  Without this reset, a prior `each` that exited early leaves the iterator mid-hash and the next `each` call resumes there.

Examples

Iterate all keys in an arbitrary order:

```
my %h = (apple => 1, pear => 2, plum => 3);
for my $k (keys %h) {
    print "$k => $h{$k}\n";
}
```

Iterate in a deterministic order by running the keys through `sort`:

```
for my $k (sort keys %h) {
    print "$k => $h{$k}\n";     # apple, pear, plum
}
```

Iterate in **insertion order** by tracking keys separately - hashes themselves do not remember insertion order:

```
my %h;
my @order;
for my $pair (["apple", 1], ["pear", 2], ["plum", 3]) {
    my ($k, $v) = @$pair;
    push @order, $k unless exists $h{$k};
    $h{$k} = $v;
}
for my $k (@order) {
    print "$k => $h{$k}\n";     # apple, pear, plum (insertion)
}
```

Count entries without materialising the list:

```
my $n = keys %h;                # scalar context, O(1)
print "hash has $n entries\n";
```

Preallocate buckets when you know the hash will grow large. The assignment is a size hint, rounded up to the next power of two:

```
my %big;
keys(%big) = 10_000;            # allocates 16384 buckets
$big{$_} = 1 for 1 .. 10_000;   # no rehash churn during fill
```

Walk an array by index - useful when you need both the index and the element together:

```
my @a = ("zero", "one", "two");
for my $i (keys @a) {
    print "$i: $a[$i]\n";
}
```

Sort a hash by value, descending numeric:

```
for my $k (sort { $h{$b} <=> $h{$a} } keys %h) {
    printf "%4d %s\n", $h{$k}, $k;
}
```

Edge cases

- **Empty hash or array**: returns the empty list in list context, `0` in scalar context. No warning, no special case to code around.
- **`require v5.12` for arrays**: `keys @array` is a syntax error on perls older than 5.12. Put `use v5.12;` at the top of files that use the array form if portability to ancient perls matters.
- **Hash order is not reproducible across runs**: Perl randomises hash seeding at startup. Never build a test, cache key, or file format that assumes a particular `keys %h` order. Sort if you need determinism.
- **Hash order is not stable across Perl versions**: the randomised order within a run is stable; the algorithm itself is not guaranteed between releases. Do not pickle `keys` output and expect it to round-trip on a different Perl.
- **Deleting during iteration**: safe only for the key most recently returned by `each` or `keys`. Deleting a different key may cause other keys to be visited twice or skipped.
- **Lvalue keys on arrays is a syntax error**: `keys(@a) = 100` is not valid. The bucket-preallocation form works on hashes only.
- **Lvalue keys cannot shrink**: `keys(%h) = 10` on a hash that already has 1024 buckets has no effect. `%h = ()` clears the contents but preserves the bucket count; `undef %h` frees the buckets.
- **Memory cost of the list form**: `keys %h` in list context materialises every key as a fresh SV. For a million-entry hash that is a million allocations plus the returned list. Iterate with `each` or `while (my ($k, $v) = each %h)` when you want streaming access without the memory spike.
- **Tied hashes**: dispatch through `FIRSTKEY` / `NEXTKEY`. Order and side effects are whatever the tie class provides. In particular, tied hashes may reshuffle on insertion in ways ordinary hashes do not, and a tied `keys` may be expensive if the backing store is remote.
- **Scalar context on a tied hash**: may or may not be O(1). Ordinary hashes answer `scalar keys %h` in constant time; a tied class has to implement `SCALAR` explicitly to avoid a full walk.
- **Scalar keys on an array equals `scalar @array`**: both return the element count. Prefer `scalar @array` for clarity unless the surrounding code is already phrased

in keys/values/each terms.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- values - companion list of the values in the same order as keys; returns aliases, not copies
- each - streaming (key, value) pair walk sharing the same iterator that keys resets
- exists - test whether a specific key is present without building the full key list
- delete - remove a key; safe mid-iteration only for the most recently returned key
- sort - impose a deterministic order on the arbitrary sequence keys returns
- scalar - force scalar context to get the count without materialising the key list

Processes

kill

Send a signal to a list of processes.

kill is Perl's front-end to the kill(2) system call. It delivers SIGNAL to each process identified by LIST and returns the number of arguments that were successfully signalled. It is also the standard way to ask the kernel "does this PID still exist and may I signal it?" without actually disturbing the target, via the signal-zero form.

Synopsis

```
kill SIGNAL, LIST
kill SIGNAL            # tainting side-effect only; returns 0
```

What you get back

The number of arguments in LIST that were successfully passed to kill(2). This is **not** necessarily the number of processes that actually received the signal - when SIGNAL is negative, or when a PID identifies a process group, one argument can target many processes. On permission or "no such process" errors for an argument, that argument is not counted and $! is set to the corresponding errno (EPERM, ESRCH, EINVAL).

```
my $cnt = kill 'HUP', $child1, $child2;
kill 'KILL', @goners;
```

With an empty LIST, no signal is sent and the return value is 0. The bare kill SIGNAL form is sometimes written purely to trigger taint checks on SIGNAL; see perlsec.

SIGNAL: name or number

`SIGNAL` may be either a signal name (a string) or a signal number. The string form is recommended for portability because the same signal can have different numbers on different operating systems.

A signal name may carry the `SIG` prefix or not - `'TERM'` and `'SIGTERM'` name the same signal.

```
kill 'TERM', $pid;      # portable
kill 'SIGTERM', $pid;   # also fine
kill 15, $pid;          # SIGTERM on Linux; may differ elsewhere
kill 9, $pid;           # SIGKILL on Linux
```

The list of signal names available on the current platform lives in `$Config{sig_name}`, provided by the `Config` module.

SIGNAL 0: liveness check

If `SIGNAL` is the number `0` or the string `'ZERO'` (or `'SIGZERO'`), no signal is actually delivered. `kill(2)` still performs its permission check, so the call tells you whether it would be *possible* to signal the process - that is, the process exists and is owned by the same user, or the caller is the super-user.

```
if (kill 0, $pid) {
    # process exists and we may signal it
}
elsif ($!{ESRCH}) {
    # no such process - it has exited and been reaped
}
elsif ($!{EPERM}) {
    # it exists but we are not allowed to signal it
}
```

This is the canonical idiom for checking that a child is still alive, even as a zombie, and has not changed its UID. It does **not** reap the child - use `waitpid` for that.

Negative SIGNAL: signal a process group

A negative signal name or number signals a whole process group instead of a single process. `kill '-KILL', $pgrp` and `kill -9, $pgrp` both send `SIGKILL` to every process in the group identified by `$pgrp`.

```
kill '-TERM', $pgrp;    # polite shutdown of the whole group
kill -9, $pgrp;         # forced
```

Positive signals are almost always what you want. Reach for a negative signal only when the target is deliberately a process group leader (for example a child you placed in its own group with `setpgrp` so you can terminate the subtree at once).

PID 0, negative PIDs

The behaviour of `kill` when a *PID* is zero or negative depends on the operating system. On POSIX-conforming systems (Linux included):

- **PID `0`** - signal the sender's own process group.
- **PID `-1`** - signal every process the caller has permission to signal (super-user: the whole system, minus a few special PIDs).
- **Any other negative PID** - behaves like a negative `SIGNAL` against the absolute value: signal the process group whose PGID equals `abs(PID)`.

If both `SIGNAL` and the PID are negative, the result is undefined; a future Perl may warn. Do not combine the two.

Examples

Politely ask a child to shut down, then escalate:

```
kill 'TERM', $child;
sleep 2;
kill 'KILL', $child if kill 0, $child;
waitpid $child, 0;
```

Reap nothing, just check whether a PID file still names a live process:

```
open my $fh, "<", "/run/daemon.pid" or die $!;
chomp(my $pid = <$fh>);
close $fh;

if (kill 0, $pid) {
    print "daemon alive (pid $pid)\n";
} else {
    print "stale pid file: $!\n";
    unlink "/run/daemon.pid";
}
```

Signal a whole process group created by a shell pipeline child:

```
my $pgrp = getpgrp($child);
kill '-TERM', $pgrp;
```

Install a handler and send yourself a signal:

```
local $SIG{USR1} = sub { warn "got USR1\n" };
kill 'USR1', $$;        # $$ is our own PID
```

Broadcast to several workers and find out how many were reachable:

```
my @workers = (1234, 1235, 9999);   # 9999 has exited
my $hit = kill 'HUP', @workers;     # probably 2
warn "lost a worker: $!\n" if $hit < @workers;
```

Edge cases

- **Empty LIST**: `kill 'TERM'` sends nothing and returns `0`. The call still evaluates `SIGNAL`, which is the only reason to write it (taint propagation).
- **Unknown signal name**: raises an exception (`Unrecognized signal name "FOO"`). Validate against `$Config{sig_name}` if the name comes from user input.
- **`$!` after partial success**: `kill` walks `LIST` left to right. `$!` reflects the **last** failing argument, not all of them. If you need per-PID errors, call `kill` once per PID.
- **Zombies still count as alive**: `kill 0, $zombie_pid` returns truthy until the child has been reaped with `wait` or `waitpid`. This is usually what you want for a liveness check; occasionally it surprises.
- **Signal delivery is asynchronous**: a successful `kill` only means the signal was *queued*. The handler in `%SIG` on the receiving process may run later, and Perl's safe-signal machinery defers delivery to the next opcode boundary.
- **Sending to yourself**: `kill SIGNAL, $$` works and is the usual way to test your own `%SIG` handlers.
- **No LIST, with taint**: under `-T`, writing `kill 'TERM'` propagates taintedness of `'TERM'` for the side-effect of triggering the check - the form has no other use.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `fork` - create the child process you are later going to signal
- `wait` - reap any terminated child, clearing zombies that `kill 0` would still report as alive
- `waitpid` - reap a specific child, optionally non-blocking (`WNOHANG`) so it pairs cleanly with `kill 0`
- `getpgrp` / `setpgrp` - inspect and change process-group membership, which is what negative-SIGNAL `kill` operates on
- `%SIG` - install handlers for the signals you send with `kill`
- `perlipc` - full treatment of signals, handlers, and safe-signal semantics

Control flow

last

Exit a loop immediately, skipping the rest of the body and the `continue` block.

`last` is Perl's equivalent of C's `break`. It transfers control out of the enclosing loop to the statement that follows it. The current iteration's remaining statements do not run, and neither does the loop's `continue` block - that is the key difference from `next`. With no argument it targets the innermost enclosing `while`, `until`, `for`, `foreach`, or bare block; with a `LABEL` it targets a named loop further out.

Synopsis

```
last
last LABEL
last EXPR       # LABEL computed at runtime, since 5.18
```

What you get back

Nothing. `last` performs flow control; it does not produce a value. It cannot be used to return a result from a block that normally yields one, such as `eval { ... }`, `sub { ... }`, or `do { ... }`. In those contexts either the construct produces no value or the program dies with `Can't "last" outside a loop block` - see *Edge cases* below.

Targeting a loop by label

Without a label, `last` refers to the innermost enclosing loop. That is usually what you want:

```
while (my $line = <$fh>) {
    last if $line =~ /^__END__$/;
    process($line);
}
```

With a label you can break out of an outer loop from within a nested one. Labels are conventionally all-uppercase:

```
OUTER: for my $row (@grid) {
    for my $cell (@$row) {
        last OUTER if $cell eq 'STOP';
    }
}
# control resumes here
```

`last EXPR` (Perl 5.18+) computes the label at runtime. `EXPR` must evaluate to a string naming an enclosing label:

```
my $target = 'OUTER';
last $target;
```

Interaction with `continue` blocks

A loop's `continue` block normally runs at the end of every iteration, including the last. `last` **skips** it - that is its defining difference from `next`:

```
my $i = 0;
while ($i < 10) {
    last if $i == 3;
    print "body $i\n";
} continue {
    $i++;                   # runs after every iteration EXCEPT
```

(continues on next page)

(continued from previous page)

```
                            # the one terminated by last
}
# prints body 0, body 1, body 2; then exits the loop.
# $i stays at 3 because continue did not fire the final time.
```

If you want `continue` to run, use `next` with a guard instead, or advance the counter before the `last`.

Behaviour in nested loops

`last` only leaves one loop at a time - the innermost one, unless labelled. In this example the inner `last` exits the `for` but the `while` keeps running:

```
while (1) {
    for my $x (1 .. 5) {
        last if $x == 3;
    }
    # control lands here every iteration of the while
    last;                   # needed to exit the while as well
}
```

To unwind several levels at once, label the outer loop and target it:

```
SEARCH: for my $file (@files) {
    open my $fh, '<', $file or next;
    while (my $line = <$fh>) {
        if ($line =~ /$pattern/) {
            $found = $file;
            last SEARCH;  # exits both the while and the for
        }
    }
}
```

Bare blocks count as loops

A bare `{ ... }` block is, for flow-control purposes, a loop that executes exactly once. `last` can exit such a block early, which is the idiomatic way to write "try a sequence of checks, bail out on the first match":

```
{
    last if $cached;
    recompute();
    store_in_cache();
}
# control continues here
```

This is the only `last` form that does not involve an iterating construct.

Examples

Stop reading a file on a blank line - the classic header-terminator idiom:

```
LINE: while (<$fh>) {
    last LINE if /^$/;
    push @header, $_;
}
```

Find-and-report across a two-dimensional structure:

```
my $hit;
ROW: for my $r (0 .. $#grid) {
    for my $c (0 .. $#{ $grid[$r] }) {
        if ($grid[$r][$c] eq $needle) {
            $hit = [$r, $c];
            last ROW;
        }
    }
}
```

Early exit from a bare block used as a try-once sequence:

```
my $result;
{
    $result = $cache{$key}, last if exists $cache{$key};
    $result = compute($key);
    $cache{$key} = $result;
}
```

Computed label (Perl 5.18+). Rarely needed, but useful when the target loop is chosen dynamically:

```
my $level = $deep ? 'OUTER' : 'INNER';
OUTER: for (...) {
    INNER: for (...) {
        last $level if $done;
    }
}
```

Edge cases

- **Illegal in `grep` and `map`.** Both expect their block to produce a value for every input element; `last` precludes that. The parser accepts the code (the block is not lexically a loop it can see through), but executing it dies with `Can't "last" outside a loop block`. Filter with a conditional inside the block instead, or switch to an explicit `for` loop.
- **`do { ... }` is not a loop.** `last` inside `do { ... }` does not terminate the `do`; it unwinds to the nearest enclosing real loop. If there is none, the program dies with `Can't "last" outside a loop block`. For early exit from a `do` used as an expression, see the workarounds in *perlsyn* under “Statement Modifiers” - typically

a bare block plus `last`, or a one-shot `for` loop.

- **`sub { ... }` is not a loop.** `last` inside a sub body does **not** return from the sub; it unwinds past the sub to the enclosing loop in the caller. Use `return` to leave a sub.
- **`last` inside `eval` does not escape the `eval`.** `eval { ... }` is not itself a loop, so `last` looks outward past the `eval` for the nearest enclosing loop and unwinds to it. The `eval` is exited as a side effect of that unwind, but `$@` is left empty - no exception was raised. If the `eval` has no enclosing loop above it, the program dies with `Can't "last" outside a loop block`. To leave an `eval` normally, fall off the end or use `die` (caught by the `eval` itself) or `return` (if the `eval` is inside a sub and you want to leave the sub).
- **Precedence.** Unlike most named operators, `last` has the same precedence as assignment and is exempt from the looks-like-a-function rule. So `last ("foo") . "bar"` passes `"foo" . "bar"` as the label, not just `"foo"`. Use a space, or omit the parentheses, to avoid surprises:

```
last LABEL;
last "LABEL";
```

- **Unknown label.** `last NOPE` where no enclosing loop is tagged `NOPE` dies with `Label not found for "last NOPE"`. This is a runtime error, not a compile-time one - the label is resolved against the dynamic call stack.
- **Loop modifier form has no block to exit.** `EXPR if COND` and similar statement-modifier forms are not loops; `last` inside the expression unwinds past them.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `next` - skip to the next iteration, running the `continue` block first; the counterpart to `last` that keeps the loop alive
- `redo` - restart the current iteration without re-testing the condition and without running `continue`
- `return` - leave a subroutine with a value; the right tool when you reach for `last` inside `sub { ... }`
- `continue` - the loop-trailer block that `last` skips and `next` honours; read its page for the three-way illustration of `last` / `next` / `redo`

SCALARs and strings

lc

Return a lowercased copy of a string.

`lc` takes a string, converts every cased character to its lowercase equivalent, and returns the result. The original is never modified. If the argument is omitted, `lc` operates on `$_`. The exact set of characters that change depends on the string's encoding and the pragmas in scope at the call site - ASCII-only by default, full Unicode under `use feature 'unicode_strings'` or when the input is already a character string with the UTF-8 flag.

Synopsis

```
lc EXPR
lc
```

What you get back

A new string. The return value is always a fresh scalar - modifying it does not affect the argument, and modifying the argument afterward does not affect the returned string. Length in characters is preserved: `lc` never adds or removes characters, even in the rare Unicode cases where upper- and lower-case forms have different lengths in other directions (see `fc` for folding, which can change length).

```
my $str = lc("Perl is GREAT");   # "perl is great"
```

Global state it touches

- Reads `$_` when called without an argument.
- Observes `use locale` for `LC_CTYPE` - with locale in effect the current locale's lowercasing table applies to code points below 256.
- Observes `use bytes` - under `use bytes` only `A-Z` change, to `a-z`.
- Observes `use feature 'unicode_strings'` - forces Unicode rules regardless of the UTF-8 flag on the input.

Which casing rules apply

Perl picks one of four rulesets, in priority order. The first one whose condition holds wins:

1. **`use bytes` in effect** - ASCII rules. Only `A-Z` map to `a-z`; every other byte is left alone, including bytes in the 128-255 range that would otherwise be Latin-1 letters.
2. **`use locale for LC_CTYPE` in effect** - the current locale's tables apply to code points below 256; code points 256 and above (only reachable when the string already carries the UTF-8 flag) use Unicode rules. From Perl 5.20 onward, a UTF-8 locale uses full Unicode rules throughout.
3. **The argument has the UTF-8 flag set** - Unicode rules apply to every character.
4. **`use feature 'unicode_strings'` or `use locale ':not_characters'` in effect** - Unicode rules apply to every character, regardless of the UTF-8 flag.

5. **Otherwise** - ASCII rules. Characters outside `A-Z` are returned unchanged, including Latin-1 uppercase letters like À-Þ.

The upshot: if you want predictable Unicode behaviour on every string regardless of how it was constructed, enable `use feature 'unicode_strings'` (or `use v5.12` and above, which turns it on for you).

Examples

Basic ASCII lowercasing:

```
my $s = lc("Hello, World!");          # "hello, world!"
```

Default to `$_`:

```
for ("FOO", "Bar", "BAZ") {
    print lc, "\n";                   # foo / bar / baz
}
```

Unicode characters only lowercase when the rules allow it:

```
use feature 'unicode_strings';
my $s = lc("ÄÖÜ");                    # "äöü"
```

Without `unicode_strings` and without the UTF-8 flag on the input, non-ASCII characters pass through unchanged:

```
my $bytes = "\xC4\xD6\xDC";           # Ä Ö Ü as Latin-1 bytes
my $lower = lc $bytes;                # unchanged: "\xC4\xD6\xDC"
```

`lc` is what backs the `\L...\E` escape inside double-quoted strings:

```
my $str = "Perl is \LGREAT\E";        # "Perl is great"
```

Case-insensitive compare by lowercasing both sides:

```
sub ieq { lc($_[0]) eq lc($_[1]) }
ieq("Perl", "PERL");                  # true
```

For correct case-insensitive comparison across Unicode, prefer `fc` (the Unicode folding function) over `lc` - see *See also*.

Edge cases

- **`undef` argument** raises an `uninitialized` warning under `use warnings` and returns the empty string.
- **Empty string** returns the empty string.
- **Numbers are stringified first**: `lc(42)` returns `"42"`.
- **`LATIN CAPITAL LETTER SHARP S` (U+1E9E)** lowercases to U+00DF (ß) under Unicode rules, but only if the result can be represented without crossing the 255/256 boundary in a way the current ruleset accepts. Under `use locale` on a non-UTF-8

locale, Perl leaves the character unchanged rather than guessing - and from Perl 5.22 onward this raises a locale warning.

- **Locale and the UTF-8 flag interact**: under `use locale` on a non-UTF-8 locale, characters below 256 follow the locale while characters 256 and above follow Unicode. A string containing both ranges will get two different casing tables applied to it.
- **Tied variables** have their `FETCH` called once. `lc` does not modify the tied value; it returns a plain (non-tied) scalar.
- **`lc` is a unary named operator**, not a list operator. `lc $a, $b` parses as `(lc $a), $b` - only `$a` is lowercased, and the comma operator discards the result. Use parentheses or `map` when you mean to lowercase multiple strings:

```
my @lower = map { lc } @words;
```

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `uc` - the uppercasing counterpart, with the same pragma and locale rules
- `lcfirst` - lowercase only the first character; handy for de-capitalising sentences or identifiers
- `fc` - Unicode casefold, the correct choice for case-insensitive comparison when input may contain non-ASCII
- `$_` - the default subject `lc` reads when called with no argument
- `use locale` - controls whether locale tables or ASCII/Unicode rules apply to characters below 256
- `use feature 'unicode_strings'` - forces full Unicode casing regardless of the UTF-8 flag on the input

SCALARs and strings

lcfirst

Return a copy of a string with its first character lowercased.

`lcfirst` touches **only** the first character; the rest of the string is copied verbatim. The input is not modified - `lcfirst` returns a new string. It is the internal function implementing the `\l` escape in double-quoted strings, so `"\l$name"` and `lcfirst($name)` produce the same result.

If `EXPR` is omitted, `lcfirst` operates on `$_`.

Synopsis

```
lcfirst EXPR
lcfirst
```

What you get back

A new string equal to EXPR with its first character replaced by the lowercase form that character's case-folding rules produce. The rest of the string is untouched. If EXPR is the empty string, the empty string is returned. If EXPR is undef, the result is the empty string and an `uninitialized` warning is emitted under `use warnings`.

`lcfirst` never mutates its argument. To lowercase the first character in place, assign the result back:

```
$name = lcfirst $name;
```

For the all-characters variant, see `lc`.

Global state it touches

- `$_` - read when EXPR is omitted.
- `LC_CTYPE` locale - consulted when `use locale` is in effect (see *Pragmas and case rules* below).

Pragmas and case rules

`lcfirst` behaves the same way under various pragmas as `lc` does. The active rule set for the first character depends on which pragmas are in scope at the call site:

- **`use bytes`** - ASCII rules only. Only the bytes A-Z are folded to a-z; every other byte is returned unchanged.
- **`use locale`** (for `LC_CTYPE`) - the current locale decides the fold for code points below 256. Code points 256 and above fold by Unicode rules when the string has the UTF-8 flag set. A UTF-8 locale engages full Unicode rules from Perl 5.20 onward.
- **UTF-8-flagged string** - Unicode case-folding rules apply.
- **`use feature 'unicode_strings'`** or **`use locale ':not_characters'`** - Unicode rules apply regardless of the UTF-8 flag.
- **Otherwise** - ASCII rules. Characters outside ASCII are returned unchanged.

This means the same `lcfirst("É...")` can return `"é..."` under `use utf8` or `use feature 'unicode_strings'`, and `"É..."` (unchanged) under pure-ASCII defaults. When portability across pragmas matters, state the rule set explicitly:

```
use feature 'unicode_strings';
my $s = lcfirst $input;        # Unicode rules regardless of UTF-8␣
↪flag
```

Examples

Basic call, lowercasing the first letter of a word:

```
my $s = lcfirst "Hello, World";    # "hello, World"
```

Title-case normalisation for a list of names, where the caller wants the first letter lowercased for a URL slug:

```
my @slugs = map { lcfirst } @CamelCaseNames;
```

Default-argument form reads from `$_`:

```
for ("Apple", "Banana", "Cherry") {
    print lcfirst, "\n";           # "apple", "banana", "cherry"
}
```

Only the **first** character changes - later capitals are preserved. This matters for `camelCase` identifiers derived from `PascalCase`:

```
my $method = lcfirst "GetUserName";   # "getUserName"
```

Unicode rules must be requested explicitly, either via a UTF-8-flagged input string or via the `unicode_strings` feature:

```
use feature 'unicode_strings';
my $s = lcfirst "Éclair";          # "éclair"
```

```
my $s = lcfirst "Éclair";          # without unicode_strings and no
                                   # UTF-8 flag: "Éclair" unchanged
```

The `\l` escape in a double-quoted string is exactly `lcfirst` on the next character:

```
my $name = "Perl";
print "\l$name\n";                 # "perl\n"
```

Edge cases

- **Empty string**: `lcfirst("")` returns `""`. No warning.
- **`undef` input**: `lcfirst(undef)` returns `""`. Emits an `uninitialized` warning under `use warnings`.
- **First character already lowercase**: returned unchanged; no special case, no shortcut the user needs to know about.
- **First character has no lowercase mapping** (digit, punctuation, symbol, most CJK): returned unchanged.
- **Multi-codepoint case folds**: some Unicode characters lowercase to more than one code point (e.g. Turkish dotted/dotless I pairs in locale-tailored folds). `lcfirst` follows Unicode's *simple* lowercase mapping, which is always single-codepoint - it does not perform full case folding. Use `lc` combined with normalisation, or an explicit `Unicode::CaseFold`, when full-fold semantics matter.

- **Locale surprises around 255/256**: under `use locale` with a non-UTF-8 locale, a first character whose lowercase would cross the 255/256 boundary is returned unchanged, and from Perl 5.22 onward a `locale` warning is emitted.
- **Not list-aware**: `lcfirst` is a scalar operator. `lcfirst @list` takes `scalar(@list)` - the element count - and lowercases its first character, almost never what the caller meant. Use `map { lcfirst } @list` for per-element lowercasing.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `lc` - lowercase every character, not only the first; same pragma-sensitivity rules
- `ucfirst` - uppercase the first character; the exact inverse operation
- `uc` - uppercase every character
- `fc` - Unicode case-folding suitable for caseless comparison, not display
- `$_` - default argument when EXPR is omitted

SCALARs and strings

length

Return the number of characters in a string.

`length` stringifies its argument and returns how many **characters** that string contains. "Characters" means logical Perl characters, not bytes: a string holding ten codepoints has length `10` regardless of how many bytes those codepoints occupy when encoded as UTF-8 on disk or on the wire.

Synopsis

```
length EXPR
length
```

What you get back

A non-negative integer - the count of characters in the stringified value of EXPR. If EXPR is omitted, `length` operates on `$_`. If EXPR is `undef`, the result is `undef`, not `0`; this is the one case where `length` does not return a number, and it is deliberate - it lets you distinguish an undefined scalar from an empty string without a separate `defined` check:

```
length(undef)       # undef
length("")          # 0
length("abc")       # 3
```

Characters, not bytes

On a normal Perl string, `length` counts characters. The byte count of the same string encoded as UTF-8 is generally different and is what external systems (file sizes, network payloads, `Content-Length` headers) want. Get it by encoding first:

```
use Encode;
my $s     = "na\x{EF}ve";          # five characters
my $chars = length $s;              # 5
my $bytes = length(encode('UTF-8', $s));  # 6
```

See `Encode` and `perlunicode` for the full story on how Perl strings carry an internal character-vs-byte flag and when that flag matters.

Examples

Basic count:

```
length "hello"                      # 5
length ""                           # 0
```

Default argument is `$_`:

```
for ("a", "bb", "ccc") {
    print length, "\n";             # 1, 2, 3
}
```

Distinguishing undefined from empty:

```
my $x;
my $y = "";
print defined(length $x) ? "set" : "undef", "\n";   # undef
print defined(length $y) ? "set" : "undef", "\n";   # set
```

A Unicode string - character count vs byte count:

```
my $s = "caf\x{E9}";                # four characters, one of them
↪non-ASCII
length $s;                          # 4
length encode('UTF-8', $s);         # 5
```

Numbers are stringified before counting, which is occasionally useful and occasionally surprising:

```
length 12345                        # 5
length 3.14                         # 4  ("3.14")
length 1e6                          # 7  ("1000000")
```

Edge cases

- **`undef` in, `undef` out.** `length(undef)` returns `undef`, not `0`. Under `use warnings` reading an undefined scalar through `length $x` where `$x` is undef does **not** emit an `uninitialized` warning, unlike most other operators.
- **Whole array or hash**: `length` does not count elements. It stringifies its argument, so `length @arr` first evaluates `@arr` in scalar context (its element count) and then counts the digits of that number. For the actual size use `scalar @arr` or `scalar keys %hash`:

```
my @arr = (1) x 100;
length @arr;                    # 3  (digits of "100")
scalar @arr;                    # 100
```

- **Tied or magical scalars**: `length` triggers FETCH, so the counted value is whatever the tie layer returns at that moment.
- **Overloaded objects**: `length $obj` invokes the `""` stringification overload (or falls back to the default reference form) and counts characters in the resulting string.
- **Wide characters from byte input**: a string read from a handle without an encoding layer is a byte string. `length` counts bytes then - because each byte is one character to Perl. Decode first if you want character counts:

```
open my $fh, "<:raw", $path or die $!;
my $bytes = do { local $/; <$fh> };
my $text  = decode('UTF-8', $bytes);
length $bytes;                  # byte count
length $text;                   # character count
```

- **Locale and pragmas**: unlike `lc` / `uc` / `fc`, `length` does not vary by `use locale`. A character is a character regardless.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `scalar` - force scalar context; the correct way to get an element count from an array (`scalar @arr`) instead of the length of its stringified count
- `substr` - extract a substring by character offset; pairs naturally with `length` for slicing work
- `index` - find the position of a substring; returns a character offset measured the same way `length` measures
- `sprintf` - `%s` field widths are character counts, same notion as `length`
- `reverse` - in scalar context reverses a string character-by-character; same character model as `length`
- `pos` - regex-match position, also in characters

Filehandles, files, directories

link

Create a hard link from `NEWFILE` to the existing `OLDFILE`.

`link` adds a second directory entry that refers to the same underlying file as `OLDFILE`. After a successful call, the file has two names: `OLDFILE` and `NEWFILE`. Both names are equal citizens - the file itself is not deleted until every name is removed and no process holds the file open. The call is a thin wrapper around the `link(2)` system call and inherits its constraints: both paths must resolve on the **same filesystem**, and on POSIX systems only the superuser may hard-link a directory (most Linux kernels refuse even for `root`).

Synopsis

```
link OLDFILE, NEWFILE
```

What you get back

1 on success, `0` on failure. On failure, `$!` is set to the system error - typical values are `EXDEV` (cross-device link), `EPERM` (target is a directory, or filesystem forbids hard links), `EEXIST` (`NEWFILE` already exists), `EACCES` (insufficient permission), and `ENOENT` (`OLDFILE` missing).

```
link $src, $dst
    or die "link $src -> $dst failed: $!";
```

Global state it touches

- `$!` - set on failure to the system error code.

Examples

Create a second name for an existing file:

```
link "report.txt", "report.bak"
    or die "link failed: $!";
```

Use `stat` to observe the link count going up. The third element of the `stat` list is the number of hard links pointing at the inode:

```
link "data", "data.alt" or die $!;
my $nlink = (stat "data")[3];
print "data has $nlink names\n";    # "data has 2 names"
```

Atomically replace a file by building the new version under a temporary name, then swapping with `link` + `rename`:

```
open my $fh, ">", "config.new" or die $!;
print $fh $new_contents;
close $fh;
rename "config.new", "config" or die "rename: $!";
```

(For the genuinely atomic-under-crash variant you want `link` + `unlink` + `rename`; see the commentary in `perlport`.)

Detect a cross-device failure and fall back to copying:

```
use Errno qw(EXDEV);
unless (link $src, $dst) {
    if ($! == EXDEV) {
        # /tmp and $HOME are typically different filesystems
        copy_file($src, $dst);
    } else {
        die "link $src -> $dst: $!";
    }
}
```

Edge cases

- **Directories**: `link` on a directory fails with `EPERM` on effectively every modern system. POSIX forbids it for non-root, and Linux forbids it even for root. Use `symlink` when you want a second name for a directory.
- **Cross-filesystem**: the kernel returns `EXDEV` if `OLDFILE` and `NEWFILE` resolve to different filesystems. Hard links cannot span mount points because they share an inode number, which is only meaningful within one filesystem.
- **Existing target**: if `NEWFILE` already exists, the call fails with `EEXIST`. `link` never overwrites. Remove the target first with `unlink` if replacement is intended.
- **Symbolic link as `OLDFILE`**: the link is made to the symlink's **target**, not to the symlink itself, on most systems. If you need to link the symlink, dereference it explicitly or use a platform that exposes `linkat` with `AT_SYMLINK_FOLLOW` cleared (not available through Perl core).
- **Relative paths** are resolved against the current working directory at the moment of the call, for both operands.
- **Permissions**: `link` does not require write permission on `OLDFILE` - only search permission on its directory and write permission on the directory containing `NEWFILE`.
- **Same path both sides**: `link $f, $f` fails with `EEXIST`.
- **Unlinking**: removing `OLDFILE` with `unlink` after a successful `link` leaves the file fully reachable through `NEWFILE`. The data is freed only when the last name is unlinked and no open file descriptor refers to it.
- **Portability**: not every filesystem supports hard links. FAT, exFAT, and many network filesystems either refuse or silently behave as copies. See `perlport` for the platform matrix.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `symlink` - create a symbolic link instead of a hard link; works across filesystems and on directories
- `unlink` - remove a directory entry; the file itself survives as long as another link or open descriptor remains
- `rename` - move or rename a file within one filesystem; atomic where `link` + `unlink` is not
- `stat` - inspect the link count (field 3) to see how many names refer to the same inode
- `$!` - the system error set when `link` returns `0`

Sockets

listen

Mark a socket as passive so it can accept incoming connections.

`listen` is the third step in the classic server setup - after `socket` creates the endpoint and `bind` fixes it to a local address, `listen` switches it into the listening state and sizes the kernel's backlog queue of pending connections. Incoming connections are then drained one at a time with `accept`. `QUEUESIZE` is the maximum number of connections the kernel will hold for you before it starts refusing new ones.

Synopsis

```
listen SOCKET, QUEUESIZE
```

What you get back

True on success, false on failure (with `$!` set to the errno from the underlying `listen(2)`). Always check the return value - a server that silently fails to enter the listening state will accept no connections, and the cause (a stale socket file, a port collision, an unbound descriptor) is only visible through `$!`.

```
listen $srv, SOMAXCONN
    or die "listen on $path: $!";
```

Global state it touches

`listen` reads no special variables and writes only `$!` on failure. The call is a thin wrapper over the kernel's `listen(2)`; effects are on the socket descriptor, not on Perl state.

Examples

A minimal TCP server. `socket`, `bind`, `listen`, `accept` in order - miss any step and `accept` fails:

```
use Socket;

socket(my $srv, PF_INET, SOCK_STREAM, getprotobyname("tcp"))
    or die "socket: $!";
setsockopt($srv, SOL_SOCKET, SO_REUSEADDR, 1)
    or die "setsockopt: $!";
bind($srv, sockaddr_in(8080, INADDR_ANY))
    or die "bind: $!";
listen($srv, SOMAXCONN)
    or die "listen: $!";

while (accept(my $cli, $srv)) {
    # serve $cli ...
    close $cli;
}
```

A Unix-domain server. Same sequence, different address family:

```
use Socket;

my $path = "/tmp/myservice.sock";
unlink $path;                                # stale socket file would␣
↪cause EADDRINUSE
socket(my $srv, PF_UNIX, SOCK_STREAM, 0)  or die "socket: $!";
bind($srv, sockaddr_un($path))            or die "bind: $!";
listen($srv, 16)                          or die "listen: $!";
```

Using the POSIX-defined cap `SOMAXCONN` rather than hard-coding a number. The kernel silently clamps larger values to its own limit anyway; `SOMAXCONN` documents intent:

```
use Socket qw(SOMAXCONN);
listen($srv, SOMAXCONN) or die "listen: $!";
```

A small backlog for a service that processes connections faster than they arrive:

```
listen($srv, 5) or die "listen: $!";
```

Re-listening on an already-listening socket. A second call with a different `QUEUESIZE` is legal on Linux and resizes the backlog in place:

```
listen($srv, 128) or die "listen: $!";
# ... later, under load:
listen($srv, 1024) or die "listen: $!";   # grow the queue
```

Edge cases

- **Call order matters.** Calling `listen` on a socket that has not been `bind`-ed fails with `EDESTADDRREQ` (or on some kernels an autobound ephemeral port - do not rely on that). Calling `accept` before `listen` fails with `EINVAL`.
- **Only for connection-oriented sockets.** `listen` is meaningful on `SOCK_STREAM` and `SOCK_SEQPACKET`. Calling it on a `SOCK_DGRAM` socket fails with `EOPNOTSUPP`; UDP has no notion of pending connections.
- **`QUEUESIZE` is advisory.** The kernel clamps it to `/proc/sys/net/core/somaxconn` (Linux) regardless of what you ask for. A value of `0` is accepted but means "rely on kernel-default backlog"; it does not disable listening.
- **Negative values are silently treated as `0`** by the kernel. Perl does not diagnose this - check your input before passing it to `listen`.
- **`EADDRINUSE` at `listen` vs at `bind`.** Port conflicts for TCP/UDP surface at `bind`; `listen` rarely fails with this. For Unix-domain sockets a leftover socket file from a previous run causes `bind` to fail with `EADDRINUSE` - remove it with `unlink` before binding.
- **Stale connections in the queue.** When `accept` runs, the returned connection may already be closed by the peer (the client gave up while queued). Handle that like any other I/O error from the new socket, not as a `listen` problem.
- **After `fork`.** A listening socket inherited by a child remains listening; both parent and child can `accept` from the same queue. This is the standard pre-fork server pattern - do not call `listen` again in the child.
- **`SIGPIPE` is unrelated.** `listen` itself never raises `SIGPIPE`; that signal arises on writes to a closed peer after `accept`.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `socket` - creates the endpoint `listen` will mark as passive; always the first call in the sequence
- `bind` - assigns a local address to the socket; must run before `listen` or the call fails
- `accept` - pulls the next pending connection off the backlog queue that `listen` established
- `setsockopt` - set `SO_REUSEADDR` before `bind` to avoid `TIME_WAIT` collisions when restarting a server
- `shutdown` - half-close an accepted connection; not used on the listening socket itself
- `$!` - holds the errno after a failed `listen`; the only way to tell `EADDRINUSE` from `EACCES` from `EOPNOTSUPP`

Scoping

local

Save the current value of a package variable and restore it when the enclosing scope exits.

`local` is the dynamic-scope operator. It does **not** declare a new variable - it reaches into an existing package (global) variable, stashes the current value on a hidden save stack, and arranges for the original value to be put back when control leaves the current block, `eval`, or `do FILE`. Called subroutines see the temporary value. For most "I want a variable local to this block" needs, the right tool is `my`; reach for `local` specifically when the variable must be a package global - the punctuation variables, filehandles, or entries in the symbol table - and you want that global to have a different value for the duration of a block and every subroutine it calls.

Synopsis

```
local EXPR
local $var
local $var = EXPR
local (@list) = LIST
local $hash{key}
local $array[i]
local *GLOB
```

What you get back

The value of the localized expression (the new value, after any assignment in the same statement). The save-stack bookkeeping is a side effect; the return value matters only when `local` appears inside a larger expression:

```
our $x = 2;
foo($x, local $x = $x + 1, $x);   # foo() receives (2, 3, 3)
```

Dynamic scope, not lexical scope

`local` and `my` are different species of scoping:

- `my` creates a **new, lexically scoped** variable. Only code textually inside the enclosing block can see it. Called subroutines cannot.
- `local` does **not** create anything. It temporarily overrides the value of an **existing package variable**. Every piece of code - this block and every subroutine it calls, directly or transitively - sees the new value until the scope ends.

That is why `local` is the right tool for punctuation variables like `$/`, `$\`, `$,`, `$_`, and `$@`: those are package globals that the Perl runtime (and anything called from your code) reads at well-known names. A `my` shadowing would not affect them.

```
sub slurp {
    my ($path) = @_;
    open my $fh, "<", $path or die "open $path: $!";
```

(continues on next page)

(continued from previous page)

```
    local $/;                       # undef $/ for this sub only
    return <$fh>;                   # read to EOF in one go
}
```

The `local $/` line above is the single most common `local` idiom in real code: temporarily undefining the input record separator so that `readline` (`<$fh>`) returns the whole file. When `slurp` returns, `$/` is restored to whatever it was before - even if the caller had also changed it.

What you can and cannot localize

You can `local`ize:

- **Package scalars, arrays, hashes** - `local $Pkg::var`, `local @Pkg::arr`, `local %Pkg::hash`. Bareword `local $var` targets the variable in the current package.
- **Already-declared `our` variables** - `our` creates a lexical alias to a package variable, so `local` on it localizes the underlying global.
- **Single elements and slices of package arrays/hashes** - `local $hash{key}`, `local $array[3]`, `local @hash{qw(a b)}`, `local @array[0..2]`.
- **Globs** - `local *name` creates a fresh symbol-table entry so that `$name`, `@name`, `%name`, `&name`, and the `name` filehandle are all dynamically reset together.
- **Conditional lvalues** - `local ($cond ? $v1 : $v2)` when the chosen branch is itself localizable.

You **cannot** `local`ize:

- A `my` variable. `my` variables are lexicals living in a pad, not in the symbol table; they have no package name for `local` to save under. Trying it is a compile-time error: `Can't localize lexical variable $x`.
- A `state` variable. Same reason.
- Read-only magic globals. `local $1 = 2` fails with `Modification of a read-only value attempted` - the capture variables cannot be assigned to. (The one exception is `$_`: `local $_` has, since 5.14, explicitly stripped magic so it can be reused safely in a subroutine.)

Localizing composite-type elements

`local $hash{key}` and `local $array[i]` save the **named slot**, not the value that happens to be there. When the scope ends, the original value is restored to that same slot - even if the element was deleted or the array was shortened in the meantime. A deleted hash key springs back; a popped array element reappears, padding the array with `undef` if necessary.

```
our %hash = (a => "is");
{
    local $hash{a} = "drill";
    delete $hash{a};                # gone for now...
```

(continues on next page)

(continued from previous page)

```
}
print $hash{a}, "\n";              # ...but restored to "is"
```

Examples

Basic: give a global a temporary value for one block. Subroutines called from inside the block see the new value.

```
our $verbose = 0;
sub log_msg { print "[v=$verbose] $_[0]\n" }

{
    local $verbose = 1;
    log_msg("inside");             # prints "[v=1] inside"
}
log_msg("outside");                # prints "[v=0] outside"
```

Slurp-a-file idiom with `$/`:

```
my $content = do {
    open my $fh, "<", $path or die "open $path: $!";
    local $/;                      # list context for <> now reads␣
↪all
    <$fh>;
};
```

Temporarily trap `$@` so an inner `eval` does not clobber the caller's pending error:

```
sub try_cleanup {
    local $@;                      # caller's $@ preserved
    eval { risky_cleanup() };
    # even if eval failed, caller's $@ is untouched
}
```

Python-style `print` defaults, scoped to one block:

```
{
    local $, = " ";
    local $\ = "\n";
    print 1, 2, 3;                 # "1 2 3\n"
}
print 1, 2, 3;                     # "123" - defaults restored
```

List form needs parentheses. The parentheses also give the right-hand side list context - exactly like `my`:

```
our (@wid, %get);
local (@wid, %get) = (@defaults, %overrides);
```

Localize a single hash element - useful for threading overrides through a call without touching unrelated keys:

```
our %config = (timeout => 30, retries => 3);
{
    local $config{timeout} = 5;
    do_probe();                  # sees timeout => 5
}
# %config back to (timeout => 30, retries => 3)
```

Glob localization - whole symbol-table entry for LOG is replaced:

```
{
    local *LOG;
    open LOG, ">", "/tmp/trace.$$" or die $!;
    run_traced();                # sees our private LOG filehandle
}
# original LOG (if any) is back
```

Edge cases

- **Runtime operator, not a declaration.** `local` executes each time control reaches it. Inside a loop it saves and restores on every iteration - measurable overhead. Lift it out of the loop when the intent is "for the whole loop":

  ```
  { local $/ = "\n\n";            # once, not per iteration
      while (<$fh>) { ... }
  }
  ```

- **Assignment is evaluated before the save.** The right-hand side runs in the enclosing dynamic scope, so `local $x = $x + 1` reads the old `$x`, then saves, then assigns the new value.
- **Scope boundary is dynamic, not lexical.** The save is undone when the **current block exits at runtime**, not when the source block ends textually. Exiting via `return`, `die`, `last`, `next`, or a non-local goto still triggers the restore.
- **`local` on a `my` is a compile-time error.** The parser rejects `my $x; local $x;` with `Can't localize lexical variable $x`. Use `our` (or a fully qualified name) if you genuinely need dynamic scoping on that name.
- **Tied arrays and hashes** do not currently behave the way the POD describes - localizing the whole aggregate is buggy upstream. Localizing individual elements of a tied aggregate is safe. This caveat is inherited from upstream Perl.
- **Read-only magicals cannot be assigned.** `local $1 = "x"` dies at runtime. You can `local $_` (magic is stripped since 5.14) but not `local $1`, `local $&`, etc.
- **Negative array indices** in `local $array[-1]` are documented as "particularly surprising" upstream; treat the behaviour as unstable and avoid.
- **`delete local`** extends `local` to the removal of an element: `delete local $hash{key}` deletes the entry for the current block and restores it on exit. It returns the value that was there before localization.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `my` - lexical (compile-time, block-scoped) declaration; the right tool when you want a truly private variable
- `our` - lexical alias to a package variable; common partner for `local` when the global is in another package
- `state` - persistent lexical; cannot be `localized`
- `delete` - combined with `local` (`delete local $h{k}`) to scope an element deletion to the current block
- `eval` - common `local` target: `local $@` around an inner `eval` prevents it leaking errors to the caller
- `$/` - input record separator; canonical `local` target for slurp-mode file reads
- `$_` - default scalar; `local $_` strips magic (since 5.14) so a subroutine can reuse it safely
- `$@` - last `eval` error; `local $@` shields the caller from an inner `eval`'s error

Time

localtime

Convert an epoch time to a broken-down calendar time in the local time zone.

`localtime` takes a Unix epoch value - seconds since 1970-01-01 UTC, the shape returned by `time` - and decomposes it into year, month, day, hour, minute, second, weekday, yearday, and a daylight-saving flag, all expressed in the **local** time zone. The time zone is read from the `TZ` environment variable if set, otherwise from the system default (typically `/etc/localtime`). For the UTC companion that ignores `TZ`, see `gmtime`.

Synopsis

```
localtime EXPR
localtime
```

What you get back

The return shape depends on context, and `localtime` is one of the handful of built-ins where the **same expression in list context and scalar context produces completely different answers**.

List context - a 9-element list, all numeric, taken straight out of the C `struct tm`:

```
#     0     1     2     3     4     5     6     7     8
my ($sec, $min, $hour, $mday, $mon, $year, $wday, $yday, $isdst) =
                                                  localtime(time);
```

Index	Name	Range	Notes
0	`$sec`	`0..60`	`60` is possible for leap seconds
1	`$min`	`0..59`	
2	`$hour`	`0..23`	
3	`$mday`	`1..31`	1-based day of the month
4	`$mon`	`0..11`	**0-based**: `0` = January, 11 = December
5	`$year`	years - 1900	e.g. 129 for 2029
6	`$wday`	`0..6`	`0` = Sunday, 3 = Wednesday
7	`$yday`	`0..365`	0-based day of the year; 365 in leap year
8	`$isdst`	boolean	true when DST is in effect for the local TZ

The 0-based `$mon` and 1900-based `$year` are long-standing C inheritances; most bugs written against `localtime` come from forgetting exactly one of them. The fix for `$year` is `+= 1900`:

```
my @t = localtime;
my $full_year = $t[5] + 1900;
```

Scalar context - the familiar English `ctime(3)` string, always 24 characters, always in English regardless of locale:

```
my $now_string = localtime;      # "Thu Oct 13 04:54:34 1994"
```

For a locale-aware or custom-formatted string, do not try to pick apart the scalar form. Go through the list form and `POSIX::strftime`:

```
use POSIX qw(strftime);
my $now_string = strftime "%a %b %e %H:%M:%S %Y", localtime;
```

Global state it touches

- **`TZ`** in `%ENV` - selects the local time zone. A program that wants to interpret a timestamp in a specific zone sets `$ENV{TZ}` and calls `POSIX::tzset` before `localtime` (see *Edge cases* for the caveat).
- System zoneinfo (`/etc/localtime`, `/usr/share/zoneinfo/...`) when `TZ` is unset - read lazily by the C library, not by Perl directly.
- `%ENV` changes to `TZ` do **not** always take effect on the next call; see *Edge cases*.

`localtime` does not touch `$_` or any output-related globals.

Examples

Current wall-clock date in a human-readable string:

```
my $now = localtime;             # "Wed Apr 23 14:07:12 2025"
```

Current date as a 9-element list - note the two offsets:

```
my ($s,$m,$h,$md,$mo,$y,$wd,$yd,$dst) = localtime;
printf "%04d-%02d-%02d %02d:%02d:%02d\n",
       $y+1900, $mo+1, $md, $h, $m, $s;    # "2025-04-23 14:07:12"
```

Month name from `$mon` using a lookup table - this is the canonical way, because `$mon` is 0-based exactly so it indexes an array:

```
my @abbr = qw(Jan Feb Mar Apr May Jun Jul Aug Sep Oct Nov Dec);
my ($mday, $mon) = (localtime)[3,4];
print "$abbr[$mon] $mday";       # e.g. "Apr 23"
```

Formatting with `POSIX::strftime` - the right answer whenever you need anything other than the bare English `ctime` string:

```
use POSIX qw(strftime);
my @now = localtime;
my $stamp = strftime "%Y-%m-%d %H:%M:%S", @now;   # "2025-04-23␣
↪14:07:12"
```

Interpreting a stored epoch in a specific zone. Set `TZ`, call `POSIX::tzset`, then `localtime`:

```
use POSIX qw(tzset);
local $ENV{TZ} = "Europe/Berlin";
tzset();
my $wall = localtime(1_700_000_000);   # "Tue Nov 14 23:13:20 2023"
```

Context trap - `localtime` inside `print LIST` is in **list** context, so you get nine numbers concatenated with no spaces. Use `scalar` to force the string form:

```
print localtime, "\n";           # e.g. "12724232312505230"
print scalar localtime, "\n";    # "Wed Apr 23 14:07:12 2025"
```

Edge cases

- **No argument**: `localtime` with no argument uses `time` - the current wall-clock moment.
- **Negative epoch**: dates before 1970-01-01 UTC are accepted on systems with a signed `time_t`. Portability of very distant past or future times depends on the platform's C library.
- **`$year` pitfall**: `$year + 1900` gives the full year. Writing `"19$year"` was a Y2K bug and is still wrong; write `1900 + $year`.
- **`$mon` pitfall**: `$mon` is 0-based. `localtime` output feeding anything 1-based (including `POSIX::mktime`) does **not** need adjustment - `mktime` expects the same 0-based convention. External systems (databases, ISO-8601 strings) usually want `$mon + 1`.
- **`$isdst` is advisory**, not directly comparable across zones. `1` means "the local zone currently applies its DST offset"; `0` means "standard time"; `-1` occasionally

appears when the zone rules cannot decide (e.g. the hour that does not exist on a spring-forward day).

