:

```
$_ = 0;
print cos, "\n";                    # 1
```

Inverse cosine via the identity from `perlfunc`:

```
sub acos { atan2( sqrt(1 - $_[0] * $_[0]), $_[0] ) }

print acos(0.5), "\n";              # 1.0471975511966 (= π/3)
```

Using for the full set of inverse and hyperbolic functions rather than rolling your own:

```
use Math::Trig;
print acos(0.5), "\n";              # same result, no hand-written␣
↪formula
```

Edge cases

- **Non-numeric arguments coerce to `0`.** `cos("hello")` returns 1 because the string is numified to `0` first. Under `use warnings` this produces an `Argument "hello" isn't numeric in cos` warning. Validate input with `looks_like_number` from `Scalar::Util` if the source is untrusted.
- **Very large arguments lose precision.** `cos` first reduces its argument modulo 2π, and for `|x|` on the order of `1e16` the nearest representable double differs from `x` by more than π. The result is still a number in `[-1, 1]`, but it is essentially

random. Reduce the angle yourself before the call if you are accumulating a phase over many iterations.

- **`undef` coerces to `0`** and returns 1, with the usual `uninitialized` warning under `use warnings`.
- **IEEE specials**: `cos("inf")`, `cos("-inf")`, and `cos("nan")` all return `NaN`. Compare with `$result != $result` (the only value not equal to itself) to detect `NaN`, or use `POSIX::isnan`.
- **No complex-number support** in the built-in. For complex arguments use , which overloads `cos` via operator overloading:

```
use Math::Complex;
my $z = cplx(1, 2);
print cos($z), "\n";              # 2.03272300701967-3.
↪0518977991518i
```

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `sin` - sine of an angle in radians; the companion function most often used alongside `cos`
- `atan2` - two-argument arctangent, the usual building block for inverse trig (`acos`, `asin`) in pure Perl
- `sqrt` - square root; appears in the classical `acos` identity `acos(x) = atan2(sqrt(1 - x*x), x)`
- - `acos`, `asin`, `atan`, hyperbolic variants, `deg2rad`/`rad2deg`, and great-circle helpers
- - overloads `cos` (and the rest of the trig family) for complex arguments
- `POSIX` - exposes `acos` directly, plus `isnan`/`isinf` for detecting the non-finite results discussed above

SCALARs and strings

crypt

One-way `passwd(5)`-style hashing of a plaintext string with a salt.

`crypt` is a thin wrapper over the system C library's `crypt(3)` function. It turns `PLAINTEXT` and `SALT` into a short string - a *digest* - and returns it. The same `PLAINTEXT` and `SALT` always produce the same digest; small changes in either produce a completely different digest. There is no inverse function: you cannot recover `PLAINTEXT` from a digest.

> **Warning**
>
> `crypt` is **not a general-purpose encryption function**, despite the name. It cannot be undone. It is also **not a modern password hash** on most traditional configurations - the historical Unix scheme considers only the first eight bytes of `PLAINTEXT` and produces a 13-byte digest over a 12-bit salt, which is unsuitable for protecting passwords against contemporary attackers. What `crypt` is good for is verifying a user-supplied string against an already-stored digest produced by the same system's `crypt`. For anything else - encryption, key derivation, or hashing large data - use a real cryptographic library. See *See also* below.

Synopsis

```
crypt PLAINTEXT, SALT
```

Both arguments are strings. The return value is a string digest.

What you get back

A string whose exact shape depends on the host's `crypt(3)` implementation. Traditionally it is 13 bytes: two bytes of salt followed by 11 bytes from the set `[./0-9A-Za-z]`. Modern glibc, musl, and BSD libcs accept extended salts that select stronger schemes (MD5, SHA-256, SHA-512, bcrypt, yescrypt) and return longer digests in the `$id$salt$hash` passwd-file format.

Treat the digest as opaque. Do not parse it, do not assume a length, and do not assume which bytes of `SALT` the implementation consumed. The correct way to verify a plaintext against an existing digest is to pass the digest itself back in as the salt:

```
if (crypt($plain, $digest) eq $digest) { ... }
```

The salt used to create the digest is embedded in the digest, so this re-runs the same scheme with the same parameters on the candidate plaintext. Code written this way works with the classical DES scheme and with every modern extension a given `crypt(3)` exposes, without having to know which one produced the stored digest.

Global state it touches

`crypt` does not read or write any Perl special variable. On Unicode input it may emit a fatal `Wide character in crypt` error (see *Edge cases*).

Examples

Verify a password against a stored `passwd`-style digest:

```
my $stored = (getpwuid($<))[1];       # encrypted field from passwd

print "Password: ";
chomp(my $word = <STDIN>);
```

(continues on next page)

(continued from previous page)

```
if (crypt($word, $stored) eq $stored) {
    print "ok\n";
} else {
    die "Sorry...\n";
}
```

Create a fresh digest for a new password using a random two-character salt from the classical alphabet. The set is only a recommendation; the exact characters accepted in a salt are whatever the host `crypt(3)` allows, and Perl imposes no restriction of its own:

```
my @chars = ('.', '/', 0..9, 'A'..'Z', 'a'..'z');
my $salt  = $chars[rand 64] . $chars[rand 64];
my $hash  = crypt($plaintext, $salt);
```

Request a specific modern scheme by using an extended salt (glibc and compatible libcs). The `$id$` prefix selects the algorithm - `$1$` is MD5-crypt, `$5$` is SHA-256-crypt, `$6$` is SHA-512-crypt, `$2b$` is bcrypt where supported:

```
my $hash = crypt($plaintext, '$6$rounds=100000$' . $random_salt);
```

Re-verify using the stored digest as the salt - scheme-agnostic:

```
my $candidate = crypt($plaintext, $stored_digest);
my $match     = $candidate eq $stored_digest;
```

Constant-time comparison of the two digests is still the caller's responsibility; plain `eq` leaks timing information. If the threat model cares, compare byte-by-byte with a loop that does not short-circuit, or use a comparison routine from a crypto module.

Edge cases

- **First-8-byte truncation on classical DES.** On traditional Unix `crypt(3)`, only the first eight bytes of `PLAINTEXT` affect the digest: `crypt("password123", $s)` and `crypt("password456", $s)` collide. Extended schemes (`$1$`, `$5$`, `$6$`, `$2b$`, ...) do not have this limit, but the classical scheme is what you get from an unprefixed two-byte salt.
- **Salt-length assumptions are wrong.** Do not assume `substr($digest,0,2)` is the salt. Extended digests carry the salt in a different position and length. Re-use the full digest as the salt argument (`crypt($plain, $digest)`) and let `crypt(3)` parse it.
- **Unicode input.** If `PLAINTEXT` or `SALT` contains characters above codepoint 255, Perl attempts to downgrade a copy of the string to bytes before calling `crypt(3)`. If every character fits in a byte, the downgrade succeeds silently. If any character does not, `crypt` dies with `Wide character in crypt`. Encode explicitly (e.g. `Encode::encode_utf8`) if your plaintext might contain wide characters.
- **Unsupported scheme returns failure.** Passing a `$id$` prefix the host `crypt(3)` does not understand typically returns `undef` or a short string starting with `*0` or `*1`. Always check the return shape before using it.

- **`crypt(3)` may be absent or restricted.** On a small number of hosts the library function has been removed or replaced with a stub for export-control reasons. `crypt` in Perl is only as capable as the underlying libc call; if the libc call is a stub, so is this.
- **Not suitable for hashing large data.** `crypt` ignores most of its input on the classical scheme and is slow per call on the stretched schemes. It is the wrong tool for checksumming files or building content-addressable storage.

Differences from upstream

Fully compatible with upstream Perl 5.44. pperl dispatches to the host `crypt(3)` the same way perl5 does, so the accepted salt formats and the exact digest shape match whatever the system library produces - including the availability of `$1$`/`$5$`/`$6$`/`$2b$` extended schemes.

See also

- `Digest::MD5` - MD5-128 over arbitrary byte strings; use for fingerprinting data, not for password storage
- `Digest::SHA` - SHA-1/2 family digests; use for integrity checks and as a building block for HMAC and key derivation
- `Crypt::Bcrypt`, `Crypt::Argon2`, `Crypt::Passphrase` - CPAN modules for modern password hashing; prefer these over `crypt` for any new password-verification code
- `Crypt::Eksblowfish`, `Crypt::ScryptKDF` - CPAN modules for bcrypt and scrypt-based key derivation
- `getpwuid` - fetch the encrypted-password field from the local `passwd` database; its second field is the digest you pass as `SALT` when verifying
- `chomp` - remove the trailing newline from a password read with `<STDIN>` before passing it to `crypt`

I/O · Classes and OO

dbmclose

Break the binding between a DBM file and a hash previously attached by `dbmopen`.

`dbmclose` is the teardown counterpart to `dbmopen`. It flushes any pending writes, releases the DBM library's handles, and leaves `HASH` as an ordinary, untied hash you can continue to use or discard. In modern code `dbmclose` has been largely superseded by `untie` - the two accomplish the same thing, but `untie` works for every tied variable, not just DBM-bound hashes. Prefer `untie` unless you are maintaining existing dbmopen/`dbmclose` pairs and want them to read symmetrically.

Synopsis

```
dbmclose HASH
dbmclose %hash
```

What you get back

True on success, false on failure. Failure modes are rare - the common one is passing a hash that was never tied to a DBM file in the first place, in which case `dbmclose` returns false and sets `$!`. Most programs do not check the return value; the interesting errors (disk full, quota exceeded) surface on the writes that preceded the close, not on `dbmclose` itself. Check it when the DBM file is on a filesystem where a delayed write failure at close time is plausible:

```
dbmclose(%cache)
    or warn "dbmclose failed: $!";
```

Global state it touches

`dbmclose` reads and mutates the tie state of `HASH`. It does not touch any of the usual I/O-related special variables (`$,`, `$\`, `$|`, the selected filehandle); DBM access does not flow through the PerlIO layers that `print` and friends use. On failure, `$!` is set by the underlying DBM library.

Examples

Open a DBM file, iterate it, close it:

```
dbmopen(%HIST, '/usr/lib/news/history', 0666)
    or die "dbmopen: $!";
while (my ($key, $val) = each %HIST) {
    print $key, ' = ', unpack('L', $val), "\n";
}
dbmclose(%HIST);
```

Equivalent using the modern `tie`/`untie` pair - this is what new code should look like:

```
use AnyDBM_File;
use Fcntl;
tie(my %HIST, 'AnyDBM_File', '/usr/lib/news/history', O_RDWR, 0666)
    or die "tie: $!";
# ... use %HIST ...
untie %HIST;
```

Guard against closing an unbound hash:

```
my %h;
dbmclose(%h)
    or warn "not tied to a DBM file: $!";   # warns
```

Pair with an `eval` block to localise any cleanup errors without aborting the surrounding code:

```
eval {
    dbmclose(%cache) or die "dbmclose: $!";
    1;
} or warn $@;
```

Edge cases

- **Hash not tied to a DBM file**: returns false, sets `$!`. No exception is raised. The hash is left unchanged.
- **Hash tied via `tie`, not `dbmopen`**: `dbmclose` still works and is equivalent to `untie` for that hash, because dbmopen is itself implemented as a `tie` under the hood. Mixing the two APIs is legal but confusing - pick one per hash and stay with it.
- **References still held to the tied object**: like `untie`, `dbmclose` severs the binding between the hash and the DBM file, but if other code still holds a reference to the underlying tied object the DBM library may not actually release its handles until that reference is dropped. The symptom is a DBM file that stays locked or open past the `dbmclose` call. A `use warnings` program receives the `untie attempted while N inner references still exist` warning in that case.
- **Calling `dbmclose` twice on the same hash**: the first call succeeds, the second returns false. Idempotent-style code should either track whether the hash is currently tied or ignore the failure.
- **Hash is `local`'d or goes out of scope without `dbmclose`**: the binding is broken implicitly when the hash is destroyed, and the DBM library closes the file as part of that teardown. Explicit `dbmclose` is preferable because it makes write-flush failures visible at a known point in the program.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `dbmopen` - the opening half of the pair; every `dbmclose` matches a prior dbmopen on the same hash
- `untie` - the modern, general-purpose replacement; works for every tied variable, not just DBM-bound hashes
- `tie` - the modern counterpart to `dbmopen`, used with `AnyDBM_File`, `DB_File`, `GDBM_File`, `NDBM_File`, or `SDBM_File` to bind a hash to a DBM file
- `close` - unrelated, but the analogous operation for filehandles: needed when you care about write-flush failures surfacing at a known point

I/O · Classes and OO

dbmopen

Bind a DBM file on disk to a hash so hash reads and writes become lookups and stores in the database.

dbmopen is the old-style way to tie a hash to a dbm, ndbm, sdbm, gdbm, or Berkeley DB file. It has been largely superseded by `tie` with an explicit DBM backend module (`DB_File`, `GDBM_File`, `SDBM_File`, `NDBM_File`, `AnyDBM_File`), which gives you control over which implementation is used and over per-backend options. Reach for dbmopen when you are reading legacy code or when the one-liner brevity matters more than backend choice.

Unlike `open`, the first argument is **not** a filehandle - it is the hash that will be bound. `HASH` is written with the `%` sigil.

Synopsis

```
dbmopen %HASH, $DBNAME, $MASK
dbmopen(%HASH, $DBNAME, 0)       # open existing only; never create
dbmclose %HASH                   # or: untie %HASH
```

What you get back

A true value on success, a false value on failure. On failure `$!` is set to the system error that prevented the bind. The common failure cases are "database does not exist and `MASK` is `0`" and permission errors on the backing files.

```
dbmopen(%cache, $path, 0)
    or die "cache $path missing or unreadable: $!";
```

After a successful call, `%HASH` behaves like any other hash: `$HASH{key} = $value` writes to the database, `$HASH{key}` reads from it, `delete` removes an entry, `exists` tests membership, and `each` / `keys` / `values` iterate. The data lives on disk; the hash is only a view.

Arguments

- **`HASH`** - the hash variable to bind. Must be written with `%`. Any existing contents are discarded. The hash stays bound until `dbmclose` or `untie` is called on it, or until it goes out of scope.
- **`DBNAME`** - the database pathname **without** the backend's file extension. Traditional dbm / sdbm stores use two files named `` `DBNAME.dir` `` and `` `DBNAME.pag` ``; gdbm and Berkeley DB use a single file. Passing `"/var/lib/app/cache"` opens `/var/lib/app/cache.dir` + `/var/lib/app/cache.pag` under sdbm, or `/var/lib/app/cache` under gdbm.
- **`MASK`** - creation mode for any files that have to be created, in the same form as the third argument to `chmod` (typically an octal literal like `0666` or `0644`). The active `umask` is applied to `MASK`, so real on-disk permissions are `MASK & ~umask`. **A `MASK` of `0` suppresses creation**: if the database does not already exist, dbmopen returns false and `$!` is set.

Global state it touches

- `$!` - set on failure (database missing, permission denied, backing store corrupt).
- The active `umask` - masks `MASK` when new backing files are created.

Examples

Open a history database, iterate with `each`, then close:

```
dbmopen(%HIST, '/usr/lib/news/history', 0666)
    or die "open history: $!";
while (my ($key, $val) = each %HIST) {
    print $key, ' = ', unpack('L', $val), "\n";
}
dbmclose %HIST;
```

Open read-only, refusing to create the database:

```
dbmopen(%cache, "$ENV{HOME}/.app/cache", 0)
    or die "no cache at $ENV{HOME}/.app/cache: $!";
my $hit = $cache{$key};
dbmclose %cache;
```

Pick a specific backend by loading its module before calling dbmopen. `AnyDBM_File` consults `@AnyDBM_File::ISA` to decide which implementation dbmopen uses:

```
use DB_File;
dbmopen(%NS_Hist, "$ENV{HOME}/.netscape/history.db", 0644)
    or die "open netscape history: $!";
```

Write-protected database - assignment silently fails (or croaks depending on the backend); guard with `eval` when you need to probe:

```
dbmopen(%db, $path, 0) or die $!;
my $writable = eval { $db{__probe__} = 1; delete $db{__probe__}; 1 }
 ↪;
warn "read-only\n" unless $writable;
```

Large database - avoid `keys` / `values`, which materialise the whole list in memory. Use `each` instead:

```
dbmopen(%big, $path, 0) or die $!;
while (my ($k, $v) = each %big) {
    process($k, $v);
}
dbmclose %big;
```

Edge cases

- **Hash sigil is required.** `dbmopen %h, $name, 0666` - writing `$h` or `\%h` does not work. The first slot is the hash's name as a hash, not a reference.
- **`MASK = 0` is the "open existing only" idiom.** A plausible-looking `0666` silently creates a fresh empty database if the file is missing, which is almost never what a reader wants on a cache lookup path.
- **Extensions are managed by the backend.** Do not pass `"cache.dir"` or `"cache.pag"` - pass `"cache"`. `sdbm` appends `.dir` / `.pag`; `gdbm` writes to the bare name.
- **One open per process for older DBM.** If the backend is the traditional `dbm(3)` library (rare today), a process may only have a single DBM open at a time. `sdbm` and `gdbm` do not have this limit.
- **Value size limits.** `sdbm` caps keys + values at roughly 1008 bytes per record; oversize writes are truncated or rejected. `gdbm` and Berkeley DB have much higher limits. When in doubt, use `tie` with `DB_File` and check the backend's own limits.
- **Numeric values are bytes on disk.** Storing `$h{k} = 42` writes the string `"42"`, not an integer. Pack explicitly with `pack` / `unpack` when the field needs a fixed binary layout (as in the news-history example above).
- **Closing is optional but recommended.** The bind is released when the hash goes out of scope, but explicit `dbmclose` or `untie` flushes pending writes and surfaces close-time errors.
- **Re-binding an already-bound hash.** Calling `dbmopen` on a hash that is already bound closes the previous binding first.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `dbmclose` - release a `dbmopen` binding and flush pending writes
- `tie` - the modern replacement; pair with `DB_File`, `GDBM_File`, `SDBM_File`, or `AnyDBM_File` to pick a backend explicitly
- `untie` - release a binding made with either `dbmopen` or `tie`
- `each` - stream entries without materialising the whole database in memory
- `umask` - masks the `MASK` argument when backing files are created
- `open` - the ordinary file-open built-in, which takes a filehandle and not a hash

Control flow

defer

Schedule a block to run when the enclosing scope exits, for any reason.

`defer` is a flow-control keyword, not a function. Writing `defer { ... }` inside a scope records the block for later execution; when control leaves the enclosing block - by falling

off the end, by `return`, by `die`, by `goto`, or by a loop-control statement (`next`, `last`, `redo`) - the stored block runs on the way out. It is the standard idiom for pairing acquisition with release (open/close, lock/unlock, push/pop) without relying on object destructors or wrapping every path in `eval`.

The feature is **experimental** and must be enabled. Either opt in explicitly or pick up the bundle:

```
use feature 'defer';    # explicit
use v5.36;              # bundle - enables defer among others
```

Under `use warnings 'experimental::defer'` (or plain `use warnings`) the first use emits an experimental warning. Silence it with `no warnings 'experimental::defer'` once you have decided to rely on the feature.

Synopsis

```
defer BLOCK
```

`defer` takes a brace-delimited block and nothing else. There is no expression form, no filehandle form, and no return value - the statement exists for its side effect on scope exit.

What you get back

`defer` is a statement, not an expression. It contributes no value to its surrounding context. The block's own return value is discarded when it runs at scope exit.

When the deferred block runs

The deferred block is invoked **once**, when control leaves the directly enclosing block, regardless of how control leaves:

- normal fallthrough off the end of the block,
- explicit `return` from the containing subroutine,
- an exception thrown by `die` or propagated from a called sub,
- `goto` out of the block,
- loop control via `next`, `last`, or `redo`.

If the flow of execution never reaches the `defer` statement itself, the block is **not** enqueued and does not run. This is the direct opposite of an `END` phaser, which the compiler enqueues unconditionally:

```
use feature 'defer';

{
    defer { say "This will run"; }
    return;
    defer { say "This will not"; }   # never reached, never␣
```

(continues on next page)

(continued from previous page)

```
 ↪scheduled
}
```

LIFO ordering

Multiple `defer` blocks in the same scope run in **last-in, first-out** order - the most recently scheduled block runs first. This matches the natural nesting of resource acquisition: the last thing acquired is the first thing released.

```
use feature 'defer';

{
    defer { say "1"; }
    defer { say "2"; }
    defer { say "3"; }
}
# prints 3, then 2, then 1
```

Global state it touches

None directly. The deferred block sees interpreter globals (`$_`, `$!`, `$@`, selected filehandle, etc.) with whatever values they hold **at the moment the block runs**, not at the moment it was scheduled. A `defer` that wants to preserve `$!` or `$@` across cleanup must save and restore them itself - otherwise a system call inside the block will clobber them and the caller of the enclosing sub will see the overwritten values.

```
defer {
    local ($!, $@);
    close $fh;          # clobbers $! on failure - local'd copy␣
 ↪absorbs it
}
```

Examples

Pair an open with its `close`, guaranteed to run even on `die`:

```
use feature 'defer';

sub read_config {
    open my $fh, "<", "config.ini" or die "open: $!";
    defer { close $fh; }

    while (<$fh>) { ... }
    # close $fh runs here on fallthrough, on return, and on die.
}
```

Unlock a shared resource on every exit path:

```
use feature 'defer';

sub critical_section {
    $lock->acquire;
    defer { $lock->release; }

    do_work();            # release runs on fallthrough
    return if $shortcut;  # release runs before the return completes
    die "boom" if $bad;   # release runs, then the exception
↪propagates
}
```

LIFO cleanup of nested resources - the outer resource is released last, which is usually what you want:

```
use feature 'defer';

sub copy_file {
    open my $in,  "<", $src or die "open $src: $!";
    defer { close $in; }

    open my $out, ">", $dst or die "open $dst: $!";
    defer { close $out; }

    print {$out} $_ while <$in>;
    # close $out runs first, then close $in.
}
```

Temporarily adjust interpreter state and restore it on exit without using `local`:

```
use feature 'defer';

sub with_separator {
    my $saved = $,;
    $, = " | ";
    defer { $, = $saved; }

    print @_, "\n";
}
```

Edge cases

- **Conditional scheduling.** A `defer` statement only schedules its block when control actually reaches it. An early `return` or `die` that happens before the `defer` line leaves nothing to run. Place the `defer` immediately after the paired acquisition so they cannot become separated by an intervening failure.
- **Once scheduled, always runs.** There is no mechanism to un-schedule a `defer` block. If the acquisition that the block releases has failed, either do not schedule the `defer` (keep it after the success check) or make the block idempotent so a redundant release is harmless.

- **No control-flow escape from the block**. A `defer` block may throw an exception, but it may **not** `return` from the enclosing sub, `goto` a label outside itself, or run `next`, `last`, or `redo` for a loop that encloses the `defer`. Those constructs are fine *inside* the `defer` when they act on loops **contained entirely within** the block's own body:

```
defer {
    foreach (1 .. 5) { last if $_ == 3; }   # permitted
}

foreach (6 .. 10) {
    defer { last if $_ == 8; }              # forbidden
}
```

- **Exception during exception unwind**. If the `defer` block is running because an exception is propagating and the block itself throws, the language does not specify the resulting exception - only that the caller will see one. Do not rely on which exception wins. Wrap risky cleanup in `eval` if you need both signals preserved.
- **Exceptions propagate normally**. An exception thrown by a `defer` block that is running for any other reason (normal exit, return, loop control) propagates to the caller exactly like any other exception. A failing `close` in cleanup can therefore turn a successful-looking function into a caller-visible `die`.
- **`$@` and `$!` inside the block**. On the exception-driven exit path, `$@` holds the in-flight exception while the `defer` block runs. Reading it is fine; replacing it changes what the caller sees after the unwind completes.
- **Scope granularity**. `defer` binds to the **immediately** enclosing block, not to the enclosing sub. A `defer` inside `if (...) { defer { ... } }` runs when the `if` block exits, not when the sub returns. Put the `defer` at subroutine scope if you want subroutine-exit semantics.
- **Experimental warning**. Under `use warnings` the first occurrence warns. Opt in deliberately with `no warnings 'experimental::defer'` once you have committed to the feature.
- **Not available without the feature guard**. Without `use feature 'defer'` (or a bundle that enables it), `defer { ... }` is parsed as a call to a subroutine named `defer` followed by a block - almost certainly not what you meant, and usually a compile-time error.

Differences from upstream

Fully compatible with upstream Perl 5.44. The feature remains marked experimental in pperl to mirror upstream's classification; behaviour (scheduling on statement execution, LIFO order, exception propagation, restrictions on control-flow escape) matches Perl 5.44.

See also

- `eval` - the established tool for turning exceptions into return values; `defer` complements it by guaranteeing cleanup without an explicit `eval` wrapper on every path
- `die` - one of the exit paths that triggers deferred blocks; read alongside `defer` when designing cleanup
- `return` - another exit path; a `defer` scheduled before a `return` runs before the caller resumes
- `local` - the other idiom for scoped state restoration; pick `local` for dynamic scoping of a single variable, `defer` for arbitrary cleanup actions
- `$@` - current exception; visible inside a `defer` block running on the exception-unwind path
- `$!` - system errno; easily clobbered by cleanup syscalls, `local`-ise inside the deferred block if the caller needs it preserved

Misc

defined

Test whether a value, variable, or subroutine is defined.

`defined` returns true when `EXPR` holds any value other than the undefined value `undef`, and false when it holds `undef`. It is the one and only way to tell `undef` apart from the other false values (`0`, `""`, `"0"`), which a plain boolean test cannot.

Synopsis

```
defined EXPR
defined
defined &SUBROUTINE
```

What you get back

A boolean: true if `EXPR` is defined, false if it is `undef`.

With no argument, `defined` operates on `$_`.

The result is context-sensitive only in the usual boolean sense; `defined` does not propagate list context into `EXPR`.

Why it exists, and why a plain boolean is not enough

Many operations return `undef` to signal failure, end of file, a system error, an uninitialised variable, or some other exceptional condition. `defined` lets you distinguish that sentinel from a legitimate result. A simple boolean test treats `undef`, `0`, `""`, and `"0"` the same - all four are false - so you cannot use truthiness to tell “nothing was returned” apart from “zero was returned”:

```
my $n = some_count();
if ($n)          { ... }   # false for 0 AND for undef
if (defined $n) { ... }   # false only for undef
```

Note that undef is itself a valid scalar value. Its presence does not *necessarily* mean something went wrong: pop @empty returns undef, but so does pop @array when the element popped happened itself to be undef. defined tells you the value is undef; it does not tell you why.

Default argument: $_

With no argument, defined tests $_:

```
while (<$fh>) {
    next unless defined;          # same as: defined $_
    chomp;
    ...
}
```

defined &subroutine

defined &func asks whether subroutine func has ever been defined. A forward declaration (sub func;) does **not** make it defined; an actual body does:

```
sub greet { "hello" }
print defined &greet   ? "yes\n" : "no\n";   # yes
print defined &missing ? "yes\n" : "no\n";   # no
```

A subroutine that is not defined may still be *callable*: the package's AUTOLOAD method can bring it into existence on first call. defined &func reflects the current state of the symbol table, not what a future AUTOLOAD might produce. See perlsub.

The return value is unaffected by forward declarations.

Hash elements: defined vs exists

On a hash element, defined asks about the **value**, not the key:

```
my %h = (a => 1, b => undef);

print exists  $h{a} ? 1 : 0, "\n";   # 1
print defined $h{a} ? 1 : 0, "\n";   # 1

print exists  $h{b} ? 1 : 0, "\n";   # 1   - key is present
print defined $h{b} ? 1 : 0, "\n";   # 0   - value is undef

print exists  $h{c} ? 1 : 0, "\n";   # 0   - key not present
print defined $h{c} ? 1 : 0, "\n";   # 0   - also autovivifies? no,␣
 ↪rvalue is safe
```

Use `exists` to ask "is this key in the hash?" and `defined` to ask "does this slot hold a usable value?". The two differ whenever a value was explicitly assigned `undef` or left `undef` by construction (e.g. `$h{b} = undef`, or `@h{qw(a b c)} = (1)`).

The same distinction applies to array elements: `exists $a[7]` reports whether the array is long enough and the slot has been assigned, while `defined $a[7]` reports whether that slot currently holds a non-`undef` value.

Examples

The common `pop`-until-empty idiom - stops only when the array is exhausted, not on a legitimate falsy element:

```
while (defined(my $val = pop @ary)) {
    process($val);
}
```

Check a system call for failure:

```
my $target = readlink $sym;
die "can't readlink $sym: $!" unless defined $target;
```

Call a coderef only if one was supplied:

```
sub dispatch {
    my ($cb, @args) = @_;
    return defined &$cb ? $cb->(@args) : die "no callback";
}
```

Provide a default without clobbering a legitimate `0` or `""`:

```
$debugging = 0 unless defined $debugging;
```

The modern form is the defined-or operator `//`, which does exactly this test inline:

```
$debugging //= 0;
my $name = $user // "anonymous";
```

Regex capture: `$1` being defined tells you the capture group participated in the match, even if it matched the empty string:

```
"ab" =~ /a(.*)b/;
print defined $1 ? "matched '$1'\n" : "no match\n";   # matched ''
```

Aggregates: `defined @array`, `defined %hash` are no longer supported

Historically `defined @array` and `defined %hash` reported whether memory for the aggregate had ever been allocated - an implementation detail that was rarely what callers actually wanted. Modern Perl rejects these forms. Test the aggregate's size instead:

```
if (@array) { print "array has elements\n" }
if (%hash)  { print "hash has members\n"   }
```

In boolean context an array evaluates to its element count and a hash evaluates to a true value iff it has any keys. That is the test you almost always wanted.

Testing *an element* of an aggregate is still fine and is the usual use: `defined $array[$i]`, `defined $hash{$key}`.

Overuse

`defined` is frequently overused. Zero and the empty string are defined values. A regex match that captures zero characters still sets `$1` to a defined empty string - the match did not fail; it matched something that happened to be of length zero. When a function returns `undef`, it is admitting it cannot give you a meaningful answer. Reach for `defined` when you are questioning the integrity of a value. For "is it zero?" or "is it empty?" a plain comparison to `0` or `""` is what you want.

Edge cases

- **Bare `defined`** with no argument tests `$_`. Inside `map`, `grep`, or a `while (<$fh>)` loop this is the idiomatic form.
- **`defined(&func)` vs `defined(&{$ref})`**: both work. The second dereferences a code reference and asks whether the referenced slot currently holds a defined subroutine body.
- **`defined $hash{$key}` does not autovivify the key** - `defined` is an rvalue context and leaves the hash unchanged. Contrast with `$hash{$key}{inner} = 1`, which does autovivify.
- **Chained hash/array access**: `defined $h{a}{b}` autovivifies `$h{a}` into an empty hash ref in order to perform the inner lookup, even though the outer `defined` reads the result. This is a consequence of how the dereference chain is evaluated, not of `defined` itself. To probe nested structure without autovivifying, check each level with `exists` first.
- **`defined $&`, `defined $1`**: after a successful match these are defined; after a failed match they retain whatever value they had from the previous successful match in the same scope. `defined` alone is not a safe "did the match succeed" test - check the match operator's return value instead.
- **`defined` is not an lvalue**. `defined $x = $y` is a syntax error; parenthesise the assignment: `defined($x = $y)`.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `undef` - the value `defined` tests against, and the operator that produces or clears it
- `exists` - ask whether a hash key or array index is present, independent of whether its value is `undef`
- `ref` - when the question is not "is it defined" but "what kind of reference is this"
- `//` *and* `//=` - defined-or operator; the modern inline form of `defined($x) ? $x : $default`
- `$_` - the default argument when `defined` is called with no expression

Hashes

delete

Remove the named key-value pair(s) from a hash, or element(s) from an array, and return what was removed.

`delete` reaches into an aggregate and removes the specified entries outright - not just by setting them to `undef`. After `delete`, `exists` on the same key or index returns false, `keys` no longer lists it, and iterating the hash with `each` skips it. The argument must be an element or slice of a hash or array; its final operation selects what to remove, and anything leading up to that operation (dereferences, method calls) is just navigation.

Synopsis

```
delete $hash{KEY}           # scalar key
delete @hash{LIST}          # hash slice: values of the listed keys
delete %hash{LIST}          # key/value hash slice (5.20+)
delete $array[INDEX]        # array element
delete @array[LIST]         # array slice
```

What you get back

In list context, `delete` returns the value or values removed, in argument order. A slice argument whose key or index did not exist yields `undef` at the matching position, so the length of the returned list matches the length of the key/index list.

In scalar context, `delete` returns the value of the last element removed, or `undef` if the key/index was not present.

The 5.20+ key/value hash-slice form `delete %hash{LIST}` returns a list of alternating key/value pairs - two elements for every deleted entry - which makes it the idiomatic way to pluck a named set of entries and keep both sides.

```
my %h = (foo => 11, bar => 22, baz => 33);
my $v = delete $h{foo};             # 11
my @v = delete @h{qw(bar quux)};    # (22, undef)
my %kv = delete %h{qw(baz quux)};  # (baz => 33, quux => undef)
```

Global state it touches

- **%ENV** - `delete $ENV{VAR}` unsets the environment variable for the current process and its future children. The effect is real, not just the Perl-side hash; system calls see the change.
- **tied aggregates** - `delete` dispatches to the `DELETE` method of the tying package. The return value is whatever the implementation chooses to hand back; some tied hashes return the deleted value, some do not.
- **$_** - unaffected. `delete` does not default to anything; `EXPR` is mandatory.

Examples

Remove one key, inspect what was there:

```
my %cfg = (host => "db1", port => 5432, user => "alice");
my $old_host = delete $cfg{host};
# $old_host is "db1"; exists $cfg{host} is false
```

Free memory by removing many entries in one call (hash slice):

```
delete @cache{@stale_keys};
```

Pluck a set of named entries and keep the pairs (5.20+ kv-slice):

```
my %h = (a => 1, b => 2, c => 3);
my %taken = delete %h{qw(a c)};
# %taken is (a => 1, c => 3); %h is (b => 2)
```

Delete through a nested structure. Leading navigation can be arbitrary - only the final operation decides what gets removed:

```
my $tree = { users => { alice => { roles => [qw(admin ro)] } } };
delete $tree->{users}{alice}{roles}[0];
# roles is now (undef, "ro")
delete $tree->{users}{alice};
# the whole user record is gone
```

Avoid autovivification on the read side while still removing on the write side. `delete` never vivifies the intermediate hashes it walks through:

```
delete $h{outer}{inner};    # does not create $h{outer} if absent
```

Compare with `splice` when you want indices to renumber. `delete` on an array element leaves a hole; `splice` closes the hole:

```
my @a = (10, 20, 30, 40);
delete $a[1];
# @a is (10, undef, 30, 40); $#a is still 3

my @b = (10, 20, 30, 40);
```

(continues on next page)

(continued from previous page)

```
splice(@b, 1, 1);
# @b is (10, 30, 40); $#b is 2
```

Edge cases

- **`delete` vs assigning `undef`**: `$h{k} = undef` leaves k in the hash with an undefined value; `exists $h{k}` is still true. `delete $h{k}` removes the key entirely.
- **Missing key in scalar context**: `delete $h{nope}` returns `undef`. That's indistinguishable from deleting a key whose value was `undef`; use `exists` first if the distinction matters.
- **`each` + `delete` inside the loop**: safe when you delete only the current key (the key just returned by `each`). Deleting *other* keys during iteration can skip entries or revisit them - Perl's hash iterator is not stable across structural change. The safe rewrite is to collect keys first:

```
for my $k (grep { $h{$_} < 0 } keys %h) {
    delete $h{$k};
}
```

- **Trailing array deletions shrink the array**: if the deleted elements are at the top end, `$#array` drops to the highest index still testing true under `exists`. Holes in the middle stay as holes.
- **`delete` on an array is discouraged**: the concept of "missing index" is not coherent for arrays - indices are positional, not named. Leave array shrinkage to `shift`, `pop`, or `splice`. `WARNING` in upstream POD restated: reach for an array `delete` only when you know you want a hole.
- **`delete local $h{k}`**: removes the entry for the enclosing block and reinstates it on scope exit. Useful for temporarily hiding configuration keys from code called inside the block without losing the original value:

```
{
    local $ENV{LANG};         # still present, but undef
    delete local $ENV{PATH};  # gone for this block only
    run_thing();
}   # both restored to original values here
```

- **Tied hash, tied array**: `delete` calls `DELETE`; the return value is whatever the tie implementation supplies. A tied DBM hash deletes the entry on disk.
- **Readonly target**: `delete` on a readonly element croaks with `Modification of a read-only value attempted`.
- **The expression must end in an element or slice**: `delete $h{k} + 1` is a compile-time error; `delete` has lower precedence than arithmetic and expects an lvalue-ish aggregate lookup, not a computed value.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `exists` - the query counterpart; use it before `delete` when you need to tell "was never there" apart from "was there with value `undef`"
- `each` - hash iterator; safe to combine with `delete` only when you delete the current key
- `keys` - snapshot of hash keys; the usual way to build a deletion list that won't interact with iterator state
- `values` - companion to `keys` when you want the deleted-value set without the keys
- `splice` - the right tool when you want to remove array elements *and* renumber remaining indices
- `undef` - clears a whole aggregate (`undef %h`, `undef @a`) or a single scalar; the customary way to empty a hash or array wholesale rather than deleting every key

I/O · Control flow

die

Raise an exception.

`die` throws an exception built from `LIST`. If the exception happens inside an `eval`, the `eval` terminates with `undef` and `$@` holds the exception value. If nothing catches it, Perl prints the message to `STDERR` and the interpreter exits with a non-zero status. The exception can be a plain string, a list that stringifies into one, or a reference - typically a blessed object carrying structured error state.

Synopsis

```
die LIST
die $message
die $exception_object
die                          # re-raise / propagate current $@
```

What you get back

`die` does not return. Control transfers to the nearest dynamically enclosing `eval` (which then returns `undef` in scalar context or the empty list in list context), or - if there is no enclosing `eval` - the interpreter unwinds, runs `END` and `DESTROY` handlers, and exits.

The exception value itself lands in `$@`:

- **String exceptions** - the stringified message, including any appended `at FILE line N.\n` (see below).
- **Reference exceptions** - the reference itself, unchanged. This is the idiomatic way to throw a blessed exception object.

On uncaught exit, the exit code is derived from `$!` and `$?`:

```
exit $! if $!;              # errno
exit $? >> 8 if $? >> 8;    # child exit status
exit 255;                   # last resort
```

Rely only on the exit code being non-zero; the exact value is a best-effort encoding of whatever global error state was live at the moment of the throw.

Global state it touches

- `$@` - written with the exception on unwind into an `eval`, read by the no-argument form of `die` to propagate an existing exception, and read by the uncaught-exception printer.
- `$!` - read when deriving an exit code for an uncaught exception, and commonly interpolated into the message itself (`die "open $f: $!"`).
- `$?` - read when deriving an exit code if `$!` is zero. `END` and `DESTROY` handlers can still mutate it before the process actually exits.
- `$.` - the current input line number, appended to string exceptions that lack a trailing newline.
- `$SIG{__DIE__}` - if set, the handler runs *before* the exception is propagated, with the exception as its argument. The handler can replace the exception by calling `die` again with a different value.
- `$^S` - readable by `$SIG{__DIE__}` handlers to tell whether the die is happening inside an `eval`.

The trailing-newline rule

Whether `die` appends location information depends on one character at the end of the message:

- **Message ends in `"\n"`** - used verbatim. Nothing is appended. Use this form when the message is already a complete, user-facing diagnostic.
- **Message does not end in `"\n"`** - Perl appends `" at FILE line N"`, and if a file is being read, `", <HANDLE> line M"`, then a final `"."` and newline. Use this form during development, or whenever locating the `die` call in the source is more useful than a tidy message.

```
die "bad config\n";                 # "bad config\n"
die "bad config";                   # "bad config at script.pl line␣
 ↪42.\n"
```

A common idiom is to append `", stopped"` to make the location suffix read naturally:

```
die "/etc/games is no good, stopped";
# /etc/games is no good, stopped at canasta line 123.
```

Reference exceptions never get location information appended - stringifying an object to inspect it would defeat the point of throwing an object. If you want file and line in-

side a structured exception, capture them at construction time (`__FILE__`, `__LINE__`, or `caller`).

Reference-valued exceptions

Passing a reference - typically a blessed object - lets `$@` carry structured state instead of a string you later have to parse:

```
package MyApp::Error;
sub new   { my ($c, %a) = @_; bless { %a }, $c }
sub code  { $_[0]{code}  }
sub where { $_[0]{where} }

eval {
    die MyApp::Error->new(code => 'EPARSE', where => 'line 12');
};
if (my $err = $@) {
    if (ref($err) && $err->isa('MyApp::Error')) {
        warn "parse error at ", $err->where;
    }
    else {
        die $err;   # not ours - re-raise
    }
}
```

Overload stringification on exception classes so that an uncaught exception still prints a useful message:

```
use overload '""' => sub { "[MyApp::Error ".$_[0]->code."]\n" };
```

The stringified form should end in a newline and be non-empty, matching the treatment of string exceptions.

Because `$@` is a global, copy it into a lexical before inspecting it - any method call, `ref`, or `isa` you run during handling can itself `eval` internally and clobber `$@`:

```
if (my $err = $@) { ... }       # safe
if ($@) { $@->method; ... }     # unsafe: method may reset $@
```

Propagation: `die` with no argument (or empty string)

When `LIST` is empty or stringifies to `""`, `die` does not throw a fresh exception - it re-raises whatever is in `$@`:

- If `$@` holds a **string**, `die` appends `"\t...propagated at FILE line N.\n"` and re-throws. This is the canonical way to let an exception continue up the call stack after a partial-match check:

  ```
  eval { risky() };
  die unless $@ =~ /Expected exception/;
  ```

- If `$@` holds an **object reference with a `PROPAGATE` method**, that method is invoked as `$@ = eval { $@->PROPAGATE(__FILE__, __LINE__) }`, and the re-

turn value replaces `$@` before the re-throw. Implement `PROPAGATE` on an exception class when you want the exception to record the chain of re-raises.

- If `$@` holds an object reference with **no** `PROPAGATE`, the reference is re-thrown unchanged.
- If `$@` is also empty, the string `"Died"` is used.

The `$SIG{__DIE__}` hook

Setting `$SIG{__DIE__}` installs a handler that runs when `die` fires, with the exception as its argument. The handler can inspect or replace the exception by calling `die` again with a different value. It runs **even inside `eval`**, which is the usual reason to want it out of the way:

```
local $SIG{__DIE__} = sub {
    die @_ if $^S;              # inside eval: do nothing special
    log_fatal(@_);              # outside eval: log before we exit
};
```

`$^S` is `undef` during compilation, true inside an `eval`, and false at the top level - use it to gate handler work that only makes sense for uncaught exceptions.

Examples

Bail out with a clean message (note the trailing newline suppresses file/line appending):

```
chdir '/var/spool' or die "can't cd to spool: $!\n";
```

Die without a newline during development so the location is appended:

```
die "unexpected empty record";
# unexpected empty record at parse.pl line 87.
```

Catch a string exception:

```
eval {
    parse($input);
};
if ($@) {
    warn "parse failed: $@";    # $@ already ends in "\n" if the
                                # die'd message did
}
```

Throw and catch a blessed exception object:

```
eval {
    die MyApp::Error->new(code => 'EIO', detail => $!);
};
if (my $err = $@) {
    if (ref($err) && $err->isa('MyApp::Error')) {
        handle($err);
```

(continues on next page)

(continued from previous page)

```
    }
    else {
        die $err;               # re-raise anything unexpected
    }
}
```

Conditional propagation - catch one class, let the rest through:

```
eval { work() };
die unless $@ =~ /^recoverable:/;
recover();
```

Edge cases

- **List with two or more items** is stringified and concatenated to form the message: `die "read failed on ", $file, ": $!"`. The newline rule applies to the concatenated result.
- **Empty list** (`die;` or `die "";`) triggers the propagation path described above, not a fresh exception.
- **Reference with trailing newline inside the stringified form** is irrelevant: location is never appended to a reference, regardless of what its `""` overload produces.
- **`die` inside `DESTROY` during global destruction** can still fire `$SIG{__DIE__}` but may not propagate as expected - the interpreter is already unwinding. Keep destructors defensive.
- **Uncaught `die` during `END` block** runs remaining `END` blocks but sets exit status per the `$!`/`$?` rule above.
- **Nested `eval` and `$SIG{__DIE__}`**: the handler runs for *every* die, including those caught by an inner `eval`. Guard with `$^S` if the handler has side effects.
- **Re-throwing the current `$@`**: prefer bare `die;` over `die $@;`. The bare form triggers the propagation machinery (`...propagated` suffix, `PROPAGATE` hook); `die $@` does not - it treats `$@` as a fresh exception value.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `eval` - the only construct that catches a `die`; its block form traps exceptions into `$@`
- `warn` - same formatting rules (trailing-newline suppresses location), but writes to `STDERR` and does not unwind
- `caller` - capture file and line at throw time when building a structured exception object
- `exit` - use when you want a specific exit code without the exception-handling machinery

- `$@` - where the exception lands after an `eval` catches it, and the source the no-arg `die` re-raises from
- `$SIG{__DIE__}` - pre-throw hook that can inspect or rewrite the exception
- `$^S` - tells a `$SIG{__DIE__}` handler whether it is running inside an `eval`

Control flow · Modules

do

Execute a block of code or run a Perl source file as if it were part of the current program.

do wears two unrelated hats that share only a keyword. do BLOCK groups statements into a single expression and returns the value of the last one - a syntactic tool, not a function. do EXPR treats the string as a filename and compiles-and-runs the file at runtime. Read whichever section matches the form you see; mixing them up is the most common source of confusion around this keyword.