- **TZ reload caveat**: most C libraries (glibc included) cache the parsed zone rules on the first lookup. A later assignment to `$ENV{TZ}` is **not** picked up automatically - call `POSIX::tzset` after every change, or the old zone will keep being used.
- **Scalar string is always English** and is **not** affected by `LC_TIME` or any other locale setting. For a localized string, go through `POSIX::strftime` with `LC_TIME` set to the desired locale.
- **Thread safety**: on systems where the C `localtime(3)` call is not reentrant, concurrent threads mutating `TZ` can race. In practice pperl and modern glibc use the reentrant `localtime_r` internally, but `TZ` is still a process-wide global.
- **Leap seconds**: `$sec` can legally be `60` on systems with leap second support. Most systems smear or ignore them and you will never see it; code that must not break on `60` handles it already.
- **`%a` / `%b` width** under `POSIX::strftime`: the abbreviated weekday and month names are **not guaranteed three characters** in every locale. Code that assumes a fixed column width will misalign in German, French, and many others.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `gmtime` - same decomposition in UTC; does not consult `TZ` and is the right choice when you want a time zone–independent value
- `time` - the epoch source that `localtime` most often receives as its argument
- `POSIX::strftime` - format a `localtime` list into any string layout you need, locale-aware
- `POSIX::mktime` - inverse direction: take a 9-element list back to an epoch value
- `POSIX::tzset` - re-read `TZ` after changing it, mandatory if you want the change to take effect
- `$ENV{TZ}` - the environment variable `localtime` reads to pick the local zone

Misc

lock

Place an advisory lock on a shared variable, array, hash, or subroutine until the lock goes out of scope.

`lock` is the synchronisation primitive of Perl's interpreter-threads model (`use threads; use threads::shared`). When `THING` is a variable that has been declared `:shared` - or a reference to a shared aggregate - `lock` acquires an advisory mutex on that datum for the rest of the enclosing block. When the block exits, the lock is released. Any other thread calling `lock` on the same datum blocks until the holder releases it.

The lock is **advisory**: it stops other threads that also call `lock` on the same variable, nothing else. A thread that just reads or writes the shared variable without locking it is not blocked and not serialised. `lock` is a convention, not a barrier.

Synopsis

```
lock $shared_scalar
lock @shared_array
lock %shared_hash
lock &shared_sub
lock $ref_to_shared_aggregate
```

What you get back

The argument itself:

- For a scalar, the scalar value.
- For an array, hash, or subroutine, a reference to it.

The return value is rarely used. `lock` is called for its side effect (acquiring the mutex), not for its value.

Lock is scoped, not statement-scoped

The lock is released when the innermost enclosing block exits, not when the `lock` statement finishes. Two consequences:

- `lock` inside a `{ ... }` block serialises only that block's duration. Exiting the block - by fall-through, `return`, `last`, `die`, whatever - releases the lock.
- You cannot release a lock early. There is no `unlock`. If you need a shorter critical section, introduce a tighter `{ ... }` block:

```
{
    lock %shared_hash;
    $shared_hash{$key} = $value;
}   # lock released here
do_unlocked_work();
```

Weak keyword

`lock` is a **weak keyword**. If a subroutine named `lock` is in scope at the point of the call (declared or imported before the call site), that subroutine is called instead of the built-in. This makes `lock` safe to use as a method or function name in code that does not use threads. To force the built-in when a same-named sub is in scope, call it via its package: `CORE::lock($thing)`.

Examples

Serialise a hash update between threads:

```
use threads;
use threads::shared;

my %counts :shared;

sub bump {
    my $key = shift;
    lock %counts;
    $counts{$key}++;
}
```

Lock an aggregate through a reference. `lock` follows one level of reference to find the datum to lock:

```
my @queue :shared;
my $queue_ref = \@queue;

sub enqueue {
    my $item = shift;
    lock $queue_ref;        # locks @queue
    push @queue, $item;
}
```

Narrow the critical section with an inner block so unrelated work runs unlocked:

```
my $result;
{
    lock %cache;
    $result = $cache{$key};
}
expensive_post_processing($result);   # runs without the lock
```

Without `use threads::shared`, `lock` is a no-op. This makes it harmless to leave in code that may run single-threaded:

```
# no `use threads::shared` here
lock $x;                    # does nothing, does not warn
```

Edge cases

- **Unshared variable**: `lock` on a variable that was not declared `:shared` and is not a reference to shared data does nothing useful. Under upstream this may croak in some cases; under others it is silently a no-op. Do not rely on `lock` to catch the "forgot to share" bug.
- **Reference vs aggregate**: `lock \%h` and `lock %h` both lock `%h`. `lock` dereferences one level to find the shared datum.

- **Recursive locking within one thread**: the same thread may re-acquire a lock it already holds; the mutex is recursive per thread. Another thread still blocks.
- **No `unlock`**: releasing before block exit requires restructuring into a tighter scope. `undef $lock_guard` patterns from other languages do not apply - `lock` is not a value you store.
- **Weak-keyword ambiguity**: a `sub lock` declared or imported earlier wins over the built-in. Use `CORE::lock` to disambiguate.
- **Not cross-process**: `lock` coordinates threads within one interpreter process. For file-level locking across processes use `flock`; for advisory filesystem locks they are separate mechanisms with no interaction.

Differences from upstream

- pperl does not implement interpreter threads. The `lock` opcode is recognised by the parser but has no runtime effect - it behaves exactly as upstream `lock` does under a build without `threads::shared`: a silent no-op returning its argument. Code that uses `lock` defensively (as the upstream documentation recommends for single-threaded compatibility) runs unchanged. Code that depends on `lock` for actual synchronisation will not be synchronised under pperl.
- The companion distribution `threads::shared` is not available under pperl; `use threads::shared` fails at compile time. Parallelism in pperl is exposed through JIT auto-parallelisation (Rayon) on specific loop shapes, not through user-visible ithreads.

See also

- `flock` - advisory lock on a filehandle, coordinating between processes rather than threads
- `wait` - reap a child process; the process-level equivalent of waiting for another unit of execution
- `fork` - the other concurrency primitive in core Perl, with no shared memory by default
- `our` - declare a package-scoped variable; commonly paired with `:shared` in threaded code
- `local` - dynamic-scope binding, sometimes confused with `lock` because both are scope-bounded and both restore on block exit

Numeric functions

log

Return the natural logarithm (base *e*) of a number.

`log` is the inverse of `exp`. It takes a numeric `EXPR`, coerces it to a double-precision float if necessary, and returns its logarithm to the base *e* (Euler's number, approximately `2.718281828459045`). If `EXPR` is omitted, `log` operates on `$_`.

There is no built-in for logarithms to an arbitrary base - use basic algebra (see the examples below) or `POSIX::log10` / `POSIX::log2` for the two common fixed bases.

Synopsis

```
log EXPR
log
```

What you get back

A double-precision float: the natural logarithm of `EXPR`. Concretely:

- `log(1)` is `0`.
- `log(exp(1))` is `1` (the defining identity).
- `log(x)` is strictly increasing for `x > 0`.

Special inputs follow IEEE-754 rules as provided by the platform C library's `log(3)`:

- `log(0)` returns negative infinity (`-Inf`).
- `log(x)` for `x < 0` returns `NaN`.
- `log(Inf)` returns `Inf`; `log(NaN)` returns `NaN`.

The result is always a float, even when the input is an integer or a string.

Examples

The defining identity - the natural log of *e* is 1:

```
use POSIX ();
print log(exp(1)), "\n";            # 1
```

A base-10 logarithm, built from `log` by change of base. The base-*N* log of a number equals its natural log divided by the natural log of *N*:

```
sub log10 {
    my ($n) = @_;
    return log($n) / log(10);
}

print log10(1000), "\n";            # 3
print log10(0.01), "\n";            # -2
```

The same idiom generalised to any base - useful for bits (base 2), decibels (base 10), or anything else:

```
sub log_base {
    my ($base, $n) = @_;
    return log($n) / log($base);
}
```

(continues on next page)

(continued from previous page)

```
print log_base(2, 1024), "\n";      # 10
print log_base(16, 65536), "\n";    # 4
```

Operating on `$_` - handy inside `map` or a `while` line loop:

```
my @natural_logs = map { log } 1, 2, 3, 4;
```

Numeric coercion of a string argument - `log` evaluates its operand in numeric context just like the arithmetic operators:

```
print log("7.389056"), "\n";        # ~2 (log of e^2, give or take)
```

Edge cases

- **`log(0)` is `-Inf`**, not an error and not a division-by-zero exception. Perl does not die; you get a float infinity back and any further arithmetic propagates it:

  ```
  my $x = log(0);                   # -Inf
  print $x + 1, "\n";               # -Inf
  ```

- **log of a negative number is `NaN`**. Again, no exception - the caller is responsible for range-checking if that matters:

  ```
  my $x = log(-1);                  # NaN
  print $x == $x ? "num" : "nan", "\n";   # nan (NaN != NaN)
  ```

  Guard the input if you need a defined result:

  ```
  die "log domain error" unless $n > 0;
  my $l = log($n);
  ```

- **Non-numeric strings** coerce to `0` and therefore produce `-Inf`, and under `use warnings` trigger `Argument "..." isn't numeric`:

  ```
  use warnings;
  print log("hello"), "\n";         # -Inf, with warning
  ```

- **No argument form uses `$_`.** `log` with an empty argument list reads the current topic; inside `map { log }` or `while (<>) { print log; }` this is the usual shortcut.
- **Integer vs float input** makes no difference to the result type: the return value is always a float. `log(2)` and `log(2.0)` are the same value.
- **Precision** is whatever the platform C library's `log(3)` delivers - typically ~15–17 significant decimal digits on x86-64 Linux. Results are not bit-for-bit portable across architectures.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `exp` - the inverse: `exp(log($x))` is `$x` for `$x > 0`, and `log(exp($x))` is `$x` for all finite `$x`
- `**` - the exponentiation operator; `$x ** $y` is equivalent to `exp($y * log($x))` for positive `$x`
- `POSIX::log10` - base-10 logarithm, direct from the C library; faster and slightly more accurate than `log($x)/log(10)`
- `POSIX::log2` - base-2 logarithm, same story
- `POSIX::log1p` - `log(1 + $x)` computed accurately for small `$x`, where the naive form loses precision

Filehandles, files, directories

lstat

Return the 13-element status list for a path **without** following a symbolic link.

`lstat` does exactly what `stat` does - same 13-element result, same special _ filehandle cache, same failure semantics - with one difference: if the argument names a symbolic link, `lstat` returns information about the *link itself* (its own mode, owner, size, mtime), not the target the link points to. For anything that is not a symbolic link, `lstat` and `stat` are indistinguishable. On systems without symbolic links `lstat` silently degrades to `stat`.

Synopsis

```
lstat FILEHANDLE
lstat EXPR
lstat DIRHANDLE
lstat
```

What you get back

In list context, the same 13-element list as `stat`:

```
my ($dev,$ino,$mode,$nlink,$uid,$gid,$rdev,$size,
    $atime,$mtime,$ctime,$blksize,$blocks)
       = lstat($path);
```

Field meanings are identical to `stat` - device, inode, mode (type + permissions), link count, owner uid/gid, rdev, size, atime, mtime, ctime, preferred I/O block size, and allocated blocks. The type bits in `$mode` are what distinguish a symbolic link: on the link itself they report `S_IFLNK`, whereas `stat` on the same name would report the type of the *target*.

In scalar context `lstat` returns a true value on success and the empty string on failure. On failure the list form returns the empty list and `$!` is set to the reason (`ENOENT`, `EACCES`, etc.).

If `EXPR` is omitted, `lstat` operates on `$_`.

The _ filehandle

Every successful `lstat` (and every successful `stat` or filetest) populates the interpreter's internal "last stat buffer". Passing the bareword `_` as the argument reuses that buffer instead of making another system call:

```
if (-l $path && (my @s = lstat(_))) {
    # $path was a symlink; @s describes the link, not the target
}
```

Because `-l` itself does an `lstat` under the hood, the `lstat(_)` above costs nothing extra. This is the canonical way to "ask several questions about one file without re-stat'ing it". Note that a *filetest* on a bareword filename (`-l $path`) leaves the buffer describing the link; a filetest on a filehandle follows the open descriptor and thus leaves a `stat`-shaped buffer. When you want symlink data, reach for `lstat` explicitly.

Global state it touches

- `$_` - the argument when `EXPR` is omitted.
- `$!` - set on failure to the `errno` from the underlying `lstat(2)` call.
- The special `_` filehandle - overwritten on every successful call.

Examples

Distinguish a symlink from its target. `stat` on a symlink silently follows it; `lstat` does not:

```
symlink "/etc/passwd", "link.tmp";

my $via_stat  = (stat  "link.tmp")[7];  # size of /etc/passwd
my $via_lstat = (lstat "link.tmp")[7];  # size of the link inode
                                        # (length of "/etc/passwd")
```

Walk a directory and separate links from regular files without a second syscall per entry, using the `_` buffer:

```
use Fcntl ':mode';

for my $name (readdir $dh) {
    next if $name eq '.' || $name eq '..';
    lstat "$dir/$name" or next;
    if (S_ISLNK((lstat(_))[2])) {
        print "link: $name\n";
    } elsif (-f _) {
```

(continues on next page)

(continued from previous page)

```
        print "file: $name\n";
    } elsif (-d _) {
        print "dir:  $name\n";
    }
}
```

Detect a dangling symlink - `lstat` succeeds on the link, `stat` fails because the target is gone:

```
if (lstat $path and not stat $path) {
    warn "$path is a dangling symlink: $!\n";
}
```

Follow the link manually when you want both pieces of information:

```
my @link   = lstat $path       or die "lstat $path: $!";
my $target = readlink $path    // die "readlink $path: $!";
my @target = stat $path        or die "stat $path: $!";
```

No-argument form operating on `$_`, idiomatic in `File::Find` preprocess blocks and `grep` filters:

```
my @symlinks = grep { lstat; -l _ } @paths;
```

Edge cases

- **Not a symlink**: `lstat` behaves exactly like `stat` - there is no penalty to preferring `lstat` when you are about to branch on `-l`.
- **Systems without symlinks**: `lstat` silently falls back to `stat`. Code written against `lstat` stays portable; it just loses the distinguishing behaviour.
- **Filehandle / dirhandle argument**: a passed FILEHANDLE or DIRHANDLE refers to an already-opened descriptor, which cannot itself be a symlink (the kernel resolved the link at `open` time). `lstat FILEHANDLE` therefore returns the same result as `stat` on that handle. Use the EXPR form on the *path* when you need the link metadata.
- **`lstat(_)` after a failed `lstat`**: the `_` buffer is left in whatever state the last *successful* stat put it in. A failed `lstat` does not clear it. Always check the return value before reading `_`.
- **Relative paths**: resolved against the process's current working directory, same as `stat`.
- **Permission to `lstat`**: requires search (x) permission on every directory component of the path, but - unlike `stat` - does **not** require any permission on the link target. `lstat` therefore succeeds on links into directories you cannot read.
- **Bareword vs expression**: `lstat $fh` where `$fh` holds a filehandle stats the handle; `lstat "$fh"` stringifies `$fh` and stats the resulting (usually meaningless) pathname. Quote intentionally.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `stat` - the link-following counterpart; identical return shape and _ semantics
- `readlink` - read the *target* string of a symbolic link without stat'ing it
- `symlink` - create a symbolic link
- `-l` - filetest operator for "is a symbolic link"; internally performs an `lstat` and leaves the result in _
- `$_` - default argument when EXPR is omitted
- `$!` - reason for failure when `lstat` returns the empty list

Regular expressions and pattern matching

m//

Search a string for a pattern and report whether - and what - it matched.

`m//` is the match operator. It compiles PATTERN as a regular expression (see the *regex guide*), runs it against a target string, and returns a value shaped by calling context and by the modifiers you apply. The target is whatever sits on the left of `=~` or `!~`; without a binding operator the target is `$_`. The leading `m` is optional when the delimiter is `/`, so `/PATTERN/` and `m/PATTERN/` mean the same thing.

Synopsis

```
$str =~ m/PATTERN/flags
$str =~ /PATTERN/flags
m/PATTERN/flags              # target is $_
/PATTERN/flags               # target is $_
$str =~ m{PATTERN}flags      # any paired non-word delimiters
```

What you get back

Context decides the shape of the return value.

- **Scalar context, no `/g`**: 1 on match, the empty string on no match. Both are usable as booleans; the empty string is a dual-value false that also equals `0` numerically.
- **List context, no `/g`**: the list of capture values `($1, $2, $3, ...)` on a successful match; if the pattern has no capture groups, the singleton `(1)`; on failure, the empty list. This is how `if (my ($x, $y) = $s =~ /(\w+)=(\w+)/)` works.
- **Scalar context, `/g`**: each call advances through the string, returning true for the next match and false once there are no more. `pos` on the target tracks where the next attempt will begin.
- **List context, `/g`**: every match in one shot. With capture groups, the flat list of all captures from every match. Without captures, the list of every full match.

Successful matches also populate the regex special variables (`$1` through `$9`, `$&`, `$``, `$'`, `$+`, `%+`, `%-`) for the enclosing dynamic scope. A failed match leaves them holding their previous values - always test the match itself, never a capture variable, to decide whether a match happened.

Global state it touches

- `$_` - the default target when no `=~` binding is given.
- `$1`, `$2`, ... - numbered captures, set on success, unchanged on failure.
- `$&`, `$``, `$'` - match, prematch, postmatch.
- `$+` - the highest-numbered capture that actually matched (useful with alternations).
- `%+`, `%-` - named-capture hashes.
- `${^LAST_SUCCESSFUL_PATTERN}` - the last pattern that matched in the current dynamic scope; also the pattern the empty form `m//` reuses (see *Edge cases*).
- `pos` on the target string - read and updated by `/g` matching; reset on failure unless `/c` is also set.
- Locale / Unicode rule sources when `/l`, `/u`, or `/d` are in effect.

Delimiters

With `m`, any pair of non-whitespace characters works as the delimiter, and bracketing pairs nest:

```
m/pattern/
m{pattern}
m[pattern]
m(pattern)
m<pattern>
m!pattern!
m#pattern#
m,pattern,
```

Picking a delimiter that does not appear in the pattern avoids backslash-clutter - known as LTS, *leaning toothpick syndrome*. A path-matching pattern reads cleanly with `m{...}` or `m!...!` and badly with `m/.../`.

Two delimiter choices change semantics:

- **`'` (single quote)** - no variable interpolation inside `PATTERN`. `m'$foo'` matches the literal four characters.
- **`?`** - `m?PATTERN?` matches only once between calls to `reset`. The leading `m` is mandatory; since Perl 5.22 the bare `?...?` form is a syntax error.

When the delimiter is a word character (a letter or digit), a space is required after `m`: `m q foo q` is legal, `mqfooq` is not.

Modifiers

Pattern-compile modifiers (also accepted by `qr`, `s`, and `split`):

- **`m`** - multi-line: `^` and `$` match at every embedded newline, not only at string ends.
- **`s`** - single-line: `.` matches every character including newline.
- **`i`** - case-insensitive matching.
- **`x`** - ignore whitespace and #-comments in the pattern; `xx` extends this into character classes.
- **`p`** - preserve copies of the matched string. Since 5.20 this is a no-op - `${^PREMATCH}`, `${^MATCH}`, `${^POSTMATCH}` are always available after a successful match.
- **`a`**, **`u`**, **`l`**, **`d`** - character-set rules for `\d`, `\s`, `\w`, and the POSIX classes. `/a` restricts them to ASCII; `/aa` additionally forbids ASCII/non-ASCII matching under `/i`.
- **`n`** - non-capturing: `(…)` behaves like `(?:…)` and does not populate `$1`, `$2`, ….
- **`o`** - compile the pattern exactly once even if interpolated variables change. Almost always the wrong tool; use `qr` to build a reusable compiled pattern instead.

Match-process modifiers (specific to `m//` and `s///`):

- **`g`** - global matching. Scalar-context behavior is iterative (advances `pos` on each call); list-context behavior returns every match at once.
- **`c`** - only meaningful with `/g`. A failed `/g` match keeps `pos` where it was instead of resetting to the start; required for `lex`-style scanners built around `\G`.

Examples

Test whether a string contains a pattern:

```
if ($line =~ /error/i) {
    warn "matched: $line";
}
```

Bind a capture in one go:

```
if (my ($key, $val) = $line =~ /^(\w+)\s*=\s*(.*)$/) {
    $config{$key} = $val;
}
```

Pull every number out of a string with list-context `/g`:

```
my @nums = "x=1 y=22 z=333" =~ /(\d+)/g;
# @nums = (1, 22, 333)
```

Iterate matches one at a time with scalar-context `/g`, using `pos` to see where the engine is:

```
my $s = "foo 1 bar 22 baz 333";
while ($s =~ /(\d+)/g) {
```

(continues on next page)

(continued from previous page)

```
    printf "matched %s at offset %d\n", $1, pos($s) - length($1);
}
```

Extended form with the x modifier and named captures:

```
if ($ts =~ m{
        ^ (?<year>\d{4}) -
          (?<mon> \d{2}) -
          (?<day> \d{2}) $
    }x) {
    printf "year=%s mon=%s day=%s\n", $+{year}, $+{mon}, $+{day};
}
```

Avoid LTS by picking a delimiter that does not appear in the pattern:

```
next if $path =~ m{^/usr/local/};
```

Use `\G` with `m//gc` to walk a string token-by-token without losing position on a failed arm:

```
while (1) {
    if    ($s =~ /\G(\d+)/gc)    { push @tok, ['num',  $1] }
    elsif ($s =~ /\G(\w+)/gc)    { push @tok, ['word', $1] }
    elsif ($s =~ /\G(\s+)/gc)    { next                    }
    else                         { last                    }
}
```

Edge cases

- **Empty pattern**: `//` and `m//` reuse the last successfully matched pattern in the current dynamic scope. If nothing has matched yet, an empty pattern matches everywhere. Passing user input straight into `m/$pat/` when `$pat` might be empty is a sharp edge - wrap it in a non-capturing group: `m/(?:$pat)/`. The last successful pattern is also readable as `${^LAST_SUCCESSFUL_PATTERN}`.
- **Defined-or ambiguity**: Perl resolves `$x // $y` as the defined-or operator, never as two empty matches. In pathological positions (`print $fh //`) Perl still assumes defined-or; force a match by writing `m//` explicitly or spacing out the delimiters.
- **Failed match leaves captures stale**: `$1` after a failing `/…/` still holds the capture from the *previous* successful match - always gate capture use on the match result.
- **`/o` with changing variables**: `m/$x/o` locks the first value of `$x` into the compiled pattern. Later changes to `$x` are silently ignored. Reach for `qr` instead when you want an explicit, reusable compilation.
- **Interpolation when the delimiter is `'`**: `m'$var'` is a literal-dollar-var match. This is rarely what you want, and the same effect is available with `\Q…\E` or `quotemeta` in any other delimiter.
- **`/g` plus target modification**: modifying the target between `/g` iterations resets `pos` to the start. Iterate over a copy if you need to mutate the original as you go.

- **`\G` outside `/g`**: without `/g`, `\G` anchors at the `pos` the target had at call time and matches at most once. On a string that has never had a `/g` applied, `\G` is equivalent to `\A`.
- **`m?…?` reset scope**: `reset` clears `m??` state only for the current package. A `m??` in one package is not affected by `reset` called from another.
- **Comparison operators near an empty regex**: `$x //= 1` is always the defined-or assignment; if you genuinely want the empty regex, write `m//` rather than `//`.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `qr` - compile a pattern once and reuse it; avoids `/o` and keeps the pattern a first-class value
- `s` - same pattern syntax, replaces what it matches
- `tr` - character-by-character translation; a different tool with a superficially similar shape
- `split` - when you want the pieces between matches rather than the matches themselves
- `pos` - read or set the position `/g` matching resumes from
- *Regular expressions guide* - the regex language itself: assertions, character classes, backreferences, named captures

Lists

map

Apply a block or expression to each element of a list and return the flattened results.

`map` evaluates `BLOCK` (or `EXPR`) once per element of `LIST`, with `$_` aliased to that element, and collects everything each evaluation returns into a single flat list. Because each evaluation may yield zero, one, or many values, the output length is independent of the input length - that flattening is the point of `map`. In list context `map` returns the generated list; in scalar context it returns the total element count.

Synopsis

```
my @out = map { BLOCK } LIST;        # block form
my @out = map EXPR, LIST;            # expression form
my @out = map { f($_) } grep { ... } sort LIST;   # chained
```

What you get back

A single flat list built by concatenating the return values of each evaluation, in input order:

- Return one value per input → transform (same length out).
- Return a list per input → 1-to-N expansion (longer out).
- Return the empty list `()` → skip this input (shorter out; `map`-as-filter idiom).

In scalar context the return value is the count of generated elements, not a reference and not a boolean. Assigning the result to a hash is well-defined: the flat list is consumed as alternating key/value pairs.

```
my @doubled = map { $_ * 2 }          1 .. 4;     # (2, 4, 6, 8)
my @words   = map { split /\s+/, $_ } @lines;     # 1-to-N
my @kept    = map { $_ > 0 ? $_ : () } @nums;     # filter
my $count   = map { $_ * $_ } @nums;              # scalar ctx
```

Global state

`$_` is **aliased** to each element of `LIST`, not copied. Modifying `$_` inside the block modifies the source element. This is occasionally useful but usually a footgun - reach for a plain `foreach` loop when you mean to mutate in place.

```
my @v = (1, 2, 3);
my @r = map { $_ *= 10; $_ } @v;
# @v is now (10, 20, 30) - the source was mutated
```

Aliasing to a non-variable (a literal, a function return value, a hash-slice element that doesn't exist yet) and then assigning to `$_` fails at runtime with `Modification of a read-only value`. See `$_`.

`map` also localises `$_` around the call, so an outer `$_` visible to the caller is restored when `map` returns.

Examples

Transform - uppercase every word:

```
my @upper = map { uc } @words;
```

1-to-N expansion - split each line on whitespace into its tokens:

```
my @tokens = map { split /\s+/ } @lines;
```

Filter idiom - keep only truthy, transformed values:

```
my @positives = map { $_ > 0 ? $_ : () } @numbers;
```

Build a hash from a list - each evaluation returns a two-element list:

```
my %seen = map { $_ => 1 } @keys;
my %idx  = map { ($keys[$_] => $_) } 0 .. $#keys;
```

Composed pipeline - sort, filter, transform. `map`, `grep`, and `sort` all take a `LIST` on the right, so they chain right-to-left:

```
my @top = map  { "$_->{name}: $_->{score}" }
          sort { $b->{score} <=> $a->{score} }
          grep { $_->{score} >= 50 }
          @records;
```

Flatten structure - each input contributes a variable number of outputs:

```
my @leaves = map { ref($_) eq 'ARRAY' ? @$_ : $_ } @mixed;
```

Pair with index using `List::Util::pairs` or an explicit index variable - `map` itself does not expose one:

```
my @numbered = do {
    my $i = 0;
    map { sprintf "%d. %s", ++$i, $_ } @items;
};
```

Edge cases

- **`$_` is aliased, not copied.** Assigning to `$_` writes back to the source. If the source element is read-only (a constant, the return value of a function call flattened into `LIST`) the assignment raises `Modification of a read-only value`. Treat `$_` as input-only unless you specifically want the side effect.
- **`map` is not a loop.** `last`, `next`, `redo`, and loop labels do not apply to `map`. They refer to the enclosing real loop and will behave accordingly - usually not what the author intended. Use `foreach` when you need loop-control flow.
- **Void context is deprecated.** `map { ... } LIST;` with the result discarded emits a `Useless use of map in void context` warning under `use warnings`. When you want the side effects, not the list, write a `foreach`.
- **`BLOCK` vs `EXPR` parser ambiguity.** `{` starts both a block and a hash-reference constructor. `map { ... } LIST` and `map { ... }, LIST` look identical to the parser at the opening brace; Perl guesses based on what it finds next. A block starting with what looks like a hash key plus `=>` is especially likely to be guessed wrong:

  ```
  my %h = map {  "\L$_" => 1  } @a;   # guessed EXPR, wrong
  my %h = map { +"\L$_" => 1  } @a;   # unary + forces BLOCK
  my %h = map {; "\L$_" => 1  } @a;   # leading ; forces BLOCK
  my %h = map { ($_, 1) }       @a;   # parens - unambiguous
  my %h = map { lc($_) => 1 }   @a;   # function call -
   ↪unambiguous
  ```

  To return an anonymous hash per element, force the hash-ref constructor with `+{`:

```
my @hashes = map +{ lc($_) => 1 }, @array;
```

- **Order is stable**. `map` evaluates left-to-right and concatenates results left-to-right. The generated list preserves input order, with each input's contribution appearing contiguously.
- **Empty `LIST`**. `map` evaluates the block zero times and returns the empty list. The block is not evaluated for its side effects.
- **Nested `map`**. Inner `map` sees its own `$_`; the outer `$_` is shadowed for the duration of the inner evaluation. Capture the outer value first if both are needed:

```
my @pairs = map {
    my $outer = $_;
    map { [$outer, $_] } @inner
} @outer;
```

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `grep` - same shape as `map`, but keeps elements for which the block is true rather than transforming them; chains naturally with `map` and `sort`
- `sort` - orders a list; commonly composed with `map` via the Schwartzian transform (`map` → `sort` → `map`)
- `for` / `foreach` - use when you want iteration for side effects, mutation of the source, or loop-control (`last`/`next`/`redo`)
- `x` - list repetition operator; orthogonal to `map` but often used to build the `LIST` that `map` consumes
- `List::Util::reduce` - fold a list to a single value; use when the result is not a list but an aggregate (sum, max, first match)
- `$_` - the element alias inside the block; read-only when the source element is a literal or function return value

Control flow · Classes and OO

method

Declare a named instance method inside a `class` block.

`method` defines a subroutine that expects to be invoked on an object of the enclosing class. It behaves like `sub`, with two additional guarantees that `sub` does not give you: the lexical `$self` is bound to the invocant automatically, and signatures are always on - you write parameters as if `use feature 'signatures'` were in effect, and `$self` does not appear in that signature.

`method` is only valid inside a `class` declaration. Outside a class block it is a compile-time error.

Experimental feature

The `class`, `method`, and `field` keywords are part of the experimental `class` feature (introduced in Perl 5.38). Enabling it with `use feature 'class';` emits a warning in the `experimental::class` category. The syntax and semantics may still change between Perl releases.

Synopsis

```
method NAME BLOCK
method NAME SIGNATURE BLOCK
method NAME : ATTRS BLOCK
method SIGNATURE BLOCK        # anonymous
method BLOCK                  # anonymous
```

What you get back

`method` is a declaration, not an expression, in its named form - it installs the method in the enclosing class's method table and evaluates to nothing useful at the statement position. The anonymous form returns a code reference that remembers the class context and can be called later with an object invocant.

The body of a `method` is called with the object as the invocant. The return value of the method is whatever the block returns, following the same context rules as a regular subroutine call.

What `method` gives you that `sub` does not

Four things differ from writing `sub` inside a `class` block:

- **`$self` is pre-declared.** A lexical `$self` is created in the method's scope and initialised to the invocant. You do not - and should not - shift it off `@_`.
- **Signatures are always enabled.** You can write `method greet($name) { ... }` without `use feature 'signatures'`. The `$self` invocant is consumed before the signature binds, so it never appears in the parameter list.
- **Fields are in scope.** Any `field` variables declared in the enclosing class are visible by their lexical names inside the method body. A plain `sub` inside a `class` block does not see fields.
- **It is registered as a method.** The method table of the class records the name, which is what the method-resolution machinery looks up for `$obj->name(...)` dispatch. A plain `sub` inside the class block is a helper, not a method.

Put the other way: a `sub` inside a `class` block is an ordinary package subroutine that happens to live in that package's namespace. It has no `$self`, no field visibility, and is not part of the class's method interface - call it via `ClassName::helper(...)` if you must, not via an arrow.

Examples

A minimal class with a method and a field:

```
use v5.38;
use feature 'class';
no warnings 'experimental::class';

class Greeter {
    field $greeting = "Hello";

    method greet($name) {
        return "$greeting, $name";
    }
}

my $g = Greeter->new;
say $g->greet("world");           # Hello, world
```

Signature defaults work exactly as they do for `sub`:

```
class Greeter {
    field $greeting = "Hello";

    method greet($name = "someone") {
        return "$greeting, $name";
    }
}

say Greeter->new->greet;          # Hello, someone
```

A method with no parameters still uses the signature form - the empty `()` is not required, but it is allowed and is the common style when the method takes arguments elsewhere in the class:

```
class Counter {
    field $n = 0;

    method inc        { $n++ }
    method value ()   { return $n }
}
```

An anonymous method - useful as a factory or as a callback that needs access to `$self` and fields:

```
class AnonMethodFactory {
    method make_printer {
        return method { say "called on $self" };
    }
}
```

A lexical (private) method declared with `my method`. Invoke it via the `->&` operator, which bypasses method lookup and calls the lexical directly as if it were a method:

```
class LexicalMethod {
    my method _check ($x, $y) {
        return $x > 0 && $y > 0;
    }

    method process ($x, $y) {
        return unless $self->&_check($x, $y);
        # ...
    }
}
```

Regular `sub` inside a class, contrasted with `method` - the `sub` is a helper, the `method` is the public interface:

```
class Temperature {
    field $celsius;

    sub _c_to_f ($c) { $c * 9 / 5 + 32 }   # helper, no $self, no
↪fields

    method fahrenheit {
        return _c_to_f($celsius);
    }
}
```

Edge cases

- **Outside a `class` block is a compile-time error.** `method foo { ... }` at the top level, or inside a `package` that is not a `class`, does not parse. Use `sub` there.
- **`$self` is read-only in the sense that you cannot declare another lexical with the same name** at the top of the method - it is already in scope. Assigning to `$self` (e.g. `$self = ...`) is permitted but rarely useful and does not change the caller's invocant.
- **`@_` is not the argument list you expect.** Under the signatures that `method` enables, `@_` inside the body is empty after the signature binds, just as in any signature-using sub. Read parameters from the signature, not `@_`.
- **Method-resolution order is set by the enclosing class.** `method` itself does not take an MRO option; inheritance and dispatch follow whatever the `class` declaration configured via `:isa` and related attributes.
- **`method` does not participate in prototypes.** Methods are invoked through dispatch, not direct symbol-table calls, so prototypes (the `:prototype(...)` attribute on a `sub`) have no effect here. Use the signature to constrain the call shape.
- **Attributes.** The `method NAME : ATTRS BLOCK` form accepts attributes the same way `sub NAME : ATTRS BLOCK` does. The set of useful attributes on methods is still settling with the `class` feature; consult upstream before relying on custom ones.
- **Anonymous-method return-from-method trap.** `return method { ... }` re-

turns a code reference. `method { ... }` as the last expression of a method without `return` is still a code reference, but readers often misread it as a block - prefer explicit `return` for clarity.

Differences from upstream

Fully compatible with upstream Perl 5.44.

The `class` feature - and therefore `method` - is marked experimental in upstream; pperl inherits that status and the `experimental::class` warning category.

See also

- `class` - declares the package that `method` lives in; `method` only parses inside a `class` block
- `field` - per-instance variables that are visible by name inside every `method` of the enclosing class
- `sub` - declare a regular subroutine; use this for helpers inside a class that do not need `$self` or field access
- `__CLASS__` - the name of the current class, useful inside methods that need to dispatch back to class-level code
- `return` - explicit return from a method body; recommended when the last expression is itself a `method { ... }` anonymous form
- `my` - prefix a `method` with `my` to declare a lexical (private) method invoked via `->&`

Filehandles, files, directories

mkdir

Create a single directory on the filesystem.

`mkdir` asks the operating system to create the directory named by `FILENAME`, with permission bits given by `MODE` (further restricted by the process `umask`). It creates exactly **one** directory - every parent component in `FILENAME` must already exist. For recursive creation, reach for `File::Path::make_path` instead.

Synopsis

```
mkdir FILENAME, MODE
mkdir FILENAME
mkdir
```

What you get back

1 on success, `0` on failure with `$!` set to the system errno. Unlike most I/O primitives, the failure value is a plain false `0`, not `undef` - check the return value, then consult `$!` for the reason:

```
mkdir $path, 0755
    or die "mkdir $path failed: $!";
```

Default arguments

Both arguments default:

- `MODE` defaults to `0777`. The kernel masks the supplied mode with the current process `umask`, so the directory's effective mode is `MODE & ~umask`. A typical `umask` of `022` turns the default `0777` into `0755` on disk.
- `FILENAME` defaults to `$_`. Bare `mkdir;` inside a loop over pathnames creates each in turn:

```
mkdir for qw(logs cache tmp);
```

Pass `MODE` explicitly whenever the directory should be private (mail spools, key stores, session directories). Otherwise prefer a permissive `MODE` and let the user's `umask` narrow it - the `umask` page discusses the trade-off in detail. Setting bits outside the permission range (e.g. setuid/setgid/sticky) yields implementation-defined behaviour per POSIX 1003.1-2008.

Global state it touches

- Sets `$!` (errno) on failure; leaves it untouched on success.
- Reads `FILENAME` from `$_` when called with no arguments.
- The effective permission bits depend on the process `umask`.

Examples

Create a directory with an explicit mode:

```
mkdir "build", 0755
    or die "mkdir build: $!";
```

Create it only if missing, without treating "already there" as an error:

```
use Errno qw(EEXIST);
unless (mkdir "cache", 0700) {
    die "mkdir cache: $!" unless $! == EEXIST;
}
```

Private directory - do not let `umask` widen it:

```
mkdir "$ENV{HOME}/.secrets", 0700
    or die "mkdir secrets: $!";
```

Bare form over a list, using `$_` as the filename:

```
for (qw(a b c)) {
    mkdir or warn "mkdir $_: $!";
}
```

Recursive creation is **not** `mkdir`'s job - use `File::Path`:

```
use File::Path qw(make_path);
make_path("var/log/app/2026", { mode => 0755 })
    or die "make_path failed: $!";
```

Edge cases

- **Parent must exist**. `mkdir "a/b/c"` fails with `ENOENT` if `a/b` is missing. Use `File::Path::make_path` for deep paths.
- **Target already exists**. Fails with `EEXIST`, regardless of whether the existing entry is a directory, file, or symlink. Check `$!` against `Errno::EEXIST` when "already there" is acceptable.
- **Trailing slashes**. POSIX 1003.1-1996 allows any number of trailing slashes; Perl strips them before the syscall so that filesystems which reject `"foo/"` still behave consistently.
- **Permission mismatch**. `MODE` is masked by `umask`. If you need an exact mode on disk, either save and restore the umask, or `chmod` the directory after creation:

  ```
  mkdir $dir, 0700 or die $!;
  chmod 0700, $dir;                    # defeat any umask surprises
  ```

- **`MODE` omitted entirely**. `mkdir $path` is `mkdir $path, 0777` - still masked by `umask`, so the on-disk mode is typically `0755`, not `0777`.
- **Non-permission bits in `MODE`**. Setuid / setgid / sticky bits on a `mkdir` call have implementation-defined results. Set them with a follow-up `chmod` if you need them.
- **Read-only filesystem or missing write permission on the parent** fails with `EROFS` or `EACCES` respectively. `$!` discriminates.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `rmdir` - remove an empty directory; the inverse operation
- `chmod` - adjust permission bits after creation when `umask` would otherwise narrow them
- `umask` - the mask that silently restricts every `mkdir MODE`
- `stat` - inspect an existing path's type and mode, e.g. to distinguish "already a directory" from "exists as a file"

- `File::Path::make_path` - recursive directory creation; the right tool when intermediate parents may not exist

SysV IPC

msgctl

Perform a control operation on a System V IPC message queue.

`msgctl` is a direct wrapper around the C `msgctl(2)` system call. It inspects, modifies, or removes the message queue identified by `ID`. The operation selected by `CMD` determines how `ARG` is used - either as an input descriptor, an output buffer, or ignored entirely. The symbolic constants needed for `CMD` (`IPC_STAT`, `IPC_SET`, `IPC_RMID`, and on Linux `IPC_INFO`, `MSG_STAT`, `MSG_INFO`) live in `IPC::SysV`, which you have to pull in before the names resolve.

Synopsis

```
use IPC::SysV;

msgctl $id, IPC_STAT, $buf       # read queue info into $buf
msgctl $id, IPC_SET,  $buf       # write queue info from $buf
msgctl $id, IPC_RMID, 0          # destroy the queue
```

What you get back

Return value follows the same convention as `ioctl`:

- `undef` on error, with `$!` set.
- The string `"0 but true"` when the underlying call returned `0`. This is the zero-valued success case - it tests true in boolean context and compares equal to `0` in numeric context, so one check handles both success and failure.
- The raw non-zero integer return otherwise (for example the index returned by Linux-specific `MSG_STAT`).

The `"0 but true"` convention exists precisely so that `msgctl(...) or die` does the right thing even when the syscall legitimately returns zero:

```
msgctl $id, IPC_RMID, 0
    or die "msgctl IPC_RMID failed: $!";
```

How ARG is used

`ARG` plays three different roles depending on `CMD`. The kernel only touches the memory in the directions the command requires:

- **`IPC_STAT`** - `ARG` must be a **writable scalar**. The kernel fills it with the packed `msqid_ds` structure describing the queue (permissions, owner, last-send/last-receive times, queue byte limits, counts). Unpack with `IPC::SysV` helpers rather than hand-rolling the layout; `msqid_ds` varies across kernels and libc versions.

- **IPC_SET** - ARG must contain a packed `msqid_ds` **produced by a prior IPC_STAT** on the same (or compatible) queue. Only a few fields are honoured: `msg_perm.uid`, `msg_perm.gid`, `msg_perm.mode` (low 9 bits), and `msg_qbytes`. The rest is ignored.
- **IPC_RMID** - ARG is unused. Pass `0`. The queue is marked for destruction; any blocked `msgsnd` / `msgrcv` on it fails with `EIDRM`.

On Linux only, `MSG_STAT` and `MSG_INFO` also accept a writable scalar for ARG and return extra data; these are non-portable and should be gated behind a runtime check.

Global state it touches

- `$!` - set on failure with the system errno (`EPERM`, `EACCES`, `EINVAL`, `EIDRM`, `EFAULT` are the common values).
- No other special variables are touched.

Examples

Read the queue header and inspect the current byte limit:

```
use IPC::SysV qw(IPC_STAT);

my $buf = "";
msgctl($id, IPC_STAT, $buf)
    or die "msgctl IPC_STAT failed: $!";

# Layout is platform-dependent; use IPC::SysV helpers to decode.
```

Shrink the queue's byte budget. Round-trip through `IPC_STAT` so the immutable fields keep their current kernel values:

```
use IPC::SysV qw(IPC_STAT IPC_SET);

my $buf = "";
msgctl($id, IPC_STAT, $buf) or die "stat: $!";
# ... modify msg_qbytes inside $buf via IPC::SysV ...
msgctl($id, IPC_SET,  $buf) or die "set: $!";
```

Destroy a queue when done. ARG is ignored, but it still has to be passed - `0` is the conventional placeholder:

```
use IPC::SysV qw(IPC_RMID);

msgctl($qid, IPC_RMID, 0)
    or warn "could not remove queue $qid: $!";
```

Idiomatic success test that works for the `"0 but true"` case:

```
my $rc = msgctl($id, IPC_RMID, 0);
die "msgctl failed: $!" unless defined $rc;   # undef = error
# $rc is now either "0 but true" or a positive integer
```

Edge cases

- **`IPC::SysV` not loaded**: bare constant names like `IPC_STAT` become barewords and, under `use strict`, a compile-time error. Always `use IPC::SysV` first.
- **Scalar passed to `IPC_STAT` is not writable**: croaks with `Modification of a read-only value attempted`. Use a plain `my $buf = ""` - not a constant, not a string literal.
- **Length mismatch on `IPC_SET`**: if `ARG` is shorter than the kernel's `msqid_ds`, the call fails with `EFAULT`. Always start from an `IPC_STAT` buffer rather than packing one from scratch.
- **Removed queue (`EIDRM`)**: once `IPC_RMID` has been issued, any further operation on the same ID fails with `$!` set to `EIDRM`, not `EINVAL`. Scripts that poll a queue must treat `EIDRM` as "queue is gone, stop."
- **Permission errors**: `IPC_SET` and `IPC_RMID` require effective UID match or `CAP_SYS_ADMIN`. Kernel returns `EPERM`, not `EACCES`, for ownership failures.
- **Return-value trap**: `if (msgctl(...) == 0)` is **wrong** - on success the value is the string `"0 but true"`, which stringifies as non-empty but compares numerically equal to `0`. Test with `defined` for the error case, or rely on `or die`.
- **Platform availability**: System V IPC is not universal. On systems where the kernel omits it, `msgctl` raises the runtime exception `msgctl not implemented`.

Differences from upstream

Fully compatible with upstream Perl 5.44 on Linux. System V IPC is the only supported IPC surface; pperl targets Linux, so the portability caveats that upstream `perlport` lists for non-Linux platforms do not apply.

SysV IPC

msgget

Create or look up a System V IPC message queue and return its id.

`msgget` is the entry point to the System V message-queue family: every later `msgsnd`, `msgrcv`, or `msgctl` call needs an id, and this is where that id comes from. `KEY` names the

queue across the whole system (a `key_t` integer, typically built with `IPC::SysV::ftok` or the special value `IPC_PRIVATE`). `FLAGS` is the bitwise-or of permission bits (low nine, same layout as file modes) and optional `IPC_CREAT` / `IPC_EXCL` flags. The call is a direct wrapper around the `msgget(2)` syscall.

Synopsis

```
use IPC::SysV qw(IPC_CREAT IPC_EXCL IPC_PRIVATE S_IRUSR S_IWUSR);

my $id = msgget($key, IPC_CREAT | 0600);
my $id = msgget(IPC_PRIVATE, 0600);
my $id = msgget($key, IPC_CREAT | IPC_EXCL | 0600);
```

What you get back

A non-negative integer message-queue id on success, or `undef` on failure (with `$!` set to the `errno` value from the underlying syscall). The id is an opaque handle - do not do arithmetic on it, just pass it back to the other `msg*` built-ins.

```
my $id = msgget($key, IPC_CREAT | 0600)
    // die "msgget($key) failed: $!";
```

Global state it touches

- `$!` - set on failure to the `errno` from `msgget(2)` (commonly `EACCES`, `EEXIST`, `ENOENT`, `ENOSPC`, `ENOMEM`).

No other special variables are involved. The queue itself lives in the kernel, not in the Perl process, and persists across `exec` and after the creating process exits - it must be removed explicitly with `msgctl` and `IPC_RMID`.

Examples

Create a private queue that no other process can name - the usual choice when the queue is shared only with children of this process:

```
use IPC::SysV qw(IPC_PRIVATE);
my $id = msgget(IPC_PRIVATE, 0600) // die "msgget: $!";
```

Create or attach to a named queue using a `key_t` derived from a file path. `ftok` turns a path plus a single-character project id into a stable key so unrelated processes can agree on a queue:

```
use IPC::SysV qw(ftok IPC_CREAT);
my $key = ftok("/var/run/myapp", 'M');
my $id  = msgget($key, IPC_CREAT | 0600) // die "msgget: $!";
```

Create exclusively - fail if the queue already exists. This is how you detect that a previous instance of your program is still around:

```
use IPC::SysV qw(IPC_CREAT IPC_EXCL);
my $id = msgget($key, IPC_CREAT | IPC_EXCL | 0600);
if (!defined $id) {
    die "queue already exists" if $!{EEXIST};
    die "msgget: $!";
}
```

Attach to an existing queue without creating one - omit `IPC_CREAT`. Returns `undef` with `$!` set to `ENOENT` if no such queue exists:

```
my $id = msgget($key, 0) // die "no queue for key $key: $!";
```

Remove the queue when done. `msgget` itself has no teardown counterpart; removal goes through `msgctl`:

```
use IPC::SysV qw(IPC_RMID);
msgctl($id, IPC_RMID, 0) or warn "msgctl IPC_RMID: $!";
```

Edge cases

- **`KEY` must be an integer**, typically a `key_t`. Passing a string triggers the usual numeric-conversion rules and will almost certainly name the wrong queue. Build keys with `IPC::SysV::ftok` or use `IPC_PRIVATE`.
- **`IPC_PRIVATE` always creates a new queue**, regardless of whether `IPC_CREAT` is set. The key is not reusable - you cannot `msgget` the same queue later from an unrelated process using `IPC_PRIVATE`.
- **Permission bits apply at every call, not just creation**. Attaching to an existing queue without `IPC_CREAT` still checks the permission bits against the queue's owner/group and the current process's effective uid/gid. Mismatched bits give `EACCES`.
- **`IPC_EXCL` without `IPC_CREAT` is meaningless** - the kernel ignores it. If you want exclusive creation, always pair them.
- **System-wide limits**. Creation can fail with `ENOSPC` when the kernel's `MSGMNI` limit is hit, or `ENOMEM` under memory pressure. These are not bugs in your program; they are operational conditions.
- **Queue lifetime outlives processes**. A queue created here persists until explicitly removed with `msgctl` and `IPC_RMID`, or until the system reboots. Forgotten queues leak kernel resources that `ipcs` and `ipcrm` are used to find and clean up.
- **Not all systems have SysV message queues.** On platforms that omit them, the built-in croaks with `msgget not implemented on this architecture`. The portability warning in upstream POD applies.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `msgsnd` - send a message to the queue returned by `msgget`
- `msgrcv` - receive a message from that queue
- `msgctl` - query, set options on, or remove the queue; teardown after `msgget` goes through here
- `semget` - same API shape for System V semaphores when you need synchronization rather than data transfer
- `shmget` - same API shape for System V shared memory when you need direct memory sharing rather than message passing
- `IPC::SysV` - provides `ftok` and the `IPC_*` / `S_*` constants `msgget` expects in `FLAGS`

SysV IPC

msgrcv

Receive a message from a System V IPC message queue.

`msgrcv` is the Perl binding for the `msgrcv(2)` syscall. It pulls one message off the queue identified by `ID`, stores the message type and payload into `VAR`, and returns a truthy value on success or false on error. `SIZE` is the maximum number of payload bytes the caller is willing to accept; `TYPE` selects which message to receive; `FLAGS` is the bitmask passed to the kernel (`IPC_NOWAIT`, `MSG_NOERROR`, etc.).

The returned buffer is **not** just the message body - the first `sizeof(long)` bytes are the message type the sender passed to `msgsnd`, followed by the payload. Use `unpack` with the `l! a*` template to split them apart.

Synopsis

```
use IPC::SysV qw(IPC_NOWAIT MSG_NOERROR);

msgrcv $qid, my $buf, 1024, 0, 0            or die "msgrcv: $!";
msgrcv $qid, my $buf, 1024, 0, IPC_NOWAIT;  # non-blocking
my ($type, $payload) = unpack "l! a*", $buf;
```

What you get back

True on success, false on error with `$!` set. On success, `VAR` is overwritten with the received frame: a native `long` (the message type) immediately followed by up to `SIZE` bytes of payload. The variable is marked tainted under `-T`.

`VAR` is grown or shrunk to fit the actual frame length - you do not need to pre-size it. The content before the call is discarded.

To get the type and payload as separate values:

```
my ($type, $msg) = unpack "l! a*", $buf;
```

Arguments

- `ID` - the queue id previously returned by `msgget`.
- `VAR` - a lvalue scalar that receives the raw frame. Its previous value is discarded on success.
- `SIZE` - the maximum payload size in bytes. If the next matching message is larger than this, `msgrcv` fails with `E2BIG` and the message stays on the queue - **unless** `MSG_NOERROR` is set in `FLAGS`, in which case the message is truncated silently and the extra bytes are lost.
- `TYPE` - selects which message to receive:
  - `0` - the first message on the queue, whatever its type.
  - positive `N` - the first message whose type is exactly `N`.
  - negative `-N` - the first message of the lowest type that is `<= abs(N)`, useful for priority queues.
- `FLAGS` - bitmask of `IPC_NOWAIT` (return `ENOMSG` immediately instead of blocking when no matching message is available), `MSG_NOERROR` (truncate instead of failing on oversized messages), and the Linux-specific `MSG_EXCEPT` (with a positive `TYPE`, receive the first message whose type is *not* `TYPE`).

The constants live in `IPC::SysV`; the bare names do not become visible until you import them.

Global state it touches

- `$!` - set on error to the underlying `errno` (`ENOMSG`, `E2BIG`, `EIDRM`, `EINVAL`, `EACCES`, `EFAULT`, `EINTR`).
- Taint mode - the received `VAR` is marked tainted, since its contents came from another process.

Examples

Blocking receive of any message, then split type and payload:

```
use IPC::SysV qw(IPC_CREAT S_IRUSR S_IWUSR);

my $qid = msgget(IPC_PRIVATE, S_IRUSR | S_IWUSR) // die "msgget: $!
 ↪";
msgrcv $qid, my $buf, 4096, 0, 0            or die "msgrcv: $!";
my ($type, $payload) = unpack "l! a*", $buf;
print "got type=$type payload=$payload\n";
```

Receive only messages of type 42:

```
msgrcv $qid, my $buf, 4096, 42, 0           or die "msgrcv: $!";
```

Non-blocking poll - return immediately if the queue is empty:

```
use IPC::SysV qw(IPC_NOWAIT);
use Errno qw(ENOMSG);

if (msgrcv $qid, my $buf, 4096, 0, IPC_NOWAIT) {
    my ($type, $msg) = unpack "l! a*", $buf;
    handle($type, $msg);
} elsif ($! == ENOMSG) {
    # queue was empty; try again later
} else {
    die "msgrcv: $!";
}
```

Truncate oversized messages rather than failing:

```
use IPC::SysV qw(MSG_NOERROR);

msgrcv $qid, my $buf, 64, 0, MSG_NOERROR    or die "msgrcv: $!";
# payload is at most 64 bytes, excess discarded without error
```

Priority-style receive - take the lowest-numbered message whose type is <= 3:

```
msgrcv $qid, my $buf, 4096, -3, 0           or die "msgrcv: $!";
```

Edge cases

- **VAR must be an lvalue**. Passing a constant or a read-only scalar (for instance an element of `@_` that was passed by reference to a literal) raises `Modification of a read-only value attempted`.
- **Frame layout is native `long`, not four bytes**. On 64-bit Linux the type occupies 8 bytes; on 32-bit systems it occupies 4. The `l!` in `unpack "l! a*"` - the `!` - is mandatory; a plain `l` assumes 4 bytes and will corrupt payloads on 64-bit hosts.
- **`SIZE` excludes the type header for `MSG_NOERROR` purposes**. The kernel compares `SIZE` against the payload length, not the frame length. Size the buffer for the largest payload you expect; the type header is written beyond it.
- **Signal interruption**. A blocking `msgrcv` returns false with `$! == EINTR` when a signal arrives before a message is available. Retry the call unless the signal is meant to abort the receive loop.
- **Queue removed while blocked**. If another process calls `msgctl` with `IPC_RMID` while this process is asleep in `msgrcv`, the call returns false with `$! == EIDRM`.
- **Permissions**. Receiving requires read permission on the queue. `EACCES` means the queue exists but the current uid/gid doesn't match the queue's mode bits.
- **`TYPE = 0` sees FIFO order**. There is no "any" priority short of explicit negative `TYPE` - messages of all types are pulled in send order.
- **Kernel support**. Linux kernels built without `CONFIG_SYSVIPC`, and container runtimes that don't expose the IPC namespace, fail every `msgrcv` with `ENOSYS`. Check during startup if your deployment target is uncertain.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `msgsnd` - the counterpart that puts messages on the queue; its `pack "l! a*"` template is the inverse of what you `unpack` here
- `msgget` - obtain the queue id `ID` you pass in
- `msgctl` - inspect or delete the queue, including the `IPC_RMID` that causes a blocked `msgrcv` to return `EIDRM`
- `unpack` - split the returned frame into type and payload with `l! a*`
- `IPC::SysV` - source of the `IPC_NOWAIT`, `MSG_NOERROR`, and related flag constants
- `IPC::Msg` - object-oriented wrapper that hides the pack/unpack dance behind a `rcv` method

SysV IPC

msgsnd

Send a message to a System V IPC message queue.

`msgsnd` is a thin wrapper around the `msgsnd(2)` syscall. It appends `MSG` to the queue identified by `ID` (the queue id previously returned by `msgget`), and returns true on success or false on error with `$!` set. `MSG` is **not** free-form: it must start with a native `long` message type, followed by the payload bytes. `FLAGS` control blocking and error-on-overflow behaviour, typically `0` or `IPC_NOWAIT`.

Synopsis

```
msgsnd ID, MSG, FLAGS
```

What you get back

True on success, false on failure. On failure `$!` is set to the `errno` from `msgsnd(2)` - common values are `EAGAIN` (queue full, `IPC_NOWAIT` was set), `EIDRM` (queue was removed), `EINTR` (signal interrupted a blocking call), and `EACCES` (no write permission on the queue).

Because the return value is a plain boolean, always check it before assuming the message was enqueued:

```
msgsnd($qid, $msg, 0)
    or die "msgsnd($qid) failed: $!";
```

Message format

The kernel reserves the first `sizeof(long)` bytes of every queued message for the **message type**, a positive `long` integer that `msgrcv` callers use to select which messages to dequeue. The payload follows, uninterpreted.

Build the buffer with `pack` using the `l!` (native `long`) and `a*` (raw bytes) specifiers:

```
my $type    = 1;
my $payload = "hello queue";
my $msg     = pack("l! a*", $type, $payload);
msgsnd($qid, $msg, 0) or die "msgsnd: $!";
```

The message type **must be greater than zero**. Zero and negative values are reserved for the selector semantics of `msgrcv` and cause `msgsnd(2)` to fail with `EINVAL`.

Global state it touches

- `$!` - set to the `errno` from the failed syscall when `msgsnd` returns false. Untouched on success.

Examples

Send a simple typed message with the default blocking behaviour. If the queue is full, the call waits until space is available:

```
use IPC::SysV qw(IPC_PRIVATE IPC_CREAT S_IRUSR S_IWUSR);

my $qid = msgget(IPC_PRIVATE, IPC_CREAT | S_IRUSR | S_IWUSR)
    // die "msgget: $!";

my $msg = pack("l! a*", 1, "job-42");
msgsnd($qid, $msg, 0) or die "msgsnd: $!";
```

Non-blocking send - return immediately with `EAGAIN` in `$!` if the queue is full, rather than sleeping:

```
use IPC::SysV qw(IPC_NOWAIT);
use Errno qw(EAGAIN);

unless (msgsnd($qid, $msg, IPC_NOWAIT)) {
    if ($! == EAGAIN) {
        warn "queue full, dropping message\n";
    } else {
        die "msgsnd: $!";
    }
}
```

Use the type field as a priority / channel tag. Receivers pick by type via `msgrcv`:

```
my %CHANNEL = (log => 1, metric => 2, alert => 3);
```

(continues on next page)

(continued from previous page)

```
sub send_event {
    my ($kind, $body) = @_;
    my $msg = pack("l! a*", $CHANNEL{$kind}, $body);
    msgsnd($qid, $msg, 0) or die "msgsnd[$kind]: $!";
}

send_event(alert  => "disk > 90%");
send_event(metric => "rps=1240");
```

Send a structured payload - `pack` the header fields after the mandatory type prefix:

```
my $type = 1;
my $body = pack("N N a*", $job_id, $retry_count, $payload);
msgsnd($qid, pack("l! a*", $type, $body), 0)
    or die "msgsnd: $!";
```

Edge cases

- **Message type must be positive.** Passing `0` or a negative type fails with `EINVAL`. The type-selection semantics in `msgrcv` reserve those values for selector logic.
- **Message exceeds `msg_qbytes`.** If `MSG` is larger than the queue's configured per-message limit, `msgsnd` fails with `EINVAL` regardless of `FLAGS`. Check and raise the limit with `msgctl` `IPC_SET` if you control the queue.
- **Queue full without `IPC_NOWAIT`.** The call blocks until another process dequeues, the queue is removed (`EIDRM`), or a signal interrupts it (`EINTR`). Retry on `EINTR` if the signal is expected and benign.
- **Queue full with `IPC_NOWAIT`.** Fails immediately with `EAGAIN`. This is the only way to enforce bounded latency on the send side.
- **Missing type prefix.** Forgetting to `pack` the `l!` type prefix passes the raw payload as-is; the first `sizeof(long)` bytes are then interpreted as the type - typically a large positive or negative number - and the rest as the body. Receivers filtering by type see nothing.
- **`ID` is a queue id, not a key.** Pass the integer returned by `msgget`, not the `KEY` you gave to `msgget`. Confusing the two yields `EINVAL` or, worse, a successful send to an unrelated queue that happens to share the numeric value.
- **Permissions.** The process must have write permission on the queue (the `w` bit of the queue's mode for its effective uid/gid). Otherwise the call fails with `EACCES`.
- **Tainting.** `MSG` is read as a byte string; no taint checking is performed on it here. If `MSG` came from an untrusted source, the receiver side (`msgrcv`, which *does* taint its output) is where filtering belongs.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `msgget` - obtain the queue id passed as `ID`; call this first, or receive the id from whoever created the queue
- `msgrcv` - the matching receive primitive; its `TYPE` argument selects against the `l!` prefix written here
- `msgctl` - inspect the queue's `msg_qbytes` limit or remove the queue when done
- `pack` - build the `l! a*` buffer `msgsnd` requires; also the tool for any further structure inside the payload
- `$!` - carries the `errno` from a failed `msgsnd`; compare against `Errno` constants to branch on specific failures

Scoping

my

Declare one or more lexically scoped variables.

`my` introduces new variables whose visibility is bounded by the enclosing block, file, or `eval`. The compiler records the declaration at compile time; the storage is allocated and (re)initialised each time control enters the scope. Unlike `local`, `my` does not temporarily replace a package variable - it creates a genuinely new variable that exists only while the scope is live and is invisible outside it, including to any subroutines the scope calls.

Synopsis

```
my EXPR
my TYPE EXPR
my EXPR : ATTRS
my TYPE EXPR : ATTRS
```

A single variable may be written without parentheses; a list of two or more must be parenthesised:

```
my $x;
my ($a, $b, @rest);
my Foo $obj;
my $x : shared = 0;
```

What you get back

`my` is a declaration, not a value-producing operator in the ordinary sense. In rvalue position it yields its variable (or the list of variables) as an lvalue you can assign to. The common idioms are:

```
my $x = $expr;               # scalar context on RHS
my ($first, @rest) = @list; # list context on RHS; destructuring
my @copy = @src;             # list context; @copy gets the elements
my %h = @pairs;              # list context; pairs populate the hash
```

When no initialiser is given, each declared variable starts as `undef` (scalar), empty list (array), or empty hash.

Scope and lifetime

- **Block scope.** A `my` variable is visible from the point immediately after its declaration to the end of the innermost enclosing block, file, `eval`, `do`, `require`, or `use`'d file.
- **Control-expression scope.** The controlling expression of `if` / `unless` / `elsif` / `else`, `while` / `until`, `for` / `foreach` is part of the scope of the declaration it contains. In `while (my $line = <$fh>) { ... }` the variable `$line` is live throughout the loop body and its `continue` block, but not beyond.
- **Fresh storage on every entry.** Each time control re-enters the scope, the variable is created anew. This is the key difference from `state`, which preserves its value across entries.
- **Closures capture storage, not values.** An anonymous sub created inside the scope keeps that particular instance of the variable alive for as long as the sub is reachable.

```
sub make_counter {
    my $n = 0;
    return sub { ++$n };    # closes over this $n
}
my $c = make_counter();
$c->(); $c->();             # 1, 2
```

List form and destructuring

With parentheses, `my` supplies list context to the right-hand side and destructures the result:

```
my ($sec, $min, $hour) = localtime;
my ($head, @tail)      = @list;       # @tail absorbs the rest
my ($x, $y)            = ($y, $x);    # swap via list assignment
```

Use `undef` as a placeholder to skip a position:

```
my (undef, $min, $hour) = localtime;  # discard seconds
```

Without parentheses, `my $foo` is a single-variable declaration and the comma operator applies to whatever follows:

```
my $foo, $bar = 1;          # WRONG: declares $foo only;
                            # $bar is the package variable
my ($foo, $bar) = (0, 1);   # Right.
```

Context traps

`my` does not change how the right-hand side is evaluated - it only modifies the variable on the left. A scalar `my $foo` imposes scalar context; a parenthesised `my (...)` imposes list context:

```
my  $line  = <$fh>;         # scalar context: one line
my ($line) = <$fh>;         # list context: first of a list
my  @lines = <$fh>;         # list context: all remaining lines
```

The classic mistake is writing `my ($foo) = <$fh>` when a single line was wanted - the parentheses turn on list context and the filehandle returns a one-element list; the value happens to be the first line, but the surrounding context is wrong for anything that follows.

`my` vs `local` vs `our` vs `state`

Four declarations, four different meanings:

- `my` - introduces a **new lexical** variable. Not visible to called code. Fresh storage each entry.
- `local` - does **not** declare anything. It saves the current value of an **existing package** variable and restores it when the enclosing scope exits. Visible to called code through dynamic scope. Use it for the handful of magical globals (`$_`, `$/`, `$\`, `$,`, `$|`, `%ENV`, ...) that cannot be lexicalised.
- `our` - declares a **lexical alias** for a package (global) variable. The storage lives in the package's symbol table; `our` just lets you refer to it without the package prefix for the rest of the lexical scope. Satisfies `use strict 'vars'`.
- `state` - like `my` in visibility, but the storage **persists** across re-entries to the scope. Initialisation runs once; subsequent entries leave the value alone.

```
package Counter;
our   $total = 0;           # package global; $Counter::total
my    $cache;               # lexical; invisible outside this file
state $calls = 0;           # lexical; keeps its value across calls
sub tick {
    local $\ = "\n";        # temporarily override output separator
    ++$calls;
    print ++$total;
}
```

Critical point: `my $var` does **not** mask a package variable with the same name. The package variable remains accessible through its fully qualified form while the lexical is in scope:

```
package main;
our $x = 10;
my  $x = 20;
print "$x and $::x\n";      # "20 and 10\n"
```

TYPE and attributes

Both forms are part of the language but their semantics are still evolving (upstream wording).

- **TYPE** - a bareword class name, a constant declared via `use constant`, or `__PACKAGE__`. Historically bound to the `fields` pragma; for ordinary use it serves as a hint and does not enforce a type at runtime.

  ```
  my Foo $obj = Foo->new;
  ```

- **ATTRS** - a colon-introduced attribute list handled by the `attributes` pragma (and `Attribute::Handlers` since 5.8.0).

  ```
  my $x : shared;
  my @buf : Locked;
  ```

See `perlsub` upstream for the authoritative wording.

Declaration is not yet in scope on its own RHS

The newly declared variable is not visible until **after** the declaring statement finishes. That makes this idiom well-defined:

```
my $x = $x;                 # new $x initialised from the old $x
```

and this condition dependent on a pre-existing outer `$x`:

```
my $x = 123 and $x == 123;  # false unless the old $x was 123
```

Within a single statement, any further mentions of the name refer to the pre-declaration binding (or raise a `strict 'vars'` error if no such binding exists):

```
our $x = 2;
foo($x, my $x = $x + 1, $x); # foo() receives (2, 3, 2)
```

Examples

Typical subroutine entry - name the arguments:

```
sub distance {
    my ($x1, $y1, $x2, $y2) = @_;
    return sqrt( ($x2-$x1)**2 + ($y2-$y1)**2 );
}
```

Loop-local index with `for my`:

```
for my $i (1 .. 10) {
    # $i is fresh each iteration; invisible after the loop
}
```

File-scoped private state - the variable exists for the life of the interpreter but is unreachable from outside this file:

```
my $cache = {};
sub lookup { $cache->{ $_[0] } //= _compute($_[0]) }
```

Private subroutine via a lexical coderef:

```
my $helper = sub { ... };
$helper->($x);
```

Shadowing warning - redeclaring in the same scope emits a `shadow`-category warning under `use warnings`:

```
use warnings 'shadow';
my $x = 1;
my $x = 2;                  # warning: "my" variable $x masks ...
```

Edge cases

- **Only alphanumeric identifiers.** Magical built-ins such as `$/`, `$_`, `$\`, `%ENV`, `@ARGV` cannot be lexicalised. Use `local` to scope them dynamically.
- **No package qualification.** `my $Foo::bar` is a syntax error: `my` variables are not package-owned and cannot carry a `::` qualifier.
- **Missing parentheses around a list.** `my $a, $b` declares only `$a`; `$b` is the package variable. Always parenthesise two or more names.
- **List-context surprise.** `my ($line) = <$fh>` forces list context on the read; the RHS is a one-element list, not a scalar. Drop the parentheses if you want scalar semantics.
- **`foreach` without `my`.** `for $i (...)` localises `$i` dynamically in the manner of `local`. Prefer `for my $i (...)` to confine the index lexically.
- **Shadowing in loops.** A `my` inside a loop body declares a fresh variable every iteration. If that is unwanted (e.g. a counter that should survive iterations), declare it outside the loop or use `state`.
- **Closure capture.** A closure over a `my` variable keeps that particular instance alive. Different calls to an enclosing sub produce independent closures over independent variables.
- **`use strict 'vars'` interaction.** `my` satisfies strict-vars within its scope; variables without a declaration must be `our`, fully qualified, or predeclared with `use vars`.
- **Compile-time vs run-time.** The name binding happens at compile time; the initialiser runs at run time, and re-runs on each scope entry. Expensive initialisers inside hot loops pay that cost every iteration.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `our` - lexical alias for a package variable; satisfies `strict 'vars'` without creating new storage
- `local` - dynamically scoped save/restore of an existing package variable; the tool for magical globals
- `state` - lexical like `my`, but storage persists across scope re-entries
- `undef` - placeholder in a parenthesised `my` list, and the initial value of an uninitialised scalar
- `use strict` - makes `my` / `our` / fully-qualified names mandatory, catching accidental globals
- `attributes` - pragma that interprets the `: ATTRS` portion of a `my` declaration

Control flow

next

Start the next iteration of the enclosing loop immediately.

`next` is Perl's equivalent of C's `continue` statement: it abandons the rest of the current iteration's body and jumps to the loop's iteration step. If the loop has a `continue` block, that block runs first, then the controlling expression is re-tested (or the next element is taken for `foreach`), and execution resumes at the top of the body. With a label, `next LABEL` targets a specific enclosing loop rather than the innermost one.

Synopsis

```
next
next LABEL
next EXPR
```

What you get back

Nothing. `next` is a flow-control operator, not an expression - it unwinds out of the current iteration and therefore never yields a value to its caller. Attempting to use it in a value-producing position (for example as the right-hand side of an assignment inside `eval {}`, `sub {}`, or `do {}`) is a misuse: the surrounding construct never completes normally, so there is no return value to observe.

Loop targeting

Without a label, `next` refers to the **innermost enclosing loop** (`while`, `until`, `for`, `foreach`, or a bare block, which counts as a one-shot loop). With a label it refers to the named loop, no matter how deeply nested the `next` sits inside other loops:

```
OUTER: for my $row (@grid) {
    for my $cell (@$row) {
        next OUTER if $cell eq 'skip-row';
        process($cell);
    }
}
```

`next EXPR`, available since Perl 5.18, evaluates `EXPR` at run time and uses its string value as the label name. Otherwise it behaves exactly like `next LABEL`:

```
my $target = pick_label();
next $target;                    # same as: next FOO if $target eq
↪"FOO"
```

Use the runtime form sparingly - a static `next LABEL` is easier to read and to verify by eye.

Interaction with `continue` blocks

A loop's `continue` block runs at the end of every iteration, whether that iteration ended normally or via `next`. This is the whole point of having a `continue` block: it groups the bookkeeping that must happen on every pass.

```
my $i = 0;
LINE: while (my $line = <$fh>) {
    next LINE if $line =~ /^\s*#/;  # skip comments
    process($line);
}
continue {
    $i++;                           # runs even for skipped lines
}
```

`last` skips the `continue` block; `next` does not. This is the simplest distinguishing property of the two, and the reason `continue` exists as its own construct rather than being baked into the loop body.

Examples

Basic `while` loop - discard comment lines, process the rest:

```
while (my $line = <$fh>) {
    next if $line =~ /^\s*#/;
    next if $line =~ /^\s*$/;       # blank
    handle($line);
}
```

`foreach` with an accumulator - skip entries that fail a predicate:

```
my $total = 0;
for my $n (@values) {
```

(continues on next page)

(continued from previous page)

```
    next unless defined $n;
    next if $n < 0;
    $total += $n;
}
```

Nested loops with a label - move on to the next outer row as soon as we spot a sentinel in the inner scan:

```
ROW: for my $row (@grid) {
    for my $cell (@$row) {
        next ROW if $cell eq 'END';
        count($cell);
    }
}
```

`continue` block that always runs, even on `next`:

```
my @kept;
ITEM: for my $x (@input) {
    next ITEM if $x->{hidden};
    push @kept, $x;
}
continue {
    log_seen($_);                    # every $x is logged, kept or
↪not
}
```

Escaping a bare block - a standalone `{ ... }` is a one-shot loop, so `next` jumps past the remaining statements and out of it:

```
{
    last_chance() or next;           # bare block: next == fall out
    commit();
}
```

Edge cases

- **Illegal inside `grep` / `map` / a `do { }` value block.** These constructs are not loops - their block is evaluated for its value, not iterated in the loop-control sense. Using `next` to exit them is a misuse and is called out explicitly in upstream perlfunc. Use a conditional expression instead:

  ```
  my @kept = grep { wanted($_) } @xs;          # not: grep {
  ↪next unless ... }
  my @mapped = map { transform($_) // () } @ys; # empty list ==
  ↪skip
  ```

- **Not a `return`.** `next` cannot deliver a value out of a value-returning block such as `eval { }`, `sub { }`, or `do { }`. If you find yourself reaching for `next` to leave such a block, you want `return`, or a conditional that produces the value you need.

- **A bare block is a one-shot loop.** `{ ... }` with no `while` / `for` prefix is semantically a loop that runs exactly once, so `next` exits it. This is occasionally useful for early-out patterns, but `last` is the more common choice because it makes the intent clearer.
- **Unknown label is a fatal error.** `next NOSUCH` dies at run time with `Can't "next" outside a loop block` when no enclosing loop carries that label.
- **`continue` runs on `next`, not on `last`.** This is the usual cause of surprise when refactoring: moving bookkeeping out of the loop body into `continue` changes behaviour only for `last`, not for `next`.
- **Precedence and parsing quirks.** Unlike most named operators, `next` has the same precedence as assignment, and it is exempt from the looks-like-a-function rule. That means `next ("foo") . "bar"` passes `"foobar"` to `next`, not just `"foo"`. Parenthesise defensively when the label name comes from an expression:

```
next(($cond ? "A" : "B"));
```

- **Threads, signals, destructors.** `next` unwinds the current iteration's lexical scope: `my` variables go out of scope, `local` values are restored, and `DESTROY` fires on scope-exit objects, just as if the iteration had ended normally. Pending `$SIG{...}` handlers are not affected.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `last` - exit the enclosing loop entirely, skipping any `continue` block
- `redo` - restart the current iteration without re-testing the condition and without running `continue`
- `return` - the right tool for leaving `sub { }`, `eval { }`, or `do { }` with a value; `next` cannot do this
- `grep` - filter a list; use a conditional expression, not `next`, to drop elements
- `map` - transform a list; return the empty list `()` from the block to drop an element

Modules

no

The compile-time inverse of `use` - call a module's `unimport` method to turn off what `use` turned on.

`no MODULE LIST` is handled by the parser exactly like `use MODULE LIST`, except it calls `MODULE->unimport(LIST)` instead of `MODULE->import(LIST)`. Both run at compile time, both are lexically scoped, and both require the module to already be loaded. The common case is switching a pragma off inside a block - `no strict 'refs'`, `no warnings 'uninitialized'`, `no feature 'switch'` - without touching the enclosing file.

Synopsis

```
no MODULE LIST
no MODULE
no MODULE VERSION LIST
no MODULE VERSION
```

What you get back

no is a declaration, not an expression. It has no useful return value and cannot appear where a value is expected. The effect is a side effect on the compile-time state of the enclosing lexical scope.

How it expands

The parser rewrites

```
no MODULE LIST;
```

into the rough equivalent of

```
BEGIN {
    require MODULE;
    MODULE->unimport(LIST);
}
```

- the same shape as `use`, with `unimport` swapped in for `import`. Consequences that follow from this:
- **Compile time.** The `BEGIN` block runs as soon as the parser reaches the no statement, before any later code in the file is compiled. This is why `no strict 'refs'` takes effect on the statements that follow it in the same file, not at runtime.
- **Lexical scope.** Pragmas that honour lexical scope (`strict`, `warnings`, `feature`, `integer`, `utf8`, and the other core pragmas) see their "off" effect confined to the innermost enclosing block, `eval`, or file. Leaving the block restores the previous state.
- **`require` still happens.** `no MODULE` loads `MODULE` if it has not been loaded yet, then calls `unimport` on it. You do not need a matching `use` earlier in the file.
- **`unimport` is mandatory.** If the package has no `unimport` method, the call dies at compile time with `Can't locate object method "unimport" via package "MODULE"`. Most non-pragma modules do not define `unimport` - no is really only useful for modules that advertise it.

Examples

Turn off a single warning category inside a block:

```
use warnings;
```

(continues on next page)

(continued from previous page)

```
for my $row (@rows) {
    no warnings 'uninitialized';
    print join(",", @$row), "\n";   # empty fields render as ""
}
# 'uninitialized' warnings are back on here
```

Relax `strict 'refs'` for one statement that needs symbolic dereferencing:

```
use strict;

sub install {
    my ($name, $code) = @_;
    no strict 'refs';
    *{"main::$name"} = $code;       # symbolic typeglob assignment
}
```

Disable an experimental feature warning while using the feature:

```
use feature 'signatures';
no warnings 'experimental::signatures';

sub greet ($who) { "hello, $who\n" }
```

Roll back a default feature bundle to plain Perl semantics:

```
use v5.36;                          # enables strict, warnings, say,␣
↪signatures…
no feature 'switch';                # …but not given/when
```

Turn off a user pragma that provides its own `unimport`:

```
use My::Pragma qw(loud);
{
    no My::Pragma;                  # My::Pragma->unimport called␣
↪here
    quiet_code();
}
```

Edge cases

- **`no VERSION` is a compile error.** `use VERSION` exists as a compile-time version check against the running interpreter; there is no sensible inverse, so `no 5.36;` dies with `No such class 5.36`. The version check only goes one way.
- **`no MODULE VERSION` *does* parse.** It requires `MODULE` to be at least `VERSION` (same check as `use`), then calls `MODULE->unimport(LIST)`. The version check is about the loaded module, not the interpreter.
- **Module without `unimport`.** Dies at compile time. There is no fallback to a no-op; if you are writing a module and want `no` to be a silent no-op, define an empty `sub unimport {}`.

- **Bareword `MODULE` only.** Like `use`, the module name must be a bareword known at compile time. `no $name;` is a syntax error - the parser needs the literal token to decide which `unimport` to call.
- **Does not undo `use`.** `no Foo` calls `Foo->unimport`, which by convention reverses what `Foo->import` did to the current lexical scope - but that is a convention, not a language guarantee. A sloppy `unimport` can leave state behind, and side effects from `require Foo` (BEGIN blocks, `@INC` hooks, installed subs in other packages) are **not** rolled back.
- **Effect ends at the enclosing block.** For lexical pragmas, the "off" state stops at the next `}`, `eval` boundary, or end of file. Code in a different file that `requires` or `uses` this one is unaffected.
- **`import`/`unimport` are just method calls.** `MODULE->unimport(LIST)` runs exactly like any other class method - it sees `MODULE` as the first argument and `LIST` after. The method can inspect the caller via `caller` to find out which package to modify.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `use` - the positive form; no is literally `use` with `unimport` in place of `import`
- `require` - the runtime load step that no performs before calling `unimport`
- `package` - declares the current package, which is the scope a pragma's `unimport` typically modifies
- `import` - the conventional counterpart method; no calls `unimport`, `use` calls `import`
- `BEGIN` - the compile-time phase in which no runs
- `caller` - how an `unimport` method identifies the package it should affect

SCALARs and strings · Numeric functions

oct

Interpret a string as a number written in octal, hexadecimal, or binary, and return the resulting integer.

The name is misleading: `oct` is really a *radix-prefix* parser. It inspects the leading characters of `EXPR` and picks the base from them - `0x`/`x` for hexadecimal, `0b`/`b` for binary, `0o`/`o` (or no prefix at all) for octal. If `EXPR` is omitted, `oct` works on `$_`. Think of it as the inverse of `sprintf "%o"` / `"%x"` / `"%b"` for the common case where you have the textual form and need the number.

Synopsis

```
oct EXPR
oct                 # operates on $_
```

What you get back

A non-negative integer. The numeric value of EXPR interpreted in whichever base its prefix selected (octal by default). The result is always >= `0` - `oct` does not parse a leading sign and does not return floating-point values.

An empty string, a string with no recognised digits, or `undef` returns `0`.

Prefix rules

The leading characters of EXPR (after any leading whitespace, which is silently skipped) determine the base:

Prefix	Base	Example input	Result
`0x` or `x`	16 (hex)	`"0xff"`	255
`0b` or `b`	2 (binary)	`"0b1010"`	10
`0o` or `o`	8 (octal)	`"0o755"`	493
(none)	8 (octal)	`"755"`	493
(none, leading `0`)	8 (octal)	`"0755"`	493

The `0o`/`o` octal prefix was added in Perl 5.33.5 to match integer literal syntax; older forms (`0755` and a bare `755`) have always been octal.

Underscores between digits are ignored, so values copied straight from Perl integer literals parse cleanly:

```
oct("0xDEAD_BEEF")      # 3735928559
oct("0b1111_0000")      # 240
oct("07_55")            # 493
```

Examples

Decode a permission string typed by a user - the whole reason `oct` exists. The string `"755"` is **not** the number 755; it is the octal representation of the number 493. `chmod` expects the number:

```
my $mode = "0755";
chmod oct($mode), "script.sh";          # chmod 0755
```

```
my $mode = "755";                       # no leading zero - still␣
↪octal
chmod oct($mode), "script.sh";          # same result
```

Parse hex and binary literals read from a config file or a command line:

```
my $mask  = oct("0xff00");              # 65280
my $flags = oct("0b1010_0101");         # 165
```

Handle arbitrary radix-prefixed strings - decimal, octal, hex, or binary - in one expression. This is the classic `oct`-as-dispatcher idiom: a leading `0` (in any of its forms) means "not decimal", so route through `oct`; otherwise keep the value as-is:

```
my $n = $val =~ /^0/ ? oct($val) : $val;
```

Default-argument form operates on `$_`, handy inside `map`:

```
my @perms = map { oct } @mode_strings;
```

Round-trip with `sprintf` to go the other direction:

```
my $perm = (stat $file)[2] & 07777;
my $text = sprintf "%o", $perm;         # e.g. "644"
my $back = oct($text);                  # back to the same integer
```

Edge cases

- **Empty or undef input**: `oct("")` and `oct(undef)` both return `0`. `undef` triggers an `uninitialized` warning under `use warnings`.
- **No prefix defaults to octal**: `oct("12")` is `10`, not 12. This is a frequent surprise - if your strings might be decimal, test for a leading `0` first (see the idiom above) or do not use `oct` at all and parse explicitly.
- **Underscores are ignored** wherever they appear between digits. `oct("0x_de_ad")` is `57005`. Leading and trailing underscores are also silently accepted.
- **Invalid characters terminate parsing**: parsing stops at the first character that does not belong to the selected base; the rest of the string is discarded without a warning. `oct("0x1g2")` returns `1`, `oct("755.5")` returns `493`, `oct("12abc")` returns `10` (octal, stopped at `a`), `oct("0b102")` returns `2` (binary `10`, stopped at `2`).
- **Leading whitespace is skipped silently.** A leading `+` or `-` is **not** a sign - it is a non-digit, so parsing returns `0`. `oct` cannot produce a negative number.
- **Floating-point and exponent notation are not understood.** There is no `0x1.8p3` support; the `.` terminates parsing.
- **Case of prefix and digits is insensitive**: `0X`, `0B`, `0O`, and hex digits `a-f`/`A-F` are all accepted.
- **Overflow**: values larger than the platform integer silently promote to floating point, losing low-order precision for very large hex/binary inputs.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `hex` - forces base 16 regardless of prefix; use it when the input is *always* hex and you do not want `oct`'s autodetection
- `int` - truncate a numeric value toward zero; unrelated to radix parsing but often reached for by accident
- `chmod` - the canonical consumer of `oct`; takes a numeric mode, so string-form modes must go through `oct` first
- `sprintf` - the inverse direction: format %o, %x, %b turn an integer into its octal/hex/binary textual form

Filehandles, files, directories

open

Associate a filehandle with a file, a command, or an in-memory scalar.

open is the primary way a Perl program acquires a filehandle. The three-argument form - `open $fh, MODE, EXPR` - is the one to use in new code: the mode is stated explicitly, the filename cannot be reinterpreted as a shell pipeline, and leading or trailing whitespace in `EXPR` is preserved verbatim. The older two-argument form exists for compatibility and for the "magic" filename interpretation it enables; do not feed it untrusted input.

Synopsis

```
open my $fh, "<",  $path           or die "read $path: $!";
open my $fh, ">",  $path           or die "write $path: $!";
open my $fh, ">>", $path           or die "append $path: $!";
open my $fh, "+<", $path           or die "rw $path: $!";
open my $fh, "<:encoding(UTF-8)", $path or die $!;
open my $mem, ">",  \$buf          or die $!;   # in-memory
open my $pipe, "-|", "ls", "-la"   or die $!;   # read from cmd
open my $pipe, "|-", "gzip", ">$f" or die $!;   # write to cmd
```

What you get back

1 on success; `undef` on failure, with `$!` set to the OS error. For the pipe forms (`|-` / `-|`), the successful return value is the pid of the child process - useful when you need to `waitpid` on it later. After a one- or two-argument pipe open on the literal command `-`, open returns twice (parent gets the child pid, child gets `0`); use `defined($pid)` or `//` to distinguish the two.

Always check the return value. A failed open leaves the filehandle closed, and every subsequent read or write on it will set `$!` to `Bad file descriptor` and emit a warning under `use warnings`.

```
open my $fh, "<", $path
    or die "open $path: $!";
```

Global state it touches

- `$!` - set on failure to the OS-level error.
- `${^OPEN}` - default I/O layers installed by the open pragma or the `-CioD` switch. These apply only when `MODE` in the three-argument form contains no explicit layer; a bare `<` or `>` honours them, `<:raw` or any other explicit layer suppresses them.
- `$^F` - highest file descriptor not marked close-on-exec; the new fd inherits the close-on-exec flag based on this.
- Selected filehandle via `select` - unchanged by open, but becomes relevant the moment you `print` to the new handle without naming it.
- For pipe forms, `$?` and `${^CHILD_ERROR_NATIVE}` are set when the handle is later closed.

Modes

The second argument names an I/O role. The common cases:

Mode	Meaning	`fopen(3)` equivalent
`<`	read	`r`
`>`	write, truncate or create	`w`
`>>`	append, create if missing	`a`
`+<`	read and write, no truncation	`r+`
`+>`	read and write, truncate first	`w+`
`|-`	pipe to command (we write)	-
`-|`	pipe from command (we read)	-
`<&`, `>&`, `<&=`, `>&=`	dup or fdopen an existing handle	-

Newly created files get permissions `0666 & ~umask`. `+<` is almost always what you want for read-write; `+>` clobbers the file first.

I/O layers attach after the mode: `<:encoding(UTF-8)`, `>:raw`, `>>:crlf`, `<:encoding(UTF-8):crlf`. An explicit layer suppresses `${^OPEN}` defaults; a lone colon (`<:`) falls back to the OS default (`:raw` on Unix, `:crlf` on Windows).

Examples

Read a UTF-8 text file line by line:

```
open my $fh, "<:encoding(UTF-8)", "notes.txt"
    or die "open notes.txt: $!";
while (my $line = <$fh>) {
    chomp $line;
    # ... use $line ...
```

(continues on next page)

(continued from previous page)

```
}
close $fh or warn "close: $!";
```

Write a binary file with no encoding translation:

```
open my $out, ">:raw", "image.bin"
    or die "open image.bin: $!";
print $out $bytes;
close $out or die "close: $!";
```

In-memory filehandle - `print` into a scalar, useful for capturing output that expects a real handle:

```
my $buf = "";
open my $mem, ">", \$buf or die $!;
print $mem "hello\n";
close $mem;
# $buf now contains "hello\n"
```

Read from a command, list form so arguments are not subject to shell metacharacter interpretation:

```
open my $ls, "-|", "ls", "-la", $dir
    or die "ls: $!";
while (<$ls>) { print }
close $ls;                      # $? holds the exit status
```

Temporary anonymous file - pass `undef` as the third argument with a read-write mode, then `seek` back to the start to read what you wrote:

```
open my $tmp, "+>", undef or die $!;
print $tmp "scratch data\n";
seek $tmp, 0, 0;
my $line = <$tmp>;
```

Edge cases

- **Two-argument "magic" open**: `open $fh, $name` honours leading `<`, `>`, `>>`, a trailing `|`, and strips surrounding whitespace from `$name`. Fine for a literal filename you typed yourself; **never** for a filename that came from user input, the network, or an environment variable. Use the three-argument form.
- **Two-argument `-`**: `open $fh, "<-"` or `open $fh, "-"` opens `STDIN`; `open $fh, ">-"` opens `STDOUT`. Three-argument equivalents are `open $fh, "<", "-"` and `open $fh, ">", "-"`.
- **Reopening `STDOUT` / `STDERR`**: close them first, then reopen against the new target. `open STDOUT, ">", \$buf` redirects all subsequent `print STDOUT` output into `$buf`.
- **Bareword filehandles** (`open FH, ...`) are package globals and are disabled under `use v5.36` or later via the `bareword_filehandles` feature. Prefer a lexical

scalar.

- **Layers and `${^OPEN}`**: any explicit layer, even `:`, disables the defaults from the open pragma. If you rely on a pragma default, omit the colon entirely (`<`, not `<:`).
- **Pipe to a command with shell metacharacters**: the two-argument pipe form (`open $fh, "|cat -n | lpr"`) runs through `/bin/sh -c`. The three-argument list form (`open $fh, "|-", "cat", "-n"`) does not and is the safer default.
- **In-memory scalar strings**: treated as octet strings. Without truncation, the scalar may not contain code points above `0xFF`.
- **Automatic close on scope exit**: a lexical filehandle closes when its refcount hits zero, but the implicit close does not report errors. For files you wrote to, close explicitly and check the return value.
- **open vs sysopen**: open wraps `fopen(3)` semantics with PerlIO layers on top. For direct `open(2)` flags like `O_EXCL` or `O_NOFOLLOW`, use `sysopen`.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `close` - release a filehandle; check its return value for buffered writes and pipe commands
- `sysopen` - open with raw `open(2)` flags when you need `O_EXCL`, `O_NOFOLLOW`, or similar precision
- `binmode` - push or replace I/O layers on an already open handle
- `read` - fixed-size byte reads from the handle open returned
- `readline` - record-at-a-time reads (what `<$fh>` calls)
- `fileno` - the underlying OS file descriptor, for `flock`, `select`, or `fcntl`
- `$!` - OS error set when open returns `undef`

Filehandles, files, directories

opendir

Open a directory for reading.

`opendir` attaches `DIRHANDLE` to the directory named by `EXPR` so the directory's entries can be read with `readdir` and the position manipulated with `telldir`, `seekdir`, and `rewinddir`. When you're done, `closedir` releases the handle. `DIRHANDLE` lives in a namespace distinct from file handles - a bareword you have already used with `open` is free to reuse here, and vice versa.

Synopsis

```
opendir DIRHANDLE, EXPR
opendir my $dh, EXPR
```

What you get back

1 on success, `0` on failure. On failure `$!` holds the reason - the directory does not exist, is not a directory, is not readable, or the process has hit its open-file limit. Always check the return; a silent failure here turns into a mysteriously empty `readdir` later.

```
opendir my $dh, $path
    or die "opendir $path: $!";
```

Global state it touches

- `$!` - set to the system error string on failure, left untouched on success. Capture it before any other system call disturbs it.

Handle semantics

Three forms of `DIRHANDLE` are accepted, and the choice matters:

- **Bareword** - `opendir DIR, $path` creates a package-global dirhandle named `DIR` in the current package. It stays open until you `closedir` it explicitly or the program exits. Avoid in new code; the global namespace is shared across the whole package.
- **Undefined scalar** - `opendir my $dh, $path` autovivifies `$dh` into a reference to a fresh anonymous dirhandle. When `$dh` goes out of scope and its refcount drops to zero, the handle is closed automatically. This is the form to use.
- **Expression** - any expression whose value is usable as an indirect dirhandle (typically a real dirhandle name held in a variable). The handle identity comes from the expression's value, not its syntactic form.

Dirhandles and filehandles share the same underlying I/O object: a given object can be open as one or the other at a time, never both. Passing a dirhandle to `read` or a filehandle to `readdir` is a usage error, not a silent read of zero bytes.

Examples

The canonical `opendir` / `readdir` / `closedir` idiom:

```
opendir my $dh, $dir
    or die "opendir $dir: $!";
while (my $entry = readdir $dh) {
    next if $entry eq '.' or $entry eq '..';
    print "$dir/$entry\n";
}
closedir $dh;
```

Read every entry into a list in one go. `readdir` in list context returns all remaining entries:

```
opendir my $dh, '.' or die "opendir .: $!";
my @entries = grep { !/^\.\.?\z/ } readdir $dh;
closedir $dh;
```

Rely on lexical scope for cleanup - no explicit `closedir` needed:

```
sub list_dir {
    my ($path) = @_;
    opendir my $dh, $path or return;
    return grep { !/^\.\.?\z/ } readdir $dh;
    # $dh goes out of scope here, handle is closed
}
```

Handle a missing-or-unreadable directory without dying:

```
if (opendir my $dh, $path) {
    while (defined(my $e = readdir $dh)) { ... }
    closedir $dh;
} else {
    warn "skipping $path: $!";
}
```

Revisit the start of a directory with `rewinddir` rather than reopening:

```
opendir my $dh, $dir or die $!;
my @first_pass  = readdir $dh;
rewinddir $dh;
my @second_pass = readdir $dh;
closedir $dh;
```

Edge cases

- **Failure sets `$!`, not `$@`.** `opendir` reports through `$!` like the rest of the I/O family; `$@` is untouched.
- **Reusing an open dirhandle.** `opendir` on a handle that is already open silently closes the old directory before opening the new one. Prefer explicit `closedir` when the code is meant to be readable.
- **Relative paths.** `EXPR` is resolved against the current working directory at the moment of the call. If you `chdir` later, a relative path you captured earlier may no longer mean the same thing - the already-opened dirhandle keeps pointing at the right inode regardless.
- **Symlinks.** `opendir` follows symlinks by default: opening a link to a directory opens the target. The entries returned by `readdir` are the target's entries, not the link.
- **Bareword vs lexical lifetime.** A bareword dirhandle is global and outlives the enclosing block; a lexical `my $dh` is cleaned up when the scope ends. Mixing the

two by accident (`opendir DH, $path` inside a sub) leaks dirhandles on repeated calls.

- **File vs dir handle mix-up**. You cannot `print` to a dirhandle nor `readdir` from a filehandle. The error surfaces at the later call, not at `opendir`.
- **`glob` vs `opendir`**. `glob` expands shell-style patterns and returns paths; `opendir` enumerates raw directory entries (including `.` and `..`) without interpretation. Use `glob` when you want pattern matching; use `opendir` when you want every entry exactly as the filesystem stores it.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `readdir` - read the next entry (or all remaining entries) from a dirhandle opened with `opendir`
- `closedir` - release a dirhandle; implicit when a lexical `$dh` goes out of scope
- `rewinddir` - reset the read position to the start without reopening
- `seekdir` - reposition the dirhandle to a token previously returned by `telldir`
- `telldir` - current read position as an opaque token suitable for `seekdir`
- `glob` - pattern-based alternative when you want shell-style filename expansion instead of raw directory enumeration

SCALARs and strings

ord

Return the Unicode code point of the first character of a string.

`ord` takes a string, looks at its first character, and returns that character's numeric code point as an integer. Note *character*, not byte - if the string is a wide-character string containing the letter é (U+00E9), `ord` returns 233, regardless of how many bytes é occupies in memory. For the empty string, `ord` returns `0`. If `EXPR` is omitted, `ord` operates on `$_`.

For the reverse direction - turning a code point back into a character - see `chr`.

Synopsis

```
ord EXPR
ord
ord($str)
```

What you get back

A non-negative integer. For an ASCII input it is in the range `0..127`; for a Latin-1 input `0..255`; for a general Unicode string anything up to `0x10FFFF`. `ord` never returns a negative number and never returns a non-integer. Only the first character of the argument is consulted - trailing characters are ignored. To walk every code point of a string, combine with `split //` or `unpack "U*"`.

Global state it touches

With no argument, `ord` reads `$_`. It neither writes nor reads any other special variable. The interpretation of the input as characters (not bytes) depends on whether the scalar is internally flagged as UTF-8 - see *Edge cases* below.

Examples

Basic ASCII lookup:

```
print ord("A");             # 65
print ord("0");             # 48
print ord("\n");             # 10
```

Empty string returns zero, matching the “no first character” contract:

```
print ord("");              # 0
```

Default-argument form inside a `while` loop over `$_`:

```
while (<STDIN>) {
    last if ord == 4;       # stop on EOT (Ctrl-D) as first char
    print;
}
```

Decode a wide character. `ord` sees the character, not the bytes:

```
use utf8;
print ord("é");             # 233        (U+00E9)
print ord("€");             # 8364       (U+20AC)
print ord("😀");            # 128512     (U+1F600)
```

Walk every code point in a string - useful for debugging encoding surprises:

```
use utf8;
my $s = "héllo";
print join(",", map { ord } split //, $s), "\n";
# 104,233,108,108,111
```

Pair with `chr` for a no-op round-trip on any single character:

```
my $c = "Z";
print chr(ord($c)) eq $c ? "same\n" : "changed\n";   # same
```

Edge cases

- **Character vs byte semantics**: `ord` returns the code point of the first *character*, which for a UTF-8-flagged scalar is not the same as the first *byte*. `ord("\x{100}")` returns 256, even though that character occupies two bytes in memory. To inspect the first byte instead, force byte semantics:

  ```
  use bytes;
  print ord("\x{100}");       # 196   (first UTF-8 byte, 0xC4)
  no bytes;
  print ord("\x{100}");       # 256
  ```

  Reach for `use bytes` only when you genuinely need byte-level inspection; it is a local, surgical pragma.

- **Non-UTF-8 scalar containing high bytes**: if the scalar is a plain byte string (no UTF-8 flag) and its first byte is `0xC4`, `ord` returns 196, not 256. The byte is interpreted as Latin-1. Whether a given scalar is UTF-8-flagged depends on how it was built - `use utf8` in source, `decode_utf8`, a `:utf8` I/O layer, `chr` of a value above 255, and so on.

- **`undef`**: `ord(undef)` returns `0` and, under `use warnings`, emits `Use of uninitialized value in ord`.

- **Numeric argument**: `ord(65)` stringifies 65 to `"65"` first, then takes the first character - so it returns `ord("6") == 54`, not 65. This surprises people; if you have an integer and want to round-trip through a character, use `chr` first or skip `ord` entirely.

- **Multi-character argument**: only the first character matters. `ord("ABC")` returns 65; the `B` and `C` are never consulted.

- **Surrogate and non-character code points**: `ord` will happily return `0xD800..0xDFFF` or `0xFFFE`/`0xFFFF` if those appear in the input. Perl does not refuse to store them; validation, if needed, is the caller's job.

- **Maximum value**: on a standard build, `ord` can return up to `0x7FFFFFFF` (31-bit) for a string produced by `chr` of a value in that range. Real-world Unicode text tops out at `0x10FFFF`.

- **Precedence**: the unary form `ord $x` binds tighter than `,` but looser than most arithmetic operators, so `ord $x + 1` parses as `ord($x) + 1`, not `ord($x + 1)`. Parenthesise when in doubt.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `chr` - the inverse operation; turns a code point back into a one-character string
- `sprintf` - use `%c` to format an integer as its character, or `%x` / `%04x` to render an `ord` result in hex

- `unpack` - `unpack "U*"` for every code point of a string; `unpack "C*"` for every byte
- `lc` / `uc` - case-fold a character before taking its code point when you want case-insensitive comparisons
- `$_` - the default argument when `ord` is called without one

Scoping

our

Declare a lexically scoped alias to a package variable.

`our` does **not** create a new variable. It introduces a name into the current lexical scope that refers to the package variable of the same name in the current package. For the duration of that scope, the unqualified name is legal under `use strict 'vars'`, and every read or write through it hits the underlying package variable.

If the package variable did not exist yet, `our` does not conjure it either - it simply names it. Package variables spring into existence when first assigned to, and an `our` declaration makes that first assignment possible without a fully qualified name.

Synopsis

```
our $x;
our ($a, $b, $c);
our @EXPORT_OK = qw(foo bar);
our $VERSION : shared = '1.00';
```

What you get back

`our` returns its list of variables, so it can appear in any expression position where `my` can:

```
(our $x, our $y) = (1, 2);
our $count = 0;
```

As a declaration it has no separate return value beyond that - the useful effect is the scoping side effect, not the value.

Scope and what the alias actually is

The alias lives in the **enclosing lexical block**, just like `my` and `state`. It ends at the closing brace of that block (or the end of the file for a top-level declaration). Outside the scope, the unqualified name is no longer legal under `use strict 'vars'` - the package variable itself is untouched and still reachable by its fully qualified name.

```
package Foo;
use strict;

$Foo::foo = 23;
```

(continues on next page)

(continued from previous page)

```
{
    our $foo;         # alias to $Foo::foo
    print $foo;       # 23
}

print $Foo::foo;      # 23 - the package variable is unaffected
print $foo;           # error: requires explicit package name
```

Because `our` aliases a **package** variable, the package is fixed at the point of declaration, not at the point of use. Changing packages with `package` mid-scope does not rebind the alias:

```
package Foo;
our $bar;             # declares $Foo::bar for the rest of this scope
$bar = 20;

package Bar;
print $bar;           # 20 - still refers to $Foo::bar
```

our vs my

`our` and `my` look alike on the page and are constantly confused. They do opposite things.

- `my` creates a fresh **private** variable that lives only inside its lexical scope. It has no name in any package's symbol table and nothing outside the scope can reach it.
- `our` creates a lexically scoped **alias** to a **public** package variable. The variable lives in the symbol table; any other code that knows its fully qualified name can read or write it.

Use `my` by default. Reach for `our` when you deliberately want package-global state: module exporter lists (`our @EXPORT`, `our @EXPORT_OK`), `our $VERSION`, a package-wide configuration hash other code is expected to poke at, or the traditional `our @ISA` for inheritance.

```
package My::Module;

our $VERSION   = '1.23';
our @EXPORT_OK = qw(frobnicate);
our @ISA       = ('Exporter');
```

Each of those names is an alias to `$My::Module::VERSION`, `@My::Module::EXPORT_OK`, `@My::Module::ISA` - exactly what `Exporter` and `UNIVERSAL::isa` go looking for.

our vs local

`local` and `our` often appear together and are complementary, not alternatives.