Synopsis

```
do BLOCK                          # group statements, yield last value
do EXPR                           # load and run a Perl file
do { ... } while CONDITION;       # post-test loop idiom
```

What you get back

- do BLOCK - the value of the last expression evaluated in the block, in whatever context the surrounding expression imposes.
- do EXPR - the value of the last expression evaluated in the file on success; `undef` on failure, with `$@` set to the compile error or `$!` set to the I/O error.

do BLOCK - group statements into one expression

do BLOCK is not a function. It is a syntactic construct that turns a brace-delimited sequence of statements into a single term whose value is the value of the last statement. Reach for it when the language wants an expression but you have several statements to run:

```
my $x = do {
    my $tmp = fetch_raw();
    $tmp =~ s/\s+\z//;
    lc $tmp;
};                                # $x = cleaned, lower-cased value
```

When do BLOCK is modified by a trailing `while` or `until`, the block runs **once before** the condition is tested - this is the standard post-test loop idiom:

```
do {
    $line = <$fh>;
} while defined $line && $line !~ /^END\b/;
```

On any other statement, `while` and `until` as statement modifiers test the condition first. do is the exception.

next, last, redo do not work inside do BLOCK

A do BLOCK is **not** a loop, even when trailed by `while` or `until`. Loop-control keywords do not see it:

```
do {
    last if $done;              # WRONG - not a loop
} while $more;
```

If you need loop control, wrap the body in a bare block, which *is* a loopable scope:

```
{
    last if $done;
    redo if $retry;
}
```

Or use an explicit `while` loop.

return inside a bare do BLOCK

`return` in a do BLOCK returns from the **enclosing subroutine**, not from the block itself. That is occasionally what you want and occasionally a bug - either way, know which one you are writing:

```
sub classify {
    my $n = shift;
    my $kind = do {
        return "zero" if $n == 0;   # returns from classify(), not
↪the do
        $n > 0 ? "pos" : "neg";
    };
    "$kind ($n)";
}
```

To yield a value from the block without returning from the sub, just let the last expression be the value - that is the whole point of do BLOCK.

do EXPR - load and run a Perl source file

do EXPR evaluates EXPR, treats the result as a filename, reads the file, compiles it, and runs it in the current package. It is similar to, but not quite the same as,

```
eval `cat stat.pl`;
```

The do form runs no external process, keeps the original filename for error messages, and **cannot see lexicals in the enclosing scope** - which eval STRING can. Like eval STRING, the file is reparsed on every call, so do FILE inside a loop is almost always wrong.

Path resolution and @INC

The filename is interpreted like this:

- Absolute paths (`/foo/stat.pl`), paths beginning with `./`, and paths beginning with `../` are used as-is.
- Any other relative path is searched along `@INC`, and on success the found path is recorded in `%INC` under the key you passed.

```
do '/etc/myapp/stat.pl';        # exact file
do './stat.pl';                 # exact file, current directory
do 'stat.pl';                   # search @INC
do 'MyApp/config.pl';           # search @INC
```

Since Perl 5.26 `.` is not in `@INC` by default, so a bare `do 'stat.pl'` no longer falls back to the current directory. If the file is not found, Perl emits the hint:

```
do "stat.pl" failed, '.' is no longer in @INC;
did you mean do "./stat.pl"?
```

Pass `./stat.pl` when you mean the current directory.

Return value and error reporting

`do EXPR` has three outcomes you must distinguish:

Outcome	Return	`$@`	`$!`
File compiled and ran	value of last expression	`""`	unchanged
File read but did not compile	`undef`	compile error	may also be set
File could not be read	`undef`	`""`	I/O error

Because compilation failure can incidentally set `$!` as well, **always check `$@` first**:

```
my $return;
for my $file ("/etc/myapp.rc", "$ENV{HOME}/.myapprc") {
    unless ($return = do $file) {
        warn "couldn't parse $file: $@" if $@;
        warn "couldn't do $file: $!"    unless defined $return;
        warn "couldn't run $file"       unless $return;
    }
}
```

The three `warn`s correspond to the three failure shapes above plus the fourth case - the file ran but its last expression was false.

Why not use do FILE for modules

For loading library code, use `require` or `use` instead of do EXPR. `require` caches through %INC (so a file is loaded at most once), raises an exception on failure instead of returning `undef`, and integrates with @INC hooks. `use` adds compile-time loading and import handling on top. do EXPR exists for configuration files and ad-hoc script inclusion - not for libraries.

Examples

Group statements into an expression:

```
my $config = do {
    open my $fh, "<", $path or die $!;
    local $/;
    <$fh>;
};                                # $config = whole file as one string
```

Post-test loop with do … while:

```
my $n;
do {
    print "enter a positive number: ";
    chomp($n = <STDIN>);
} until defined $n && $n =~ /\A\d+\z/ && $n > 0;
```

Read a Perl-syntax configuration file, with full three-way error handling:

```
my $cfg = do '/etc/myapp/config.pl';
if (!defined $cfg) {
    die $@ ? "config parse error: $@"
           : "config read error: $!";
}
die "config did not return a true value" unless $cfg;
```

Conditional value selection where each branch is several statements:

```
my $greeting = do {
    if ($user) {
        my $name = $user->display_name;
        "hello, $name";
    }
    else {
        "hello, stranger";
    }
};
```

Temporary localisation that must span several statements and still yield a value:

```
my $dump = do {
    local $Data::Dumper::Sortkeys = 1;
    local $Data::Dumper::Indent   = 1;
```

(continues on next page)

(continued from previous page)

```
    Data::Dumper::Dumper(\%state);
};
```

Global state it touches

- `@INC` - searched when `do EXPR` is called with a relative path other than `./…` or `../…`.
- `%INC` - updated with the resolved path when `do EXPR` succeeds on an `@INC` search.
- `$@` - set by `do EXPR` on compile failure; cleared on success.
- `$!` - set by `do EXPR` on I/O failure (file could not be read).
- `$0`, `__FILE__`, `__LINE__` - the currently compiling filename is set to the file being loaded while `do EXPR` parses it, so warnings and `die` messages point at the right file.

`do BLOCK` touches no globals; it is a pure syntactic construct.

Edge cases

- **`do BLOCK` is not a loop.** `next`, `last`, and `redo` inside a `do … while` do not apply to the block. Use a bare block or a real `while` loop.
- **`return` in `do BLOCK` returns from the enclosing sub.** Not from the block. There is no way to return a value from a `do BLOCK` other than making it the last expression evaluated.
- **Statement modifiers are pre-test everywhere else.** `STATEMENT while COND` tests first; `do BLOCK while COND` tests after the first run. This is a deliberate language exception.
- **Relative paths without `./` search `@INC`.** Since 5.26, `.` is not in `@INC`, so `do 'stat.pl'` does not mean "current directory file" any more; pass `./stat.pl` if that was the intent.
- **`do EXPR` cannot see enclosing lexicals.** The file is parsed as if at the top level. If you need access to lexicals, use `eval STRING` - with the usual taint and injection caveats.
- **The file is re-parsed every call.** `do EXPR` is not cached via `%INC` the way `require` is. Calling it in a loop re-reads and re-compiles the file each iteration.
- **Check `$@` before `$!`.** A compilation failure can also set `$!` as a side effect; the compile error in `$@` is the one you actually want to report.
- **A file that compiles but returns a false value is ambiguous.** `unless ($ret = do $file) { … }` fires for both "file failed" and "file ran and returned `0`". If your config file is allowed to end in a false value, use `defined` and `$@` explicitly instead of truth-testing the return.
- **`do` with no argument is a syntax error.** Both forms require a term: a block or an expression.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `eval` - `eval BLOCK` traps exceptions without reading a file; `eval STRING` parses arbitrary code and **can** see enclosing lexicals, unlike do `EXPR`
- `require` - load a library file with `%INC` caching and automatic exception on failure; the right tool for modules
- `return` - note that `return` inside do `BLOCK` returns from the enclosing subroutine, not from the block
- `@INC` - module search path consulted by do `EXPR` on relative filenames
- `%INC` - records the resolved path after a successful `@INC`-searched do `EXPR`
- `$@` - compile-time error from do `EXPR`
- `$!` - I/O error from do `EXPR` when the file cannot be read

Control flow

dump

Cause the running program to produce a core dump immediately.

dump is a pre-historic Perl operator whose original purpose was to freeze a running interpreter to a core file so that the (separately supplied) undump utility could turn that core file back into an executable. The resulting binary, when run, would restart the program by jumping to `LABEL` via `goto`, skipping the startup cost of re-reading and re-compiling the source. That workflow has been dead for decades: undump was never shipped with Perl, modern operating systems make core-to-executable conversion essentially impossible, and the whole operator is now a historical curiosity. As of Perl 5.30 it must be spelled `CORE::dump()` to discourage accidental use.

There is almost no situation in modern Perl where dump is the right answer. If you reached for it because you want a stack trace, use `Carp::confess`. If you want to exit abnormally, use `die` or `exit`. If you want a snapshot of the program state, use a checkpointing tool at the OS level.

Synopsis

```
CORE::dump();
CORE::dump LABEL;
CORE::dump EXPR;
```

What you get back

Nothing. dump does not return: control leaves the Perl interpreter the way `abort(3)` leaves a C program. The process is terminated by the kernel's core-dump handling (`SIGABRT`-style), with the usual side effects: an exit status reflecting the signal, a possible

`core` file in the current directory if the user's `RLIMIT_CORE` and the kernel's `core_pattern` allow it, and no orderly shutdown of the Perl runtime. `END` blocks do **not** run. `DESTROY` methods do **not** run. Buffered output on any filehandle is lost.

Global state it touches

None directly. `dump` bypasses the normal end-of-program machinery entirely - it does not read or write special variables, does not flush buffers, and does not run destructors. Whatever state the interpreter happens to be in at the moment of the call is what lands in the core file.

Examples

Trigger a core dump from a running program (requires `CORE::` as of 5.30):

```
CORE::dump();
```

With a label - originally, the undump-produced binary would resume execution here. With undump gone this is purely decorative; the process still just aborts:

```
RESTART:
    # ... initialisation ...
CORE::dump RESTART;
```

Runtime-computed label name (the `dump EXPR` form, available since Perl 5.18):

```
my $label = pick_entry_point();
CORE::dump $label;
```

What you almost certainly want instead. For a post-mortem with a stack trace:

```
use Carp;
Carp::confess("unreachable state: $state");
```

For a clean abnormal exit with a status code:

```
die "fatal: $reason\n";      # exit via $@, runs END / DESTROY
exit 1;                      # plain exit, runs END / DESTROY
```

Edge cases

- **Spelling since 5.30**: a bare `dump` or `dump LABEL` at statement level is a compile-time error unless written as `CORE::dump` or `CORE::dump(...)`. This is deliberate - the core team made the operator hard to reach by accident.
- **`LABEL` is not resolved at call time**: historically the label was looked up only after undump reincarnated the program, so a typo would not be caught at dump-time. Today the point is moot - the program never resumes, so the label is pure documentation.
- **`dump EXPR`**: the expression is evaluated in scalar context and must yield a label name. It has no effect on the outcome, for the same reason.

- **Parser quirks**: dump has the same precedence as assignment and is exempt from the looks-like-a-function rule. `dump ("foo") . "bar"` parses with `"bar"` as part of the argument, not as a post-concatenation. In practice this only matters if you are writing dump at all, which you should not be.
- **Open files are lost**: any filehandle open at the moment of dump is gone when (in the historical workflow) the reincarnated program starts. The POD warning about "possible resulting confusion by Perl" dates from the era when someone might actually try this; today the warning is academic because nothing resumes.
- **Core files may not be produced**: whether a core file actually lands on disk depends on `ulimit -c`, the kernel's `kernel.core_pattern`, filesystem permissions, and whether the process is running under a supervisor that captures or discards core files. dump succeeding in aborting the process is not the same as a core file being available afterwards.
- **Portability**: on systems without meaningful core-dump support the operator reduces to "abort the process"; see `perlport` for historical notes.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `exit` - terminate the program normally, running `END` blocks and destructors; this is what you almost certainly want instead of dump
- `die` - raise an exception; with no handler it terminates the program but still runs `END` blocks and flushes output
- `goto` - the control-transfer operator whose `LABEL` form dump was historically meant to cooperate with after reincarnation
- `Carp::confess` - stack-trace-on-exit, the modern answer for "I want to see program state at the point of failure"
- `warn` - emit a diagnostic without terminating; combine with a stack-trace module when you want information without aborting
- `perlrun` - documents the historical `-u` command-line switch that performs a dump immediately after compilation

Arrays · Hashes

each

Step through a hash or array one entry at a time.

`each` advances a per-container iterator and hands back the next entry. For a hash that entry is a `(key, value)` pair; for an array it is an `(index, value)` pair. When the iterator has walked every entry, the next call returns the empty list (or `undef` in scalar context) and then rewinds, so a fresh `while (each ...)` loop starts from the beginning. Hash order is randomised per process and per hash; array order is strictly lowest index first.

Synopsis

```
while (my ($k, $v) = each %h) { ... }
while (my ($i, $v) = each @a) { ... }
while (each %h) { ... }              # sets $_ to the key
my $k = each %h;                     # scalar context: key/index only
```

What you get back

- **List context**: a two-element list `($key, $value)` for a hash, `($index, $value)` for an array. On exhaustion, the empty list.
- **Scalar context**: the key (for a hash) or the index (for an array). On exhaustion, `undef`.
- **Bare `each %h` in a `while`/`for` condition**: tests *definedness* of the returned key/index, not truth, and assigns the key to `$_`. This is what makes `while (each %h) { print "$_\n" }` work even when a key is the empty string or `0`.

After exhaustion the iterator is implicitly reset, so the call *after* the one that returned empty restarts iteration from the top.

Global state it touches

Every hash and every array carries **its own internal iterator**. `each`, `keys`, and `values` all advance and share that one iterator - they are three views of the same cursor, not three independent loops. This is the single most important fact about `each`:

- Calling `keys %h` or `values %h` (in any context, even as a one-off count like `scalar keys %h`) **resets** the hash's iterator. A `while (each %h)` loop interrupted by `scalar keys %h` in the body will restart from the top on the next iteration - or worse, loop forever.
- **Referencing a hash in list context resets its iterator too** (e.g. `my @copy = %h`, or passing %h to a sub). Array iterators are *not* reset by list-context reference.
- Two loops iterating the same %h share one cursor. Nesting `while (each %h) { ... while (each %h) { ... } ... }` visits each entry at most once total, not `n * m` times.
- An anonymous hash/array in the condition (`each %{ +{ a => 1 } }`) builds a *new* container every iteration, so the iterator is always fresh - the loop never terminates.
- The bare-`each` form assigns to `$_`; if you rely on `$_` elsewhere in the loop body, save it with `local`.

Every entry to a `while (each ...)` loop picks up whatever iterator position the container happens to be at. There is no way to isolate a loop's iterator from other code that touches the same container. If the loop body calls a function that might read the same hash, the safe pattern is a `foreach` loop over `keys` instead.

Examples

Basic hash iteration:

```
my %colour = (red => "#f00", green => "#0f0", blue => "#00f");
while (my ($name, $hex) = each %colour) {
    print "$name = $hex\n";
}
# order is unspecified
```

Array iteration (Perl 5.12+):

```
my @letters = ('a' .. 'e');
while (my ($i, $c) = each @letters) {
    print "[$i] $c\n";
}
# [0] a
# [1] b
# [2] c
# [3] d
# [4] e
```

Printing a hash in sorted order - `each` does **not** sort, so reach for `keys` plus `sort` instead:

```
for my $k (sort keys %colour) {
    print "$k = $colour{$k}\n";
}
```

Bare `each` in a `while` condition, which sets `$_` to the key every iteration (Perl 5.18+):

```
while (each %ENV) {
    print "$_=$ENV{$_}\n";
}
```

Safe deletion during iteration - you may delete the key *just returned* by `each` without disturbing the cursor:

```
while (my ($key, $value) = each %hash) {
    delete $hash{$key} if $value < 0;   # safe
}
```

Iterating a hash with a `foreach` loop when anything in the body might touch `%hash` (the robust pattern - snapshot the keys first):

```
for my $key (keys %hash) {
    my $value = $hash{$key};
    # body is free to read %hash, call subs that read it, even
    # mutate it cautiously - our iteration list is fixed already.
}
```

Multi-value `foreach` over a hash (Perl 5.36+), which makes `each` unnecessary for most loops and sidesteps the shared-iterator trap:

```
foreach my ($key, $value) (%hash) {
    print "$key => $value\n";
}
```

Edge cases

- **Iterator not reset between re-entries**: a `while (each %h)` loop that exits early via `last`, `return`, or `die` leaves the iterator mid-walk. The next `while (each %h)` on the same hash picks up where the first left off, not at the start. Call `keys %h` in void context - `keys %h;` - to force a reset before the new loop.
- **`keys`/`values` resets the iterator**: any call to `keys` or `values` on the same hash - including `scalar keys %h` inside the loop body - rewinds the cursor.
- **List-context reference resets a hash's iterator, not an array's**: `my @flat = %h` rewinds %h's cursor; the equivalent `my @copy = @a` does not touch @a's iterator.
- **Delete-during-iteration is unspecified** except for the entry most recently returned. Deleting any other key may cause entries to be visited twice or skipped entirely.
- **Add-during-iteration is unspecified** - inserting a new key mid loop may or may not be visited, and may disturb the order of entries not yet seen.
- **Anonymous container in the condition**: `each %{ +{ a => 1 } }` or `each @{ [1,2,3] }` constructs a fresh container each time the condition is evaluated, so the iterator is always new and the loop never terminates.
- **Tied hashes and arrays** delegate to `FIRSTKEY`/`NEXTKEY` (hashes) or `FETCHSIZE`/`FETCH` (arrays), so iteration order is whatever the tied class chooses and none of the guarantees above necessarily hold.
- **Definedness vs truth in the loop condition**: `while (each %h)` and `while (my $k = each %h)` both test *definedness* of the expression, so a key of `"0"` or `""` does not terminate the loop. This is special-cased for `each` specifically.
- **Scalar expressions**: `each $href` on a scalar holding a reference was an experimental feature in 5.14 and was **removed in 5.24**. Dereference explicitly: `each %$href`, `each @$aref`.
- **Shared state across subs**: passing %h to a sub that calls `each %h`, `keys %h`, or `values %h` on it perturbs your caller's iterator. If you publish a hash, assume callers may break your loop; prefer `foreach (keys ...)` for robustness.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `keys` - snapshot of all keys (hash) or indices (array); **resets the iterator** `each` uses
- `values` - snapshot of all values; **resets the iterator** `each` uses

- `delete` - safe for the entry just returned by `each`, unsafe for any other during iteration
- `exists` - test key/index membership without perturbing the iterator
- `for` / `foreach` - the safer loop when the body might touch the container; combine with `keys` to snapshot first
- `sort` - pair with `keys` when you need a defined iteration order; `each` never sorts

User and group info

endgrent

Close the group database after iterating it.

`endgrent` is the cleanup half of the group-database iteration trio `setgrent` / `getgrent` / `endgrent`. It tells the C library that you are done walking `/etc/group` (or the NSS source behind it), releasing any file descriptors or cached state the library opened on your behalf. After `endgrent`, the next `getgrent` call starts a fresh iteration from the top.

Synopsis

```
endgrent;
endgrent();
```

No arguments, no meaningful return value.

What you get back

The return value is unspecified and must not be relied on. `endgrent` is called for its side effect - closing the group database - not for a result. Treat it as a void call.

```
endgrent;                               # correct
my $ok = endgrent;                      # wrong: $ok is not a success␣
↪flag
```

If your platform does not implement `endgrent`, the call croaks with `The endgrent function is unimplemented` at runtime. This is effectively a compile-once check - if the function works on your system at all, it will continue to.

Global state it touches

`endgrent` operates purely on the libc-internal group-iteration state that `setgrent` and `getgrent` share. It reads and writes no Perl special variables. It does not alter `$!`: a failure path that sets `errno` in the underlying C call is not surfaced to Perl.

The iteration state is **per-process**, not per-thread. In a threaded program, one thread's `endgrent` closes the iteration for every thread - see *Edge cases*.

Examples

The canonical iterate-and-close pattern. Always pair a `setgrent` / `getgrent` loop with `endgrent` so long-running programs do not leak the file descriptor the C library keeps open:

```
setgrent;
while (my @g = getgrent) {
    my ($name, $passwd, $gid, $members) = @g;
    print "$name ($gid): $members\n";
}
endgrent;
```

Dropping into `endgrent` mid-iteration is legal - it simply abandons whatever cursor position the library was holding:

```
setgrent;
while (my @g = getgrent) {
    last if $g[0] eq 'wheel';       # found what we wanted
}
endgrent;                           # release the handle anyway
```

Restarting iteration. `endgrent` followed by `setgrent` is the portable way to rewind:

```
setgrent;
my @first_pass  = collect_groups();
endgrent;

setgrent;
my @second_pass = collect_groups();  # starts over from the top
endgrent;
```

Defensive cleanup in a `END` block for programs that might die mid-walk:

```
setgrent;
END { endgrent }
while (my @g = getgrent) { ... }    # any die still triggers END
```

Edge cases

- **Calling endgrent without a prior `setgrent` or `getgrent`** is harmless. The C library silently does nothing if no iteration is in progress.
- **Calling it twice in a row** is also harmless - the second call is a no-op.
- **Parser ambiguity.** `endgrent` takes no argument and has the precedence of a named unary operator. A bareword expression immediately to its right will be parsed as an argument and rejected:

```
endgrent or die;                    # WRONG: parses as␣
↪endgrent(or die)
endgrent() or die;                  # right: empty parens␣
↪disambiguate
```

In practice there is nothing to check the return value against, so this trap rarely bites - but the same rule applies to any chained expression.

- **Threads share the iteration.** `endgrent` from one thread ends iteration for all threads of the same process, because the underlying state is process-global. Do not interleave `getgrent` calls across threads expecting each to see every record.
- **NSS and caching.** On systems where the group database is served through NSS (nss_ldap, nss_sss, etc.), `endgrent` releases per-module caches that the NSS backend may hold. Long-lived daemons that walk the group database periodically should call `endgrent` after each walk to avoid accumulating backend state.
- **No effect on name-lookup calls.** `getgrnam` and `getgrgid` are independent of the iteration cursor. `endgrent` does not invalidate their results or cached data, and you do not need to call `endgrent` before or after them.
- **Unimplemented on some platforms.** Perl croaks `The endgrent function is unimplemented` if the host libc has no `endgrent(3)`. All modern Linux, BSD, and macOS systems provide it.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `setgrent` - open or rewind the group database before walking it; always the prologue to an iteration that ends with `endgrent`
- `getgrent` - pull the next record from the iteration `endgrent` closes
- `getgrnam` - look up one group by name, independent of the iteration cursor; no `endgrent` needed
- `getgrgid` - same as `getgrnam` but keyed on numeric gid
- `endpwent` - the parallel cleanup call for the passwd database; the two iterations are independent and both need closing if you opened both

Network info

endhostent

Close the hosts database after iteration.

`endhostent` releases any resources held by the hosts database after a walk driven by `gethostent`. It pairs with `sethostent`, which opens or rewinds the database, and is a direct wrapper around the C library call of the same name. Calling it when no iteration is in progress is harmless.

Synopsis

```
endhostent;
endhostent();
```

`endhostent` takes no arguments. Parentheses are optional.

What you get back

No useful return value. The call is made for its side effect - tearing down whatever per-process state the platform's `gethostent(3)` keeps between iterations (file descriptors on traditional `/etc/hosts` iteration, resolver sockets on NSS-backed systems).

Global state it touches

- The hosts-database iteration cursor shared by `gethostent`, `sethostent`, `gethostbyname`, and `gethostbyaddr`. After `endhostent`, the next `gethostent` call restarts from the beginning (typically after an implicit `sethostent`).
- `$?` carries the C-library `h_errno` value on systems where host lookups surface it. Most implementations of `endhostent` itself do not touch `h_errno`, but a subsequent `gethostent` can.

This state is per-process, not per-thread. Two threads iterating hosts concurrently will interleave records and neither will see the full set - pair `sethostent` / `gethostent` / `endhostent` within one thread.

Examples

Close the database after a full walk:

```
sethostent(1);                          # 1 = keep connection open
while (my @h = gethostent()) {
    print "$h[0]\n";                    # canonical hostname
}
endhostent();
```

Always pair `endhostent` with `sethostent` in a subroutine so the iteration state does not leak to the caller:

```
sub list_hosts {
    sethostent(0);
    my @names;
    while (my ($name) = gethostent()) {
        push @names, $name;
    }
    endhostent();
    return @names;
}
```

Defensive cleanup - `endhostent` is safe even when no iteration is in progress, so it is fine to call unconditionally on an error path:

```
eval {
    sethostent(1);
    process_hosts();
    1;
} or do {
    my $err = $@;
```

(continues on next page)

(continued from previous page)

```
    endhostent();
    die $err;
};
endhostent();
```

Using the by-name accessor object interface from `Net::hostent` does not change the rule - the underlying iterator is the same one `endhostent` closes:

```
use Net::hostent;
sethostent(1);
while (my $h = gethostent()) {
    print $h->name, "\n";
}
endhostent();
```

Edge cases

- **No-op when nothing is open**: calling `endhostent` without a prior `sethostent` or `gethostent` is defined and does nothing observable.
- **Interleaving with name / address lookups**: a `gethostbyname` or `gethostbyaddr` call in the middle of an iteration may reset the cursor on some platforms (any implementation that internally calls `sethostent(0)` for single-shot lookups). Do not mix the two styles against the same database without re-calling `sethostent` afterwards.
- **Platforms without a hosts iterator**: on systems whose resolver does not support enumeration (most modern NSS setups querying DNS only), `gethostent` returns the empty list immediately. `endhostent` is still callable and still a no-op.
- **Thread safety**: the host iterator is process-global. In a multi-threaded program, guard the `sethostent` / `gethostent` / `endhostent` trio with your own mutex.
- **Prototype / parsing**: `endhostent` has no arguments, so there is no parser-ambiguity trap. Writing `endhostent LIST` is a syntax error rather than being silently interpreted as a call with arguments.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `sethostent` - open or rewind the hosts database; the opening half of the iteration pair
- `gethostent` - read one record from the open database; returns the empty list when the iteration is exhausted
- `gethostbyname` - single-shot lookup by name; does not require `sethostent` / `endhostent`
- `gethostbyaddr` - single-shot lookup by address

- endnetent - same pattern for the networks database
- endservent - same pattern for the services database
- $? - receives h_errno from failed host lookups on platforms where the C library exposes it

Network info

endnetent

Close the networks database after iteration.

endnetent releases the resources held by the networks database - typically the /etc/networks file or its NSS-backed equivalent - that were opened implicitly by the first call to getnetent, getnetbyname, or getnetbyaddr, or explicitly by setnetent. After endnetent the iteration cursor is gone; a subsequent getnetent starts a fresh sweep from the top of the database. It is a thin wrapper over the system C library's endnetent(3).

Synopsis

```
endnetent;
endnetent();
```

What you get back

A system-defined true value. The C function returns void; Perl surfaces a placeholder so the call can stand as a statement. Do not compare the return value against anything - there is nothing useful in it.

Global state it touches

endnetent operates on the process-wide networks-database cursor owned by libc. That cursor is shared with getnetent, getnetbyname, getnetbyaddr, and setnetent; a call here invalidates the iteration state those functions depend on. No Perl special variable is touched.

Examples

Paired with setnetent and getnetent for a complete sweep of the networks database:

```
setnetent(1);                          # stayopen = 1
while (my @net = getnetent()) {
    my ($name, $aliases, $addrtype, $net) = @net;
    print "$name\t$net\n";
}
endnetent();                           # release the cursor
```

Close after the handful of lookups you actually needed, so the database file does not stay open for the rest of the program:

```
setnetent(0);
my @loopback = getnetbyname("loopback");
my @link     = getnetbyname("link-local");
endnetent();
```

Safe to call when the database was never opened - libc treats it as a no-op:

```
endnetent();                        # harmless on a fresh process
```

Edge cases

- **No arguments, list-operator precedence.** `endnetent` takes no arguments but parses as a list operator, so a stray term after it is swallowed: `endnetent $x` is `endnetent($x)` and produces a "Too many arguments" compile-time error. Write `endnetent;` or `endnetent();`.
- **Repeated calls.** Calling `endnetent` twice in a row is a no-op on the second call on every libc we target. Do not rely on it raising an error.
- **Interleaving with other DB iterators.** The networks cursor is independent of the cursors used by `getpwent`, `getgrent`, `gethostent`, `getprotoent`, and `getservent`. `endnetent` does not close those - call the matching `end*ent` for each iterator you opened.
- **Forking between `setnetent` and `endnetent`.** The cursor lives in the parent's libc state; a child inherits it at `fork` time but further `getnetent` calls in either process will desynchronise. Close and re-open in the child.
- **NSS backends.** On glibc the networks database routes through NSS, so the meaning of "close" depends on the configured service (`files`, `nis`, `ldap`, ...). User-visible behaviour - iteration restarts on the next `getnetent` - is the same; the cost of `endnetent` is not.
- **Thread safety.** The libc networks cursor is a single process-global resource. pperl does not serialize access to it; a program that iterates the networks database from multiple threads must do its own locking.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `setnetent` - open the networks database and choose whether it stays open across individual lookups
- `getnetent` - read the next entry from the cursor that `endnetent` closes
- `getnetbyname` - single lookup by network name; implicitly opens the database but does not close it
- `getnetbyaddr` - single lookup by numeric address, same implicit-open, no-implicit-close rule

- `endhostent` - the hosts-database analogue; same pattern, independent cursor
- `endservent` - the services-database analogue for completeness of the `end*ent` family

Network info

endprotoent

Close the protocols database after iteration.

`endprotoent` is the terminator for the `getprotoent` / `setprotoent` / `endprotoent` iteration triad that walks the system protocols database (typically `/etc/protocols`). It releases whatever handle or state the system C library kept open for the iteration. You call it once the sequential walk is done; `getprotobyname` and `getprotobynumber` do not need it - they open and close the database on each call.

Takes no arguments, returns nothing useful. This is a thin wrapper over the system `endprotoent(3)` call.

Synopsis

```
endprotoent
```

What you get back

No meaningful return value. Calling it in list or scalar context yields the empty list / undef-equivalent; nothing you'd want to check. Its value is the side effect of closing the protocols database.

Examples

Walk every protocol, then close the database:

```
setprotoent(1);                          # 1 = keep the file open
 ↪between calls
while (my @p = getprotoent()) {
    my ($name, $aliases, $proto) = @p;
    print "$proto\t$name\n";
}
endprotoent();
```

Short-circuit mid-walk - `endprotoent` still closes cleanly:

```
setprotoent(0);
while (my @p = getprotoent()) {
    last if $p[0] eq 'tcp';
}
endprotoent();
```

Paired with a direct lookup, `endprotoent` is unnecessary - name and number lookups manage their own state:

```
my @tcp = getprotobyname('tcp');        # no endprotoent needed
```

Edge cases

- **Calling without a prior `setprotoent` / `getprotoent`**: harmless. The system call is idempotent; closing an already-closed database is a no-op on every supported platform.
- **No arguments accepted**: `endprotoent $x` is a syntax error - the built-in has arity zero.
- **Not reentrant**: the protocols database is a single global resource inside the C library. Two concurrent iterations in the same process step on each other's state. Use per-thread or per-subprocess walks if you need parallelism.
- **Platform quirks**: behaviour is whatever the host system's `endprotoent(3)` does. See `perlport` for the list of platforms where the network-database routines diverge or are absent entirely.
- **Stubbed on platforms without `/etc/protocols`**: on systems where the C library has no protocols database, the call is a no-op rather than an error.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `setprotoent` - open the protocols database and optionally keep it open across `getprotoent` calls; pair with `endprotoent` to bracket a walk
- `getprotoent` - read the next entry during an iteration; drives the loop that `endprotoent` terminates
- `getprotobyname` - single-shot lookup by protocol name; self-contained, no `endprotoent` needed
- `getprotobynumber` - single-shot lookup by protocol number; same independence from the iteration triad
- `endservent` - the analogous terminator for the services database; same idiom, different table
- `endhostent` - the analogous terminator for the hosts database

User and group info

endpwent

Close the passwd-database iterator opened by `getpwent` or `setpwent`.

`endpwent` is the companion teardown call for a passwd-file walk. After iterating the password database with repeated `getpwent` calls, `endpwent` releases whatever per-process state the C library allocated to hold the iteration cursor (an open file descriptor on `/etc/passwd`, a cached buffer for NSS, a connection to `nscd` / `sssd`, an LDAP

session, depending on the host's name-service configuration). It takes no arguments and wraps the system `endpwent(3)` call directly.

Synopsis

```
endpwent
```

What you get back

A single boolean value. The return is rarely checked - on every platform PetaPerl supports, `endpwent` cannot meaningfully fail, and real code treats it as a void call.

Global state it touches

`endpwent` mutates no Perl-visible variable. The state it clears is entirely inside the C library: the per-process passwd iterator, shared with `getpwent` and `setpwent` (and, on some systems, with `getpwnam` / `getpwuid` when those happen to reuse the same underlying stream). Calling `endpwent` in one thread affects every other thread in the same process - the iterator is per-process, not per-thread.

Examples

Standard iterate-then-close idiom:

```
setpwent;
while (my @ent = getpwent) {
    my ($name, undef, $uid) = @ent;
    print "$uid\t$name\n";
}
endpwent;
```

Ensure the iterator is closed even if the loop exits early:

```
setpwent;
eval {
    while (my @ent = getpwent) {
        my ($name, undef, $uid, $gid) = @ent;
        die "found it\n" if $uid == $target;
    }
};
endpwent;       # always run, regardless of how the loop ended
```

Pair with a `local` guard so nested code cannot leave the iterator half-walked:

```
sub each_user {
    my $cb = shift;
    setpwent;
    my $guard = Guard::guard { endpwent };   # or a manual eval-and-
↪rethrow
```

(continues on next page)

(continued from previous page)

```
    while (my @ent = getpwent) { $cb->(@ent) }
}
```

endpwent with no prior iteration is harmless:

```
endpwent;                                   # no-op on a fresh␣
↪process
```

Edge cases

- **No arguments, no parentheses needed.** endpwent is a named unary operator with zero arguments; write it bare. endpwent() is accepted but adds nothing.
- **Idempotent.** Calling endpwent twice in a row, or calling it before any getpwent / setpwent, is defined as a successful no-op on every supported platform.
- **Does not invalidate records you already fetched.** Arrays and hashes returned by earlier getpwent / getpwnam / getpwuid calls are plain Perl data and remain valid after endpwent - only the iterator cursor is closed.
- **Thread safety.** The iterator is process-wide. If two threads are walking the passwd database simultaneously, endpwent closes the shared cursor for both - neither thread will get the full record set. Use a lock around the whole setpwent / loop / endpwent block when iterating from threads.
- **Name-service backends.** On hosts using LDAP, NIS, sssd, or any other non-flat-file backend, endpwent may release a network handle. A long-running daemon that iterates the passwd database periodically should call endpwent at the end of each pass rather than leaking one handle per pass.
- **Not a forced cache flush.** endpwent closes the iterator; it does **not** flush the C library's getpwnam / getpwuid caches. A subsequent getpwnam may still return a cached record.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- setpwent - rewind or open the passwd-database iterator before a walk; pairs with endpwent as the open/close bracket
- getpwent - fetch the next record from the iterator that endpwent closes
- getpwnam - direct lookup by login name, independent of the iterator in most implementations
- getpwuid - direct lookup by numeric UID, same independence note as getpwnam
- endgrent - analogous teardown for the group-database iterator; the two are almost always called together

Network info

endservent

Close the services database after a walk with `getservent`.

`endservent` is the teardown half of the services-database iteration triplet. After `setservent` opens the database (typically `/etc/services` on Linux) and a sequence of `getservent` calls walks it entry by entry, `endservent` releases the underlying handle and any buffered state the C library is holding. It wraps the POSIX `endservent(3)` call one-to-one.

Synopsis

```
endservent;
endservent();
```

What you get back

Nothing useful. The function is called for its side effect; it does not return a meaningful value. Do not test the return value.

Global state it touches

- The system-wide services-database iterator opened by `setservent` or implicitly by the first `getservent` / `getservbyname` / `getservbyport` call. `endservent` closes that iterator.
- `$!` is **not** meaningfully set by this call; the POSIX contract for `endservent(3)` defines no error return.

Examples

Paired with `setservent` and `getservent` to enumerate every entry in `/etc/services`:

```
setservent 0;
while (my @e = getservent) {
    last unless @e;
    my ($name, $aliases, $port, $proto) = @e;
    print "$name/$proto = $port\n";
}
endservent;
```

Close a walk early. The database was opened implicitly by the first `getservent`; `endservent` is still the right way to release it:

```
while (my @e = getservent) {
    last if $e[0] eq 'http';
}
endservent;
```

Defensive cleanup around a block that may leave the iterator open. Harmless when no iteration is in progress:

```
eval {
    setservent 1;
    scan_services();
    1;
} or do {
    endservent;          # always release the handle
    die $@;
};
endservent;
```

Edge cases

- **Calling without a preceding `setservent` or `getservent`** is harmless. The underlying C call tolerates a no-op close.
- **Calling twice** is harmless for the same reason. Repeated `endservent` does not report an error.
- **Does not affect the name and port lookup functions** - `getservbyname` and `getservbyport` open and close their own short-lived handles and are unaffected by the iterator state that `endservent` manages.
- **No prototype, no arguments**. `endservent $x` is a compile-time error. Use `endservent;` or `endservent();`.
- **Not portable beyond Unix-like systems**. On platforms where the C library lacks `endservent(3)`, the call croaks with `endservent not implemented`.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `setservent` - open the services database and, with a non-zero `STAYOPEN`, keep the handle across subsequent lookups
- `getservent` - read the next entry from the open services database; pair every iteration loop with `endservent`
- `getservbyname` - one-shot lookup by service name; does not interact with the iterator `endservent` closes
- `getservbyport` - one-shot lookup by port number; same independence from the iterator
- `endprotoent` - the protocols-database analogue, same shape and same rules
- `endhostent` - the hosts-database analogue

I/O

eof

Test a filehandle for end-of-file.

`eof` reports whether the next read on a filehandle will return end-of-file. The three call forms look similar but mean different things: `eof FILEHANDLE` asks about a specific handle, bare `eof` asks about the handle most recently read from, and `eof()` with empty parentheses asks about the virtual `ARGV` stream fed by `<>`. The forms are not interchangeable - picking the wrong one is the classic bug with this built-in.

Synopsis

```
eof FILEHANDLE
eof()
eof
```

What you get back

1 if the next read on the handle would return end-of-file, or if the handle is not open. `0` otherwise. `eof` never blocks waiting for more input on a regular file, but on a pipe or terminal it may have to read and push back one character to decide - see *Edge cases*.

Global state it touches

- `ARGV` - the magical filehandle backing the `<>` operator. `eof()` examines and may advance it; `eof` inside a `while (<>)` loop queries it indirectly.
- `@ARGV` - the list of file names `<>` iterates over. `eof()` called before `<>` has been used triggers `@ARGV` inspection and, if empty, arranges for `STDIN` to be read.
- `$.` - the current input line number, attached to the handle `eof` queries. Not written by `eof` itself, but relevant in the idioms below where `close ARGV` resets it at file boundaries.

The three forms, spelled out

`eof FILEHANDLE` - asks about that one handle. `FILEHANDLE` may be a bareword, a scalar holding a handle, or an expression evaluating to one. Returns true for a closed or never-opened handle.

`eof` (no parentheses, no argument) - asks about the *last file read*. Inside a `while (<>) { ... }` loop this means "the current `ARGV` file" - the physical file currently being streamed, not the whole `<>` sequence. `eof` becomes true at every file boundary, once per input file.

`eof()` (empty parentheses) - asks about the `<>` stream as a whole. It becomes true only at the end of the *last* file in `@ARGV`. If `<>` has not been used yet, `eof()` will examine `@ARGV`, fall back to `STDIN` when `@ARGV` is empty, and may actually open the first file to answer the question.

Bare `eof` and `eof()` look almost identical and do completely different things. The parentheses matter.

Examples

Check a specific handle before the next read:

```
open my $fh, "<", "data.txt" or die $!;
while (not eof $fh) {
    my $line = <$fh>;
    # process $line
}
close $fh;
```

The classic `while (<>)` idiom, resetting `$.` at each file boundary. Bare `eof` (no parens) is what you want here - it fires once per input file:

```
while (<>) {
    next if /^\s*#/;
    print "$.\t$_";
} continue {
    close ARGV if eof;        # not eof() - resets $. per file
}
```

Insert a marker before the last line of the last file. `eof()` with parentheses catches the end of the *entire* <> stream, not each file:

```
while (<>) {
    if (eof()) {
        print "--------------\n";
    }
    print;
    last if eof();            # needed when reading from a terminal
}
```

Guard against a closed handle. `eof` on a closed or never-opened handle returns true without warning:

```
my $fh;                       # never opened
if (eof $fh) {
    warn "handle not ready";
}
```

Edge cases

- **`eof` before any read returns false, not true.** Bare `eof` with no prior read has no "last file read" to refer to and Perl treats it as false. Writing `if (eof) { ... }` at the top of a program does not mean "if there is no input" - use `eof()` for that.
- **`eof()` before <> is used has side effects.** It examines `@ARGV`, and if `@ARGV` is empty it arranges for <> to read from `STDIN`. A stray `eof()` at program start can therefore silently bind the program to `STDIN`.
- **`eof()` after <> has exhausted its input** assumes you are starting another `@ARGV` pass. If `@ARGV` is empty at that point, the next <> reads `STDIN`. This is usually not what you want; set `@ARGV` explicitly or test the bare-`eof` form instead.

- **`eof` on a terminal consumes a character.** The implementation reads one byte and ungetcs it to tell whether more input exists. On terminals the pushback may not survive after end-of-file is reached - do not call `eof FH` on a terminal after you have already hit EOF there, or the handle can lose its end-of-file condition.
- **Closed or never-opened handle** - `eof FILEHANDLE` returns true. There is no way to distinguish "closed" from "at EOF" using `eof` alone; check `fileno` or track the open state yourself if that matters.
- **`eof(ARGV)` equals bare `eof` inside `while (<>)`.** Both query the current ARGV file. Prefer bare `eof` for brevity and to make the parenthesised `eof()` form visually distinct.
- **You rarely need `eof` at all.** The input operators return `undef` at end-of-file, so `while (my $line = <$fh>) { ... }` and `while (<>) { ... }` handle termination without any `eof` test. Reach for `eof` only when you need to act *at* the boundary - last line, per-file reset, final-file marker.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `readline` - read a line from a handle; returns `undef` at end-of-file, which replaces most uses of `eof`
- `read` - block read of a fixed byte count; returns `0` at end-of-file
- `getc` - read a single character; returns `undef` at end-of-file
- `close` - close a handle; the common partner of `eof` in the `close ARGV if eof` per-file-reset idiom
- `ARGV` - the magical handle fed by `<>` that `eof` and `eof()` query

Control flow

eval

Run a piece of Perl code with any fatal error trapped instead of killing the program.

`eval` is Perl's exception-catching mechanism and its runtime code-loader in one. It comes in two real forms: **block eval** (`eval { ... }`), which catches exceptions thrown by already-compiled code, and **string eval** (`eval EXPR`), which compiles and runs a string of Perl source at runtime. Either way, a `die` that would otherwise terminate the program becomes an assignment to `$@` and a normal return.

Synopsis

```
eval BLOCK                  # catch exceptions in compiled code
eval EXPR                   # compile and run source at runtime
eval                        # short for: eval $_
```

What you get back

The value of the last expression evaluated inside the mini-program, or the value handed to an explicit `return`. The evaluation happens in the same context as the surrounding `eval` - void, scalar, or list - so `wantarray` inside an `eval` reports the caller's context, not "some `eval` context."

If anything inside raises an exception (`die`, a division by zero, a string-eval syntax error, any other trappable fatal), `eval` returns `undef` in scalar context and the empty list in list context, and the exception lands in `$@`:

```
my $n = eval { risky() };   # undef on failure, $@ holds the error
if ($@) { ... }
```

On success, `$@` is set to the empty string. Every completed `eval` touches `$@` - there is no "leave it alone" option. A control-flow operator that bypasses the normal exit (`last`, `goto` out of the block) can leave `$@` unchanged, which is a corner case rather than a feature to rely on.

Global state it touches

- `$@` - written on every normal exit of the `eval`: the thrown exception on failure, the empty string on success. Read to determine whether the `eval` caught something.
- `$^S` - reflects whether Perl is currently inside an `eval` (or `try`). `undef` during parsing, true while executing inside an `eval`/`try` block, false at the top level. Read primarily by `$SIG{__DIE__}` handlers that want to act differently for caught vs. uncaught exceptions.
- `$SIG{__DIE__}` - fires on **every** `die`, including those that an enclosing `eval` is about to catch. Use `local $SIG{__DIE__}` inside an `eval` to suppress a globally installed hook for the duration of the trap.
- `$SIG{__WARN__}` - unaffected by `eval`. Warnings emitted inside the block still go through the normal warning path; `eval` does not redirect them into `$@`.
- `$_` - the source of the no-argument form (`eval` with nothing after it is exactly `eval $_`).

Block eval vs. string eval

The two forms look similar but do very different things.

- **Block eval** (`eval { ... }`) is parsed and compiled together with the surrounding program. At runtime it is just a marker that says "catch any `die` thrown from inside this block." Because the code is already compiled, block eval is cheap and safe - the compiler already checked it for syntax errors. This is the form to reach for whenever the goal is exception handling.
- **String eval** (`eval EXPR`) evaluates `EXPR` in scalar context, then parses and executes the resulting string as if it were a block in the lexical scope of the surrounding code. The parse happens every time the `eval` is reached. A syntax error in the string becomes a runtime `$@`, not a compile-time failure of the enclosing program. This is the form for loading code decided at runtime - optional features,

user-supplied expressions, dynamically constructed subs - and it carries the costs and hazards that implies.

Both forms run in the lexical scope of the surrounding code: outer `my` variables are visible, and package variable assignments, subroutine definitions, and format definitions made inside the `eval` persist after it returns.

The $@ contract

After an `eval` completes normally, `$@` is always one of:

- The empty string - the block ran to completion with no exception.
- A string ending in a newline - a `die "message\n"` or a string exception the callee already terminated.
- A string with appended location (`... at FILE line N.\n`) - a `die "message"` without a trailing newline, or a runtime error Perl itself raised.
- A reference, typically a blessed exception object - `die` called with a reference.

Check `$@` immediately after the `eval` and nowhere else. Any method call, `ref` test, `isa` check, or regex match done during handling can itself invoke an `eval` internally (for instance, during autoloading or overload resolution) and overwrite `$@` before you finish inspecting it. Copy into a lexical first:

```
eval { work() };
if (my $err = $@) {         # safe snapshot
    if (ref $err && $err->isa('MyApp::Error')) { handle($err) }
    else                                       { die $err      }
}
```

Nested `eval` and `local $@`

The outer `eval` sees whatever `$@` holds when the outer block finishes - not what it held partway through. If inner code has its own `eval`, that inner `eval` sets `$@` (to the empty string on success), which can clobber an error the outer code wanted to preserve. The guard is `local $@` around the inner work:

```
eval {
    # ... some work that might fail ...
    {
        local $@;           # shield outer $@
        eval { optional_step() };
        # ignore whatever optional_step did to $@
    }
    die "still needed\n" if $condition;
};
warn "outer caught: $@" if $@;
```

Before Perl 5.14, `$@` was assigned before localized variables were restored, so code that wanted to filter errors had to stage the value through a temporary. On 5.14+ (which 5.44 inherits) the order is fixed and the temporary is unnecessary.