- `our` makes the package variable reachable under its unqualified name inside a lexical scope. It does **not** save or restore the value.

- `local` saves a package variable's current value and arranges for it to be restored when the enclosing dynamic scope ends. It does **not** make the name legal under `use strict 'vars'`.

The idiomatic pairing - temporarily change a package global inside a subroutine - uses both:

```
sub with_verbose {
    our $verbose;        # make the unqualified name legal here
    local $verbose = 1;  # save old value, restore on return
    do_work();
}
```

our vs state

`state` is the other lexical declaration. It creates a private variable whose value persists across calls to the enclosing subroutine. `our` shares none of that machinery - its variable is public and has no per-call semantics. Pick `state` for per-subroutine memoisation, `our` for package-global state.

Scope of the declaration itself

Like `my`, `state`, and `local`, `our` can appear anywhere an expression can (outside string interpolation). The declaration takes effect **immediately** - even within the same statement - so the variable satisfies `use strict 'vars'` from the declaration onward. But the declaration does **not** retroactively cover earlier uses of the same name in the same statement:

```
package main;
my $x = 2;
foo($x, our $x = $x + 1, $x);   # foo() receives (2, 3, 2)
foo($x, our $z = 5, $z);        # foo() receives (3, 5, 5)
```

The rule: each occurrence of the name is resolved as of its own position in the statement. After the declaration, the name is the alias; before it, the name means whatever it meant before.

The declaration also lets you reference the package variable on the right-hand side of its own initialiser, which is something `my` does not allow:

```
my  $foo = $foo;   # error under strict: undeclared $foo on RHS
our $foo = $foo;   # fine: RHS $foo is the package variable
```

Multiple variables and placeholders

More than one variable requires parentheses:

```
our ($bar, $baz);
```

Inside a parenthesised list, `undef` is a valid placeholder that discards the corresponding value of a list assignment:

```
our ( undef, $min, $hour ) = localtime;
```

Repeated declarations

Multiple `our` declarations with the same name in the same lexical scope are allowed when they are in **different** packages - each rebinds the alias to its package's variable:

```
use warnings;

package Foo;
our $bar;            # declares $Foo::bar for the rest of this scope
$bar = 20;

package Bar;
our $bar = 30;       # declares $Bar::bar - aliases the Bar variable
print $bar;          # 30
```

A second `our` declaration for the same name **in the same package and scope** is merely redundant - it rebinds to the same variable. Under `use warnings` Perl reports it the way it reports a repeated `my`, but there is no fresh variable and nothing is shadowed:

```
use warnings;
package Bar;
our $bar = 30;
our $bar;            # warning, but still the same $Bar::bar
print $bar;          # 30
```

Attributes and TYPE

`our` accepts the full declaration syntax of `my`:

```
our $x : shared;
our MyType $obj;
our $VERSION : shared = '1.00';
```

`TYPE` is currently bound to the `fields` pragma. Attributes are processed by the `attributes` pragma (and, since 5.8.0, by `Attribute::Handlers`). See the `attributes` pragma for the set of standard attributes. Ordinary user-level code rarely uses either.

Examples

Module preamble - the overwhelmingly most common use:

```
package My::Thing;
use strict;
use warnings;

our $VERSION   = '0.01';
our @ISA       = ('Exporter');
our @EXPORT_OK = qw(thingify);
```

Declare and assign in one step:

```
package Cfg;
our $timeout = 30;   # same as $Cfg::timeout = 30
```

Temporarily override a package global inside a call:

```
sub quiet_run {
    our $verbose;
    local $verbose = 0;
    run_one_job();
}
```

Cross-package alias - declaration in `Foo`, use in `Bar`:

```
package Foo;
our $shared = 'hello';

package Bar;
# $shared here still refers to $Foo::shared, because the lexical
# alias was introduced while the current package was Foo.
print $shared;       # hello
```

Parenthesised list with placeholder:

```
our ( undef, $min, $hour, undef, $mon, $year ) = localtime;
```

Edge cases

- **`our` does not create the variable.** It declares an alias. The package variable exists the moment anything assigns to it (or takes a reference to it); `our $x;` alone does not allocate a new slot in the symbol table.
- **The alias is lexical, the variable is not.** Leaving the scope of the `our` ends the alias, not the variable. Another scope in another file that declares `our $x;` in the same package sees the same storage.
- **Same-statement resolution.** Only occurrences of the name **after** the `our` declaration in a statement use the alias. Earlier occurrences keep their prior binding (see the `foo()` example above).
- **Package, not current package at use.** The alias is bound to the package in force at the point of declaration. Switching package later does not re-target it.
- **Not the same as `use vars`.** `use vars '$x'` makes `$x` legal under `strict` for the rest of the **package**, regardless of scope. `our $x` is lexical. Prefer `our`; `use vars` is legacy.
- **Not a file-scoped pragma.** A top-level `our $x;` in a file covers until the end of the file, which is a lexical scope - but `require`-ing that file from elsewhere does not extend the alias into the requiring file's scope.
- **Attribute and TYPE semantics are still evolving.** Anything beyond `: shared` in user code is rare; read the `attributes` and `fields` pragma documentation before relying on them.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `my` - declare a private lexical variable; the default choice when you want a new variable
- `local` - dynamically scope a temporary value for a package variable; pairs with `our` when you need both strict legality and save/restore
- `state` - declare a private lexical variable that persists across calls to the enclosing subroutine
- `package` - set the current package, which is what `our` aliases into
- `use` - compile-time module loader; `use strict 'vars'` is the pragma that makes `our` necessary in the first place
- `undef` - valid placeholder inside a parenthesised `our` list to discard a value on assignment

SCALARs and strings · Fixed-length data

pack

Convert a list of Perl values into a binary string according to a template.

`pack` is the low-level serialiser: you describe the byte layout with a `TEMPLATE`, hand it a `LIST` of values, and it returns a scalar whose characters are the concatenated machine-level encoding of those values. It is the inverse of `unpack` and the standard way to build fixed-width records, wire protocols, C struct layouts, raw IP addresses for `sockaddr_in`, and any other byte-level payload that Perl does not model as a first-class type.

This page is a **directive reference**. For a narrative introduction - "I have this wire protocol, how do I parse it?" - start at the *pack/unpack tutorial*.

Synopsis

```
my $bytes = pack TEMPLATE, LIST;
my $ip    = pack "C4",     split /\./, "192.168.1.1";
my $rec   = pack "Z8 Z8 L", $user, $host, $ts;
```

What you get back

A plain Perl scalar holding the packed bytes. Its length is the sum of the widths of every template directive; its contents are binary and may contain embedded `NUL` bytes. Treat it as a byte string, not as text - writing it to a handle with a `:utf8` or `:encoding(…)` layer will re-encode it. Use `binmode $fh` or open with `">:raw"` before emitting.

By default the result is in **character mode** (`C0`). A template that starts with `U`, or switches to `U0` mid-template, produces a UTF-8-encoded Unicode string instead. Do not use this as a substitute for the `Encode` module.

Template syntax

A `TEMPLATE` is a sequence of **directives**. Each directive is an ASCII letter, optionally followed by:

- a **repeat count** - a decimal integer, `*`, or `[...]`
- one or more **modifiers** - `!`, `<`, `>`
- a **group** - `(` ... `)` gathers directives so a repeat count or endianness modifier applies to the whole

Whitespace between directives is ignored. A `#` introduces a comment running to end-of-line - the same convention as Perl source.

Directive table

Every pack directive in one place. **W** is the width in bytes per scalar consumed (a `C` consumes one value and produces one byte; an `a3` consumes one value and produces three bytes). **Endian** column: *native* means the CPU's byte order; *big* / *little* are fixed regardless of host.

Directive	Consumes	W	Signed	Endian	Modifiers	Notes
a	1 string	count	-	-	-	NUL-padded to width, truncates if too long
A	1 string	count	-	-	-	Space-padded to width
Z	1 string	count	-	-	-	NUL-terminated; `Z*` always appends a trailing `NUL`
b	1 string	count/8	-	-	-	Bit string, LSB first within each byte
B	1 string	count/8	-	-	-	Bit string, MSB first within each byte
h	1 string	count/2	-	-	-	Hex string, low nybble first

continues on next page

Table 1 – continued from previous page

Directive	Consumes	W	Signed	Endian	Modifiers	Notes
H	1 string	count/2	-	-	-	Hex string, high nybble first
c	1 integer	1	yes	-	-	Signed char
C	1 integer	1	no	-	-	Unsigned char (octet)
W	1 integer	1	no	-	-	Unsigned char; allows values above 255 in U0 mode
s	1 integer	2	yes	native	! < >	s! = native short
S	1 integer	2	no	native	! < >	S! = native unsigned short
l	1 integer	4	yes	native	! < >	l! = native long
L	1 integer	4	no	native	! < >	L! = native unsigned long
i	1 integer	native	yes	native	! < >	sizeof(int); at least 32 bits
I	1 integer	native	no	native	! < >	sizeof(unsigned int)
q	1 integer	8	yes	native	< >	Requires 64-bit-integer Perl
Q	1 integer	8	no	native	< >	Requires 64-bit-integer Perl
n	1 integer	2	no	big	!	Portable network order; n! = signed

continues on next page

Table 1 – continued from previous page

Directive	Consumes	W	Signed	Endian	Modifiers	Notes
N	1 integer	4	no	big	!	Portable network order; N! = signed
v	1 integer	2	no	little	!	"VAX" order; v! = signed
V	1 integer	4	no	little	!	"VAX" order; V! = signed
j	1 integer	IV size	yes	native	< >	Perl-internal signed integer
J	1 integer	UV size	no	native	< >	Perl-internal unsigned integer
f	1 number	4	-	native	< >	Single-precision IEEE 754
d	1 number	8	-	native	< >	Double-precision IEEE 754
F	1 number	NV size	-	native	< >	Perl-internal float (NV)
D	1 number	varies	-	native	< >	Long double; format varies by platform
p	1 string / undef	ptr	-	native	< >	Pointer to NUL-terminated string; undef → null pointer
P	1 string / undef	ptr	-	native	< >	Pointer to fixed-length buffer; count = buffer length
u	1 string	varies	-	-	-	Uuencoded; count = max bytes per output line (default 45)

continues on next page

Table 1 – continued from previous page

Directive	Consumes	W	Signed	Endian	Modifiers	Notes
`U`	1 code-point	varies	-	-	-	Unicode character number; encodes to UTF-8 in `U0` mode
`w`	1 integer ⩾ 0	varies	no	-	-	BER-compressed integer, big-endian base-128
`x`	nothing	1	-	-	!	Insert one `NUL`; `x!N` aligns to multiple of `N`
`X`	nothing	−1	-	-	!	Back up one byte; `X!N` aligns backward
`@`	nothing	absolute	-	-	!	Zero-fill or truncate to position N within group
`.`	1 integer	absolute	-	-	!	Zero-fill or truncate to position given by the value
`( … )`	-	-	-	-	`< > !`	Group: repeat count and endianness propagate inside
`/`	-	-	-	-	-	**Unpack-only.** In pack, use *length-item*`/`*item*

The modifiers:

Modifier	Effect
`!`	On `s` / `S` / `l` / `L` / `i` / `I`: use native `sizeof(…)` instead of fixed width. On `x` / `X`: turn into alignment commands. On `n` / `N` / `v` / `V`: interpret as signed. On `@` / `.`: count bytes of the internal representation, not characters.
`>`	Force **big-endian** byte order ("big end touches the construct").
`<`	Force **little-endian** byte order.

Applied to a group, `<` / `>` cascade into every byte-ordered directive inside the group and are silently ignored by directives that do not accept them.

Repeat counts

A directive letter may be followed by:

- a **number** `N` - apply the directive that many times, consuming `N` values from `LIST`
- `*` - consume all remaining values; for `x` / `X` / `@` this is equivalent to `0`; for `u` it selects the default of 45
- `[N]` - equivalent to a bare `N`
- `[template]` - the repeat count is the packed byte length of *template*. `x[L]` skips as many bytes as a packed long; `x![d]` aligns to a double boundary

String and bit/nybble directives treat the count as **width of a single value**, not count-of-values: `pack "A4", "abcdef"` produces `"abcd"`, not four copies of `"abcdef"`.

Grouping

Parentheses group directives. A group may take a repeat count or an endianness modifier:

```
pack "(sl)<", -42, 4711     # same as "s<l<", -42, 4711
pack "(CCS)*", @triplets    # repeat group for every triplet
```

Within each repetition of a group, `@` positioning starts over at 0 - `pack '@1A((@2A)@3A)', qw(X Y Z)` produces `"\0X\0\0YZ"`.

Length-prefixed payloads (`/`)

Write `length-item/sequence-item`. The length is computed from the sequence value and packed according to *length-item*; then the sequence itself is packed according to *sequence-item*:

```
my $msg = pack "n/a*", "hello, world";
# "\x00\x0chello, world" - 16-bit big-endian length, then the bytes
```

The length directive may be any integer directive (`n`, `N`, `w`, `C`, …) or even a string directive (`A4`, `Z*`) when you want the length written as ASCII.

Examples

Build a fixed-width record with two NUL-terminated strings and a 32-bit native timestamp:

```
my $rec = pack "Z8 Z8 L", "alice", "server01", $now;
# 8 + 8 + 4 = 20 bytes
```

Portable network byte order - prefer `n` / `N` / `v` / `V` over native-width directives when the bytes leave the machine:

```
my $be = pack "n N", 42, 4711;      # big-endian 16 + 32 bit
my $le = pack "v V", 42, 4711;      # little-endian
my $sx = pack "s>l>", -42, 4711;    # signed big-endian via modifier
my $gx = pack "(sl)<", -42, 4711;   # signed little-endian via group
```

Align a field inside a C struct. `x![d]` inserts just enough `NUL` bytes to reach the next multiple of a double's width:

```
# struct { char c; double d; char cc[2]; }
my $s = pack "c x![d] d c2", $c, $d, $c1, $c2;
```

Round-trip through a hex string:

```
my $raw = pack "H*", "deadbeef";    # "\xde\xad\xbe\xef"
my $hex = unpack "H*", $raw;        # "deadbeef"
```

Edge cases

- **Too few values**: missing values are treated as `""`. `pack "A4 A4", "hi"` yields `"hi \0\0\0\0"`, not a fatal error.
- **Too many values**: extras are silently ignored.
- **`a` vs `A` vs `Z`**: all three pad to an exact width. `a` pads with `NUL`, `A` pads with space, `Z` pads with `NUL` **and** guarantees a trailing `NUL` - so `Z8` encodes at most 7 data bytes plus the terminator.
- **Character width vs byte width** - the single most common trap. Counts for `a` / `A` / `Z` and offsets for `@` / `.` are in **characters of the packed string**, not bytes. In `C0` mode a character is one byte; in `U0` mode a character may span multiple UTF-8 bytes. Use the `!` modifier on `@` / `.` when you need byte offsets regardless of mode.
- **Endianness on `s` / `S` / `l` / `L` / `i` / `I` / `q` / `Q`**: native only, not portable. Use `n` / `N` / `v` / `V` or apply `>` / `<` explicitly. `f` / `d` are likewise native; IEEE 754 alone does not pin down endianness.
- **`Inf` / `NaN` packed as integers**: fatal error. No sensible mapping exists.
- **`q` / `Q` on non-64-bit Perl**: raises an exception.
- **`p` and `P` capture pointers** into the caller's memory. The referent must remain live until the packed string is consumed - a temporary string passed to `p` may be freed before you read it back. Avoid outside XS code.

- **Grouping and @**: positioning with `@` starts over at 0 inside every repetition of a group. `pack '@1A((@2A)@3A)', qw(X Y Z)` produces `"\0X\0\0YZ"`, not what a naive reading suggests.
- **Floating-point round-trip loss**: Perl stores numbers as doubles, so `unpack("f", pack("f", $x))` generally does not equal `$x` - packing through single precision truncates.
- **Writing packed bytes to a text handle**: a handle with `:utf8` or `:encoding(…)` will re-encode the bytes. Use `binmode $fh` or open with `">:raw"`.

Differences from upstream

Fully compatible with upstream Perl 5.44.

Scoping · Modules · Classes and OO

package

Declare the compile-time namespace for the declarations that follow.

`package` tells the compiler which symbol table to use when it resolves unqualified names in the code it is about to parse. It does **not** create a package in any run-time sense - packages spring into existence the first time something is stored in them. What a `package` statement really does is re-point the compiler: from here on, `$foo` means `$NAMESPACE::foo`, `&bar` means `&NAMESPACE::bar`, and so on, until the next `package` statement or the end of the enclosing scope.

Synopsis

```
package NAME;
package NAME VERSION;
package NAME      { ... }
package NAME VER { ... }
```

What you get back

`package` is a compile-time directive, not an expression. It has no useful runtime value - treat it as a statement. Its effect is on the parser: all subsequent unqualified identifiers resolve in `NAME`'s symbol table until scope ends.

The form with `VERSION` has one visible side effect: it sets `$NAME::VERSION` to a `version` object built from `VERSION`. This happens exactly once per `package NAME VERSION` statement, at compile time.

Global state it touches

- **The current compile-time package.** Every `package` statement replaces it for the rest of the scope. `__PACKAGE__` returns the current value at any point in the source.
- `$NAME::VERSION` - set when the `VERSION` argument is provided. Set it only once per package.
- The target symbol table (stash) is created on first use. A package's stash is itself a hash named `%NAME::` (so `main`'s is `%main::`), keyed by the unqualified symbol names it holds. Nothing is populated by the `package` statement itself; subsequent declarations (`sub`, `our`, assignments to `$NAME::foo`, etc.) fill it.

The four forms

`package NAMESPACE`

Switches the compile-time package to `NAMESPACE` from this point to the end of the current scope (enclosing block, file, or `eval`). This is the classic "one package per file" form:

```
package My::Thing;

sub new { ... }          # defines &My::Thing::new
our $count = 0;          # defines $My::Thing::count

1;
```

`package NAMESPACE VERSION`

Same scoping as the bare form, plus it sets `$NAMESPACE::VERSION` to a `version` object. `VERSION` must be a **strict** version literal: either a positive decimal (`1.23`, `0.001`) or a dotted-decimal v-string with a leading `v` and at least three components (`v1.2.3`). Exponent notation is not allowed.

```
package My::Thing 1.042;
package My::Thing v1.2.3;
```

Set `$VERSION` only once per package - a second `package NAME VERSION` statement in the same package overwrites the first, and `use Module VERSION` consumers see only the final value.

package NAMESPACE BLOCK

Lexically scopes the package switch to BLOCK. Inside the braces the compile-time package is NAMESPACE; **outside the closing brace the previous package is restored**. This is the only form that reverts automatically.

```
package Outer;
our $x = 1;              # $Outer::x

package Inner {
    our $y = 2;          # $Inner::y
}

our $z = 3;              # $Outer::z again
```

package NAMESPACE VERSION BLOCK

The block form with a version literal. Scope reverts at the closing brace; `$NAMESPACE::VERSION` stays set.

```
package My::Sub v0.9.1 {
    sub ping { "pong" }
}
```

What package does and does not scope

`package` affects **dynamic (package) variables** and unqualified name resolution. It does not affect lexicals:

- `my`, `state` - created in the lexical pad, invisible to package lookup. A `package` statement does nothing to them.
- `local` - dynamically scopes a package variable, which still belongs to whatever package its fully-qualified name names.
- `our` - declares a lexical alias to a package variable in the *current compile-time package*. This is the mechanism that lets `our $count` inside `package My::Thing` alias `$My::Thing::count`.

Switching packages after an `our` declaration does not retarget the alias: the alias was bound to the package in effect when `our` was compiled.

```
package Foo;
our $x;                  # aliases $Foo::x
package Bar;
$x = 1;                  # still writes $Foo::x
```

Interaction with use v5.36 and newer

`use v5.36` (and any `use v5.36` or later) enables `strict` and `warnings` implicitly. Once strict is on, unqualified package variables require an `our` declaration (or full qualification). Combined with a `package` statement, the idiomatic modern file skeleton is:

```
package My::Thing 1.00;

use v5.36;              # strict, warnings, say, signatures, ...

our @EXPORT_OK = qw(thingify);

sub thingify { ... }

1;
```

The `package NAME VERSION` form and `use VERSION` are independent: the first sets `$My::Thing::VERSION`; the second enables language features for the current file.

Special identifiers that always mean `main::`

A small set of identifiers are forced into the `main::` package regardless of the current package:

- `STDIN`, `STDOUT`, `STDERR`, `ARGV`, `ARGVOUT`
- `@ARGV`, `@INC`, `%ENV`, `%SIG`, `%INC`
- All punctuation variables: `$_`, `$!`, `$@`, `@_`, etc.
- The single-character identifier `_`, in all its sigils: the underscore filehandle used by `stat` and the `-X` file tests, the scalar `$_`, and the array `@_`.

Writing to `$!` inside `package Foo` still writes to `$main::!`. This is by design: these names would be useless if they moved with the package.

Examples

A minimal module file. The file name must match the package name (`require` translates `::` to the directory separator):

```
# lib/My/Greeter.pm
package My::Greeter 1.00;
use v5.36;

sub new  { my ($cls, %a) = @_; bless { %a }, $cls }
sub greet { my $self = shift; "hello, $self->{name}\n" }

1;
```

Two packages in one file using the block form. Scope reverts automatically, so the `1;` at the bottom belongs to no package in particular - it's evaluated in whichever package was active at the top of the file (`main` for a script, the file's own package for a module):

```
package My::Thing {
    sub do_stuff { ... }
}
```

(continues on next page)

(continued from previous page)

```
package My::Thing::Helper {
    sub helper { ... }
}
```

Switching back and forth in the statement form - legal but rarely what you want:

```
package A;
sub one { 1 }           # &A::one

package B;
sub two { 2 }           # &B::two

package A;
sub three { 3 }         # &A::three
```

Setting a version and reading it back. Note that `$VERSION` is a `version` object, not a plain string; stringify or compare with `version`:

```
package Foo 1.23;

say $Foo::VERSION;      # 1.23
say ref $Foo::VERSION;  # version
```

`our` inside a package gives you a lexically-scoped alias to a package variable - the canonical way to declare module-level globals under `strict`:

```
package Counter;
use v5.36;

our $count = 0;         # aliases $Counter::count
sub bump { $count++ }
```

Edge cases

- **`package NAMESPACE VERSION` accepts only strict version literals.** Exponent notation (`1e3`), non-numeric strings, and two-component v-strings (`v1.2`) are compile errors.
- **Setting `$VERSION` twice** in the same package (whether by two `package NAME VERSION` statements or by explicit assignment after a `package NAME VERSION`) is legal but confusing - `use Module VERSION` checks the final value, and CPAN tooling reads whichever one it finds first. Declare the version once.
- **The block form is a separate lexical scope.** `my` and `state` variables declared inside a `package NAME { ... }` are not visible outside, just like any other block.
- **`package NAMESPACE` without a trailing statement or block** affects the rest of the file. A `package` at the top of a script permanently switches the script out of `main`, which means `$main::ARGV[0]` is still your argument list but freshly declared globals belong to the new package. This is almost never what a script wants.

- **A file that contains only `package Foo;` and no other code** still compiles cleanly and creates the `Foo::` stash on first reference - but `require`ing it returns the value of the last statement, which is the `package` statement itself (false). Put `1;` at the end of every module file.
- **Nested block forms** restore the immediately enclosing package, not `main`:

```
package Outer;
package Inner {
    package Innermost {
        # __PACKAGE__ is Innermost
    }
    # __PACKAGE__ is Inner again
}
# __PACKAGE__ is Outer again
```

- **`package` inside `eval`.** The package switch is scoped to the `eval` body. Symbols created during the `eval` persist in their stashes (stashes are global), but the compile-time package reverts when the `eval` ends.
- **Apostrophe as package separator.** The apostrophe was Perl's original namespace separator: `$main'sail` meant `$main::sail`, long before `::` existed. It survives only for reading Perl 4 era code and is disabled under modern feature bundles, so a current program written with `use v5.36` (or any recent bundle) will not recognise it. Do not write it; the double-colon `::` is the only separator current code should use.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `use` - load a module at compile time and import symbols from its package; typically paired with a `package` declaration at the top of the loaded file
- `require` - load a module or file at runtime; the loaded file's `package` statement determines which stash its declarations populate
- `bless` - associate a reference with a package so method calls dispatch to that package's subs; the glue between `package` and OO
- `my` - declare a lexical variable that `package` does **not** affect; the counterpart to package globals
- `our` - declare a lexical alias to a package variable in the current compile-time package; the strict-safe way to use module-level globals
- `local` - dynamically scope a package variable's value without changing which package it belongs to

Processes

pipe

Open a pair of connected filehandles - one for reading, one for writing.

`pipe` wraps the `pipe(2)` system call. It creates an unnamed, unidirectional byte channel in the kernel and hands you two filehandles: `READHANDLE`, from which bytes can be read, and `WRITEHANDLE`, into which bytes can be written. Anything written to `WRITEHANDLE` becomes available on `READHANDLE` in the same order. The classic use is communication between a parent process and a child produced by `fork`: one side writes, the other reads.

Synopsis

```
pipe READHANDLE, WRITEHANDLE
```

What you get back

True on success, false on failure (with `$!` set to the reason - typically `EMFILE` or `ENFILE` when the process or system file-table is full). Both handles are created as side effects on the arguments; there is no "pipe object" return value.

On success you now hold **two** open file descriptors. Every descriptor you create is a descriptor you must `close` - especially the end each process does **not** use after a `fork` (see *Edge cases*).

Global state it touches

- `$!` - set on failure to the `errno` from the underlying `pipe(2)` call.
- `$|` - **autoflush** on the write-side handle. `print` buffers through PerlIO, so without autoflush the reader may see nothing until the writer exits or the buffer fills. Set `$|` on the write handle (typically via `select`) before writing, or your protocol will deadlock.
- `$^F` - the **maximum system filehandle**. New descriptors with `fileno` greater than `$^F` (default 2, i.e. above `STDERR`) have the close-on-exec flag set automatically, so they do not leak into programs started by `exec`. Lower `$^F` to keep the pipe open across `exec`; raise it, or dup onto a low-numbered fd, to force inheritance.

Examples

A parent writes a line; a forked child reads it:

```
pipe my $reader, my $writer or die "pipe: $!";

my $pid = fork // die "fork: $!";
if ($pid == 0) {
    # child: reads only
    close $writer;
    my $line = <$reader>;
    print "child saw: $line";
    close $reader;
```

(continues on next page)

(continued from previous page)

```
    exit 0;
}

# parent: writes only
close $reader;
$writer->autoflush(1);
print $writer "hello from parent\n";
close $writer;
waitpid $pid, 0;
```

The child reports the other direction - a child produces data, the parent consumes it:

```
pipe my $reader, my $writer or die "pipe: $!";

my $pid = fork // die "fork: $!";
if ($pid == 0) {
    close $reader;
    $writer->autoflush(1);
    print $writer "$_\n" for 1 .. 5;
    close $writer;
    exit 0;
}

close $writer;
while (my $line = <$reader>) {
    print "got: $line";
}
close $reader;
waitpid $pid, 0;
```

Autoflush from the selected-handle side, for code that predates `IO::Handle` method calls:

```
pipe my $reader, my $writer or die "pipe: $!";
my $old = select $writer; $| = 1; select $old;
```

For most uses, `open` with a pipe mode is simpler - it forks, pipes, and `exec`s for you:

```
open my $fh, '|-', 'gzip', '-c' or die $!;   # write to gzip's stdin
print $fh "data\n";
close $fh;

open my $fh, '-|', 'ls', '-l'   or die $!;   # read from ls's stdout
while (my $line = <$fh>) { print $line }
close $fh;
```

Reach for bare `pipe` when you need both directions, need to retain the unexec'd child, or are building something `open`'s two pipe-forms do not cover - then `IPC::Open2` / `IPC::Open3` wrap the `pipe` + `fork` + `exec` dance for you.

Edge cases

- **Close the end you do not use.** After `fork`, **both** processes hold **both** descriptors. The reader must close the write end, and the writer must close the read end. Skip this and you get the classic pipe bug: the reader's `<$reader>` never returns EOF, because the kernel still sees a writer open (the reader's own, idle, copy of `$writer`). The program hangs.
- **Writing to a reader-less pipe raises `SIGPIPE`.** Once every copy of the read end is closed, the next `print` on the write side delivers `SIGPIPE`, whose default action is to kill the process. Install `$SIG{PIPE} = 'IGNORE'` (or a handler) to turn it into a normal write failure with `$!` set to `EPIPE`, which you can then check.
- **Deadlock in pipe loops.** Two processes each writing to the other through pipes will block forever if both write buffers fill before either process reads. Kernel pipe buffers are small (typically 64 KiB). Drain one side, use non-blocking I/O, or use `select` / `IO::Select` to multiplex.
- **Buffering hides writes.** Without `$|` (or `$writer->autoflush(1)`) on the write side, data sits in PerlIO's buffer until the buffer fills or the handle is closed. A reader blocked on `<$reader>` will wait - often indefinitely - for data that has already been "written" from the writer's point of view.
- **Unidirectional only.** `pipe` produces a one-way channel: write to `WRITEHANDLE`, read from `READHANDLE`, not the reverse. For bidirectional communication use `socketpair` or two pipes.
- **Binary data.** The handles returned by `pipe` start in the default PerlIO layer stack. If you are moving raw bytes across the pipe, apply `binmode` to both ends; otherwise CRLF or encoding layers inherited from the process defaults can rewrite your data.
- **Close-on-exec and `fileno`.** On systems with `FD_CLOEXEC`, any new descriptor whose `fileno` exceeds `$^F` is created with the close-on-exec flag set. Pipe descriptors typically land well above 2, so by default they do **not** survive `exec` - which is normally what you want. Lower `$^F` *before* calling `pipe` if you intend to pass the descriptors to an `exec`'d program.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `fork` - the other half of the pipe idiom; `pipe` is almost always called just before a `fork`
- `open` - the `'|-'` and `'-|'` modes fork, pipe, and `exec` a child in one call; prefer them when you need exactly one direction to one external command
- `close` - closing the unused end in each process is mandatory, not optional
- `read` - byte-oriented reads from `READHANDLE` when the line-oriented `<$fh>` form is the wrong shape
- `print` - the normal way to push data into `WRITEHANDLE`; remember `$|`

- `fileno` - recover the underlying file descriptor, e.g. to hand to `select` / `IO::Select` or to a lower-level system call

Arrays

pop

Remove and return the last element of an array.

pop shortens the array by one and hands you the element that was removed. The array is modified in place. With no argument, pop operates on `@_` inside a subroutine and on `@ARGV` everywhere else - the same default target as `shift`.

Synopsis

```
pop @arr
pop @$aref
pop                 # default: @_ inside a sub, @ARGV outside
```

What you get back

The element that was removed, as a scalar. If the array was empty, the return value is `undef` and the array stays empty - this is not an error and emits no warning, so code that always calls pop in a loop needs its own termination check.

```
my @empty;
my $x = pop @empty;         # $x is undef, no warning
```

Note that pop also returns `undef` when the last element *was* `undef`. The two cases are indistinguishable from the return value alone; use `@arr` in boolean context, or `scalar @arr`, to tell them apart before popping.

```
my @arr = ('one', 'two', undef);
my $x = pop @arr;           # $x is undef - but so would an empty␣
↪pop be
```

Global state it touches

pop with no argument reads `@_` (inside a subroutine) or `@ARGV` (at file scope, in `BEGIN`/`INIT`/`CHECK`/`END` blocks, and inside `eval STRING`). It does not interact with `$_`, `$,`, `$\`, or any other punctuation variable.

Examples

Basic use - pull the last element off a plain array:

```
my @arr  = ('cat', 'dog', 'mouse');
my $item = pop @arr;        # $item is 'mouse'
# @arr is now ('cat', 'dog')
```

LIFO stack - `push` to add, pop to remove, both at the same end:

```
my @stack;
push @stack, 'a';
push @stack, 'b';
push @stack, 'c';
my $top = pop @stack;       # 'c'; @stack is ('a', 'b')
```

Discard the last element when you do not need its value. pop in void context is perfectly valid and is the idiomatic way to drop the tail:

```
pop @arr;                   # shorten @arr by one, value thrown away
```

Default target inside a subroutine - pop with no argument pops from @_, which is how a sub peels its last argument off the argument list:

```
sub last_arg {
    return pop;             # pops from @_
}
last_arg(1, 2, 3);          # returns 3
```

Pop through an array reference. Dereference with `@$aref` (or `@{ $aref }` for any non-trivial expression) and pop works exactly as on a named array:

```
my $aref = [10, 20, 30];
my $x    = pop @$aref;      # 30; $aref now points to [10, 20]
```

Edge cases

- **Empty array returns undef, not an error.** No warning is issued, even under `use warnings`. A loop of the form `while (defined(my $x = pop @arr)) { ... }` terminates on empty *or* on a genuine undef element - use `while (@arr)` instead if the array may legitimately contain undef.
- **Bareword expression in place of ARRAY.** pop requires an array, not an arbitrary expression. pop `@$aref` works because `@$aref` is array syntax; pop `$aref` was briefly allowed as an experiment between 5.14 and 5.22 and has been a compile error since 5.24. Always write the explicit @ sigil on the dereference.
- **Tied arrays.** pop `@tied` calls the tied class's POP method if defined; otherwise the default FETCHSIZE + FETCH + DELETE + STORESIZE fallback applies. Side effects of those methods fire in that order.
- **pop shortens the array.** After pop `@arr`, `$#arr` decreases by one and `scalar @arr` drops by one. If you need to inspect the tail without removing it, read `$arr[-1]` or `$arr[$#arr]` directly - see $#arr in perlvar.
- **No-argument form changes meaning by scope.** At file scope, pop; means pop @ARGV. Inside a subroutine it means pop `@_`. The same source line therefore behaves differently depending on where it appears - a common surprise when code is refactored into or out of a sub. Write the target explicitly (pop `@ARGV` or pop `@_`) whenever the intent is not obvious from context.
- **pop on an array aliased through @_.** Subroutine arguments are aliases to the caller's values. pop `@_` removes the alias entry from `@_` but does not shorten the

caller's array; to shrink the caller's array the sub must be passed the array *by reference* and pop `@$aref` used instead.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `push` - the counterpart; append to the same end of the array that pop removes from
- `shift` - remove and return the *first* element; same defaulting rules as pop (`@_` in a sub, `@ARGV` otherwise)
- `unshift` - prepend to the front; paired with `shift` the way `push` is paired with pop
- `splice` - remove or replace an arbitrary slice; `splice @arr, -1` is the long-hand form of `pop @arr`
- `last` - loop-control keyword, unrelated to array end; listed because the names are often confused
- `$#arr` - last index of `@arr`; changes when pop shortens the array

Regular expressions and pattern matching

pos

Report or set where the next `/g` regex match will resume in a string.

`pos` reads (or, as an lvalue, writes) the offset that the regex engine stores on a scalar after a global match (`m//g`, `s///g`). The offset counts characters, not bytes, and is the position **after** the last successful match - the place the next `/g` iteration will start scanning. With no argument `pos` operates on `$_`.

Synopsis

```
pos SCALAR
pos $str = N
pos
```

What you get back

An integer offset, or `undef` when no position is recorded. `0` is a valid offset and means "start of string"; it is not the same as `undef`, which means "no `/g` match has run, or the last one failed and reset the position." Always distinguish the two with `defined`:

```
if (defined pos $str) {
    # a /g scan is in progress
}
```

Used as an lvalue, `pos SCALAR` returns an assignable location:

```
pos($str) = 5;          # next /g match starts at char offset 5
```

Global state it touches

pos reads and writes the per-scalar regex position attached to its operand. With no argument it targets $_. The stored offset is what \G anchors against in the next match, so every call to pos potentially changes where \G binds.

Examples

Walk every word in a string with /g in scalar context, using pos to report progress:

```
my $s = "one two three";
while ($s =~ /(\w+)/g) {
    printf "%-5s ends at %d\n", $1, pos $s;
}
# one   ends at 3
# two   ends at 7
# three ends at 13
```

Skip ahead before starting the scan. The first match begins at offset 4, not 0:

```
my $s = "AAA BBB CCC";
pos($s) = 4;
$s =~ /(\w+)/g;
print $1, "\n";             # BBB
```

Anchor a follow-up match to the previous one with \G. Without \G the engine would scan forward past any gap; with it, the match must start exactly where the last one ended:

```
my $s = "12ab34cd";
while ($s =~ /\G(\d+)(\w+?)(?=\d|\z)/g) {
    print "num=$1 tail=$2\n";
}
# num=12 tail=ab
# num=34 tail=cd
```

Restart a scan by clearing the position:

```
pos($s) = undef;            # next /g starts from offset 0 again
```

Edge cases

- **Bare pos** targets $_. pos inside `while (<>) { ... }` therefore reports the position on the current input line.
- **Characters, not bytes.** For a string containing multi-byte characters, pos returns the character offset. The (deprecated) `use bytes` pragma switches to byte offsets; new code should not rely on it.

- **Failed `/g` match resets the position to `undef`** - the next `/g` starts over at offset `0`. Add the `/c` modifier (`m//gc`) to preserve the position on failure, which is the usual idiom when composing several alternative `\G`-anchored patterns against the same string.
- **Reads during a match are stale.** `pos` reflects the **previous** match's end. Expressions like `(?{ pos() = 5 })` or `s//pos() = 5/e` influence the next match, not the one currently running.
- **Zero-length match flag.** Setting `pos` also clears the internal *matched with zero-length* flag, so a subsequent zero-width match at the same position is allowed again. See the *performance chapter* of the regex guide under *zero-length-match termination*.
- **Non-lvalue operand.** `pos` requires a real scalar variable for the lvalue form; `pos("literal") = 3` is a compile-time error.
- **Offset `0` vs `undef`.** `pos` of `0` means the next `/g` starts at the beginning; `undef` means no position is set. They behave identically for the first match but differ after the zero-length-match flag state is considered.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `m` - the `/g` modifier is what creates and advances the position `pos` reads; the `/c` modifier on failure preserves it
- `qr` - precompile a pattern once, then reuse it in `\G`-anchored `/g` loops without reparsing
- `split` - the other everyday way to walk a string in pieces; no `pos` involved, but often a cleaner choice when the delimiters are simple
- `\G` *anchor* - zero-width anchor that binds to the current `pos`; the main reason to touch `pos` in the first place
- `$_` - default target of bare `pos`

I/O

print

Write a list of values to a filehandle.

`print` is the everyday output primitive. It stringifies each item in `LIST`, joins them with the current value of `$,` (the output field separator, usually empty), writes them to `FILEHANDLE`, and finally appends `$\` (the output record separator, usually empty). If `FILEHANDLE` is omitted, output goes to the currently selected handle (see `select`), which defaults to `STDOUT`. If `LIST` is omitted, `$_` is printed.

Synopsis

```
print LIST
print FILEHANDLE LIST
print {EXPR} LIST
print
```

What you get back

1 on success, `undef` on failure (with `$!` set). The return value is rarely checked - most `print` calls target `STDOUT` or `STDERR` and a write failure to either is already a program-ending condition. Check the return value when writing to a file, pipe, or socket where partial writes and broken pipes matter.

```
print $fh @records
    or die "write to $path failed: $!";
```

Default filehandle, default separators

Three pieces of global state shape every `print` call:

- The **currently selected filehandle**, changed with `select`. `print LIST` (no explicit filehandle) writes there. At program start this is `STDOUT`.
- `$,` - **output field separator**, inserted between list items. Default is the empty string, so `print 1, 2, 3` produces 123, not `1 2 3`. Also known as `$OFS` under `use English`.
- `$\` - **output record separator**, appended after the whole list. Default is the empty string, so `print` does **not** add a newline. Also known as `$ORS` under `use English`.

Setting both gives Python-like `print` semantics:

```
local $, = " ";
local $\ = "\n";
print 1, 2, 3;          # "1 2 3\n"
```

Use `local` when changing these inside a subroutine so the change does not leak to the caller.

`say` is exactly `print` with `$\` forced to `"\n"` for that one call - reach for it when you want a newline every time and do not want to touch `$\`.

Examples

Basic write to `STDOUT`:

```
print "hello, world\n";
```

Write to a filehandle with the indirect-object form. Note: **no comma** between the filehandle and the list:

```
open my $fh, ">", "out.txt" or die $!;
print $fh "line 1\n", "line 2\n";
close $fh;
```

Write to a filehandle held in an expression. Any filehandle more complex than a bareword or a plain scalar needs the `{EXPR}` block form:

```
my @logs = (\*STDOUT, \*STDERR);
print { $logs[$level] } "message\n";
```

Join list items with `$,` and terminate the record with `$\`:

```
local $, = ", ";
local $\ = ".\n";
print "apples", "pears", "plums";   # "apples, pears, plums.\n"
```

A list containing `undef` - each `undef` stringifies to the empty string and triggers an `uninitialized` warning under `use warnings`:

```
use warnings;
my $x;
print "value=", $x, "\n";           # "value=\n" plus a warning
```

List context vs scalar context. `@arr` in `LIST` position expands to its elements; wrap in `scalar` to print the count instead:

```
my @arr = (10, 20, 30);
print @arr, "\n";                   # "102030\n"
print scalar @arr, "\n";            # "3\n"
```

Suppressing the `undef` warning for a block where missing values are expected and intended to render as empty:

```
no warnings 'uninitialized';
print join(",", @row), "\n";        # empty fields render as ""
```

Edge cases

- **No arguments**: `print;` prints `$_` to the selected handle. Used idiomatically inside `while (<>) { print; }`.
- **The filehandle-or-first-arg ambiguity**: Perl decides whether the first token is a filehandle by parsing, not by runtime type. A bareword or a simple scalar variable immediately followed by a term (no comma) is taken as a filehandle:

  ```
  print STDERR "oops\n";            # STDERR is the filehandle
  print $fh "oops\n";               # $fh is the filehandle
  ```

  An expression that returns a filehandle does **not** work in that position - `print $handles[0] "x"` is a syntax error. Use the block form: `print { $handles[0] } "x"`.

- **List context applies to every argument**. A subroutine call in `LIST` runs in list context, not scalar:

```
print localtime(), "\n";          # prints nine numbers, no␣
 ↪spaces
print scalar localtime(), "\n";   # prints the familiar date␣
 ↪string
```

- **`print (…)` parses as a function call**. `print (2+3)*4` prints 5, then discards `*4`. Parenthesise the whole argument list, or prefix with `+`:

```
print((2+3)*4);                   # prints 20
print +(2+3)*4;                   # prints 20
```

- **Closed filehandle**: returns `undef` and sets `$!` to `"Bad file descriptor"`. Under `use warnings` a `print() on closed filehandle` warning is emitted.
- **Encoding layers**: `print` writes whatever the handle's PerlIO stack says to write. If the handle has a `:utf8` or `:encoding(...)` layer, strings are encoded on the way out. Bytes-mode handles expect byte strings; passing a wide-character string writes raw codepoints and emits a `Wide character in print` warning.
- **Autoflush**: `print` buffers through PerlIO. Set `$|` on the selected handle to flush after every write - commonly needed for progress output on pipes or when coordinating with another process:

```
$| = 1;                           # autoflush current handle
```

- **Printing to a closed pipe or socket** raises `SIGPIPE`. The default action is to terminate the process; install a handler (`$SIG{PIPE} = 'IGNORE'` or a sub) to turn it into a normal write failure you can check.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `say` - `print` with `$\` forced to `"\n"` for the call; use it when every record ends in a newline
- `printf` - same targeting rules as `print`, but the first argument is a `sprintf` format string and `$\` is **not** appended
- `sprintf` - build the formatted string without writing it; combine with `print` when you want to log it somewhere else first
- `select` - change which filehandle the no-argument form of `print` writes to
- `$,` - output field separator inserted between list items
- `$\` - output record separator appended after the list
- `$|` - autoflush flag for the currently selected handle

I/O

printf

Write a formatted string to a filehandle.

`printf` is `print FILEHANDLE sprintf(FORMAT, LIST)` with one deliberate exception: the output record separator `$\` is **not** appended. The targeting rules are otherwise the `print` rules - bareword or simple-scalar filehandle immediately before the argument list, or the `{EXPR}` block form for anything more complex. If `FILEHANDLE` is omitted, output goes to the currently selected handle (see `select`), which starts life as `STDOUT`.

See `sprintf` for the format-specifier reference - everything `%d`, `%s`, `%.3f`, `%*d`, `%1$s`, `%v`, vector flags, locale-sensitive `%f`, and so on. This page covers only the `printf`-specific surface: filehandle resolution, the format-is-first rule, and the quirks around the no-argument form.

Synopsis

```
printf FORMAT, LIST
printf FILEHANDLE FORMAT, LIST
printf {EXPR} FORMAT, LIST
printf FH                       # bareword filehandle, $_ as format
```

What you get back

1 on success, `undef` on failure (with `$!` set). As with `print`, the return value is rarely checked for writes to `STDOUT` / `STDERR`, and worth checking for writes to files, pipes, and sockets where partial writes and broken pipes matter.

```
printf $fh "%-20s %8d\n", $name, $count
    or die "write to $path failed: $!";
```

Global state it touches

- **Selected filehandle** (changed via `select`): the destination when `FILEHANDLE` is omitted. Starts as `STDOUT`.
- `$\` (output record separator): deliberately **not** appended - this is the one semantic difference between `printf FORMAT, LIST` and `print FILEHANDLE sprintf(FORMAT, LIST)`. Put the newline in the format string.
- `$,` (output field separator): **not** consulted. `printf` splices list elements into the format according to the conversions, not with a separator.
- `$_`: used as the **format** when both `FORMAT` and `LIST` are omitted, not appended to output. Almost never what you want; see *Edge cases*.
- `$!`: set on write failure.
- `$|`: autoflush flag for the selected handle. `printf` buffers through PerlIO like `print`.

- `LC_NUMERIC` locale: when `use locale` is active and `POSIX::setlocale` has been called, the decimal separator for floating-point conversions (`%f`, `%e`, `%g`) follows the locale.

Examples

Basic formatted write to `STDOUT`. Unlike `say` or `print`-with-`$\`, the trailing newline is on you:

```
printf "%s is %d years old\n", $name, $age;
```

Width and precision for a tidy column:

```
printf "%-20s %8.2f\n", $item, $price;
```

Write to a filehandle. Bareword and simple scalar work directly; no comma between the filehandle and the format:

```
open my $fh, ">", "report.txt" or die $!;
printf $fh "%5d  %s\n", $n, $msg;
close $fh;
```

Filehandle held in a more complex expression - use the `{EXPR}` block form (same rule as `print`):

```
my @logs = (\*STDOUT, \*STDERR);
printf { $logs[$severity] } "[%s] %s\n", $tag, $msg;
```

Repeated format with a list that spans multiple records. `printf` does **not** re-apply the format per record - conversions are consumed once, left to right:

```
printf "%s=%s\n", "user", "alice";        # "user=alice\n"
printf "%s=%s\n%s=%s\n",                  # two records, one call
       "user", "alice", "host", "db1";
```

Locale-sensitive decimal separator:

```
use POSIX qw(setlocale LC_NUMERIC);
use locale;
setlocale(LC_NUMERIC, "de_DE.UTF-8");
printf "%.2f\n", 1234.5;                  # "1234,50\n"
```

Edge cases

- **No LIST given, `$_` becomes the format.** `printf;` and `printf FH;` (bareword filehandle) format `$_`. If `$_` contains any % conversions they expand against an empty argument list - each `%s` / `%d` becomes the empty string and `use warnings` emits a `Missing argument in printf` warning. To write `$_` verbatim use `print`, not `printf`.
- **Indirect filehandle without a list is ambiguous** and not supported. `printf $fh;` parses `$fh` as the format, not the filehandle. If you need a no-argument form with a

scalar filehandle, go through `print` or pass an explicit format: `printf $fh "%s", $_`.

- **The first argument is always the format.** `printf(@_)` uses `$_[0]` as the format and the remaining elements as arguments - this is a parsing rule, not a convention. Build the format deliberately; don't splat user-supplied lists into `printf` unless the first element is known-safe.
- **No `$\` is appended.** Embedding `"\n"` in the format is the idiomatic terminator. Setting `local $\ = "\n"` has no effect on `printf` output.
- **`$,` is ignored.** The output field separator is a `print` concept; `printf` joins nothing - it substitutes.
- **`printf (…)` parses as a function call**, just like `print`. `printf ("%d", 1)*2` computes `printf(...)` then multiplies the return value by 2 and discards it. Wrap the whole argument list in parens or prefix with `+` if you need to disambiguate.
- **Closed filehandle**: returns `undef` and sets `$!` to `"Bad file descriptor"`. Under `use warnings` a `printf() on closed filehandle` warning is emitted.
- **Encoding layers**: `printf` writes through the handle's PerlIO stack. A `:utf8` or `:encoding(...)` layer encodes on the way out; a bytes-mode handle with a wide-character string emits `Wide character in printf` and writes raw code-points.
- **`SIGPIPE` on closed pipe/socket**: default action terminates the process. Install `$SIG{PIPE}` to turn it into a checkable write failure.
- **Don't use `printf` where `print` suffices.** `printf "%s", $msg` is slower and more error-prone than `print $msg` - the format string is parsed on every call, and a stray `%` in `$msg` used as a format becomes a bug waiting to happen.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `print` - unformatted write with the same filehandle rules; faster, and appends `$\` where `printf` does not
- `sprintf` - build the formatted string without writing it; the format-specifier reference lives here
- `say` - `print` with `$\` forced to `"\n"`; reach for it when every record ends in a newline
- `select` - change which filehandle the no-filehandle form of `printf` writes to
- `$\` - output record separator; deliberately not appended by `printf`
- `$_` - used as the format when both `FORMAT` and `LIST` are omitted

Misc

prototype

Return the prototype string of a subroutine, or `undef` if it has none.

`prototype` inspects a subroutine and gives back the prototype the parser will use when compiling calls to it. `FUNCTION` is either a name (bareword or string) or a code reference. With no argument, the subroutine named by `$_` is looked up. A `CORE::` prefix asks for the prototype-equivalent of a core built-in.

Prototypes are the old compile-time parsing hints declared with `sub foo ($$@) { ... }`. They control how the parser shapes calls - they are **not** subroutine signatures (`sub foo ($x, $y) { ... }`), which are a separate feature that `prototype` does not report on.

Synopsis

```
prototype FUNCTION
prototype
prototype \&foo
prototype 'Some::Package::foo'
prototype 'CORE::push'
```

What you get back

A string describing the prototype, or `undef` when:

- the subroutine exists but has no prototype declared, or
- the name resolves to a `CORE::` built-in whose argument shape the prototype mini-language cannot express (for example `system`, `print`, `sort`).

The string is exactly the text that appeared between the parentheses in the sub declaration, canonicalised: whitespace removed, each character one of the prototype letters below.

Character	Meaning in the prototype
`$`	one scalar argument
`@`	list - absorbs all remaining arguments
`%`	hash - absorbs all remaining arguments as a list
`&`	code block or code reference
`*`	typeglob or bareword treated as one
`\$ \@ \% \& \*`	reference to a scalar / array / hash / code / glob (caller writes `@ary`, callee receives `\@ary`)
`\[...]`	reference where any of the bracketed sigils is accepted
`+`	array or hash, passed by reference automatically
`_`	scalar that defaults to `$_` if omitted
`;`	subsequent arguments are optional

A leading `&` with no parentheses after it, as in `sub f (&@) { ... }`, is what lets `map`, `grep` and `sort`-lookalikes take a block without a comma.