String eval security

String eval runs whatever is in the expression. If any part of that string came from untrusted input - a file, a network peer, a user form - the `eval` hands the attacker the full Perl interpreter. Rules of thumb:

- Never pass user input through `eval EXPR` unmodified. "It's only a number" is not a safeguard - `"1; system 'rm -rf /'"` is also only a string.
- If runtime-chosen code is genuinely needed, constrain the input against a strict allow-list *before* interpolation, and prefer data-driven dispatch (a hash of coderefs) over generating source.
- Floating-point values interpolated into source are fragile. Under `use locale` the decimal separator may not be a dot, and values like `"NaN"` or `"Infinity"` stringify to letters that the parser reads as barewords, not numbers.
- Source filters activated inside a string `eval` leak out into the surrounding file scope (unless `evalbytes` is used). This is a long-standing quirk, not a feature.

Block eval has none of these problems - the code was compiled with the rest of the program.

`BEGIN` inside string eval

`BEGIN { ... }` blocks embedded in a string `eval` execute immediately, before the rest of the `eval`'d code runs, matching their behaviour in a normal compilation unit. Set `${^MAX_NESTED_EVAL_BEGIN_BLOCKS}` to `0` to make any embedded `BEGIN` throw instead:

```
local ${^MAX_NESTED_EVAL_BEGIN_BLOCKS} = 0;
eval $untrusted;            # any BEGIN inside $untrusted dies
```

This does not make a string eval safe - it only removes one specific attack on compile-time side effects.

`try/catch`

Under `use feature 'try'` (stable since 5.40, available in 5.44), the `try/catch/finally` construct provides dedicated exception-handling syntax:

```
use feature 'try';

try {
    risky();
}
catch ($e) {
    warn "caught: $e";
}
finally {
    cleanup();
}
```

Differences from `eval { ... }; if ($@) { ... }`:

- The caught value is bound to a fresh lexical `$e` (or whatever name is given), not to `$@`. No need for the `my $err = $@` snapshot dance.
- `$@` is not set as a side effect - the `try` block has no global after-effect on it.
- `try` is not itself a loop, but control-flow operators behave analogously to `eval BLOCK`: `return` inside `try` returns from the enclosing sub, and `next`/`last`/`redo` target an outer loop.
- `finally` runs on every exit path and cannot itself use `return`/`next`/`last`/`redo`. It is marked experimental in 5.44 and emits a warning under `experimental::try`.

Reach for `try`/`catch` in new code. The `eval`-plus-`$@` idiom remains correct and is still the right tool whenever the surrounding code must run on older Perls or must not require the feature guard.

Examples

Trap a runtime error and keep going:

```
my $q = eval { $x / $y };
if ($@) { warn "division failed: $@"; $q = 0 }
```

Detect whether a feature is available without aborting at startup:

```
my $have_socket = eval { socket(my $s, PF_INET, SOCK_STREAM, 0); 1 }
 ↪;
die "no sockets on this build" unless $have_socket;
```

Load a module whose absence should be tolerated:

```
my $json = eval { require JSON::XS; JSON::XS->new } //
           do { require JSON::PP; JSON::PP->new };
```

Catch a blessed exception, re-throw anything else:

```
eval {
    parse($input);
};
if (my $err = $@) {
    if (ref($err) && $err->isa('MyApp::ParseError')) {
        report($err);
    }
    else {
        die $err;
    }
}
```

Nested `eval` with `local $@` so an inner optional step does not erase an outer diagnostic:

```
eval {
    do_main_work();
    { local $@; eval { maybe_cleanup() } }   # ignore cleanup errors
```

(continues on next page)

(continued from previous page)

```
    die "main still failed\n" if $something_else_wrong;
};
warn $@ if $@;
```

Suppress a globally installed `$SIG{__DIE__}` hook for the duration of a private trap:

```
eval {
    local $SIG{__DIE__};            # don't trigger hooks while we
↪probe
    $answer = $x / $y;
};
warn $@ if $@;
```

A `$SIG{__DIE__}` hook that logs only uncaught exceptions, using `$^S` to tell the two cases apart:

```
$SIG{__DIE__} = sub {
    return if $^S;              # inside eval/try - let it propagate
    log_fatal(@_);              # top level - record before exit
};
```

Runtime-built dispatch (string eval used deliberately, input is not user-supplied):

```
for my $op (qw(add sub mul div)) {
    eval "sub ${op}_of { \$_[0] "
       . { add=>'+', sub=>'-', mul=>'*', div=>'/' }->{$op}
       . " \$_[1] }";
    die $@ if $@;
}
```

Edge cases

- **No argument** - `eval;` is `eval $_`. Rarely what you want; write `eval { ... }` or `eval EXPR` explicitly.
- **Final semicolon** - may be omitted from the end of `EXPR` or `BLOCK`. `eval "1+2"` and `eval "1+2;"` are equivalent.
- **`eval BLOCK` is not a loop** - `next`, `last`, and `redo` cannot leave or restart the block. They look for an enclosing loop and will croak if there is none.
- **`return` inside `eval BLOCK`** returns from the *enclosing subroutine*, not from the `eval` - the `eval` block is not a function body. To produce a value from the block, put the value as the final expression.
- **Warnings are not trapped.** `warn` inside an `eval` still writes to `STDERR`. Route them into `$@` only if you set `$SIG{__WARN__}` to do so yourself.
- **Control flow out of `eval`** - a `goto`, `last`, or `next` that jumps out of the block skips the normal `eval` exit and therefore may leave `$@` untouched. Do not build logic that depends on this.

- **Quotes on EXPR - `eval $x` vs. `eval "$x"`** behave identically: both run the code contained in `$x`. The double quotes add visual noise, not semantics.
- **`eval '$x'` vs. `eval { $x }`** - both return the value of `$x`. The block form is compiled with the surrounding program; prefer it unless the code genuinely needs to be constructed at runtime.
- **`eval ''` inside the `DB` package** - does not see the usual surrounding lexical scope but the scope of the first non-`DB` caller. Only debugger authors hit this.
- **XS load failures** - some binary-interface problems during `require` of an XS module are fatal even inside `eval`, unless `$ENV{PERL_DL_NONLAZY}` is set. Version skew between the running interpreter and a pre-built `.so` is the common case. pperl does not load XS; the caveat applies when `eval`'d code delegates loading to a classic perl5.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `die` - the counterpart: throws the exception that `eval` catches. The trailing-newline rule on the message shapes what lands in `$@`.
- `do` - `do FILE` reads and evaluates a file the way string eval reads and evaluates a string; useful for configuration files written in Perl.
- `return` - inside `eval BLOCK` returns from the enclosing sub, not from the block; use a trailing expression to hand a value back from the `eval` itself.
- `require` - commonly wrapped in `eval` to probe for optional modules without aborting at compile time.
- `evalbytes` - string eval that treats its argument as a byte string and allows source filters to work normally; use when byte-level semantics matter.
- `$@` - where a caught exception lands, cleared to the empty string on successful `eval`. The error family page also covers the classic `$@`-clobbering hazard.
- `$^S` - tells `$SIG{__DIE__}` and `$SIG{__WARN__}` handlers whether an `eval` or `try` is currently active.
- `$SIG{__DIE__}` - pre-throw hook; fires even for exceptions an enclosing `eval` is about to catch, which is the usual reason to `local`-ize it for the duration of a trap.

Control flow

evalbytes

Compile and run a string of Perl source, forcing the source to be interpreted as **bytes** rather than characters.

`evalbytes` is the byte-oriented twin of string `eval`. It takes an EXPR (or `$_` when EXPR is omitted), treats the string as a raw byte stream, and parses it as Perl source. The parse is insulated from the caller's `use utf8` pragma: whatever encoding rules the string itself

declares win. Reach for it when the code you are about to compile was read from disk, the wire, or a build step, and you need the parser to see exactly the bytes you handed it.

Synopsis

```
evalbytes EXPR
evalbytes
CORE::evalbytes EXPR    # when the feature is not enabled
```

What you get back

In scalar context, the value of the last expression evaluated; in list context, a list. On a compile or run-time error, `undef` (or an empty list) and `$@` is set to the error message; `$@` is the empty string on success. Return shape matches string `eval` exactly - the only difference is how the source text itself is decoded.

```
my $result = evalbytes $source;
die $@ if $@;
```

How it differs from string `eval`

Two concrete behaviours distinguish `evalbytes` from `eval EXPR`:

- **The source is parsed as bytes.** Every octet in the string is a separate input character to the lexer, regardless of whether the string is internally marked as `utf8`. A multi-byte UTF-8 sequence in the source shows up to the parser as the individual bytes, not as the decoded code point.
- **Code points above 255 are a hard error.** If the string contains any character whose ordinal exceeds `0xFF`, it cannot be a byte stream and the compile fails with `Wide character in eval` stored in `$@`. Downgrade with `utf8::encode` first if the source currently holds decoded text.

`use utf8` and `no utf8` **inside** the evaluated code have their usual effect: the pragma switches on once the parser reaches it and affects the remainder of that compilation. It is the source's outer framing that is fixed to bytes, not what the source itself declares.

Enabling the name without `CORE::`

`evalbytes` is feature-gated. To call it as a bareword:

```
use feature 'evalbytes';
```

A `use v5.16` (or higher) declaration enables the `evalbytes` feature automatically, along with the rest of the `:5.16` feature bundle. Without either, the unqualified name is not recognised and you must write `CORE::evalbytes` explicitly - useful inside generated code or one-liners that do not carry a version declaration.

```
use v5.16;
my $n = evalbytes '1 + 2';        # 3
```

```
# no feature, no version bundle:
my $n = CORE::evalbytes '1 + 2';  # 3
```

Global state it touches

- `$@` - cleared before the compile, then set to the error message on failure or the empty string on success. Same contract as `eval`.
- `$_` - read as the source text when EXPR is omitted.

Source filters activated *inside* the evaluated code apply to the code itself, exactly as they would inside a string `eval`. The filter sees the same bytes the parser sees.

Examples

Evaluate a literal byte string - no surprises, no encoding choices to make:

```
use feature 'evalbytes';
my $n = evalbytes 'my $x = 40; $x + 2';   # 42
```

Evaluate source read from a file that is known to be UTF-8 encoded but whose declared pragma inside the source is what should govern parsing:

```
use feature 'evalbytes';
open my $fh, '<:raw', 'script.pl' or die $!;
my $src = do { local $/; <$fh> };
my @values = evalbytes $src;
die "compile failed: $@" if $@;
```

Reading with `:raw` keeps `$src` a byte string. `evalbytes` then feeds those bytes to the parser verbatim; a `use utf8;` line at the top of the script will do its own work once the parser reaches it.

Compare with string `eval` when the caller has `use utf8`:

```
use utf8;
use feature 'evalbytes';

my $src = "length('caf\xc3\xa9')";   # bytes for 'café' in UTF-8

print eval $src;         # 3  (characters: c, a, f, é)
print "\n";
print evalbytes $src;    # 5  (bytes:     c, a, f, 0xC3, 0xA9)
print "\n";
```

Under `use utf8` the caller's own literal `"length('caf\xc3\xa9')"` is a **character** string to `eval`, so `length` inside the evaluated code sees one é character. `evalbytes` forces the same source to be parsed as the byte sequence `c a f 0xC3 0xA9`, so `length` reports the byte count.

Catching a wide-character error:

```
use feature 'evalbytes';
my $src = "print \x{2603}";          # contains U+2603 SNOWMAN
evalbytes $src;
warn "rejected: $@" if $@;           # "Wide character in eval ..."
```

Omitting EXPR - source comes from `$_`:

```
use feature 'evalbytes';
for ('1+1', '2*3', '10-7') {
    my $r = evalbytes;
    print "$_ = $r\n";
}
```

Edge cases

- **Wide character in source**: any code point above `0xFF` aborts the compile and leaves `Wide character in eval` in `$@`. Run `utf8::encode` on the source (or read the file in `:raw`) before calling.
- **`use utf8` is local to the evaluated code.** It affects string literals and identifiers inside the evaluated text once the parser reaches the pragma line. It does **not** change how `evalbytes` frames the outer source - that framing is always "bytes".
- **Feature not enabled**: without `use feature 'evalbytes'` and without a `use v5.16+` bundle, the bareword is unrecognised. Write `CORE::evalbytes` to bypass the feature gate.
- **`evalbytes` with no argument and `$_` undef**: compiles an empty string, which succeeds and returns `undef` in scalar context, the empty list in list context, with `$@` empty.
- **Source filters** inside the evaluated code see the byte stream. A filter that expects decoded characters will misbehave; write filters for `evalbytes` in terms of bytes.
- **Lexicals and package state**: same rules as string `eval`. The evaluated code shares the caller's current package and sees the caller's in-scope lexicals; its own `my` variables vanish when the eval finishes.
- **`die` inside `evalbytes`**: caught the same way as for `eval`. The thrown value lands in `$@`; execution continues after the `evalbytes` call.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `eval` - the character-mode counterpart; parses EXPR according to the caller's Unicode framing, so `use utf8` in the caller changes how the source is interpreted
- `die` - throw an exception from within evaluated code; sets `$@` just like any other run-time error

- do - compile and run a file; takes its source from disk rather than a string, and is not affected by the caller's utf8 framing
- require - load and compile a file once; the standard tool when the source lives on disk and should only run on first reference
- utf8 - the pragma controlling character vs byte semantics of string literals; evalbytes exists precisely to pin the outer framing to bytes regardless of this pragma
- $@ - the error slot populated on evalbytes failure, cleared on success

Processes

exec

Abandon this program and run another in the same process.

exec replaces the current process image with another program. It does **not** return on success - execution continues in the new program, with the same process id, open filehandles subject to the close-on-exec flag, and whatever environment was in effect. It returns false (and sets $!) only when the target could not be launched *and* it was executed directly rather than through the shell. Reach for system when you want the child to run and control to come back.

Synopsis

```
exec LIST
exec PROGRAM LIST
exec { PROGRAM } LIST
```

What you get back

Nothing, on success - the process has been replaced and this Perl interpreter is gone. On failure exec returns false and leaves the reason in $!. Failure is only detectable for the direct-exec path; when the argument is handed to the shell, a missing program is reported by the shell itself and exec still counts as having "succeeded" in launching /bin/sh.

```
exec '/usr/bin/vi', $file
    or die "couldn't exec vi: $!";
```

Because exec normally does not return, Perl emits a warning under use warnings if it appears in void context followed by another statement that is not die, warn, or exit. Either handle the failure inline with or die, or wrap the call in a block to silence the warning:

```
exec('foo') or die "couldn't exec foo: $!";
{ exec('foo') }; die "couldn't exec foo: $!";
```

Shell or no shell - the single-string rule

`exec` picks between two launch mechanisms based on the shape of `LIST`:

- **Two or more arguments** → `exec` calls `execvp(3)` directly with the list. No shell is involved, no metacharacter interpretation, no word splitting.
- **Exactly one argument** → `exec` scans that single string for shell metacharacters. If any are found, the whole string is passed to `/bin/sh -c` for parsing. If none are found, the string is split on whitespace and handed to `execvp` directly.

The rule matters for both correctness and security. A one-argument string containing a space but no metacharacters is split into words and executed directly - which is often what you want. A one-argument string containing `|`, `>`, `$`, `;`, glob characters, or quotes goes through the shell, and the shell will happily expand wildcards, interpret variables, and split on `$IFS`.

```
exec '/bin/echo', 'Your arguments are:', @ARGV;  # direct execvp
exec "sort $outfile | uniq";                     # pipeline → shell
exec "ls /tmp";                                  # no metachars →␣
↪split + execvp
```

To **force** the no-shell path even with a single logical command, use the indirect-object form described next.

Indirect-object form - set argv[0], skip the shell

Placing a block or scalar before `LIST` (with no comma) tells `exec` two things at once: run *this* program, and pass *those* arguments as `argv`. The first element of `LIST` becomes `argv[0]` - the name the child sees for itself - which need not match the program path.

```
exec { '/bin/echo' } 'echo', 'hi';   # argv[0] is "echo"
my $shell = '/bin/csh';
exec $shell '-sh';                   # login-shell convention:␣
↪argv[0] = "-sh"
exec { '/bin/csh' } '-sh';           # same, more direct
```

The indirect-object form always treats `LIST` as a multi-valued list, even if it has only one element. That disables the metacharacter scan entirely:

```
my @args = ('echo surprise');
exec @args;              # one element → shell scan → /bin/sh -c
↪'echo surprise'
exec { $args[0] } @args; # always direct execvp, "echo surprise" is␣
↪argv[0]
```

In the second form there is no program on disk literally named `echo surprise`, so `execvp` fails, `exec` returns false, and `$!` holds the reason. That's the safe behaviour: the caller gets to decide what to do, rather than the shell running something unexpected.

Global state it touches

- `$!` - set on failure to the `errno` from the underlying `execvp(3)` call. Only meaningful when `exec` actually returns.
- `$?` - left unchanged by `exec` itself, but a failed shell-mediated attempt may leave the shell's exit status visible to a wrapping `system`.
- The process's open filehandles, environment (`%ENV`), current working directory, `umask`, signal dispositions, and resource limits all carry into the replacement program - `exec` replaces the program, not the process.

Examples

Run a program with an explicit argument list, direct `execvp`:

```
exec '/usr/bin/git', 'status', '--short'
    or die "exec git: $!";
```

Hand a command line to the shell deliberately, using metacharacters:

```
exec "find . -name '*.tmp' -print0 | xargs -0 rm"
    or die "exec pipeline: $!";
```

Set a distinctive `argv[0]` so the child's `ps` line identifies its role:

```
exec { '/usr/local/bin/worker' } 'worker[queue=email]', @flags
    or die "exec worker: $!";
```

Fork-and-exec - the classic pattern for launching a child without replacing yourself:

```
my $pid = fork // die "fork: $!";
if ($pid == 0) {
    exec '/usr/bin/gzip', '-9', $file
        or die "exec gzip: $!";
}
waitpid $pid, 0;
```

Guarantee the no-shell path when the argument list was assembled from data:

```
my @cmd = build_command();          # may contain one element or
↪many
exec { $cmd[0] } @cmd
    or die "exec $cmd[0]: $!";
```

Edge cases

- **Never returns on success.** Any code after a bare `exec` is reachable only on failure. Under `use warnings`, a following statement other than `die`, `warn`, or `exit` triggers a warning - Perl's hint that you probably meant `system`.
- **Single-argument trap.** `exec $cmd` where `$cmd` came from user input is a shell-injection vector if `$cmd` contains metacharacters. Use the indirect-object form or pass a pre-split list.

- **Output buffering.** Perl attempts to flush handles opened for output before handing control to the new program, but this is not guaranteed on every platform. If you have pending output on an unflushed handle, set `$|` on the selected handle - or call the `autoflush` method on each `IO::Handle` - before `exec`.
- **`END` blocks and `DESTROY`.** `exec` does **not** run `END` blocks, and it does **not** invoke `DESTROY` on your objects. The process image is replaced; Perl-level cleanup never happens. Anything that needs a clean shutdown (temp files, lockfile removal, buffered log flushes) must happen before `exec`.
- **Close-on-exec.** Filehandles with the `FD_CLOEXEC` flag set are closed by the kernel during `execvp`; others stay open. Control this with `fcntl` or the `$^F` system filehandle threshold.
- **Shell-mediated failure is invisible.** When `exec` routes through `/bin/sh -c`, a missing target program is reported by the shell and `exec` itself has already been replaced by `/bin/sh`. Your Perl code will not see a failure return.
- **One-arg list with no metacharacters** is *still* split on whitespace and passed to `execvp` - so `exec "ls /tmp"` is a direct exec of `/bin/ls` with one argument, not a shell call.
- **Empty `LIST`** is a runtime error; there is no program to run.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `system` - run a program and wait for it; what you almost certainly wanted if `exec` is at the top of the file
- `fork` - pair with `exec` in the child to launch a program without replacing the parent
- `wait` - collect a child produced by `fork` + `exec`
- `die` - terminate the current program with an error; the idiomatic partner of `exec ... or die`
- `$!` - error reason set when direct-exec fails
- `$|` - autoflush flag; set before `exec` so no buffered output is lost when the process image is replaced

Hashes

exists

Test whether a hash or array element, or a named subroutine, is present - without creating it and without caring what it holds.

`exists` asks a structural question: *is there an entry at this location?* It does not ask what the entry's value is. An entry whose value is `undef` still exists. An entry that has never been assigned does not - looking it up with a plain read would return `undef`, but `exists` distinguishes the two cases.

Synopsis

```
exists $hash{KEY}
exists $array[INDEX]
exists &subroutine
exists $ref->{A}{B}          # autovivifies $ref->{A}!
```

What you get back

A boolean: 1 (a true scalar) if the element or subroutine is present, the empty string "" (a false scalar) if not. The result is always a plain scalar - there is no list-context variant.

```
my %h = (a => undef);
exists $h{a};                # 1   (key exists)
defined $h{a};               # ""  (value is undef)
exists $h{b};                # ""  (key does not exist)
```

`exists` is not `defined`

The two answer different questions and they disagree exactly when an existing entry holds `undef`:

State	`exists`	`defined`	Plain read
Never assigned	false	false	`undef`
Assigned `undef`	**true**	false	`undef`
Assigned any other value	true	true	that value

Use `exists` when you need to know whether a key has been placed in the structure - e.g. an option hash where a bare key means "the caller opted in, value doesn't matter." Use `defined` when you need to know whether a value is usable.

Examples

Hash-key test. Classic option-hash idiom - presence, not truth:

```
sub configure {
    my %opt = @_;
    my $verbose = exists $opt{verbose};     # caller passed verbose
 ↪=> anything
    my $color   = $opt{color} // "auto";    # caller-supplied or
 ↪default
    ...
}
```

Distinguishing "missing" from "present but undef":

```
my %cache = (user_42 => undef);             # cached: "we looked,
 ↪nothing there"
```

(continues on next page)

(continued from previous page)

```
if (exists $cache{user_42}) {
    # hit - even though the value is undef, we already did the␣
 ↪lookup
} else {
    # miss - have to query the database
}
```

Sparse-array test. Deleting an array element leaves a hole that `exists` reports as false:

```
my @a = (10, 20, 30);
delete $a[1];
exists $a[0];                # 1
exists $a[1];                # ""   (hole)
exists $a[2];                # 1
exists $a[99];               # ""   (past the end)
```

Subroutine existence. True once the sub has been declared, even if the body is a forward declaration with no definition yet:

```
sub later;                   # forward declaration
exists &later;               # 1
defined &later;              # ""   (no body yet)

sub later { 42 }
defined &later;              # 1
```

Nested structure - the **safe** way. Check each level before descending, because the arrow-chain form has a side effect (see Edge cases):

```
if (exists $tree{users}
    && exists $tree{users}{$id}
    && exists $tree{users}{$id}{email}) {
    send_mail($tree{users}{$id}{email});
}
```

Edge cases

- **Autovivification of intermediate levels.** This is the single most important pitfall. `exists $ref->{A}{B}{C}` tests the innermost key, but evaluating the expression autovivifies every **intermediate** hash - `$ref->{A}` and `$ref->{A}{B}` spring into existence as empty hashes even when the `exists` test returns false:

  ```
  my %h;
  exists $h{a}{b}{c};          # returns "" (false)
  exists $h{a};                # now returns 1 - $h{a} was␣
   ↪created!
  exists $h{a}{b};             # likewise - now an empty hash
  ```

  The innermost element is the only one that does not autovivify. The same happens through references: `exists $ref->{A}` on an undef `$ref` vivifies `$ref` into

a hash reference. If you need to probe a deep structure without mutating it, walk it one level at a time with `exists` at each step, or use a dedicated helper like `Data::Diver` semantics (a chained `eval` / `no autovivification` pragma scope).

- **`exists` on a key with value `undef` is true.** This is the defining difference from `defined`. `delete` removes both the key and the value; assigning `undef` keeps the key.
- **Array bounds.** `exists $a[$i]` is false when `$i` is past the end of the array **or** when the slot has been `delete`d mid-array. Negative indices count from the end: `exists $a[-1]` tests the last element if the array is non-empty.
- **Array `exists` is discouraged upstream.** The notion of deleting an array element is not conceptually clean - `delete $a[1]` leaves a hole rather than shifting. Most code that reaches for `exists $a[$i]` is better served by a bounds check (`$i <= $#a`) or by using a hash.
- **`exists &sub()` is a syntax error.** The argument must name a subroutine, not call one. `exists &sub` asks "is `sub` declared?"; `exists &sub()` would mean "does the return value of calling `sub` exist?", which is meaningless.
- **`AUTOLOAD` does not count.** `exists &sub` is false for a sub that would spring into existence via `AUTOLOAD` on first call. A failing `exists` therefore does not guarantee a call would fail.
- **Tied variables.** For tied hashes and arrays, `exists` calls the `EXISTS` method on the tied object. The tie implementation decides what "existing" means - a `DBM` tie checks the on-disk record, a lazy tie might materialise the entry. See `perltie`.
- **The argument must be an lvalue expression whose final operation is a key or index lookup, or a subroutine name.** `exists func()`, `exists $scalar`, `exists @array`, `exists %hash` are all errors. Only element access and `&sub` are accepted.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `defined` - asks whether the value is usable, not whether the key is present; differs from `exists` only when the stored value is `undef`
- `delete` - removes an entry so that `exists` on it becomes false; the counterpart to `exists`
- `each` - iterates key/value pairs of a hash; only visits keys for which `exists` is true
- `keys` - returns the list of existing keys; `exists $h{$k}` is equivalent to asking whether `$k` is among `keys %h`, but O(1) instead of O(n)
- `ref` - classifies what a reference points to; useful before `exists` on `$ref->{...}` if you are not sure `$ref` is a hash reference
- `scalar` - force scalar context; note that `exists` is already scalar-only and does not need it

Control flow

exit

Terminate the program with a status value.

`exit` evaluates `EXPR`, runs end-of-program cleanup (`END` blocks and object destructors), and then exits the process with that value as its status code. With no argument it exits `0` - success.

Synopsis

```
exit EXPR
exit
```

What you get back

Nothing. `exit` does not return to its caller. It is a statement in the control-flow sense even though the grammar lets you write it inside an expression. Code after `exit` in the same block is unreachable:

```
exit 1;
print "never\n";            # dead code
```

Status values and the 8-bit truncation

The operating system stores an exit status in **8 bits**. Whatever integer you pass to `exit` is taken modulo 256 by the kernel before the parent process sees it. `exit 256` looks like `exit 0` to the shell. `exit -1` becomes `255`. Pass only values in `0..255` and you avoid the surprise.

The only universally portable values are `0` for success and `1` for a generic error. Other numbers have conventions - the `sysexits.h` range `64..78` on Unix, specific codes expected by `sendmail` filters, and so on - but those are agreements between your program and a specific caller, not guarantees of the language. Exiting `69` (`EX_UNAVAILABLE`) tells a `sendmail` incoming-mail filter to defer the message; the same `69` from a script run by `cron` means nothing in particular.

```
exit 0;                     # success
exit 1;                     # generic failure
exit 2;                     # conventional "misuse" (grep, diff)
exit 77;                    # conventional "skip" (Automake test)
```

Cleanup: `END` blocks and destructors

`exit` is **not** an immediate syscall. Before the process goes away, Perl:

1. Runs every `END` block in **reverse order of compilation** (LIFO).
2. Calls `DESTROY` on any object whose refcount drops to zero as global destruction tears down pads, the symbol table, and package globals.

Both kinds of cleanup can observe **and change** `$?`. The value you passed to `exit` is placed in `$?` on entry to the `END`/`DESTROY` phase; whatever `$?` holds when the last cleanup returns is the status the process exits with.

```
END { $? = 0 if $? == 2; }  # rewrite "misuse" to success

exit 2;                     # process actually exits 0
```

This is occasionally useful and regularly astonishing. If a module you did not write installs an `END` block that touches `$?`, your carefully chosen status code can arrive at the parent shell altered.

When you need a hard, unconditional exit that bypasses `END` and `DESTROY` entirely, call `POSIX::_exit`:

```
use POSIX ();
POSIX::_exit(3);            # no END, no DESTROY, status = 3
```

Reach for `_exit` in child processes after `fork` where the parent owns the cleanup, and in signal handlers where running arbitrary Perl code is unsafe.

`exit` is not `die`

`exit` is the wrong tool for reporting an error from a library or a subroutine. A caller higher up the stack may want to catch the failure, log it, and continue - an `eval` block or a `Try::Tiny` wrapper cannot recover from `exit`. The process is gone.

```
sub load_config {
    my ($path) = @_;
    open my $fh, "<", $path
        or die "open $path: $!";   # correct - trappable
    ...
}

# NOT:
# open my $fh, "<", $path or exit 1;
```

Use `die` for error conditions. Reserve `exit` for the top level of the program where you have decided, as the application, that the run is over.

`exit` inside `eval`

`exit` is **not** caught by `eval`. Unlike `die`, which unwinds to the nearest `eval` and sets `$@`, `exit` walks straight past every `eval` frame on the stack, runs `END`/`DESTROY`, and terminates.

```
eval { exit 5 };            # process exits 5; the eval block
print "after eval\n";       # never runs
```

If you are writing a plugin host or a test harness that must survive misbehaved user code calling `exit`, there is no language-level catch. The conventional workaround is to fork, let the child call `exit`, and inspect the child's status in the parent:

```
my $pid = fork // die "fork: $!";
if ($pid == 0) {
    run_user_code();        # may call exit
    exit 0;
}
waitpid $pid, 0;
my $status = $? >> 8;
```

Examples

Early return from the program after a prompt:

```
my $ans = <STDIN>;
exit 0 if $ans =~ /^[Xx]/;
```

Exit with a status derived from a child process - extract the high byte of `$?` so the shell sees the same code the child produced:

```
system @cmd;
exit $? >> 8 if $?;
```

Rewrite a status in an `END` block - whatever `$?` holds at the end of cleanup is the exit status delivered to the parent:

```
END {
    $? = 0 if $? == 2 && $ENV{IGNORE_MISUSE};
}
```

Bypass cleanup in a forked child so the parent's destructors do not run twice:

```
use POSIX ();
my $pid = fork // die "fork: $!";
if ($pid == 0) {
    exec @cmd;
    POSIX::_exit(127);      # exec failed; do NOT run parent's END
}
```

Edge cases

- **`exit` with no argument** is `exit 0`. Many scripts rely on falling off the end of the file to get an implicit `0`; writing `exit;` makes the intent explicit.
- **Non-integer argument**: `EXPR` is evaluated in scalar context and converted to an integer. `exit "3x"` exits 3; `exit "hello"` exits `0` with a warning under `use warnings`.
- **Negative values** are taken modulo 256 by the kernel. `exit -1` appears to the shell as 255. Pass only `0..255` to avoid the coercion.
- **Values above 255** lose their high bits. `exit 256` looks like success; `exit 300` looks like `exit 44`. If you need to convey a larger value, write it to a file or to `STDERR` and exit with a small status code.

- **`END` blocks can cancel your status but not the exit itself**. An `END` block cannot stop the process from terminating - it can only change `$?`, and therefore the status seen by the parent.
- **Global destruction order is not the reverse of construction**. During the final sweep Perl walks package globals in an implementation-defined order. Do not rely on one `DESTROY` running before another; if ordering matters, tear the objects down explicitly before calling `exit`.
- **Inside a `BEGIN` block**, `exit` terminates the compilation phase and exits the process. `END` blocks already registered run; later `BEGIN`/`END`/code in the file does not.
- **Threads**: in a program with multiple Perl interpreter threads, `exit` terminates the whole process, not just the calling thread. Use `threads->exit` for per-thread exit.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `die` - raise a trappable exception; the right choice for reporting errors from a subroutine
- `warn` - emit a diagnostic without terminating; pairs with `die` the way `print` pairs with `exit`
- `END` blocks - compile-time-registered cleanup code run in LIFO order on any exit, including `exit EXPR`
- `DESTROY` methods - per-object cleanup called during global destruction after `END` blocks have run
- `$?` - child-process / final exit status; visible to and mutable by `END` blocks and destructors
- `POSIX::_exit` - immediate termination that bypasses `END` and `DESTROY`; use in forked children and signal handlers

Numeric functions

exp

Raise *e* to a power.

exp returns *e* (the base of natural logarithms, roughly `2.718281828459045`) raised to the power of `EXPR`. It is the inverse of `log`: for any finite positive `$x`, `exp(log($x))` reproduces `$x` to within floating-point rounding. With no argument, `exp` operates on `$_`.

Synopsis

```
exp EXPR
exp
```

What you get back

A double-precision floating-point number. The result is always non-negative: `exp(0) == 1`, exp of any positive value is greater than 1, and exp of any negative value lies in the open interval `(0, 1)`.

On every Linux target pperl supports, the underlying type is IEEE 754 binary64, so the range of finite results is roughly `5e-324` up to `1.7976931348623157e+308`. Arguments above about `709.78` overflow to `Inf`; arguments below about `-745` underflow to `0.0`.

Examples

Get *e* itself, and verify the round-trip against `log`:

```
my $e = exp(1);                         # 2.718281828459045
printf "%.15f\n", exp(log(42));         # 42.000000000000000
```

No-argument form reads `$_`:

```
for (1, 2, 3) {
    printf "exp(%d) = %.6f\n", $_, exp;
}
# exp(1) = 2.718282
# exp(2) = 7.389056
# exp(3) = 20.085537
```

Compose with other numeric built-ins. The hyperbolic sine, for example, has no dedicated operator but falls out of exp:

```
sub sinh { (exp($_[0]) - exp(-$_[0])) / 2 }
printf "%.6f\n", sinh(1);               # 1.175201
```

Overflow at the top of the IEEE 754 range:

```
print exp(709), "\n";                   # 8.21840746949e+307
print exp(710), "\n";                   # Inf
```

Underflow at the bottom:

```
print exp(-745), "\n";                  # 5e-324  (smallest subnormal)
print exp(-746), "\n";                  # 0
```

Edge cases

- **Very large positive argument**: Any argument greater than roughly `709.78` produces `Inf`. `Inf` propagates through subsequent arithmetic (`Inf + 1 == Inf`, `Inf - Inf` is `NaN`) and stringifies as `"Inf"`.
- **Very negative argument**: Arguments below roughly `-745` underflow to `0.0`. Values in between render as denormal floats with progressively reduced precision.
- **`NaN` input**: `exp(NaN)` is `NaN`. `NaN` compares unequal to everything including itself - test with `Scalar::Util::looks_like_number` or `$x != $x` rather than `==`.

- **`exp(0)`** is exactly 1, not a rounded approximation.
- **Non-numeric argument**: Perl coerces the argument through its standard string-to-number rules before calling the C `exp(3)` routine. `exp("")` and `exp("abc")` are therefore `exp(0) == 1`, with an `Argument "…" isn't numeric` warning under `use warnings`. A leading-numeric string like `"3.5xyz"` becomes `3.5`, again with a warning.
- **`undef` argument**: Coerced to `0`, yielding 1, with an `uninitialized` warning under `use warnings`.
- **List context**: `exp` is a unary numeric function. It ignores list context and always returns a single scalar. `my @r = exp(2)` puts one element into `@r`.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `log` - natural logarithm, the inverse of `exp`; `exp(log($x)) == $x` for positive `$x`
- `sqrt` - square root; `sqrt($x) == exp(log($x)/2)` for positive `$x`
- `sin` - sine, the other transcendental unary built-in
- `cos` - cosine; with `sin` and `exp` covers the standard transcendentals available without a module
- `abs` - absolute value, useful when feeding a signed quantity into `log` after `exp`-based manipulation
- `$_` - default argument when `exp` is called without an explicit operand

SCALARs and strings

fc

Return the Unicode casefolded form of a string for case-insensitive comparison.

`fc` is the string operation that powers case-insensitive string equality. It produces a form of the string where case distinctions have been erased, so two strings are considered case-insensitively equal when - and only when - their `fc` results are byte-for-byte identical. It is also the function behind the `\F` escape in double-quoted strings.

Synopsis

```
use feature 'fc';           # or: use v5.16;

fc EXPR
fc                          # operates on $_
"\F...\E"                   # same casefold, inside a double-quoted
 ↪string
```

`fc` is gated behind the `fc` feature. Enable it explicitly with `use feature 'fc'`, pull it in via a version bundle (`use v5.16` or newer, `use feature ':5.16'`), or call it fully qualified as `CORE::fc` without any pragma.

What you get back

A string containing the casefolded form of EXPR. The result is a fresh string; the argument is never modified. Length may change - casefolding `"\x{1E9E}"` (LATIN CAPITAL LETTER SHARP S) normally expands to `"ss"`, two characters from one.

Treat the return value as opaque: it is a key suitable for equality comparison, not for display. `fc("Hello")` is `"hello"` for ASCII, but in the general case the output is not something you'd show to a user.

Why not `lc` or `uc`?

Lowercasing and uppercasing are **not** reliable for case-insensitive comparison. Both of these are wrong:

```
lc($a) eq lc($b)            # Wrong
uc($a) eq uc($b)            # Also wrong
```

They fail on characters whose lower/upper mapping is not symmetric - most famously the German sharp S. `lc("\x{1E9E}")` is `"\x{1E9E}"` (no lowercase form), but `uc("ß")` is `"SS"`. Casefolding sidesteps this by mapping both sides into a dedicated equality form:

```
fc($a) eq fc($b)            # Right
```

The regex-based equivalent that was correct before `fc` existed:

```
$a =~ /^\Q$b\E\z/i
```

`fc` is the direct, non-regex way to get the same answer.

Global state it touches

- `$_` - used as the argument when EXPR is omitted.
- `use locale` - inside a `use locale` scope, casefolding of characters crossing the 255/256 boundary is disabled (see *Edge cases* below for the U+1E9E rule).
- `use feature 'unicode_strings'` - affects `fc` the same way it affects `lc`: forces full Unicode semantics on byte strings that would otherwise be treated under legacy 8-bit rules.

Examples

Case-insensitive equality, the canonical use:

```
use feature 'fc';
fc("Hello") eq fc("HELLO");             # true
fc("café")  eq fc("CAFÉ");              # true
```

The German sharp S - the textbook case where `lc` and `uc` both fail but `fc` succeeds:

```
use feature 'fc';
my $a = "straße";
my $b = "STRASSE";
fc($a) eq fc($b);                       # true
lc($a) eq lc($b);                       # false - "straße" ne
 ↪"strasse"
```

Using `fc` as a hash key for case-insensitive lookup:

```
use feature 'fc';
my %seen;
for my $word (@words) {
    $seen{ fc $word }++;                # groups "Foo", "FOO", "foo"
}
```

No argument - operates on `$_`:

```
use feature 'fc';
for (@lines) {
    next unless fc eq "quit";           # matches "QUIT", "Quit", ..
 ↪.
    last;
}
```

Inside a double-quoted string via `\F` (same operation, inline):

```
use feature 'fc';
my $name = "Alice";
my $key  = "\F$name\E";                 # "alice" - same as fc(
 ↪$name)
```

Calling without the feature pragma, fully qualified:

```
my $folded = CORE::fc($input);          # works in any scope
```

Edge cases

- **No argument**: `fc` with no argument folds `$_`.
- **`undef` argument**: stringifies to the empty string, which folds to the empty string. Emits an `uninitialized` warning under `use warnings`.
- **Feature not enabled**: `fc EXPR` without `use feature 'fc'` (or a `use v5.16+` bundle) is a compile-time error - the parser does not recognise `fc` as a keyword. `CORE::fc(EXPR)` always works.
- **Length can change**: full casefolds may expand one character to several. `fc("\x{1E9E}")` is `"ss"`. Never rely on `length(fc $s) == length($s)`.
- **Not a round-trip**: `fc` is one-way. There is no "uncasefold" operation; the original case is gone.

- **U+1E9E under `use locale`**: `fc` of *LATIN CAPITAL LETTER SHARP S* (U+1E9E) normally folds to `"ss"`. Under `use locale` that mapping is suppressed because it crosses the 255/256 codepoint boundary, which locale rules do not handle cleanly. Instead `fc` returns `"\x{17F}\x{17F}"` (two *LATIN SMALL LETTER LONG S*). Since each *long s* itself folds to `"s"`, two of them compare equal to a single U+1E9E folded outside the locale scope - so equality semantics are preserved even though the byte form differs.
- **Turkic and "simple" folds are not provided**: Perl implements only the *full, non-Turkic* form of casefolding. For the simple form or the Turkic variant, use `Unicode::UCD::casefold` or the CPAN module `Unicode::Casing`.
- **Not the same as NFKC or NFC**: `fc` erases case, not compatibility differences. `fc("ffi")` (*LATIN SMALL LIGATURE FFI*) is `"ffi"` after fold, not `"ffi"`. Combine with `Unicode::Normalize` if you need both.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `lc` - lowercases a string; use for display, not for case-insensitive comparison
- `uc` - uppercases a string; same caveat as `lc`
- `lcfirst` - lowercases only the first character
- `ucfirst` - uppercases only the first character
- `index` - substring search; pair with `fc` on both operands for a case-insensitive variant
- `$_` - the default argument when `EXPR` is omitted

Filehandles, files, directories

fcntl

Perform a `fcntl(2)` file-control operation on a filehandle.

`fcntl` is the direct Perl binding for the POSIX `fcntl(2)` system call. It reads or changes per-descriptor state - non-blocking mode, close-on-exec, advisory record locks, descriptor flags - by invoking `FUNCTION` against `FILEHANDLE`, with `SCALAR` acting as either the input argument, the output buffer, or both, depending on which `FUNCTION` you pass.

The `FUNCTION` codes are not Perl-level literals; they are C preprocessor macros exposed by the `Fcntl` module. Load it first, or `FUNCTION` will be an undefined bareword:

```
use Fcntl;
```

Synopsis

```
use Fcntl;
fcntl FILEHANDLE, FUNCTION, SCALAR
my $flags = fcntl($fh, F_GETFL, 0);
fcntl($fh, F_SETFL, $flags | O_NONBLOCK);
```

What you get back

On success, the integer the kernel returned. When that integer is `0`, Perl substitutes the dual-valued string `"0 but true"` - true in boolean context, numeric `0` in numeric context, and exempt from the `Argument "..." isn't numeric` warning. This lets you test the result with `or die` even for operations whose success value is literally zero:

```
fcntl($fh, F_SETFD, FD_CLOEXEC)
    or die "F_SETFD: $!";
```

On failure, `fcntl` returns `undef` and sets `$!` to the relevant `errno`. You do **not** need to wrap the return in `defined` - the `"0 but true"` convention makes a plain truth test sufficient.

For `FUNCTION` codes that write back through `SCALAR` (such as `F_GETLK`), the updated bytes land in the scalar you passed; the return value still follows the rule above.

How SCALAR is used

`SCALAR` plays three different roles depending on `FUNCTION`:

- **Input integer.** For flag-setting calls like `F_SETFD` or `F_SETFL`, `SCALAR` is the integer bitmask to install.
- **Ignored placeholder.** For flag-getting calls like `F_GETFD` or `F_GETFL`, `SCALAR` is unused by the kernel; pass `0` by convention.
- **In/out struct buffer.** For record-locking calls like `F_GETLK`, `F_SETLK`, and `F_SETLKW`, `SCALAR` must hold a packed `struct flock` - build it with `pack` before the call, and for `F_GETLK` decode the returned bytes with `unpack` afterward.

When `SCALAR` is used as an output buffer, pre-size it to at least the length of the struct the kernel will write; an undersized scalar is grown automatically, but pre-sizing makes the intent obvious.

Global state it touches

- `$!` - set on failure to the `errno` from `fcntl(2)`.
- Descriptor-level flags on `FILEHANDLE` (e.g. `O_NONBLOCK`, `FD_CLOEXEC`) persist for the lifetime of the descriptor, survive dup and `fork` according to POSIX rules, and are **not** Perl-visible through any other variable. The only way to read them back is another `fcntl` call with `F_GETFL` / `F_GETFD`.

Examples

Make a socket non-blocking - the canonical use:

```
use Fcntl qw(F_GETFL F_SETFL O_NONBLOCK);

my $flags = fcntl($remote, F_GETFL, 0)
    or die "F_GETFL: $!";
fcntl($remote, F_SETFL, $flags | O_NONBLOCK)
    or die "F_SETFL: $!";
```

Set close-on-exec so the descriptor is not inherited by child processes across `exec`:

```
use Fcntl qw(F_SETFD FD_CLOEXEC);

fcntl($fh, F_SETFD, FD_CLOEXEC)
    or die "F_SETFD: $!";
```

Read the current descriptor flags and test a bit:

```
use Fcntl qw(F_GETFD FD_CLOEXEC);

my $fd_flags = fcntl($fh, F_GETFD, 0);
defined $fd_flags or die "F_GETFD: $!";
if ($fd_flags & FD_CLOEXEC) {
    # descriptor will close on exec
}
```

Place an advisory write lock on the whole file. The `struct flock` layout is platform-specific; on Linux `s s l l i` covers `l_type l_whence l_start l_len l_pid`:

```
use Fcntl qw(F_SETLK F_WRLCK SEEK_SET);

my $lock = pack('s s l l i', F_WRLCK, SEEK_SET, 0, 0, 0);
fcntl($fh, F_SETLK, $lock)
    or die "lock refused: $!";
```

Toggling off a single flag - mask out `O_NONBLOCK` to return a handle to blocking mode:

```
use Fcntl qw(F_GETFL F_SETFL O_NONBLOCK);

my $flags = fcntl($fh, F_GETFL, 0);
fcntl($fh, F_SETFL, $flags & ~O_NONBLOCK)
    or die "F_SETFL: $!";
```

Edge cases

- **Forgot `use Fcntl`**: `F_GETFL` and friends parse as barewords and evaluate to a warning-level nuisance under `use strict` / `use warnings`, or to the string `"F_GETFL"` otherwise - either way the call fails with `EINVAL`. Always load `Fcntl` first.

- **"0 but true" return**: do not compare the return with `== 0` as a failure test. Use a plain boolean (`or die`) or `defined` - the former is the idiom.
- **F_SETLK vs F_SETLKW**: `F_SETLK` returns `undef` and sets `$!` to `EAGAIN` / `EACCES` when another process holds a conflicting lock. `F_SETLKW` blocks until the lock is granted. Pick deliberately; mixing them up is the usual source of hangs.
- **F_GETLK output**: on success the `struct flock` bytes in `SCALAR` are overwritten with information about the conflicting lock (or `l_type == F_UNLCK` if the region is free). `unpack` back with the same template you packed with.
- **Not every system implements every FUNCTION**: `fcntl` raises an exception on a machine that does not implement `fcntl(2)` at all. On systems that do, unsupported `FUNCTION` codes fail with `EINVAL` via `$!`. The `Fcntl` module only exports constants the current platform actually defines.
- **`fcntl` vs `ioctl`**: both share the argument-processing and return-value convention, but they target different kernel interfaces. Use `fcntl` for descriptor flags and advisory locks; use `ioctl` for device-specific control codes.
- **`fcntl` vs `flock`**: `flock` uses whole-file BSD-style `flock(2)` locks, which on Linux interoperate with `fcntl` POSIX locks only in limited ways. If you need byte-range locking or POSIX semantics (lock released on *any* `close` of the file by the owning process), use `fcntl` with `F_SETLK`; otherwise `flock` is simpler.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `Fcntl` - the module that exports the `F_*` / `O_*` / `FD_*` / `SEEK_*` constants `fcntl` expects; always `use` it first
- `ioctl` - same calling and return-value convention as `fcntl`, but for device control codes rather than file-control flags
- `flock` - simpler whole-file advisory locks; reach for it when you don't need byte-range or POSIX semantics
- `open` - opens the filehandle in the first place; some flags `fcntl` adjusts (e.g. `O_NONBLOCK`, `O_APPEND`) are also settable at open time
- `sysopen` - low-level open that takes the same `O_*` flags from `Fcntl`; use it when you want the flags applied atomically rather than via a follow-up `fcntl(F_SETFL)`
- `pack` / `unpack` - required for building and decoding the `struct flock` buffer used by `F_GETLK` / `F_SETLK`

Scoping · Classes and OO

field

Declare a per-instance variable inside a `class` block.