Global state it touches

`prototype` with no argument reads `$_` as the subroutine name. No other globals are consulted or modified.

Examples

Read a user-defined prototype:

```
sub add ($$)   { $_[0] + $_[1] }
print prototype 'add';                  # $$
print prototype \&add;                  # $$
```

A sub with no prototype returns `undef`:

```
sub plain { "hi" }
print defined(prototype 'plain') ? "yes" : "no";   # no
```

A `CORE::` query for a built-in whose shape fits the prototype language:

```
print prototype 'CORE::push';           # \@@
print prototype 'CORE::keys';           # \[%@]
print prototype 'CORE::pos';            # ${\;}
```

A `CORE::` query for a built-in that cannot be expressed as a prototype:

```
print defined(prototype 'CORE::system') ? "yes" : "no";   # no
print defined(prototype 'CORE::print')  ? "yes" : "no";   # no
```

Use it to build a wrapper that inherits the callee's calling convention - useful when writing generic dispatchers:

```
sub wrap {
    my $name  = shift;
    my $proto = prototype $name;
    # install a new sub with the same prototype string
    eval "sub wrapped_$name ($proto) { goto &$name }";
}
```

Edge cases

- **No argument uses `$_`.** `prototype` with nothing between it and the next term consults `$_` as the sub name. A loop like `for (@names) { print prototype, "\n" }` works by accident of this rule.
- **Signatures are not prototypes.** `sub f ($x, $y) { ... }` declares a signature - `prototype 'f'` returns `undef`, because the sub has no prototype. To declare both, use the `:prototype(...)` attribute: `sub f :prototype($$) ($x, $y) { ... }`.
- **Unknown name returns `undef`.** If the sub has never been declared, `prototype` returns `undef` without raising an error. Combine with `defined` and `exists`

`&Some::Package::name` when you need to tell "no prototype" apart from "no such sub".

- **Auto-loaded subs**. If the sub is handled by `AUTOLOAD`, it has not been compiled yet, so `prototype` reports `undef` even when the eventual callable would have one. Force a stub first (`*foo = \&foo` after loading) if you must query it.
- **References versus names are interchangeable**. `prototype \&foo` and `prototype 'foo'` return the same string; pick whichever is cheaper at the call site. A reference skips package-name lookup.
- **Fully qualified names**. Unqualified names are looked up in the current package. For callers-of-callers, always qualify: `prototype 'Other::Pkg::fn'`.
- **Empty prototype is not `undef`**. `sub nullary () { 42 }` gives `prototype 'nullary'` the empty string `""`, which is defined and false. Use `defined`, not truthiness, to test for "has a prototype".

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `sub` - declare the subroutine whose prototype you are about to read
- `defined` - the correct test for "does this sub have a prototype," since an empty-string prototype is valid
- `ref` - companion inspector when `FUNCTION` is a code reference and you want to verify the ref type before calling `prototype`
- `caller` - neighbour introspector that answers "who called me," often used with `prototype` when building wrappers
- `wantarray` - runtime context query, the counterpart to compile-time prototype inspection
- `perlsub` - the prototype mini-language and how the parser applies it to call sites

Arrays

push

Append one or more values to the end of an array.

`push` adds every element of `LIST` to the end of `ARRAY`, in order. It is the paired counterpart of `pop` at the tail and of `unshift` / `shift` at the head. The array grows in place; no new array is returned.

Synopsis

```
push @arr, $val
push @arr, @more
```

(continues on next page)

(continued from previous page)

```
push @arr, list, of, values
push @$aref, $val
```

What you get back

The **new number of elements** in ARRAY after the append - i.e. `scalar @arr` as it stands once push returns. Not the pushed values, not the old length, not the array itself.

```
my @colors = ("red");
my $n = push @colors, "blue", "green";   # $n is 3
```

Useful when the push and the subsequent length check would otherwise be two statements:

```
if (push @queue, $job > $limit) { ... }  # one call, count + test
```

Examples

Basic append of a single value:

```
my @animals = ("cat");
push @animals, "mouse";                  # ("cat", "mouse")
```

Append several values in one call - each argument becomes its own element:

```
my @colors = ("red");
push @colors, "blue", "green";           # ("red", "blue", "green")
```

Append the contents of another array. The second array is flattened into the list, so its **elements** are appended, not the array as a single item:

```
my @a = (1, 2);
my @b = (3, 4);
push @a, @b;                             # (1, 2, 3, 4)
```

Queue discipline - push at the tail, `shift` at the head:

```
my @queue;
push @queue, $job;                       # enqueue
my $next = shift @queue;                 # dequeue
```

Stack discipline - push and pop at the same end:

```
my @stack;
push @stack, $frame;                     # enter
my $top = pop @stack;                    # leave
```

Push onto an array held by reference. The reference must be dereferenced with `@{ ... }` (or the short `@$ref` form) before push sees an array:

```
my $aref = [1, 2];
push @$aref, 3;                          # $aref now refers to [1,␣
 ↪2, 3]
push @{ $aref }, 4, 5;                   # same, explicit deref
```

Count elements after appending without a temporary:

```
my $size = push @log, $entry;
warn "log is large: $size entries" if $size > 1000;
```

Edge cases

- **Arrayref needs a deref.** `push $ref, $x` is a compile-time error in Perl 5.24+. Use `push @$ref, $x` or `push @{ $ref }, $x`. An experimental feature allowed a scalar first argument in 5.14–5.22 and was removed; do not rely on it.
- **Array arguments auto-flatten.** `push @a, @b` appends `@b`'s elements individually. To append `@b` as a single nested entry you need an arrayref: `push @a, \@b` or `push @a, [ @b ]`.
- **Hash arguments also flatten.** `push @a, %h` appends alternating keys and values in hash iteration order - almost never what you want. Use `push @a, \%h` to store the hash by reference instead.
- **List context but scalar return.** `push` is documented as taking a `LIST` and therefore evaluates its arguments in list context, but the value `push` itself produces is always the resulting count. Inside `print push @a, @b` the count is what gets printed, not the array.
- **Empty `LIST`.** `push @a;` (no second argument) is a no-op and returns the current `scalar @a`. Legal and occasionally useful for "give me the count without modifying anything" - though `scalar @a` is clearer.
- **Tied arrays.** `push` on a tied array calls `PUSH` on the tied object if defined; otherwise it falls back to repeated `STORE` calls at `FETCHSIZE`-derived indices. See `perltie`.
- **Autovivification.** Pushing through an undef-valued reference vivifies an anonymous array:

  ```
  my %index;
  push @{ $index{$key} }, $value;          # $index{$key} becomes␣
   ↪an arrayref
  ```

  After the first `push`, `$index{$key}` holds an arrayref containing `$value`. This is the standard idiom for building a hash-of-arrays incrementally.
- **Readonly array.** Pushing onto a readonly or fixed-size array (e.g. an element of `@_` bound to a caller's variable, or an array locked with `Hash::Util::lock_value`) raises `Modification of a read-only value attempted`.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `pop` - remove and return the last element; paired with `push` to form a stack
- `shift` - remove and return the first element; paired with `push` to form a queue
- `unshift` - `push`'s mirror image at the head of the array; returns the new length the same way
- `splice` - insert, remove, or replace any range; `push @a, @b` is equivalent to `splice @a, scalar @a, 0, @b`
- `scalar` - force scalar context on an array when you want the count without a `push`
- `@ARGV` - the canonical array most programs `push` onto or consume with `shift`

SCALARs and strings

q//

Single-quoted string literal with a choice of delimiter.

`q//` is the generic form of the customary `'...'` string literal. It produces a compile-time constant string, does **not** interpolate variables, and does **not** process the backslash escape sequences that `qq//` and regex literals recognise. Reach for `q//` whenever the literal you want to write would be awkward under `'...'` - most often because the string itself contains single quotes - or when a different delimiter simply reads better in context.

Synopsis

```
q/STRING/
q(STRING)
q[STRING]
q{STRING}
q<STRING>
q!STRING!
q#STRING#
'STRING'
```

Any non-alphanumeric character works as a delimiter. The four ASCII bracket pairs (`()`, `[]`, `{}`, `<>`) nest; all other delimiters do not. `'...'` is a shorthand for `q(...)` with identical semantics.

What you get back

A string in scalar context - the exact byte sequence between the opening and closing delimiter, with two rewrites:

- `\\` becomes a single backslash.

- `\<delim>` becomes a literal copy of the delimiter character (this is what lets you include the delimiter inside the body).

Every other character, including every other `\`, stays verbatim. There is no `\n`, no `\t`, no `$var` expansion, no `\x{...}`, no `\N{...}` - the inside of `q//` is as close to "what you typed is what you get" as Perl offers.

In list context `q//` still evaluates to the single string.

Delimiters and nesting

Non-bracketing delimiters use the same character fore and aft:

```
my $a = q!I said, "You said, 'She said it.'"!;
my $b = q/path/to/file/;   # WRONG - ends at the second "/"
my $b = q{path/to/file};   # RIGHT - braces nest, slashes are␣
↪literal
```

Bracket delimiters nest, so balanced brackets inside the body are fine and only an unbalanced closer ends the string:

```
my $c = q{foo{bar}baz};    # "foo{bar}baz"
my $d = q(f(o(o)b)ar);     # "f(o(o)b)ar"
```

Whitespace between `q` and the delimiter is allowed **except** when the delimiter is `#` - `q#foo#` is the string `"foo"`, but `q #foo#` is the operator `q` followed by a line comment, and the string body continues on the next line. When the delimiter is a word character (matches `/\w/`), whitespace between `q` and the delimiter is **required**: `q XfooX` is `"foo"`, `qXfooX` is a syntax error.

Escape rules

Inside `q//` the backslash has exactly two special jobs:

Sequence	Produces
`\\`	a single backslash
`\<delim>`	a literal copy of the delimiter

Anything else beginning with `\` stays as two characters:

```
print q(\n), "\n";       # prints "\n" then a real newline
print length q(\n);      # 2
print q(\t\r\0);         # prints "\t\r\0" - six characters
```

This is the single most frequent source of confusion for authors coming from double-quoted strings - in `q//` and `'...'`, `\n` is a backslash followed by the letter n, **not** a newline.

Examples

Embedding both quote marks without escaping:

```
my $msg = q{I said "hello", she said 'hi'.};
```

Windows-style path, where backslashes are plentiful and double-quote interpolation would be a hazard:

```
my $path = q(C:\Users\alice\Documents);
print $path;                  # C:\Users\alice\Documents
```

A literal $ without interpolation - qq// would require escaping every $ and @, q// leaves them alone:

```
my $expr = q($total = $x + $y);
print $expr;                  # $total = $x + $y
```

The one-and-only way to put the delimiter inside the body: escape it with a backslash. Note that the backslash itself is consumed.

```
my $s = q!He said "ouch\!" loudly!;
print $s;                     # He said "ouch!" loudly
```

A regex pattern stored as a plain string, deferred to qr// at use site - q// keeps backslashes literal so the pattern survives intact:

```
my $pat = q(\d{3}-\d{4});
if ($phone =~ /$pat/) { ... }
```

Multi-line literal with no escape processing - each line break in the source becomes a line break in the string:

```
my $sql = q{
    SELECT id, name
    FROM   users
    WHERE  active = 1
};
```

Edge cases

- **q// is compile-time.** The parser resolves the string when the source is read; there is no runtime cost beyond using the already-built constant. Same as '...'.
- **'...' and q(...) are indistinguishable** after parsing. The choice is purely stylistic - pick whichever reads better for the content.
- **Empty string.** q() and '' both yield the zero-length string.
- **No \n, no \t, no interpolation**, ever. If you need either, switch to qq// or "...". Mixing the two in one line is fine: q(literal) . qq(interpolated $x).
- **Backslash at end of body.** A single \ immediately before the closing delimiter escapes it, so q(foo\) is a syntax error - the \) becomes a literal) and the string is unterminated. Write q(foo\\) to end a string with one backslash.

- **Unbalanced brackets with bracket delimiters.** Because brackets nest, `q{foo{bar}` is a syntax error - the inner `{` opens a nested level and the outer `}` closes it, leaving the string unterminated. Use a non-bracket delimiter, or balance the brackets, or escape one of them: `q{foo\{bar}`.
- **# as delimiter needs no space from q**, but every other delimiter that is a word character (letters, digits, _) requires whitespace between q and the opening delimiter.
- **Quoting Perl code is fragile.** `q{ if ($x eq "}") { ... } }` is a syntax error: the `}` inside the embedded double-quoted string closes the outer brace before Perl sees the inner string. Tools like `Text::Balanced` exist because hand-writing a robust Perl source quoter is unpleasant.
- **Parser ambiguity with / as delimiter.** `q/.../` uses `/` the same way `m//` does. Inside the body no regex syntax applies, but a slash in the content will end the string prematurely - pick a different delimiter (`q{...}`, `q(...)`) when slashes appear in the text.
- **Heredocs with `<<'TAG'`** follow the same escape rules as `q//`: no interpolation, no escape processing beyond `\\` and `\TAG` not being special (the tag terminates on its own line). Use a single-quoted heredoc when you want `q//` semantics across many lines without a closing delimiter in the middle of the text.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `qq//` - double-quoted literal; same delimiter flexibility as `q//` plus variable interpolation and the full `\n`/`\t`/`\x{...}` escape vocabulary
- `qw//` - list of whitespace-separated words; what you want when the literal is a list of short tokens, not a single string
- `qr//` - compile a regex literal; the pattern-matching member of the quote-like family
- `qx//` - run a command in the shell and capture its output; same delimiter rules, semantics of backticks
- `quotemeta` - runtime equivalent of `\Q...\E`, useful when you need to feed a `q//` literal into a regex as a fixed string
- `$"` - list separator used when arrays interpolate inside `qq//`; irrelevant to `q//` itself but the usual reason someone reaches for `q//` is to **avoid** this machinery

SCALARs and strings

qq//

Build a double-quoted, interpolated string with a delimiter you pick.

`qq//` is the long form of the `"..."` string literal. It produces the same string `""` would, so `qq/hello $name\n/` and `"hello $name\n"` are interchangeable. The point of qq is

the delimiter: when the content contains " (or backslash sequences that would interfere with double quotes), you pick a different delimiter and keep the string readable instead of threading \" through it.

Synopsis

```
qq/STRING/
qq{STRING}
qq(STRING)
qq[STRING]
qq<STRING>
qqXSTRINGX        # any non-word, non-whitespace char works as␣
 ↪delimiter
```

What you get back

A scalar string. Variables referenced inside are interpolated at the point qq// is evaluated (not at parse time); backslash escape sequences are expanded. The result has no implicit newline - you have to write \n yourself.

Choosing a delimiter

Any character that is not a word character (/\w/) and not whitespace may follow qq. The four bracket pairs nest:

```
qq(foo (bar) baz)          # "foo (bar) baz" - inner () balanced
qq{ if ($x) { 1 } else { 0 } }
qq[a[b[c]d]e]
qq<<a<b>c>>
```

Non-bracketing delimiters use the same character at both ends and do not nest:

```
qq|one|two|                # SYNTAX ERROR - first | closes
qq/a\/b/                   # "a/b" - backslash escapes the delimiter
```

If the delimiter is a word character, whitespace between qq and the delimiter is required:

```
qq XfooX                   # OK - "foo"
qqXfooX                    # WRONG - parsed as identifier qqXfooX
```

as delimiter needs no space and is occasionally handy for strings containing every other punctuation mark:

```
qq#He said "hi" & waved.#  # "He said \"hi\" & waved."
```

The extra_paired_delimiters feature (5.36+) recognises a wide set of Unicode bracket pairs as nesting delimiters; enable it with use feature 'extra_paired_delimiters' when you want, say, guillemets or CJK brackets.

What gets interpolated

- **Scalars**: `$x`, `$hash{key}`, `$array[0]`, `$ref->{k}[2]`.
- **Arrays**: `@arr` expands in order, elements joined by `$"` (default `" "`). Equivalent to `join $", @arr`.
- **Slices**: `@h{qw(a b)}`, `@a[1..3]`.
- **Dereferences with arrows and subscripts**: `$ref->{key}[0]`.

What is **not** interpolated:

- **Method calls**: `$obj->meth` inside `qq//` interpolates `$obj` and leaves the literal text `->meth` in the string.
- **Function calls**: `@{[ func() ]}` is the usual workaround - array reference dereference runs arbitrary code and splices its result in.
- **Punctuation arrays** other than `@_`, `@+`, `@-`: only interpolate when braced (`@{*}`). Bare `@*` is a literal `@*`.

```
my $obj = Some::Class->new;
qq/$obj->name/;                          # interpolates $obj, leaves "-
↪>name"
qq/@{[ $obj->name ]}/;                   # calls the method,␣
↪interpolates result
```

Escape sequences

Available inside `qq//` (and anywhere else interpolation happens):

Sequence	Meaning
`\t`	tab (HT)
`\n`	newline (platform-virtual line terminator)
`\r`	carriage return (CR)
`\f`	form feed (FF)
`\b`	backspace (BS)
`\a`	alarm / bell (BEL)
`\e`	escape (ESC)
`\0`	NUL
`\\`	literal backslash
`\"`	literal double quote
`\x1b`	hex char, 0x00–0xFF
`\x{263A}`	hex char, any codepoint (braced form)
`\o{23072}`	octal char, any codepoint
`\033`	octal char, 000–777 (prefer `\o{}`)
`\cA`	control char - 64 xor'd with uppercased next char
`\N{GREEK SMALL LETTER ALPHA}`	named Unicode char (needs `use charnames`)
`\N{U+03B1}`	Unicode char by codepoint (always Unicode, even on EBCDIC)

Case and quoting modifiers apply until `\E` or end of string:

Sequence	Meaning
`\l`	lowercase the next character only
`\u`	titlecase (not uppercase!) the next character only
`\L`	lowercase until `\E`
`\U`	uppercase until `\E`
`\F`	foldcase until `\E`
`\Q`	quote regex metacharacters until `\E` (calls `quotemeta`)
`\E`	end the most recent `\L` / `\U` / `\F` / `\Q`

`\L`, `\U`, `\F`, `\Q` stack - each needs its own `\E`.

```
say "\u$name";                          # capitalise first letter
say "\U$name\E's account";              # uppercase $name, rest␣
 ↪untouched
say "match $file literally: \Q$file\E";
```

`\Q` inside `qq//` is applied **after** interpolation, so `qq/\Q$pat\E/` equals `quotemeta($pat)`. (In regex quote operators `qr//` and `m//`, `\Q` is applied after interpolation but before regex compilation - the difference matters when `$pat` itself contains regex metacharacters you want to keep literal.)

Perl has no `\v` escape in string literals - it is a regex metacharacter. Use `\x0b`, `\cK`, or `\N{VT}` for a vertical tab.

Global state it touches

- `$"` - list separator used when interpolating arrays and slices. Default `" "`. Change with `local $" = ","` for one scope.

No other interpreter globals participate in `qq//` evaluation itself. Interpolated variables are of course whatever their current values are at the point `qq//` runs.

Examples

Plain interpolation, identical in meaning to the `"..."` form:

```
my $name = "world";
my $s = qq/hello, $name!\n/;            # "hello, world!\n"
```

String that contains double quotes - qq with a different delimiter avoids backslash litter:

```
my $msg = qq{He said "yes" and then "maybe".};
# vs:   "He said \"yes\" and then \"maybe\"."
```

Multi-line HTML snippet with nested braces - the `()` pair nests:

```
my $user = "rj";
my $html = qq(
```

(continues on next page)

(continued from previous page)

```
  <p>Welcome, $user.</p>
  <p>You have @{[ scalar @inbox ]} messages.</p>
);
```

Array interpolation with a custom separator:

```
my @tags = qw(perl rust docs);
local $" = ", ";
say qq/tags: @tags/;                    # "tags: perl, rust, docs"
```

Method-call trap - `->` is literal inside `qq//`:

```
my $obj = File::Spec->new;
qq/path is $obj->rel2abs('.')/;         # "path is <stringified $obj>-
↪>rel2abs('.')"
qq/path is @{[ $obj->rel2abs('.') ]}/;
                                        # actually calls rel2abs()
```

Building an SQL fragment where `$ident` is untrusted - `\Q..\E` keeps embedded `%`, `_`, and backslashes literal under a `LIKE` clause only after you have handled proper parameterisation; for actual SQL escaping use the driver's quoting, not `\Q`:

```
my $needle = "100% sure";
my $pat = qq/\Q$needle\E/;              # the regex-safe form
# $pat eq "100\\%\\ sure"
```

Stacked modifiers:

```
say qq/\Qfoo \ubar \Ubaz\E qux\E done/;
# "foo\ Bar\ BAZ qux done"
#  \Q quotes spaces/?; \u titlecases b; \U uppercases baz until \E;
#  outer \E ends \Q.
```

Edge cases

- **Parse-time delimiter choice.** Perl picks the closing delimiter the moment it reads the opening one. `qq/.../` expects a `/`; there is no way to switch mid-string. If you need both kinds of braces, pick a non-bracket delimiter.
- **Backslash at end of string with non-bracket delimiter.** `qq/a\/` is `a/` (backslash escapes the delimiter, string continues); to get a literal trailing backslash, change delimiter: `qq{a\\}`.
- **No nesting for non-bracket delimiters.** `qq|a|b|` is the string `a` followed by the identifier `b` followed by `|` - a syntax error in most contexts. Pick bracket delimiters when the content contains the delimiter char.
- **`#` as delimiter** is a special case only because of how comments interact: `qq#...#` is a string, but `qq #...#` (with whitespace) is the operator `qq` followed by a comment, with the string taken from the next line. This mirrors the behaviour of all `q`-family operators.

- **Empty string**. qq// is the empty string, same as "".
- **Interpolated undef**. Stringifies to the empty string and, under use warnings, triggers an uninitialized warning at the point of interpolation, not at the point $var was assigned undef.
- **$ or @ followed by non-identifier**. Stays literal: qq/cost: \$5/ and qq/cost: $5/ both produce cost: $5 (there is no variable named $5 in the Perl 5 identifier sense - $5 is a regex capture, which does exist, so the second form interpolates capture group 5, whatever it currently is). For a literal $ or @, escape it: \$, \@.
- **\N{...} without charnames**. Named characters require use charnames ':full' (or similar) to be loaded in scope; without it you get a compile-time error. \N{U+HEX} and the single-name forms in the :loose set work without it.
- **Locale-sensitive case mapping**. With use locale including LC_CTYPE, \l, \u, \L, \U use the current locale's case tables. Without it, Unicode case tables are used for codepoints above 0xFF, and ASCII rules below. \F uses Unicode foldcase regardless of locale (except under a UTF-8 locale, where it matches \L).
- **One level only**. The result of interpolation is not re-scanned. my $v = '$x'; qq/$v/ is the two-character string $x, not the value of $x.

Differences from upstream

Fully compatible with upstream Perl 5.44.

Regular expressions and pattern matching

qr//

Compile a pattern once and hand back a reusable regex object.

qr// quotes its STRING as a regular expression, interpolates it the same way m does, and returns a Regexp object you can store, pass around, and splice into other patterns. The

compiled pattern carries its modifiers with it, so every later use sees the flags the pattern was built with.

Synopsis

```
my $re = qr/STRING/;
my $re = qr/STRING/msixpodualn;
my $re = qr{STRING};
my $re = qr'STRING';            # single-quote delimiter: no
 ↪interpolation
```

What you get back

A blessed Regexp object. `ref` returns the string `"Regexp"`. Stringifying the object yields a normalised form of the pattern with its modifiers encoded in a `(?flags:...)` wrapper, which is exactly the form the regex engine embeds when the object is interpolated into another pattern:

```
my $re = qr/my.STRING/is;
print $re;                      # (?^si:my.STRING)
```

The object is opaque - do not dereference it. The stringified form is intended for interpolation and debugging, not for manual parsing.

Global state it touches

- `$1`, `$2`, ..., `$+`, `$&`, `$`` `, `$'`, %+, %- - **not** set by `qr//` itself. Compilation does not match. These are populated only when the compiled pattern is later used by `m`, `s`, or `split`.
- `$@` - set if the pattern contains a syntax error and the error is trapped with `eval`. An untrapped compile error raises a fatal `Bareword "..." not allowed`-style exception at the point of the `qr//`.
- Locale and Unicode pragmas in effect at the `qr//` site (`use locale`, `use utf8`) are baked into the compiled object. Changing the pragma later does not change the object.

Modifiers

All modifiers that apply to `m` also apply to `qr//`. They are captured in the returned object and propagate when the object is interpolated into another pattern.

Flag	Meaning
`m`	Multi-line: `^` and `$` match at internal newlines.
`s`	Single-line: `.` matches a newline.
`i`	Case-insensitive match.
`x`	Extended: whitespace and # comments ignored in the pattern. `xx` also ignores whitespace inside `[...]`.
`p`	Preserve-match (no-op on Perl 5.20+; `${^PREMATCH}`, `${^MATCH}`, `${^POSTMATCH}` are always available).
`o`	Compile once; interpolated variables are frozen at first use. Rarely needed - `qr//` already caches.
`a`	ASCII-restrict `\d`, `\s`, `\w`, and POSIX classes. `aa` further forbids ASCII-to-non-ASCII matches under `i`.
`l`	Use the current locale's rules.
`u`	Use Unicode rules.
`d`	Default dual rules (legacy; usually picked up automatically).
`n`	Non-capture: unnamed `(...)` groups do **not** fill `$1`, `$2`, ...

When a compiled pattern is embedded in a larger pattern, the character-set and `msixn` flags it was built with stay in effect for that span only. The `o` modifier is the one exception - it is not propagated.

Examples

Compile once, use many times. Looping over patterns built ahead of time avoids recompiling on every iteration:

```
my @rules = map qr/$_/i, qw(error warn fail panic);
for my $line (@lines) {
    for my $rx (@rules) {
        print $line if $line =~ $rx;
    }
}
```

Interpolate a compiled pattern inside another pattern. The outer pattern sees the inner pattern's flags via the `(?flags:...)` wrapper:

```
my $word = qr/\w+/;
my $csv  = qr/^$word(?:,$word)*$/;
"alpha,beta,gamma" =~ $csv;          # matches
```

Single-quote delimiter for a literal pattern with no interpolation - useful when the pattern contains `$` or `@` that must stay literal:

```
my $price = qr'\$\d+\.\d{2}';        # matches "$1.99", not a sigil
"total: \$9.95" =~ $price;           # matches
```

Pattern re-use across calls. Storing the compiled form in a closure amortises compilation across every call to the returned sub:

```
sub matcher_for {
    my $pat = shift;
    my $rx  = qr/\Q$pat\E/i;        # \Q...\E quotes regex
↪metacharacters
    return sub { $_[0] =~ $rx };
}

my $is_error = matcher_for("ERROR:");
$is_error->($line);
```

Capture inside an interpolated `qr//` still populates `$1` at match time, not at `qr//` time:

```
my $num = qr/(\d+)/;
"port 8080" =~ /:$num$/;
print $1;                           # 8080
```

Using `/n` to suppress capture in `$1`, `$2`, ... while keeping named captures available:

```
my $rx = qr/(foo)(?<kw>bar)/n;
"foobar" =~ $rx;
print $+{kw};                       # "bar"
print defined $1 ? "yes" : "no";    # "no"
```

Edge cases

- **No match at compile time**. `qr//` only *compiles*. To test a string, use the object with `m` or `=~`: `$string =~ $rx`.
- **Interpolated variables are captured at `qr//` time**, not at use time. `my $rx = qr/$pat/; $pat = "other";` leaves `$rx` holding the pattern built from the original `$pat`. To re-capture, rebuild the `qr//`.
- **Compile-time pattern errors are fatal**. `qr//` raises an exception at the `qr//` site. Wrap in `eval` when the pattern comes from user input and an error should be recoverable:

  ```
  my $rx = eval { qr/$user_input/ };
  die "bad pattern: $@" if $@;
  ```

- **`ref($rx)` returns `"Regexp"`** - not `"SCALAR"`, not `"CODE"`. Use this to detect a compiled pattern in a polymorphic argument slot: `ref($arg) eq 'Regexp'`.
- **Stringification is lossy for re-parsing**. The normalised form is legal as an interpolation target but is not guaranteed to be a human-readable copy of the original source. Do not re-`qr//` the stringified output.
- **Locale and Unicode bake-in**. A `qr//` built inside `use locale` behaves with locale rules forever, even when used outside that scope. Rebuild under the desired pragma if the behaviour needs to change.

- **`\Q...\E` for literal text**. To compile a pattern that matches a user-provided string verbatim, wrap it with `\Q...\E`: `qr/\Q$literal\E/`. Without `\Q`, metacharacters in the string are interpreted as regex syntax.
- **Empty pattern**. `qr//` compiles to the empty pattern, which is treated specially at match time: `$str =~ $empty` reuses the *last successful* pattern in that scope. This is a match-time behaviour of `m`, not a `qr//`-specific trait, but it is a common trap when passing a default `qr//` around.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `m` - match a compiled pattern or a literal pattern against a string; the primary consumer of a `qr//` object
- `s` - substitute using a compiled pattern; accepts a `qr//` in the search slot
- `split` - split on a compiled pattern; the `qr//` form is the most efficient
- *Regular expressions guide* - full regex syntax reference; read this for the meaning of the modifiers and escape sequences
- `ref` - returns `"Regexp"` for a `qr//` object; the standard type check
- `eval` - wrap `qr//` when the pattern source is untrusted and a compile error should be recoverable

Regular expressions and pattern matching

quotemeta

Return a copy of a string with every regex-significant character backslash-escaped, so the result can be interpolated into a pattern and match its own literal content.

`quotemeta` exists to bridge string data and regex syntax. When user input, filenames, or configuration values end up on the right-hand side of `=~`, any character that happens to be a regex metacharacter (`.`, `*`, `+`, `?`, `(`, `[`, `\`, `|`, ...) would otherwise fire its special behaviour. `quotemeta` preempts that by inserting a backslash before every ASCII non-word character, leaving letters, digits, and underscore untouched.

Synopsis

```
quotemeta EXPR
quotemeta
```

What you get back

A new string. Every ASCII character that does **not** match `/[A-Za-z_0-9]/` is preceded by a backslash; word characters pass through unchanged. The result is always safe to paste into a regex as a literal pattern fragment.

quotemeta is a pure value producer - it does not modify its argument.

```
my $safe = quotemeta 'a.b*c';     # 'a\.b\*c'
```

Global state it touches

Reads $_ when called with no argument. Within the scope of use locale, additional non-ASCII Latin-1 characters are quoted to protect against locales that treat punctuation like | as a word character.

Examples

Bare form defaults to $_, like most list built-ins:

```
for ('a+b', 'c.d') {
    print quotemeta, "\n";     # a\+b
}                              # c\.d
```

Interpolating user input into a substitution. Without quotemeta, .*? in $substring would be regex-active and match far more than intended:

```
my $sentence  = 'The quick brown fox jumped over the lazy dog';
my $substring = 'quick.*?fox';
my $quoted    = quotemeta $substring;
$sentence =~ s{$quoted}{big bad wolf};
# $sentence unchanged - the literal text 'quick.*?fox' is not␣
 ↪present
```

The \Q...\E escape in a double-quoted string is exactly quotemeta applied to the enclosed region. The two forms below are equivalent:

```
my $pat1 = "\Q$substring\E";
my $pat2 = quotemeta($substring);
```

Building a regex that matches a literal filename anywhere in a path:

```
my $name = 'my.config[prod].ini';
if ($path =~ /\Q$name\E\z/) {
    # matches exactly the filename, no metachar surprises
}
```

Escaping a list of terms for an alternation:

```
my @terms = ('C++', 'C#', '.NET');
my $alt   = join '|', map { quotemeta } @terms;
# 'C\+\+|C\#|\.NET'
```

Edge cases

- **No argument**: `quotemeta` with no expression quotes `$_`. Inside a loop like `for (@input) { push @safe, quotemeta }` this is the idiomatic form.
- **Already-safe strings are untouched**: pure word-character input (`[A-Za-z0-9_]+`) round-trips identically.
- **Literal backslashes inside `\Q...\E`** interact with double-quotish backslash interpolation before `\Q` sees the text. A sequence like `"\Q\t\E"` quotes a literal tab character, not a backslash followed by `t`. When you need actual backslashes in the quoted region, keep the data in a variable and use `quotemeta $var` rather than embedding it in a double-quoted literal.
- **No way to inject a literal `$` or `@` inside `\Q...\E`**: a protected `\$` becomes the four-character sequence `\\$` in the output, and an unprotected `$` starts scalar interpolation before `\Q` runs. Drop out of the quoted region to splice in sigils.
- **Unicode-aware quoting** (Perl 5.16+): on UTF-8 strings - and on byte strings under `use feature 'unicode_strings'` or `use v5.12` or greater - non-ASCII characters are quoted only when they carry the Unicode properties `Pattern_Syntax`, `Pattern_White_Space`, `White_Space`, `Default_Ignorable_Code_Point`, or `General_Category=Control`. Identifier-class characters (letters, marks, digits) are left alone. This is the stable contract: Perl promises that any future regex metacharacter will have `Pattern_Syntax` set, so strings safe today stay safe.
- **Legacy non-UTF-8 strings** outside `unicode_strings` scope have every upper-Latin-1 code point (`\x80`–`\xFF`) quoted, for backwards compatibility with pre-5.16 behaviour.
- **Locale quoting**: within `use locale`, all non-ASCII Latin-1 code points are quoted whether the string is UTF-8 or not. ASCII-range quoting is unaffected by locale.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `m` - the match operator; `quotemeta` exists to feed safe literals into its pattern
- `qr` - compiled regex objects; `qr/\Q$var\E/` is the usual way to pin a pattern around a literal string
- `s` - substitution; the most common site of `quotemeta`-style escaping on the left-hand pattern
- `\Q` *and* `\E` - the double-quotish escape pair that is just `quotemeta` with different syntax
- `$_` - default input when `quotemeta` is called without an argument

Lists

qw//

Build a list of barewords by splitting a delimited string on whitespace, without quoting or comma-separating each word.

`qw//` is a compile-time quote-like operator, not a runtime function. The parser sees `qw(foo bar baz)` and emits the constant list `("foo", "bar", "baz")` - no splitting happens at run time, and the list is assembled once regardless of how often the code is executed. Reach for it wherever you would otherwise type a list of short, simple string literals separated by commas: import lists, `@ISA`, `@EXPORT`, hash-key sets, test-name tables.

Synopsis

```
qw(foo bar baz)
qw[foo bar baz]
qw{foo bar baz}
qw<foo bar baz>
qw!foo bar baz!
qw/foo bar baz/
```

Any non-alphanumeric character works as a delimiter. The four bracket pairs `()`, `[]`, `{}`, `<>`) nest; all other delimiters do not.

What you get back

A list of strings in list context - one element per run of non-whitespace characters in the body, with leading and trailing whitespace discarded and runs of internal whitespace treated as a single separator.

In scalar context `qw//` evaluates to the **last** element of the list, which is almost never what the author intended. `use warnings` flags the common scalar-context mistakes (see *Edge cases*).

Examples

Import list for a module - the canonical use:

```
use POSIX qw(setlocale localeconv strftime);
```

`@EXPORT` / `@EXPORT_OK` / `@ISA` tables:

```
our @ISA      = qw(Exporter);
our @EXPORT   = qw(sum min max);
```

Build a small hash where every key maps to 1 (a set):

```
my %is_keyword = map { $_ => 1 } qw(if unless while until for);
if ($is_keyword{$word}) { ... }
```

Compare the three ways of writing the same list - commas-and-quotes, fat-comma auto-quoting, and `qw//`:

```
my @a = ("foo", "bar", "baz");                  # explicit strings
my @b = (foo => "1", bar => "2", baz => "3");   # fat comma only
my @c = qw(foo bar baz);                        # qw//
```

Array initialisation with many short tokens:

```
my @months = qw(
    Jan Feb Mar Apr May Jun
    Jul Aug Sep Oct Nov Dec
);
```

Positional argument list to a function:

```
run_tests(qw(smoke integration regression));
```

Edge cases

- **No commas inside the body.** A comma is taken as part of a word: `qw(foo, bar)` yields the two-element list `("foo,", "bar")`, not three elements. `use warnings` emits `Possible attempt to separate words with commas`.
- **No comment syntax.** `#` is a literal character inside the body. `qw(foo # comment\n bar)` contains the word `#` and the word `comment`. `use warnings` emits `Possible attempt to put comments in qw() list`.
- **No backslash escapes.** `\` is literal - you cannot escape a whitespace character to include it in a word, and you cannot `\`-escape the delimiter. `use warnings` emits a warning for any `\` in the body.
- **No interpolation.** `qw($x @y)` produces the two literal strings `"$x"` and `"@y"`. Use `("$x", @y)` (or `q()`/`qq()`) when you want a variable's value.
- **Whitespace is the only separator.** Tabs and newlines split words exactly like spaces, which is why multi-line `qw(...)` lists are idiomatic for long tables.
- **Words with embedded whitespace are impossible.** If you need `"hello world"` as a single element, `qw//` is the wrong tool - use `("hello world", ...)` with real quotes.
- **Empty body.** `qw()` is the empty list, equivalent to `()`.
- **Scalar context** yields the last element, not the count. Wrap in `scalar(() = qw(...))` if you genuinely want the count, or assign to an array first:

  ```
  my @w = qw(foo bar baz);
  print scalar @w;                  # 3
  ```

- **Parser ambiguity with `//`.** `qw//` uses `/` as a delimiter just like `m//` and `s///`. Inside the body, no regex metacharacters apply - it is a flat string split on whitespace. The visual similarity to a regex is a reading hazard, not a semantic one.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `q//` - single-quote literal string; no interpolation, unlike `qq//`
- `qq//` - double-quote literal string with full interpolation
- `qr//` - compile a regex literal; the `//` family member for pattern matching
- `split` - the runtime equivalent when your word list is not known until run time: `split(" ", $str)` behaves almost exactly like a dynamic `qw//`
- `join` - the inverse operation, gluing a list back into a single delimited string

Processes

qx//

Run a shell command and capture its standard output.

`qx//` (and its twin, the backtick form `` `STRING` ``) interpolates `STRING` like a double-quoted string, hands the result to the system shell, waits for the child to finish, and returns whatever the child wrote to `STDOUT`. Standard error is untouched - it still goes to the parent's `STDERR` unless you redirect it inside the command. The child's exit status lands in `$?`.

Synopsis

```
my $out   = `date`;
my $out   = qx/date/;
my @lines = `ls -1 /etc`;
my $raw   = qx'echo $HOME';     # single-quote form: no Perl␣
↪interpolation
```

What you get back

Context-sensitive:

- **Scalar context** - one string containing the entire captured `STDOUT`, including any embedded newlines. `undef` if the shell or command could not be started.
- **List context** - a list of lines, split on the current value of `$/` (the input record separator, newline by default). Empty list if the shell or command could not be started.

The exit status of the child is always placed in `$?`, whether or not the captured output is used. A child that writes nothing and exits cleanly yields `""` in scalar context, `()` in list context, and `0` in `$?` - distinguishing "started but produced no output" from "failed to start" requires checking `$?` against `-1` or `$!`.

Global state it touches

- `$?` - set to the child's wait status (`waitpid`-style) on every call. `-1` means the child could not be started, in which case `$!` holds the reason.
- `$!` - set when the shell or command failed to start.
- `$/` - governs how list-context output is split into lines.
- `$|` - affects whether buffered Perl output reaches the child's environment before the child runs; set it on output handles before `qx//` if ordering with prior `print` matters.
- `%ENV` - exported to the child as its environment.
- The current working directory, umask, and open file descriptors are inherited by the child.

Examples

Capture a single line:

```
my $today = `date`;
chomp $today;
print "today is $today\n";
```

Capture line-by-line in list context:

```
my @users = `who`;
for my $line (@users) {
    my ($name) = split /\s+/, $line;
    print "logged in: $name\n";
}
```

Interpolation happens before the shell sees the string - Perl variables expand first, shell variables expand in the child:

```
my $dir = "/etc";
my $out = `ls $dir`;            # Perl interpolates $dir
my $sh  = qx'echo $HOME';       # single-quote form: $HOME is shell
 ↪'s
```

Redirect `STDERR` into the captured stream:

```
my $both = `gcc -v hello.c 2>&1`;
```

Discard `STDERR`, keep only `STDOUT`:

```
my $out = `find / -name core 2>/dev/null`;
```

Check the exit status:

```
my $out = `make test`;
if ($? == -1) {
```

(continues on next page)

(continued from previous page)

```
    die "failed to execute make: $!";
}
elsif ($? & 127) {
    die sprintf "make died with signal %d", $? & 127;
}
elsif ($? >> 8) {
    die sprintf "make exited with status %d", $? >> 8;
}
```

Edge cases

- **No shell metacharacters**: if `STRING` contains no shell metacharacters, Perl bypasses the shell and `execs` the command directly - same optimisation as `system`. This is faster and avoids one `sh -c` level of quoting.
- **Single-quote delimiter**: `qx'...'` suppresses Perl's double-quote interpolation. The literal `$var` is passed to the shell, which does its own expansion. Useful when the variable names belong to the shell, not to your Perl program.
- **Alternate delimiters**: `qx//` accepts any balanced or non-alphanumeric delimiter - `qx{ls -l}`, `qx(ls -l)`, `qx[ls -l]`, `qx!ls -l!`. Pick one that doesn't collide with shell syntax in your command. `qXfooX` is a syntax error - the delimiter must not be alphanumeric.
- **Backticks don't capture STDERR**: nothing written to the child's `STDERR` ends up in the returned string. Redirect with `2>&1` inside the command if you want it, or run the command through `open` with a pipe for finer control.
- **STDIN is inherited**: the child reads from whatever the Perl process had on `STDIN` at the time of the call. To feed the child specific input, use `open` in pipe mode instead.
- **Exit status vs `$!`**: a non-zero `$?` means the child ran and exited with an error; `$!` is only meaningful when `$?` is `-1` (the shell itself could not be launched).
- **Memory cost in scalar context**: the whole captured output is buffered in memory before being returned. For commands that produce very large or unbounded output, open a pipe with `open` and read it incrementally.
- **Function form**: `qx//` can also be spelled `readpipe` when you want a function-call syntax - useful when the command string is built dynamically and you'd rather pass it as a scalar than splice it into a quote-like.
- **Output buffering**: Perl flushes its buffered output handles before forking the child, but portability varies. When preceding `qx//` with `print` to a pipe or file, set `$|` on that handle to be sure your output reaches the destination before the child starts.
- **Shell selection**: the shell used is `/bin/sh` on Unix. Commands that rely on bash-isms need an explicit `bash -c '...'` wrapper.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `system` - run a shell command without capturing output; reach for this when you only care about the exit status
- `exec` - replace the current process with a command; no capture, no return
- `readpipe` - the named-function form of `qx//`; takes the command as a regular string argument
- `open` - pipe-mode (`open my $fh, "-|", CMD`) for streaming a child's output line by line instead of buffering the whole capture
- `$?` - the child wait status set by every `qx//` call; decode with `>> 8` for exit code and `& 127` for terminating signal
- `$/` - controls how list-context `qx//` splits output into lines

Numeric functions

rand

Return a pseudo-random floating-point number in the half-open range `[0, EXPR)`.

`rand` draws the next value from the interpreter's pseudo-random number stream and scales it to `0 <= n < EXPR`. The result is a regular Perl number (a double), never an integer on its own - wrap with `int` when you want a whole number. `EXPR` is optional and defaults to `1`, so a bare `rand` yields a float in `[0, 1)`.

Synopsis

```
rand EXPR
rand
```

What you get back

A double-precision float `n` with `0 <= n < EXPR`. The upper bound is **exclusive**: `rand(6)` never returns `6`, only values strictly below it. For an integer result, compose with `int`:

```
my $die = int(rand(6)) + 1;       # 1..6
```

The distribution is (approximately) uniform across the range. `rand` is a scalar operator - it returns one value per call, regardless of context.

Global state it touches

`rand` consumes the interpreter's internal PRNG state, shared with `srand`. Two rules follow from that:

- **Autoseeding**: the first call to `rand` in a program automatically calls `srand` if you haven't already. The seed is chosen from process-level entropy, so unseeded programs produce a different stream on every run.
- **Shared stream**: every subsequent `rand` call - anywhere in the program, in any module - draws from the same sequence. Calling `srand($seed)` with a fixed seed makes that sequence deterministic and reproducible, which is what you want for test fixtures and debugging. Calling `srand()` with no argument re-seeds from entropy.

There is no per-thread or per-scope isolation. If you need an independent stream for one piece of code, do not use `rand`; reach for a dedicated generator module.

Examples

Basic draw in `[0, 1)`:

```
my $u = rand();                    # e.g. 0.4173...
```

Dice roll - canonical `int(rand(N)) + 1` idiom:

```
my $roll = int(rand(6)) + 1;       # 1..6
```

Random element of an array:

```
my @colors = qw(red green blue yellow);
my $pick   = $colors[ rand @colors ];
```

`rand @colors` uses the array's length (scalar context forced by `rand`'s prototype), so this works for any array size.

Reproducible stream - fix the seed for tests:

```
srand(42);
my @sample = map { rand() } 1..5; # same five numbers every run
```

One-line shuffle idiom. Readable, but **biased** - `sort` compares pairs more than once, and a one-shot `rand()` per comparison does not produce a uniform permutation:

```
my @shuffled = sort { rand() <=> 0.5 } @list;   # biased; do not use
```

For a fair shuffle, use `List::Util::shuffle`:

```
use List::Util qw(shuffle);
my @shuffled = shuffle @list;
```

Simulate a weighted coin - note the exclusive upper bound means `rand() < 0.3` fires with probability exactly `0.3`:

```
my $heads = rand() < 0.3 ? "heads" : "tails";
```

Edge cases

- **EXPR is `0`**: treated as `1`, so `rand(0)` behaves like `rand(1)`. This is documented upstream behaviour and is preserved here, but it is a historical quirk - do not rely on it for new code.
- **EXPR is negative**: the result is undefined in practice - you may get `0`, you may get a negative float, and the behaviour is not portable across Perl versions. If you want a value in `[-N, 0)`, write `rand($n) - $n` explicitly.
- **EXPR is `undef`**: stringifies to `""`, numifies to `0`, and therefore behaves like `rand(0)` → `rand(1)`. Under `use warnings` you get an `uninitialized` warning.
- **EXPR is non-numeric**: the usual scalar-to-number coercion applies. `rand("3abc")` is `rand(3)` with a non-numeric warning.
- **Not cryptographically secure**: `rand` uses a fast PRNG suitable for simulation, shuffling, and test fixtures. It is **not** suitable for session tokens, password salts, key material, or any security-sensitive value. For those, read from `/dev/urandom` directly or use `Crypt::URandom` / `Crypt::PRNG`.
- **Thread/fork behaviour**: after `fork`, both parent and child inherit the same PRNG state and will produce the **same** stream unless one of them calls `srand()` to re-seed. A common footgun in pre-forking servers - seed in the child.
- **Large EXPR**: the generator produces 48 bits of randomness per draw; for `EXPR` close to or above `2**48`, the output is no longer finely distributed over the range. For cryptographic widths you shouldn't be using `rand` anyway (see above).

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `srand` - seed the PRNG explicitly for reproducibility, or re-seed in a forked child
- `int` - truncate a `rand` result toward zero to get a uniform integer in `[0, N)`
- `List::Util::shuffle` - fair Fisher-Yates shuffle; prefer this over the `sort { rand() <=> 0.5 }` idiom
- `Crypt::URandom` - cryptographically-secure random bytes from the OS entropy source; use this for tokens, salts, and key material
- `Crypt::PRNG` - cryptographically-secure PRNG with a rich API when you need more than raw bytes

I/O · Fixed-length data

read

Read a fixed amount of buffered input from a filehandle into a scalar.

`read` pulls up to `LENGTH` characters from `FILEHANDLE` and stores them in `SCALAR`, returning how many were actually read. It goes through the handle's PerlIO stack and is therefore buffered on top of the underlying OS read - contrast with `sysread`, which bypasses the buffer and calls `read(2)` directly. The optional `OFFSET` argument lets you splice the incoming data into the middle of `SCALAR` rather than overwriting it.

Synopsis

```
read FILEHANDLE, SCALAR, LENGTH
read FILEHANDLE, SCALAR, LENGTH, OFFSET
```

What you get back

- The **number of characters read**, which may be less than `LENGTH`.
- `0` at end of file.
- `undef` on error, with `$!` set.

`SCALAR` is grown or shrunk so that the last character actually read becomes the last character of the scalar - unless `OFFSET` is given, in which case only the slice at `OFFSET` is overwritten and anything beyond it is left alone (see *The OFFSET argument* below).

A short read is **not** an error. On a regular file it normally means you reached end of file; on a pipe, socket, or terminal it means no more data is available right now. Loop until you either have the bytes you need or `read` returns `0` / `undef`:

```
my $buf = "";
my $want = 4096;
while ($want > 0) {
    my $got = read($fh, $buf, $want, length $buf);
    die "read error: $!" unless defined $got;
    last if $got == 0;                  # EOF
    $want -= $got;
}
```

Global state it touches

- `$!` - set when `read` returns `undef`.
- `${^UTF8CACHE}` / the handle's PerlIO layers - determine whether `LENGTH` is counted in bytes or in characters (see *Character vs byte semantics* below).

`read` does not interact with `$_`, `$/`, `$\`, or `$,`. Unlike `readline`, it does not care about the input record separator.

The OFFSET argument

`OFFSET` controls **where in `SCALAR`** the incoming data lands. It does not seek the filehandle.

- **Omitted** - data replaces the entire contents of `SCALAR`.
- **Positive, within length** - data is written starting at position `OFFSET`. Characters before `OFFSET` are preserved; characters from `OFFSET` to the end of `SCALAR` are overwritten or extended.
- **Positive, beyond length** - `SCALAR` is first padded with `"\0"` bytes out to `OFFSET`, then the read is appended. Useful for reading into a fixed slot inside a larger buffer you are assembling.
- **Negative** - counts backwards from the end of `SCALAR`. `-1` means "overwrite the last character and append from there."

```
my $buf = "HEADER";
read($fh, $buf, 16, length $buf);      # append 16 chars after
 ↪"HEADER"

my $slab = "";
read($fh, $slab, 512, 1024);           # pad to 1024 "\0" bytes,␣
 ↪then
                                       # read 512 chars - $slab is
                                       # now 1536 chars long
```

Character vs byte semantics

`LENGTH` is measured in whatever unit the handle deals in:

- **Byte-mode handle** (the default, and every handle opened without an encoding layer): `LENGTH` is a byte count. `read($fh, $buf, 10)` pulls 10 bytes and `length $buf` is 10.
- **`:utf8` layer**: `LENGTH` is a **character** count. Perl decodes UTF-8 on the way in, and `$buf` holds decoded codepoints. The number of bytes consumed from the file can be anywhere from `LENGTH` to `4 * LENGTH`, depending on the text.
- **`:encoding(...)` layer**: same rule as `:utf8`, for any encoding the layer knows.

```
open my $fh, "<:utf8", "greek.txt" or die $!;
read($fh, my $buf, 5);                 # 5 characters, not 5 bytes
```

Mixing a byte-mode read with UTF-8 data produces mojibake and, under `use warnings`, a `Malformed UTF-8` warning if you later decode the result. Pick the layer at `open` time and stick with it.

Buffered vs unbuffered I/O

`read` is **stdio-buffered** through PerlIO - internally it calls `fread(3)` (or PerlIO's replacement) against the handle's buffer. That has two consequences worth remembering:

- You can mix `read`, `readline` / `<$fh>`, `getc`, and `seek` freely on the same handle. They all see the same buffer.
- You must **not** mix `read` with `sysread` on the same handle. `sysread` bypasses the buffer and goes straight to `read(2)`; any bytes already pulled into the buffer by a previous `read` become invisible to `sysread`, and vice versa. If you need raw syscall semantics, use `sysread` exclusively on that handle.