`field` introduces a new variable whose storage is private to each object of the enclosing class. Every method and every `ADJUST` block of that class sees the field as if it were a lexical in scope at that point - but the value each sees is the value belonging to the *current* instance. Fields are the class feature's replacement for hash-slot bookkeeping on a blessed reference.

The feature is still marked **experimental** in Perl 5.44 (see *Differences from upstream*); enable it with `use feature 'class';` and silence the warning category with `no warnings 'experimental::class';` if you don't want the noise.

Synopsis

```
field $scalar;
field $scalar = EXPR;
field @array  : ATTRIBUTES;
field %hash   : ATTRIBUTES = EXPR;
```

What you get back

`field` is a declaration, not an expression. It produces no value and cannot appear on the right-hand side of anything. Each `field` statement allocates one slot per instance in the class's layout; the slot is the field variable itself, bound to a per-object storage location on entry to any method or `ADJUST` block.

Scalars, arrays, and hashes are all allowed:

```
class Thing {
    field $scalar = 42;
    field @array  = qw(this is just an array);
    field %hash   = (species => 'Martian', planet => 'Mars');
}
```

Where field declarations are legal

Only directly inside a `class` block. `field` is not a general-purpose declarator - it is not legal inside a `method` body, an `ADJUST` block, a nested `sub`, or plain `package` code. The compiler rejects it anywhere else:

```
class C {
    field $ok;                  # OK
    method m {
        field $nope;            # compile error
    }
}
```

A field must be declared before it can be referred to by any method or initializer in the same class body.

Field initializers

If a `= EXPR` is present, the expression runs once per constructor call, after all fields declared earlier in the class body have been initialized. This matters when a later field's default depends on an earlier one:

```
class WithACounter {
    my $next_count = 1;
    field $count = $next_count++;
}
```

Inside an initializer, `$self` does **not** exist - the object is still being built. Use the `__CLASS__` token when the initializer needs the class name (for example, to call a class method that subclasses can override):

```
class WithCustomField {
    use constant DEFAULT_X => 10;
    field $x = __CLASS__->DEFAULT_X;
}

class DifferentCustomField :isa(WithCustomField) {
    sub DEFAULT_X { rand > 0.5 ? 20 : 30 }
}
```

An instance of `DifferentCustomField` will see `__CLASS__` resolve to its own name, so the initializer picks up the overridden `DEFAULT_X`.

Field attributes

Attributes after a colon control how the field participates in construction and whether accessor methods are generated for it.

`:param`

Take the field's value from a named argument to the constructor:

```
field $x :param;
field $y :param(the_y_value);
```

By default the parameter name is the field's name with the sigil stripped (`$x` → `x`). An explicit name in parentheses overrides that. Without a defaulting expression the parameter is **required** - omitting it from `->new( . . . )` throws. With a defaulting expression the parameter is optional, and three default operators are available:

- `=` - default applies only when the caller omitted the parameter.
- `//=` - default also applies when the caller passed `undef`.
- `||=` - default also applies when the caller passed a false value.

```
class Point {
    field $x :param = 0;          # default if omitted
    field $y :param //= 0;        # default if omitted or undef
```

(continues on next page)

(continued from previous page)

```
    field $z :param ||= 0;       # default if omitted, undef, or 0
}
```

:reader

Generate a zero-argument accessor method that returns the field. Without an explicit name the method is named after the field (sigil stripped):

```
field $s :reader;

# equivalent to:
field $s;
method s () { return $s }
```

An explicit name is allowed:

```
field $x :reader(get_x);        # method get_x () { return $x }
```

Readers can be applied to array and hash fields too; in list context the method yields the contents, and in scalar context the element count - the usual context behaviour of the underlying variable:

```
field @users :reader;
...
scalar $instance->users;        # count of users
```

:writer

Generate a one-argument setter method that assigns its argument to the field and returns the invocant (to support chaining). The default method name is the field name (sigil stripped) prefixed with `set_`:

```
field $s :writer;

# equivalent to:
field $s;
method set_s ($new) { $s = $new; return $self }
```

An explicit name is allowed:

```
field $x :writer(write_x);      # method write_x ($new) { ... }
```

`:writer` currently only works on scalar fields; applying it to an array or hash field is a compile-time fatal error. Build array or hash writers by hand.

Global state it touches

None directly. Field storage lives on the instance, and initializer expressions run in the constructor's scope - they can read any variable visible at the point of declaration, but `field` itself touches no documented special variable.

Examples

Minimal class with one field, initialized in `ADJUST`:

```
use feature 'class';
no warnings 'experimental::class';

class Greeter {
    field $greeting;

    ADJUST {
        $greeting = "Hello";
    }

    method say_to ($name) {
        say "$greeting, $name";
    }
}

Greeter->new->say_to("world");   # Hello, world
```

Constructor parameters via `:param`, with a mix of required and defaulted fields:

```
class Point {
    field $x :param;             # required
    field $y :param = 0;         # optional, defaults to 0

    method as_string { "($x, $y)" }
}

Point->new(x => 3)->as_string;          # (3, 0)
Point->new(x => 3, y => 4)->as_string;  # (3, 4)
```

Auto-generated accessors cover the common boilerplate:

```
class Person {
    field $name :param :reader;
    field $age  :param :reader :writer;
}

my $p = Person->new(name => "Ada", age => 36);
$p->name;            # "Ada"
$p->age;             # 36
$p->set_age(37);     # returns $p
```

Array and hash fields with defaults:

```
class Bag {
    field @items = ();
    field %counts;

    method add ($item) {
        push @items, $item;
        $counts{$item}++;
        return $self;
    }

    method unique { keys %counts }
}
```

Initializer that depends on an earlier field:

```
class Rect {
    field $w :param;
    field $h :param;
    field $area = $w * $h;       # evaluated after $w, $h are set
}
```

Edge cases

- **Lexical visibility is method-scoped, not file-scoped.** A field is visible from any `method` or `ADJUST` block of the same class, regardless of source file order. It is *not* visible from plain `sub` definitions inside the class block - only from `method`.
- **Per-instance, not per-class.** Two instances of the same class have independent storage for every field. Assigning in one instance does not affect another. If you want class-wide state, use a file-scoped `my` variable outside the field list.
- **Sigil determines type.** `field $x` is a scalar slot, `field @a` an array slot, `field %h` a hash slot. Unlike hash-based objects, there is no way to retype a field at runtime; the slot's container type is fixed by the sigil at declaration.
- **`$self` is unavailable in initializers.** The object is not yet constructed when the initializer runs. Use `__CLASS__` for the class name, and defer anything requiring the full object to `ADJUST`.
- **Initializer order is declaration order.** Later initializers may refer to earlier fields; the reverse is a reference to an uninitialized variable.
- **`:writer` on non-scalar fields is fatal at compile time.** The attribute is defined only for scalars in 5.44; applying it to `@arr` or `%h` aborts compilation of the class.
- **`:param` without a default is mandatory.** `Class->new()` with the parameter missing throws. Add `= EXPR`, `//= EXPR`, or `||= EXPR` to make it optional.
- **No direct external access.** Without `:reader` / `:writer` (or a hand-written method) a field is unreachable from outside the class - that is the encapsulation the class feature provides.
- **Experimental warning.** Parsing a `field` declaration emits an `experimental::class` warning unless that category is suppressed; see *Differences from up-*

stream.

Differences from upstream

Fully compatible with upstream Perl 5.44. Upstream marks the `class` feature - and therefore `field` - as experimental; pperl tracks the same status and emits the same `experimental::class` warning. The known upstream bugs listed in `perlclass` (segfaults around in-file inheritance, `refaliasing` interactions, and leaky encapsulation) apply equally to pperl.

See also

- `class` - declares the class whose body is the only place `field` is legal
- `method` - the only subroutine form that sees field variables by name
- `my` - ordinary lexical declaration; use it for class-wide state that should *not* be per-instance
- `our` - package-global declaration; use it for genuinely global state a class wants to expose
- `bless` - the pre-5.38 way to build objects; `field` replaces the hash-slot bookkeeping that `bless`-based classes needed
- `ref` - check an object's class at runtime; still works on instances produced by a `class` constructor

I/O

fileno

Return the OS-level file descriptor number behind a filehandle.

`fileno` looks past Perl's buffered filehandle abstraction and gives you the raw integer descriptor the kernel uses. It is the bridge between Perl I/O and system calls that speak descriptors directly - `select`, `POSIX::dup2`, `fcntl`, or anything in `IO::Poll` / `IO::Select`. On a directory handle it asks the same question against `dirfd(3)`, which not every platform provides.

Synopsis

```
fileno FILEHANDLE
fileno DIRHANDLE
fileno EXPR             # EXPR evaluated as an indirect handle
```

What you get back

- An integer `>= 0` - the OS file descriptor - for a normal open handle backed by a real kernel object.
- `-1` when the handle is open but has **no** real descriptor. This is what you get for in-memory handles created by `open` with a scalar reference as the third argument (`open my $fh, ">", \$buf`).

- `undef` when the handle is closed, never opened, or - on a directory handle - when the platform lacks `dirfd(3)`. In the dirhandle case `$!` is set.

The three return classes matter. Code that checks `fileno($fh)` for truth conflates "no such fd" with "fd number 0" (STDIN). Always compare explicitly:

```
my $fd = fileno $fh;
die "handle not open"      unless defined $fd;
die "handle has no real fd" if $fd == -1;
```

Global state it touches

- `$!` - set when `fileno` on a directory handle fails because the platform has no `dirfd(3)` equivalent.

`fileno` does not read or write any other I/O globals. It does not flush, it does not seek, it does not change the currently selected handle.

Examples

The common case - turn a Perl filehandle into the fd number a system call wants:

```
open my $fh, "<", "/etc/hostname" or die $!;
print fileno $fh, "\n";             # e.g. "3"
```

Standard handles always have fixed descriptors `0`, 1, 2:

```
print fileno STDIN,  "\n";          # 0
print fileno STDOUT, "\n";          # 1
print fileno STDERR, "\n";          # 2
```

Check whether two handles are duplicates of the same underlying descriptor (the idiom from the upstream POD, adjusted for the `-1` case):

```
if (fileno($this) != -1 && fileno($this) == fileno($that)) {
    print "\$this and \$that are dups\n";
} elsif (fileno($this) != -1 && fileno($that) != -1) {
    print "\$this and \$that have different "
        . "underlying file descriptors\n";
} else {
    print "at least one handle has no real file descriptor\n";
}
```

In-memory handles have no kernel object, so `fileno` returns `-1`:

```
my $buf = "";
open my $mh, ">", \$buf or die $!;
print fileno $mh, "\n";             # -1
```

Build a descriptor bitmap for `select` - the textbook use for `fileno`:

```
my $rin = "";
vec($rin, fileno($sock),  1) = 1;
vec($rin, fileno(STDIN),  1) = 1;
my $n = select(my $rout = $rin, undef, undef, 5.0);
```

Directory handles, where the platform supports `dirfd(3)`:

```
opendir my $dh, "." or die $!;
my $dfd = fileno $dh;
if (defined $dfd) {
    # use with fstat, openat, fchdir, ...
} else {
    warn "no dirfd on this platform: $!";
}
```

Edge cases

- **Closed handle**: returns `undef`. No warning under `use warnings` - `fileno` is deliberately quiet so it can be used as a probe.
- **Never-opened bareword**: `fileno NOSUCH` returns `undef`; strict mode will refuse the bareword at compile time unless it's declared.
- **In-memory scalar handles**: return `-1`, not `undef`. Treating `-1` as "open but unusable for system calls" is the intended contract - the handle itself still works for `print`, `readline`, etc.
- **`fileno(-1)` trap**: an explicit `if (fileno $fh) { ... }` is a bug waiting to happen: `fd 0` is STDIN. Use `defined` and compare against `-1` explicitly.
- **Indirect filehandle via expression**: if `FILEHANDLE` is any expression other than a bareword or simple scalar, its value is taken as an **indirect handle name** (a string), not as a handle object. To pass a handle held in a data structure, dereference first:

```
fileno $handles[0];                 # indirect: uses the string
fileno ${ \$handles[0] };           # still wrong
fileno $handles[0]->fileno;         # wrong: calling a method
 ↪on ""
my $fh = $handles[0]; fileno $fh;   # right
```

- **Directory handle on platforms without `dirfd(3)`**: returns `undef` and sets `$!`. Linux has `dirfd(3)`, so on pperl's supported targets this path is not exercised.
- **Tied handles**: `fileno` calls the tie class's `FILENO` method if defined; otherwise returns `undef`. The tied class is responsible for returning a sensible value (`-1` for "no fd" is the convention).
- **Dup'd handles**: two handles opened with `open` from the same underlying fd (e.g. `open my $copy, ">&", $orig`) return the **new** descriptor, not the original - the dup created a fresh fd.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `open` - creates the filehandles that `fileno` inspects; the `>&` and `<&=` modes take descriptor numbers that round-trip through `fileno`
- `opendir` - source of directory handles for the dirhandle form of `fileno`
- `close` - after which `fileno` on the same handle returns `undef`
- `select` - the four-argument form consumes bitmaps built from `fileno` values
- `binmode` - works on the PerlIO layer above the fd; `fileno` reaches beneath it

Control flow

finally

Run cleanup code on the way out of a `try`/`catch`, whether the body succeeded, threw, or jumped away.

`finally` introduces a third block that can follow a `try`/`catch` pair. Its body runs exactly once, after the `try` body completes - however it completes. A normal fall-through, an exception caught by the `catch`, an exception that escapes because there is no matching `catch`, a `return` from the enclosing sub, a `goto`, a `last`/`next`/`redo` leaving the enclosing loop: every one of these routes through the `finally` block before control continues. The pattern is equivalent to scheduling a `defer` block at the top of the `try`, with a syntax that keeps the cleanup visually attached to the try/catch it belongs to.

Synopsis

```
use feature 'try';
no warnings 'experimental::try';

try    { BODY }
catch ($e) { HANDLE }
finally { CLEANUP }
```

What you get back

`finally` has no return value. The final expression of the block is evaluated for its side effects and then discarded - it does **not** contribute to the value of the enclosing `try`/`catch` expression, even if the whole construct is the last statement of a sub or do block being used to produce a value.

```
my $v = do {
    try    { compute() }
    catch ($e) { $DEFAULT }
    finally { log("done"); 999 }   # 999 is discarded
```

(continues on next page)

(continued from previous page)

```
};
# $v is either compute()'s value or $DEFAULT
```

Use `finally` for cleanup that has to happen, not for computing a result.

Feature status

`finally` is part of the `try` feature, but unlike `try` and `catch` (which became non-experimental in Perl 5.40) it remains experimental in Perl 5.44. Using it without silencing the warning produces:

```
finally is experimental at ... line N.
```

Enable the feature and silence the warning together:

```
use feature 'try';
no warnings 'experimental::try';
```

Because the warning category is `experimental::try` - the same one that `try`/`catch` used to emit - silencing it enables `finally` without re-enabling warnings on the now-stable parts of the feature you do want diagnostics for.

When the block runs

The contract is "on the way out, no matter how." Concretely, `finally` runs after each of the following:

- **Normal completion of `try`.** The `try` body fell off the end or returned its last expression value; `finally` runs next, then the statement after the `try` construct.
- **Exception caught by `catch`.** The `try` body threw, the `catch` matched and handled it; `finally` runs after the `catch` body.
- **Exception not caught.** There is no `catch`, or the `catch` itself re-threw with `die`; `finally` still runs, then the exception continues propagating to the next dynamic `eval`/`try` outward.
- **`return` inside `try` or `catch`.** The enclosing sub is about to return; `finally` runs, then the return takes effect.
- **Loop control (`last`, `next`, `redo`) inside `try` or `catch`.** `finally` runs, then the loop control takes effect in the enclosing loop.
- **`goto &sub` or `goto LABEL` leaving the `try`.** `finally` runs before the jump completes.

The ordering matters: if the `catch` itself raises a new exception, `finally` still runs, and the new exception is the one that propagates (the original is replaced, just as with any `die` inside a handler).

Restrictions on the block body

A `finally` block is a cleanup point, not a control-flow redirect. Perl rejects any control-flow statement that would try to override how the construct is already unwinding:

- **`return`** inside `finally` is a syntax / compile-time error.
- **`goto`** inside `finally` is a syntax / compile-time error.
- **Loop controls** (`last`, `next`, `redo`) targeting a loop *outside* the `finally` block are rejected.

Inside a plain loop that is *contained* in the `finally` body, the loop controls apply to that inner loop as normal - the restriction is on leaving the `finally` block, not on looping inside it.

`die` is permitted. A `finally` block that throws replaces any in-flight exception from the `try`/`catch` with the new one. This is usually a bug (you lose the original failure), so guard cleanup code that might itself fail:

```
finally {
    eval { $fh->close };        # swallow close errors during
 ↪cleanup
}
```

Relationship to `defer`

`finally BLOCK` is "`defer BLOCK` placed at the top of the `try`, attached instead to the try/catch pair." Both run on every exit path from their containing scope; both forbid the same control-flow statements in their body; both discard their return value.

The difference is scope attachment:

- `defer` attaches to the *innermost enclosing block* and fires on that block's exit. It is the general-purpose cleanup primitive and works in any block.
- `finally` attaches to the `try`/`catch` *construct* and fires when that construct is done. It is syntactic sugar for the common case where the cleanup is specifically about what the `try` was doing.

```
# These two are behaviourally equivalent:

try {
    my $fh = acquire();
    defer { release($fh) }
    work($fh);
}
catch ($e) { warn $e }

try {
    my $fh = acquire();
    work($fh);
}
```

(continues on next page)

(continued from previous page)

```
catch ($e) { warn $e }
finally { release_last() }      # if $fh were available here
```

Note one practical consequence: variables declared inside the `try` body go out of scope before `finally` runs. If the cleanup needs a resource allocated inside the `try`, either declare it in an outer scope, or use `defer` inside the `try` where the variable is live.

Examples

Always close a handle, even on error:

```
use feature 'try';
no warnings 'experimental::try';

open my $fh, '<', $path or die "open $path: $!";
try {
    process($fh);
}
catch ($e) {
    warn "processing failed: $e";
}
finally {
    close $fh;
}
```

Release a lock regardless of outcome:

```
my $lock = $mutex->lock;
try {
    critical_section();
}
finally {
    $lock->release;
}
```

Observability: log every exit path:

```
try {
    run($job);
}
catch ($e) {
    $job->mark_failed($e);
    die $e;                     # re-throw; finally still runs
}
finally {
    metrics->tick('job.exit', $job->id);
}
```

Value-producing `try`/`catch`, with `finally` for cleanup only:

```
my $result = do {
    try    { fetch($url) }
    catch ($e) { $CACHED }
    finally { close_connection() }
};
# $result is fetch() or $CACHED; finally's value is never used
```

Edge cases

- **`catch` can be omitted.** `try { ... } finally { ... }` is legal and runs `finally` on both normal and exceptional exit; the exception then propagates as if no `try` were there.
- **Nested `try`/`finally`**: `finally` blocks fire innermost-first as scopes unwind, matching `defer` semantics.
- **Exception inside `finally`**: replaces any in-flight exception. The original is lost unless you captured it in the `catch` first.
- **`$@` during `finally`**: not reliable for "what just happened." If the `finally` needs to know whether it is running after success or failure, set a flag in the `catch` block and inspect it:

  ```
  my $failed;
  try   { risky() }
  catch ($e) { $failed = $e; die $e }
  finally {
      if ($failed) { rollback() } else { commit() }
  }
  ```

- **Global destruction**: `finally` blocks registered by a `try` that is still active when the interpreter starts tearing down run, but the same caveats as `die` inside `DESTROY` apply - keep the body defensive.
- **Parse requires the feature**: without `use feature 'try'`, the word `finally` is not a keyword and parses as a bareword function call, which usually produces a confusing unrelated error. Always enable the feature before using the syntax.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `try` - introduces the block whose exit `finally` hooks; see *Try Catch Exception Handling* in perlsyn
- `catch` - the optional middle block that handles exceptions thrown by `try`; `finally` runs after it either way
- `defer` - the general-purpose "run on scope exit" block; `finally` is `defer` attached to a `try`/`catch` pair

- `die` - the only way to cause the `catch` branch to fire; a `die` inside `finally` replaces any in-flight exception
- `eval` - the older exception-catching mechanism; `try`/`catch`/`finally` supersede the common `eval { ... }; if ($@)` idiom with cleaner scoping and proper control-flow semantics

I/O

flock

Place an advisory lock on an open file.

`flock` is Perl's portable file-locking primitive. It calls the underlying `flock(2)`, `fcntl(2)`, or `lockf(3)` - whichever the platform provides - on `FILEHANDLE` and blocks by default until the requested lock can be granted. Locks cover the **whole file**, never a byte range, and are **advisory**: they coordinate only among processes that also call `flock` on the same file. Code that ignores the lock can still read or modify the contents.

Synopsis

```
flock FILEHANDLE, OPERATION
```

What you get back

True on success, false on failure (with `$!` set). Always check the return value - with `LOCK_NB` a failure is the normal "someone else holds it" signal, not an error:

```
flock($fh, LOCK_EX | LOCK_NB)
    or die "already locked: $!";
```

On a platform that implements none of `flock(2)`, `fcntl(2)` locking, or `lockf(3)`, `flock` raises a fatal error rather than returning false. On Linux (pperl's only supported platform) this never happens.

OPERATION values

`OPERATION` is one of the mutually exclusive request types, optionally bitwise-or'ed with the non-blocking flag. Traditional numeric values are 1, 2, 4, 8 but portable code imports the symbolic names from `Fcntl`, either individually or as a group via the `:flock` tag:

```
use Fcntl qw(:flock);
```

- `LOCK_SH` - shared lock. Multiple processes may hold a shared lock on the same file simultaneously. Used for readers.
- `LOCK_EX` - exclusive lock. Only one process may hold it; no other process may hold any lock on the file at the same time. Used for writers.
- `LOCK_UN` - release whatever lock this filehandle currently holds.
- `LOCK_NB` - bitwise-or with `LOCK_SH` or `LOCK_EX` to make the call non-blocking; `flock` returns false immediately if the lock cannot be granted, instead of waiting.

An `flock` call with a new mode atomically replaces an existing lock on the same filehandle (for example, upgrading `LOCK_SH` to `LOCK_EX`).

Global state it touches

- Sets `$!` on failure.
- Flushes `FILEHANDLE`'s output buffer before locking or unlocking, so locked-region data hits the OS before another process can see the lock state change.

Examples

Exclusive lock for a writer, blocking until granted:

```
use Fcntl qw(:flock);
open my $fh, ">>", "counter.log" or die $!;
flock($fh, LOCK_EX)               or die "lock failed: $!";
print $fh "tick\n";
flock($fh, LOCK_UN)               or die "unlock failed: $!";
close $fh;
```

Non-blocking attempt - skip the work if another process is already running:

```
use Fcntl qw(:flock);
open my $fh, ">", "/var/run/myjob.lock" or die $!;
flock($fh, LOCK_EX | LOCK_NB)
    or do { warn "another instance running\n"; exit 0 };
# ... work ...
# lock auto-released when $fh is closed / program exits
```

Classic mailbox appender. Note the `seek` to `SEEK_END` after locking - on very old systems `>>` append mode is not atomic, so the write position must be re-established once the lock is held:

```
use Fcntl qw(:flock SEEK_END);

sub lock_mbox   { flock($_[0], LOCK_EX) or die "lock: $!" }
sub unlock_mbox { flock($_[0], LOCK_UN) or die "unlock: $!" }

open my $mbox, ">>", "/var/mail/$ENV{USER}" or die $!;
lock_mbox($mbox);
seek($mbox, 0, SEEK_END) or die "seek: $!";
print $mbox $msg, "\n\n";
unlock_mbox($mbox);
close $mbox;
```

Shared read lock while loading a config file, letting other readers proceed concurrently:

```
use Fcntl qw(:flock);
open my $fh, "<", "config.dat" or die $!;
flock($fh, LOCK_SH)             or die "lock: $!";
```

(continues on next page)

(continued from previous page)

```
my @lines = <$fh>;
close $fh;                      # releases the lock
```

Upgrading a shared lock to exclusive - the second `flock` atomically swaps modes:

```
flock($fh, LOCK_SH) or die $!;
# ... inspect contents ...
flock($fh, LOCK_EX) or die $!;  # now we intend to write
```

Edge cases

- **Locks are per-filehandle, not per-file**. Two independent opens of the same path each have their own lock slot. This is why locking your own file twice from the same process through different handles can deadlock or behave surprisingly on `fcntl(2)`-based systems.
- **Closing the filehandle releases the lock.** There is no separate "unlock" step required at program exit; `LOCK_UN` is useful only when you want to keep the handle open after.
- **`LOCK_NB` failure is not a croak.** It returns false and sets `$!` to `EWOULDBLOCK`. Treat it as an expected outcome, not an error.
- **Advisory only.** A process that never calls `flock` sees no locks. Use `flock` as a cooperation protocol among your own programs, not as a security mechanism.
- **Whole files only.** There is no byte-range locking through `flock`. For record-level locking use `fcntl` with `F_SETLK` / `F_SETLKW`.
- **NFS and other network filesystems.** Some older NFS implementations cannot honour `flock` across hosts; the call may silently become a no-op or return success without providing exclusion. Use `fcntl` locking if network coordination matters.
- **Fork inheritance.** When the platform uses real `flock(2)` (Linux does), locks are inherited across `fork`; the child shares them with the parent. On `fcntl(2)`-emulated platforms locks do not survive the fork, which makes writing locking servers considerably harder.
- **Buffer flushing.** Perl flushes `FILEHANDLE`'s output buffer on every `flock` call. Code that mixes buffered `print` with locking does not need an explicit flush before the lock boundary.
- **Interaction with dup-style opens.** An open of the form `open(my $A, ">>&=", $B)` shares the underlying file descriptor with `$B`, so `flock($A)` and `flock($B)` act on the same lock slot. A `>>&` dup gives each handle its own descriptor and its own lock slot.

Differences from upstream

Fully compatible with upstream Perl 5.44. pperl runs on Linux only, where `flock(2)` is always available, so the "platform has no locking primitive - fatal error" path documented upstream never triggers in practice.

See also

- `fcntl` - byte-range and advisory locking with finer control; use it when whole-file granularity is too coarse or when network filesystems require it
- `open` - produces the filehandle `flock` operates on; remember that the required open mode (< vs >) matters for `fcntl`-emulated `LOCK_SH` / `LOCK_EX`
- `close` - releases any `flock` still held on the handle
- `seek` - pair with `flock` when appending to files that other processes may have extended while you waited for the lock
- `fork` - lock inheritance across child processes depends on the underlying locking primitive
- `Fcntl` - source of the `LOCK_SH`, `LOCK_EX`, `LOCK_UN`, `LOCK_NB` constants and the `:flock` import tag

Processes

fork

Create a new process running the same program at the same point.

`fork` issues the `fork(2)` system call. After it returns, **two** processes are executing the same Perl program at the same statement - the original (parent) and a near-identical copy (child). The two are distinguished only by `fork`'s return value. File descriptors and, on some systems, the locks held on them are shared between parent and child; everything else is copied. On Linux the copy is cheap: data pages are shared copy-on-write, so the actual duplication happens only as each side writes to memory.

Synopsis

```
my $pid = fork;
```

What you get back

Three return values, one per role:

- **Parent**: the child's PID (a positive integer).
- **Child**: `0`.
- **Failure**: `undef`, with `$!` set to the `errno` from the underlying `fork(2)` (typically `EAGAIN` - resource limit hit - or `ENOMEM`).

The canonical dispatch is a three-way branch. Test for `undef` first, then for `0`, so the parent path is the fall-through:

```
my $pid = fork // die "fork failed: $!";
if ($pid == 0) {
    # child
    exec $cmd, @args;
    die "exec failed: $!";
```

(continues on next page)

(continued from previous page)

```
}
# parent continues here, with $pid = child's PID
```

The two-line "fork or die" idiom:

```
defined(my $pid = fork) or die "fork: $!";
```

Writing `fork or die` (without `defined`) is a bug: it treats the child's legitimate `0` return as failure and dies in every child.

Flush before you fork

Perl attempts to flush all output handles before the `fork(2)` call, but you should not rely on that alone - any unflushed buffered data that does slip through is duplicated in both processes, so the same bytes get written twice. The canonical defence is to disable buffering on any handle you intend to use across a fork:

```
STDOUT->autoflush(1);           # or: $| = 1 while STDOUT is␣
↪selected
STDERR->autoflush(1);

print "about to fork\n";        # now actually on the wire
my $pid = fork // die "fork: $!";
```

Loading `IO::Handle` is not required for `autoflush` in modern Perl - the method is available on all filehandles. Setting `$|` on the currently selected handle has the same effect for that one handle.

Reaping children - or `$SIG{CHLD}`

Every child that terminates before its parent reaps it becomes a **zombie**: a kernel process-table entry held open so the parent can read the exit status. Ignore them and the process table fills up.

Two ways to keep it clean:

- Actively reap with `wait` or `waitpid`:

```
my $pid = fork // die "fork: $!";
if ($pid == 0) {
    # ... child work ...
    exit 0;
}
my $reaped = waitpid $pid, 0;     # block until this child exits
my $status = $?;                  # exit status of the child
```

- Tell the kernel you do not care:

```
$SIG{CHLD} = 'IGNORE';            # children auto-reaped, no␣
↪status
```

Useful for fire-and-forget workers. You lose the exit status - `wait` and `waitpid` will also no longer see the children.

For long-running parents that do care about exit status, install a reaper handler that drains all pending children without blocking:

```
$SIG{CHLD} = sub {
    while ((my $pid = waitpid -1, POSIX::WNOHANG) > 0) {
        # optionally inspect $? here
    }
};
```

See `perlipc` for fuller patterns.

What the child inherits

- **Open file descriptors**: shared. A `print` in either process advances the same underlying file offset. Close the descriptors the child does not need, and reopen handles the child should not share with the parent - particularly `STDIN`/`STDOUT`/`STDERR` when they are connected to a pipe or socket driving the parent's caller. A backgrounded CGI script that forks and exits without closing its inherited `STDOUT` will leave the HTTP client hanging, because the child still holds the socket open:

  ```
  open STDIN,  '<', '/dev/null' or die $!;
  open STDOUT, '>', '/dev/null' or die $!;
  open STDERR, '>', '/dev/null' or die $!;
  ```

- **Memory**: logically copied, physically copy-on-write. Mutating a large data structure in one side materialises only the touched pages.
- **Process ID**: changes. `$$` (also `$PID` / `$PROCESS_ID` under `English`) is re-read from the kernel on access after a fork, so both parent and child see their own PID.
- **Signal handlers, %ENV, working directory, umask, process group, controlling terminal**: all copied.
- **Pending alarms and timers**: not inherited by the child (per POSIX).
- **Locks held via `flock`**: shared with the parent - both processes hold the same lock on the same open file description. Locks acquired via `fcntl` record locks behave differently; consult `fcntl(2)`.

Examples

Classic fork/exec - launch an external command without going through the shell:

```
my $pid = fork // die "fork: $!";
if ($pid == 0) {
    exec '/usr/bin/gzip', '-9', $file;
    die "exec: $!";                  # only reached if exec fails
}
waitpid $pid, 0;
die "gzip failed: $?" if $?;
```

Fan out N workers, then reap them all:

```
my @kids;
for my $i (1 .. 4) {
    my $pid = fork // die "fork: $!";
    if ($pid == 0) {
        do_work($i);
        exit 0;
    }
    push @kids, $pid;
}
waitpid $_, 0 for @kids;
```

Parent/child communication through a pipe. Open the pipe **before** forking so both sides inherit the two ends:

```
pipe(my $reader, my $writer) or die "pipe: $!";
my $pid = fork // die "fork: $!";
if ($pid == 0) {
    close $reader;
    $writer->autoflush(1);
    print $writer "hello from $$\n";
    exit 0;
}
close $writer;
chomp(my $line = <$reader>);
waitpid $pid, 0;
print "got: $line\n";
```

Note the `close` on the unused end in each process - leave both ends open in both processes and the reader will never see EOF.

Detach a daemon-style child and let the kernel reap it:

```
$SIG{CHLD} = 'IGNORE';
my $pid = fork // die "fork: $!";
if ($pid == 0) {
    # child: will be auto-reaped on exit
    run_background_task();
    exit 0;
}
# parent moves on, never calls wait
```

Edge cases

- **fork inside a thread or after DESTROY-sensitive code**: only the calling thread survives in the child; anything waiting on a mutex or joined thread in another thread is gone. Keep fork points before you spawn threads.
- **Buffered filehandles in the child**: any data still buffered at the moment of fork is present in both processes' buffers. When each side eventually flushes, the bytes are written twice. Autoflush before forking.

- **`exit` in the child runs `END` blocks and `DESTROY`-ers** written by the parent. That is rarely what you want - prefer `POSIX::_exit` in the child after an `exec` failure, or ensure `END` blocks check `$$` against the PID recorded at program start.
- **Error vs child confusion**: `fork` returns `0` legitimately in the child and `undef` on failure. Use `//` and `defined`, never `||` / truth tests.
- **`EAGAIN`**: transient - the kernel's per-user process limit is reached. Retry with a short sleep, or lower your concurrency.
- **Working directory and `chdir` in the child** do not affect the parent. The same is true of `%ENV`, `umask`, and signal handlers: the child has its own copy from the moment of fork on.
- **Seeks on shared descriptors are shared**: if parent and child both write to the same inherited `STDOUT`, their output interleaves at whatever the OS scheduler decides. Coordinate with explicit locking or give each child its own output handle.

Differences from upstream

Fully compatible with upstream Perl 5.44.

pperl targets Linux only, so `fork` is always a real `fork(2)`. Unlike traditional perl5 on Windows - where `fork` is emulated with interpreter-level *pseudo-processes* sharing a single OS process, with the quirks documented in `perlfork` - the pperl `fork` creates an independent OS process with its own PID, address space, and process table entry. Code that assumed pseudo-process semantics (shared global state across "forked" sides) will not port to pperl.

See also

- `exec` - replace the current process image; the typical next call in a child right after `fork`
- `wait` - block until any child exits and return its PID and status in `$?`
- `waitpid` - reap a specific child, optionally non-blocking via `WNOHANG`
- `exit` - terminate the current process; use in the child to end it without falling through into the parent's code
- `pipe` - create a pair of connected filehandles before forking to give parent and child a communication channel
- `$$` - the current process ID, re-read after `fork` so each side sees its own PID
- `%SIG` - in particular `$SIG{CHLD}`, controlling whether children are auto-reaped or must be collected with `wait` / `waitpid`
- `perlipc` - fuller treatment of forking, signals, pipes, and reaping moribund children

I/O

format

Declare a picture-based report template for use by `write`.

`format` is a **declaration**, not an executable statement. It binds a named picture - a block of fixed-column output lines with embedded field markers - to the symbol table, where `write` later looks it up by name. Pictures do not interpolate variables; each picture line is followed by an argument line whose expressions fill the fields in order. `format` is a legacy feature of Perl; upstream notes its use is limited and points at `perlform` for the full field grammar.

Synopsis

```
format NAME =
FORMLIST
.

format =          # declares the "STDOUT" format
FORMLIST
.
```

A `FORMLIST` is a sequence of lines, each one of three kinds: a comment (`#` in column 1), a **picture line**, or an **argument line** supplying values for the picture line immediately above it. A single `.` in column 1 terminates the declaration.

What you get back

`format` is a declaration and has no runtime value. It installs the compiled picture into the current package's format table under `NAME` (or `STDOUT` if `NAME` is omitted). It is not called; it is triggered indirectly by `write`.

The pieces of a picture

Each picture line mixes literal text with **field markers**. A field begins with `@` (regular field) or `^` (special field, used for fill mode and for blankable numeric fields) and extends through pad characters that set both the width and the justification:

- `<` - left-justified text
- `>` - right-justified text
- `|` - centered text
- `#` - right-justified numeric; a leading `0` pads with zeroes; `.` places the decimal point
- `...` - at the tail of a text field, renders three dots when the value was truncated
- `@*` - variable-width field that emits a multi-line scalar verbatim
- `^*` - variable-width field that emits the next line of a scalar and consumes that portion of the source variable

Two suppression tokens may appear anywhere on a picture line and are not part of any field:

- ~ - if every field on this line is empty, the line is suppressed entirely; the ~ itself renders as a space otherwise
- ~~ - like ~, and additionally repeats the line until every field on it is exhausted (every source scalar is empty or every `shift`-style expression returns undef)

`perlform.pod` gives the full grammar of picture lines including fill mode, multi-line fields, overflow (####), and locale-dependent decimal points.

The argument line

The line immediately below a picture line is the **argument line**: a comma-separated list of expressions, one per field, evaluated in list context before the picture is rendered. A single list-returning expression may fill multiple fields. The argument list may be broken across lines if and only if the first token on the first line is an opening brace:

```
format Report =
@<<<<<<<< @>>>>>>
{ $name,
  $score }
.
```

Globals that control `write`

Output through `format` is driven entirely by per-filehandle globals. Each is attached to the **currently selected filehandle**; changing them for another handle requires a `select` dance (see below):

- `$~` - name of the current format used for each record (defaults to the filehandle's own name)
- `$^` - name of the current top-of-page format (defaults to the filehandle's name with `_TOP` appended)
- `$=` - page length in lines (default 60)
- `$-` - lines remaining on the current page; `write` decrements it and triggers the top-of-page format when it reaches zero
- `$%` - current page number, incremented automatically
- `$:` - characters that fill mode (^) may break on (default `" \n-"`)
- `$^L` - string emitted before each top-of-page except the first (default `"\f"`)

Under `use English` these are `$FORMAT_NAME`, `$FORMAT_TOP_NAME`, `$FORMAT_LINES_PER_PAGE`, `$FORMAT_LINES_LEFT`, `$FORMAT_PAGE_NUMBER`, `$FORMAT_LINE_BREAK_CHARACTERS`, and `$FORMAT_FORMFEED`.

Because these are per-handle, setting them for a handle other than the currently selected one needs `select`:

```
my $ofh = select $fh;
$~ = 'Report';
$^ = 'Report_TOP';
select $ofh;
```

Top-of-form

When `write` decrements `$-` to zero, it emits `$^L` (except on the very first page), resets `$-` to `$=`, increments `$%`, and invokes the format named by `$^`. The default top-of-page format name is the filehandle's name with `_TOP` appended, so declaring `STDOUT_TOP` suffices for writes through `STDOUT`.

Examples

A minimal report with a header:

```
format STDOUT_TOP =
        Inventory
Name            Qty   Price
---------------------------
.
format STDOUT =
@<<<<<<<<<<<<<  @>>  @##.##
$name,          $qty, $price
.

for my $row (@rows) {
    ($name, $qty, $price) = @$row;
    write;
}
```

Switching formats for a non-selected handle:

```
open my $fh, '>', 'report.txt' or die $!;
my $ofh = select $fh;
$~ = 'Report';
$^ = 'Report_TOP';
select $ofh;
write $fh;
```

Fill mode with ~~ to drain a multi-line scalar one line at a time:

```
format STDOUT =
Note: ^<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<
      $note
~~    ^<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<
      $note
.
```

The ^ fields consume `$note` as they render; the ~~ line repeats until `$note` is empty.

Edge cases

- **Lexical visibility**: a format sees a `my` variable only when declared inside that variable's scope. A top-level format cannot see `my` variables declared inside a subroutine; use package globals or declare the format inside the sub.

- **Quoted pictures**: if you build a picture with `eval` from a double-quoted string, `@name` looks like an array interpolation. Escape it or use single quotes around the template.
- **A lone `.` is the terminator**: a picture whose literal text would begin with `.` in column 1 must indent that line. This also bites format code sent through naive mail transports that cut at `.` on a line of its own.
- **Numeric overflow**: a #-field narrower than the formatted number renders as #### rather than truncating silently.
- **Locale decimal point**: if `use locale` was in effect when the format was **declared**, `LC_NUMERIC` picks the decimal character. Toggling `use locale` at `write` time does not change the picture.
- **Control characters** inside a fixed-width text field are replaced by spaces to preserve column alignment.
- **Mixing `print` and `write`**: legal on the same handle, but `$-` only tracks lines emitted by `write`. Adjust `$-` manually if interleaved `print` output consumes page lines you care about.
- **No footer mechanism**: there is no `$FORMAT_BOTTOM_NAME`. Footers are done by hand - test `$-` before each `write` and emit the footer yourself when it reaches a threshold.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `write` - render one record through the current format into the selected filehandle; the only way a declared format produces output
- `select` - change which filehandle is current, required when setting `$~`, `$^`, `$=`, `$-`, `$%`, `$:`, or `$^L` for a handle other than `STDOUT`
- `$~` - current format name
- `$^` - current top-of-page format name
- `$=` - page length
- `$-` - lines left on the current page
- `$%` - current page number
- `$:` - fill-mode break characters
- `perlform.pod` - full picture-line grammar, fill-mode rules, `formline` / `$^A` internals, and worked report examples

Misc

formline

Format a list of values into a picture string and append the result to the format accumulator `$^A`.

`formline` is the low-level engine behind Perl's `format` / `write` report mechanism. It takes a `PICTURE` string describing field widths and alignment, interpolates the values from `LIST` into those fields, and appends the resulting text to the global `$^A` accumulator (also known as `$ACCUMULATOR` under `use English`). Every call to `write` flushes `$^A` to the associated filehandle and clears it; outside of `write`, you manage `$^A` yourself - read it for the formatted text, then reset it to `""` before the next call.

`PICTURE` is the same mini-language that `format` uses: `@<<<<` for a left-justified text field, `@>>>>` for right-justified, `@||||` for centered, `@####.##` for a right-justified numeric field with a decimal point, `@*` for an unbounded multi-line text field, and `^<<<` (and friends) for the fill-mode field that consumes its scalar argument incrementally. See `perldoc perlform` for the full picture vocabulary.

Synopsis

```
formline PICTURE, LIST
formline $picture, @values
```

What you get back

`formline` always returns 1. The useful output is the side effect: the formatted text is **appended** to `$^A`. If you need the text as a value, read `$^A` after the call and then clear it:

```
$^A = "";
formline '@<<<<<<<<<  @>>>>', $name, $score;
my $line = $^A;
$^A = "";
```

Because the result goes to an accumulator, consecutive `formline` calls build up multi-line output without any intermediate join.

Global state it touches

- `$^A` - the **format accumulator**. `formline` appends to it; it is never cleared automatically. Also known as `$ACCUMULATOR` under `use English`.
- `$:` - the set of characters on which fill-mode fields (`^*`, `^<<<`) are allowed to break. Defaults to `" \n-"`. Also known as `$FORMAT_LINE_BREAK_CHARACTERS` under `use English`.
- `LC_NUMERIC` locale - if `use locale` is in effect when the picture is compiled, the decimal point character in numeric fields (`@###.##`) follows the locale.
- Fill-mode fields (`^...`) **mutate their scalar arguments in place**, chopping off the portion that was consumed so the next `formline` call picks up where the previous one left off. Pass a copy if you need the original preserved.

Examples

Build one formatted line and read it back:

```
$^A = "";
formline '@<<<<<<<<  @>>>>>', "widget", 42;
print $^A, "\n";            # "widget       42\n"
$^A = "";
```

Build a multi-line block in one call - the picture may contain newlines, and each line of the picture consumes its own values from `LIST`:

```
$^A = "";
formline <<'END', "Alice", 30, "Bob", 25;
@<<<<<<<<<<  @###
@<<<<<<<<<<  @###
END
print $^A;                  # "Alice         30\nBob           25\n"
$^A = "";
```

An `swrite` helper - `formline` is to `write` what `sprintf` is to `printf`:

```
sub swrite {
    my $picture = shift;
    local $^A = "";
    formline $picture, @_;
    return $^A;
}

my $row = swrite '@<<<<<<<<  @>>>>', "total", 1234;
```

Fill-mode field consumes its scalar across repeated calls - note that `$text` shrinks each time:

```
my $text = "the quick brown fox jumps over the lazy dog";
$^A = "";
formline '^<<<<<<<<<<<<<<', $text;
formline "\n";
formline '^<<<<<<<<<<<<<<', $text;
print $^A;                  # two lines, word-broken on spaces
$^A = "";
```

Numeric field with decimal places and overflow filling - a value that does not fit is rendered as # characters:

```
$^A = "";
formline '@##.##', 3.14159;
formline "\n";
formline '@##.##', 9999.9;  # overflow
print $^A;                  # "  3.14\n######\n"
$^A = "";
```

Edge cases

- **Quoting the picture**: inside double quotes, `@` introduces an array interpolation. Write pictures as single-quoted strings or heredocs with a quoted terminator (`<<'END'`) to keep `@` literal. The classic trap: `formline "@<<<<<<<", $name` interpolates `@<` before `formline` ever sees the string.
- **Newlines in the picture**: `formline` does not care how many newlines `PICTURE` contains. The `~` (suppress-if-all-empty) and `~~` (repeat-until-exhausted) tokens treat the whole picture as one logical line, so a record format with `~~` typically needs one `formline` per physical line. A `format` declaration splits a multi-line form into one `formline` call per output line; when calling `formline` directly, you make that split yourself.
- **Accumulator is not cleared**: the most common mistake is forgetting to reset `$^A` between logical uses. Appending is the defined behaviour, not a bug. Use `local $^A = "";` inside helpers.
- **Field count vs. value count**: surplus values in `LIST` are silently ignored; missing values render as empty (regular field) or blanked (special `^` numeric field).
- **`undef` in a regular field** stringifies to the empty string under `use warnings` and triggers a `uninitialized` warning. A special field (`^###`) blanks the whole field on undef without warning.
- **Using a format scalar - capturing `write` output**: opening a filehandle onto a scalar reference is often easier than driving `formline` manually:

```
open my $fh, ">", \my $out or die $!;
format FH =
@<<<<<<<<  @>>>>
$name,     $score
.
$~ = "FH";
select((select($fh), $~ = "FH")[0]);
write $fh;
```

  Reach for `formline` directly when you want the picture-to-string path without involving a filehandle or a named `format` declaration.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `write` - drives one or more `formline` calls from a named `format` and flushes `$^A` to a filehandle
- `format` - declaration syntax for the picture/value pairs that `write` feeds into `formline`
- `sprintf` - the other "format into a string" primitive; use `sprintf` for `printf`-style %-directives, `formline` for fixed-width report columns and fill-mode text blocks

- `$^A` - the accumulator `formline` writes into; read it for the result, clear it before the next logical use
- `$:` - characters that fill-mode fields (^*, ^<<<) may break on

I/O

getc

Read the next single character from a filehandle.

`getc` returns one character of input from `FILEHANDLE`, advancing the handle's read position by that character. If `FILEHANDLE` is omitted, `getc` reads from `STDIN`. At end-of-file or on a read error, `getc` returns `undef` and - in the error case - sets `$!`. The unit is a **character**, not a byte: under a `:utf8` or `:encoding(...)` PerlIO layer a single call consumes however many bytes make up one decoded codepoint.

Synopsis

```
getc FILEHANDLE
getc
```

What you get back

A one-character string on success, or `undef` at end-of-file or on error. Distinguish the two by checking `$!`:

```
my $ch = getc $fh;
if (!defined $ch) {
    die "read error: $!" if $!;
    # otherwise clean EOF
}
```

Because `undef` collapses with the empty string `""` under stringy comparisons, always test with `defined`, never with `length` or a string match.

Global state it touches

- `$!` - set when `getc` returns `undef` because of a read error (not set for a clean end-of-file).
- The current input filehandle - the no-argument form reads from `STDIN`, not from the handle selected with `select`. `select` governs default output, not default input.
- The handle's PerlIO layer stack - determines whether the returned scalar is a byte or a decoded character, and whether CRLF translation is applied on the way in.

Examples

Read one character from `STDIN`:

```
my $ch = getc;
print "got: $ch\n" if defined $ch;
```

Read from an explicit filehandle and detect end-of-file:

```
open my $fh, "<", "input.txt" or die "open: $!";
while (defined(my $ch = getc $fh)) {
    print $ch;
}
close $fh;
```

Read characters, not bytes, from a UTF-8 file. Each call returns one decoded codepoint even when the underlying byte stream uses multi-byte sequences:

```
open my $fh, "<:encoding(UTF-8)", "utf8.txt" or die $!;
my $ch = getc $fh;      # e.g. "ä" as one character, even though
                        # it occupies two bytes on disk
```

Consume a yes/no prompt without waiting for a whole line - requires turning off terminal line buffering first (see *Edge cases*):

```
print "continue? [y/n] ";
system "stty", "-icanon", "eol", "\001";
my $key = getc(STDIN);
system "stty", "icanon", "eol", "^@";
print "\n";
exit unless defined $key and lc $key eq "y";
```

Edge cases

- **Terminal line buffering**: on an interactive `STDIN`, the terminal driver hands Perl nothing until the user presses Enter, so `getc` blocks until a full line is available and then returns only its first character. `getc` itself cannot bypass this. To read a single keypress, put the terminal into non-canonical ("cbreak") mode first - shell out to `stty`, use `POSIX::termios` via the `POSIX` module for a portable in-process solution, or use the CPAN module `Term::ReadKey` for a friendlier interface. Remember to restore the terminal mode on exit, including from signal handlers.
- **Bytes vs characters under I/O layers**: the return value is whatever the handle's layer stack produces. A bytes-mode handle yields one byte per call; a `:utf8` or `:encoding(...)` handle yields one decoded character per call, consuming as many bytes off the stream as that character takes. Malformed input under a decoding layer triggers the layer's usual warning or error rather than silently returning garbage.
- **End-of-file vs error**: both return `undef`. `$!` is cleared before the call is entered but only set when an actual read error occurred, so `defined $ch or $! and die ...` is the idiom.
- **Closed or unopened filehandle**: returns `undef` and sets `$!` to `Bad file descriptor`. Under `use warnings` a `getc() on closed filehandle` warning is emitted.

- **Efficiency**: `getc` is one-character-at-a-time, which crosses the PerlIO layer stack per call. For bulk scanning, `read`, `sysread`, or `readline` are substantially faster; reserve `getc` for interactive prompts and protocol parsers that genuinely need character-at-a-time control.
- **Default handle is `STDIN`, not `ARGV`**: unlike the diamond operator `<>`, `getc` without an argument does not walk `@ARGV` or fall back to the magic `ARGV` handle - it reads `STDIN` directly.
- **Wide terminal input**: reading a character from a terminal in raw mode still returns one codepoint only when the input layer decodes UTF-8. A paste containing a multi-byte character under a bytes-mode handle surfaces as several separate `getc` calls, one per byte.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `read` - read a fixed number of characters or bytes in one call, much faster than looping `getc`
- `readline` - read one whole record (line) at a time, governed by `$/`
- `sysread` - unbuffered read straight from the OS, bypassing the PerlIO layer stack
- `eof` - test whether the next `getc` / `readline` would return `undef` for end-of-file
- `$!` - errno set when `getc` returns `undef` because of a read error

User and group info

getgrent

Read the next entry from the system group database.

`getgrent` walks the host's group database one entry at a time, the way a plain loop over `/etc/group` would read it line by line, and returns a Perl-shaped view of each record. It is the iterator form of the group lookups - use it when you want every group, or every group matching some predicate. For single-entry lookup by name or gid, reach for `getgrnam` or `getgrgid` instead.

A first call to `getgrent` implicitly opens the database. Iteration continues across further calls until the database is exhausted, at which point `getgrent` returns the empty list (or `undef` in scalar context). Call `setgrent` to rewind to the start, or `endgrent` to close the database and free any resources the C library is holding.

Synopsis

```
my ($name, $passwd, $gid, $members) = getgrent;
my $name                            = getgrent;        # scalar␣
↪context
```

What you get back

In **list context**, a four-element list - one entry per group:

Index	Field	Meaning
0	`$name`	Group name (e.g. `"wheel"`)
1	`$passwd`	Group password, typically `"x"` on shadow-password hosts
2	`$gid`	Numeric group id
3	`$members`	Space-separated string of member login names

When iteration runs off the end, the return is the empty list. If you write `if (my @gr = getgrent)` the loop terminates cleanly on end-of-database.

In **scalar context**, `getgrent` returns just `$name`. When the database is exhausted, it returns `undef` - which is the signal most scripts test against to end a `while` loop.

`$members` is a plain string, not an array. Split it on whitespace when you need the list:

```
my @logins = split ' ', $members;
```

Global state it touches

`getgrent` keeps **per-process iteration state** inside the C library (conceptually a file position inside the group database). Two calls in the same process share that state; a nested loop that calls `getgrent` inside another `getgrent` loop will interleave records and miss most of them. Serialise the passes, or capture all entries into an array first:

```
my @all;
while (my @gr = getgrent) { push @all, [ @gr ] }
endgrent;
```

The iterator is not reset when a subroutine returns. If library code you do not control calls `getgrent`, it moves your position. Guard with `setgrent` when you need a clean start.

Examples

Walk every group and print the name and member count:

```
while (my ($name, undef, $gid, $members) = getgrent) {
    my $n = length $members ? scalar(split ' ', $members) : 0;
    printf "%-16s gid=%d members=%d\n", $name, $gid, $n;
}
endgrent;
```

Collect all groups a given login belongs to:

```
my $user = 'alice';
my @groups;
while (my ($name, undef, undef, $members) = getgrent) {
```

(continues on next page)

(continued from previous page)

```
    push @groups, $name
        if grep { $_ eq $user } split ' ', $members;
}
endgrent;
```

Scalar context - list every group name, one per line:

```
while (defined(my $name = getgrent)) {
    print $name, "\n";
}
endgrent;
```

Rewind and re-read, for example to build two indexes in one pass each:

```
setgrent;
my %by_name = map { $_->[0] => $_ }
              map { [ getgrent ] } 1 .. ();   # collect…
# …or just loop twice with an explicit setgrent before each pass.
setgrent;
while (my @gr = getgrent) { ... }
endgrent;
```

Convert a numeric gid from `stat` to a group name without a second lookup by caching the iterator output:

```
my %name_of;
while (my ($name, undef, $gid) = getgrent) {
    $name_of{$gid} = $name;
}
endgrent;

my $gid = (stat $path)[5];
print "group: $name_of{$gid}\n";
```

Edge cases

- **End of iteration vs. a real entry**: in list context, an exhausted database returns the empty list - which assigns as zero elements, so `my @gr = getgrent; @gr or last;` is the idiomatic termination test. In scalar context, test with `defined` rather than truthiness, since a legitimate group name could in principle be the string `"0"`.
- **No password field on modern Linux**: `$passwd` is almost always `"x"` (real hashes live in `/etc/gshadow`). Do not treat a non-`"x"` value as "password set" without consulting the shadow database.
- **Empty `$members`**: groups with no explicit members (users listed only by primary gid) have `$members` as the empty string. `split ' ', ""` returns an empty list - the idiomatic way to get members as an array without a special case.
- **Implicit primary-gid membership is not reported**: `$members` lists only the users explicitly named in the group's `/etc/group` record. A user whose primary gid

matches this group but who is not also listed in the `members` field does **not** appear. Cross-check with `getpwent` if you need both kinds of membership.

- **Nested iteration clobbers position**: a second `getgrent` loop started before the first one finishes shares the same cursor. Use `setgrent` between passes, or snapshot the database into memory up front.
- **Taintedness**: the `$passwd` field is tainted under `-T`, same as for `getpwent` - treat it as untrusted input even though the usual value is `"x"`.
- **Process-wide, not thread-wide**: on systems without thread-safe variants the iteration state is per process, not per thread. Two threads walking `getgrent` at once will miss records.
- **`endgrent` is optional but polite**: leaving the database open to program exit works, but if you are done iterating, call `endgrent` so the C library can drop its buffers.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `getgrnam` - single lookup by group name; use when you already know the name and want just one record
- `getgrgid` - single lookup by numeric gid; the usual partner of `stat` when you need a group name for a file
- `setgrent` - rewind the iterator to the start of the group database before another full-scan pass
- `endgrent` - close the database and release any resources the C library holds open
- `getpwent` - the parallel iterator over the passwd database; pair with `getgrent` when resolving full user-to-group relationships
- `scalar` - force scalar context when you only need the group name and want to skip the other fields

User and group info

getgrgid

Look up a group record by numeric group ID.

`getgrgid` asks the system group database for the entry whose `gid` is `GID` and returns what it finds. It is the numeric counterpart of `getgrnam` and mirrors the C library call `getgrgid(3)`. In list context you get the unpacked record fields; in scalar context you get the group name.

Synopsis

```
my ($name, $passwd, $gid, $members) = getgrgid($gid);
my  $name                           = getgrgid($gid);
```

What you get back

In **list context**, four values unpacked from `struct group`:

```
#    0        1         2      3
my ( $name,  $passwd,  $gid,  $members ) = getgrgid($gid);
```

- `$name` - the group name.
- `$passwd` - the group password field. On modern systems this is typically `"x"` or empty; real hashes live in a shadow database.
- `$gid` - the numeric group ID (the same number you passed in, echoed back from the record).
- `$members` - a **single space-separated string** of member login names, not a list. Split it yourself when you need an array:

  ```
  my @users = split / /, (getgrgid($gid))[3];
  ```

In **scalar context**, just the group name:

```
my $name = getgrgid(0);    # "root" on most Linux systems
```

If no group with the given `GID` exists, the function returns the empty list in list context and `undef` in scalar context. A system-level failure (e.g. NSS backend unreachable) is reported the same way; check `$!` if you need to distinguish.

Global state it touches

- `$!` - set on system-level failure of the underlying `getgrgid(3)` call. Not set when the `GID` simply has no matching entry; that is a normal "not found", not an error.
- The process-wide group-database iteration cursor maintained by libc. `getgrgid` does **not** advance or reset the cursor used by `getgrent`, `setgrent`, and `endgrent`, but it shares the same underlying file descriptor on most implementations - interleaving direct lookups with iteration is portable in theory and surprising in practice.

Examples

Look up the primary group name for the current process:

```
my $group = getgrgid($();           # $( is the real GID
print "running as group: $group\n";
```

Resolve a file's group ID to a name, with a sensible fallback for orphaned GIDs (files owned by a group that no longer exists):

```
my $gid   = (stat $file)[5];
my $name  = getgrgid($gid) // "<unknown gid $gid>";
```

Unpack the full record and list the members:

```
if (my ($name, undef, $gid, $members) = getgrgid(100)) {
    my @users = split / /, $members;
    print "group $name ($gid) has ", scalar(@users), " members\n";
}
```

Guard against the "no such group" case explicitly - the empty list in boolean/list context is already falsy, so an `if` suffices:

```
unless (my @gr = getgrgid($gid)) {
    die "no group with gid $gid\n";
}
```

Pair with `getpwuid` to render a directory listing's owner and group columns:

```
my @st   = stat $path                 or die "stat $path: $!";
my $user = getpwuid($st[4]) // $st[4];
my $grp  = getgrgid($st[5]) // $st[5];
printf "%-8s %-8s %s\n", $user, $grp, $path;
```

Edge cases

- **Scalar vs list context matters.** `getgrgid($gid)` in scalar context yields only the group name; wrap in parentheses or assign to a list to get the full record:

  ```
  my $name    = getgrgid(0);              # "root"
  my @record  = getgrgid(0);              # four-element list
  my $gid_out = (getgrgid(0))[2];         # the gid field
  ```

- **`$members` is a string, not an array.** The whitespace-joined form is historical and matches perl5's `pp_gpwent` / `pp_ggrent` output. Splitting on `/ /` (single space) is the canonical idiom; splitting on `/\s+/` is slightly more forgiving if a backend ever uses tabs.

- **Empty groups** return `$members` as the empty string. `split / /, ""` yields the empty list, which is what callers usually want.

- **Numeric coercion.** `GID` is passed to the C call as an integer. A non-numeric scalar is coerced: `"0root"` becomes `0`. Pass a clean integer.

- **GID namespace overlap.** Multiple group entries with the same `gid` are legal in `/etc/group` and in NSS. `getgrgid` returns **one** of them - which one is backend-defined. Do not rely on which name comes back when GIDs collide; use `getgrnam` for the reverse direction when the name matters.

- **NSS / nsswitch.conf.** The lookup follows the system's name service switch - `files`, `sss`, `ldap`, etc. A successful lookup in a test harness on one host may fail on another with a different NSS configuration. This is a property of the C library, not of Perl.

- **Large groups.** Very large group-member lists (hundreds of members) can arrive truncated if the backend's internal buffer is smaller than the rendered line. This is a libc / NSS limitation; Perl faithfully surfaces whatever the system returned.
- **Threaded builds.** On systems that provide `getgrgid_r`, perl transparently calls the reentrant variant. Callers see no difference.
- **Taint.** Under `-T`, `$passwd` and `$members` come back tainted - the first because it may encode credentials, the second because administrators can change it. `$name` and `$gid` are not tainted.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `getgrnam` - the inverse lookup: group record by name rather than by `gid`
- `getgrent` - iterate every group entry when you need to scan rather than look up
- `setgrent` and `endgrent` - reset and release the iteration cursor used by `getgrent`
- `getpwuid` - the passwd-side counterpart; pair with `getgrgid` to render owner/group columns
- `User::grent` - by-name accessor object that overrides `getgrgid` when you prefer `$gr->name` over positional unpacking

User and group info

getgrnam

Look up a Unix group by name and return its `/etc/group` record.

`getgrnam` wraps the C library's `getgrnam(3)`. Given a group name like `"wheel"` or `"staff"`, it returns the matching record from the system's group database - the name, the encrypted password placeholder, the numeric GID, and the list of member login names. Use it when you have a group name in hand and need the GID or the membership list; use `getgrgid` for the inverse lookup.

Synopsis

```
my ($name, $passwd, $gid, $members) = getgrnam NAME
my $gid = getgrnam NAME
```

What you get back

List context yields a four-element list:

```
my ($name, $passwd, $gid, $members) = getgrnam "wheel";
```

Index	Field	Meaning
0	`$name`	canonical group name (same as `NAME` on hit)
1	`$passwd`	group password field, typically `"x"` or empty
2	`$gid`	numeric group ID
3	`$members`	space-separated string of member login names

`$members` is a single scalar, **not** an array. Split it yourself when you want a list:

```
my @logins = split /\s+/, (getgrnam("wheel"))[3];
```

Scalar context yields the numeric GID (the "other thing", since the lookup was by name):

```
my $gid = getgrnam "wheel";
```

No such group: list context returns the empty list; scalar context returns `undef`. Test scalar returns for definedness rather than truth - GID `0` (`root`) is a valid hit that is also false:

```
defined(my $gid = getgrnam $group) or die "no group '$group'";
```

Global state it touches

None directly. `getgrnam` is a stateless lookup - unlike `getgrent`, it does not advance the group-database iterator, and `setgrent` / `endgrent` do not affect it. It does, however, share the underlying C library's static result buffer with other `getgr*` calls on platforms without thread-safe variants; copy the fields you care about before calling another `getgr*` function.

Examples

Resolve a group name to its GID:

```
my $gid = getgrnam "wheel";
defined $gid or die "no 'wheel' group on this system";
print "wheel GID = $gid\n";
```

List the members of a group:

```
my @fields = getgrnam "staff"
    or die "no 'staff' group";
my @members = split /\s+/, $fields[3];
print "staff has ", scalar(@members), " members: @members\n";
```

Use a group name to set the effective GID (requires privilege):

```
my $gid = getgrnam "video"
    // die "no 'video' group";
$) = "$gid $gid";                   # effective + supplementary
```

Check whether a user is listed as a group member. Note that the primary group (the user's GID in `/etc/passwd`) is **not** in `$members` - check both:

```
sub in_group {
    my ($user, $group) = @_;
    my @g = getgrnam $group or return 0;
    return 1 if grep { $_ eq $user } split /\s+/, $g[3];
    my @u = getpwnam $user or return 0;
    return $u[3] == $g[2];          # primary group match
}
```

Object-oriented form via `User::grent`, which overrides the built-in with a by-name record:

```
use User::grent;
my $g = getgrnam "wheel";
printf "wheel: gid=%d members=%s\n", $g->gid, "@{$g->members}";
```

Edge cases

- **Missing group**: list context returns `()`, scalar returns `undef`. A bare `if (getgrnam $g)` is fine in list context but wrong in scalar context when the GID could be `0`:

  ```
  if (defined(my $gid = getgrnam $g)) { ... }   # correct
  if (my $gid = getgrnam $g)           { ... }  # wrong for GID 0
  ```

- **Members is a string, not a list**. Forgetting this and writing `scalar @members = getgrnam $g` (or indexing `$members[0]`) silently gives wrong results. Always `split /\s+/` the fourth field.
- **Primary-group members are absent from the list**. A user whose `/etc/passwd` GID matches the group is a member in the kernel's eyes but will not appear in `$members`. Lookups that classify users by group must consult `getpwnam` too.
- **Password field is not a password**. On every modern Linux the second field is `"x"` (shadow redirection) or empty. It is never the plaintext or hash of a group password. Do not rely on its format.
- **Case sensitivity**: group names are case-sensitive on Linux. `getgrnam "Wheel"` does not find `wheel`.
- **Name with embedded whitespace or colon**: the group database format does not allow either, so such names cannot exist; the lookup simply fails.
- **NSS backends**: on systems configured with LDAP, SSSD, or other name-service switch modules, `getgrnam` consults those as well as `/etc/group`. Results therefore depend on `/etc/nsswitch.conf` and the configured backends, not on `/etc/group` alone.
- **Taint**: the fields come from outside the program, so under `-T` they are tainted and must be laundered before use in sensitive operations.
- **Thread safety**: pperl automatically substitutes the thread-safe `getgrnam_r` when the platform provides it. On platforms without it, concurrent `getgr*` calls across

threads can clobber each other's results.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `getgrgid` - inverse lookup by numeric GID; reach for this when you have the GID and want the group name or member list
- `getgrent` - iterate every group in the database when you do not know the name or GID in advance
- `setgrent` - rewind the `getgrent` iterator to the start of the group database
- `endgrent` - close the group-database file descriptor opened by iteration
- `getpwnam` - the parallel call for the user database; use alongside `getgrnam` when you need to resolve a user's primary group
- `User::grent` - object-oriented wrapper that overrides `getgrnam` to return a record object with named accessors (`name`, `passwd`, `gid`, `members`) instead of a positional list

Network info

gethostbyaddr

Look up a host record by its packed IP address.

`gethostbyaddr` performs a reverse DNS lookup: given a packed binary address (four bytes for IPv4, sixteen for IPv6) and the matching address family, it calls the system's C `gethostbyaddr(3)` routine and returns the host record. The typical use case - *"whose machine is this packet from?"* - wants the scalar-context form: a single hostname. The list-context form exposes the full `struct hostent`: canonical name, aliases, address family, address length, and every address the resolver knows for that host.

Synopsis

```
my $name = gethostbyaddr $packed_addr, $addrtype;
my ($name, $aliases, $addrtype, $length, @addrs) = gethostbyaddr
 ↪$packed_addr, $addrtype;
```

What you get back

Scalar context - the canonical hostname as a plain string, or `undef` if the reverse lookup fails.

List context - a five-element list mirroring the C `struct hostent`:

- `$name` - the canonical hostname the resolver mapped the address to.
- `$aliases` - a space-separated string of alternate names. Single scalar, not a list.

- `$addrtype` - the address family of the returned addresses, typically `AF_INET` (2) or `AF_INET6` (10).
- `$length` - the length of each address in bytes (4 for IPv4, 16 for IPv6).
- `@addrs` - every address returned for the host, each a packed binary string of `$length` bytes. Often just one, but multi-homed hosts can yield several.

On lookup failure in list context, the return is the empty list.

Global state it touches

- `$?` - set to the C `h_errno` value on failure, when the platform exposes it. Test with `$? != 0` to distinguish `HOST_NOT_FOUND` from `TRY_AGAIN` and similar transient errors.
- `$!` - not meaningfully set by DNS failures. Reverse lookups fail via `h_errno`, not `errno`; do not check `$!` after a failed call.
- The host database iteration cursor shared with `gethostent`, `sethostent`, and `endhostent`. A call to `gethostbyaddr` may reset a cursor left open by `gethostent`.

Examples

Scalar form - map a dotted-quad to a hostname:

```
use Socket;
my $packed = inet_aton("127.0.0.1");
my $name   = gethostbyaddr($packed, AF_INET);
print defined $name ? "$name\n" : "no PTR record\n";
```

Round-trip - forward lookup, then reverse the first address:

```
use Socket;
my $packed = gethostbyname("www.perl.org");
my $name   = gethostbyaddr($packed, AF_INET);
print "$name\n";
```

Identify the peer on an accepted socket connection:

```
use Socket;
my $peer = getpeername($sock);
my ($port, $iaddr) = sockaddr_in($peer);
my $host = gethostbyaddr($iaddr, AF_INET);
printf "connection from %s:%d\n", $host // inet_ntoa($iaddr), $port;
```

List form - every name and address the resolver knows for the host:

```
use Socket;
my $packed = inet_aton("8.8.8.8");
my ($name, $aliases, $type, $len, @addrs) = gethostbyaddr($packed,␣
↪AF_INET);
```

(continues on next page)

(continued from previous page)

```
print "canonical: $name\n";
print "aliases:   $_\n" for split ' ', $aliases;
print "address:   ", inet_ntoa($_), "\n" for @addrs;
```

By-name interface via the `Net::hostent` override - accessor methods instead of positional unpacking:

```
use Net::hostent;
use Socket;
my $h = gethostbyaddr(inet_aton("127.0.0.1"), AF_INET);
print $h->name, "\n" if $h;
```

Edge cases

- **`ADDR` is a packed binary string, not a dotted-quad.** Passing `"127.0.0.1"` directly does not work - Perl will call the resolver with nine raw bytes and get nothing useful back. Always go through `Socket::inet_aton`, `Socket::inet_pton`, or an equivalent packer first.
- **`ADDRTYPE` must match the address width.** `AF_INET` wants a four-byte `ADDR`; `AF_INET6` wants sixteen. A mismatch either returns `undef` or, on some platforms, reads past the buffer. Use the constant from `Socket`, not a hand-typed integer.
- **Check for `undef` on the scalar form.** A missing PTR record returns `undef`, not an empty string. Many addresses on the public internet have no reverse mapping at all.
- **`@addrs` may not include the address you queried.** The resolver returns the full record for the canonical host, which may contain additional addresses that happen to share the hostname.
- **Scalar context runs the full resolver call anyway.** The C routine always populates the whole `hostent`; Perl just discards the list. There is no performance advantage to the scalar form beyond clearer code.
- **Reverse of a forward lookup is not guaranteed to round-trip.** `gethostbyaddr(gethostbyname($h), AF_INET)` may return a different name from `$h` - reverse DNS maps to the canonical hostname, which often differs from the alias the forward query used.
- **IPv6 support is platform-dependent.** Not every libc's `gethostbyaddr(3)` handles `AF_INET6` cleanly. For portable dual-stack reverse resolution use `Socket::getnameinfo`.
- **Thread safety.** The underlying C routine keeps per-process static state for the host cursor. Concurrent calls from multiple threads may interleave results. Scripts that need thread-safe reverse resolution should use `Socket::getnameinfo`.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `gethostbyname` - the forward lookup: hostname → packed address
- `gethostent` - iterate every entry in the host database instead of looking up one address
- `sethostent` - rewind the host iterator and control whether the file stays open across lookups
- `Socket::inet_aton` - build the packed `ADDR` argument from a dotted-quad string
- `Socket::inet_ntoa` - render a packed address from `@addrs` back to dotted-quad form
- `Socket::getnameinfo` - modern, protocol-agnostic reverse resolver that handles IPv6 and is thread-safe

Network info

gethostbyname

Look up a host record by DNS name.

`gethostbyname` resolves a hostname to its IP address(es) and canonical record by calling the system's C `gethostbyname(3)` routine. The typical use case - *"give me the packed IP of this host"* - wants the scalar-context form and nothing more. The list-context form exposes the full host record: canonical name, aliases, address family, address length, and every address on file.

Synopsis

```
my $packed_ip = gethostbyname $name;
my ($name, $aliases, $addrtype, $length, @addrs) = gethostbyname
 ↪$name;
```

What you get back

Scalar context - the first IP address as a packed binary string (four bytes for IPv4, sixteen for IPv6), or `undef` if the lookup fails. Convert to a dotted-quad with `Socket::inet_ntoa`:

```
use Socket;
my $packed = gethostbyname("www.perl.org");
my $dotted = inet_ntoa($packed) if defined $packed;
```

List context - a five-element list mirroring the C `struct hostent`:

- `$name` - the canonical hostname.
- `$aliases` - a space-separated string of alternate names.

- `$addrtype` - the address family, typically `AF_INET` (2) or `AF_INET6` (10).
- `$length` - the length of each address in bytes (4 for IPv4, 16 for IPv6).
- `@addrs` - every address returned for the name, each a packed binary string of `$length` bytes.

On lookup failure in list context, the return is the empty list.

Global state it touches

- `$?` - set to the C `h_errno` value on failure, when the platform exposes it. Test with `$? != 0` to distinguish "no such host" (`HOST_NOT_FOUND`) from "try again" (`TRY_AGAIN`) and similar.
- The host database iteration cursor shared with `gethostent`, `sethostent`, and `endhostent`. A call to `gethostbyname` may reset a cursor left open by `gethostent`.

Examples

Scalar form - the common case:

```
use Socket;
my $packed = gethostbyname("localhost");
defined $packed or die "cannot resolve localhost: $!";
print inet_ntoa($packed), "\n";      # 127.0.0.1
```

List form - enumerate every address for a multi-homed host:

```
use Socket;
my ($name, $aliases, $type, $len, @addrs) = gethostbyname("www.
↪example.com");
for my $addr (@addrs) {
    print inet_ntoa($addr), "\n";
}
```

Unpack an IPv4 address by hand, without `Socket`:

```
my $packed = gethostbyname("127.0.0.1");
my ($a, $b, $c, $d) = unpack("W4", $packed);
print "$a.$b.$c.$d\n";               # 127.0.0.1
```

Forward then reverse - resolve a name, then look the address back up:

```
use Socket;
my $packed = gethostbyname("www.perl.org");
my $back   = gethostbyaddr($packed, AF_INET);
print "$back\n";
```

By-name interface via the `Net::hostent` override - accessor methods instead of positional unpacking:

```
use Net::hostent;
my $h = gethostbyname("www.perl.org");
print $h->name, " ", join(",", @{$h->aliases}), "\n";
```

Edge cases

- **Always call in scalar context when you want "the IP".** The list-context form is never what a quick resolver wants and allocates four extra return values. The upstream docs flag this explicitly: *"Make sure* `gethostbyname` *is called in SCALAR context and that its return value is checked for definedness."*
- **Check for `undef` on the scalar form.** A failed lookup returns `undef`, not an empty string. A literal `0.0.0.0` address, by contrast, is a valid four-byte packed string and stringifies to the zero byte sequence, not to `undef`.
- **`@addrs` may be empty** in list context even when the first four return values are defined - some resolvers produce a record with no addresses. Always iterate, don't index `[0]` blindly.
- **Aliases are one scalar, not a list.** `$aliases` is a single space-separated string. Split on whitespace if you need a list.
- **Numeric IP strings are accepted.** Passing `"127.0.0.1"` returns the packed form of that address without a DNS round-trip - the resolver short-circuits numeric input.
- **IPv6.** `gethostbyname` queries only the IPv4 (`AF_INET`) address family. For dual-stack resolution use `Socket::getaddrinfo`, which returns records for every address family the host offers.
- **Thread safety.** The underlying C routine keeps per-process static state for the host cursor. Concurrent calls from multiple threads may interleave results. Scripts that need thread-safe resolution should use `Socket::getaddrinfo`.
- **`h_errno` vs `$!`.** DNS failures set `h_errno` (exposed via `$?`), not `errno` / `$!`. Checking `$!` after a failed `gethostbyname` is meaningless.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `gethostbyaddr` - the reverse lookup: packed address → host record
- `gethostent` - iterate every entry in the host database instead of looking up one name
- `sethostent` - rewind the host iterator and control whether the file stays open across lookups
- `Socket::inet_ntoa` - turn the packed scalar-context result into a dotted-quad string

- `Socket::inet_aton` - the pure name-to-packed helper when you don't need the full host record
- `unpack` - decode the packed address manually when `Socket` is not available

Network info

gethostent

Fetch the next entry from the host database.

`gethostent` walks the host database - on traditional Unix systems the `/etc/hosts` file, on modern systems whatever NSS source is configured - returning one record per call until the database is exhausted. Use it when you want to enumerate every known host, not when you want to resolve a single name: `gethostbyname` is the right tool for a targeted lookup.

The iteration cursor is shared with `sethostent` (which rewinds it) and `endhostent` (which closes it). Between those two calls `gethostent` yields each record in order, then returns the empty list (or `undef` in scalar context) once the end of the database is reached.

Synopsis

```
my ($name, $aliases, $addrtype, $length, @addrs) = gethostent;
my $name = gethostent;
```

What you get back

List context - a five-element list mirroring the C `struct hostent`:

- `$name` - the canonical hostname for this entry.
- `$aliases` - a space-separated string of alternate names.
- `$addrtype` - the address family, typically `AF_INET` (2) or `AF_INET6` (10).
- `$length` - the length in bytes of each address (4 for IPv4, 16 for IPv6).
- `@addrs` - every address recorded for this host, each a packed binary string of `$length` bytes.

At end-of-database the return is the empty list. A distinction worth keeping in mind: the upstream perlfunc note that a missing entry may return *"a single meaningless true value"* applies to the by-name and by-address lookups, not to `gethostent` - iteration past the end is a clean empty list.

Scalar context - the canonical `$name` only, or `undef` at end-of-database. Use list context whenever you need anything beyond the name; reconstructing the other fields is not possible after the fact.

Convert a packed address from `@addrs` with `Socket::inet_ntoa` for IPv4 or `unpack` directly:

```
use Socket;
print inet_ntoa($addrs[0]), "\n";
```

Global state it touches

- The **host database cursor**, shared with `sethostent`, `endhostent`, `gethostbyname`, and `gethostbyaddr`. A by-name or by-address lookup may reset or invalidate a cursor left mid-iteration by `gethostent`; don't interleave the two styles without a fresh `sethostent` between them.
- `$?` - set to the C `h_errno` value on failure, where the platform exposes it. A plain end-of-database is not a failure and leaves `$?` alone.
- `$!` - `gethostent` is a database iterator, not a syscall wrapper in the `open`/`read` sense. DNS and NSS errors surface through `h_errno` (via `$?`), not through `$!`.

Examples

Enumerate every host in the database:

```
use Socket;
sethostent(1);
while (my ($name, $aliases, $type, $len, @addrs) = gethostent) {
    my @dotted = map { inet_ntoa($_) } @addrs;
    print "$name  @dotted\n";
}
endhostent;
```

Scalar context - list just the canonical names:

```
sethostent(0);
while (defined(my $name = gethostent)) {
    print "$name\n";
}
endhostent;
```

Build a name-to-address hash in one pass, then look up entries locally without further DNS calls:

```
use Socket;
my %ip_of;
sethostent(1);
while (my ($name, $aliases, undef, undef, @addrs) = gethostent) {
    next unless @addrs;
    $ip_of{$name} = inet_ntoa($addrs[0]);
    $ip_of{$_}    = inet_ntoa($addrs[0]) for split ' ', $aliases;
}
endhostent;

print $ip_of{"localhost"} // "not in hosts DB", "\n";
```

By-record interface via the `Net::hostent` override - accessor methods instead of positional unpacking:

```
use Net::hostent;
while (my $h = gethostent) {
    printf "%-30s %s\n", $h->name, join(",", @{$h->aliases});
}
```

Edge cases

- **No implicit rewind.** `gethostent` does not open or rewind the database on its own. First call after program start works because the C library lazily opens the database, but once the end is reached further calls keep returning end-of-database until a `sethostent` rewinds the cursor. Always pair enumeration with an explicit `sethostent` / `endhostent`.
- **`STAYOPEN` argument to `sethostent`.** Passing a true value asks the library to keep the database file open across lookups, which matters for NSS sources that otherwise reconnect on every call. Passing `0` permits the library to close and reopen between calls.
- **End-of-database is the empty list, not `undef`.** In list context the loop condition `while (my @r = gethostent)` works because the empty list is false. In scalar context use `while (defined(my $name = gethostent))` - a hostname of `"0"` is theoretically valid and would falsely terminate a truthiness-based loop.
- **`@addrs` may be empty** even for a returned record on some NSS backends. Guard the address-unpacking step:

  ```
  next unless @addrs;
  ```

- **Aliases are one scalar, not a list.** `$aliases` is a single space-separated string. Split on whitespace if you want a list.
- **NSS source mix.** On glibc-based systems the hosts database may draw from `/etc/hosts`, DNS, mDNS, and other NSS modules depending on `nsswitch.conf`. DNS-backed NSS modules typically do **not** enumerate - `gethostent` against a DNS-only hosts database returns the empty list immediately. On most real deployments only the `files` source contributes entries to iteration.
- **Interleaving with by-name / by-address lookups.** A call to `gethostbyname` or `gethostbyaddr` can reset the shared cursor. Finish the iteration first, or restart it with `sethostent` after the lookup.
- **Thread safety.** The underlying C routine keeps per-process static state for the iteration cursor. Concurrent calls from multiple threads interleave results unpredictably. Confine enumeration to a single thread.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `sethostent` - rewind the iterator and control whether the database stays open across calls
- `endhostent` - close the iterator and release the database handle
- `gethostbyname` - targeted lookup by name instead of full enumeration
- `gethostbyaddr` - targeted reverse lookup by packed address
- `getnetent` - same iteration pattern for the networks database
- `Socket::inet_ntoa` - turn a packed address from `@addrs` into a dotted-quad string

User and group info

getlogin

Return the login name of the user associated with the controlling terminal.

`getlogin` wraps the C library function of the same name. On Linux it consults the kernel's record of who owns the current controlling terminal - traditionally recorded in `/var/run/utmp` - and returns that name as a string. It answers the question *"who logged in on this tty?"*, which is **not** the same question as *"who is running this process?"*. A process that has changed its real or effective UID, or that has no controlling terminal at all (a daemon, a cron job, a container entrypoint), will usually see `getlogin` return the empty string or `undef`.

Synopsis

```
my $name = getlogin;
```

What you get back

A string - the login name recorded for the controlling terminal - or the empty string / `undef` when no such record is available. Treat both empty-string and undefined as "unknown" and fall back to a UID-based lookup:

```
my $login = getlogin || getpwuid($<) || "Kilroy";
```

Using `||` here is deliberate: the empty string and `undef` both mean "no answer" and both should trigger the fallback.

Global state it touches

- Reads `$<` indirectly only via the idiomatic `getpwuid` fallback above; `getlogin` itself takes no arguments and consults no Perl variables.
- Sets `$!` on the underlying system-call failure paths exposed by the C library.

Examples

The canonical who-is-this-user pattern, robust against detached sessions and UID changes:

```
my $login = getlogin || getpwuid($<) || "Kilroy";
print "hello, $login\n";
```

Bare call in a shell-attached script:

```
my $name = getlogin;
print defined $name && length $name
    ? "tty owner: $name\n"
    : "no controlling tty\n";
```

Contrast with `getpwuid`, which answers a different question - *"who is the effective user running this code?"*:

```
my $tty_user  = getlogin           // "";
my $proc_user = getpwuid($<);
print "tty=$tty_user proc=$proc_user\n";
# After `sudo -u bob script.pl`, tty_user is your login,
# proc_user is "bob".
```

Inside a daemon or a cron job there is no controlling terminal, so `getlogin` has nothing to report:

```
# running from cron
my $name = getlogin;
# $name is "" or undef; always pair with a getpwuid fallback
```

Edge cases

- **No controlling terminal**: daemons, systemd services, cron jobs, container entry-points, and anything started without a tty see the empty string or `undef`. This is the common case outside interactive shells - always provide a fallback.
- **sudo and su**: `getlogin` returns the **original** login name (the tty owner), not the target user. After `sudo -u bob script.pl` you get your own login, while `getpwuid` with `$<` returns bob. Pick the one that matches the question you are actually asking.
- **Not an authentication primitive**: the record `getlogin` reads can be forged or stale; a process that inherits a tty from an unrelated session can see a name that has nothing to do with its own credentials. Never gate privileged behaviour on the return value. Use `getpwuid` on `$<` / `$>` instead.
- **Empty string vs `undef`**: platforms differ on which they return when there is no record. The `||` fallback handles both; a `defined`-only check does not.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `getpwuid` - resolves `$<` or `$>` to a name, and is the correct building block for *"who is running this process?"*
- `getpwnam` - the reverse lookup when you already have a login name and need the passwd entry
- `getpwent` - iterate the whole passwd database when you need more than one entry
- `$<` - real UID; the natural argument to `getpwuid` in the `getlogin` fallback idiom
- `$>` - effective UID; use this instead of `$<` when you care about the identity under which privileged operations will actually run

Network info

getnetbyaddr

Look up a network record by its numeric network address.

`getnetbyaddr` translates a numeric network number and address family into a network database entry by calling the system's C `getnetbyaddr(3)` routine. It is the reverse of `getnetbyname` and consults the same system network database (typically `/etc/networks` or an NSS backend). In scalar context it returns just the canonical network name; in list context it returns the full record.

Synopsis

```
my $name = getnetbyaddr $addr, $addrtype;
my ($name, $aliases, $addrtype, $net) = getnetbyaddr $addr,
 ↪$addrtype;
```

What you get back

Scalar context - the canonical name of the network, or `undef` if no entry matches.

List context - a four-element list mirroring the C `struct netent`:

- `$name` - the canonical network name.
- `$aliases` - a space-separated string of alternate names.
- `$addrtype` - the address family of the record, typically `AF_INET` (2).
- `$net` - the network number as an unsigned integer, in host byte order.

On lookup failure in list context, the return is the empty list. If the entry exists but is empty, the return is a single meaningless true value per the shared `get*` family convention.

Arguments

- ADDR - the network number as an **integer in host byte order**, not a packed string. This is the native-integer form you get back from a prior `getnetbyname` call, or that you build with `Socket::inet_aton` followed by `unpack("N", ...)` to convert from network to host order.
- ADDRTYPE - the address family, almost always `AF_INET` from the `Socket` module.

Global state it touches

- The network database iteration cursor shared with `getnetent`, `setnetent`, and `endnetent`. A call to `getnetbyaddr` may reset a cursor left open by `getnetent`.
- `$!` - the C `errno` value on failure, where the platform sets it. Most `/etc/networks` lookups fail silently with `errno` untouched, so treat `undef` as the primary failure signal.

Examples

Look up the loopback network by its integer number:

```
use Socket;
my $name = getnetbyaddr(127 << 24, AF_INET);
print "$name\n";                    # loopback
```

List context - the whole record:

```
use Socket;
my ($name, $aliases, $type, $net)
    = getnetbyaddr(127 << 24, AF_INET);
printf "%s (net=%08x)\n", $name, $net;
```

Round-trip from a dotted string, via `Socket`:

```
use Socket;
my $packed = inet_aton("127.0.0.0");     # packed, network order
my $net    = unpack("N", $packed);        # integer, host order
my $name   = getnetbyaddr($net, AF_INET);
```

By-name interface via the `Net::netent` override - accessor methods instead of positional unpacking:

```
use Net::netent;
my $n = getnetbyaddr(127 << 24, AF_INET);
print $n->name, "\n" if defined $n;
```

Forward then reverse - resolve a name, then look the address back up:

```
use Socket;
my $net  = (getnetbyname("loopback"))[3];
my $back = getnetbyaddr($net, AF_INET);
print "$back\n";                         # loopback
```

Edge cases

- **Integer, not packed string.** `ADDR` is a plain integer in host byte order. Passing the four-byte packed form that `gethostbyaddr` consumes here will silently look up the wrong number. This is the most common mistake with this function.
- **Classful only, on most systems.** The underlying `/etc/networks` database predates CIDR. Entries are classful network numbers (e.g. `127`, `10`, `192.168`), and the system call is not useful for arbitrary CIDR subnets. For modern subnet reasoning use `Socket` or a CPAN module like `NetAddr::IP`.
- **Empty `/etc/networks`.** Many Linux distributions ship a nearly empty `/etc/networks`; expect most lookups to return `undef` on such a host. This is a configuration fact, not a bug in the call.
- **List-context empty database entry.** Per the shared `get*` family rule, an entry that exists but has no fields returns a single meaningless true value, not the four-element list. In practice no platform produces such an entry for networks; guard with `defined` and element count if you care.
- **`ADDRTYPE` other than `AF_INET`.** The C library accepts the argument but has no defined behavior for non-Internet families here. Pass `AF_INET` unless the target system documents otherwise.
- **Thread safety.** The underlying C routine keeps per-process static state for the network cursor. Concurrent calls from multiple threads may interleave results. Where the platform offers `getnetbyaddr_r`, Perl substitutes it automatically.
- **List-operator precedence.** Like the rest of the `get*` family, `getnetbyaddr` parses as a list operator. `getnetbyaddr $n, AF_INET or die` binds the `or die` to the whole argument list, which is usually what you want; add parens when in doubt.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `getnetbyname` - the forward lookup: canonical or alias name → network record
- `getnetent` - iterate every entry in the network database instead of looking up one address
- `setnetent` - rewind the network iterator and control whether the database stays open across lookups
- `endnetent` - close the network database when done iterating
- `gethostbyaddr` - the host-level analogue; takes a packed address, not an integer
- `Net::netent` - by-name wrapper that returns an object with `name` / `aliases` / `addrtype` / `net` accessors

Network info

getnetbyname

Look up a network record by name.

`getnetbyname` resolves a symbolic network name (as listed in the system's networks database, typically `/etc/networks`) to its numeric network address by calling the C `getnetbyname(3)` routine. The scalar-context form returns the network number; the list-context form exposes the full record: canonical name, aliases, address family, and network number.

Synopsis

```
my $net = getnetbyname $name;
my ($name, $aliases, $addrtype, $net) = getnetbyname $name;
```

What you get back

Scalar context - the network number as a plain integer, or `undef` if the name is not in the networks database. This is the host-byte-order network portion of an IPv4 address, not a packed string. For the class-C network `192.168.0`, the returned value is `12625920` (that is, `0xC0A800`).

List context - a four-element list mirroring the C `struct netent`:

- `$name` - the canonical network name.
- `$aliases` - a space-separated string of alternate names.
- `$addrtype` - the address family, typically `AF_INET` (2).
- `$net` - the network number, same integer as the scalar-context form.

On lookup failure in list context, the return is the empty list.

Global state it touches

- The networks database iteration cursor shared with `getnetent`, `setnetent`, and `endnetent`. A call to `getnetbyname` may reset a cursor left open by `getnetent`.

Examples

Scalar form - look up a named network and print it as dotted-quad:

```
my $net = getnetbyname("loopback");
defined $net or die "no networks entry for loopback";
printf "%d.%d.%d.%d\n",
    ($net >> 24) & 0xFF, ($net >> 16) & 0xFF,
    ($net >> 8)  & 0xFF,  $net        & 0xFF;   # 127.0.0.0
```

List form - every field of the record:

```
my ($name, $aliases, $type, $net) = getnetbyname("loopback");
print "name=$name aliases=$aliases type=$type net=$net\n";
```

Round-trip against `getnetbyaddr` - name to number, then number back to name:

```
use Socket qw(AF_INET);
my $net  = getnetbyname("loopback");
my $back = getnetbyaddr($net, AF_INET);
print "$back\n";                          # loopback
```

By-name interface via the `Net::netent` override - accessor methods instead of positional unpacking:

```
use Net::netent;
my $n = getnetbyname("loopback");
print $n->name, "  ", $n->net, "\n";
```

Guard against a missing entry - a name that is not in the database returns `undef`, not zero:

```
my $net = getnetbyname("no-such-network");
if (defined $net) {
    print "found: $net\n";
} else {
    print "not in /etc/networks\n";
}
```

Edge cases

- **Check for `undef`, not falsehood.** A network number of `0` is a legal (if unusual) record; treating the return value as a boolean will misread that case as failure. Always test with `defined`.
- **The returned number is host-byte-order, not a packed string.** Unlike `gethostbyname`, which returns a four-byte packed address, `getnetbyname` returns a plain integer. Do not pass it to `Socket::inet_ntoa` - that function expects a packed string and will produce garbage on an integer.
- **Aliases are one scalar, not a list.** `$aliases` in the list form is a single space-separated string. Split on whitespace if you need a list.
- **Networks are typically class-boundary numbers.** The entries in `/etc/networks` are traditionally stored as the network portion only - `127` for loopback, `10` for the private class-A, not full four-octet addresses. On modern CIDR-routed networks the utility of this database is limited; most deployments keep only a handful of legacy entries.
- **No DNS fallback.** Unlike `gethostbyname`, this call consults only the local networks database. There is no equivalent of DNS for network names.
- **Empty list vs. undef.** Scalar context returns `undef` on failure; list context returns the empty list. The two are not interchangeable - code written for one context will misbehave in the other.
- **Thread safety.** The underlying C routine keeps per-process static state for the networks cursor. Concurrent calls from multiple threads may interleave results.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `getnetbyaddr` - the reverse lookup: network number → network record
- `getnetent` - iterate every entry in the networks database instead of looking up one name
- `setnetent` - rewind the networks iterator and control whether the file stays open across lookups
- `endnetent` - close the networks database after an iteration
- `gethostbyname` - the host-level counterpart, for resolving a hostname to an IP address
- `Net::netent` - by-name object wrapper returning accessor methods instead of a positional list

Network info

getnetent

Read the next entry from the networks database.