For byte-accurate, non-buffered input - for example on a non-blocking socket, or when implementing a protocol where a short read is meaningful rather than "try again" - reach for `sysread`.

Examples

Read a fixed-size header from a binary file:

```
open my $fh, "<", "packet.bin" or die "open: $!";
binmode $fh;
my $header;
my $n = read($fh, $header, 16);
die "short header: got $n bytes" unless $n == 16;
```

Append 16 bytes to the end of an existing buffer by using `OFFSET` equal to the current length:

```
my $buf = "PRELUDE:";
read($fh, $buf, 16, length $buf);      # $buf is now "PRELUDE:" . 16
 ↪new bytes
```

Read into position 1024 of a scalar, padding the gap with `"\0"`:

```
my $slot = "";
read($fh, $slot, 64, 1024);            # length($slot) == 1088
                                       # substr($slot, 0, 1024) is
 ↪"\0" x 1024
```

Loop until you have exactly `N` bytes or hit EOF - the correct pattern for pipes and sockets where a single `read` often returns fewer bytes than requested:

```
sub read_exact {
    my ($fh, $n) = @_;
    my $buf = "";
    while (length($buf) < $n) {
        my $got = read($fh, $buf, $n - length($buf), length $buf);
        return undef unless defined $got;
        return $buf if $got == 0;       # EOF; caller inspects
 ↪length
        # loop
    }
    return $buf;
}
```

Character-counted read through a UTF-8 layer:

```
open my $fh, "<:encoding(UTF-8)", "notes.txt" or die $!;
read($fh, my $chunk, 100);              # 100 characters
printf "chars=%d bytes=%d\n", length $chunk, do {
    use bytes; length $chunk;
};
```

Edge cases

- **Closed filehandle**: returns `undef` and sets `$!` to `"Bad file descriptor"`. Under `use warnings` a `read() on closed filehandle` warning is emitted.
- **Unopened filehandle**: same as closed - `undef` and `$!` set.
- **`LENGTH` of `0`**: `read` returns `0` immediately and does not touch `SCALAR`. It is **not** a reliable EOF probe; use `eof` for that.
- **Negative `LENGTH`**: a fatal runtime error (`Negative length at ...`). Validate `LENGTH` before calling.
- **Negative `OFFSET` whose magnitude exceeds the current length of `SCALAR`**: a fatal runtime error (`Offset outside string`). Clamp with `max($offset, -length $buf)` when the offset is computed.
- **Short read on a pipe or socket**: not an error. `read` returns fewer characters than requested whenever the PerlIO buffer empties before `LENGTH` is reached. Loop if you need the full count.
- **EOF mid-read**: returns the partial count. The next call returns `0`. After that, `$fh` stays at EOF until you `seek` or `clearerr`.
- **Reading from a tied handle**: `read` dispatches to the tie class's `READ` method, which is responsible for honouring `LENGTH` and `OFFSET`. Misbehaving tie classes can violate the "grow `SCALAR` so the last character read is the last character" contract.
- **Interaction with `sysread`**: do not mix them on one handle. `read` fills the PerlIO buffer in chunks of its own choosing; `sysread` ignores that buffer entirely.
- **Binary data on a text-mode handle**: on Unix-like systems there is no distinct text mode, but an encoding layer still transforms bytes. `binmode $fh` (or `open ..., "<:raw", ...`) before reading binary data.
- **`FILEHANDLE` as an expression**: a bareword or simple scalar is fine. Anything more complex must be parenthesised: `read(($handles[$i]), $buf, $len)`.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `open` - acquires the filehandle and decides whether subsequent `reads` are byte-counted or character-counted via the I/O layer
- `sysread` - the unbuffered counterpart, a direct `read(2)` system call; use it for non-blocking I/O or when a short read is meaningful

- `readline` / `<$fh>` - record-oriented input that respects `$/` instead of a byte/character count
- `getc` - read a single character; roughly `read($fh, $c, 1)` but with different EOF/undef reporting
- `binmode` - remove or add I/O layers so that `LENGTH` is unambiguously a byte count or a character count
- `eof` - the right way to test for end of file, rather than reading a zero-length chunk

I/O

readdir

Read the next entry, or all remaining entries, from a directory handle opened by `opendir`.

`readdir` is the directory counterpart of `readline`: it pulls names out of a directory handle one at a time in scalar context, or all at once in list context. The handle must already have been opened with `opendir`; iteration advances a position that `rewinddir`, `seekdir`, and `telldir` can manipulate.

Synopsis

```
readdir DIRHANDLE
my $name  = readdir $dh;
my @names = readdir $dh;
while (readdir $dh) { ... }     # sets $_
```

What you get back

Context-dependent:

- **Scalar context**: the next entry's name as a string, or `undef` when the directory is exhausted.
- **List context**: every remaining entry as a list of strings, or the empty list when the directory is already exhausted.

Entries are **bare filenames**, not paths. `readdir` returns `"foo.txt"`, never `"/some/dir/foo.txt"`. If you plan to hand the result to a file test, `open`, `stat`, or any other call that resolves paths against the current working directory, prepend the directory yourself - `readdir` does **not** `chdir` into the directory it is reading.

The list always includes the entries `.` (current directory) and `..` (parent directory) as reported by the underlying filesystem. Filter them out explicitly if you do not want them:

```
my @real = grep { $_ ne '.' && $_ ne '..' } readdir $dh;
```

Order is filesystem-dependent, not alphabetical. ext4, XFS, tmpfs, NFS, and FAT each return entries in their own internal order, which may be insertion order, hash order, or something else entirely. Never assume sorted output. If you need a predictable order, sort the result:

```
my @names = sort readdir $dh;
```

Examples

Read every name into a list, drop the dot entries, and sort:

```
opendir(my $dh, $some_dir) or die "opendir $some_dir: $!";
my @names = sort grep { !/^\.\.?\z/ } readdir $dh;
closedir $dh;
```

Iterate one entry at a time. A bare `readdir` in a `while` condition assigns to `$_` and tests the result for **definedness**, not truth - so an entry literally named `"0"` still keeps the loop running:

```
opendir(my $dh, $some_dir) or die "opendir $some_dir: $!";
while (readdir $dh) {
    print "$some_dir/$_\n";
}
closedir $dh;
```

Filetest with the directory prepended - forgetting the prefix is the classic `readdir` bug:

```
opendir(my $dh, $some_dir) or die "opendir $some_dir: $!";
my @dotfiles = grep { /^\./ && -f "$some_dir/$_" } readdir $dh;
closedir $dh;
```

Scalar context - one name per call, `undef` signals end of directory:

```
opendir(my $dh, $some_dir) or die "opendir $some_dir: $!";
while (defined(my $name = readdir $dh)) {
    next if $name eq '.' || $name eq '..';
    process("$some_dir/$name");
}
closedir $dh;
```

Rewind and read a second time - the handle stays open and usable:

```
my @first  = readdir $dh;
rewinddir $dh;
my @second = readdir $dh;   # same entries, possibly different order
```

Edge cases

- **Exhausted handle**: further calls return `undef` in scalar context, empty list in list context. Use `rewinddir` to start over.
- **Closed or invalid handle**: returns `undef` (scalar) or empty list (list) and sets `$!`. Under `use warnings` Perl emits `readdir() attempted on invalid dirhandle`.

- **Definedness test in `while`**: both `while (readdir $dh)` and `while (my $n = readdir $dh)` (and their `for` equivalents) are special-cased to test `defined`, not truth. An entry named `"0"` is returned and the loop continues.
- **`.` and `..` are always present** on POSIX filesystems, even in an otherwise empty directory. Filter them if you want only real content.
- **No path prefix**: entries are bare names. Any filetest or `open` on the raw return value tests relative to the current working directory, not `$some_dir`.
- **No sorting**: the order is whatever the kernel returns. Apply `sort` explicitly if stability matters.
- **Concurrent directory changes**: entries added or removed during iteration may or may not appear, per the platform. The only safe assumption is that entries present at `opendir` time and not removed will be reported.
- **Encoding**: `readdir` returns byte strings as the kernel stores them. On a filesystem using UTF-8 filenames, apply `Encode::decode_utf8` or configure the open pragma if you need character strings.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `opendir` - opens the directory handle that `readdir` reads from; always the first call in the sequence
- `closedir` - releases the handle once iteration is done
- `rewinddir` - resets the iteration position to the start of the directory
- `seekdir` - jumps to a previously recorded position
- `telldir` - records the current position for later `seekdir`
- `glob` - shell-style pattern matching over directory contents; higher-level when you want `*.txt` rather than every entry

I/O

readline

Read one or more records from a filehandle.

`readline` is the input primitive behind the `<FH>` diamond operator. It reads from the filehandle named by `EXPR` (a typeglob, a glob reference, or an `IO::Handle`), using the current value of `$/` to decide where one record ends. If `EXPR` is omitted, `*ARGV` is read. In scalar context it returns the next record; in list context it returns every remaining record. End-of-file is signalled by `undef` (scalar) or an empty list.

Synopsis

```
my $line  = readline $fh;       # one record, scalar context
my @all   = readline $fh;       # every remaining record
my $line  = <$fh>;              # same as scalar readline $fh
my @all   = <$fh>;              # same as list  readline $fh
readline;                       # reads from *ARGV
```

What you get back

- **Scalar context**: the next record as a string, or `undef` at end-of-file or on error. The record includes its terminator (the current `$/`) unless the last record in the file is missing one. After the returned value, `$.` is incremented - see the section on global state below.
- **List context**: a list of every remaining record until end-of-file. An empty list means the handle was already at EOF.
- **Slurp mode on an empty file**: when `$/` is `undef` and context is scalar, the first call on a zero-byte handle returns `''` (empty string, defined); the next call returns `undef`. This lets `defined($slurp = readline $fh)` distinguish an empty file from a missing one without a separate `-s` test.

Global state it touches

- `$/` - input record separator. Controls what counts as "one record". Default is `"\n"`. Special values are covered under *Record modes* below. Also known as `$INPUT_RECORD_SEPARATOR` or `$RS` under `use English`.
- `$.` - current input line number of the last handle read. `readline` increments `$.` once per record returned. `$.` is reset when the handle is explicitly `close`d, but **not** when `*ARGV` rolls from one file to the next - that continues counting across the whole input. Also `$INPUT_LINE_NUMBER` or `$NR` under `use English`.
- `$_` - the default scalar. When a `readline` call (or its `<FH>` equivalent) is used **as the condition of a `while` or `for` loop**, Perl implicitly assigns the result to `$_` and tests `defined`, not truth. `while (<$fh>) { ... }` is therefore safe on lines containing `"0"` or `""`.
- `$!` - errno. On a read error, `readline` returns `undef` (scalar) or a truncated list, and sets `$!` to the operating-system error.
- `@ARGV` - when `EXPR` is omitted (or the handle is `ARGV`), each end-of-file causes Perl to `open` the next filename from `@ARGV` and continue reading. An empty `@ARGV` makes `ARGV` read `STDIN`.

Record modes

`$/` selects one of four reading modes:

- **Line mode** (default) - `$/` is a non-empty string. A record ends at the next occurrence of that string. With the default `"\n"`, one call returns one line including its newline.

- **Paragraph mode** - `$/ = ""`. A record ends at the next run of two or more consecutive newlines. Leading blank lines before the first paragraph are skipped; the terminating blank line(s) are included in the returned string. Use `local $/ = ""` to confine the change to a block.
- **Slurp mode** - `$/ = undef`. The first call returns the entire remaining contents of the handle as one string; the next call returns `undef`. On an empty file, see the special case under *What you get back*.
- **Fixed-record mode** - `$/ = \N` (a reference to a positive integer) or `$/ = \"N"`. Each call reads exactly `N` bytes, or fewer at end-of-file. Useful for binary framing. The result is still counted as one record for `$.`.

Changes to `$/` take effect on the next `readline` call. Scope them with `local` so a subroutine does not silently change the caller's idea of "line".

Examples

Idiomatic line-by-line read. The `while` condition implicitly assigns to `$_` and tests `defined`:

```
open my $fh, "<", "input.txt" or die "open: $!";
while (<$fh>) {
    chomp;
    print "line $.: $_\n";
}
close $fh;
```

Explicit `readline` with error detection. `eof` must be checked separately from the return value, because a legitimate line can be the empty string:

```
while ( ! eof($fh) ) {
    defined( my $line = readline $fh )
        or die "readline failed: $!";
    # ... process $line ...
}
```

Slurp a whole file into a scalar:

```
my $contents = do {
    local $/;                    # undef - slurp mode
    open my $fh, "<", $path or die "open $path: $!";
    readline $fh;
};
```

Paragraph mode - read an RFC-822-style message header block:

```
open my $fh, "<", "message.eml" or die $!;
local $/ = "";
my $headers = <$fh>;             # up to the first blank line
my $body    = do { local $/; <$fh> };
```

Fixed-record mode - read 512-byte blocks from a device file:

```
open my $fh, "<:raw", "/dev/sda" or die $!;
local $/ = \512;
while (defined(my $block = <$fh>)) {
    last if length($block) < 512;   # short read at EOF
    # ... process $block ...
}
```

List context - pull every remaining line at once. Cheap for small files, ruinous for large ones:

```
open my $fh, "<", "hosts" or die $!;
my @lines = <$fh>;              # every line, including terminators
chomp @lines;
```

Reading from *ARGV with no explicit handle - the classic Perl filter idiom. @ARGV is consumed as a list of filenames, or STDIN is read if @ARGV is empty:

```
while (defined(my $line = readline)) {
    print $line;                # cat(1) in one line
}
```

Edge cases

- **EOF vs. error**: scalar `readline` returns `undef` for both. Call `eof($fh)` or check `$!` to distinguish them. Inside `while (<$fh>)` the loop exits on either; add an explicit `defined` plus `$!` check when you need to tell them apart.
- **A file with no trailing newline**: the last record is returned without a terminator in line mode. `chomp` is a no-op on such a value, which is the correct behaviour.
- **Paragraph mode on a file of only blank lines**: returns `undef` immediately - there is no non-empty paragraph to yield.
- **Slurp mode, empty file**: first call returns `''` (defined, zero-length); the second returns `undef`. Do not branch on truthiness of the first read.
- **Fixed-record mode with a short read at EOF**: returns the remaining bytes (possibly fewer than N), then `undef` on the next call. Check `length` if you need exactly N.
- **The ARGV magic handle**: when reading from *ARGV, `eof()` with no argument returns true only at the very end of **all** @ARGV files, while `eof(ARGV)` is true at the end of **each** file. You cannot use the `defined(readline) or die "...: $!"` idiom against *ARGV to distinguish EOF from error - open each filename yourself if you need that.
- **Already-closed handle**: `readline` returns `undef` and sets `$!` to `"Bad file descriptor"`. Under `use warnings` a `readline() on closed filehandle` warning is emitted.
- **Encoding layers**: `readline` returns whatever the handle's PerlIO stack produces. A `:utf8` or `:encoding(...)` layer decodes bytes into characters; a `:raw` handle returns bytes. Mixing a multi-byte `$/` with a byte handle can split characters.

- **Mid-record `$/` change**: only the next `readline` call observes the new separator. Any already-buffered data is re-scanned against it.
- **`<FH>` vs. `<$fh>` vs. `<>`**: these are all `readline` under the hood. `<FH>` reads from the typeglob `FH`; `<$fh>` reads from the handle in `$fh`; `<>` (or `<<>>` for safer filename handling) reads from `*ARGV`. The `<pattern>` form with any other content is `glob`, not `readline` - a different function entirely.
- **Loop condition assignment**: `while (my $line = <$fh>) { ... }` tests `defined`, not truth, only because the parser rewrites it. `while (($line = <$fh>)) { ... }` with the extra parentheses does **not** get the rewrite, and will loop forever on input containing `"0\n"`.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `open` - obtain the filehandle that `readline` consumes
- `read` - fixed-length byte read that ignores `$/`; use when you want a byte count, not a record
- `getc` - single-character read, likewise ignoring `$/`
- `eof` - test whether the next `readline` would return `undef`; behaves specially for `*ARGV`
- `$/` - input record separator; controls line, paragraph, slurp, and fixed-record modes
- `$.` - current input line number, incremented by every successful `readline`

Filehandles, files, directories

readlink

Return the target path a symbolic link points to.

`readlink` asks the kernel what string is stored inside a symbolic link, without following it and without touching the file the link eventually resolves to. The argument is the path of the link itself; the return value is the raw target string as recorded when the link was created. If `EXPR` is omitted, `$_` is used.

Synopsis

```
readlink EXPR
readlink
```

What you get back

On success, the link target as a string - exactly the bytes stored in the symlink, without any interpretation. On failure, `undef`, with `$!` set to the system error. Typical error codes:

- `EINVAL` - the path exists but is not a symbolic link
- `ENOENT` - the path does not exist
- `EACCES` - a directory component is not searchable
- `ELOOP`, `ENAMETOOLONG`, `ENOTDIR` - the usual path-resolution failures on components leading up to the link

The returned string is **not** canonicalised and **not** made absolute. A link created with `ln -s ../lib/libfoo.so libfoo.so` returns the literal `"../lib/libfoo.so"`, relative to the directory that contains the link itself - not to the current working directory. Resolving the target to an absolute, real path is the caller's job; see `Cwd::abs_path`.

Global state it touches

- `$_` - read as the default argument when `EXPR` is omitted
- `$!` - set on failure to the C `errno` from the underlying `readlink(2)` call

Examples

Read a link target directly:

```
my $target = readlink "/usr/bin/vi";
print defined $target ? "points to $target\n" : "not a symlink: $!\n
 ↪";
```

Default argument form inside a loop over filenames:

```
for (@paths) {
    next unless -l;                     # skip anything that isn't a␣
 ↪symlink
    my $t = readlink;                   # reads $_
    print "$_ -> $t\n" if defined $t;
}
```

Guard against non-symlinks explicitly. `readlink` on a regular file returns `undef` and sets `$!` to `EINVAL`:

```
my $t = readlink $path;
if (!defined $t) {
    die "readlink $path: $!" unless $!{EINVAL};
    # not a symlink - handle as a plain file
}
```

Resolve a relative link target against the link's own directory, which is the correct base - not the current working directory:

```
use File::Basename qw(dirname);
use File::Spec;

my $target = readlink $link // die "readlink $link: $!";
my $resolved = File::Spec->rel2abs($target, dirname($link));
```

Canonicalise fully (follow every link in the chain, collapse `.` and `..`, produce an absolute path) with `Cwd::abs_path`:

```
use Cwd qw(abs_path);
my $real = abs_path($link);              # undef if any component is␣
↪missing
```

Edge cases

- **Not a symlink**: `readlink` on a regular file, directory, or anything else that isn't a symbolic link returns `undef` and sets `$!` to `EINVAL`. Test with `-l` first if you want to distinguish "not a link" from other errors.
- **Missing path**: a component of `EXPR` that doesn't exist gives `ENOENT`, same as any other path-lookup failure.
- **Default argument**: bare `readlink` uses `$_`. No warning is emitted when `$_` is `undef`; the call simply fails with a path-lookup error.
- **Trailing components**: `readlink` operates on the final component only - intermediate symlinks in the path are followed normally. `readlink "/a/b/c"` where `/a` is itself a symlink reads the link at `c`, not at `a`.
- **Relative target, unchanged**: the returned string is stored verbatim. Never assume the string is absolute, and never join it onto the current working directory - join onto the directory that contains the link, or feed the link path (not the target) to `Cwd::abs_path`.
- **Dangling links**: a link whose target does not exist still reads fine. `readlink` does not stat the target. Use `lstat` to inspect the link itself, `stat` to inspect what it points to (and fail if the target is missing).
- **Platforms without symlinks**: on systems that do not implement symbolic links, `readlink` raises an exception rather than returning `undef`. Linux (the only supported pperl target) always has them, so this is relevant only for portable code shared with other targets.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `symlink` - create a symbolic link; inverse operation
- `link` - create a hard link (not readable with `readlink`; hard links are indistinguishable from the original name)
- `lstat` - `stat` the symlink itself rather than its target; use together with `readlink` to inspect a link fully
- `-l` - file test for "is a symbolic link"; check before calling `readlink` to disambiguate `EINVAL` from other errors
- `$!` - errno set on failure; `$!{EINVAL}` distinguishes "not a symlink" from other errors

Processes

readpipe

Run a shell command and return its standard output.

`readpipe` hands `EXPR` to the shell, waits for the child to finish, and returns whatever the child wrote to its standard output. It is the named form of the `qx` (backticks) operator - `` `cmd` `` and `qx/cmd/` both compile down to `readpipe`. Reach for the named form when you want the command in a variable, when you want to suppress the double-quote interpolation `qx` performs, or when you want to read a captured command out of `@ARGV`. If `EXPR` is omitted, `$_` is used.

Synopsis

```
readpipe EXPR
readpipe
$out  = readpipe $cmd;
@rows = readpipe $cmd;
```

What you get back

Context decides the shape:

- **Scalar context** - one string containing the entire captured output, newlines and all.
- **List context** - a list of records, split on `$/` (the input record separator, newline by default). The separator stays attached to each element unless you `chomp` it off.

`$?` is set to the child's wait status after the command finishes, exactly as with `system`. A non-zero `$?` is the usual signal that the command failed - the return value alone cannot tell you, since a failing command may still have written output (or nothing) before exiting.

```
my $out = readpipe "uname -a";
die "uname failed: \$? = $?" if $?;
```

Global state it touches

- `$_` - used as the command when `EXPR` is omitted.
- `$/` - controls how list-context output is split into records. Set it to `undef` to slurp the whole output into a single element, or to `""` for paragraph mode.
- `$?` - set to the child's wait status on return.
- `$!` - set if the shell itself could not be launched.
- `%ENV` - the shell inherits the current environment.

Examples

Capture one line of output:

```
my $host = readpipe "hostname";
chomp $host;
print "running on $host\n";
```

Command held in a variable - the reason `readpipe` exists as a named function. Backticks would still work here, but `readpipe` makes the intent explicit and avoids the visual noise of nested quoting:

```
my $cmd = "ls -1 /etc";
my @entries = readpipe $cmd;
chomp @entries;
print scalar(@entries), " entries under /etc\n";
```

Slurp everything as one string by disabling record separation:

```
local $/;                                  # slurp mode
my $log = readpipe "dmesg";
print length($log), " bytes of kernel log\n";
```

Paragraph mode - each element is one blank-line-separated block:

```
local $/ = "";
my @paragraphs = readpipe "cat README";
print scalar(@paragraphs), " paragraphs\n";
```

Check the exit status properly. The return value is output; success lives in `$?`:

```
my @files = readpipe "find . -name '*.tmp' 2>/dev/null";
if ($? == 0) {
    chomp @files;
    unlink @files;
} else {
    warn "find exited with status ", ($? >> 8), "\n";
}
```

Use `$_` as the command. Rarely the clearest form, but legal:

```
$_ = "date";
my $when = readpipe;                       # same as readpipe $_
```

Edge cases

- **No interpolation protection.** `readpipe` interpolates its argument exactly like a double-quoted string - the same as `qx`. `readpipe "rm $path"` with `$path` coming from user input is a shell-injection hole. Quote the value, or better, switch to a list-form `system` / piped `open` and skip the shell entirely.
- **Standard error is not captured.** Only the child's standard output comes back. Redirect stderr in the command itself if you want it merged: `readpipe "cmd`

2>&1".

- **Shell is mandatory.** Even a single-word `readpipe "true"` goes through `/bin/sh`, which means shell quoting, globbing, and environment-variable expansion all apply. No list form exists.
- **Large output buffers in memory.** The whole child output is read before `readpipe` returns. For a command that produces gigabytes, use a piped `open` and read incrementally instead.
- **Empty output, zero exit.** A successful command that writes nothing returns the empty string in scalar context and the empty list in list context. Distinguish "ran and said nothing" from "never ran" by checking `$?`.
- **Child died on signal.** `$?` encodes both exit code and signal - mask with `$? & 127` to get the signal number, `$? >> 8` for the exit code.
- **Windows quoting rules.** `readpipe` hands the string to the platform shell; on Windows that is `cmd.exe`, whose quoting and redirection rules differ from POSIX. pperl is Linux-only, so this is only relevant when porting scripts in.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `qx` - the operator form; `` `cmd` `` and `qx/cmd/` are shorthand for `readpipe` and carry identical semantics
- `system` - run a command without capturing output; use when you only care about exit status
- `exec` - replace the current process with the command; no return, no capture
- `open` - piped open (`open my $fh, "-|", @cmd`) streams the child's output line-by-line without buffering it all
- `$?` - child wait status set by every process-launch builtin
- `$/` - input record separator that splits list-context output

Sockets

recv

Read an incoming message from a socket into a scalar.

`recv` reads up to `LENGTH` bytes from `SOCKET` into `SCALAR`, replacing whatever `SCALAR` previously held. `SCALAR` is grown or shrunk to the number of bytes actually received. `FLAGS` is the same bit mask the underlying `recvfrom(2)` system call takes - `0` for ordinary reads; the common non-zero values are `MSG_PEEK` (look without consuming), `MSG_WAITALL` (block until `LENGTH` bytes arrive), and `MSG_DONTWAIT` (never block). For a connectionless socket `recv` returns the sender's packed address; for a connected socket it returns the empty string. Under the hood this is `recvfrom(2)`, not `recv(2)`.

Synopsis

```
recv SOCKET, SCALAR, LENGTH, FLAGS
```

What you get back

- On success from a connectionless socket (UDP, UNIX datagram): the sender's address as a packed sockaddr string. Unpack it with `Socket`'s `sockaddr_in`, `sockaddr_in6`, or `sockaddr_un` depending on the address family.
- On success from a connected socket (TCP, connected UDP): the empty string `""`. The empty string is **true** for the defined-vs-undef check but **false** in boolean context - test with `defined`, not plain truthiness.
- On error: `undef`, with `$!` set to the `errno` from the failing `recvfrom(2)` call. Typical errors: `EAGAIN` / `EWOULDBLOCK` on a non-blocking socket with no data ready, `ECONNRESET` on a TCP peer reset, `EBADF` on a closed handle.

`SCALAR` is always resized to the byte count read. A zero-byte read on a connected stream socket means the peer closed its write side cleanly - `recv` returns `""` and `SCALAR` becomes the empty string.

Global state it touches

- `$!` is set on error to the system `errno`.
- No other special variables are involved. `recv` does not honour `$/`, `$,`, or `$\` - those are line-oriented I/O concepts and `recv` is a raw datagram / byte-stream primitive.

Examples

Read one UDP datagram and identify the sender:

```
use Socket;
my $from = recv($sock, my $buf, 1500, 0)
    or die "recv: $!";
my ($port, $ip) = sockaddr_in($from);
print "got ", length($buf), " bytes from ",
      inet_ntoa($ip), ":$port\n";
```

Read from a connected TCP socket. The sender address is empty, so check with `defined` rather than boolean truth:

```
defined(recv($sock, my $buf, 4096, 0))
    or die "recv: $!";
# $buf now holds 0..4096 bytes; 0 means the peer closed.
```

Peek at the next datagram without consuming it. The second call returns the same bytes:

```
use Socket;
recv($sock, my $peek,    1500, MSG_PEEK) or die $!;
recv($sock, my $consume, 1500, 0)        or die $!;
# $peek and $consume hold the same datagram.
```

Non-blocking read loop. `EAGAIN` / `EWOULDBLOCK` is the normal "no data yet" signal, not a real error:

```
use Errno qw(EAGAIN EWOULDBLOCK);
while (1) {
    my $from = recv($sock, my $buf, 1500, 0);
    unless (defined $from) {
        last if $! == EAGAIN || $! == EWOULDBLOCK;
        die "recv: $!";
    }
    handle_datagram($from, $buf);
}
```

Force a full-length read on a stream socket that might fragment the message - `MSG_WAITALL` blocks until `LENGTH` bytes are in or the connection dies:

```
use Socket;
defined(recv($sock, my $frame, 64, MSG_WAITALL))
    or die "recv: $!";
# $frame is exactly 64 bytes, or the peer closed early.
```

Edge cases

- **UTF-8-layered socket**: if `SOCKET` has a `:utf8` layer (directly or via `:encoding(...)`), `recv` throws an exception. `recv` is byte-oriented and does not interact with PerlIO layers; use `binmode` to strip the layer before reading, or decode the resulting bytes yourself.
- **LENGTH vs datagram size**: for datagram sockets, if `LENGTH` is smaller than the incoming datagram, the excess is **discarded silently**. Size the buffer to the protocol's MTU (typically 1500 for UDP over Ethernet, 65507 for the IPv4 UDP maximum).
- **`""` return is not false-enough**: `recv` on a connected socket returns the empty string, which `!` treats as false. Code like `recv(...) or die $!` dies on every successful connected read. Use `defined`:

  ```
  defined(recv($sock, $buf, $len, 0)) or die "recv: $!";
  ```

- **Zero-byte result on a stream socket**: `recv` returns `""` and `SCALAR` becomes empty when the peer has performed an orderly shutdown. Distinguish end-of-stream from a real error by checking `length($buf) == 0` after a defined return.
- **Signals**: a blocking `recv` interrupted by a signal returns `undef` with `$!` == `EINTR`. Retry or install a proper `sigaction` with `SA_RESTART` if that's not what you want.
- **Closed socket**: `recv` on a closed or never-opened handle returns `undef`, sets `$!` to `EBADF`, and emits a `recv() on closed socket` warning under `use warnings`.
- **Pre-existing `SCALAR` contents are destroyed**. `recv` does not append; it overwrites. Use a fresh lexical or clear the scalar before each call.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `send` - the write side of the same socket; same `FLAGS` vocabulary, same connectionless-vs-connected distinction
- `socket` - create the `SOCKET` handle `recv` reads from
- `bind` - required before `recv` on a server-side datagram socket so the kernel knows which port to deliver to
- `connect` - when used on a datagram socket, makes `recv` return `""` like a stream socket and filters out datagrams from other peers
- `sysread` - byte-level read for stream sockets when you do not need the sender address; integrates with `select`-based loops
- `Socket` - `sockaddr_in`, `inet_ntoa`, `MSG_PEEK`, `MSG_WAITALL`, and the rest of the constants `recv` consumes

Control flow

redo

Restart the current iteration of a loop without re-testing the condition and without running the `continue` block.

`redo` jumps back to the top of the loop body and re-runs it on the *same* input - the conditional that guards the loop is not re-evaluated, `$_` is not advanced by `while (<FH>)`, the iterator of a `foreach` is not advanced, and any `continue { }` block attached to the loop is skipped. The current pass happens again from the beginning.

Synopsis

```
redo
redo LABEL
redo EXPR
```

What you get back

`redo` does not return a value. It is a flow-control operator: it transfers control and never falls through to the next statement. Do not try to use it as the value of an expression - in particular, it cannot be used to return a value from `eval { }`, `sub { }`, or `do { }`.

Which loop it targets

With no argument, `redo` refers to the innermost enclosing loop. With a `LABEL`, it restarts the loop tagged with that label, allowing you to reach out of nested loops:

```
OUTER: while (...) {
    while (...) {
        redo OUTER;      # restart the while (...) above
    }
}
```

`redo EXPR` (added in Perl 5.18) computes the label at runtime. The expression must evaluate to a string naming a label currently in scope:

```
my $target = "OUTER";
redo $target;
```

A bare block counts as a loop that runs once, so `redo` inside a block turns it into a looping construct:

```
{
    my $line = <STDIN>;
    redo if $line =~ /^\s*$/;   # skip blank lines, re-read
    print $line;
}
```

`redo` vs `next` vs `last`

All three take an optional `LABEL` and all three affect loop control, but they differ in what they skip:

- `last` - exit the loop entirely. `continue` block is **not** run.
- `next` - go to the next iteration. `continue` block **is** run, then the loop condition is re-tested.
- `redo` - re-run the *same* iteration. `continue` block is **not** run, and the loop condition is **not** re-tested.

The `continue`-block difference is the one that catches people out. If a loop uses `continue { }` to increment a counter or advance a cursor, `redo` will not advance it - that's the whole point, but it is also the whole foot-gun.

Examples

Re-prompt until the user gives valid input. The `continue` block is skipped, so `$attempts` only counts *completed* iterations, which is usually what you want:

```
my $attempts = 0;
while (1) {
    print "Enter a positive integer: ";
    my $n = <STDIN>;
    chomp $n;
    redo unless $n =~ /^[0-9]+$/ && $n > 0;
    print "Got $n after $attempts rejected tries.\n";
    last;
} continue {
```

(continues on next page)

(continued from previous page)

```
    $attempts++;
}
```

Restart processing of the current line after patching it - the classic "lie to yourself about what was just read" pattern, here stripping Pascal-style block comments that may span multiple input lines:

```
LINE: while (<STDIN>) {
    while (s|({.*}.*){.*}|$1 |) {}
    s|{.*}| |;
    if (s|{.*| |) {
        my $front = $_;
        while (<STDIN>) {
            if (/}/) {          # end of comment?
                s|^|$front\{|;
                redo LINE;      # re-process the patched line
            }
        }
    }
    print;
}
```

Target an outer loop by label. `redo INNER` would restart the inner loop on the current `$x`; `redo OUTER` restarts the outer loop on the current `$x` *without* advancing the `foreach` iterator:

```
OUTER: foreach my $x (@xs) {
    INNER: foreach my $y (@ys) {
        redo OUTER if should_restart($x, $y);
    }
}
```

Turn a bare block into a retry loop. Without `redo` this block runs exactly once; with `redo` it runs until the fetch succeeds:

```
my $tries = 0;
{
    my $ok = try_fetch();
    if (!$ok && ++$tries < 3) {
        sleep 1;
        redo;
    }
}
```

Edge cases

- **`continue` is not run.** This is the defining difference from `next`. If your loop relies on `continue { }` for counters, cursors, or cleanup, `redo` will bypass all of it. Either move the work into the body or use `next` instead.

- **Loop condition is not re-tested.** `while (cond) { ... redo; }` will keep looping even if cond would now be false. You are responsible for ensuring the `redo` path eventually exits via `last`, `return`, or a conditional fall-through.
- **Easy infinite loop.** `redo` with no state change is a tight infinite loop - typically not what you want. Always pair `redo` with a condition that eventually becomes false, or with a retry counter that triggers `last`.
- **`foreach` does not advance.** `foreach my $x (@xs) { redo }` keeps `$x` pinned at the current element and loops on it forever. The iterator only advances on fall-through or `next`.
- **`while (<FH>)` does not read the next line.** `$_` retains the current line across the `redo`, which is precisely why the Pascal comment stripper above works.
- **`redo` out of `grep` / `map` is not supported.** Upstream documents this as undefined; do not use `redo` to exit or restart a `grep BLOCK LIST` or `map BLOCK LIST`.
- **`redo` out of `eval`, `sub`, or `do` is not a return.** It performs flow control; there is no value to return. A `redo` that would have to cross such a boundary to reach a loop is a runtime error ("Can't `redo` outside a loop block").
- **Precedence quirk.** Unlike most named operators, `redo` has the precedence of assignment and is exempt from the looks-like-a-function rule. `redo ("foo")."bar"` passes the whole concatenation as the argument to `redo` - the parentheses do not isolate `"foo"`.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `last` - exit the loop entirely; `continue` block is not run, same as `redo`
- `next` - advance to the next iteration; `continue` block **is** run and the loop condition is re-tested
- `return` - return from the enclosing subroutine, not just the loop; unlike `redo`, it yields a value
- `continue` - the block that `redo` skips but `next` runs; the core of the three-way distinction

Classes and OO

ref

Return a string describing what a reference points to.

`ref` examines its operand and returns a string identifying the kind of referent. For a blessed reference it returns the class name; for an unblessed reference it returns one of the built-in type strings (`SCALAR`, `ARRAY`, `HASH`, `CODE`, `GLOB`, `LVALUE`, `IO`, `FORMAT`, `REF`, `VSTRING`, `REGEXP`). For anything that is not a reference it returns the empty string. With no argument, `ref` operates on `$_`.

Synopsis

```
ref EXPR
ref
```

What you get back

A string. Three mutually exclusive categories:

- **Blessed reference** - the name of the class the referent is blessed into. For example, a `bless {}, 'Dog'` reference returns `"Dog"`. Subclasses return their own name, not the parent's: a reference blessed into Puppy (an `ISA` of Dog) returns `"Puppy"`. See `bless`.
- **Unblessed reference** - one of the built-in type strings listed below, identifying the physical type of the referent.
- **Non-reference** - the empty string `""`.

The empty string is the **only** false value `ref` ever returns, so `if (ref $x)` is a safe "is this a reference?" test. See the edge cases section for why `if (ref $x eq 'HASH')` is *not* a safe "is this a hash reference?" test.

Built-in type strings

Returned for unblessed references according to the physical referent:

String	Referent
`SCALAR`	reference to an ordinary scalar
`ARRAY`	reference to an array
`HASH`	reference to a hash
`CODE`	reference to a subroutine
`GLOB`	reference to a typeglob
`LVALUE`	reference to an assignable expression
`IO`	reference to an I/O handle
`FORMAT`	reference to a format
`REF`	reference to another reference
`VSTRING`	reference to a v-string scalar
`REGEXP`	reference to a raw (unblessed) regexp

A compiled regex from `qr//` is *blessed* into the class `Regexp` at creation time, so `ref qr/.../` normally returns `"Regexp"`, not `"REGEXP"`. The bare `REGEXP` string appears only for unblessed regex referents, which are rare outside of internals.

Examples

Basic type probes:

```
ref \1              # "SCALAR"
ref []              # "ARRAY"
```

(continues on next page)

(continued from previous page)

```
ref {}               # "HASH"
ref sub { }          # "CODE"
ref \*STDOUT         # "GLOB"
ref \\1              # "REF"    (reference to a reference)
ref qr/foo/          # "Regexp" (blessed)
ref "plain string"   # ""       (not a reference)
ref 42               # ""
ref undef            # ""
```

Blessed references return the class name:

```
my $obj = bless {}, 'My::Widget';
ref $obj;                        # "My::Widget"
```

Guard before dereferencing:

```
sub stringify {
    my ($v) = @_;
    return "[undef]"           if !defined $v;
    return "[ref: " . ref($v) . "]" if ref $v;
    return $v;
}
```

No-argument form reads `$_`:

```
for my $item (@things) {
    print "skipping non-ref\n" and next unless ref;
    ...
}
```

Picking the right test

`ref` is the oldest introspection primitive in the language and it conflates three different questions. Modern code should pick the operator that matches the question being asked.

Is this a reference at all?

```
if (ref $x) { ... }             # empty string is the only false␣
↪return
```

Is this an object of (or derived from) a given class? Use the `isa` operator (or the `UNIVERSAL::isa` method) - it walks `@ISA` and honours subclassing, which a literal `ref` comparison does not:

```
if ($obj isa 'My::Widget') { ... }      # true for subclasses too
if ($obj->isa('My::Widget')) { ... }    # method form

if (ref($obj) eq 'My::Widget') { ... }  # FRAGILE: fails for␣
↪subclasses
```

What is the underlying physical type, regardless of blessing? Use `Scalar::Util::reftype` - it ignores the class and returns the built-in type string even for blessed references:

```
use Scalar::Util qw(reftype blessed);
reftype($obj);                  # "HASH" if $obj is blessed hash ref
blessed($obj);                  # class name, or undef if not␣
 ↪blessed
```

Edge cases

- **Never use `ref` as a truth value of the referent.** A reference blessed into a class literally named `0` makes `ref $obj` return the string `"0"`, which is false. This is rare by construction but the foot-gun is old and well known. Compare to the empty string instead: `if (ref $x ne "")`.
- **Class name clashes with built-in type strings.** Nothing stops you from writing `package HASH; sub new { bless {}, shift }`. Then `ref(HASH->new)` returns `"HASH"` - indistinguishable from an unblessed hash reference by `ref` alone. Use `Scalar::Util::blessed` to disambiguate, or `reftype` to ask the physical-type question directly.
- **`ref` on `qr//` returns `"Regexp"`, not `"REGEXP"`.** `qr//` objects are blessed at construction; the uppercase form is only produced for the (unusual) unblessed regex reference.
- **Tied variables**: `ref` sees through the tie to the underlying reference. Use `tied` to retrieve the object backing the tie.
- **Weak references** are still references: `ref` behaves identically for weak and strong refs. Use `Scalar::Util::isweak` to detect weakness.
- **Overloaded stringification does not affect `ref`.** The return value of `ref` is produced by the runtime, not by the object's `""` overload.
- **`ref EXPR` has very high precedence** - it is parsed as a named unary operator. Parenthesise when the argument is anything more complex than a simple variable:

```
ref $a || $b;           # parsed as (ref $a) || $b
ref($a || $b);          # what you probably meant
```

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `bless` - install a class name on a reference; the name installed here is exactly what `ref` returns afterwards
- `isa` - class-membership test that honours `@ISA` inheritance; prefer this over `ref(...) eq 'ClassName'` for OO dispatch

- `tied` - retrieve the object implementing a tied variable; `ref` on a tied scalar follows the tie to the referent
- `Scalar::Util::reftype` - physical-type string for a reference, ignoring blessing
- `Scalar::Util::blessed` - class name if blessed, `undef` otherwise; the unambiguous counterpart to `ref` for OO code
- `perlref`, `perlobj` - reference and object model reference manuals

Filehandles, files, directories

rename

Change the name of a file.

`rename` asks the operating system to rebind the path `OLDNAME` to `NEWNAME`. On a POSIX filesystem this is a single atomic directory operation: after the call returns successfully, `NEWNAME` refers to the file that used to be reachable as `OLDNAME`, and `OLDNAME` no longer exists. It is the same primitive the shell `mv` command reaches for when source and destination live on the same filesystem.

Synopsis

```
rename OLDNAME, NEWNAME
```

What you get back

`1` on success, `0` on failure with `$!` set to the `errno` the underlying `rename(2)` syscall returned. Always check the return value - a silent failure here leaves the filesystem in a state the rest of the program does not expect:

```
rename $tmp, $final
    or die "rename $tmp -> $final failed: $!";
```

Atomicity and the same-filesystem rule

`rename` is atomic **only when `OLDNAME` and `NEWNAME` resolve to the same filesystem**. Within that filesystem, no intermediate state is ever visible: another process reading the directory sees either the old name or the new name, never both and never neither. This is why the canonical "write a file safely" idiom writes to a temporary file in the same directory and then renames it into place:

```
open my $fh, ">", "$path.tmp" or die "open: $!";
print $fh $data;
close $fh or die "close: $!";
rename "$path.tmp", $path
    or die "rename: $!";
```

Across filesystems the call fails with `EXDEV` (`"Invalid cross-device link"`) and nothing is moved. The system `mv` command papers over this by falling back to copy-then-unlink; `rename` does not. For a portable cross-device move, use `move` from `File::Copy`, which performs the copy-and-unlink fallback itself.

Examples

Rename within a directory:

```
rename "draft.txt", "final.txt"
    or die "rename: $!";
```

Atomic file replacement - write to a sibling tempfile, then rename:

```
my $tmp = "$path.$$.tmp";
open my $fh, ">", $tmp or die "open $tmp: $!";
print $fh $content;
close  $fh             or die "close $tmp: $!";
rename $tmp, $path     or die "rename $tmp -> $path: $!";
```

Detect the cross-device case and fall back to `File::Copy::move`:

```
use Errno qw(EXDEV);
use File::Copy qw(move);

unless (rename $src, $dst) {
    if ($! == EXDEV) {
        move($src, $dst) or die "move: $!";
    }
    else {
        die "rename: $!";
    }
}
```

Rename every `.log` in a directory to `.log.old`:

```
for my $f (glob "*.log") {
    rename $f, "$f.old"
        or warn "rename $f: $!";
}
```

Edge cases

- **`NEWNAME` already exists**: silently clobbered. `rename` does **not** ask, warn, or refuse. If the target is a regular file it is unlinked as part of the operation; if it is a directory the call fails with `ENOTDIR` or `EISDIR` depending on whether `OLDNAME` is a directory. To get "refuse to overwrite" semantics, test with `-e` first (and accept that the check is racy - there is no portable `renameat2(RENAME_NOREPLACE)` exposed through `rename` itself).
- **Cross-filesystem (`EXDEV`)**: fails, leaves both paths intact. Use `File::Copy::move` when the destination may be on another mount.
- **Open filehandles**: on Linux (and POSIX generally) renaming a file that is currently open is fine. The open filehandle keeps pointing at the same inode; subsequent reads and writes through it continue to work. New opens use the new name.
- **Directories**: renaming a directory is allowed, but only when `NEWNAME` does not

exist or is an empty directory. Moving a directory into a subdirectory of itself fails with `EINVAL`.

- **Permissions**: `rename` needs write + execute permission on both the source and destination parent directories, not on the file itself. Failure shows up as `EACCES` or `EPERM`.
- **Sticky-bit directories** (`/tmp`): if the destination parent has the sticky bit set, you must own either the source file or the destination parent; otherwise the call fails with `EPERM` even when the directory is world-writable.
- **Symlinks**: `rename` operates on the link itself, never on its target. `rename "link", "other"` renames the symlink; the file it points at is untouched.
- **Trailing slash on `OLDNAME`**: many kernels reject this with `ENOTDIR` when the source is not a directory. Do not rely on trailing-slash behaviour being portable.
- **Same-path rename**: `rename $p, $p` succeeds and does nothing (POSIX-required behaviour) as long as `$p` exists.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `unlink` - remove a file by name; the tear-down counterpart to creating one with `rename` into place
- `link` - make an additional hard-link name for an existing file without removing the original
- `symlink` - create a symbolic link; note that `rename` on a symlink moves the link, not its target
- `File::Copy` - portable `move` and `copy` that handle the cross-filesystem (`EXDEV`) case `rename` cannot
- `$!` - `errno` after a failed `rename`; compare against constants from `Errno` (`EXDEV`, `EACCES`, `ENOENT`, ...)

Modules

require

Load a Perl source file at runtime, or demand a minimum Perl version.

`require` has three forms that do quite different things. With a version number it asserts the running interpreter is new enough. With a bareword it loads a module by transforming `Foo::Bar` into `Foo/Bar.pm` and searching `@INC`. With a runtime string or `$_` it loads a filename verbatim. All three are **runtime** operations - contrast with `use`, which is `require` + `import` wrapped in a compile-time `BEGIN` block.

Synopsis

```
require VERSION
require EXPR
require
```

What you get back

For the version-check form: 1 if the running Perl is new enough; otherwise an exception is thrown (`Perl vX.Y.Z required--this is only ...`). Nothing to check.

For the file-loading forms: the true value returned by the last statement of the loaded file, or 1 if the file enables the `module_true` feature (default under `use v5.38` and later). A second `require` of the same path returns 1 without re-executing the file. Failure throws an exception - either the compile/runtime error from the file, `Can't locate Foo/Bar.pm in @INC ...`, or `Foo/Bar.pm did not return true value`.

Wrap in `eval` when you want to test whether a module is loadable:

```
eval { require Some::Optional::Module };
if ($@) { ... }                    # module missing or broken
```

Global state it touches

- `@INC` - the search path for bareword and relative-filename forms. Entries may be directory strings, coderefs, array refs, or blessed objects (see `@INC` *hooks* below).
- `%INC` - maps the requested filename (`Foo/Bar.pm`) to the absolute path that was loaded. `require` consults it to avoid double-loading and sets it on success. An entry of `undef` marks a file whose compilation failed.
- `$_` - used as the filename when `require` is called with no argument.
- `${^HOOK}{require__before}` and `${^HOOK}{require__after}` - optional coderefs run around every `require`, available for tracing and instrumentation wrappers.

The three forms

`require VERSION` - minimum Perl check

`VERSION` is either a v-string like `v5.38.0` (compared against `$^V`) or a numeric literal like `5.038000` (compared against `$]`). If the running interpreter is older, `require` throws.

```
require v5.38;        # preferred
require 5.038;        # numeric; same effect
require 5.038_000;    # same; pre-5.6 syntax
```

This is a **runtime** check. If you want the check to happen at compile time (so the script never starts up on an old Perl), use `use VERSION` instead:

```
use v5.38;            # compile-time equivalent
```

`require` EXPR where EXPR is a bareword - module by name

A bareword is interpreted as a module name. `require` replaces every `::` with `/` and appends `.pm`, then searches `@INC`:

```
require Foo::Bar;     # looks for Foo/Bar.pm in @INC
```

This form also **autovivifies the stash** at compile time - the `Foo::Bar::` package hash springs into existence even if the load later fails. No symbols are imported; `require` only loads code.

Before trying `Foo/Bar.pm`, `require` looks for `Foo/Bar.pmc` in the same directory and prefers it if found. The `.pmc` hook lets build tools ship precompiled companion files alongside sources.

`require` EXPR where EXPR is a string - file by path

Any non-bareword expression is treated as a literal filename. No `::` translation, no `.pm` appending, no stash autovivification:

```
require "Foo/Bar.pm";           # explicit .pm path
require "$config_dir/init.pl";  # arbitrary filename

my $class = 'Foo::Bar';
require $class;                 # ERROR: looks for file "Foo::Bar"
```

The last line is the classic trap: once the module name is in a scalar, it is a string, not a bareword. To load a module whose name is computed, either do the translation by hand or go through `eval`:

```
(my $file = "$class.pm") =~ s{::}{/}g;
require $file;

eval "require $class; 1" or die $@;
```

If EXPR is omitted entirely, `$_` is used.

The `%INC` guard - loaded files stay loaded

Before searching `@INC`, `require` consults `%INC`. If the requested filename is present and has a true value, `require` returns 1 immediately without re-reading the file. If the value is `undef`, a previous load failed and `require` throws `Compilation failed in require` - Perl refuses to retry a file that has already blown up once in this interpreter.

This means a module's top-level code runs **exactly once** per interpreter, no matter how many places `require` it. Setup in a module's file body is a one-shot operation; do not rely on it running for every `require` call in every caller.

A hook is free to set `%INC` itself; if it does not, `require` records the hook as the "source" of the load.

The 1; convention

Historically every loadable file had to return a **true** value as its last expression, or `require` threw `filename did not return true value`. The canonical way to guarantee this is a trailing `1;`:

```
package My::Thing;
# ... module code ...
1;                                  # mandatory, pre-5.38
```

As of Perl 5.38 the `module_true` feature - enabled by default under `use v5.38` or later - makes every `required` file implicitly return true on successful compilation. Files that opt in no longer need `1;`. Files that don't, still do.

This only affects the compilation unit that turned the feature on; legacy modules loaded by a modern caller still need their own `1;`.

When the loaded file does return a value and `module_true` is off, that value is what `require` returns - but **only on the first load**. Subsequent `require` calls of the same file return 1 from the `%INC` cache. To capture a file's return value reliably, use `do`:

```
my $config = do "config.pl"
    or die "config.pl: ", $@ || $!;
```

@INC hooks - coderefs, array refs, and objects

Entries in `@INC` do not have to be directory strings. A reference stored in `@INC` is called a **hook** and gets a chance to satisfy the `require`.

Subroutine reference

Called with two arguments: the coderef itself and the filename (`Foo/Bar.pm`). It should return either nothing (meaning "I can't handle this; try the next entry") or up to four values:

1. A scalar reference to source text prepended to the file.
2. A filehandle the rest of the source is read from.
3. A generator or filter subroutine (see `perldoc perlfunc` for the exact protocol).
4. Optional state passed back to the generator.

```
push @INC, sub {
    my ($self, $filename) = @_;
    return unless $filename eq 'Virtual/Module.pm';
    open my $fh, '<', \"package Virtual::Module; 1;";
    return $fh;
};
```

Array reference

The first element is a coderef or object as above; the rest is state the hook can read on each call. When the first element is an object with an `INC` or `INCDIR` method, the method receives the array ref as its third argument.

```
push @INC, [\&my_loader, $db_handle, $cache];
```

Blessed object

If the object has an `INC` or `INCDIR` method, `require` calls that method; otherwise, if the object is also a coderef, it's invoked like a plain subroutine reference. `INC` methods must be declared with their fully qualified name (`sub Foo::INC { ... }`), because the unqualified symbol `INC` is hard-wired to package `main`.

A hook may freely update `%INC` to record the path it supplied; if it doesn't, `require` stores the hook reference itself.

`require` vs `use`

```
use Foo::Bar qw(x y);

# is almost exactly:

BEGIN {
    require Foo::Bar;
    Foo::Bar->import(qw(x y));
}
```

Aspect	`use`	`require`
When it runs	Compile time (inside `BEGIN`)	Runtime
Calls `import`	Yes	No
Bareword `::` → `/`	Yes	Yes, when called on a bareword
Version check form	`use v5.38`	`require v5.38`
Good for	Fixed dependencies	Optional / late-bound modules

Reach for `require` when the module is optional, loaded from a computed name, or loaded only inside a branch that may never run. Reach for `use` for everything else.

Examples

Minimum Perl version at runtime:

```
require v5.38;
```

Bareword module load - searches `@INC`, autovivifies `Data::Dumper::` at compile time:

```
require Data::Dumper;
Data::Dumper->import;
print Data::Dumper::Dumper(\%ENV);
```

Optional module - fall back gracefully when missing:

```
my $have_json = eval { require JSON::PP; 1 };
if ($have_json) {
    print JSON::PP->new->encode($data);
}
```

Load a module whose name is computed at runtime. Convert to a filename path; `require $class` would search for a literal file named `Foo::Bar`:

```
my $driver = $ENV{DB_DRIVER} // 'SQLite';
my $class  = "DBD::$driver";
(my $file  = "$class.pm") =~ s{::}{/}g;
require $file;
```

Load a configuration fragment by pathname, keeping its return value - note the do, not `require`, because we want the value every call:

```
my $config = do '/etc/myapp/config.pl'
    or die "config load failed: ", $@ || $!;
```

Install an `@INC` hook that serves a single virtual module from an in-memory string:

```
unshift @INC, sub {
    my ($self, $filename) = @_;
    return unless $filename eq 'MyApp/Version.pm';
    my $src = "package MyApp::Version; our \$VERSION = '1.23'; 1;";
    open my $fh, '<', \$src;
    $INC{$filename} = '(generated)';
    return $fh;
};
require MyApp::Version;
```

Edge cases

- **Bareword vs string**: `require Foo::Bar` and `require "Foo::Bar"` are **not** the same. The bareword form translates to `Foo/Bar.pm`; the string form looks for a file literally named `Foo::Bar`.
- **Computed class names**: `require $class` where `$class` holds `'Foo::Bar'` searches for a file named `Foo::Bar`, not `Foo/Bar.pm`. Translate the name yourself, or use `eval "require $class"` when the name is trusted.
- **No argument**: `require;` uses `$_` as the filename. Rare in modern code; almost always an accident.
- **Second-chance retries don't work**: If a `require` fails partway through compilation, `%INC` records `undef` for that filename. A later `require` of the same name sees

the undef and throws `Compilation failed in require` without re-running the file. Delete the `%INC` entry if you genuinely want to retry (this is a sharp edge; prefer fixing the underlying failure).

- **Relative `.` removal**: `.` was removed from the default `@INC` in Perl 5.26. A script that used to find `Foo/Bar.pm` next to itself now has to add its own directory explicitly (`use FindBin; use lib $FindBin::Bin;`).
- **`.pmc` shadowing**: If `Foo/Bar.pmc` exists in the same directory as `Foo/Bar.pm`, the `.pmc` wins. Stale `.pmc` files are a classic "why is my edit not taking effect" trap.
- **Parsing `require(EXPR)`**: `require` is parsed as a named unary operator; `require EXPR + 1` means `require(EXPR + 1)`. Use explicit parentheses when the argument is a non-trivial expression.
- **Stash autovivification**: `require Foo::Bar` creates the `Foo::Bar::` stash even if the file is missing. Downstream `defined &Foo::Bar::some_sub` checks may pass the "package exists" stage but fail the "sub exists" stage.
- **Filehandle from a hook must be real**: Tied filehandles are silently ignored by the hook protocol; processing falls off the end and `require` reports "not found". Use a real typeglob.
- **`INC` must be fully qualified in hook classes**: `sub Foo::INC { ... }` works; `sub INC { ... }` inside `package Foo` installs `main::INC` because of a hard-coded package rule.
- **`require()` is hard to wrap**: Many modules inspect the call stack to find their caller. A wrapper that adds a frame often breaks them. Prefer the `${^HOOK}{require__before}` / `${^HOOK}{require__after}` hooks (added in 5.38) for tracing.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `use` - compile-time `require` + `import`; the normal way to pull in a module you depend on unconditionally
- `do` - load a file and return its value on every call, with no `%INC` caching and no "must return true" rule
- `import` - the method `use` calls after `require`; `require` never calls it for you
- `@INC` - search path consulted for bareword and relative-filename loads; accepts directory strings, coderefs, array refs, and objects as hooks
- `%INC` - one-entry-per-loaded-file cache that makes `require` idempotent and records where each module came from
- `eval` - wrap `require` when the load is allowed to fail

Misc

reset

Clear every package variable whose name begins with one of a set of letters, and re-arm one-shot `m?pattern?` matches.

`reset` is a holdover from Perl 4's globals-only world. In modern code it survives in two narrow roles: re-arming `m?...?` one-match regexes so they fire again, and - at the end of a loop's `continue` block - wiping a batch of package variables before the next iteration. Its reach is limited to the current package and to **package** variables; anything declared with `my` is untouched.

Synopsis

```
reset EXPR
reset
```

EXPR is a string interpreted as a set of single characters, with hyphens allowed as ranges: `'X'`, `'a-z'`, `'abc'`, `'A-Za-z'`. Every scalar, array, and hash in the **current package** whose name starts with one of those letters is reset to its pristine, undefined state.

With no argument, only `m?pattern?` one-match searches in the current package are re-armed - variables are not touched.

What you get back

Always 1. The return value carries no success signal; there is nothing for `reset` to fail at.

Global state it touches

- **Every package variable in the current package** whose name starts with a listed letter: scalars, arrays, and hashes all together. Scalars become `undef`, arrays and hashes become empty.
- **One-match regexes** (`m?pattern?`) compiled in the current package - their "already matched" flag is cleared so the next evaluation matches again.
- Does **not** cross package boundaries. `reset 'X'` inside `package Foo` leaves `$Bar::X` alone.
- Does **not** touch lexicals. `my $x` and `our $x` behave differently here: `our` is an alias to the package variable and is reset; `my` is not.

Examples

Re-arm all one-shot matches in the current package - the typical modern use of `reset`:

```
reset;
```

Clear every package variable starting with `X` in the current package:

```
package Stats;
our $Xtotal = 0;
our @Xsamples = (1, 2, 3);
our %Xindex = (a => 1);
reset 'X';
# $Xtotal, @Xsamples, %Xindex are all emptied
```

Reset at the bottom of a loop so the next iteration starts clean:

```
while (more_work()) {
    process();
} continue {
    reset 'abc';   # wipe $a*, @b*, %c* package vars for next pass
}
```

A character range - lower-case variables only:

```
reset 'a-z';
```

Combining individual letters and ranges:

```
reset 'a-cXY';    # a, b, c, X, Y
```

Edge cases

- **`reset` with no argument does not touch variables at all.** It re-arms one-shot `m?...?` matches in the current package and nothing else. If you want to clear variables you must pass an argument.
- **Lexicals are invisible to `reset`.** A `my $Xtotal` is completely unaffected by `reset 'X'`; only the package variable `$Xtotal` is. Code that migrated from `our`/package globals to `my` will find `reset` has silently become a no-op for those variables.
- **`reset 'A-Z'` is a foot-gun.** In the `main` package that wipes `@ARGV`, `@INC`, `%ENV` and every other upper-case global, almost certainly not what was intended.
- **Scalars, arrays, and hashes share one namespace here.** `reset 'X'` clears every variable of every sigil whose name starts with `X`, not just scalars. There is no way to restrict the reset to one sigil.
- **Current package is decided at compile time** via the enclosing `package` declaration, not by the caller. A `reset` call inside a module clears that module's variables, not the caller's.
- **No regex argument form.** `reset` takes a string of letters, not a regex or a list of names. You cannot write `reset qr/^X/` or `reset '$Xtotal'` - the latter tries to reset variables starting with `$`, `X`, `t`, `o`, `a`, `l`, which is almost never what the author meant.

Differences from upstream

- pperl's `reset` is a no-op - the call parses, returns 1, and has no side effects. Package variables are not cleared and `m?pattern?` one-shot match state is not tracked. Code that relies on `reset` to wipe a batch of globals at the end of a loop, or to re-fire a one-match regex, will not see that behaviour under pperl. Prefer `my` and ordinary `m//` regexes - both work identically on pperl and upstream, and are the recommended idiom upstream as well.

See also

- `my` - lexical variables; preferred in all new code and unaffected by `reset`
- `local` - dynamically scoped save/restore of a package variable, the usual answer when you want a temporary change without a manual cleanup
- `m` - the regular `m//` form; `m?...?` is the one-shot variant that `reset` re-arms
- `continue` - loop-end block where batch-reset of iteration state is conventionally placed
- `package` - declares which package's variables `reset` will operate on
- `undef` - clear a single named variable, the per-variable alternative to a broad `reset`

Control flow

return

Leave the current subroutine, `eval`, `do FILE`, `sort` block, or regex eval block, yielding a value to the caller.

`return` is the explicit exit from a named or anonymous sub. It stops evaluation of the sub body at the point of call and hands `EXPR` back to whoever invoked the sub. The value `EXPR` produces depends on the caller's context - list, scalar, or void - which the body can inspect with `wantarray` before deciding what to return.

Synopsis

```
return EXPR
return
```

What you get back

`return` itself does not have a return value - it does not continue in the current frame. It terminates the frame and the caller receives `EXPR`, evaluated in the caller's context:

- **List context** - `EXPR` is evaluated in list context; its list value is what the caller sees.
- **Scalar context** - `EXPR` is evaluated in scalar context; its scalar value is what the caller sees.
- **Void context** - `EXPR` is still evaluated (for side effects), but the value is discarded.

With no `EXPR` the caller receives:

- **list context** - the empty list `()`
- **scalar context** - `undef`
- **void context** - nothing

This asymmetry matters: `return;` (bare) is **not** the same as `return undef;`. A bare `return` in list context yields `()`, which is false and has zero elements; `return undef;` in list context yields a one-element list containing `undef`, which is **true** (because the list has one element). Error-signalling subs should almost always use bare `return`.

```
sub find_it {
    my ($key) = @_;
    return unless exists $cache{$key};  # bare: () in list, undef in
↪scalar
    return $cache{$key};
}

if (my @hits = find_it($k)) { ... }     # () is false; undef-in-list
↪is true
```

Where return is legal

`return` unwinds these frames:

- a named or anonymous **subroutine**
- a string or block **`eval`** - `return` from inside `eval { ... }` leaves the `eval`, not the enclosing sub
- a **`do FILE`** - `return EXPR` is the file's value
- a **`sort`** **comparator block** - returns the comparison result
- a **regex eval block** - `/(?{ ... })/` and `/(?&NAME)/` code blocks

`return` is **not** legal inside these blocks - it is a compile-time or run-time error depending on the context:

- **`grep BLOCK LIST`** and **`map BLOCK LIST`** - the block is not a sub frame; use the block's last expression instead
- **`do BLOCK`** - the block is an expression, not a call; its value is already the block's last expression
- bare blocks, `if` / `while` / `for` bodies - same reason; these do not form a call frame

If you need "return a value from this block", make it the block's last evaluated expression:

```
my @evens = grep { $_ % 2 == 0 } @nums;   # not: grep { return ... }
```

Context propagation with wantarray

The caller's context reaches the callee through `wantarray`:

- `wantarray` is **true** in list context
- `wantarray` is **defined and false** (`""`) in scalar context
- `wantarray` is **`undef`** in void context

A sub that wants to return shape-appropriate values inspects it:

```
sub stats {
    my @xs = @_;
    return unless @xs;                    # bare: () / undef as
 ↪above
    my $sum = 0; $sum += $_ for @xs;
    my $avg = $sum / @xs;
    return wantarray ? ($sum, $avg) : $avg;
}

my ($s, $a) = stats(@data);               # list context  → two
 ↪values
my $a       = stats(@data);               # scalar context →
 ↪average only
stats(@data);                             # void context  →
 ↪computed, discarded
```

The same call site can be evaluated in different contexts across different invocations; `return` re-resolves `EXPR` each time.

Implicit return: last expression wins

If control reaches the end of a sub (or `eval`, or `do FILE`) without hitting `return`, the value of the last evaluated expression is returned, in the caller's context. This is the idiomatic "trailing expression" style:

```
sub square { my ($x) = @_; $x * $x }      # implicit return of $x *
 ↪$x

sub classify {
    my ($n) = @_;
    $n < 0   ? "negative"
  : $n == 0  ? "zero"
  : "positive"                            # trailing ternary is the
 ↪value
}
```

Use explicit `return` when you exit early, or when the end of the sub is a statement (e.g. a loop, an assignment) whose value is not what you want the caller to see.

Examples

Early exit on a guard:

```
sub lookup {
    my ($id) = @_;
    return unless defined $id;
    return $table{$id};
}
```

Return from an `eval` block without unwinding the enclosing sub:

```
sub try_parse {
    my ($text) = @_;
    my $parsed = eval {
        return {} if $text eq "";          # leaves eval, not try_
↪parse
        parse($text);
    };
    return $@ ? undef : $parsed;
}
```

Context-sensitive return:

```
sub users {
    return wantarray ? @all_users : scalar @all_users;
}

my @u = users();                           # the users themselves
my $n = users();                           # how many there are
```

Parser exemption - `return` is not a looks-like-a-function operator:

```
sub greet { return ("hello") . " world" } # returns "hello world"
                                           # the . " world" is part␣
↪of EXPR
greet();                                   # "hello world"
```

This is why `return (EXPR)` does **not** insulate `EXPR` from a trailing operator; anything after the closing paren is still argument to `return`. Same rule as `print`.

Illegal: `return` inside `grep` / `map`:

```
my @odd = grep { return $_ % 2 } @n;       # wrong; leaves the sub
my @odd = grep { $_ % 2 } @n;              # right
```

Inside a `grep` / `map` the block's last expression is already the value; a `return` there exits the **enclosing sub**, which is almost never what you mean.

Edge cases

- **Bare `return` vs `return undef`**: as above, bare `return` yields `()` in list context, which lets `if (my @x = f())` work as a "no results" test. `return undef` puts one element in the list and flips that test to true. Prefer bare `return` unless you specifically want a defined-undef scalar.
- **`return` from a `sort` comparator**: legitimate and common in complex comparators:

```
sort { return $a->[0] <=> $b->[0] || $a->[1] cmp $b->[1] }␣
↪@rows;
```

- **`return` from `do FILE`**: becomes the file's value, which is what `require` and `use` inspect to decide module-load success. A `.pm` ending in `1;` is the common idiom; `return 1;` near the top of the file is equivalent.
- **`return` from a regex `(?{ ... })` block**: ends the code block only, not the regex match. Rarely useful; normal block flow is almost always clearer.
- **Void-context side effects still happen**: `return expensive();` in void context still calls `expensive()`. `return` is not an optimisation hint.
- **Not a function, no parentheses needed**: `return` is an operator, not a function. `return(1, 2, 3)` and `return 1, 2, 3` are the same. The parser exemption above means parens around EXPR do not delimit it from the rest of the statement - parens are purely for grouping inside EXPR.
- **Return in a block form of `eval`**: `eval { return $x }` leaves the `eval` with `$x`; `$@` is cleared (no exception). To return from the enclosing sub via an exception, `die` instead.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `wantarray` - inspect the caller's context so `return` can yield the right shape
- `caller` - the other half of caller introspection; useful when a sub decides what to return based on who called it
- `eval` - `return` inside an `eval` block leaves the `eval`, not the enclosing sub
- `sub` - how subroutines are defined and how implicit return interacts with the last expression
- `die` - the non-local exit; use when you want to unwind past intermediate frames instead of returning through each one
- `last` - exits a loop, not a sub; do not confuse the two

SCALARs and strings · Lists

reverse

Reverse a list - or, in scalar context, reverse the characters of a string.

`reverse` is two operators wearing the same name. Context decides which one you get. In list context it returns `LIST` with its elements in the opposite order; element values are untouched. In scalar context it concatenates `LIST` into a single string and returns that string with its **characters** reversed. The single biggest trap is context: `print reverse $str` puts `reverse` in list context, where it reverses a one-element list and prints `$str` unchanged; `scalar reverse $str` is what reverses the characters - see *Edge cases*.

Synopsis

```
my @r    = reverse @arr          # list context: elements reversed
my $s    = reverse $str          # scalar context: characters
 ↪reversed
my %inv  = reverse %h            # hash invert (value → key)
reverse                          # in scalar context, reverses $_
```

What you get back

Context-dependent. The operator inspects the context of its caller and branches:

- **List context** → a new list with the elements of `LIST` in reverse order. Element values are not stringified, not modified, not copied at the character level. A list of refs stays a list of the same refs.
- **Scalar context** → a single string: the concatenation of the stringified elements of `LIST`, with all characters in reverse order. Under `use utf8` / wide strings, reversal is character-wise, not byte-wise.

This means the *same* call site returns radically different shapes depending on how you use it:

```
my @back  = reverse "abc", "def";    # ("def", "abc")
my $back  = reverse "abc", "def";    # "fedcba"
```

Used with no arguments in scalar context, `reverse` reverses `$_`. Used with no arguments in list context, `reverse` returns the empty list - **not** a reversed `$_`. `print reverse;` produces no output.

Global state it touches

Reads `$_` when called with no arguments in scalar context. That is the only global it touches. It does not modify `$_`; it returns the reversed string.

Examples

Reverse a list. The elements themselves are unchanged:

```
my @a = (1, 2, 3, 4, 5);
my @r = reverse @a;              # (5, 4, 3, 2, 1)
```

Reverse a string. Force scalar context with `scalar` when the surrounding expression would otherwise be list:

```
my $s = reverse "Hello, world";  # "dlrow ,olleH"
print scalar reverse "Hello";    # "olleH"
```

Iterate an array backward without building a second array. `reverse` in the loop header is a list-context call; Perl consumes the reversed list lazily from the loop machinery:

```
my @stack = ("first", "second", "third");
for my $elem (reverse @stack) {
    print "$elem\n";             # third / second / first
}
```

Descending sort. `reverse sort` is the idiom when your comparison is ascending and you want the opposite. For anything more complex than default string compare, swap the operands in the comparator instead:

```
my @asc  = sort { $a <=> $b } @nums;
my @desc = reverse sort { $a <=> $b } @nums;     # works
my @desc2 = sort { $b <=> $a } @nums;            # preferred
```

Invert a hash. Values become keys, keys become values:

```
my %by_name    = (alice => 1, bob => 2, carol => 3);
my %by_id      = reverse %by_name;               # (1 => "alice", ..
 ↪.)
print $by_id{2};                                 # "bob"
```

The `"dlrow ,olleH"` trick - using `reverse` in scalar context as a one-shot character flip on a string variable:

```
my $word = "stressed";
my $rev  = scalar reverse $word;                  # "desserts"
```

Edge cases

- **The #1 trap: context.** `my $s = reverse @arr` does **not** give you a reversed array; it gives you the reversed *string* formed by concatenating the array's elements and flipping every character. If you want a reversed array stored via a scalar, use a reference: `my $ref = [ reverse @arr ]`.
- **Single scalar, wrong context.** `my @r = reverse $str` returns `($str)` - a one-element list containing `$str` unchanged. There is nothing to reorder. To reverse the characters, force scalar context: `my $r = reverse $str` or `my @r = (scalar reverse $str)`.
- **Hash invert loses data on duplicate values.** `reverse %h` walks the key/value pairs as a flat list and rebuilds a hash. If two keys share a value, one of them wins and the other is silently dropped; which one wins is not defined. Check for uniqueness first if it matters:

```
my %seen;
$seen{$_}++ for values %h;
die "non-unique values" if grep { $_ > 1 } values %seen;
my %inv = reverse %h;
```

- **No arguments in list context does nothing useful.** `reverse` with no args returns `()` in list context. `$_` is only consulted in scalar context. `print reverse;` prints nothing; `print scalar reverse;` prints the reverse of `$_`.
- **Character-wise, not byte-wise.** For wide-character strings, `reverse` reverses characters, not bytes. A `:utf8` string of three code points stays three code points after reversal, regardless of their byte widths. Reversing a raw byte string with multi-byte characters you never decoded will corrupt it - decode first.
- **Self-assignment preserves holes.** `@a = reverse @a` on a non-magical or well-behaved tied array preserves non-existent elements in their reversed positions; a sparse array stays sparse.
- **`reverse sort` is not the same as `sort { $b cmp $a }`.** Both give descending order for a stable default compare, but `reverse sort` does two passes over the data and is measurably slower on large lists. Prefer swapping the comparator operands.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `sort` - pair with `reverse` for descending order, or swap `$a`/`$b` in the comparator to avoid the second pass
- `pop` - remove from the end of an array when you just want the last element, not the whole list reversed
- `shift` - remove from the front; combined with a `reversed` copy you get stack-like access to the original tail
- `split` - produce a list of characters (with `//`) or fields that you can then `reverse`
- `join` - the natural partner when you reverse a list of strings and want a single string back
- `$_` - the default target when `reverse` is called with no arguments in scalar context

I/O

rewinddir

Reset a directory handle to the start of its listing.

`rewinddir` sets the current position of `DIRHANDLE` back to the beginning of the directory, so that the next `readdir` call returns the first entry again. It is the directory-handle counterpart to `seek` on a file handle: no re-open, no re-scan of the parent directory - just a position reset on the open handle.

Synopsis

```
rewinddir DIRHANDLE
```

What you get back

1 on success, `0` on failure (with `$!` set). Failure is rare in practice - the usual cause is a handle that was never opened or has already been closed. Check the return value if you care about either case:

```
rewinddir $dh
    or die "rewinddir failed: $!";
```

Typical use

You have already walked a directory with `readdir` and want to walk it again without paying for another `opendir`:

```
opendir my $dh, $path or die "opendir $path: $!";

my @all = readdir $dh;          # first pass: collect everything

rewinddir $dh;                  # back to the top

while (my $entry = readdir $dh) {   # second pass: process one by␣
↪one
    next if $entry =~ /^\.\.?\z/;
    process("$path/$entry");
}

closedir $dh;
```

A second common pattern is reusing one handle across several scans with different filters, where re-opening would be wasteful or would race against concurrent directory changes:

```
opendir my $dh, $path or die $!;

my @perl = grep { /\.p[lm]\z/ } readdir $dh;
rewinddir $dh;
my @text = grep { /\.txt\z/  } readdir $dh;

closedir $dh;
```

Edge cases

- **Unopened or closed handle**: returns `0` and sets `$!`. Under `use warnings` you also get a `rewinddir() attempted on invalid dirhandle` warning.
- **Mid-scan directory changes**: `rewinddir` is **not** guaranteed to surface entries created (or hide entries removed) after `opendir` returned. The underlying `rewind-`

dir(3) operates on the kernel's cached directory stream; whether a rewound scan observes concurrent mkdir, unlink, or rename in the same directory is filesystem- and OS-dependent. If you need a fresh snapshot, closedir and opendir again.

- **Not a seek to an arbitrary position**: rewinddir resets to the start and nothing else. To return to a remembered mid-directory position use telldir / seekdir instead.
- **Entry order is unspecified**: rewinding replays the same stream the kernel gave you, but the order of entries is whatever the filesystem produces - not sorted, not creation order, not the order you saw last time on a different handle. Sort explicitly if order matters.
- **Portability**: rewinddir is a POSIX call. On platforms without a working rewinddir(3) it may be implemented by closing and re-opening the directory; see perlport for the historical list. On Linux (the platform pperl targets) this is not a concern.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- opendir - open a directory and obtain the handle that rewinddir operates on
- readdir - read the next entry; resumes from wherever rewinddir left the stream (the beginning)
- closedir - release the handle; pair with opendir when a rewound scan is not enough and you need a fresh snapshot of the directory
- telldir - record the current position so you can return to it later
- seekdir - restore a position previously captured by telldir; rewinddir $dh is equivalent to seekdir $dh, 0 on conforming systems, but rewinddir is the portable spelling

SCALARs and strings

rindex

Find the position of the **last** occurrence of a substring inside a string.

rindex is the right-to-left counterpart of index. It scans STR for SUBSTR and returns the zero-based offset of the rightmost match, or -1 if no match exists. When POSITION is given, the search is constrained to matches whose starting offset is less than or equal to POSITION - that is, the last occurrence at or before that position.

Synopsis

```
rindex $str, $substr
rindex $str, $substr, $position
```

What you get back

An integer. Zero or positive means the zero-based offset of the rightmost match; `-1` means `SUBSTR` does not occur in `STR` (subject to the `POSITION` constraint, if any).

Offsets are measured in **characters** when `STR` holds a character string, and in **bytes** when `STR` is a byte string. This matches `index` and the rest of Perl's string built-ins - the unit is whatever the string itself is using.

How POSITION shapes the search

`POSITION` is an **upper bound on the match's starting offset**, not on where scanning begins. The result satisfies:

- `result <= POSITION`
- `result + length(SUBSTR) <= length(STR)` (as always)

Concretely:

- `POSITION` omitted or `undef` - search the whole string; return the rightmost match.
- `POSITION` greater than or equal to `length(STR)` - behaves as if `POSITION` were `length(STR)`; the entire string is considered.
- `POSITION` less than `0` - behaves as if `POSITION` were `0`; only a match starting at offset `0` can satisfy the constraint, so the return value is `0` when `STR` begins with `SUBSTR` and `-1` otherwise.
- Empty `SUBSTR` - every offset from `0` to `length(STR)` is a valid match position, so `rindex` returns `min(POSITION, length(STR))` (or `length(STR)` when `POSITION` is omitted).

Think of `POSITION` as "find the last match at or before here," not as "start scanning here."

Examples

Basic right-to-left search:

```
rindex("banana", "a");          # 5  (the final 'a')
rindex("banana", "na");         # 4  (last "na")
rindex("banana", "z");          # -1 (not found)
```

Stepping backwards through every occurrence by using each result, minus one, as the next `POSITION`:

```
my $str = "banana";
my $pos = length($str);
while ((my $hit = rindex($str, "a", $pos - 1)) >= 0) {
    print "match at $hit\n";   # 5, 3, 1
    $pos = $hit;
}
```

`POSITION` as an upper bound - the match must **start** at or before it:

```
rindex("banana", "na", 3);      # 4? No: 4 > 3, so the match at 4
                                #   is excluded; returns 2
rindex("banana", "na", 4);      # 4  (match starting at 4 is allowed)
```

Empty SUBSTR matches at every offset, so the result is the capped position:

```
rindex("banana", "", 4);        # 4
rindex("banana", "");           # 6  (length of "banana")
```

Pairing with index to locate the last segment of a delimited string - a common idiom for splitting off a final extension or path component:

```
my $path = "/usr/local/bin/perl";
my $slash = rindex($path, "/");
my $file  = substr($path, $slash + 1);   # "perl"
```

Edge cases

- **Substring longer than string**: `rindex("abc", "abcd")` returns `-1`. No match can fit.
- **Substring equals string**: `rindex("abc", "abc")` returns `0`. The last (and only) match starts at offset `0`.
- **POSITION past the end**: `rindex($str, $sub, 9999)` behaves as if POSITION were `length($str)` - the entire string is scanned.
- **POSITION is negative**: treated as `0`. `rindex("abc", "b", -5)` returns `-1` (no match can start at offset `0` or earlier); `rindex("abc", "a", -5)` returns `0`.
- **POSITION is undef**: same as omitting it. Under `use warnings` this emits an `uninitialized` warning.
- **Empty STR, non-empty SUBSTR**: returns `-1`.
- **Empty STR, empty SUBSTR**: returns `0`.
- **Unicode**: for character strings (those the interpreter knows are text), offsets count characters, not bytes. A string flipped to byte semantics via `use bytes` or `encode_utf8` will report byte offsets instead. The rule mirrors index and substr.
- **Tainted arguments**: the result inherits taint from STR and SUBSTR under `-T`.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- index - the left-to-right counterpart; identical argument conventions, returns the **first** occurrence
- substr - typically the next call after a successful `rindex`, to slice the matched region or what follows it

- `length` - useful when computing the trailing slice: `substr($s, $hit + length($sub))`
- `pos` - for regex-driven scanning where you need the engine's match state rather than a single substring offset
- `split` - when you want every segment delimited by SUBSTR, not just the last one
- `reverse` - combined with `index` it is sometimes mistaken for a `rindex` substitute; `rindex` is both clearer and faster

Filehandles, files, directories

rmdir

Remove an empty directory.

`rmdir` asks the operating system to delete the directory named by `FILENAME`. The directory must be empty - it must contain no entries other than `.` and `..`. If `FILENAME` is omitted, `rmdir` operates on `$_`. This is a thin wrapper over the `rmdir(2)` system call and carries all of its restrictions: you cannot remove a non-empty directory, you cannot remove a directory you lack write permission on the parent of, and on most systems you cannot remove your current working directory.

Synopsis

```
rmdir FILENAME
rmdir
```

What you get back

1 on success, `0` on failure (with `$!` set to the `errno` from the failed system call). Unlike most I/O primitives `rmdir` does not return `undef` on failure - it returns the integer `0`, so the common test `rmdir $dir or die $!` still works because `0` is false.

Always check the return value. A failed `rmdir` is silent otherwise; the next line of code will happily proceed as if the directory had been removed.

```
rmdir $dir
    or die "rmdir $dir failed: $!";
```

Global state it touches

- `$_` - used as `FILENAME` when no argument is given.
- `$!` - set to the `errno` of the failed `rmdir(2)` call on failure; left untouched on success. Read it immediately; any intervening system call may overwrite it.

Examples

Plain call, explicit directory:

```
rmdir "build/tmp"
    or die "rmdir build/tmp: $!";
```

Default target. Inside `while (readdir ...)` or a loop that leaves the name in `$_`:

```
for (@empty_dirs) {
    rmdir or warn "rmdir $_: $!";
}
```

Distinguish "already gone" from a real error. `ENOENT` means the directory does not exist, which is often fine for cleanup code:

```
use Errno qw(ENOENT);
unless (rmdir $dir) {
    die "rmdir $dir: $!" unless $! == ENOENT;
}
```

Remove a directory only after emptying it first:

```
opendir my $dh, $dir or die "opendir $dir: $!";
while (my $entry = readdir $dh) {
    next if $entry eq '.' or $entry eq '..';
    unlink "$dir/$entry" or die "unlink $dir/$entry: $!";
}
closedir $dh;
rmdir $dir or die "rmdir $dir: $!";
```

Recursive removal is **not** `rmdir`'s job. Use `File::Path`'s `remove_tree` - it walks the tree and deletes entries bottom-up:

```
use File::Path qw(remove_tree);
remove_tree("build", { error => \my $err });
die "remove_tree: @$err" if @$err;
```

Edge cases

- **Directory not empty**: `$!` is set to `ENOTEMPTY` on most Unix systems (some BSDs use `EEXIST`). This is the single most common `rmdir` failure. List the directory contents or call `remove_tree` if recursive deletion is what you actually want.
- **No argument**: `rmdir` with no argument uses `$_`, not `@ARGV` and not the current directory. Writing `rmdir()` with empty parentheses is the same as `rmdir` with no argument - it still reads `$_`.
- **Symlink to a directory**: `rmdir` refuses to remove symlinks; it operates on directories only. Use `unlink` on the symlink itself. `$!` is typically set to `ENOTDIR`.
- **Current working directory**: On Linux, `rmdir "."` usually fails with `EBUSY` or `EINVAL` depending on the filesystem. Do not rely on being able to remove the directory you are sitting in; `chdir` elsewhere first.

- **Permissions**: you need write + execute permission on the **parent** directory, not on the directory being removed. Removing `/a/b/c` checks `/a/b`'s mode, not `/a/b/c`'s.
- **Sticky-bit parent** (e.g. `/tmp`): you also need to own the directory being removed or own the parent; otherwise `EPERM`.
- **Trailing slash**: `rmdir "foo/"` works and means the same as `rmdir "foo"`.
- **Race with another process**: between your `opendir`/`readdir` loop and the final `rmdir`, another process may create a file in the directory. You will then see `ENOTEMPTY` despite having just emptied it. Retry or fail loudly - do not silently ignore.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `mkdir` - create a directory; the inverse operation, with the same `FILENAME`-or-`$_` argument convention
- `unlink` - remove **files** (and symlinks); `rmdir` removes only empty directories
- `chdir` - change the current working directory, often used before `rmdir` to avoid trying to remove the directory you are in
- `opendir` / `readdir` - list a directory's contents before emptying and removing it
- `$!` - holds the `errno` of a failed `rmdir`; check for `ENOENT` / `ENOTEMPTY` / `EPERM` to branch on the reason

Regular expressions and pattern matching

s///

Search a string for a pattern and replace every match with a replacement.

`s///` is Perl's substitution operator. It finds text matching `PATTERN` in the target string, replaces each match with `REPLACEMENT`, and by default returns the number of substitutions made. With no explicit target (no =~ or !~), it operates on `$_`. The target must be a scalar lvalue - a variable, an array or hash element, or a `substr` / assignment producing one - unless the `/r` flag is used, which works on any value and returns the modified copy.

Synopsis

```
s/PATTERN/REPLACEMENT/FLAGS
$str =~ s/PATTERN/REPLACEMENT/FLAGS
$str !~ s/PATTERN/REPLACEMENT/FLAGS
my $copy = $str =~ s/PATTERN/REPLACEMENT/r
```

What you get back

By default, the count of substitutions performed as an integer: `0` when nothing matched (which is false in boolean context), a positive integer on success. The target scalar is modified in place.

With the `/r` flag, the semantics flip: the target is **not** modified, and the operator returns the (possibly changed) string. If nothing matched, `/r` still returns a copy of the original. The result of `/r` is always a plain string, even when the source is a tied variable or a blessed object with overloading.

`!~` inverts the boolean sense of the return value: it yields true when nothing was substituted, false when at least one substitution happened. The target is still modified either way.

```
my $n = ($text =~ s/foo/bar/g);      # count of replacements
my $out = $text =~ s/foo/bar/r;      # copy-and-modify, $text␣
↪untouched
```

Global state it touches

- `$_` - the default target when no `=~` or `!~` is given. `s/old/new/` with no binding reads and writes `$_`.
- `$&`, `$``, `$'`, `$1` and friends - set by each successful match, the same way `m//` sets them. Inside `REPLACEMENT` they refer to the current match, not any earlier one.
- `pos` - cleared on the target scalar by a successful non-`/g` substitution; under `/g` it advances with each match and can be inspected between iterations.
- The **last successful pattern** - used when `PATTERN` evaluates to the empty string (`s//new/` re-uses the last successful regex from this scope).
- `$/`, `$\` and output separators are not touched - `s///` produces a string, it does not write one.

Flags

The full set is `msixpodualngcer`. Match-side flags behave exactly as in `m//` and `qr`; see the *modifiers chapter* of the regex guide for the match-side details. Replacement-specific flags:

- `e` - evaluate `REPLACEMENT` as a block of Perl code. The block's value is the replacement string. Equivalent to wrapping it in `do { ... }` and stringifying the result.
- `ee` - evaluate as code, then `eval` the resulting string again. Equivalent to `eval(do { REPLACEMENT })`. Additional `e` modifiers add more `eval` layers.
- `r` - non-destructive: leave the target unchanged and return the modified copy (or an unchanged copy on no match). Cannot be combined with a non-scalar-lvalue target restriction - any expression is a valid target under `/r`.
- `g` - global: replace every non-overlapping match, not just the first.
- `c` - accepted for syntactic symmetry with `m//` but has no behavioural effect on `s///`; triggers a warning under `use warnings`.

Match-side flags in one line: `m` (multiline ^/$), `s` (`.` matches newline), `i` (case-insensitive), `x` / `xx` (extended whitespace, comments), `p` (preserve match variables; obsolete since 5.20), `o` (compile pattern once), `d` / `u` / `a` / `l` (character-set semantics), `n` (non-capturing by default). See the *modifiers chapter*.

Delimiters

Any non-whitespace character may replace `/`. If the chosen delimiter is one of `(`, `[`, `{`, or `<`, the operator takes **two** bracketed groups and a delimiter between them is optional:

```
s(foo)(bar)
s{foo}{bar}
s<foo>/bar/
s[foo]{bar}g
```

Single-quote delimiters turn off interpolation in both `PATTERN` and `REPLACEMENT` (unless `/e` is in force, which always parses `REPLACEMENT` as code):

```
s'$name'$value';    # literal $name → literal $value, no
 ↪interpolation
```

Backticks are ordinary delimiters; `s`x`y`` does not run a shell command.

When the delimiter is a character that is also an identifier character, a space after the `s` is required so the parser does not read it as part of the operator name.

Examples

Basic in-place substitution on `$_`:

```
$_ = 'the quick brown fox';
s/quick/slow/;                  # $_ is now 'the slow brown fox'
```

Explicit target with =~:

```
my $path = '/usr/bin/perl';
$path =~ s|/usr/bin|/usr/local/bin|;
# $path is '/usr/local/bin/perl'
```

Global replacement, capturing the count:

```
my $text = 'one two two three two';
my $n = ($text =~ s/two/2/g);   # $text: 'one 2 2 three 2'; $n == 3
```

Non-destructive `/r` - leaves the source alone, returns the copy. Idiomatic in `map`:

```
my @clean = map { s/\s+\z//r } @lines;   # @lines untouched
```

Code evaluation with `/e`. The right-hand side is a Perl expression whose value becomes the replacement:

```
my $s = 'abc123xyz';
$s =~ s/\d+/$& * 2/e;           # $s is 'abc246xyz'

my %percent = (n => "\n", t => "\t");
$s =~ s/%(.)/$percent{$1} || $&/ge;     # expand %-escapes
```

Chained `/r` - pure-functional transforms with no intermediate variable:

```
my $out = $text =~ s/foo/bar/r
                =~ s/baz/qux/r;
```

Capture groups and backreferences in the replacement - note the `$1` form, not `\1`:

```
# swap the first two whitespace-separated fields
s/(\S+)\s+(\S+)/$2 $1/;
```

The `1 while` idiom for substitutions that create new matches:

```
# insert commas into an integer from the right
my $n = '1234567890';
1 while $n =~ s/(\d)(\d\d\d)(?!\d)/$1,$2/;
# $n is '1,234,567,890'
```

Edge cases

- **Target must be a scalar lvalue** (unless `/r`): a variable, element, or `substr` lvalue. `s/x/y/` against a string literal or the result of a function call is a compile-time error. Under `/r` any expression is fair game since nothing is modified.
- **Empty pattern re-uses the last successful match.** `s//new/` substitutes against whatever `PATTERN` most recently matched in the enclosing scope. Convenient inside `while (m/.../g) { s//x/ }`, surprising when unrelated code has run in between.
- **Interpolation happens at runtime.** `s/$foo/$bar/` recompiles the pattern every call if `$foo` changes. Use `/o` to compile once and freeze the captured value - or precompile with `qr`, which is the modern alternative.
- **`/e` parses the replacement at compile time** even though it runs at match time. Syntax errors surface when the script is loaded, not when the substitution fires. Each extra `e` wraps one more `eval` around the value.
- **`/g` with an empty match advances by one character** to avoid an infinite loop: `s/\b/-/g` inserts between every token, it does not hang at the first position.
- **`!~` flips the return**, not the work. `$x !~ s/A/a/g` still modifies `$x`; it just returns true when no `A` was found.
- **Delimiter matching for brackets** uses the mirrored closer: `s{pat}{rep}`, `s<pat><rep>`. A delimiter other than a bracket must appear three times total: `s/pat/rep/`.
- **`/c` is a no-op on `s///`.** Accepted for parser symmetry with `m//`; using it produces a warning under `use warnings` and nothing more.

- **Assignment-as-target idiom.** `($copy = $src) =~ s/x/y/g` populates `$copy` with the modified value and leaves `$src` alone. Modern code prefers `my $copy = $src =~ s/x/y/gr`.
- **Tied or overloaded targets.** Without `/r`, `STORE` is invoked after the substitution to write the new value back; the fetched value is copied into a plain buffer before the pattern is applied. With `/r` the result is always a plain string - tie / overloading is not preserved in the return.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `m//` - the matching operator; shares match-side flag semantics and return-vs-context rules
- `tr///` - character-by-character transliteration; much faster when the job is literal character translation, not a regex
- `qr//` - precompile a pattern once and interpolate it into many `s///` or `m//` calls; the modern alternative to `/o`
- `split` - when the goal is to break a string on a pattern rather than replace matches, reach for `split` instead
- *Substitution chapter* - the chapter dedicated to `s///`; covers `/e`, `/r`, `/g`, `\K`, and zero-length-match handling
- *Regular expressions guide* - the full pattern-language reference; every match-side flag on `s///` is defined there
- `$&` - the matched text, available inside the `REPLACEMENT` of every `s///`

I/O

say

Print a list of values followed by a newline.

`say` is `print` with the output record separator forced to `"\n"` for that one call. It stringifies each item in `LIST`, joins them with `$,` (output field separator, usually empty), writes them to `FILEHANDLE`, and appends a literal `"\n"` - **not** the value of `$\`. If `FILEHANDLE` is omitted, output goes to the currently selected handle (see `select`), which defaults to `STDOUT`. If `LIST` is omitted, `$_` is printed.

`say` is a feature-gated built-in. It is available only when the `"say"` feature is enabled - automatic under `use v5.10` or higher, or explicit with `use feature 'say'` - or when called as `CORE::say`.

Synopsis

```
say LIST
say FILEHANDLE LIST
say {EXPR} LIST
say
```

What you get back

1 on success, `undef` on failure (with `$!` set). As with `print`, the return value is rarely checked for `STDOUT` or `STDERR`. Check it when writing to a file, pipe, or socket where a write failure is a recoverable condition:

```
say $fh $record
    or die "write to $path failed: $!";
```

Default filehandle, default separators

`say` reads the same global state as `print`, with one deliberate exception:

- The **currently selected filehandle**, changed with `select`. `say LIST` writes there when no filehandle is given. Defaults to `STDOUT`.
- `$,` - **output field separator**, inserted between list items. Defaults to the empty string, so `say 1, 2, 3` produces `"123\n"`, not `"1 2 3\n"`.
- `$\` - **output record separator**. `say` **ignores `$\` entirely** and appends a literal `"\n"` instead. Setting `$\` has no effect on `say`.

That last point is the whole reason `say` exists: one record, one newline, no fiddling with `$\`.

Examples

Basic write to `STDOUT`:

```
use feature 'say';
say "hello, world";                 # "hello, world\n"
```

Write to a filehandle. Same indirect-object form as `print` - **no comma** between the filehandle and the list:

```
open my $fh, ">", "out.txt" or die $!;
say $fh "line 1";
say $fh "line 2";
close $fh;
```

Write to a filehandle held in an expression. Any filehandle more complex than a bare-word or a plain scalar needs the `{EXPR}` block form:

```
my @logs = (\*STDOUT, \*STDERR);
say { $logs[$level] } "message";
```

`say` joins list items with `$,` and then appends `"\n"` regardless of `$\`:

```
local $, = ", ";
local $\ = ".\n";                    # ignored by say
say "apples", "pears", "plums";      # "apples, pears, plums\n"
```

No arguments - print `$_` plus a newline. The filehandle must be a bareword in this form; `say $fh;` would parse `$fh` as the content, not as the target:

```
for (qw(alpha beta gamma)) {
    say;                             # "alpha\n", "beta\n", "gamma\n"
}
```

List context applies to every argument:

```
my @arr = (10, 20, 30);
say @arr;                            # "102030\n"
say scalar @arr;                     # "3\n"
```

Edge cases

- **Feature gate**: without `use feature 'say'` or `use v5.10`, `say` is parsed as an ordinary subroutine call and will fail at compile time if no such sub is in scope. Use `CORE::say(...)` to call it unconditionally.
- **No arguments with an explicit filehandle**: `say FH;` prints `$_` to `FH`, but only for **bareword** filehandles. `say $fh;` parses `$fh` as the content, not the target - write `say $fh $_;` if you mean that. This matches `print`.
- **`$\` is ignored, not overridden**: `say` does not set or `local`ise `$\`. Other code that reads `$\` (including nested `print` calls) sees whatever value was already there.
- **Filehandle-or-first-arg ambiguity**: same rule as `print`. A bareword or a simple scalar immediately followed by a term (no comma) is taken as the filehandle. An expression returning a filehandle needs the block form: `say { $handles[0] } "x";`.
- **`say (…)` parses as a function call**. `say (2+3)*4` prints 5 then discards `*4`. Parenthesise the whole argument list, or prefix with `+`:

  ```
  say((2+3)*4);                      # "20\n"
  say +(2+3)*4;                      # "20\n"
  ```

- **Closed filehandle**: returns `undef` and sets `$!` to `"Bad file descriptor"`. Under `use warnings` a `say() on closed filehandle` warning is emitted.
- **Encoding layers**: `say` writes through the handle's PerlIO stack exactly like `print`. A handle with a `:utf8` or `:encoding(...)` layer encodes on the way out; the appended newline is a single `"\n"` byte and is encoded by the same layer. A wide-character string written to a bytes-mode handle triggers a `Wide character in say` warning.
- **Autoflush**: `say` buffers through PerlIO like `print`. Set `$|` on the selected handle for line-buffered output.

- **SIGPIPE**: writing to a closed pipe or socket raises SIGPIPE. The default action terminates the process; install a handler to convert it into a normal write failure.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `print` - same targeting and separator rules, but appends `$\` (empty by default) instead of a forced newline
- `printf` - formatted output; does not append a newline, you put one in the format string
- `select` - change which filehandle the no-argument form of `say` writes to
- `$,` - output field separator inserted between list items; `say` honours it
- `$\` - output record separator; `say` **ignores it** and appends `"\n"` instead
- `$|` - autoflush flag for the currently selected handle

Misc

scalar

Force EXPR to be evaluated in scalar context and return its value.

`scalar` is not really an operator in its own right - it is a context-coercion marker the parser recognises in front of a unary expression. Perl evaluates the expression in scalar context and yields whatever that expression produces there. The function exists because most positions in a Perl program already impose a context (list or scalar) on their operands, and occasionally you need to override list context with scalar context explicitly.

Synopsis

```
scalar EXPR
scalar @array
scalar %hash
scalar localtime
```

What you get back

The value of EXPR as evaluated in scalar context. The exact shape depends entirely on what EXPR is:

- For an array, the element count.
- For a hash, a true value (non-empty) or `0` (empty); in older Perls this was a bucket-usage string, but from 5.26 onward it is the key count.

- For a list-context-sensitive function, whatever that function returns when called in scalar context (for example, `localtime` returns its ctime-style string instead of the nine-element list).
- For an already-scalar expression, the same value - `scalar` is a no-op there.

Global state it touches

None. `scalar` is a pure context cast; it does not read or write any special variables of its own. The *expression* you pass in may, of course, touch whatever globals it normally touches.

Examples

Count the elements of an array inside a list-context position:

```
my @items = (10, 20, 30);
my @counts = (scalar @items);        # (3)
print scalar @items, "\n";           # 3
```

Without `scalar`, `@items` would expand to its elements and `@counts` would be `(10, 20, 30)`.

Print the human-readable date from `localtime`. In list context `localtime` returns nine fields; in scalar context it returns the familiar ctime string:

```
print localtime, "\n";               # nine numbers run together
print scalar localtime, "\n";        # "Thu Apr 23 14:02:11 2026"
```

The same trap appears everywhere a builtin is list-context-sensitive:

```
my @parts = localtime;               # (sec, min, hour, mday, ...)
my $now   = scalar localtime;        # ctime string
```

Test whether a hash is non-empty without allocating its key list:

```
if (scalar %config) {
    # %config has at least one key
}
```

`if (%config)` already imposes scalar (boolean) context, so the `scalar` here is redundant but explicit; writers sometimes include it to make intent visible to readers.

Build a list of counts from several arrays in one expression:

```
my @counts = (scalar @a, scalar @b, scalar @c);
```

Coerce a function call that would otherwise splat into a surrounding list:

```
my @row = ($id, scalar get_tags($id), $mtime);
```

Without `scalar`, `get_tags` would run in list context and its returned list would be flattened into `@row` alongside `$id` and `$mtime`.

Edge cases

- **No list-context counterpart.** There is no `list EXPR` operator; list context is the default in almost every position where you might want to impose it. If you genuinely need to coerce a scalar expression into list context, the idiom is `@{[ EXPR ]}`, though in most cases plain `(EXPR)` is enough.
- **Parenthesised list trap.** `scalar` is a unary operator. Passing it a parenthesised comma expression does **not** evaluate that expression as a list; it evaluates it as a *scalar comma operator*, which runs every sub-expression in void context except the last and returns the last in scalar context:

```
print uc(scalar(foo(), $bar)), $baz;
# equivalent to:
foo();                                  # void context
print(uc($bar), $baz);                  # $bar in scalar context
```

  If you wanted `foo()`'s return values included, `scalar (list)` is the wrong tool.
- **Hash in scalar context.** From Perl 5.26 onward, `scalar %h` returns the number of keys, the same as `scalar keys %h`. On older Perls it returned a string like `"4/8"` reporting bucket usage; pperl targets 5.44 and so always returns the key count.
- **Subroutine prototypes.** A subroutine declared with a scalar prototype (`($)`) already imposes scalar context on its argument, so `scalar` is redundant in front of the call. A `(@)` or `(\@)` prototype does not, so `scalar` still matters:

```
sub count ($) { $_[0] }
count @items;                           # @items in scalar context:␣
↪3
```

- **Redundant on already-scalar expressions.** `scalar $x`, `scalar 42`, `scalar "text"` are no-ops. Perl does not warn about them; they are occasionally used for emphasis but add nothing.
- **Not a function call.** Because `scalar` is a parser-level context marker, you cannot take `\&scalar`, cannot override it with a `sub scalar { ... }`, and cannot pass it as a code reference.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `wantarray` - inspect the context you were called in, rather than impose one on a sub-expression
- `defined` - similarly a unary operator applied to an expression; useful alongside `scalar` when testing function results
- `localtime` - canonical example of a builtin whose return shape depends on context

- `reverse` - also context-sensitive; `scalar reverse $s` reverses characters, `reverse @a` reverses a list
- `keys` - `scalar keys %h` is the long form of `scalar %h` with the same result on 5.26+

I/O

seek

Reposition a filehandle for random-access reads or writes.

`seek` moves `FILEHANDLE`'s read/write pointer to a new byte offset, mirroring the C `fseek(3)` call. After a successful `seek`, the next `read`, `readline`, or `print` on the handle starts from the new position. `POSITION` is a signed byte offset; `WHENCE` selects the anchor it is measured from.