`getnetent` wraps the C library routine of the same name. It walks the system networks database (usually `/etc/networks`, sometimes augmented by NIS or other resolver backends) one record at a time, returning the next entry on each call. Pair it with `setnetent` to rewind or control the connection, and `endnetent` to close it.

Synopsis

```
my ($name, $aliases, $addrtype, $net) = getnetent;
my $name                              = getnetent;   # scalar␣
↪context
```

What you get back

In list context, a four-element list:

- `$name` - canonical network name (e.g. `"loopback"`).
- `$aliases` - space-separated string of alternative names.
- `$addrtype` - address family, typically `AF_INET` (2).
- `$net` - network number as an integer in host byte order. Convert to dotted form with `Socket::inet_ntoa(pack("N", $net))`.

In scalar context, just `$name`.

When the iterator is exhausted (no more records), list context returns the empty list and scalar context returns `undef`. A missing entry during a direct lookup returns a single

meaningless true value per perlfunc convention, but since `getnetent` takes no key, the only terminal condition is "end of database."

Global state it touches

`getnetent` reads from a **process-wide iterator** maintained by the C library. Every call advances that iterator; there is no per-scope state, and concurrent iteration from two places in the same process will interleave records. `setnetent` rewinds it and optionally asks the library to keep the backing connection open for the duration of iteration; `endnetent` closes it.

Examples

Walk the entire networks database:

```
setnetent(1);
while (my ($name, $aliases, $addrtype, $net) = getnetent) {
    printf "%-20s %s\n", $name, join(" ", split / /, $aliases);
}
endnetent();
```

Scalar context gives just the name - useful for a quick enumeration:

```
setnetent(1);
while (defined(my $name = getnetent)) {
    print "$name\n";
}
endnetent();
```

Decode the network number into dotted form:

```
use Socket;
setnetent(1);
while (my ($name, undef, undef, $net) = getnetent) {
    printf "%-20s %s\n", $name, inet_ntoa(pack "N", $net);
}
endnetent();
```

Object-oriented access through `Net::netent` - the by-name interface from the standard library replaces the positional return list with a blessed object:

```
use Net::netent;
while (my $n = getnetent()) {
    printf "%s => %d\n", $n->name, $n->net;
}
```

Edge cases

- **Iterator exhaustion**: list context returns `()`, scalar context returns `undef`. The loop forms above terminate naturally.

- **No `setnetent` before the loop**: the first call implicitly opens the database. Calling `setnetent(1)` is still recommended - without the "stay open" flag, some C libraries reopen the file on every record and performance collapses.
- **Multiple concurrent walks**: the iterator is process-global. Two loops over `getnetent` in the same process will split the records between them. Collect into an array first if both need the full set.
- **Unsupported on some platforms**: Windows has no `/etc/networks` equivalent and the underlying C routine is absent. Attempting to call `getnetent` there raises `The getnetent function is unimplemented`. On Linux, glibc provides the function but the database is often empty - most systems rely on DNS instead, which this interface does not consult.
- **Thread safety**: the C library's iterator is not thread-safe. Perl may transparently substitute `getnetent_r` on systems that provide it, but do not assume this is universal. In a threaded program, serialise access through a single thread.
- **Tainting**: when tainting is enabled, all four return fields are tainted - they come from a file (or a remote resolver) outside the program's control.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `setnetent` - rewind the iterator and optionally keep the backing connection open across calls
- `endnetent` - close the iterator when you're done
- `getnetbyname` - look up one network by name instead of walking the whole database
- `getnetbyaddr` - look up one network by its address
- `gethostent` - the analogous walk over the hosts database, with the same `set`/`end` companion pair
- `Net::netent` - by-name object interface that replaces the positional return list

Sockets

getpeername

Return the address of the remote end of a connected socket.

`getpeername` asks the kernel who is on the other side of `SOCKET` and returns the answer as a packed `sockaddr` byte string - the same shape `connect` took and the same shape `accept` returned. You then hand that byte string to an unpacker from `Socket` (or `Socket::unpack_sockaddr_in`, `Socket::unpack_sockaddr_in6`, `Socket::unpack_sockaddr_un`) to pull out the port, address, or path.

This is the companion to `getsockname`, which returns the **local** end of the same socket.

Synopsis

```
use Socket;
my $peer = getpeername SOCKET;
my ($port, $iaddr) = unpack_sockaddr_in($peer);
```

What you get back

A packed `sockaddr` byte string on success, `undef` on failure (with `$!` set - typically `ENOTCONN` when the socket has no peer, or `EBADF` when `SOCKET` is not an open file descriptor).

The byte string is opaque. Its layout depends on the socket's address family; always decode it with an unpacker that matches the family you expect:

- `AF_INET` → `Socket::unpack_sockaddr_in` returns `($port, $iaddr)` where `$iaddr` is the 4-byte packed IPv4 address.
- `AF_INET6` → `Socket::unpack_sockaddr_in6` returns `($port, $iaddr, $scope_id, $flowinfo)`.
- `AF_UNIX` → `Socket::unpack_sockaddr_un` returns the peer's filesystem path.

If you do not know the family at the call site, ask `Socket::sockaddr_family` first:

```
my $peer   = getpeername $sock;
my $family = sockaddr_family($peer);
```

Global state it touches

`getpeername` reads the file-descriptor state of `SOCKET`. It sets `$!` on failure and does not otherwise touch interpreter globals. It does not interact with `$_`, the selected filehandle, or output separators.

Examples

Look up the remote IPv4 peer of a client-side TCP socket and render it in dotted-quad form:

```
use Socket;
my $peer = getpeername($sock)
    or die "getpeername: $!";
my ($port, $iaddr) = unpack_sockaddr_in($peer);
printf "peer is %s:%d\n", inet_ntoa($iaddr), $port;
```

Server side: every socket returned by `accept` is already connected, and `accept` itself hands back the peer address. `getpeername` is useful later, when that packed address has not been kept around:

```
while (my $client = accept(my $conn, $listen)) {
    handle($conn);
}
```

(continues on next page)

(continued from previous page)

```
sub handle {
    my ($conn) = @_;
    my $peer = getpeername($conn) or return;
    my ($port, $iaddr) = unpack_sockaddr_in($peer);
    warn "request from ", inet_ntoa($iaddr), ":$port\n";
    # ...
}
```

Resolve the peer back to a hostname - note that this issues a blocking DNS lookup:

```
use Socket;
my $peer = getpeername($sock);
my ($port, $iaddr) = unpack_sockaddr_in($peer);
my $name = gethostbyaddr($iaddr, AF_INET);
print "connected to ", $name // inet_ntoa($iaddr), "\n";
```

Mixed IPv4 / IPv6 code - decode generically via the address family:

```
use Socket qw(sockaddr_family unpack_sockaddr_in unpack_sockaddr_in6
              AF_INET AF_INET6 inet_ntop);

my $peer = getpeername($sock) or die "getpeername: $!";
my $fam  = sockaddr_family($peer);

if ($fam == AF_INET) {
    my ($port, $iaddr) = unpack_sockaddr_in($peer);
    printf "v4 %s:%d\n", inet_ntop(AF_INET, $iaddr), $port;
}
elsif ($fam == AF_INET6) {
    my ($port, $iaddr) = unpack_sockaddr_in6($peer);
    printf "v6 [%s]:%d\n", inet_ntop(AF_INET6, $iaddr), $port;
}
```

Probing whether a socket is connected at all - the `ENOTCONN` path is the well-defined way to ask:

```
if (defined getpeername($sock)) {
    # connected
} else {
    # $! == ENOTCONN for an unconnected socket
}
```

Edge cases

- **Unconnected socket**: a socket that has been `socket`'d but not yet `connect`'d or `accept`'d has no peer. `getpeername` returns `undef` and sets `$!` to `ENOTCONN`.
- **Non-socket filehandle**: passing a plain file or pipe yields `undef` with `$!` set to `ENOTSOCK`.

- **Closed or invalid filehandle**: returns `undef` with `$!` set to `EBADF`. Under `use warnings` a `getpeername() on closed socket` warning is emitted.
- **Datagram sockets**: `getpeername` only returns an address when the `SOCK_DGRAM` socket has been `connect`'d to a default peer; otherwise it fails with `ENOTCONN` even though the socket is usable via `recv` / `send`.
- **`AF_UNIX` with an unbound peer**: a Unix-domain socket whose peer never called `bind` returns a packed `sockaddr_un` with an empty path. `Socket::unpack_sockaddr_un` gives back the empty string.
- **After `shutdown`**: `getpeername` still succeeds as long as the descriptor is open; shutdown tears down data flow, not the kernel's record of the peer.
- **SOCKET is a parsed filehandle token**: like other socket built-ins, the argument is parsed as a filehandle, not evaluated as a general expression. `getpeername $handles[0]` is a syntax error; use a scalar holding the handle, or `*{...}` dereferencing.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `getsockname` - mirror call that returns the **local** end of the same socket; pairs with `getpeername` when logging both ends of a connection
- `accept` - already hands you the peer address for a freshly accepted server-side socket; use `getpeername` later when that address was not retained
- `connect` - the call that establishes the peer in the first place; the address you pass to `connect` is what `getpeername` will hand back afterwards
- `Socket` - provides the unpackers (`unpack_sockaddr_in`, `unpack_sockaddr_in6`, `unpack_sockaddr_un`) and `sockaddr_family` needed to interpret the returned byte string
- `gethostbyaddr` - turns the packed IPv4 address from the unpacker into a hostname
- `$!` - carries the reason on failure (`ENOTCONN`, `ENOTSOCK`, `EBADF`)

Processes

getpgrp

Return the POSIX process-group ID that a process belongs to.

Every Unix process is a member of exactly one process group, which in turn belongs to a session. Process groups are how the kernel addresses related processes as a unit - most visibly, they are the unit that receives a signal from the controlling terminal (`SIGINT` on Ctrl-C, `SIGTSTP` on Ctrl-Z). `getpgrp` asks the kernel for the group ID of a given process; with no argument or a `PID` of `0` it answers for the current process.

Synopsis

```
getpgrp
getpgrp PID
getpgrp 0
```

What you get back

A non-negative integer - the process-group ID in scalar context. Process-group IDs share the PID numbering space, and the group leader's PID equals the group ID, so the value returned by `getpgrp 0` is the PID of the current process's group leader.

On a system that does not implement `getpgrp(2)` at all, the call raises a fatal exception. That is vanishingly rare on modern Unix; Linux, the BSDs, macOS, and Solaris all support it.

Global state it touches

None. `getpgrp` reads kernel state for the named process and sets `$!` only on failure (which, on a POSIX system, means "no such process" for a non-zero `PID` that does not exist).

Examples

Get the current process's own group:

```
my $pgid = getpgrp;
print "my group is $pgid\n";
```

`PID` of `0` means "myself" and is the portable form - some very old systems do not accept any other value:

```
my $pgid = getpgrp 0;                  # same as getpgrp with no args
```

Detect whether the current process is its own group leader - the usual test a daemon runs before calling `setpgrp` or `POSIX::setsid` to detach from its controlling terminal:

```
if (getpgrp(0) == $$) {
    print "already a group leader\n";
}
else {
    print "group leader is ", getpgrp(0), "\n";
}
```

Look up another process's group, e.g. a child just returned by `fork`:

```
my $pid = fork // die "fork: $!";
if ($pid == 0) {
    # child
    exec @cmd;
```

(continues on next page)

(continued from previous page)

```
}
print "child $pid is in group ", getpgrp($pid), "\n";
```

Send a signal to every member of a process group. `kill` with a negative PID targets the group, and `getpgrp` is how you discover the group ID to negate:

```
my $grp = getpgrp($child);
kill 'TERM', -$grp;                    # SIGTERM to the whole group
```

Edge cases

- **Omitted argument equals `PID` of `0`**: `getpgrp` and `getpgrp 0` both report the current process's group. Prefer the explicit `0` form when portability to historical systems matters.
- **Non-existent `PID`**: returns `undef` and sets `$!` to `"No such process"` (`ESRCH`). Check `$!`, not the return value's truthiness - a legitimate group ID of `0` is falsy in Perl but is not an error condition (it is, on Linux, the idle/swapper group).
- **Not-permitted lookups**: on systems that restrict cross-session lookups, querying a `PID` in a different session can fail with `$!` set to `"Operation not permitted"` (`EPERM`). This is unusual on Linux, where any process may query any `PID`'s group.
- **`getpgrp` vs. `getpgrp PID`**: the BSD-style one-argument form was not portable to all Unixes historically; POSIX standardised both. On the platforms pperl runs on (Linux, all cranelift targets), both forms work.
- **Signed vs. unsigned**: the kernel's PID type is signed, so the returned value fits comfortably in a Perl integer. A return of `-1` is not used for success on any platform pperl targets; treat `-1` as the error sentinel only if you are porting code from a C codebase that checked it that way.
- **Not a shell alias for job control**: the shell's `jobs` and `%` notation operate on job tables the shell keeps, not on kernel process groups directly. `getpgrp` tells you the kernel truth, which can drift from a subshell's idea of the job tree.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `setpgrp` - put a process into a new or existing group; the write counterpart to `getpgrp`
- `getppid` - parent process ID; often wanted alongside the group ID when walking process relationships
- `getpriority` - read scheduling priority, which also accepts a process-group selector (`PRIO_PGRP`)
- `fork` - the child inherits its parent's process group, so `getpgrp` on a fresh child reports the parent's group until a `setpgrp` call changes it

- `kill -kill SIGNAL, -$pgid` signals every member of the group; `getpgrp` is how you find `$pgid`
- `$$` - current PID; equal to `getpgrp(0)` when the process is its own group leader

Processes

getppid

Return the process ID of the current process's parent.

`getppid` is a thin wrapper over the POSIX `getppid(2)` system call. It takes no arguments and returns an integer - the PID of whatever process `fork`ed (or `exec`ed into) the running program. Combined with `$$` (the current process's own PID), it is the standard way for a child to identify the process that spawned it.

Synopsis

```
my $parent = getppid;
```

What you get back

A positive integer - the PID of the parent process. On Linux this is `1` (init / systemd) once the original parent has exited and the child has been reparented; there is no special "orphaned" return value, the reparenting is transparent. Never returns `undef` or `0` on a supported platform; the underlying syscall is specified to always succeed.

Global state it touches

None. `getppid` reads the kernel's process table for the current process; it does not touch any Perl special variable. Note that `$$` holds *this* process's PID, not the parent's - fetch the parent with `getppid` explicitly.

Examples

Identify the parent that launched this script:

```
printf "my pid is %d, my parent is %d\n", $$, getppid;
```

Detect orphaning - a common idiom for daemons that want to exit when their controlling process goes away:

```
while (1) {
    last if getppid == 1;       # parent died, we've been reparented
↪to init
    do_work();
    sleep 1;
}
```

Child process reports back to its parent after `fork`:

```
my $pid = fork // die "fork failed: $!";
if ($pid == 0) {
    warn "child $$ spawned by $>, parent is " . getppid . "\n";
    exit 0;
}
waitpid $pid, 0;
```

Compare before and after `fork` to confirm the relationship:

```
my $before = $$;
my $pid = fork // die $!;
if ($pid == 0) {
    die "parent mismatch" unless getppid == $before;
    exit;
}
waitpid $pid, 0;
```

Edge cases

- **No arguments, no parentheses needed**: `getppid` is a niladic built-in. Write `getppid` or `getppid()`; both parse identically. Do not try to pass a PID argument - unlike `getpgrp`, there is no "parent of another process" form.
- **Orphan reparenting is invisible**: if the original parent exits, the kernel reparents the process (to `init`/`systemd` on Linux, or to the nearest ancestor with `PR_SET_CHILD_SUBREAPER` set). `getppid` silently starts returning the new parent's PID. Code that caches the return value at startup and compares later is the standard way to detect this.
- **Race at startup**: calling `getppid` extremely early, before the kernel has finished setting up the process, is not a concern in user Perl code - by the time the interpreter is running, the parent PID is stable.
- **PID wraparound**: PIDs are recycled. A stored parent PID can, over long-running time, refer to a *different* process than the original parent even without reparenting. Use `getppid == 1` (or the equivalent subreaper PID), not equality against a saved value, when the intent is "has my parent died?".
- **Threads**: since Perl 5.16 the Linux LinuxThreads workaround has been removed. `getppid` now always returns what the kernel reports for the current thread group.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `$$` - the current process's own PID; pair with `getppid` to log both ends of the parent/child relationship
- `fork` - spawn a child process; the child's `getppid` returns the forking process's PID
- `waitpid` - reap a specific child by PID; the mirror operation from the parent side

- `wait` - reap any child; same parent-side operation, unspecified PID
- `getpgrp` - process *group* ID rather than parent PID; related but distinct kernel concept
- `kill` - send a signal to a PID, including one obtained from `getppid` (e.g. notifying the parent)

Processes

getpriority

Return the current scheduling nice value of a process, a process group, or a user.

`getpriority` is a thin wrapper around the `getpriority(2)` system call. Nice values run from `-20` (most favourable to the process) to `19` (least favourable); a freshly-spawned process inherits its parent's value, typically `0`. Only the superuser can *lower* a nice value; any user may raise their own.

Synopsis

```
getpriority WHICH, WHO
```

`WHICH` selects what `WHO` means:

- `PRIO_PROCESS` - `WHO` is a process ID (`0` means the current process).
- `PRIO_PGRP` - `WHO` is a process-group ID (`0` means the current group).
- `PRIO_USER` - `WHO` is a numeric user ID (`0` means the real UID of the calling process).

The three constants come from `POSIX`; they are not built-ins and are not exported by default.

```
use POSIX qw(PRIO_PROCESS PRIO_PGRP PRIO_USER);
```

What you get back

The current nice value as an integer in the range `-20 .. 19`.

There is no distinguished error return: `-1` is a perfectly valid nice value. To detect failure, clear `$!` before the call and inspect it afterwards:

```
$! = 0;
my $nice = getpriority PRIO_PROCESS, $pid;
die "getpriority: $!" if $!;
```

On a kernel that implements `getpriority(2)` but returns an error (typically `ESRCH` for a non-existent target or `EINVAL` for a bogus `WHICH`), the function returns `-1` with `$!` set. On a platform that does not implement the call at all, `getpriority` raises a fatal exception; catch it with `eval` if the script must run on such a host.

Global state it touches

- `$!` - set when the underlying `getpriority(2)` call fails. Must be cleared before the call to distinguish a legitimate `-1` result from an error.

Examples

Read the current process's own nice value:

```
use POSIX qw(PRIO_PROCESS);
my $nice = getpriority PRIO_PROCESS, 0;
print "nice = $nice\n";             # nice = 0
```

Check another process by PID:

```
use POSIX qw(PRIO_PROCESS);
my $nice = getpriority PRIO_PROCESS, $pid;
```

Read the priority of the calling process's process group:

```
use POSIX qw(PRIO_PGRP);
my $nice = getpriority PRIO_PGRP, 0;
```

Read the priority cap associated with a user ID. The value returned is the *lowest* (most favourable) nice value held by any of that user's processes:

```
use POSIX qw(PRIO_USER);
my $nice = getpriority PRIO_USER, $uid;
```

Safe read that distinguishes `-1`-as-value from `-1`-as-error:

```
use POSIX qw(PRIO_PROCESS);
$! = 0;
my $nice = getpriority PRIO_PROCESS, $pid;
if ($!) {
    warn "cannot read priority of $pid: $!";
} else {
    print "pid $pid: nice=$nice\n";
}
```

Edge cases

- **`-1` is a valid return**, not an error indicator. Always clear `$!` before the call and test it after.
- **`WHO == 0`** is the "self" shorthand for each `WHICH`: current PID, current PGID, or real UID. Passing your own PID / PGID / UID explicitly gives the same result.
- **`PRIO_USER` with a UID that owns multiple processes** returns the numerically lowest nice value across those processes, reflecting the most favourable scheduling that user currently enjoys.
- **Missing target.** A PID, PGID, or UID with no matching process yields `-1` and sets `$!` to `ESRCH`.

- **Bad `WHICH`.** A value outside `PRIO_PROCESS` / `PRIO_PGRP` / `PRIO_USER` yields `-1` and sets `$!` to `EINVAL`.
- **No `getpriority(2)` on the host.** The call raises a fatal exception rather than returning a value. Guard with `eval` in portable code.
- **No `POSIX` import, no constants.** Writing `getpriority 0, 0` works by accident because `PRIO_PROCESS` happens to be `0` on Linux, but it is not portable. Always import and use the named constants.
- **Raising priority needs root.** `getpriority` itself is unprivileged; the matching `setpriority` call fails with `EACCES` when a non-root caller tries to *decrease* the nice value.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `setpriority` - write side of the same syscall pair; same `WHICH` constants, same caveats about `-1`
- `POSIX` - source of `PRIO_PROCESS`, `PRIO_PGRP`, and `PRIO_USER`; none of them are built-in
- `getpgrp` - process-group ID you would pass as `WHO` under `PRIO_PGRP`
- `fork` - child inherits the parent's nice value; read it back with `getpriority` after the fork if you need to confirm
- `$!` - the only channel for distinguishing a real `-1` priority from a failed call

Network info

getprotobyname

Look up an IP protocol by its textual name and return its database entry.

`getprotobyname` is the Perl wrapper around the system C library's `getprotobyname(3)`. Given a protocol name such as `"tcp"`, `"udp"`, or `"icmp"`, it returns the matching entry from the system's `/etc/protocols` database (or whatever backend `nsswitch.conf` directs to). The typical use is turning a human-readable protocol name into the numeric value that `socket` and `setsockopt` want.

Synopsis

```
getprotobyname NAME
my ($name, $aliases, $proto) = getprotobyname NAME;
my $proto                    = getprotobyname NAME;   # scalar␣
↪context
```

What you get back

In list context, a four-element-looking list with three fields:

```
my ($name, $aliases, $proto) = getprotobyname("tcp");
# $name    => canonical name, e.g. "tcp"
# $aliases => space-separated alias list, e.g. "TCP"
# $proto   => numeric protocol number, e.g. 6
```

In scalar context, just the numeric protocol number (`$proto`). That is the common form, because the protocol number is the whole reason the lookup was performed:

```
my $tcp = getprotobyname("tcp");   # 6
```

If the protocol is not found, the return is an empty list in list context and `undef` in scalar context. Always check definedness before using the result - `0` is a valid protocol number (`"ip"`), so truth-testing alone is wrong.

```
defined(my $tcp = getprotobyname("tcp"))
    or die "tcp protocol not in /etc/protocols";
```

Global state it touches

- Shares the protocol-database iteration cursor with `getprotobynumber`, `getprotoent`, `setprotoent`, and `endprotoent`. A call to `getprotobyname` may reposition or reset that cursor depending on the system C library; do not interleave name lookups with a `getprotoent` iteration loop.
- On some platforms the underlying `getprotobyname(3)` sets `$!` / `errno` on failure. Portable code should not rely on it - treat an undefined return as "not found" and move on.

Examples

Turn a name into a protocol number for `socket`:

```
use Socket;
my $proto = getprotobyname("tcp")
    // die "tcp not configured";
socket(my $sock, PF_INET, SOCK_STREAM, $proto)
    or die "socket: $!";
```

List form, to see the canonical name and aliases a system uses:

```
my ($name, $aliases, $proto) = getprotobyname("TCP");
print "name=$name aliases=$aliases number=$proto\n";
# name=tcp aliases=TCP number=6
```

Defensive lookup with a fallback for the two protocols every script actually needs:

```
my %num_for = (tcp => 6, udp => 17, icmp => 1);
sub proto_num {
```

(continues on next page)

(continued from previous page)

```
    my ($name) = @_;
    return getprotobyname($name) // $num_for{lc $name};
}
```

Scalar context is required when the return value feeds an expression; list context would flatten into the surrounding list:

```
my @args = (SOCK_STREAM, scalar getprotobyname("tcp"));
```

Edge cases

- **Case sensitivity is system-dependent.** glibc's `getprotobyname(3)` matches the canonical name and every alias case-insensitively; other C libraries may not. If portability matters, pass the lowercase form (`"tcp"`, not `"TCP"`).
- **Protocol number `0` is valid** (`"ip"`). Use `defined(...)`, not boolean truth, when checking for success.
- **Not the same as a port number.** `getprotobyname("http")` returns `undef` - `"http"` is a *service* name, not a protocol. Use `getservbyname` for service lookups.
- **Empty alias string is normal.** Many entries have no aliases; the second return value is then the empty string, not `undef`.
- **Iteration cursor side-effects.** If your program is in the middle of a `getprotoent` loop, calling `getprotobyname` may reset the cursor and skip or repeat entries. Finish the iteration, or save state, before doing name lookups.
- **Thread safety.** The underlying C call is not thread-safe on every platform - it typically uses a per-process static buffer. Perl may use the reentrant `getprotobyname_r` form when available, but do not assume it.
- **Missing `/etc/protocols` entry.** On minimal containers the database may be absent, in which case every call returns `undef`. Build protocol tables into your code when the target environment is not guaranteed to ship a protocol database.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `getprotobynumber` - the inverse lookup; use when you have the numeric protocol and want its name
- `getprotoent` - iterate every entry in the protocol database one record at a time
- `setprotoent` / `endprotoent` - control the iteration cursor shared with this function
- `getservbyname` - the equivalent lookup for services (ports), not protocols; the two are often confused
- `socket` - the usual consumer of the returned protocol number

- `Net::protoent` - object-oriented wrapper that returns a blessed record with named accessors instead of a positional list

Network info

getprotobynumber

Look up a network protocol entry by its assigned protocol number.

`getprotobynumber` wraps the system `getprotobynumber(3)` call. Given a numeric protocol identifier - the same values named by constants like `IPPROTO_TCP` (6), `IPPROTO_UDP` (17), `IPPROTO_ICMP` (1) - it returns the matching entry from the system's protocol database (typically `/etc/protocols`). The common use is turning a protocol number pulled off the wire, out of a routing table, or returned by `getsockopt` into a human-readable name.

Synopsis

```
getprotobynumber NUMBER
```

What you get back

In list context, a three-element list:

```
my ($name, $aliases, $proto) = getprotobynumber($number);
```

- `$name` - canonical protocol name (`"tcp"`, `"udp"`, `"icmp"`).
- `$aliases` - space-separated string of alternative names for the protocol, or the empty string if none.
- `$proto` - the protocol number you passed in, echoed back from the database entry.

In scalar context, you get `$name` alone. If the number is not in the database, the scalar return is `undef` and the list return is empty.

```
my $name = getprotobynumber(6);          # "tcp"
my @rec  = getprotobynumber(6);          # ("tcp", "", 6)
my $none = getprotobynumber(9999);       # undef
```

Global state it touches

Shares the protocol-database cursor with `getprotobyname`, `getprotoent`, `setprotoent`, and `endprotoent`. Calling `getprotobynumber` does not disturb an iteration in progress on most systems, but portable code that interleaves single lookups with `getprotoent` iteration should call `setprotoent` afterwards to reset the cursor.

On failure, `$!` is set to the underlying `errno`, though most implementations simply return "not found" without setting `errno`.

Examples

Resolve the canonical name of a protocol number:

```
my $name = getprotobynumber(6);
print "$name\n";                          # "tcp"
```

Full record with aliases:

```
my ($name, $aliases, $proto) = getprotobynumber(1);
print "$name ($proto): $aliases\n";     # e.g. "icmp (1): ICMP"
```

Reverse-lookup a protocol pulled out of a packet header:

```
sub protocol_label {
    my ($num) = @_;
    my $name = getprotobynumber($num);
    return defined $name ? $name : "proto-$num";
}
```

Round-trip against `getprotobyname` - useful as a sanity check that your system's protocol database knows the name you expect:

```
my $num  = getprotobyname("tcp");       # 6
my $back = getprotobynumber($num);      # "tcp"
```

Pretty-print a `getsockopt` level. The `level` argument to `getsockopt` is a protocol number; `getprotobynumber` turns it back into a label for logging:

```
my ($level) = unpack("I", $packed_level);
printf "socket option at level %s\n", getprotobynumber($level) //
 ↪$level;
```

Edge cases

- **List-operator precedence trap.** Even though `getprotobynumber` takes a single argument, it parses with list-operator precedence. The function name swallows everything to its right as one big list expression:

  ```
  getprotobynumber $number eq 'icmp'    # WRONG - equivalent to:
  getprotobynumber($number eq 'icmp')   # looks up protocol 0 or 1
  getprotobynumber($number) eq 'icmp'   # what you meant
  ```

  Always parenthesise the argument when comparing the result, or assign the lookup to a variable first.

- **Unknown number**: scalar return is `undef`; list return is the empty list. Guard with `defined`:

  ```
  defined(my $name = getprotobynumber($n))
      or die "unknown protocol number $n";
  ```

- **Non-integer argument**: converted to an integer via the usual numeric coercion before the lookup. A string like `"tcp"` coerces to `0` and you get whatever entry (if any) is registered for protocol `0`, which is usually `"ip"`. For name-based lookup, use `getprotobyname`.
- **Negative or out-of-range numbers**: no entry, returns empty / `undef`. No warning is raised.
- **The `Net::protoent` object interface**. If you import `Net::protoent`, `getprotobynumber` is overridden to return a blessed object with named accessors (`$p->name`, `$p->aliases`, `$p->proto`). Handy when you do not want to remember positional field order.
- **Database lookup, not protocol stack introspection**. This function reads `/etc/protocols` (or the equivalent NSS source). It tells you what name the system assigns to a number; it does not tell you whether the kernel actually supports that protocol or whether a socket of that type can be opened.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `getprotobyname` - the inverse: look up a protocol entry by name when you have a label like `"tcp"` and need the number
- `getprotoent` - iterate every entry in the protocol database, when you want to list or index them all
- `setprotoent` - reopen / rewind the protocol-database cursor; pair with `endprotoent` around an iteration
- `getservbyport` - the service-table analogue, turning a port number into a service name
- `getsockopt` - returns a protocol number as its `level` argument; feed it to `getprotobynumber` for readable logs
- `Socket` - exports the `IPPROTO_*` constants whose numeric values are what you pass in

Network info

getprotoent

Fetch the next entry from the protocols database.

`getprotoent` walks the system protocols database - on traditional Unix-likes that's `/etc/protocols`, on modern systems whatever the C library and NSS stack map to it - returning one record per call until the database is exhausted. It is the iterating leg of the `setprotoent` / `getprotoent` / `endprotoent` triad. Reach for `getprotobyname` or `getprotobynumber` when you want a single targeted lookup; `getprotoent` is for enumerating every protocol known to the system.

The iteration cursor is shared process-wide and owned by the C library. `setprotoent` rewinds it and optionally pins the backing descriptor open; `endprotoent` closes it. Between those two calls `getprotoent` yields each record in order, then returns the empty list (or `undef` in scalar context) once there is nothing left.

Synopsis

```
my ($name, $aliases, $proto) = getprotoent;
my $name = getprotoent;
```

What you get back

List context - a three-element list mirroring the C `struct protoent`:

- `$name` - the canonical protocol name, e.g. `"tcp"`, `"udp"`, `"icmp"`.
- `$aliases` - a space-separated string of alternate names for the same protocol. Often empty.
- `$proto` - the numeric protocol number as used in IP headers and accepted by `socket` / `getsockopt`.

At end-of-database the return is the empty list. The upstream perlfunc note about *"a single meaningless true value"* for missing entries applies to the by-name and by-number lookups, not to `getprotoent` - running off the end of the iteration is a clean empty list.

Scalar context - the canonical `$name` only, or `undef` at end-of-database. Use list context whenever you need the number or the aliases; you cannot reconstruct them from the name after the fact.

Split the aliases into a list with a plain `split`:

```
my @alts = split ' ', $aliases;
```

Global state it touches

- The **protocols database cursor**, a per-process C-library-owned resource shared with `setprotoent`, `endprotoent`, `getprotobyname`, and `getprotobynumber`. A by-name or by-number lookup may reset the cursor mid-iteration on some platforms - see *Edge cases*.
- No Perl-level special variables are read or written. Unlike `gethostent`, the protocols routines have no `h_errno` equivalent, so `$?` is not touched. End of database is not a failure and does not set `$!`.

Examples

Enumerate every protocol the system knows about:

```
setprotoent(1);
while (my ($name, $aliases, $proto) = getprotoent) {
    print "$proto\t$name\t$aliases\n";
```

(continues on next page)

(continued from previous page)

```
}
endprotoent;
```

Scalar context - list just the canonical names:

```
setprotoent(0);
while (defined(my $name = getprotoent)) {
    print "$name\n";
}
endprotoent;
```

Build a name-to-number map in one pass so later lookups don't hit the database at all:

```
my %proto_num;
setprotoent(1);
while (my ($name, $aliases, $num) = getprotoent) {
    $proto_num{$name} = $num;
    $proto_num{$_}    = $num for split ' ', $aliases;
}
endprotoent;

print $proto_num{"tcp"}, "\n";          # 6
```

By-record interface via the `Net::protoent` override - accessor methods instead of positional unpacking:

```
use Net::protoent;
while (my $p = getprotoent) {
    printf "%-10s %3d\n", $p->name, $p->proto;
}
```

Edge cases

- **No implicit rewind.** `getprotoent` does not open or rewind the database on its own. The first call after program start works because the C library lazily opens the file, but once the end is reached further calls keep returning end-of-database until a `setprotoent` rewinds the cursor. Always bracket enumeration with an explicit `setprotoent` and `endprotoent`.
- **End-of-database is the empty list, not `undef`.** In list context the loop condition `while (my @r = getprotoent)` works because the empty list is false. In scalar context use `while (defined(my $name = getprotoent))` - a protocol name of `"0"` is theoretically valid and would falsely terminate a truthiness-based loop.
- **Aliases are one scalar, not a list.** `$aliases` is a single space-separated string; split on whitespace if you want a list. An empty aliases field is the common case, not an error.
- **Interleaving with by-name / by-number lookups.** A call to `getprotobyname` or `getprotobynumber` during a walk can reset the shared cursor on some platforms. Finish the iteration first, or restart it with `setprotoent` after the lookup.

- **Not reentrant.** The database cursor is a single global resource inside the C library. Two concurrent iterations in the same process - across threads, signal handlers, or nested callbacks - corrupt each other's state. Confine each walk to one thread at a time.
- **Platforms without a protocols database.** On systems with no `/etc/protocols` equivalent, the call is a no-op that returns the empty list immediately rather than raising an error. See `perlport` for the full list of network-database quirks.
- **Tainting.** Records come from a file the kernel reads on your behalf and are not marked tainted. Treat them as untrusted anyway when the file is user-writable.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `setprotoent` - rewind the iterator and optionally pin the backing descriptor open for the full walk
- `endprotoent` - close the iterator and release the database handle once enumeration is done
- `getprotobyname` - targeted lookup by protocol name instead of full enumeration
- `getprotobynumber` - targeted lookup by numeric protocol number
- `getservent` - same iteration pattern for the services database, which references protocol names from this one
- `gethostent` - same idiom for the hosts database

User and group info

getpwent

Return the next entry from the system password database.

`getpwent` walks the password database one record at a time. The first call opens the database (typically `/etc/passwd`, possibly augmented by NSS with LDAP, SSSD, or similar); each subsequent call returns the next entry. When the iteration is exhausted the call returns an empty list in list context or `undef` in scalar context. Pair it with `setpwent` to rewind and `endpwent` to release any resources the database library is holding.

Synopsis

```
my @fields = getpwent;
my $name   = getpwent;      # scalar context: login name only
```

What you get back

In list context, a 10-element list describing one account:

```
my ( $name,   $passwd,   $uid,   $gid,   $quota,
     $comment, $gcos,    $dir,   $shell, $expire ) = getpwent;
#    0         1          2       3       4
#    5         6          7       8       9
```

- `$name` - login name.
- `$passwd` - the encrypted password field. On systems with shadow passwords this is usually `"x"` or `"*"` unless the process is privileged; the real hash lives in `/etc/shadow`. Tainted under `-T`.
- `$uid`, `$gid` - numeric user and primary group ids.
- `$quota` - disk quota on systems that support it, otherwise an empty string. On some systems this slot carries `$change` or `$age` (password-aging data).
- `$comment` - administrative comment on systems that support it, otherwise empty. On some systems this slot carries `$class`.
- `$gcos` - the GECOS field, conventionally the user's real name. User-writable on many systems, therefore tainted under `-T`.
- `$dir` - home directory.
- `$shell` - login shell. Tainted under `-T`.
- `$expire` - account or password expiration on systems that support it, otherwise absent.

In scalar context, only the login name is returned. When the iteration is exhausted the scalar value is `undef` and the list value is empty.

Whether `$quota`, `$comment`, and `$expire` carry meaningful data on the current build depends on how Perl was configured; inspect `Config` values `d_pwquota`, `d_pwage`, `d_pwchange`, `d_pwcomment`, and `d_pwexpire` to find out.

Global state it touches

`getpwent` keeps its cursor in a **process-wide**, library-owned state block inside the C library's pwd routines. Consequences:

- Two independent loops over the database in the same process interfere with each other. Each `getpwent` advances the one shared cursor.
- `setpwent` rewinds that cursor to the beginning.
- `endpwent` closes the database and drops any resources (open file descriptors, NSS module state) the library was holding.
- Threads share the cursor too. `getpwent` is not safe to call concurrently from multiple threads; if two threads iterate in parallel, neither sees every record.

`getpwent` does not read or write any Perl special variables.

Examples

Dump every account name and home directory:

```
while ( my @pw = getpwent ) {
    print "$pw[0]\t$pw[7]\n";
}
endpwent;
```

Named-field destructuring reads more clearly than numeric indexing:

```
while ( my ($name, undef, $uid, $gid, undef, undef, $gcos, $dir) =
 ↪getpwent ) {
    next if $uid < 1000;                # skip system accounts
    print "$name ($gcos) uid=$uid home=$dir\n";
}
endpwent;
```

Scalar context yields the login name, useful for enumerating users without unpacking the rest:

```
my @users;
while ( defined( my $name = getpwent ) ) {
    push @users, $name;
}
endpwent;
```

Rewind in the middle of a walk with `setpwent`:

```
my @first_pass = (getpwent)[0];
setpwent;                                # back to the top
while ( my @pw = getpwent ) { ... }
endpwent;
```

Collect all entries into a hash keyed by uid, then release the database:

```
my %by_uid;
while ( my @pw = getpwent ) {
    $by_uid{ $pw[2] } = \@pw;
}
endpwent;
```

Edge cases

- **End of iteration**: returns an empty list in list context and `undef` in scalar context. `while (my @pw = getpwent)` and `while (defined(my $name = getpwent))` are the idiomatic loop forms.
- **Forgetting `endpwent`**: leaks whatever file descriptors or NSS state the library opened until the process exits. Not a correctness bug, but noticeable in long-lived programs and in test harnesses.

- **Nested iteration is broken**: two loops in the same process share the library's single cursor. Collect one walk into a data structure before starting the next.
- **Shadow passwords**: on Linux and Solaris the real password hash is in `/etc/shadow`, readable only by root. Non-privileged processes see `"x"` or `"*"` in `$passwd` and must call the shadow-aware routines (outside of core Perl) to get the hash.
- **NSS surprises**: the database is whatever `/etc/nsswitch.conf` says it is. On a host bound to LDAP or SSSD, `getpwent` may return thousands of directory accounts, take a noticeable amount of time, and fail intermittently if the network is flaky. Consider looking accounts up by name with `getpwnam` when you know which one you want.
- **Tainting under -T**: `$passwd`, `$gcos`, and `$shell` come back tainted because users can influence them. Untaint with a deliberate regex match if you need to use them in sensitive operations.
- **Thread safety**: unlike `getpwnam` and `getpwuid`, there is no `getpwent_r` in POSIX that Perl can transparently substitute. Concurrent iteration from multiple threads is unsafe.
- **By-name interface**: `User::pwent` overrides `getpwent` with a version that returns an object exposing fields as methods (`$pw->name`, `$pw->uid`, ...). Use it when the numeric-slot unpacking gets unwieldy.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `getpwnam` - look up one account by login name; the right call when you know which user you want
- `getpwuid` - look up one account by numeric uid
- `setpwent` - rewind the `getpwent` cursor to the first entry
- `endpwent` - close the password database and release library resources; call it when the walk is done
- `getgrent` - the group-database counterpart, same iteration model
- `User::pwent` - by-name interface that returns an object with named accessors instead of a 10-element list

User and group info

getpwnam

Look up a user's passwd record by login name.

`getpwnam` wraps the system C library's `getpwnam(3)` call. Pass a login name like `"root"` or `"alice"`; you get back the passwd entry for that user, or an empty list / `undef` if no such user exists. The return shape depends on context: list context gives every field of the record; scalar context gives a single useful value - for `getpwnam` specifically, the numeric UID.

Synopsis

```
getpwnam NAME
```

What you get back

List context returns a 10-element list mirroring `struct passwd` augmented with the BSD extras:

```
my ($name,    $passwd, $uid,  $gid,   $quota,
    $comment, $gcos,   $dir,  $shell, $expire) = getpwnam($login);
```

- `$name` - login name (same string you passed in)
- `$passwd` - encrypted password, or `"x"` / `"*"` on shadow-password systems. Tainted under `-T`.
- `$uid` - numeric user ID
- `$gid` - numeric primary group ID
- `$quota` - disk quota, or `$change` / `$age` on some systems. Empty string when unsupported.
- `$comment` - administrative comment, sometimes `$class`. Empty string when unsupported.
- `$gcos` - GECOS field (usually the real name plus other user info). Tainted under `-T` because users can edit it.
- `$dir` - home directory
- `$shell` - login shell. Tainted under `-T`.
- `$expire` - account / password expiration, when supported.

Scalar context returns just `$uid`. For `getpwnam` - a lookup *by name* - scalar context gives you "the other thing," matching the rule upstream documents for all `getpw*` / `getgr*` / `gethost*` / `getnet*` / `getproto*` / `getserv*` functions.

On lookup failure both contexts return the empty list / `undef`. Always check the return before unpacking.

Global state it touches

- Sets `$!` on system-call failure (rare - "user not found" is not a failure, it's an empty return).
- Under `-T` (taint mode), `$passwd`, `$gcos`, and `$shell` come back tainted. See `perlsec` for how to launder them.
- Shares the same underlying iterator state as `getpwent`, `setpwent`, and `endpwent`. A `getpwnam` call does **not** disturb an in-progress `getpwent` loop on glibc, but portable code should not assume that.

Examples

Basic name-to-UID lookup in scalar context:

```
my $uid = getpwnam("root");          # 0
```

Full record in list context, with a defensive check:

```
my @pw = getpwnam($user)
    or die "$user: not in passwd database";
my ($name, undef, $uid, $gid, undef, undef, $gcos, $home, $shell) =
 ↪@pw;
print "$name ($uid) -> $home, shell $shell\n";
```

Assignment pattern from upstream - unpacking directly with `or die`:

```
my ($login, $pass, $uid, $gid) = getpwnam($user)
    or die "$user not in passwd file";
```

Comparing file ownership against a named user without hand-written field indexing, via the `User::pwent` override:

```
use User::pwent;
use File::stat;
my $is_theirs = (stat($filename)->uid == getpwnam($whoever)->uid);
```

`use User::pwent` replaces `getpwnam` with a version returning a blessed object with `->name`, `->uid`, `->gid`, `->dir`, `->shell` accessors - handy when you want one field and don't want to count commas. The two forms do not mix: inside one scope either use the override or the built-in, not both.

Fallback chain for "who am I running as":

```
my $login = getlogin() || getpwuid($<) || "unknown";
```

`getpwuid` is the by-UID counterpart; `getlogin` reads the controlling-tty record and can lie on detached processes, so it's the first choice, not the only one.

Edge cases

- **No such user** returns the empty list in list context and `undef` in scalar context. This is not an error - `$!` is not set. Distinguish "user missing" from "lookup failed" by checking `$!` only when you want to report an unexpected failure, not when deciding whether the user exists.
- **`$passwd` is rarely useful.** On modern Linux and BSD systems the real hash lives in `/etc/shadow`, readable only by root. You get `"x"` or `"*"` here. Use PAM or the `Authen::PAM` module for authentication rather than comparing against this field.
- **`$quota`, `$comment`, `$expire` portability.** These fields are empty or meaningless on Linux. The upstream POD lists `Config` values (`d_pwquota`, `d_pwage`, `d_pwchange`, `d_pwcomment`, `d_pwexpire`) you can check if you need to know at runtime whether the platform populates them.

- **Tainted fields under `-T`.** `$passwd`, `$gcos`, `$shell` are tainted because users can modify them (via `chsh`, `chfn`, or direct `/etc/passwd` edits in privileged contexts). Pass them through a regex capture to launder before using in a system call.
- **Return value is a "single meaningless true value"** in Boolean-ish scalar context *when the entry exists but you wanted list context.* The scalar-context documented return for `getpwnam` is the UID, which for `root` is `0` - a false value. `if (getpwnam("root")) { ... }` therefore fails for root. Use `defined` or list context:

```
if (defined getpwnam("root"))     { ... }   # correct
if (my @pw = getpwnam("root"))    { ... }   # also correct
```

- **Name is a string, not a UID.** `getpwnam(0)` stringifies `0` and looks up the literal user named `"0"`, which almost never exists. Use `getpwuid` for numeric lookups.
- **Large directories (LDAP / NIS / SSSD).** `getpwnam` goes through NSS, so the cost scales with however the local resolver answers. A miss against a misconfigured LDAP server can block for seconds. Cache results in a hash if you are looking up many users in a tight loop.
- **Threads.** Upstream notes that `getpwnam_r` is used automatically where the platform provides it; `getpwent` iteration, by contrast, remains per-process. Not a concern under pperl (no ithreads), but worth knowing if you share code with perl5.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `getpwuid` - same record, looked up by numeric UID; pair with `getpwnam` when you need to go UID → name
- `getpwent` - iterate the whole passwd database; use when you need every user, not a specific one
- `endpwent` - close the passwd iterator after `getpwent`
- `getgrnam` - group-database counterpart; needed to resolve the `$gid` field from this record back to a group name
- `getlogin` - cheap "who is on this tty" lookup; fall back to `getpwnam`/`getpwuid` when it returns empty
- `User::pwent` - object wrapper with named accessors; reach for it when you want `->uid` instead of counting list positions

User and group info

getpwuid

Look up a user's passwd record by numeric UID.

`getpwuid` wraps the system C library's `getpwuid(3)` call. Pass a numeric user ID like `0` or `$<`; you get back the passwd entry for that user, or an empty list / `undef` if no such UID

exists. The return shape depends on context: list context gives every field of the record; scalar context gives a single useful value - for `getpwuid` specifically, the login name.

Synopsis

```
getpwuid UID
```

What you get back

List context returns a 10-element list mirroring `struct passwd` augmented with the BSD extras - the same shape `getpwnam` returns:

```
my ($name,    $passwd, $uid,  $gid,   $quota,
    $comment, $gcos,   $dir,  $shell, $expire) = getpwuid($uid);
```

- `$name` - login name
- `$passwd` - encrypted password, or `"x"` / `"*"` on shadow-password systems. Tainted under `-T`.
- `$uid` - numeric user ID (same number you passed in)
- `$gid` - numeric primary group ID
- `$quota` - disk quota, or `$change` / `$age` on some systems. Empty string when unsupported.
- `$comment` - administrative comment, sometimes `$class`. Empty string when unsupported.
- `$gcos` - GECOS field (usually the real name plus other user info). Tainted under `-T` because users can edit it.
- `$dir` - home directory
- `$shell` - login shell. Tainted under `-T`.
- `$expire` - account / password expiration, when supported.

Scalar context returns just `$name` (the login name). For `getpwuid` - a lookup *by UID* - scalar context gives you "the other thing," matching the rule upstream documents for all `getpw*` / `getgr*` / `gethost*` / `getnet*` / `getproto*` / `getserv*` functions.

On lookup failure both contexts return the empty list / `undef`. Always check the return before unpacking.

Global state it touches

- Sets `$!` on system-call failure (rare - "UID not found" is not a failure, it's an empty return).
- Reads `$<` and `$>` implicitly only when you pass them in, but the common idiom `getpwuid($<)` is what turns the real-UID special variable into a useful record.
- Under `-T` (taint mode), `$passwd`, `$gcos`, and `$shell` come back tainted. See `perlsec` for how to launder them.

- Shares the same underlying iterator state as `getpwent`, `setpwent`, and `endpwent`. A `getpwuid` call does **not** disturb an in-progress `getpwent` loop on glibc, but portable code should not assume that.

Examples

Basic UID-to-name lookup in scalar context:

```
my $name = getpwuid(0);              # "root"
```

"Who am I running as" - the canonical `getpwuid` idiom, resolving the real UID to a login name:

```
my $me = getpwuid($<);               # e.g. "alice"
```

Pair with `getlogin` for a reliable fallback chain that survives detached processes and `su` sessions:

```
my $login = getlogin() || getpwuid($<) || "unknown";
```

`getlogin` reads the controlling-tty record and can lie (or return empty) when there is no tty; `getpwuid($<)` answers from the kernel's recorded UID and always works.

Full record in list context, with a defensive check:

```
my @pw = getpwuid($uid)
    or die "uid $uid: not in passwd database";
my ($name, undef, undef, $gid, undef, undef, $gcos, $home, $shell) =
 ↪@pw;
print "$name ($uid) -> $home, shell $shell\n";
```

Go UID → group name via the `$gid` field:

```
my $gid      = (getpwuid($<))[3];
my $groupnam = getgrgid($gid);
```

Object-style access via the `User::pwent` override, useful when you want named accessors instead of counting list positions:

```
use User::pwent;
my $pw = getpwuid($<);
printf "%s lives in %s, runs %s\n", $pw->name, $pw->dir, $pw->shell;
```

`use User::pwent` replaces `getpwuid` with a version returning a blessed object with `->name`, `->uid`, `->gid`, `->dir`, `->shell` accessors. The two forms do not mix: inside one scope either use the override or the built-in, not both.

Edge cases

- **No such UID** returns the empty list in list context and `undef` in scalar context. This is not an error - `$!` is not set. Distinguish "UID missing" from "lookup failed" by checking `$!` only when you want to report an unexpected failure, not when deciding whether the UID exists.

- **`$passwd` is rarely useful.** On modern Linux and BSD systems the real hash lives in `/etc/shadow`, readable only by root. You get `"x"` or `"*"` here. Use PAM or the `Authen::PAM` module for authentication rather than comparing against this field.
- **`$quota`, `$comment`, `$expire` portability.** These fields are empty or meaningless on Linux. The upstream POD lists `Config` values (`d_pwquota`, `d_pwage`, `d_pwchange`, `d_pwcomment`, `d_pwexpire`) you can check if you need to know at runtime whether the platform populates them.
- **Tainted fields under `-T`.** `$passwd`, `$gcos`, `$shell` are tainted because users can modify them (via `chsh`, `chfn`, or direct `/etc/passwd` edits in privileged contexts). Pass them through a regex capture to launder before using in a system call.
- **Scalar-return on UID 0 is never false.** Unlike `getpwnam`, whose scalar return for `root` is the UID `0` (a false value), `getpwuid`'s scalar return is the *name* `"root"` - always a true string for existing users. `if (getpwuid($uid)) { ... }` therefore works as you would expect, but reach for `defined` anyway if you care about the distinction between "missing" and "empty name":

```
if (defined getpwuid($uid))       { ... }   # unambiguous
if (my @pw = getpwuid($uid))      { ... }   # also correct
```

- **UID is a number, not a name.** `getpwuid("root")` stringifies `"root"` to `0` (with a warning under `use warnings`) and looks up UID `0`. Use `getpwnam` for name lookups.
- **Negative / oversized UIDs.** The system call accepts whatever `uid_t` accepts on the platform (typically 32-bit unsigned). Perl converts negative values via two's-complement on the way in; the result is platform-specific and almost never what you want.
- **Large directories (LDAP / NIS / SSSD).** `getpwuid` goes through NSS, so the cost scales with however the local resolver answers. A miss against a misconfigured LDAP server can block for seconds. Cache results in a hash if you are resolving many UIDs in a tight loop (e.g. annotating `ls -l`-style output).
- **Threads.** Upstream notes that `getpwuid_r` is used automatically where the platform provides it; `getpwent` iteration, by contrast, remains per-process. Not a concern under pperl (no ithreads), but worth knowing if you share code with perl5.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `getpwnam` - same record, looked up by login name; pair with `getpwuid` when you need to go name → UID
- `getpwent` - iterate the whole passwd database; use when you need every user, not a specific one
- `endpwent` - close the passwd iterator after `getpwent`
- `getgrgid` - group-database counterpart; needed to resolve the `$gid` field from this record back to a group name

- `getlogin` - cheap "who is on this tty" lookup; fall back to `getpwuid($<)` when it returns empty
- `User::pwent` - object wrapper with named accessors; reach for it when you want `->name` instead of counting list positions

Network info

getservbyname

Look up a network service by its textual name and protocol.

`getservbyname` consults the system service database (typically `/etc/services`, or whatever `nsswitch.conf` routes the `services` source to) and returns the entry whose name or alias matches `NAME` under the transport protocol named by `PROTO`. It is the Perl wrapper around the C library's `getservbyname(3)` call, and it is how you turn `"https"` into 443 without hardcoding the number.

Both arguments are strings. `NAME` is the service name or alias (`"http"`, `"ssh"`, `"imaps"`); `PROTO` is the protocol name (`"tcp"`, `"udp"`, `"sctp"`) - **not** a number, and **not** a `SOCK_STREAM`-style constant.

Synopsis

```
my $port                                = getservbyname NAME, PROTO;   #␣
↪scalar
my ($name, $aliases, $port, $proto) = getservbyname NAME, PROTO;   #␣
↪list
```

What you get back

In **scalar context**, the port number as a plain integer in host byte order - ready to feed to `pack` with `"n"` or to a `sockaddr_in` constructor. If no entry matches, the return is `undef`.

In **list context**, the four fields of the `servent` record:

- `$name` - canonical service name (the primary name, not whichever alias you looked up by).
- `$aliases` - space-separated string of alternate names.
- `$port` - port number, host byte order.
- `$proto` - canonical protocol name as returned by the resolver, normally equal to the `PROTO` you passed.

If no entry matches in list context the return is the empty list.

The port is **host byte order**. Network APIs expect network byte order, so pass it through `pack` with the `"n"` template - or let `Socket` do it via `sockaddr_in`.

Global state it touches

- Holds an open handle to the services database between calls when the database has been opened with `setservent` using a non-zero STAYOPEN. `endservent` closes it.
- Sets `$!` on lookup failures that stem from a system-level error (database file missing, NSS backend unreachable). A plain "no such service" is reported by returning `undef` / the empty list, not by setting `$!`.

Examples

Resolve a well-known service to its port:

```
my $port = getservbyname("https", "tcp");
print $port, "\n";                    # 443
```

Full record in list context:

```
my ($name, $aliases, $port, $proto) = getservbyname("http", "tcp");
print "$name ($aliases) -> $port/$proto\n";
                                      # www (www-http http) -> 80/
↪tcp
                                      # (exact aliases depend on /
↪etc/services)
```

Build a `sockaddr_in` for `connect`, converting the host-order port to network order with `pack`:

```
use Socket;
my $port  = getservbyname("smtp", "tcp")
    or die "smtp/tcp not in services db";
my $addr  = sockaddr_in($port, inet_aton("mail.example.com"));
socket(my $s, AF_INET, SOCK_STREAM, getprotobyname("tcp")) or die $!
↪;
connect($s, $addr) or die "connect: $!";
```

Distinguish "not found" from "wrong protocol" - a service that exists under `tcp` but not udp returns `undef` when the protocol does not match:

```
defined(getservbyname("https", "tcp")) or die "expected 443";
defined(getservbyname("https", "udp")) or warn "no https/udp entry";
```

Look up by alias - aliases resolve the same as the canonical name, but the returned `$name` is always the canonical one:

```
my ($name) = getservbyname("www", "tcp");
print $name, "\n";                    # "http" on most systems
```

Edge cases

- **Unknown service**: returns `undef` in scalar context, the empty list in list context. `$!` is **not** set for a plain miss - only for underlying system errors.
- **Unknown protocol**: same as an unknown service. `getservbyname("ssh", "xyzzy")` returns nothing; no separate error is raised.
- **Case sensitivity**: service and protocol names are compared case-insensitively by the system resolver on every platform we support; `"HTTPS"` and `"https"` give the same answer.
- **Port is host byte order**: passing it straight into a wire format is a bug. Use `pack("n", $port)` or `sockaddr_in($port, $addr)` - both handle the conversion.
- **`NAME` and `PROTO` are both required**. There is no one-arg form; omitting `PROTO` is a compile-time error.
- **Precedence trap**: like every named-unary-lookalike in this family, `getservbyname` is a list operator. Parenthesise when combining with operators:

```
getservbyname "http", "tcp" == 80      # WRONG: parses as
                                       # getservbyname("http", (
 ↪"tcp" == 80))
getservbyname("http", "tcp") == 80     # right
```

- **Threads**: on systems with `getservbyname_r(3)`, Perl uses the reentrant variant transparently. On the handful of platforms that lack it, concurrent lookups from multiple threads can clobber each other's results.
- **By-name interface**: `Net::servent` (core) wraps this call and returns an object with named accessors, at the cost of one allocation per lookup.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `getservbyport` - inverse lookup: port + protocol → service record
- `getservent` - walk every entry in the services database, one record at a time
- `setservent` - rewind (or persistently open) the services database before a walk
- `endservent` - close the services database opened by `setservent`
- `getprotobyname` - companion lookup for the `PROTO` argument when you also need its numeric protocol number
- `Socket` - `sockaddr_in` and `pack_sockaddr_in` consume the host-order port returned here

Network info

getservbyport

Look up a network service by its numeric port and protocol.

`getservbyport` consults the system services database (`/etc/services` on Linux, plus whatever NSS sources are configured) and returns the record for the service that listens on `PORT` under protocol `PROTO`. `PORT` is an integer **in network byte order** - the value you would pass to `bind` or receive from `sockaddr_in`, not the decimal shown in `/etc/services`. `PROTO` is a lowercase string such as `"tcp"` or `"udp"`. The call wraps the C library's `getservbyport(3)`.

Synopsis

```
getservbyport PORT, PROTO          # list context: full record
scalar getservbyport PORT, PROTO   # scalar context: service name
```

What you get back

In **list context**, a four-element list describing the service:

```
my ($name, $aliases, $port, $proto) = getservbyport($port_n, "tcp");
```

Index	Name	Meaning
0	`$name`	Canonical service name, e.g. `"http"`
1	`$aliases`	Space-separated alias list, e.g. `"www www-http"`
2	`$port`	Port number in **network byte order**
3	`$proto`	Protocol name, e.g. `"tcp"`

If the entry does not exist the list is empty, so a list-context assignment leaves every target `undef`. A bare list-context call returns a single meaningless true value on miss - always assign to a list and test the first element, or call in scalar context.

In **scalar context**, you get the canonical service name (the same `$name` as above), or `undef` if no service is registered on that port for that protocol:

```
my $name = getservbyport($port_n, "tcp")
    or warn "port $port not registered for tcp";
```

Global state it touches

- `$!` is **not** reliably set on a miss - the C `getservbyport(3)` function has no standard errno contract for "not found". Treat an empty list or `undef` return as the only trustworthy failure signal.
- Iteration state held by the services database (shared with `getservent`, `setservent`, and `endservent`) is process-global and not thread-safe.

Byte-order trap

PORT must be network byte order. The port column in `/etc/services` is a human decimal; the value the kernel and the C library use is the big-endian 16-bit encoding. Convert with `pack` / `unpack` or with the `Socket` helpers:

```
use Socket;

# Host decimal 80 -> network-order short:
my $port_n = pack("n", 80);            # two bytes, big-endian
my @rec    = getservbyport($port_n, "tcp");

# Or going the other way, a port extracted from sockaddr_in is
# already network order:
my ($port_n_from_peer, $iaddr) = sockaddr_in(getpeername($sock));
my $name = getservbyport($port_n_from_peer, "tcp");
```

Passing a host-order integer such as `80` works on little-endian hardware only by accident for low ports whose encoding happens to be non-zero in the low byte - most ports will simply miss. This is the single most common reason a `getservbyport` call "silently returns nothing".

Examples

Identify the service on port 443 over TCP:

```
use Socket;
my $port_n = pack("n", 443);
my ($name) = getservbyport($port_n, "tcp");
print $name, "\n";                     # https
```

Pair with `getpeername` to name an incoming connection's port:

```
use Socket;
my ($peer_port_n, $peer_addr) = sockaddr_in(getpeername($client));
my $service = getservbyport($peer_port_n, "tcp") // "unknown";
print "client connected from service $service\n";
```

Full record dump - useful when you want the protocol or aliases:

```
use Socket;
my @rec = getservbyport(pack("n", 53), "udp");
if (@rec) {
    my ($name, $aliases, $port_n, $proto) = @rec;
    printf "%s (%s) on %d/%s\n",
        $name, $aliases, unpack("n", pack("n", $port_n)), $proto;
}
```

Scalar context, guard clause style:

```
my $svc = getservbyport(pack("n", $port), "tcp")
    or die "no TCP service registered on port $port";
```

Iterate every registered service (the underlying database is shared with `getservent`):

```
while (my ($n, $a, $p, $proto) = getservent()) {
    next unless $proto eq "tcp";
    # …do something with $n / $p…
}
endservent();
```

Edge cases

- **Missing entry**: empty list in list context, `undef` in scalar context. A bare `if (getservbyport(...))` in list context is truthy even for a missing entry because of the "single meaningless true value" legacy return - always assign to a list or force scalar context.
- **Unknown protocol**: an unrecognised `PROTO` string (e.g. `"sctp"` on a host whose database does not include it) is treated by the C library as no-match. The call returns empty/undef, not an error.
- **Case of `PROTO`**: case-sensitive on most Linux libc implementations. Use lowercase `"tcp"` / `"udp"`; `"TCP"` will miss.
- **Host-order port**: passing `80` instead of `pack("n", 80)` is the classic bug - see *Byte-order trap* above.
- **Numeric vs string `PORT`**: Perl numifies `PORT` before passing to libc. A two-byte packed string works because `pack` with `"n"` produces bytes that numify deterministically on the supported platforms; if in doubt, `unpack("n", $packed)` first and pass the integer to keep the intent explicit.
- **Precedence with list operators**: like other named unary / list operators, `getservbyport` binds loosely. Parenthesise when the result feeds another operator:

  ```
  getservbyport $port_n, "tcp" eq "https"     # WRONG
  (getservbyport($port_n, "tcp")) eq "https"  # correct
  ```

- **Threads**: the underlying lookup shares state with `getservent` / `setservent` / `endservent`. Two threads iterating concurrently will interleave records. Use thread-local wrappers when that matters.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `getservbyname` - inverse lookup, service name to port; reach for it when you know the name and want the number
- `getservent` - iterate every service record; use when you need a full sweep rather than a single lookup
- `setservent` - rewind the services iterator, optional `STAYOPEN` flag to keep the file open across `fork`

- endservent - close the services database after an iteration
- getprotobynumber - the protocol-side companion lookup; often used right after getservbyport to translate the $proto field
- pack - build the network-order port value getservbyport expects as its first argument
- Socket - constants and sockaddr_in helpers that produce network-order ports straight from kernel structures

Network info

getservent

Read the next entry from the system services database.

getservent walks the /etc/services database one record at a time, yielding the same list of fields as getservbyname and getservbyport but without a lookup key. Each call advances an internal cursor; the cursor is opened on the first call, rewound by setservent, and released by endservent. It mirrors the POSIX getservent(3) C library routine and inherits every portability quirk that implies.

Synopsis

```
my ($name, $aliases, $port, $proto) = getservent;
my $name = getservent;          # scalar context
```

What you get back

In list context, four fields matching the order documented for every getserv* variant:

- $name - canonical service name, e.g. "http".
- $aliases - space-separated string of alternate names, e.g. "www www-http". Not an array; split it yourself if you need one.
- $port - port number as a native (host-byte-order) integer, e.g. 80.
- $proto - transport protocol, typically "tcp" or "udp".

In scalar context, just $name. When the cursor reaches end of file, getservent returns the empty list in list context and undef in scalar context - the idiomatic while (my @e = getservent) loop relies on this.

To convert the aliases into a list:

```
my @alt = split / /, $aliases;
```

Global state it touches

- **Internal database cursor** for /etc/services - shared with getservbyname, getservbyport, setservent, and endservent. Any by-name or by-port lookup on some platforms rewinds or closes this cursor as a side effect; iterate in a tight loop or wrap the iteration in setservent / endservent to be safe.

- `$!` - set when the underlying C call reports an error.
- Not thread-safe. `getservent` keeps per-process, not per-thread state; two threads iterating concurrently will interleave records and neither will see the full list.

Examples

Walk the full services database and print each entry:

```
while (my ($name, $aliases, $port, $proto) = getservent) {
    print "$name/$proto $port\n";
}
endservent;
```

Reset the cursor before iterating so earlier calls elsewhere in the program cannot leave it mid-stream:

```
setservent(0);
while (my @e = getservent) {
    # @e is ($name, $aliases, $port, $proto)
}
endservent;
```

Collect only TCP services into a hash keyed by port:

```
my %tcp;
while (my ($name, undef, $port, $proto) = getservent) {
    $tcp{$port} = $name if $proto eq 'tcp';
}
endservent;
```

Use the object-oriented by-name interface from `Net::servent`, which overrides the built-in and returns a blessed object with accessor methods:

```
use Net::servent;
while (my $s = getservent) {
    printf "%-20s %5d/%s\n", $s->name, $s->port, $s->proto;
}
```

Edge cases

- **End of file returns empty / undef, not an error.** A single-scalar false value in list context (`my @e = getservent` giving an empty list) is the terminator. Do not check `$!` to detect end of iteration.
- **Missing `/etc/services`**: on systems without the file, the first call returns the empty list immediately and `$!` is set. Nothing in the call signals the difference between an empty database and a missing one - inspect `$!` before assuming the database was simply empty.
- **Cursor sharing with by-name / by-port lookups**: calling `getservbyname` or `getservbyport` in the middle of a `getservent` loop may reset the cursor on some platforms. Either finish the walk first or re-open with `setservent`.

- **`$aliases` is a string, not a list**. `split / /, $aliases` gives you the array form. Treating `$aliases` as a list directly silently gives you the length of a one-element list.
- **Threaded programs**: iteration is per-process. Coordinate access with a lock, or prefer `getservbyname` / `getservbyport` for point queries in threaded code.
- **Scalar context returns only the name.** If you need the port, call in list context even when you only care about one field.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `getservbyname` - look up a single service by its textual name instead of iterating
- `getservbyport` - look up a single service by its numeric port
- `setservent` - rewind the shared cursor before iterating so prior calls cannot leave it mid-stream
- `endservent` - release the cursor when the walk is done, freeing the underlying file descriptor
- `getprotoent` - same iterator pattern for `/etc/protocols`, typically paired when resolving a `(port, proto)` tuple
- `Net::servent` - object-oriented wrapper whose accessors remove the need to remember field order

Sockets

getsockname

Return the local address of a connected or bound socket.

`getsockname` asks the kernel which address and port `SOCKET` is bound to on this end of the connection. The result is the same packed sockaddr structure the kernel hands to `accept` or that you would pass to `bind` - unpack it with the appropriate helper from `Socket` (for example `sockaddr_in` for IPv4, `sockaddr_in6` for IPv6). Useful when a host has multiple interfaces and you need to know which one a client reached you on, or when you asked the kernel for an ephemeral port via `bind` with port `0` and now want to know the port it picked.

Synopsis

```
getsockname SOCKET
```

What you get back

On success, the packed sockaddr for the local end of SOCKET as a byte string whose layout matches the socket's address family. On failure, undef with $! set (typically ENOTSOCK if SOCKET is not a socket, or EBADF if it is not an open filehandle).

The return value is **opaque bytes**. Do not inspect it directly - hand it to the family-appropriate unpacker:

```
use Socket;
my $packed = getsockname($sock) or die "getsockname: $!";
my ($port, $addr) = sockaddr_in($packed);      # IPv4
```

For address-family-agnostic code, call sockaddr_family on the result first and dispatch on the returned AF_* constant.

Global state it touches

None. getsockname is a pure system-call wrapper - it does not read or write $_, $! aside, or any other interpreter global.

Examples

Discover the ephemeral port the kernel assigned after bind(…, 0):

```
use Socket;
socket(my $srv, AF_INET, SOCK_STREAM, 0) or die $!;
bind($srv, sockaddr_in(0, INADDR_ANY))   or die $!;
my ($port) = sockaddr_in(getsockname($srv));
print "listening on port $port\n";
```

Identify which local IP a connected client reached you on, on a multi-homed host:

```
use Socket;
my $mysockaddr = getsockname($sock);
my ($port, $myaddr) = sockaddr_in($mysockaddr);
printf "Connect to %s [%s]\n",
    scalar gethostbyaddr($myaddr, AF_INET),
    inet_ntoa($myaddr);
```

IPv6 variant - unpack with sockaddr_in6:

```
use Socket;
my ($port, $addr) = sockaddr_in6(getsockname($sock));
printf "local: [%s]:%d\n", inet_ntop(AF_INET6, $addr), $port;
```

Family-agnostic dispatch when the socket could be either IPv4 or IPv6:

```
use Socket qw(sockaddr_family sockaddr_in sockaddr_in6
              inet_ntop AF_INET AF_INET6);
my $name = getsockname($sock) or die "getsockname: $!";
if (sockaddr_family($name) == AF_INET) {
```

(continues on next page)

(continued from previous page)

```
    my ($port, $addr) = sockaddr_in($name);
    printf "%s:%d\n", inet_ntoa($addr), $port;
} else {
    my ($port, $addr) = sockaddr_in6($name);
    printf "[%s]:%d\n", inet_ntop(AF_INET6, $addr), $port;
}
```

Edge cases

- **Unbound socket**: A socket that has been created but never bound or connected typically returns a sockaddr with the wildcard address and port `0`. It is not an error - the kernel simply reports "no local name assigned yet."
- **Not a socket**: Passing an open filehandle that is not a socket (a plain file, a pipe) returns `undef` with `$!` set to `ENOTSOCK`.
- **Closed filehandle**: Returns `undef` with `$!` set to `EBADF`. Under `use warnings` a `getsockname() on closed socket` warning is emitted.
- **Unix-domain sockets**: The packed form is an `AF_UNIX` sockaddr; unpack with `unpack_sockaddr_un`. The path may be shorter than what you passed to `bind`, and on Linux it may begin with a NUL byte for abstract-namespace sockets.
- **Wildcard address with IPv4**: A socket bound to `INADDR_ANY` reports the wildcard address (`0.0.0.0`) here, not the specific interface address the peer reached. To learn the peer's target address you must use `getsockname` *after* the kernel has routed the connection (post-`accept`), or consult `IP_PKTINFO` via `getsockopt`.
- **Call before `bind`/`connect`**: The behaviour is platform-specific but harmless. Linux returns a zeroed sockaddr of the socket's family; some BSDs return `undef` with `EINVAL`. Rely on it only after `bind`, `connect`, or `accept` have completed.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `getpeername` - the mirror call: returns the **remote** end's sockaddr for a connected socket
- `bind` - set the local address; `getsockname` reads back what the kernel actually bound, including ephemeral ports chosen for you
- `accept` - returns the remote sockaddr directly, so you rarely need `getsockname` on the accepted socket unless the listener bound to a wildcard and you want the concrete local address
- `socket` - creates the socket whose local name `getsockname` reports
- `Socket` - the module providing the unpackers (`sockaddr_in`, `sockaddr_in6`, `unpack_sockaddr_un`, `sockaddr_family`) you apply to the return value

- `getsockopt` - for per-packet destination-address information (`IP_PKTINFO`) when a wildcard-bound socket needs to know the concrete local address of an incoming datagram

Sockets

getsockopt

Read one socket option out of the kernel as an opaque packed string.

`getsockopt` asks the kernel for the current value of the option named `OPTNAME` at protocol level `LEVEL` on `SOCKET`. The kernel does not return a typed value - it returns a raw byte buffer whose layout is determined by the `(LEVEL, OPTNAME)` pair. You decode that buffer with `unpack`, usually with the `"i"` or `"I"` template, because most options are plain integers.

Synopsis

```
getsockopt SOCKET, LEVEL, OPTNAME
```

What you get back

A packed string holding the kernel's reply on success, or `undef` on failure with `$!` set to the system error. The string's contents are **opaque bytes** - its length and layout depend entirely on `(LEVEL, OPTNAME)`:

- Boolean and integer options (`SO_KEEPALIVE`, `SO_REUSEADDR`, `TCP_NODELAY`, ...) come back as a packed `int`. Decode with `unpack` using `"i"` or `"I"`.
- Timeouts (`SO_RCVTIMEO`, `SO_SNDTIMEO`) come back as a packed `struct timeval` - two `long`s on most platforms.
- Address-bound options (`SO_PEERCRED`, `IP_MULTICAST_IF`, linger structs, ...) have their own layouts; consult `getsockopt(2)` and the relevant protocol man pages for the exact struct.

Always check the return value before decoding - calling `unpack` on `undef` yields an empty result and hides the real error recorded in `$!`.

Global state it touches

- `$!` is set on failure to the `errno` value from the underlying `getsockopt(2)` call. It is not cleared on success, so check the return value, not `$!` directly.

Examples

Check whether Nagle's algorithm is currently disabled (`TCP_NODELAY` set) on a TCP socket:

```
use Socket qw(IPPROTO_TCP TCP_NODELAY);

my $packed = getsockopt($sock, IPPROTO_TCP, TCP_NODELAY)
```

(continues on next page)

(continued from previous page)

```
    or die "getsockopt TCP_NODELAY: $!";
my $nodelay = unpack("I", $packed);
print "Nagle is ", $nodelay ? "off" : "on", "\n";
```

Same idea, but obtaining the TCP protocol number at runtime from the system's protocol database rather than a `Socket` constant:

```
use Socket qw(TCP_NODELAY);

defined(my $tcp = getprotobyname("tcp"))
    or die "no protocol entry for tcp";
my $packed = getsockopt($sock, $tcp, TCP_NODELAY)
    or die "getsockopt: $!";
```

Read `SO_ERROR` to drain and clear a pending asynchronous error on a non-blocking socket after `connect` or after `select` flags it writable:

```
use Socket qw(SOL_SOCKET SO_ERROR);

my $packed = getsockopt($sock, SOL_SOCKET, SO_ERROR)
    or die "getsockopt SO_ERROR: $!";
my $err = unpack("i", $packed);
if ($err) {
    $! = $err;
    die "asynchronous socket error: $!";
}
```

Read the socket type (`SOCK_STREAM`, `SOCK_DGRAM`, ...) of an already opened handle:

```
use Socket qw(SOL_SOCKET SO_TYPE SOCK_STREAM);

my $packed = getsockopt($sock, SOL_SOCKET, SO_TYPE)
    or die "getsockopt SO_TYPE: $!";
my $type = unpack("i", $packed);
print "stream socket\n" if $type == SOCK_STREAM;
```

Read a `struct timeval` option. `SO_RCVTIMEO` returns two native `long`s - seconds and microseconds:

```
use Socket qw(SOL_SOCKET SO_RCVTIMEO);

my $packed = getsockopt($sock, SOL_SOCKET, SO_RCVTIMEO)
    or die "getsockopt SO_RCVTIMEO: $!";
my ($sec, $usec) = unpack("l!l!", $packed);
printf "receive timeout: %d.%06d s\n", $sec, $usec;
```

Edge cases

- **SOCKET is not an open socket**: the call fails, returns `undef`, and sets `$!` to `ENOTSOCK` (`"Socket operation on non-socket"`) or `EBADF` (`"Bad file descriptor"`) for a closed handle.
- **Unknown `LEVEL` / `OPTNAME`**: the kernel rejects the request with `ENOPROTOOPT` (`"Protocol not available"`). There is no way to tell this apart from the success case except by checking the return value.
- **Truthy-return idiom**: the common `getsockopt(...) or die` works because a successful call returns a non-empty packed string. A zero-length reply would make the idiom misfire, but no kernel option returns a zero-length buffer in practice - every defined option has at least one byte of payload.
- **Integer decode width**: use `"i"` or `"I"` for `int`-sized options (`SO_KEEPALIVE`, `TCP_NODELAY`, `SO_ERROR`, ...); use `"l!"` or `"L!"` only when the option's documented layout genuinely uses a native `long`. Getting the width wrong silently returns the wrong number on LP64 platforms.
- **Do not hand-pack the reply**: `getsockopt` returns whatever the kernel wrote, including any padding. Re-pack only on round-trips via `setsockopt`, and then pass the buffer back verbatim rather than reconstructing it.
- **No constants without `Socket`**: `SOL_SOCKET`, `IPPROTO_TCP`, `TCP_NODELAY`, `SO_ERROR`, and friends are not built-in names. Import them from `Socket` with `use Socket qw(...)` or `use Socket qw(:all)`.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `setsockopt` - the write half; sets the option whose value `getsockopt` reads back
- `Socket` - source of the `SOL_*`, `IPPROTO_*`, `SO_*`, `TCP_*`, `IP_*` constants you pass as `LEVEL` and `OPTNAME`
- `unpack` - required to decode the packed byte string the kernel hands back
- `getprotobyname` - run-time way to obtain the `LEVEL` protocol number when you do not want to pull in the `IPPROTO_*` constants from `Socket`
- `getsockname` - sibling introspection call; returns the local address bound to `SOCKET` rather than a single option
- `socket` - creates the socket that `getsockopt` then queries

Filehandles, files, directories

glob

Expand a shell-style filename pattern into the list of matching paths.

`glob` takes a pattern string such as `"*.c"` or `"src/**/*.pm"` and returns the filenames on disk that match, in the same style a Unix shell would produce. In list context it returns

every match at once; in scalar context it acts as a stateful iterator, returning one match per call and `undef` when the list is exhausted. With no argument, `glob` expands the pattern in `$_`.

Synopsis

```
glob EXPR
glob
<PATTERN>
```

What you get back

In list context, a (possibly empty) list of filenames. An empty list means the pattern did not match - it is **not** an error and does not set `$!`.

In scalar context, `glob` is an iterator: each call returns the next match, and after the last match one more call returns `undef`. The iterator state is per-call-site, so two `while (my $f = glob ...)` loops at different source locations do not interfere.

```
my @mp3  = glob "*.mp3";              # list context
while (my $f = glob "*.mp3") { }      # scalar context, iterator
```

Global state it touches

- `$_` - read when `glob` is called with no argument.
- `glob` itself does **not** set `$!` on "no matches". A non-match is a legitimate empty list, not a failure.
- When a `glob` expression is used as the condition of a `while` or `for` loop, Perl implicitly assigns the result to `$_` and tests for **definedness**, not truth - so a filename of `"0"` still keeps the loop running.

The <...> shortcut and how Perl picks it

`<*.c>` is an alternative syntax for `glob("*.c")`. The angle-bracket form shares a reader with `<FH>` (`readline`); the parser decides which one you meant at **compile time** based on what sits between the angle brackets:

- Bareword that could be a filehandle (`<STDIN>`, `<FH>`) → `readline`.
- A simple scalar (`<$fh>`) → `readline` on that handle.
- Anything that looks like a pattern (`<*.c>`, `<"*.txt">`, `<${dir}/*>`) → `glob`.

The named function `glob` is unambiguous and more searchable. Prefer it in new code; reach for `<...>` only for the shortest throwaway patterns.

```
my @txt = <"*.txt">;                  # same as glob '"*.txt"'
my @txt = glob "*.txt";               # recommended
```

Whitespace splits the pattern

`glob` splits its argument on whitespace and treats each segment as a separate pattern. The results are concatenated:

```
my @sources = glob "*.c *.h";       # all .c OR .h files
my @all     = glob ".* *";          # every entry in cwd
```

To glob a filename that itself contains spaces, wrap it in an inner pair of quotes so the split sees one segment:

```
my @spacey = glob '"*e f*"';        # files with "e f" in the name
my @spacey = glob q("*e f*");       # same, q() for clarity
my @spacey = <"*e f*">;             # same via the shortcut form
```

Interpolating a variable into a spacey pattern:

```
my @spacey = glob "'*${var}e f*'";
my @spacey = glob qq("*${var}e f*");
```

If the whitespace-splitting rule gets in the way, use `File::Glob`'s `bsd_glob` directly - it takes the pattern verbatim.

Brace expansion without a wildcard

If the only special characters are non-empty braces, `glob` does not touch the filesystem at all: it just enumerates the Cartesian product of the alternatives. This is useful for generating string combinations:

```
my @pairs = glob "{apple,tomato,cherry}={green,yellow,red}";
# apple=green, apple=yellow, apple=red,
# tomato=green, tomato=yellow, tomato=red,
# cherry=green, cherry=yellow, cherry=red
```

`File::Glob` - the engine, and its options

`glob` is implemented on top of `File::Glob`'s `bsd_glob`. Importing the module's tags tunes behaviour for the whole compilation unit:

- `:nocase` - case-insensitive matching.
- `:case` - force case-sensitive matching (the default on most Unix filesystems).
- `:globally` - replace the core `glob` operator with `bsd_glob` so every `glob(...)` and `<...>` in the file picks up your options.

```
use File::Glob qw(:globally :nocase);
my @txt = glob "readme*";           # README, readme.txt, Readme.md
```

Call `bsd_glob` directly when you need flags per call, or when you want to bypass the whitespace-splitting rule:

```
use File::Glob qw(bsd_glob GLOB_TILDE GLOB_BRACE);
my @files = bsd_glob("~/docs/*.{md,rst}", GLOB_TILDE | GLOB_BRACE);
```

Examples

List every Perl source file in the current directory:

```
my @perl_files = glob "*.pl *.pm";
```

Iterate MP3 files one at a time - useful when the list might be large and you do not want to materialise it:

```
while (my $song = glob "*.mp3") {
    process($song);                 # one filename per iteration
}
```

Recursive patterns are **not** built in; `*` does not cross `/`. Walk the tree with `File::Find` or combine `glob` with an explicit traversal:

```
my @all_c;
for my $dir (glob "src/*") {
    push @all_c, glob "$dir/*.c" if -d $dir;
}
```

Use the iterator form in a `while` condition - the result is assigned to `$_` and tested for definedness, so filenames like `"0"` do not terminate the loop:

```
while (<*.log>) {
    unlink $_ if -M $_ > 30;        # older than 30 days
}
```

Case-insensitive match for a whole file:

```
use File::Glob qw(:globally :nocase);
my @readmes = glob "readme*";
```

Edge cases

- **No matches**: returns the empty list. No warning, no `$!` set. If you need "pattern had to match", check `scalar @files` yourself.
- **`glob` with no argument**: uses `$_`. Bare `glob` inside `while (<>)` is rarely what you want - the pattern will be whatever line of input you just read.
- **`while (glob ...)` assigns to `$_` and tests definedness**: a filename `"0"` is false under normal boolean rules, but the loop still runs because the condition is `defined $_`. This matches the rule for `readline` in the same position.
- **Wildcards and whitespace**: the split-on-whitespace rule means `glob "a b"` searches for `a` and `b` as two patterns, not for the literal string `"a b"`. Use inner quotes or `bsd_glob` when the filename legitimately contains spaces.

- **Hidden files**: a leading `.` is not matched by `*` - you need an explicit `.*` segment (`glob ".* *"`) to include dotfiles. This matches shell glob semantics, not regex semantics.
- **Tilde expansion**: `glob "~/foo"` works because `File::Glob` expands `~` by default. Writing it through `bsd_glob` without `GLOB_TILDE` in the flags, you get a literal `~`.
- **Interpolation inside `<...>`**: `<$var/*.c>` interpolates `$var` at runtime. Using the angle-bracket form does not escape you from Perl's normal double-quote rules.
- **Angle-bracket ambiguity**: `<FOO>` is a handle read, `<$foo>` is a handle read, `<*.c>` is a glob. `<$foo/*.c>` - one scalar plus pattern characters - is a glob. The resolution is compile-time; runtime changes to `$foo` do not re-decide it.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `opendir` - open a directory handle for finer-grained traversal than pattern matching gives you
- `readdir` - read entries from a directory handle one at a time; pair with `opendir` when you need every entry (including ones `glob` hides, like dotfiles) or file-type info
- `readline` - the other meaning of `<...>`; shares the angle-bracket syntax but reads lines from a filehandle
- `File::Glob` - the underlying implementation; use `bsd_glob` directly for per-call flags and to bypass the whitespace-splitting rule
- `$_` - default pattern source for bare `glob`, and the variable implicitly assigned when `glob` is used as a `while`/`for` loop condition

Time

gmtime

Convert an epoch time to a broken-down UTC time, either as a 9-element list or as a `ctime(3)`-style string.

`gmtime` is `localtime` expressed in the Greenwich time zone. It takes an integer number of seconds since the epoch - the kind of value `time` returns - and hands back either the individual calendar fields (in list context) or a ready-to-print summary string (in scalar context). No time-zone lookup, no `TZ`, no DST: the result is always UTC.

Synopsis

```
gmtime EXPR
gmtime
```

`gmtime` without an argument uses the current `time`.

What you get back

In **list context**, a nine-element list drawn straight from the C `struct tm`:

```
#    0     1     2      3      4     5      6      7      8
my ($sec, $min, $hour, $mday, $mon, $year, $wday, $yday, $isdst)
    = gmtime(time);
```

Index	Field	Range	Notes
0	`$sec`	`0..60`	60 allows a positive leap second
1	`$min`	`0..59`	
2	`$hour`	`0..23`	
3	`$mday`	`1..31`	**1-based**
4	`$mon`	`0..11`	**0-based** - January is 0, December is 11
5	`$year`		**years since 1900** - add `1900` for AD
6	`$wday`	`0..6`	Sunday is 0
7	`$yday`	`0..365`	0 is January 1st; 365 only in leap years
8	`$isdst`	`0`	**always 0** for `gmtime` - UTC has no DST

In **scalar context**, a single `ctime(3)`-formatted English string:

```
my $s = gmtime;    # "Thu Oct 13 04:54:34 1994"
```

The scalar form is **always English and locale-independent**. For a locale-aware or differently-formatted string, build it from the list form with `POSIX::strftime`.

Global state it touches

None. `gmtime` does not read `$ENV{TZ}`, does not consult the interpreter's locale, and does not depend on or modify any of the Perl special variables. Given the same `EXPR`, it always returns the same result.

With no argument, it reads the current wall-clock time via `time`.

Examples

Current UTC broken down into its fields, with the month-0-index and year-since-1900 traps both handled:

```
my @abbr = qw(Jan Feb Mar Apr May Jun Jul Aug Sep Oct Nov Dec);
my ($sec, $min, $hour, $mday, $mon, $year) = gmtime;
printf "%s %d, %d  %02d:%02d:%02d UTC\n",
       $abbr[$mon], $mday, $year + 1900, $hour, $min, $sec;
# e.g. "Apr 23, 2026  14:07:09 UTC"
```

The scalar form - a single fixed-format string, useful for logs:

```
my $stamp = gmtime;
print "[$stamp] startup\n";
# "[Thu Apr 23 14:07:09 2026] startup"
```

Format the list with `POSIX::strftime` when you want ISO-8601 or a locale-aware rendering:

```
use POSIX qw(strftime);
my $iso = strftime "%Y-%m-%dT%H:%M:%SZ", gmtime;
# e.g. "2026-04-23T14:07:09Z"
```

Convert a stored epoch (not the current time) - any integer seconds since 1970-01-01 UTC works:

```
my $epoch = 1_700_000_000;
my @t = gmtime($epoch);
printf "%04d-%02d-%02d\n", $t[5] + 1900, $t[4] + 1, $t[3];
# "2023-11-14"
```

`$isdst` is always `0` under `gmtime` - do not use it to probe DST. Call `localtime` if you need that information:

```
my $dst_here = (localtime)[8];   # 0 or 1 depending on local zone
my $dst_utc  = (gmtime)[8];      # always 0
```

Edge cases

- **Bare call uses current time**: `gmtime` with no argument is `gmtime(time)`. Inside interpolation or a list that might swallow the call, parenthesise: `gmtime()`.
- **List vs scalar context is load-bearing**. In list context you get nine numbers; in scalar context you get a string. Forcing scalar on a bare call inside a list:

  ```
  print gmtime, "\n";                # nine digits, no spaces
  print scalar gmtime, "\n";         # "Thu Apr 23 14:07:09 2026"
  ```

- **`$mon` is 0-indexed, `$year` is since-1900**. Two of the most common Perl bugs. For a full calendar year do `$year + 1900`; for a 1-indexed month do `$mon + 1`.
- **`$mday` is 1-indexed, `$yday` is 0-indexed**. Mirrors C `struct tm` exactly - inconsistent, but stable.
- **`$sec == 60`** on a positive leap second. Code that validates with `$sec <= 59` will reject legitimate values.
- **Negative epoch values** represent dates before 1970-01-01 UTC and are accepted on platforms whose `gmtime(3)` accepts them - which Linux does. `gmtime(-1)` returns 1969-12-31 23:59:59 UTC.
- **Fractional seconds are discarded**. `EXPR` is truncated toward zero before the conversion; `gmtime(1.9)` is `gmtime(1)`. For sub-second precision, keep your own fractional part and format it separately.
- **No time-zone abbreviation in the scalar form**. Unlike `localtime`'s `ctime(3)` output on some platforms, `gmtime`'s scalar form never includes a zone name. It is always the five-field `"Wdy Mon DD HH:MM:SS YYYY"` shape.
- **`$isdst` is always `0`**, not `undef` and not `-1`. Do not test it for truth under `gmtime`; the answer is meaningless.

Alternatives and companions

- **Going the other way** - from broken-down fields back to an epoch - is the job of the `Time::Local` module. Use `timegm` (UTC) or `timelocal` (local zone) there:

```
use Time::Local qw(timegm);
my $epoch = timegm($sec, $min, $hour, $mday, $mon, $year);
```

- **Object-oriented access by field name** is offered by `Time::Piece`, which overloads `localtime` and `gmtime` to return objects with `->year`, `->mon`, `->mday` etc. The field conventions there are adjusted - `year` is already the full year, `mon` is already 1-indexed - so code written against `Time::Piece` cannot be mixed casually with code written against the built-in list form.
- **Human-readable formatting** belongs to `POSIX::strftime`; feed it the list returned by `gmtime` directly.
- **Comprehensive date arithmetic, time zones, durations** - reach for `DateTime` on CPAN. `gmtime` is the minimum viable primitive; `DateTime` is the full library.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `localtime` - same conversion, but in the local time zone; `$isdst` there is meaningful
- `time` - produces the epoch value `gmtime` consumes
- `POSIX::strftime` - format the 9-element list into an arbitrary date string (ISO-8601, locale-aware, etc.)
- `Time::Local` - inverse operation: build an epoch from broken-down UTC or local fields
- `Time::Piece` - object wrapper around `gmtime` / `localtime` with named accessors

Control flow

goto

Transfer execution elsewhere in the program without returning.

`goto` has three unrelated forms that share only a keyword. The useful one in modern Perl is `goto &NAME` - the **tail-call** form, which replaces the current subroutine frame with a call to another sub while preserving `@_`. The `goto LABEL` and `goto EXPR` forms exist, are constrained, and are almost never the right tool.

Synopsis

```
goto LABEL
goto EXPR
goto &NAME
```

What you get back

`goto` does not return. Control leaves the `goto` statement and does not come back. The return value of the construct the `goto` eventually lands in is the value of the enclosing expression.

For `goto &NAME`, the return value is whatever the target subroutine returns, propagated to the original caller as if the target had been called directly.

The tail-call form: `goto &NAME`

This is the form that matters. It exits the current subroutine - undoing any `local` bindings - and immediately calls `NAME` with the current `@_`. The current frame is **replaced**, not stacked on top of.

Consequences:

- `caller` inside the target sub sees the **original caller**, not the sub that issued the `goto`. The intermediate frame is gone.
- `@_` is passed through as-is. Modifications to `@_` before the `goto` are visible to the target.
- `local` changes made in the departing sub are undone before the target runs, exactly as they would be on a normal return.
- The target does not have to know it was reached via `goto &`; from its perspective it was called normally.

The canonical use is `AUTOLOAD` dispatch: resolve the real sub, then `goto` it so stack traces, `caller`, and `wantarray` all behave as though the real sub had been called in the first place.

`NAME` need not be a literal name. It can be any expression that yields a code reference - a scalar holding a coderef, a block returning one, or a dereferenced slot.

```
goto &$coderef;
goto &{ $dispatch{$op} };
```

For recursive tail calls, `goto __SUB__` jumps to the currently executing sub without re-resolving its name - safe under renaming and anonymous subs.

The `goto LABEL` form

Finds the statement labeled `LABEL` within the current dynamic scope and resumes execution there. In practice this means it can jump out of blocks and out of subroutines, but it **cannot jump into** a construct that requires initialization - a subroutine body, a `foreach` loop, a `given` block, the parameter of a binary or list operator, or code the optimizer removed. Jumping into such a construct is a fatal error as of Perl 5.44.

Most of what `goto LABEL` could do is better expressed with labeled loop control (`last LABEL`, `next LABEL`, `redo LABEL`) or with exceptions (`die` / `eval`). Reach for those first.

The `goto EXPR` form

Evaluates `EXPR`. If it yields a code reference, behaves like `goto &NAME`. If it yields a string, that string is used as a label name resolved at runtime - a computed goto. The same restrictions as `goto LABEL` apply to the label case.

Two parser quirks to remember:

- `goto EXPR` is exempt from the "looks like a function" rule. Parentheses after `goto` do not necessarily delimit its argument: `goto("NE")."XT"` is `goto NEXT`, not `goto "NE"` followed by a useless concatenation.
- `goto` has the same precedence as assignment, unlike most named operators.

Examples

Tail-call dispatch from `AUTOLOAD` - the target sub sees the original caller, not `AUTOLOAD`:

```
sub AUTOLOAD {
    our $AUTOLOAD;
    my ($method) = $AUTOLOAD =~ /::(\w+)\z/;
    my $code = $self->can_really($method)
        or die "no such method: $method";
    goto &$code;              # @_ forwarded, caller() unchanged
}
```

Tail recursion without growing the call stack. `__SUB__` resolves to the currently running sub:

```
sub fact {
    my ($n, $acc) = @_;
    $acc //= 1;
    return $acc if $n <= 1;
    @_ = ($n - 1, $acc * $n);
    goto __SUB__;
}
```

Computed `goto` via `goto EXPR`. The label is chosen at runtime from a list:

```
goto ("FOO", "BAR", "GLARCH")[$i];
FOO:    handle_foo();    return;
BAR:    handle_bar();    return;
GLARCH: handle_glarch(); return;
```

Delegating to a coderef held in a dispatch table. The caller never sees the intermediate frame:

```
my %ops = (
    add => sub { $_[0] + $_[1] },
```

(continues on next page)

(continued from previous page)

```
    mul => sub { $_[0] * $_[1] },
);

sub run_op {
    my $op = shift;
    goto &{ $ops{$op} // die "unknown op: $op" };
}
```

Modifying `@_` before a tail call - changes are visible to the target:

```
sub wrap {
    unshift @_, "prefix";
    goto &real_handler;       # real_handler sees ("prefix", @orig_
↪args)
}
```

Edge cases

- **`goto LABEL` cannot enter a sub, `foreach`, or `given`.** As of Perl 5.44 this is a fatal error, not a warning. It also cannot jump into optimized-away code or into most operator operands - the one exception is the first operand of a binary operator (for `=`, the right-hand side).
- **`goto LABEL` cannot get out of a `sort` comparison block.** The comparator runs in a context that does not permit the jump.
- **`goto &NAME` discards `local` bindings** from the departing sub before the target runs. Anything the sub localized is restored as though the sub had returned normally.
- **`caller` is invisible past a `goto &`.** The departing frame is gone. This is the whole point of the form for `AUTOLOAD` - do not rely on seeing the intermediate sub in a stack trace.
- **`@_` aliasing is preserved.** The target sub's `@_` aliases the same scalars the departing sub's `@_` did. Assigning to `$_[0]` in the target still modifies the caller's argument.
- **`goto &$coderef` requires a real coderef.** A string that looks like a sub name does not work in the `&` form - use `goto EXPR` (without the `&`) for that, or resolve the name to a coderef first with `\&{$name}`.
- **`goto` has assignment precedence.** `goto "A" . "B"` is `goto "AB"`, not `(goto "A") . "B"`.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `last` - exit the innermost or a named enclosing loop; the right tool for most "jump out of here" cases
- `next` - skip to the next iteration of a loop, with optional label
- `redo` - restart the current loop iteration without re-evaluating the condition
- `return` - leave the current sub with a value; compare with `goto &NAME` which leaves the sub by **replacing** it
- `caller` - inspect the call stack; note that `goto &` makes the departing frame invisible to it

Lists

grep

Filter a list to the elements where the block or expression is true.

`grep` walks `LIST` from left to right, evaluates `BLOCK` or `EXPR` once per element with `$_` aliased to that element, and returns the elements for which the test produced a true value. It is a list filter, not a loop - the list you get back is a subset of the list you passed in, in original order.

Synopsis

```
grep BLOCK LIST
grep EXPR, LIST
my @kept  = grep { COND } @list;
my @match = grep /pattern/, @list;
```

The two forms are interchangeable in power; `BLOCK` is the general case, and `EXPR` is a convenience for one-expression tests. When `EXPR` is a bare regex (`/.../`, `m/.../`, or `qr/.../`), it is implicitly matched against `$_` - this is the idiom behind `grep /^#/, @lines`.

What you get back

- **List context**: the filtered list, in original order, with each returned element an alias into the source list (see *Global state* and *Edge cases*).
- **Scalar context**: the count of elements for which the test was true. Not a boolean - it is the size of what the list context would have produced, so `0` is false, any positive count is true.

```
my @keep  = grep { $_ > 0 } @nums;   # list context: filtered list
my $count = grep { $_ > 0 } @nums;   # scalar context: count
```

Global state it touches

- `$_` is **aliased** to each element of `LIST` for the duration of one `BLOCK` or `EXPR` evaluation. On exit from `grep`, `$_` is restored to whatever it held before the call. Because the alias is to the real element - not a copy - assigning to `$_` inside the block mutates the source list in place. This is the same contract as `map` and as a `for` loop's index variable.
- The bare-regex form of `EXPR` reads and writes all the usual match-related magic variables (`$1`..`$9`, `$&`, `${^MATCH}`, `@+`, `@-`, `%+`, `%-`, `pos`) on each iteration, exactly as if you had written the match longhand.

Examples

Filter out undefined values:

```
my @vals    = (1, undef, 2, undef, 3);
my @defined = grep { defined $_ } @vals;
# @defined = (1, 2, 3)
```

Regex filter via the expression form - the bare regex matches against `$_`:

```
my @lines    = ("# comment", "code", "# another", "more code");
my @code     = grep !/^#/, @lines;       # drop comments
my @comments = grep  /^#/, @lines;       # keep comments
```

Custom test via the block form, when the condition is more than one expression:

```
my @users    = (
    { name => "alice", active => 1, age => 30 },
    { name => "bob",   active => 0, age => 25 },
    { name => "carol", active => 1, age => 17 },
);
my @adults_active = grep {
    $_->{active} && $_->{age} >= 18
} @users;
```

Count without building the list - use scalar context:

```
my @errors = ("ok", "fail", "ok", "fail", "fail");
my $nfail  = grep { $_ eq "fail" } @errors;   # 3
if (grep { $_ eq "fail" } @errors) {          # boolean use
    warn "had failures";
}
```

Remove blank and whitespace-only lines:

```
my @clean = grep { /\S/ } @lines;
```

Filter the keys of a hash by some property of the value:

```
my %scores  = (alice => 42, bob => 17, carol => 95);
my @passing = grep { $scores{$_} >= 50 } keys %scores;
```

Edge cases

- **`$_` is an alias, not a copy.** Modifying `$_` inside the block modifies the original list element. This is occasionally useful but more often a bug; write a read-only test:

```
my @bumped = grep { $_++; $_ > 10 } @nums;   # MUTATES @nums
```

  If the elements are themselves not variables (e.g. literals, constants, or the result of a function call), assigning to `$_` is a runtime error - "Modification of a read-only value".

- **Returned elements are aliases too.** Elements of the returned list share storage with the source list, just like the index variable of a `for` loop. Writing to them through the returned list propagates back:

```
my @arr  = (1, 2, 3, 4);
my @even = grep { $_ % 2 == 0 } @arr;
$even[0] = 99;      # @arr is now (1, 99, 3, 4)
```

  This is rarely wanted. Copy explicitly with `map { $_ } grep ...` or a fresh `my` when you need independent storage.

- **Expression form vs. block form - precedence.** `grep EXPR, LIST` uses a comma to separate the test from the list; `grep BLOCK LIST` does not. Mixing them trips you up:

```
grep /x/, @arr;          # EXPR form, correct
grep { /x/ } @arr;       # BLOCK form, correct
grep { /x/ }, @arr;      # WRONG: comma after block is a syntax
                         # error or silently wrong depending on
                         # context
```

- **grep in chained expressions.** `grep` takes a `LIST`, which means everything after the first argument is consumed as part of the list. Parenthesise when you want to follow `grep` with more terms:

```
my @out = (grep { /x/ } @a), @b;   # concatenates filtered @a
 ↪and @b
my @bad =  grep { /x/ } @a,  @b;   # filters BOTH @a and @b
 ↪together
```

- **Not a loop.** `grep` is an expression, not a control structure. `last`, `next`, and `redo` inside the block target the nearest enclosing *loop*, not the `grep` itself - they will exit or restart whatever `for`/`while` the `grep` sits inside, not the `grep`. Use an early `return` from a helper sub if you need to short-circuit, or switch to `List::Util` `first` when all you want is the first match.

- **Empty input is empty output.** `grep` over an empty list is an empty list in list context and `0` in scalar context. No special case needed.

- **Hash flattening.** `grep { ... } %h` walks the hash's alternating key/value flattening; the block sees keys and values interleaved in `$_`. This is almost never what you want; filter the keys and rebuild instead:

```
my %filtered = map  { $_ => $h{$_} }
               grep { some_test($_, $h{$_}) } keys %h;
```

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `map` - same iteration contract with the same `$_` alias semantics, but returns what the block *produced* for each element rather than the element itself
- `sort` - reorder a list; often chained with `grep` as `sort { ... } grep { ... } @list`
- `any` / `all` - short-circuiting boolean tests over a list from `List::Util`; use these instead of `scalar grep` when you only need a yes/no answer and the list is large or the test is expensive
- `first` (from `List::Util`) - return the first element matching a block and stop; the right tool when `grep` is being used only to fetch one match
- `for` / `foreach` - the looping construct with the same `$_` aliasing rule; reach for it when you want side effects, not a filtered list
- `$_` - the default scalar that `grep` aliases on every iteration

SCALARs and strings · Numeric functions

hex

Interpret a string as a hexadecimal numeral and return its numeric value.

`hex` reads `EXPR` as a sequence of hex digits - optionally introduced by a `0x` or `x` prefix - and returns the integer those digits represent. If `EXPR` is omitted, `$_` is used. The companion operation, turning a number back into a hex string, is `sprintf` with the `"%x"` or `"%X"` format.

Synopsis

```
hex EXPR
hex                 # operates on $_
```

What you get back

A non-negative number. `hex` itself never returns a negative value: it has no notion of sign, it only decodes digits.

- If the result fits in a native integer (typically 64-bit unsigned on a 64-bit build), you get an integer.

- If the decoded value exceeds that range, `hex` falls back to an IEEE 754 double. A warning is emitted under `use warnings` and precision may be lost for values above `2**53`.

To convert the other direction:

```
sprintf "%x", 255            # "ff"
sprintf "0x%08X", 4096       # "0x00001000"
```

Examples

Plain hex digits, with or without the `0x` prefix:

```
print hex '0xff';            # 255
print hex 'ff';              # 255
print hex 'DEADBEEF';        # 3735928559
```

Underscores between digits are permitted as visual separators, the same way numeric literals allow them:

```
print hex '1_0000';          # 65536
print hex 'cafe_f00d';       # 3405700109
```

Operating on `$_`:

```
for ('10', '20', 'ff') {
    print hex, "\n";         # 16, 32, 255
}
```

Round-tripping a value through hex:

```
my $n = 0xC0FFEE;
my $s = sprintf "%x", $n;    # "c0ffee"
print hex $s;                # 12648430
```

Values that overflow native integer width warn and return a float:

```
use warnings;
my $big = hex 'fffffffffffffffff';   # 19 'f's - too wide for u64
# "Integer overflow in hexadecimal number" warning
# $big is now an IEEE 754 double, with lost precision
```

Edge cases

- **Non-hex characters terminate parsing.** The first character that is not a hex digit, underscore, or recognised prefix ends the scan. Under `use warnings` this emits `Illegal hexadecimal digit '…' ignored`:

  ```
  use warnings;
  print hex '1f garbage';    # 31, with a warning
  print hex '0xAZ';          # 10, with a warning on 'Z'
  ```

- **Leading whitespace is not skipped.** Unlike `oct`, `hex` treats whitespace as a non-hex character, so a leading space stops parsing before any digit is seen:

```
print hex ' ff';          # 0
```

- **Empty string and `undef` return `0`.** An empty `EXPR` yields `0` with no warning. A bare `undef` yields `0` and emits the usual `Use of uninitialized value` warning under `use warnings`.
- **No sign handling.** A leading `-` or `+` is a non-hex character and terminates parsing before any digit, so `hex '-ff'` returns `0`. To parse a signed hex string, strip the sign yourself:

```
my $s = '-ff';
my $n = ($s =~ s/^-//) ? -hex($s) : hex($s);   # -255
```

- **Prefix forms.** The accepted prefixes are `0x`, `0X`, `x`, and `X`. A lone `0` is not a prefix - it's a digit. There is no `#` or `$` prefix.
- **Case is irrelevant** for the digits `a-f` and for the prefix letter `x`.
- **Underscore placement.** A single underscore may precede each digit. Two consecutive underscores, a leading underscore before the prefix, or a trailing underscore terminate parsing as non-hex characters.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `oct` - decodes strings with auto-detected base: `0x...` as hex, `0b...` as binary, `0...` as octal, anything else as decimal. Use it when the input's base is not known in advance
- `sprintf` - the reverse direction; `"%x"` / `"%X"` format a number into a lowercase or uppercase hex string, `"%#x"` adds the `0x` prefix, `"%08x"` zero-pads to a fixed width
- `printf` - same `"%x"` formatting, written straight to a filehandle
- `pack` - templates `H` (high nibble first) and `h` (low nibble first) convert between a hex-digit string and packed binary bytes; use these when moving hex data to and from a binary protocol
- `unpack` - the inverse of `pack`; with `"H*"` it turns a byte string into a hex digit string in one call

Scoping · Modules

import

Populate the caller's namespace with names a module chooses to export.

`import` is **not** a built-in function. It is a class method a module defines so that `use` has somewhere to hand off the argument list. When you write `use Module LIST`, Perl loads the module and then calls `Module->import(LIST)` at compile time, in the package that

contains the `use` statement. Whatever that method does - install subroutines into the caller's stash, flip feature bits, set pragma flags - is the module's entire `import` contract.

Most modules never write `import` by hand; they inherit it from `Exporter` and declare `@EXPORT` / `@EXPORT_OK` instead. Pragmas (`strict`, `warnings`, `feature`) write their own `import` because what they install is lexical state, not subroutines.

Synopsis

```
Module->import;
Module->import(LIST);
Module->import(@symbols);
```

Inside a module, the definition looks like:

```
package My::Module;
sub import {
    my ($class, @args) = @_;
    # install names into caller's package
}
```

What you get back

The return value of `import` is discarded by `use`. A module that is called directly as a method inherits whatever convention the author chose - by convention, return nothing useful.

The visible effect is in the caller's package: after `use Module qw(foo bar)` returns, `foo` and `bar` are callable without a package prefix from the code that ran the `use`.

How `use` calls `import`

`use Module LIST` is, in effect:

```
BEGIN {
    require Module;
    Module->import(LIST);
}
```

Three consequences fall out of that equivalence:

- **Compile time.** `import` runs while the enclosing file is still being parsed. Any subroutine prototypes or lexical pragmas it installs are visible to the rest of the file from that point on. Anything done at runtime - opening files, reading configuration - happens earlier than a naive reading of the source suggests.
- **`caller` reflects the `BEGIN` block**, not the surrounding subroutine. An `import` method that inspects `caller(0)` sees the package that wrote `use Module`, which is exactly what it wants; it does **not** see the subroutine that contains the `use` statement.
- **Absent list vs empty list.** `use Module` with no list calls `Module->import` with no arguments - the module installs its defaults. `use Module ()` with an **explicit**

empty list skips the `import` call entirely. This is the idiom for "load the file but do not touch my namespace."

`no Module LIST` is the mirror image: it calls `Module->unimport(LIST)` instead of `import`. Pragmas use this to turn features off for the enclosing lexical scope.

Defining an `import` method

The common path is inheritance from `Exporter`:

```
package My::Utils;
use Exporter 'import';                  # installs Exporter::import
our @EXPORT_OK = qw(slurp trim);
sub slurp { ... }
sub trim  { ... }
1;
```

Callers then write:

```
use My::Utils qw(slurp trim);
slurp($path);
```

A hand-rolled `import` has the same shape as any method - it receives the class name as its first argument and the `use` argument list as the rest:

```
package My::Feature;
sub import {
    my ($class, @flags) = @_;
    my $caller = caller;
    no strict 'refs';
    for my $name (@flags) {
        *{ "${caller}::${name}" } = \&{ "${class}::${name}" };
    }
}
```

The caller's package name comes from `caller`, not from `$class` - `$class` is whatever module the user named on the `use` line.

Examples

Default import - whatever the module's `@EXPORT` list contains:

```
use List::Util;                         # imports nothing by default
use File::Basename;                     # imports basename, dirname,␣
↪...
```

Explicit import list - only the names you ask for:

```
use List::Util qw(sum min max);
my $total = sum(1, 2, 3);               # 6
```

Empty list - load the file, touch nothing:

```
use POSIX ();                           # no POSIX::* names imported
my $pi = POSIX::acos(-1);               # fully qualified call
```

Importing from a pragma - lexical effect in the enclosing block:

```
use strict;
use warnings;
{
    no warnings 'uninitialized';        # unimport in this block only
    print "x=", $x, "\n";
}
```

Calling `import` directly after a runtime `require`:

```
require My::Plugin;
My::Plugin->import(@config);            # deferred to runtime on␣
↪purpose
```

This pattern loads the module only when a code path actually needs it, trading compile-time checking for startup speed.

Edge cases

- **No such thing as a built-in `import`.** `print import(@list)` calls the subroutine named `import` in the current package (if one exists); it is not a language-level operator. Parsing rules apply as for any user-defined subroutine.
- **Omitted list vs empty list** is the most common source of confusion. `use Mod` calls `import`; `use Mod ()` does not. The `()` is not a stylistic empty - it is a signal.
- **Version argument runs `VERSION`, not `import`.** `use Mod 1.23 LIST` calls `Mod->VERSION(1.23)` **before** `Mod->import(LIST)`. A bare `use Mod 1.23` is still a version check followed by a default `import`. To version-check and skip imports, write `use Mod 1.23 ()`.
- **No `import` defined at all.** If the module neither writes nor inherits an `import`, `use Module LIST` with a non-empty list does not error - the method call falls through silently as `UNIVERSAL::can('import')` returns false and `use` treats it as "nothing to do." Non-empty `LIST` is then effectively ignored, which is almost never what the caller wanted.
- **`import` runs once per `use` statement**, not once per process. `use Mod qw(foo); use Mod qw(bar);` calls `import` twice, even though the file is loaded only once - `@INC` / `%INC` gate the file load, not the method call.
- **Symbol installation is not automatic.** Writing an `import` method that merely returns does nothing; you must assign into the caller's stash (`*{"${caller}::name"} = \&sub`) or delegate to `Exporter`.
- **Pragmas typically install lexical state**, not package-level subroutines. Their `import` calls functions like `warnings::import_into` or manipulates `%^H`; this is why a pragma's effect is scoped to the enclosing block rather than persisting in the package.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `use` - the compile-time loader that invokes `import`; understanding one requires the other
- `no` - the mirror of `use`; calls `unimport` with the same argument-passing rules
- `require` - loads the file without calling `import`; pair with an explicit `Module->import(...)` when you want to defer or skip the compile-time dispatch
- `package` - defines the namespace that an `import` method populates from the caller's point of view
- `caller` - how an `import` method discovers which package to install names into
- `bless` - unrelated to `import`, but often invoked in the same module files; both shape how a package presents itself to its users

SCALARs and strings

index

Find the position of a substring inside a string.

`index` scans `STR` left-to-right looking for the first occurrence of `SUBSTR` and returns the zero-based position where it starts. No regular-expression metacharacters, no case folding, no wildcards - `SUBSTR` is matched literally, character for character. When the search fails, `index` returns `-1`.

Synopsis

```
index STR, SUBSTR
index STR, SUBSTR, POSITION
```

What you get back

An integer. On a match, the zero-based offset of the first character of `SUBSTR` inside `STR`. On no match, `-1`. The sentinel is the idiomatic way to test:

```
if (index($line, $needle) >= 0) { ... }   # found
if (index($line, $needle) == -1) { ... }  # not found
```

`POSITION` and the return value use the **same** zero-based scale, so you can feed one back into the other to walk every occurrence:

```
my $pos = -1;
while (($pos = index($text, $needle, $pos + 1)) != -1) {
    push @hits, $pos;
}
```

How POSITION is interpreted

`POSITION` is the earliest offset the match is allowed to start at. The search still proceeds to the end of `STR`; `POSITION` does not bound the search, it only shifts where it begins.

- `POSITION` omitted or `undef` - search from offset `0`.
- `POSITION` negative or otherwise before the start - treated as `0`.
- `POSITION` past the end of `STR` - treated as the end, so the only way to match is if `SUBSTR` is the empty string (which matches at any offset, including the end).

An empty `SUBSTR` always matches, and matches at `POSITION` (clamped into range). This follows from the "first position where `SUBSTR` occurs" rule: the empty string occurs everywhere.

```
index("hello", "");      # 0
index("hello", "", 3);   # 3
index("hello", "", 99);  # 5   (clamped to end of string)
```

Examples

Find a single character or a whole word:

```
index("Perl is great", "P");     # 0
index("Perl is great", "g");     # 8
index("Perl is great", "great"); # 8
```

Report a miss:

```
index("Perl is great", "Z");     # -1
```

Skip past an earlier match with `POSITION` to find the second occurrence:

```
index("Perl is great", "e", 5);  # 10
```

Walk every occurrence of a substring:

```
my $s = "abcabcabc";
my $p = -1;
while (($p = index($s, "bc", $p + 1)) != -1) {
    print "hit at $p\n";
}
# hit at 1
# hit at 4
# hit at 7
```

A common idiom - test for containment without building a regex:

```
if (index($path, "/tmp/") != -1) {
    warn "path touches /tmp";
}
```

Pairs naturally with `substr` to split on the first occurrence of a separator:

```
my $line = "key=value=with=equals";
my $eq   = index($line, "=");
my ($k, $v) = $eq >= 0
    ? (substr($line, 0, $eq), substr($line, $eq + 1))
    : ($line, undef);
```

Edge cases

- **Empty `SUBSTR`** matches at `POSITION` (clamped into `STR`). `index($s, "")` is `0`; `index($s, "", $n)` is `$n` capped at `length $s`. Never `-1`.
- **Empty `STR` with non-empty `SUBSTR`** returns `-1`. Empty `STR` with empty `SUBSTR` returns `0`.
- **Negative `POSITION`** is clamped to `0`. `index` does **not** interpret negative offsets as "from the end" - that is `rindex`'s job, and even there the semantics differ.
- **`POSITION` past the end of `STR`** is clamped to `length STR`, so only an empty `SUBSTR` can match.
- **Undef arguments** stringify to `""` and trigger an `uninitialized` warning under `use warnings`. `index(undef, "x")` is `-1`; `index("abc", undef)` is `0` (empty-substring rule).
- **Characters, not bytes.** `index` operates on the logical character sequence of the string. For a string of wide characters, the returned offset is a character offset, not a byte offset. If you need byte offsets, downgrade or encode the string first (`use bytes` for a lexical byte view, or `Encode::encode_utf8` to work on an octet string).
- **Case sensitivity**: `index` is case-sensitive. Lowercase both arguments first if you want a case-insensitive search, or use `=~ /\Q$needle\E/i` and `@-` / `$-[0]` to recover the position.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `rindex` - same matching rules, scans from the right and returns the offset of the **last** occurrence at or before `POSITION`
- `substr` - extract the matched region once `index` has located it, or replace it in place
- `length` - upper bound for a valid `POSITION`; returns character length on the same scale `index` uses
- `pos` - position tracking for regex-based scanning; use together with `m//g` when you need captures rather than a raw offset
- `sprintf` - build the search string when `SUBSTR` is assembled from parts; `index` takes a literal, so prepare it first

Numeric functions

int

Return the integer portion of a number, truncating toward zero.

`int` takes a single scalar, forces it to numeric context, and drops its fractional part. The discard is always **toward zero** - not toward negative infinity - so `int(3.9)` is `3` and `int(-3.9)` is `-3`, not `-4`. Non-numeric strings are coerced with the usual Perl numeric-conversion rules (leading whitespace, optional sign, digits; the rest is discarded, with an `Argument "..." isn't numeric` warning under `use warnings`). If `EXPR` is omitted, `int` operates on `$_`.

Synopsis

```
int EXPR
int
int($x)
```

What you get back

A number with no fractional part, same sign as the input. The result is an integer value if the truncated magnitude fits in the platform's native integer range (typically 64-bit); otherwise Perl keeps it as a floating-point value whose fractional part happens to be zero. Either way it compares and prints as an integer.

```
my $n = int(7.8);           # 7
my $m = int(-7.8);          # -7
```

`int` is not a rounding function. For rounding, see *See also*.

Examples

Positive truncation - the fractional part is discarded:

```
print int(3.9), "\n";               # 3
print int(3.1), "\n";               # 3
print int(3.0), "\n";               # 3
```

Negative truncation - the trap. `int` truncates toward zero, so `int(-3.9)` is `-3`, which is *larger* than `-3.9`. This is the opposite of a mathematical floor:

```
print int(-3.9), "\n";              # -3   (not -4)
print int(-3.1), "\n";              # -3
```

Works on `$_` when called with no arguments - handy inside `map` or `while (<>)`:

```
my @whole = map { int } @floats;    # truncate every element
```

Strings are coerced, keeping the leading numeric prefix:

```
print int("42.7 bottles"), "\n";    # 42
print int("  -5.5xyz"), "\n";       # -5
```

(continues on next page)

(continued from previous page)

```
print int("hello"), "\n";           # 0    (with a warning under␣
↪`use warnings`)
```

Division producing a fraction, then truncated - a common idiom for integer division of signed values, **with the caveat above about negatives**:

```
my $pages = int($total_items / $per_page);   # floor only for non-
↪negative $total_items
```

The classic floating-point surprise. `-6.725 / 0.025` is *mathematically* `-269`, but the IEEE-754 result is slightly greater than `-269` (around `-268.99999999999994`). `int` truncates toward zero, giving `-268`:

```
print int(-6.725 / 0.025), "\n";    # -268, not -269
```

This is not an `int` bug - every truncation/rounding function has to cope with inputs like this. See *Edge cases* below.

Edge cases

- **`int` on `$_`**: with no argument, operates on `$_`. Inside `map { int }` this is what you want; inside a larger expression it can surprise a reader who missed the implicit argument. Prefer `int($x)` when the source variable isn't obvious from context.
- **Already-integer input**: `int(5)` is 5. No conversion, no warning, no precision loss.
- **Very large floats lose precision before `int` sees them**. A double-precision float can represent every integer up to `2**53` exactly; beyond that, consecutive representable values are spaced 2, then 4, then 8 apart. `int(1e20)` returns a float whose integer value is close to but not equal to `10**20`. If you need exact large integers, keep them as integers throughout - don't route them through floating point.
- **Floating-point representation artefacts**: inputs like `-6.725 / 0.025` (see *Examples*) don't land on the mathematical integer they "should." Use `sprintf "%.0f"` or `POSIX::floor`/`POSIX::ceil` if you need rounding behaviour that tolerates this.
- **Infinities and NaN**: `int('Inf')` returns `Inf`; `int('-Inf')` returns `-Inf`; `int('NaN')` returns `NaN`. `int` has no integer to truncate to, so it returns the special value unchanged. This matches every alternative (`sprintf "%d"`, `POSIX::floor`, `POSIX::ceil`) - none of them give you a finite integer here.
- **`undef`**: `int(undef)` returns `0` and emits a `Use of uninitialized value` warning under `use warnings`.
- **Non-numeric strings**: `int("abc")` returns `0` and emits `Argument "abc" isn't numeric` under `use warnings`. A string that starts with a numeric prefix (`"42abc"`) yields the prefix's integer value (42) with the same warning - `int` inherits this from Perl's standard numeric coercion, not from any custom parsing.
- **Booleans and dualvars**: `int` reads the numeric half. `int(!!1)` is 1; `int(!!0)` is `0`. For a dualvar whose string and numeric values disagree, `int` uses the numeric side.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `abs` - magnitude without sign; pair with `int` when you want the truncated magnitude regardless of sign
- `sprintf` - `sprintf "%d", $x` also truncates toward zero, but additionally formats the result as a string; use when you want the truncated value *and* a specific textual form
- `POSIX::floor` - round *toward negative infinity*; `floor(-3.9)` is `-4`, which is what most mathematical contexts (graphics, bucketing) actually want
- `POSIX::ceil` - round *toward positive infinity*; `ceil(-3.1)` is `-3`, `ceil(3.1)` is `4`; the mirror of `floor`
- `POSIX::round` - round to the nearest integer, halves away from zero; use this when you want statistical rounding rather than truncation
- `sprintf` with `"%.0f"` - round to nearest integer, halves to even (banker's rounding) on most platforms; subtly different from `POSIX::round` at half-values

Filehandles, files, directories

ioctl

Perform a device-control `ioctl(2)` system call on a filehandle.

`ioctl` is the direct Perl binding for the POSIX `ioctl(2)` syscall - the catch-all kernel interface for device-specific operations that do not fit the regular read/write model: terminal window size, serial line parameters, socket device queries, tape positioning, and anything else a driver chooses to expose through a request code. It dispatches `FUNCTION` against `FILEHANDLE`, passing `SCALAR` as the third argument - either a small integer or a pointer to a byte buffer, depending on what the specific `FUNCTION` expects.

Unlike `fcntl`, whose request codes live in the `Fcntl` module, `ioctl` request codes are almost never exported as ready-made constants. The usual path is:

```
require "sys/ioctl.ph";
```

which pulls in the translated `<sys/ioctl.h>` header. If that file does not exist, or does not define the code you need, build it from the C headers with the `h2ph` tool shipped with Perl, or define the constant yourself from the kernel header.

Synopsis

```
require "sys/ioctl.ph";
ioctl FILEHANDLE, FUNCTION, SCALAR
ioctl($fh, $request, $buf)
my $rv = ioctl($fh, $request, $arg) || -1;
```

What you get back

On success, the integer the kernel returned. When that integer is `0`, Perl substitutes the dual-valued string `"0 but true"` - true in boolean context, numeric `0` in numeric context, and exempt from the `Argument "..." isn't numeric` warning. This means a plain boolean test reliably distinguishes success from failure even for requests whose success value is literally zero:

```
ioctl($fh, $request, $buf) or die "ioctl: $!";
```

On failure, `ioctl` returns `undef` and sets `$!` to the relevant `errno`. The full mapping:

OS returns	Perl returns
`-1`	`undef`
`0`	string `"0 but true"`
any other value	that integer

When you need the raw kernel return - for request codes that encode information in the return value itself - use the idiom from `perlfunc`:

```
my $retval = ioctl($fh, $request, $arg) || -1;
printf "System returned %d\n", $retval;
```

How SCALAR is used

`SCALAR` is handed to the kernel as the third argument of the C `ioctl` call, and its role depends on the request code:

- **Pointer to a buffer.** The usual case. Most `ioctl` requests read from or write into a C struct whose layout is defined by the driver. Build the buffer with `pack` before the call and, for requests that write back, decode with `unpack` afterward. Pre-size the scalar to at least the struct's length - Perl will grow an undersized scalar automatically, but pre-sizing makes the intent obvious and avoids surprises if the driver writes more than you expected.
- **Small integer.** A minority of requests take a bare integer rather than a pointer. If `SCALAR` has no string value but does have a numeric value, Perl passes the number instead of a pointer. To guarantee this dispatch - even for a scalar that might have been stringified earlier - add `0` to it first:

  ```
  my $n = 0 + $n;       # force numeric representation
  ioctl($fh, $request, $n);
  ```

- **Ignored.** For request codes that take no third argument, pass `0` as a placeholder. The kernel ignores it; the convention keeps the call readable.

Global state it touches

- `$!` - set on failure to the `errno` returned by `ioctl(2)`.
- Device or descriptor state on `FILEHANDLE` - `ioctl` typically mutates kernel state associated with the underlying file descriptor or its device (terminal attributes, socket options, tape position). That state is not Perl-visible through any other variable; read it back with another `ioctl` call using the matching `TIOCG...` / `SIOCG...` request.

Examples

Query the terminal window size on Linux. `TIOCGWINSZ` writes a `struct winsize` (two `unsigned short` rows/cols plus two ignored fields) into the buffer:

```
require "sys/ioctl.ph";

my $winsize = "\0" x 8;
ioctl(STDOUT, TIOCGWINSZ(), $winsize)
    or die "TIOCGWINSZ: $!";
my ($rows, $cols) = unpack('S S', $winsize);
print "terminal is $rows rows by $cols cols\n";
```

Count bytes available for reading on a socket without consuming them (`FIONREAD` is widely supported across Unixes):

```
require "sys/ioctl.ph";

my $pending = pack('L', 0);
ioctl($sock, FIONREAD(), $pending)
    or die "FIONREAD: $!";
my $n = unpack('L', $pending);
print "$n bytes pending\n";
```

Put a socket into non-blocking mode through the `FIONBIO` request - an alternative to the `fcntl` / `F_SETFL` approach, and the form historically portable to some older systems:

```
require "sys/ioctl.ph";

my $on = pack('L', 1);
ioctl($sock, FIONBIO(), $on)
    or die "FIONBIO: $!";
```

Distinguishing "syscall returned 0" from "syscall failed" using the `"0 but true"` convention:

```
my $rv = ioctl($fh, $request, $buf);
if (!defined $rv) {
    die "ioctl failed: $!";
} elsif ($rv eq "0 but true") {
    # kernel returned 0 - success with a zero value
} else {
```

(continues on next page)

(continued from previous page)

```
    # kernel returned $rv
}
```

Rolling your own request code when `sys/ioctl.ph` is missing or incomplete. The encoding (`_IOR` / `_IOW` / `_IOWR`) is kernel-specific; on Linux the macro expands to a 32-bit value that you can precompute and hardcode:

```
use constant TIOCGWINSZ => 0x5413;   # Linux <asm-generic/ioctls.h>

my $winsize = "\0" x 8;
ioctl(STDOUT, TIOCGWINSZ, $winsize) or die $!;
```

Edge cases

- **Forgot the `.ph` require**: constants like `TIOCGWINSZ` parse as barewords with no defined value, triggering an `EINVAL` from the kernel. Either `require "sys/ioctl.ph"` or define the constant yourself with `use constant`.
- **`"0 but true"` return**: do not compare the return with `== 0` as a failure test. Use a plain boolean (`or die`) or `defined`. Comparing for equality to the literal string also works (`$rv eq "0 but true"`) but is rarely necessary.
- **Scalar/integer dispatch surprise**: a scalar that was numeric but got stringified - for instance via interpolation into a message - flips from integer-argument to buffer-pointer semantics on the next call. Force numeric representation with `0 + $x` when the request code expects an integer.
- **Struct layout is platform-specific.** `struct winsize`, `struct termios`, `struct ifreq`, and friends differ between kernels and even between architectures on the same kernel. Do not hardcode `pack` templates from memory; verify against the target system's header.
- **Undersized output buffer.** If the driver writes more bytes than `SCALAR` currently holds, the scalar is grown, but you have no hint in Perl that this happened. Pre-size to at least the struct's length with `"\0" x N` so that reads past the end of the buffer are driver bugs, not Perl bugs.
- **Not every system implements every request.** `ioctl` itself is POSIX, but specific request codes are driver-defined. An unsupported request fails with `ENOTTY` or `EINVAL`; an `ioctl` call on a system without `ioctl(2)` at all raises an exception.
- **`ioctl` vs `fcntl`**: identical argument-processing and return-value convention, different kernel interface. Use `fcntl` for descriptor flags and POSIX locks; use `ioctl` for device control codes.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `fcntl` - same calling and return-value convention; used for descriptor-level flags and advisory locks rather than device-specific control codes
- `pack` / `unpack` - required for building and decoding the struct buffers most `ioctl` requests exchange with the kernel
- `open` / `sysopen` - open the device or special file whose driver the `ioctl` request will talk to
- `binmode` - some `ioctl` requests (e.g. terminal mode changes) interact with PerlIO buffering; switch to raw mode when the driver and PerlIO disagree about line discipline
- `select` / `sysread` - the normal I/O path; reach for `ioctl` only when the operation you need is not expressible as a read or write

Classes and OO

isa

Test whether an object is an instance of a class or of any subclass derived from it.

`isa` is a **binary operator**, not a function. The left operand is an expression that should yield an object reference; the right operand names a class. It returns true when the left operand is a blessed reference whose class is - or inherits from - the class on the right. It returns false for anything else, including `undef`, unblessed references, and plain strings. It never throws.

Unlike the old `UNIVERSAL::isa` method, `isa` is safe to apply to arbitrary values: calling `$x->isa("Foo")` on a plain string that happens to name a class (`$x = "Foo"`) invokes the class method and returns true, which is almost never what the caller meant. `isa` as an operator only reports true for **blessed instances**.

Synopsis

```
use feature 'isa';          # or: use v5.36;

$obj isa Some::Class
$obj isa "Different::Class"
$obj isa $name_of_class
```

What you get back

1 for a blessed object whose class is, or derives from, `CLASS`. The defined empty string `""` (a false value that is numerically zero and exempt from `uninitialized` warnings) in every other case.

The operator never raises an exception: undefined, unreferenced, and misbranded values simply test false.

Feature gate

`isa` is available from Perl 5.31.6 and became non-experimental in Perl 5.36. It is a **lexical feature**, enabled by either of:

```
use feature 'isa';
use v5.36;                  # enables the 5.36 feature bundle
```

Under `no feature 'isa'` (or in a scope that never enabled it), the bareword `isa` reverts to being a normal identifier, and the expression is a syntax error.

The right-hand side

The right operand of `isa` is resolved to a class name at compile time when it is a bareword:

```
$obj isa Some::Class        # bareword - resolved at compile time
```

Any other expression is evaluated at runtime and must yield a string naming the class:

```
$obj isa "Different::Class" # string literal
$obj isa $class_name        # scalar variable
$obj isa (ref $other)       # any expression yielding a string
```

Barewords on the right side do **not** need to be declared, imported, or loaded; `isa` only consults the symbol table of `CLASS` to walk `@ISA`. A class that was never loaded simply has no parents, so `$obj isa Unknown::Class` just tests false.

Examples

Basic instance check:

```
use feature 'isa';

package Animal { }
package Dog    { our @ISA = ('Animal'); }

my $rex = bless {}, 'Dog';

$rex isa Dog;               # true
$rex isa Animal;            # true - via @ISA
$rex isa Cat;               # false
```

Gate a method call on the actual class:

```
sub describe {
    my ($thing) = @_;
    return "unknown" unless $thing isa Animal;
    return $thing->sound;
}
```

Safe on arbitrary values - no exception on non-references:

```
undef      isa Animal;      # false
"Animal"   isa Animal;      # false - a string is not an instance
[]         isa Animal;      # false - unblessed ref
{}         isa Animal;      # false - unblessed ref
\&main::x  isa Animal;      # false - unblessed code ref
```

Dispatch on a class name captured at runtime:

```
for my $class (qw(Dog Cat Fish)) {
    if ($rex isa $class) {
        say "rex is a $class";
    }
}
```

Why `isa` is preferred over `UNIVERSAL::isa` as a method:

```
my $x = "Dog";
$x->isa('Dog');             # TRUE - string "Dog" is treated as a␣
↪class name
$x isa Dog;                 # false - $x is not a blessed instance
```

The first form silently does the wrong thing on any string that happens to match a loaded class name. The operator form is type-aware and reports what the caller actually wanted to know.

Edge cases

- **Left operand is undef**: the operator returns false. No `uninitialized` warning is emitted - this is a deliberately quiet test.
- **Left operand is an unblessed reference**: false. `isa` requires a blessed reference; array refs, hash refs, and code refs that have never been passed through `bless` fail the test.
- **Left operand is a plain string**: false, even when the string matches a loaded class name. This is the behavioural split from `UNIVERSAL::isa` called as a method.
- **Right operand names an unknown class**: the operator does not autoload or require the module. It walks the class's `@ISA`; an unknown class has no `@ISA`, so the test is false.
- **Multiple inheritance**: `isa` honours whatever method resolution order is active in the class (`mro`, `c3` or the default depth-first search). The lookup is the same walk that method dispatch uses.
- **Reblessed objects**: the test reflects the current blessing. Calling `bless` again on a reference changes what `isa` reports.
- **Parser precedence**: `isa` is a non-associative named operator at the same precedence as the relational operators (`lt`, `gt`, `le`, `ge`). Chaining (`$a isa B isa C`) is a syntax error, as with the other relationals.
- **Feature not enabled**: without `use feature 'isa'` (or `use v5.36`), the parser sees `isa` as an ordinary bareword and the expression fails to compile.

- **Right operand as a subroutine call**: write it in parens. `$obj isa some_class()` parses; `$obj isa some_class` treats `some_class` as the literal class name (bareword).

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `bless` - attach a class name to a reference so that `isa` (and method dispatch) has something to report
- `ref` - retrieve the class name of a blessed reference, or the underlying type for unblessed ones; complements `isa` when you need the name rather than a yes/no answer
- `class` - the native class declaration syntax (feature `class`, Perl 5.38+); objects built with `class` are ordinary blessed references and work with `isa` unchanged
- `UNIVERSAL::isa` - the historical method form. Works on every reference, but also returns true for plain strings that happen to name a class; use the operator in new code
- `mro` - controls the method resolution order that `isa` walks through `@ISA`
- `perlop` - full operator-precedence table; `isa` sits with the non-associative relational operators

Lists

join

Concatenate a list of strings with a separator between each adjacent pair, and return the single resulting string.

`join` takes a separator as its first argument and any number of values as the rest. It stringifies every value in `LIST`, glues them together with `EXPR` placed between each pair, and returns one scalar. The separator is inserted **between** items only - never at the start, never at the end. With zero or one items the separator never appears at all.

Synopsis

```
join $sep, @list
join "", @chars
join "\n", @lines
```

What you get back

A single string. The result is a fresh scalar; modifying it does not reach back into `LIST`. In scalar context you get that string; `join` is effectively always scalar because it only ever produces one value.

Examples

Comma-separated values, the canonical use:

```
my @cols = ("alice", 42, "ops");
my $row  = join ",", @cols;          # "alice,42,ops"
```

Build a file path with `/` as the separator:

```
my @parts = ("var", "log", "app.log");
my $path  = "/" . join("/", @parts);  # "/var/log/app.log"
```

Join lines with a newline between each - note that the trailing line does **not** get a newline, because `join` puts the separator *between* items:

```
my @lines = ("first", "second", "third");
my $text  = join "\n", @lines;       # "first\nsecond\nthird"
```

No-separator concatenation. Use the empty string `""`, not `undef` - `undef` triggers an uninitialized warning under `use warnings` and stringifies to `""` anyway:

```
my @chars = ("h", "e", "l", "l", "o");
my $word  = join "", @chars;         # "hello"
```

An empty `LIST` yields an empty string - this is safe to rely on and needs no guard:

```
my @empty;
my $s = join ",", @empty;            # ""
```

Edge cases

- **Empty `LIST`**: returns `""`. The separator is never used.
- **Single-item `LIST`**: returns that item stringified, with no separator anywhere: `join ",", ("only")` is `"only"`.
- **Separator is stringified**: pass a number, a reference, an object with overloaded `""` - `join` calls the same stringification every other Perl operator would. `join 0, 1, 2, 3` is `"10203"`.
- **Multi-character separator**: `EXPR` can be any string, not just a single character. `join ", ", @cols` gives `"a, b, c"`.
- **`undef` items in `LIST`**: each `undef` stringifies to `""` and emits an `uninitialized` warning under `use warnings`. Two adjacent `undef`s still get a separator between them: `join ",", (undef, undef)` is `","`.
- **`join` is not the inverse of `split` on a single character** when the separator you pass differs from the pattern used to split. `split` takes a *pattern*; `join` takes a literal string. Round-tripping `join "\t", split /\s+/, $s` loses the distinction between runs of whitespace and a single tab.
- **Not a pattern**: unlike `split`, the first argument to `join` is not a regex. `join /,/, @x` is a syntax surprise - the separator is always a string.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `split` - the inverse: take a string and a pattern, return a list of pieces
- `sprintf` - when you need per-item formatting, padding, or field widths that `join` can't express
- `pack` - when the output is a binary record, not a separator-delimited text string
- `map` - transform items before joining, e.g. `join ",", map { uc } @names`

Arrays · Hashes

keys

List all keys of a hash, or all indices of an array.

`keys` is the introspection primitive for associative and indexed containers. Given `%HASH` it returns the hash's keys; given `@ARRAY` (from Perl 5.12 onward) it returns the array's indices `0 .. $#ARRAY`. The list is what you iterate over, count, sort, or feed to another list-consuming operator. `keys` is also the idiomatic way to reset the iterator that `each` walks.

Synopsis

```
my @k = keys %h;
my @i = keys @a;
my $n = keys %h;        # scalar context: count
keys(%h) = 1000;        # preallocate buckets (hash only)
```

What you get back

In list context, a list of every key currently in `%HASH`, or every valid index of `@ARRAY`. In scalar context, the count - without building the list - so `scalar keys %h` is the cheap way to ask "how many entries?"

Hash keys are returned in an **arbitrary** order. The order is stable for a given unmodified hash - `keys`, `values`, and `each` all walk it in the same sequence - but it is not the insertion order, not sorted, and deliberately randomised per hash to defeat algorithmic complexity attacks (see `perlsec`). Any insertion or deletion may reshuffle. The one documented exception: deleting the key most recently returned by `each` or `keys` does not perturb the remaining order.

Array indices, by contrast, come back lowest-first: `(0, 1, 2, …, $#ARRAY)`.

The returned hash keys are **copies**. Modifying an element of the returned list does not modify the hash. Compare `values`, which returns aliases.

Global state it touches

- **Iterator of %HASH / @ARRAY**: `keys` resets the internal iterator shared with `each` and `values`. This is the idiomatic reset - call `keys %h` in void context specifically to discard any partial `each` walk:

```
keys %h;                # reset iterator, no list built
while (my ($k, $v) = each %h) { ... }
```