Synopsis

```
seek FILEHANDLE, POSITION, WHENCE
seek $fh, 0, 0             # rewind to start
seek $fh, 0, 1             # no-op: clear EOF, keep position
seek $fh, -1024, 2         # 1024 bytes before EOF
```

What you get back

1 on success, a false value on failure (with `$!` set). Always check the return value - seeking past a short file, on an unseekable handle (pipe, socket, `TTY`), or after a write error all fail here rather than at the next read.

```
seek $fh, $offset, 0
    or die "seek to $offset failed: $!";
```

WHENCE values

`WHENCE` is an integer with three meaningful values. Use the symbolic constants from `Fcntl` for readability:

- `0` / `SEEK_SET` - `POSITION` is measured from the **start of the file**. `POSITION` must be non-negative.
- `1` / `SEEK_CUR` - `POSITION` is added to the **current position**. Negative values move backward, positive values forward. `seek $fh, 0, 1` is the canonical "move nowhere, but clear EOF" idiom.
- `2` / `SEEK_END` - `POSITION` is added to the **end-of-file** offset. `POSITION` is typically zero or negative.

```
use Fcntl qw(SEEK_SET SEEK_CUR SEEK_END);

seek $fh, 0,     SEEK_SET;   # rewind
```

(continues on next page)

(continued from previous page)

```
seek $fh, 0,      SEEK_END;   # go to EOF (e.g. to append)
seek $fh, -$n,    SEEK_CUR;   # $n bytes back from here
```

Bytes, not characters

Even when the handle has a character-oriented layer such as `:encoding(UTF-8)`, `seek`, `tell`, and the `sysseek` family operate on **byte offsets**. A `seek` to a byte offset that lands in the middle of a multi-byte sequence will produce decoding errors or replacement characters on the next read.

If you need to position by characters, read forward from a known byte boundary rather than trying to translate character counts to byte offsets. `tell` values are safe to feed back into `seek` because they were produced at byte boundaries the I/O layer already crossed cleanly.

Global state it touches

- `$!` - set to the system error message on failure.
- The filehandle's PerlIO buffer is discarded on success, so any data read ahead by buffering is dropped and the next read pulls fresh bytes from the underlying file.
- The end-of-file flag on `FILEHANDLE` is cleared on success, even when `POSITION` and `WHENCE` leave the position unchanged.

Examples

Rewind to the start of a file before re-reading it:

```
seek $fh, 0, 0 or die "rewind failed: $!";
while (my $line = <$fh>) { ... }
```

Append by positioning at end-of-file, then writing. For append-only use, prefer opening with >> - this form is for handles already open for read-write:

```
seek $fh, 0, 2 or die $!;           # SEEK_END
print $fh "appended line\n";
```

Read a fixed-width record by index, where each record is 128 bytes:

```
my $record = 42;
seek $fh, $record * 128, 0 or die $!;
read $fh, my $buf, 128;
```

Emulate `tail -f` - the `seek $fh, 0, 1` resets the EOF condition so the next `readline` retries the file for new data:

```
while (1) {
    while (my $line = <$fh>) { print $line }
    sleep 1;
```

(continues on next page)

(continued from previous page)

```
    seek $fh, 0, 1;                 # clear EOF, keep position
}
```

Save a position with `tell`, read ahead, then restore:

```
my $mark = tell $fh;
my $peek = <$fh>;
seek $fh, $mark, 0 or die $!;       # back to where we were
```

Edge cases

- **Unseekable handles**: pipes, sockets, TTYs, and most special devices return false and set `$!` to `ESPIPE` (`Illegal seek`). Check the return value; do not assume every filehandle is seekable.
- **Mixing reads and writes on the same handle** on a file opened `+<` or `+>` requires a `seek` (or `tell`, or an explicit flush) when switching direction. A WHENCE of 1 with `POSITION` of `0` is the usual no-op separator:

  ```
  seek $fh, 0, 1;                   # allowed to switch read <->␣
  ↪write
  ```

- **Seeking past EOF** on a file opened for writing is legal and creates a sparse hole up to `POSITION` on filesystems that support holes; the next write fills part of the hole and the bytes in between read back as `"\0"`.
- **`sysread` / `syswrite` users**: do **not** mix `seek` with `sysread` or `syswrite`. `seek` operates on the PerlIO buffer layer; the unbuffered sys-family bypasses it, so their effective positions drift apart. Use `sysseek` for handles you access through the sys-family.
- **Character offsets via arithmetic**: multiplying a character count by an assumed encoding width is wrong for `UTF-8` and other variable-width encodings. Use byte offsets obtained from `tell`, or read forward from a known boundary.
- **Directory handles**: `seek` does not work on directory handles. Use `seekdir` with a position from `telldir`.
- **Closed filehandle**: returns a false value and sets `$!`; under `use warnings` a `seek() on closed filehandle` warning is emitted.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `tell` - read the current byte offset; the value round-trips safely through `seek` with `WHENCE 0`
- `sysseek` - unbuffered seek for handles accessed via `sysread` / `syswrite`; use this instead of `seek` when bypassing PerlIO

- `read` - buffered fixed-length read; the natural partner for positioning by byte offset
- `readline` - line-oriented read; `seek $fh, 0, 1` before a retry is the `tail -f` idiom
- `eof` - test for end-of-file; `seek` clears the EOF flag a prior read may have set
- `Fcntl` - source of the `SEEK_SET`, `SEEK_CUR`, `SEEK_END` constants

I/O

seekdir

Restore a directory handle to a position previously captured by `telldir`.

`seekdir` moves the read cursor of `DIRHANDLE` to `POS`, so that the next `readdir` call returns the entry that would have been returned when `POS` was first obtained from `telldir` on the same handle. It is the directory counterpart of `seek` on a file handle - with the crucial restriction that `POS` is not a byte offset you can compute, it is an opaque cookie you must have taken from `telldir` earlier.

Synopsis

```
seekdir DIRHANDLE, POS
```

What you get back

No meaningful value. `seekdir` returns what the underlying `seekdir(3)` returns, which on Linux is nothing useful - do **not** branch on the return value. To detect trouble, check `$!` after the call, or verify that the handle is still open before calling.

Typical use

You are walking a directory, notice an entry you want to revisit later, and remember where you were so you can return to it after reading on:

```
opendir my $dh, $path or die "opendir $path: $!";

my %bookmarks;
while (my $entry = readdir $dh) {
    $bookmarks{$entry} = telldir $dh  # position AFTER reading
 ↪$entry
        if $entry =~ /\.conf\z/;
}

# later: re-read the entry that follows the first .conf file
seekdir $dh, $bookmarks{(sort keys %bookmarks)[0]};
my $next = readdir $dh;

closedir $dh;
```

Returning to the start is the common special case - a `seekdir $dh, 0` call is equivalent to `rewinddir` on conforming systems, but `rewinddir` is the idiomatic spelling for that intent:

```
seekdir $dh, 0;      # works, but say what you mean:
rewinddir $dh;       # clearer
```

Edge cases

- **POS must come from `telldir` on the same handle.** Passing an integer you made up, a value from a different handle, or a stale value from a handle that has since been closed and re-opened is undefined behaviour. The kernel may accept it silently and hand you garbage on the next `readdir`, skip entries, or return duplicates.
- **Directory compaction between `telldir` and `seekdir`**: if the filesystem has compacted or reorganised the directory between the two calls (files created, deleted, or renamed in the same directory by any process), the POS cookie may no longer refer to the same entry - or to any entry at all. This is a property of the underlying `seekdir(3)` and is not a pperl limitation. For stable iteration over a changing directory, snapshot the list with `readdir` in list context and work off the copy.
- **Unopened or closed handle**: sets `$!`. Under `use warnings` you get a `seekdir() attempted on invalid dirhandle` warning. Nothing in the return value tells you this happened - check `$!` or use `defined fileno($dh)` / explicit bookkeeping if you need to guard.
- **Not a byte offset**: POS is an opaque token. Arithmetic on it (`seekdir $dh, $pos + 1`) is meaningless; the only safe values are `0` (start of directory, and even then prefer `rewinddir`) and values returned by `telldir`.
- **Entry order is unspecified**: `seekdir` replays whatever order the kernel originally returned. That order is not sorted, not alphabetical, and not guaranteed to match a fresh `opendir` of the same path later. If your code sorts, sort explicitly each time.
- **SEEK_CUR-style relative seeks do not exist** for directory handles. There is no equivalent of `seek`'s whence argument.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `telldir` - produce the POS cookie that `seekdir` consumes; the two are only useful as a pair
- `readdir` - read the next entry; resumes from the position `seekdir` just set
- `rewinddir` - the idiomatic way to return to the start of a directory; prefer it over `seekdir $dh, 0`
- `opendir` - open the directory and obtain the handle `seekdir` operates on

- `seek` - the file-handle analogue, but with a true byte offset and a `whence` argument; directory handles have neither

I/O · Filehandles, files, directories

select

Either set the default output filehandle, or call the `select(2)` syscall for I/O multiplexing. Same name, two unrelated jobs - disambiguated by argument count.

The one-argument form (or no-argument form) is about where `print`, `printf`, `say`, and `write` send their output when you don't name a filehandle. The four-argument form is a direct wrapper around the BSD `select(2)` syscall for waiting on sets of file descriptors.

Synopsis

```
select FILEHANDLE              # set default output handle, return␣
 ↪old
select                         # return current default output␣
 ↪handle
select RBITS, WBITS, EBITS, TIMEOUT   # select(2) syscall
```

What you get back

`select FILEHANDLE` returns the *previously* selected filehandle (as a typeglob), so the idiomatic save/restore pattern works:

```
my $old = select $fh;
$| = 1;
select $old;
```

`select` (no arguments) returns the currently selected filehandle. At program start this is `STDOUT`.

`select RBITS, WBITS, EBITS, TIMEOUT` returns different things in different contexts:

- In scalar context: the number of filehandles ready, or `-1` on error with `$!` set.
- In list context: `($nfound, $timeleft)` - the same `$nfound` plus the remaining time from `TIMEOUT`. Many kernels do not update `$timeleft`; on those systems it is always equal to the input `TIMEOUT`.

On timeout expiry `$nfound` is `0`. The three bit masks (`RBITS`, `WBITS`, `EBITS`) are updated in place to indicate which descriptors are ready - pass copies if you want to preserve the original masks.

Global state it touches

The one-argument form changes one piece of interpreter-global state: the currently selected output filehandle. While that handle is selected, these variables refer to **it**, not to `STDOUT`:

- `$|` - autoflush flag

- `$,` - output field separator
- `$\` - output record separator
- `$#`, `$%`, `$=`, `$-`, `$~`, `$^` - format-related variables

That is why `my $old = select($fh); $| = 1; select($old);` works: `$|` is a *property of the selected handle*, not a global scalar.

The four-argument form touches no per-interpreter state. It may leave `$!` set on error.

Examples

Enable autoflush on a handle without disturbing the default:

```
my $old = select $fh; $| = 1; select $old;
```

Redirect `print` temporarily and restore on block exit:

```
{
    my $old = select $log_fh;
    print "entry: $msg\n";       # goes to $log_fh
    select $old;
}
```

Sleep for 250 milliseconds using the four-argument form:

```
select undef, undef, undef, 0.25;
```

Wait up to 5 seconds for `STDIN` to become readable:

```
my $rin = '';
vec($rin, fileno(STDIN), 1) = 1;
my $nfound = select my $rout = $rin, undef, undef, 5;
if ($nfound) {
    my $line = <STDIN>;
}
```

Build a read mask over multiple handles:

```
sub fhbits {
    my $bits = '';
    vec($bits, fileno($_), 1) = 1 for @_;
    return $bits;
}
my $rin = fhbits(\*STDIN, $sock);
my ($nfound, $timeleft) =
    select my $rout = $rin, undef, undef, 10;
```

Edge cases

- **Method-style alternative.** `$fh->autoflush(1)` sets the autoflush flag on `$fh` without changing the default handle. Prefer it when you only need to tweak one property of one handle - no global state involved.
- **Typeglob localization is cleaner for scoped redirects.** `local *STDOUT = $fh` rebinds `STDOUT` itself for the dynamic scope; on `die` the original is restored automatically. `select` does **not** restore on `die`. The two are not equivalent: with `select` an explicit `print STDOUT ...` still reaches the *real* `STDOUT`; with the `local *STDOUT` form, even `print STDOUT ...` goes to the rebound handle.
- **Bit-mask form requires bytes, not a list of fileno integers.** A bit mask is a packed bit string built with `vec`; passing a list of integers or a reference silently produces wrong results (or an empty mask).
- **`undef` for a mask means "don't wait on this set."** Pass `undef` for masks you don't care about. An empty string `''` technically also works but is less idiomatic.
- **Fractional timeouts work.** `TIMEOUT` is a float in seconds. `0.25` is 250 ms; `0` returns immediately (polling).
- **`TIMEOUT` of `undef`** means block indefinitely until at least one descriptor is ready or a signal arrives.
- **Masks are modified in place.** On return, each mask holds only the bits for descriptors that are ready. If you need the originals afterwards, pass copies - the idiom `my $rout = $rin` on the call line does exactly that.
- **Do not mix buffered I/O with the four-argument form.** `select` reports readiness at the kernel level; `readline`, `read`, and the diamond operator `<>` read through PerlIO buffers that may already hold unread data the kernel doesn't know about. Use `sysread` for data once `select` says a descriptor is ready.
- **Spurious readiness on sockets.** On some Unixes `select(2)` may report a socket as "ready for reading" when a following `read` would still block. Set `O_NONBLOCK` on the socket if this matters.
- **Restart-after-signal behaviour is system-dependent.** A signal (e.g. `SIGALRM`) may cause `select` to return early with `$! == EINTR`, or the kernel may restart the call transparently. Portable code checks for `EINTR` explicitly.
- **Argument count disambiguates the two forms.** One argument (or none) is the default-handle form; exactly four is the syscall form. Other counts are a syntax error.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `print` - reads the selected handle when no filehandle is given; `select` is how you change which handle that is
- `printf` - same default-handle rule as `print`

- `write` - format-based output; the top-of-form and page-length variables follow the selected handle, not `STDOUT`
- `fileno` - maps a filehandle to the integer descriptor number you need when building a mask
- `vec` - packs descriptor numbers into the bit string the four-argument form expects
- `sysread` - the unbuffered read you use after the four-argument `select` says a descriptor is ready
- `IO::Select` - object wrapper over the four-argument form that hides the bit-mask arithmetic

SysV IPC

semctl

Perform a control operation on a System V semaphore set.

`semctl` is the Perl-level binding for the `semctl(2)` system call. It reads or modifies the state of the semaphore set identified by `ID` - getting or setting a single semaphore's value, fetching or installing the full value vector, reading the associated `semid_ds` metadata, or removing the set entirely. `CMD` selects the operation; `SEMNUM` selects which semaphore within the set (ignored for set-wide commands like `IPC_STAT`, `IPC_RMID`, `GETALL`, `SETALL`); `ARG` is the command's input or output buffer.

`semctl` is a thin wrapper - the semantics, the command constants, and the shape of `ARG` all come straight from the C-level call. You will almost always want:

```
use IPC::SysV;
```

first, to pull in the `IPC_STAT`, `IPC_RMID`, `GETVAL`, `SETVAL`, `GETALL`, `SETALL`, `GETPID`, `GETNCNT`, `GETZCNT` constants.

Synopsis

```
semctl $id, $semnum, $cmd, $arg
semctl $id, 0,       IPC_RMID, 0           # destroy set
semctl $id, $n,      SETVAL,   $value      # set one
semctl $id, 0,       SETALL,   $packed     # set all
```

What you get back

Return follows the same convention as `ioctl`:

- `undef` on error (with `$!` set).
- The string `"0 but true"` when the underlying call returned `0` - this string is false numerically (so it prints `0` in numeric context) but true in boolean context, letting you distinguish success-with-zero from failure in one test.
- The actual integer return value otherwise.

The idiomatic test is therefore:

```
my $rc = semctl($id, $n, GETVAL, 0);
defined $rc or die "semctl: $!";
```

Check `defined`, not truth - a legitimately zero semaphore value would fail a plain `if ($rc)`.

For `CMD` values that read data into `ARG` (`IPC_STAT`, `GETALL`), `ARG` must be a **modifiable lvalue** (a plain variable, not a literal or expression); on success the buffer is overwritten in place with the returned bytes and you unpack it yourself.

Global state it touches

Sets `$!` on failure. No other interpreter globals involved.

Examples

Read a single semaphore's current value:

```
use IPC::SysV qw(GETVAL);
my $value = semctl($id, $semnum, GETVAL, 0);
defined $value or die "GETVAL: $!";
```

Set a single semaphore:

```
use IPC::SysV qw(SETVAL);
semctl($id, $semnum, SETVAL, 1)
    or die "SETVAL: $!";
```

Read all semaphore values at once. The buffer has to be pre-allocated to the right size - `nsems` native shorts - before the call. `pack` with an unused count is the usual way:

```
use IPC::SysV qw(GETALL);
my $nsems = 4;
my $buf   = pack("s!*", (0) x $nsems);      # allocate room
semctl($id, 0, GETALL, $buf) or die $!;
my @vals = unpack("s!*", $buf);
```

Install a full set of values:

```
use IPC::SysV qw(SETALL);
my $buf = pack("s!*", 1, 0, 0, 1);
semctl($id, 0, SETALL, $buf)
    or die "SETALL: $!";
```

Fetch the `semid_ds` structure for the set. `ARG` is written in place with the packed struct; its layout is platform-specific, so unpack with the help of `IPC::Semaphore` rather than by hand unless you have to:

```
use IPC::SysV qw(IPC_STAT);
my $ds = "";
semctl($id, 0, IPC_STAT, $ds)
    or die "IPC_STAT: $!";
```

Destroy the semaphore set. SEMNUM and ARG are unused; pass 0:

```
use IPC::SysV qw(IPC_RMID);
semctl($id, 0, IPC_RMID, 0)
    or die "IPC_RMID: $!";
```

Edge cases

- **ARG must be a real variable for read commands.** GETALL and IPC_STAT write into ARG; passing a literal (`semctl($id, 0, GETALL, "")`) or a read-only expression is a runtime error. The variable's existing contents are overwritten, not appended to.
- **ARG must be pre-sized.** The kernel writes exactly `nsems * sizeof(short)` bytes for GETALL, or `sizeof(struct semid_ds)` for IPC_STAT. Passing a shorter buffer is undefined behaviour in the underlying C call; `pack("s!*", (0) x $nsems)` is the standard idiom for GETALL.
- **Native short, not portable short.** Semaphore values are C `short` (signed, typically 16-bit). Use `s!` in pack / unpack - the `!` picks the platform-native type. Plain `s` forces little-endian 16-bit and will produce wrong results on big-endian or LP64-short systems.
- **"0 but true" returns.** GETVAL on a semaphore whose value is 0, GETPID/GETNCNT/GETZCNT returning zero, and other zero-valued successes all return the literal string `"0 but true"`. Arithmetic contexts see 0; boolean contexts see true. Use `defined` to check for failure.
- **SEMNUM is ignored for set-wide commands.** IPC_STAT, IPC_RMID, SETALL, GETALL act on the whole set. Pass 0 by convention; passing any other value is harmless but obscures intent.
- **After IPC_RMID the id is invalid.** Every subsequent `semctl` or semop on `$id` fails with EINVAL / EIDRM. Do not cache the id past removal.
- **The set is kernel-global and persists across process exits.** A set created by a crashed script remains until someone calls IPC_RMID (or the system reboots). Use `ipcs -s` / `ipcrm -s` from the shell to inspect or clean up leaked sets.
- **Permissions come from semget.** The `IPC_CREAT | mode` passed at creation time controls who may issue which `semctl` commands. EACCES from `semctl` means the mode bits disallow the requested operation for the current effective uid.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- semget - create or look up the semaphore set whose id you then pass to `semctl`
- semop - the actual wait / signal operations; `semctl` is for control and inspection, semop does the work

- `msgctl` - the analogous control call for System V message queues; same return-value convention
- `shmctl` - the analogous control call for System V shared memory; same return-value convention
- `pack` - how to build the ARG buffer with `s!` for semaphore values and the `semid_ds` struct
- `IPC::Semaphore` - object wrapper that hides `semctl` behind named methods; reach for it when a script does more than one or two calls

SysV IPC

semget

Create or look up a System V semaphore set and return its identifier.

`semget` is the entry point into the SysV semaphore API. It wraps the `semget(2)` system call: given a numeric KEY that names the set, the number of semaphores NSEMS in the set, and a FLAGS word combining permission bits with creation flags, the kernel either returns the id of a matching existing set or, if `IPC_CREAT` is in FLAGS, creates a new set and returns its id. The returned id is the handle every other semaphore call (`semop`, `semctl`) expects.

Synopsis

```
semget KEY, NSEMS, FLAGS
```

What you get back

The semaphore set identifier (a non-negative integer) on success, or `undef` on failure with `$!` set to the `errno` from the underlying `semget(2)` call. The id is **not** a file descriptor - it is a kernel-wide SysV IPC handle that outlives your process and persists until explicitly removed with `semctl($id, 0, IPC_RMID, 0)`.

```
use IPC::SysV qw(IPC_CREAT IPC_PRIVATE);

my $semid = semget(IPC_PRIVATE, 3, IPC_CREAT | 0600)
    // die "semget: $!";
```

Global state it touches

- `$!` - set to the `errno` value from `semget(2)` on failure (EACCES, EEXIST, ENOENT, ENOSPC, EINVAL, ENOMEM).

The KEY argument

KEY is an integer that names the semaphore set system-wide. Three conventions matter:

- **`IPC_PRIVATE`** (imported from `IPC::SysV`) - the kernel allocates a fresh key unused by any other set. The resulting id is known only to this process and anyone it passes

the id to, typically children after `fork`. Use this when the set is an implementation detail of one process tree.

- **A fixed integer literal** - every cooperating process hard-codes the same number. Fragile across unrelated programs that might pick the same integer.
- **A key derived from `ftok(3)`** - `IPC::SysV::ftok($path, $proj_id)` turns a filesystem path plus a project byte into a numeric key. The standard recipe for unrelated processes that need to agree on a key without hard-coding a magic number.

The FLAGS argument

`FLAGS` combines **permission bits** (low 9 bits, like a `chmod` mode: `0600`, `0660`, `0666`) with **creation flags** from `IPC::SysV`:

- `IPC_CREAT` - create the set if it does not already exist. Without this flag, `semget` only looks up an existing set with the given key.
- `IPC_CREAT | IPC_EXCL` - create the set, but fail with `EEXIST` if one already exists for `KEY`. The SysV analogue of `O_CREAT | O_EXCL` in `open`.

Permission bits are checked by the kernel on every subsequent `semop` and `semctl` call against the invoking process's uid/gid.

Examples

Create a private set of three semaphores usable by this process and its children:

```
use IPC::SysV qw(IPC_PRIVATE IPC_CREAT);
my $semid = semget(IPC_PRIVATE, 3, IPC_CREAT | 0600)
    // die "semget: $!";
```

Look up an existing, named set without creating it. `NSEMS` must match the size the set was created with, or can be `0` if you do not care:

```
use IPC::SysV qw(ftok);
my $key   = ftok("/var/run/myapp.pid", ord('M'));
my $semid = semget($key, 0, 0) // die "no set for key $key: $!";
```

Create-or-open idiom - try exclusive create, fall back to lookup. The first process through initialises the set; later ones just attach:

```
use IPC::SysV qw(ftok IPC_CREAT IPC_EXCL);

my $key = ftok("/var/run/myapp.pid", ord('M'));
my $semid = semget($key, 4, IPC_CREAT | IPC_EXCL | 0660);
if (defined $semid) {
    # We created it - initialise every semaphore to 1.
    semctl($semid, 0, SETALL, pack("s!*", (1) x 4))
        or die "SETALL: $!";
} else {
    $semid = semget($key, 4, 0) // die "semget lookup: $!";
}
```

Remove a set when you are done with it. SysV sets leak across process exit - nothing cleans them up for you:

```
use IPC::SysV qw(IPC_RMID);
semctl($semid, 0, IPC_RMID, 0) or warn "semctl RMID: $!";
```

Edge cases

- **`NSEMS` on lookup**: when looking up an existing set (no `IPC_CREAT`), `NSEMS` of `0` means "any size"; a positive value must be less than or equal to the set's actual size or `semget` fails with `EINVAL`.
- **`IPC_PRIVATE` still obeys `FLAGS`**: permission bits apply. A set created with `0400` is read-only even to the creating process for `semop` calls that modify it.
- **Kernel limits**: `semget` can fail with `ENOSPC` when the system-wide semaphore-set limit is reached, or `EINVAL` when `NSEMS` exceeds the per-set maximum. See `ipcs -sl` for the current limits on Linux.
- **Leaked sets**: a set persists until `IPC_RMID` or reboot. Long-running daemons that forget to remove their sets accumulate them; `ipcs -s` lists the survivors, `ipcrm -s $id` removes one.
- **Key collisions**: two unrelated programs picking the same hard-coded `KEY` will see each other's set - hence the `ftok(3)` idiom.
- **Not a filehandle**: `$semid` is an integer, not a handle. Do not pass it to `close`, `fcntl`, or any filehandle operation.
- **Forks inherit ids, not ownership**: a child sees the same `$semid` value as the parent and can use it, but the set itself is owned by the uid that created it, not by any particular process.
- **Numeric context**: the id is a plain integer, safe to print, compare, and store in a file for another process to pick up.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `semop` - perform wait/signal operations on the set returned by `semget`
- `semctl` - control operations on the set: initialise values (`SETALL`, `SETVAL`), read them (`GETALL`, `GETVAL`), and remove the set (`IPC_RMID`)
- `msgget` - the message-queue counterpart, same `KEY`, `FLAGS` conventions
- `shmget` - the shared-memory counterpart, same `KEY`, `FLAGS` conventions
- `IPC::SysV` - imports `IPC_CREAT`, `IPC_EXCL`, `IPC_PRIVATE`, `IPC_RMID`, `SETALL`, `GETALL`, and the `ftok` helper
- `IPC::Semaphore` - object wrapper around the raw `sem*` built-ins when you would rather not pack structs by hand

SysV IPC

semop

Perform one or more System V semaphore operations atomically.

`semop` is the workhorse of SysV semaphore use: it takes a semaphore set identifier (from `semget`) and a packed list of operations, then asks the kernel to apply them all or none. Each operation names a single semaphore within the set, an amount to add to it (typically `-1` to wait, `+1` to signal), and a flag word. The kernel blocks the caller until every requested operation can proceed, then commits them as one unit. This is what makes `semop` usable as a mutual-exclusion or counting-resource primitive between unrelated processes.

Synopsis

```
semop $semid, $opstring
```

What you get back

True on success, false on error with `$!` set. The truth value is the only result - `semop` communicates outcome by the side effect on the semaphore set, not through its return. Check it on every call:

```
semop($semid, $ops)
    or die "semop failed: $!";
```

A false return means no operation in `OPSTRING` was applied; SysV semantics guarantee all-or-nothing.

Global state it touches

Sets `$!` on failure, with the usual errno values from `semop(2)`: `EAGAIN` when `IPC_NOWAIT` was set and the operation would block, `EIDRM` when the semaphore set was removed while waiting, `EINTR` when a signal interrupted the wait, `EINVAL` for a bad semaphore number or identifier, `EACCES` for a permission mismatch against the set's mode.

The operation structure

`OPSTRING` is a concatenation of fixed-width records. Each record is three native-width `short` integers and is produced with `pack`:

```
pack("s!3", $semnum, $semop, $semflag)
```

- `$semnum` - the index of the target semaphore within the set (`0` through `nsems-1`, where `nsems` is the size passed to `semget`).
- `$semop` - the amount to add to the semaphore's value. Negative values wait until the semaphore is at least `|$semop|` before subtracting; positive values add unconditionally and wake waiters; zero waits until the semaphore reaches zero.

- `$semflag` - bitwise OR of `IPC_NOWAIT` (fail with `EAGAIN` instead of blocking) and `SEM_UNDO` (have the kernel reverse the operation if the process exits without undoing it - essential for lock-like uses where a crash must not leave the semaphore held).

The length of `OPSTRING` implies the number of operations: the kernel processes `length($opstring) / sizeof(struct sembuf)` records. Passing two records packed end-to-end asks for two operations applied atomically.

The `s!` in the template is the **native** `short`, which matches the `sembuf` layout on Linux. Plain `s` is a fixed 16-bit value - also in native byte order, but always exactly two bytes - so it will silently mis-pack on any platform where `sizeof(short) != 2`.

Examples

Wait on (decrement by 1) semaphore 0 of the set in `$semid`:

```
my $op = pack("s!3", 0, -1, 0);
semop($semid, $op)
    or die "wait on semaphore failed: $!";
```

Signal (increment by 1) the same semaphore:

```
my $op = pack("s!3", 0, 1, 0);
semop($semid, $op)
    or die "signal failed: $!";
```

Try to acquire without blocking - fail fast if someone else holds it:

```
use POSIX qw(EAGAIN);
my $op = pack("s!3", 0, -1, IPC_NOWAIT);
unless (semop($semid, $op)) {
    die "semop: $!" unless $! == EAGAIN;
    # contended; caller decides what to do
}
```

Acquire semaphore 0 with automatic release on process exit - the pattern for crash-safe mutual exclusion:

```
my $op = pack("s!3", 0, -1, SEM_UNDO);
semop($semid, $op) or die "lock: $!";
# critical section
my $release = pack("s!3", 0, 1, SEM_UNDO);
semop($semid, $release) or die "unlock: $!";
```

Two operations applied atomically - wait for semaphore 0 and semaphore 1 together, releasing neither if either would block:

```
my $ops = pack("s!3", 0, -1, 0)
        . pack("s!3", 1, -1, 0);
semop($semid, $ops) or die "paired wait: $!";
```

Wait for semaphore 0 to reach zero - the “barrier” form, where `$semop` is zero rather than negative:

```
my $op = pack("s!3", 0, 0, 0);
semop($semid, $op) or die "barrier: $!";
```

Edge cases

- **Short `OPSTRING`**: the length must be an exact multiple of the `sembuf` record size. A truncated or padded string gives `EINVAL`. Always build the string from `pack` calls, never by hand.
- **Native width matters**: `s!3` not `s3`. A script written with plain `s` works on a 16-bit-short host by accident and breaks elsewhere.
- **Zero-length `OPSTRING`**: asks for zero operations. The kernel accepts this and returns success without side effects - rarely what you want. Guard the call with `return unless length $ops`.
- **Signal interruption**: a blocked `semop` returning with `$!` set to `EINTR` is not a bug - retry unless you installed a handler that wants to abort. Perl's default `$SIG{*}` handling does not automatically restart the syscall.
- **`SEM_UNDO` with matched pairs**: the kernel tracks the cumulative adjustment per semaphore per process. Acquiring twice with `SEM_UNDO` then releasing once leaves an outstanding `-1` to be undone on exit. Pair every `-1` with a matching `+1` in normal flow; `SEM_UNDO` is insurance against crashes, not a substitute for releasing.
- **Removed set while waiting**: if another process calls `semctl` with `IPC_RMID`, every blocked `semop` returns false with `$!` set to `EIDRM`. The semaphore identifier is invalid from that point on.
- **Permissions**: `semop` checks alter-permission on the set. A process that can `semget` a read-only handle still cannot `semop` it.
- **Large operation counts**: the kernel caps the number of operations per call at `SEMOPM` (typically 32). Building an `OPSTRING` with more records fails with `E2BIG`.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `semget` - obtain the identifier you pass as the first argument; the two are always used together
- `semctl` - set or query semaphore values, and remove the set when you're done with it
- `pack` - build each `sembuf` record; `s!3` is the template you want
- `msgsnd` - the message-queue counterpart when you need to pass data rather than signal availability
- `shmget` - the shared-memory counterpart; semaphores are typically used to guard access to a SysV shared-memory segment

- `IPC::SysV` - exports the `IPC_NOWAIT`, `SEM_UNDO`, and `IPC_RMID` constants used in `$semflag` and in `semctl` commands
- `IPC::Semaphore` - object wrapper over `semget` / `semop` / `semctl` when a procedural interface feels too bare

Sockets

send

Send a message on a socket.

`send` writes the scalar `MSG` to `SOCKET` through the operating system's socket layer, not through PerlIO. On a connected socket (`SOCK_STREAM` after `connect`, or an accepted peer) the three-argument form issues a `send(2)` - use the four-argument form on an unconnected datagram socket (`SOCK_DGRAM`) to route each message to `TO`, which triggers `sendto(2)` under the hood. `FLAGS` is the bitmask the system call accepts (commonly `0`; see your platform's `send(2)` man page for `MSG_DONTWAIT`, `MSG_OOB`, `MSG_NOSIGNAL`, and friends).

Synopsis

```
send SOCKET, MSG, FLAGS, TO
send SOCKET, MSG, FLAGS
```

What you get back

The **number of bytes** accepted by the kernel, or `undef` on error with `$!` set. Always check the return value:

```
my $n = send $sock, $buf, 0
    or die "send failed: $!";
```

Two properties bite people:

- The count is **bytes**, not characters. `length $buf` on a wide string and the returned count will not agree.
- On `SOCK_STREAM` sockets the kernel may accept **fewer bytes than you gave it** - a short write. Loop until the whole buffer is drained, or use `syswrite` which has the same short-write semantics but works on any filehandle.

Global state it touches

- `$!` - set to the system error on failure.
- The socket's PerlIO layer stack is **not** consulted. Output layers (`:utf8`, `:encoding(...)`, `:crlf`) have no effect on what `send` writes. In particular, a `:utf8` layer causes `send` to **throw an exception** rather than silently encode - the socket layer and the PerlIO layer cannot both own byte framing.

Examples

Connected TCP - three-argument form:

```
use Socket;
socket my $sock, PF_INET, SOCK_STREAM, getprotobyname("tcp")
    or die "socket: $!";
connect $sock, sockaddr_in(80, inet_aton("example.com"))
    or die "connect: $!";
send $sock, "GET / HTTP/1.0\r\n\r\n", 0
    or die "send: $!";
```

Unconnected UDP - four-argument form with an explicit destination:

```
use Socket;
socket my $sock, PF_INET, SOCK_DGRAM, getprotobyname("udp")
    or die "socket: $!";
my $to = sockaddr_in(514, inet_aton("10.0.0.1"));
send $sock, "<14>hello syslog\n", 0, $to
    or die "send: $!";
```

Handle short writes on a stream socket:

```
my $offset = 0;
while ($offset < length $buf) {
    my $n = send $sock, substr($buf, $offset), 0;
    defined $n or die "send: $!";
    $offset += $n;
}
```

Send with a flag - `MSG_DONTWAIT` makes a single non-blocking attempt and returns `undef` with `$!` set to `EAGAIN`/`EWOULDBLOCK` if the kernel buffer is full:

```
use Socket qw(MSG_DONTWAIT);
my $n = send $sock, $buf, MSG_DONTWAIT;
if (!defined $n) {
    if ($!{EAGAIN} || $!{EWOULDBLOCK}) {
        # back off, retry later
    } else {
        die "send: $!";
    }
}
```

Edge cases

- **Wide characters**: passing a string with codepoints above `0xFF` on a byte socket writes the UTF-8 encoding of each character and emits a `Wide character in send` warning under `use warnings`. Encode explicitly with `Encode::encode` before calling `send`.
- **`:utf8` layer on the socket**: `send` **croaks**. Either open the socket without the layer, or call `binmode` on `$sock` to strip it before the first `send`. An `:encoding(...)`

layer implicitly adds `:utf8`, so it's banned too.

- **Four-arg form on a connected socket**: passing `TO` to a connected `SOCK_STREAM` socket is an error - the kernel returns `EISCONN`. Use the three-argument form once connected.
- **Three-arg form on an unconnected datagram socket**: fails with `ENOTCONN` (or `EDESTADDRREQ` on some platforms). Either `connect` the datagram socket first (which pins a default peer), or supply `TO`.
- **Empty `MSG` on UDP**: valid - sends a zero-length datagram the peer can read with `recv`. On TCP it is a no-op that returns `0`.
- **`SIGPIPE` on a closed stream peer**: writing to a `SOCK_STREAM` whose remote end has closed raises `SIGPIPE`, which by default terminates the process. Pass `MSG_NOSIGNAL` in `FLAGS` (Linux) or install `$SIG{PIPE} = 'IGNORE'` to get an `EPIPE` return instead.
- **`sendmsg(2)`**: Perl exposes `send`/`sendto`, not `sendmsg`. Scatter/gather writes and ancillary data (credentials, file descriptors over `AF_UNIX`) require an XS module such as `Socket::MsgHdr`.
- **Non-socket filehandle**: `send` on a non-socket returns `undef` with `$!` set to `ENOTSOCK`. Use `syswrite` for pipes and regular files.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `recv` - the inverse; reads bytes from a socket with the same layer restrictions and the same `FLAGS` argument
- `syswrite` - raw write that bypasses PerlIO buffering on any filehandle; use it for pipes and files where `send` refuses to work
- `connect` - establishes the peer address that lets you use the three-argument form of `send`
- `socket` - creates the filehandle `send` writes to; the socket type (`SOCK_STREAM` vs `SOCK_DGRAM`) decides which form of `send` is legal
- `bind` - assigns a local address; needed before `send` on a datagram socket if the peer expects replies to a known port
- `binmode` - strips a stray `:utf8` layer that would otherwise make `send` throw

User and group info

setgrent

Rewind the group-database iterator back to the first entry.

`setgrent` tells the system's group-database iterator to start over. The next call to `getgrent` returns the first group record again, regardless of how far a previous iteration walked. It takes no arguments, returns no useful value, and exists so that a program can

re-scan the group database without having to close and reopen it by hand. Pair it with `endgrent` at the end of a scan to release the underlying file descriptor.

Synopsis

```
setgrent;
setgrent();
```

What you get back

The return value is unspecified and conventionally ignored. Call `setgrent` for its side effect - positioning the iterator - not for its value.

Global state it touches

- The **per-process group-database iterator** maintained by the C library (`getgrent(3)`). It is global to the process, not scoped to a package or a lexical: any other code walking `getgrent` in the same process, including inside threads that share the iterator, sees the rewind.
- `$!` - on systems whose `setgrent(3)` reports errors (rare; most implementations return `void`), a failure leaves `errno` set. Portable code does not rely on this.

`setgrent` does not touch `$_`, `@ARGV`, or any filehandle.

Examples

Rewind between two passes over the group database - first to collect all group names, then to collect the members of a specific group:

```
my @names;
while (my @g = getgrent) {
    push @names, $g[0];
}

setgrent;                               # start over
while (my @g = getgrent) {
    next unless $g[0] eq 'wheel';
    print "wheel members: $g[3]\n";
    last;
}
endgrent;
```

Use `setgrent` at the top of a sub that is called repeatedly and wants a fresh scan every time:

```
sub groups_containing {
    my ($user) = @_;
    setgrent;
    my @groups;
```

(continues on next page)

(continued from previous page)

```
    while (my ($name, undef, undef, $members) = getgrent) {
        push @groups, $name if grep { $_ eq $user } split / /,
↪$members;
    }
    endgrent;
    return @groups;
}
```

Pair `setgrent` / `endgrent` around a scan so an unrelated caller that was mid-iteration is not surprised when control returns:

```
setgrent;
while (my @g = getgrent) {
    # ... process ...
}
endgrent;
```

Edge cases

- **No argument form only.** Unlike `sethostent`, `setnetent`, `setprotoent`, and `setservent`, which take a `STAYOPEN` flag, `setgrent` takes nothing. Passing an argument is a compile-time error.
- **Calling `setgrent` without an intervening `getgrent` is a no-op on most systems** - the iterator is simply positioned at the first entry, and the first `getgrent` after it reads that entry. Don't rely on `setgrent` as an "open the group file" primitive; its only defined behaviour is "rewind".
- **Process-global state.** `setgrent` inside one module rewinds the iterator for every other module in the same process. If a library walks `getgrent` to completion and a caller then calls `setgrent`, the library's cursor is gone. Treat the iterator as a shared resource: own it for the duration of a scan, bracketed by `setgrent` and `endgrent`.
- **Threads share the iterator.** Two threads calling `getgrent` concurrently will each see a subset of the records; `setgrent` from one thread disturbs the other. For per-thread iteration, read `/etc/group` directly or use a thread-safe wrapper; the built-in is not reentrant.
- **Not all platforms implement it identically.** On systems without `setgrent(3)` the call is a no-op and silently succeeds. On systems that do implement it, the exact cost (reopening `/etc/group`, restarting an NSS query, re-querying LDAP) depends on the backing name-service and can be non-trivial - avoid calling it in a tight loop.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `getgrent` - read the next group record; consumes the iterator that `setgrent` rewinds
- `endgrent` - close the iterator when the scan is finished; the symmetric bookend to `setgrent`
- `getgrnam` - lookup a single group by name without touching the iterator at all; prefer this for one-shot queries
- `getgrgid` - lookup a single group by GID; same reasoning as `getgrnam`
- `setpwent` - the equivalent rewind for the password database

Network info

sethostent

Open or rewind the hosts database for iteration.

`sethostent` prepares the system hosts database (typically `/etc/hosts` plus any name-service sources configured by the platform) for a sequential walk with `gethostent`, and rewinds the cursor if iteration is already in progress. `STAYOPEN` is a flag passed through to the underlying C `sethostent(3)` call: a true value asks the resolver to keep the database open across subsequent `gethostby*` lookups, which on some systems avoids reopening the file or reconnecting to the name service for every query.

Synopsis

```
sethostent STAYOPEN
sethostent 0
sethostent 1
```

What you get back

Returns nothing useful. The call is invoked for its side effect of priming the iterator; ignore the return value.

Global state it touches

Mutates **process-global** resolver state maintained by the C library: the hosts-database file descriptor or name-service handle, and the per-process iteration cursor read by `gethostent`. Two pieces of code in the same process walking the hosts database simultaneously will step on each other - there is one cursor, not one per caller. On failure `$!` is set by the underlying system call; there is no `h_errno`-style reporting for this function.

Examples

Walk every entry in the hosts database:

```
sethostent(0);
while (my ($name, $aliases, $addrtype, $length, @addrs)
        = gethostent()) {
    print "$name\n";
}
endhostent();
```

Ask the resolver to keep the database open while a batch of name-to-address lookups runs, then close it:

```
sethostent(1);
for my $host (@hosts) {
    my $packed = gethostbyname($host);
    # ...
}
endhostent();
```

Rewind an in-progress iteration to start over from the first entry:

```
sethostent(0);
my $first = (gethostent())[0];
sethostent(0);                          # back to the top
my $first_again = (gethostent())[0];
```

Edge cases

- **`STAYOPEN` is mandatory syntax, not mandatory semantics.** The argument must be present - `sethostent;` is a compile error - but many platforms ignore the flag and always keep the database open for the duration of the iteration. Pass `0` when you have no preference.
- **Not every platform has a meaningful hosts iterator.** On systems where the hosts database is served exclusively by DNS or a name service that does not expose enumeration, `gethostent` returns the empty list on the first call regardless of `sethostent`. The call itself still succeeds.
- **Thread safety.** The resolver cursor is per-process, not per-thread. Two threads iterating concurrently will interleave records and neither will see the full list. Upstream Perl substitutes `*_r` variants for point lookups like `gethostbyname` where available; there is no thread-safe variant of the iterator.
- **Interaction with `gethostby*` caches.** On some libc implementations a `sethostent(1)` issued before a burst of `gethostbyname` / `gethostbyaddr` calls keeps the backing file open between queries; on others it has no effect. Measure before relying on it as an optimisation.
- **Pair with `endhostent`.** Leaving the database open after iteration can leak a file descriptor or a resolver connection. Always close the walk with `endhostent`.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `gethostent` - read the next entry from the hosts database after `sethostent` has primed the cursor
- `endhostent` - close the database and release resolver state when iteration is done
- `gethostbyname` - point lookup by name; benefits from `sethostent(1)` on platforms that honour it
- `gethostbyaddr` - point lookup by address; same caveat as `gethostbyname`
- `setnetent` - the networks-database counterpart, same iteration pattern
- `setservent` - the services-database counterpart

Network info

setnetent

Open or rewind the networks database for iteration.

`setnetent` prepares the system networks database so that subsequent calls to `getnetent` return entries starting from the first one. It is a direct wrapper around the C library's `setnetent(3)` and reads the same underlying source as the C call - typically `/etc/networks` on Linux, or whatever `nsswitch.conf` / NSS backends have been configured to provide.

The `STAYOPEN` argument is a hint to the C library: a true value asks it to keep the database file open across related calls (`getnetbyname`, `getnetbyaddr`, `getnetent`) so individual lookups do not each pay the cost of opening and closing the file. On modern glibc this flag is effectively ignored - the database is handled efficiently either way - but passing it costs nothing and keeps the code portable to systems where it still matters.

Synopsis

```
setnetent STAYOPEN
setnetent 0
setnetent 1
```

What you get back

`setnetent` returns nothing meaningful. In list context it returns an empty list, in scalar context `undef`. Do not rely on the return value; the call's effect is the side effect of positioning the database iterator at the start.

If the underlying C call fails (for example the database file is missing or unreadable) the error is silent from Perl's perspective - `getnetent` will simply return an empty list on the first call.

Global state it touches

- The process-wide **networks-database cursor** maintained by the C library. Every call to `getnetent` advances this cursor; `setnetent` rewinds it. `endnetent` closes the database and releases any resources held by a `STAYOPEN` hint.
- No Perl special variables are read or written.

Because the cursor is per-process, not per-thread, interleaving networks-database iteration from multiple threads in the same interpreter will corrupt each iterator's position. Perform the iteration from a single thread, or serialise access.

Examples

Rewind the database and iterate from the first entry:

```
setnetent(1);
while (my ($name, $aliases, $addrtype, $net) = getnetent()) {
    printf "%-20s %d\n", $name, $net;
}
endnetent();
```

Re-run the iteration from the top without closing in between. The second `setnetent` rewinds, so the second loop sees every entry again:

```
setnetent(1);
my @first_pass  = collect_nets();
setnetent(1);
my @second_pass = collect_nets();
endnetent();

sub collect_nets {
    my @out;
    while (my @ent = getnetent()) { push @out, $ent[0] }
    return @out;
}
```

Pairing with `Net::netent` for a named-field interface over the same data source - `setnetent` still controls the cursor:

```
use Net::netent;
setnetent(1);
while (my $n = getnetent()) {
    printf "%s -> %s\n", $n->name, $n->net;
}
endnetent();
```

Edge cases

- **`STAYOPEN` is a hint, not a guarantee.** On systems where the C library ignores it, passing 1 and passing `0` produce identical observable behaviour.

- **No implicit `setnetent` before `getnetent`.** A fresh process that calls `getnetent` without first calling `setnetent` still starts from the first entry on most systems, but this is a libc convention rather than a guarantee. Call `setnetent` explicitly when you want to be sure.
- **Calling `setnetent` mid-iteration rewinds the cursor.** Any in-progress `while (getnetent)` loop restarts from the top - useful for a deliberate second pass, a bug if it happens by accident from a helper sub that also iterates.
- **Interaction with `getnetbyname` / `getnetbyaddr`.** On systems where the C library honours `STAYOPEN`, a by-name or by-address lookup during iteration will *not* disturb the iterator. On systems that ignore the hint, each lookup may reset the cursor. Do not mix by-name lookups with `getnetent` iteration if you need stable positioning.
- **Permissions.** The networks database is typically world-readable, but NSS backends (LDAP, `sssd`) may impose their own authorisation. A lookup that worked as `root` can yield nothing as a normal user without Perl seeing an error.
- **Empty or missing `/etc/networks`.** On most Linux systems this file is empty or absent by default. `setnetent` still succeeds; the following `getnetent` returns an empty list on the first call. This is not an error condition.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `getnetent` - the iterator primed by `setnetent`; reaches for the next row on each call
- `endnetent` - close the database and release any resources held open by `STAYOPEN`; call it when iteration is done
- `getnetbyname` - lookup a single entry by name without running the iterator
- `getnetbyaddr` - lookup a single entry by packed address without running the iterator
- `sethostent` - the same idiom for the hosts database
- `setservent` - the same idiom for the services database
- `Net::netent` - object-oriented wrapper returning named fields instead of a positional list

Processes

setpgrp

Set the process group of a process.

`setpgrp` moves the process identified by `PID` into the process group identified by `PGRP`. A `PID` of `0` means the current process; a `PGRP` of `0` means “use `PID` as the new group id” - that is, make the process a group leader. With no arguments it defaults to `setpgrp(0,`

`0`), which makes the current process the leader of a new process group whose id equals its own pid.

This is the Perl interface to the underlying `setpgid(2)` / `setpgrp(2)` system call. It is the building block for detaching a process from its controlling terminal and for job-control schemes that want to send signals to a whole group at once with `kill`.

Synopsis

```
setpgrp PID, PGRP
setpgrp            # same as setpgrp(0, 0)
```

What you get back

1 on success, `undef` on failure with `$!` set to the reason (commonly `EPERM` when the target process is not the caller or a child of the caller, or `ESRCH` when no such process exists). Check the return value - silently proceeding with a process still in the old group is almost never what you want.

```
setpgrp(0, 0)
    or die "setpgrp failed: $!";
```

Global state it touches

- `$!` - set to the `errno` value on failure. Not touched on success.

Examples

Detach the current process into a new process group of its own. This is the classic first step of a daemonisation sequence, run after `fork` and before closing the standard handles:

```
setpgrp(0, 0)
    or die "setpgrp failed: $!";
```

Move a just-spawned child into its own group so that a `SIGTERM` sent to the group kills the child and any grandchildren it spawns, without touching the parent:

```
my $pid = fork // die "fork: $!";
if ($pid == 0) {
    setpgrp(0, 0) or die "setpgrp: $!";
    exec @cmd or die "exec: $!";
}
# parent: signal the whole group with a negative pid
kill 'TERM', -$pid;
```

Read the group id back after setting it, using `getpgrp`:

```
setpgrp(0, 0) or die $!;
my $pgid = getpgrp(0);
print "now leader of group $pgid\n";
```

Handle the portability failure mode - on a platform without the underlying system call the function raises an exception rather than returning `undef`:

```
eval { setpgrp(0, 0) };
if ($@) {
    warn "no process-group support on this platform: $@";
}
```

Edge cases

- **No arguments defaults to `(0, 0)`.** Writing `setpgrp;` is the same as `setpgrp(0, 0)` - make the current process a new group leader. The no-argument form is the portable form (see below).
- **BSD 4.2 compatibility.** The historical BSD 4.2 `setpgrp` took no arguments. Scripts that must run on such systems can only rely on the `setpgrp(0, 0)` / `setpgrp()` forms; any other argument combination is non-portable.
- **Raises, not returns `undef`, on unsupported platforms.** On a machine that implements neither POSIX `setpgid(2)` nor BSD `setpgrp(2)`, `setpgrp` raises an exception. This is the one failure mode that does **not** go through `$!` - wrap in `eval` if you need to degrade gracefully.
- **`EPERM` on cross-session moves.** The kernel rejects attempts to move a process into a group in a different session, or to move a process that has already called `exec`. Catch `$! == EPERM` and fall back rather than retrying.
- **Signalling the whole group.** Once a group is established, `kill SIG, -$pgid` delivers `SIG` to every process in the group. The negative-pid convention is a property of `kill`, not of `setpgrp` - but it's the reason you usually call `setpgrp` in the first place.
- **Not a session leader.** `setpgrp` changes process group, not session. To detach from the controlling terminal entirely you need `POSIX::setsid`, which creates a new session and a new group in one step.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `getpgrp` - read the current process group id; the obvious companion for verifying a `setpgrp` call took effect
- `POSIX::setpgid` - the POSIX-named wrapper around the same system call, preferred in new code because its argument order and semantics are unambiguous across platforms
- `POSIX::setsid` - create a new session *and* a new process group in one call; use this, not `setpgrp`, for full terminal detachment
- `fork` - the call that almost always precedes `setpgrp`; a child that wants its own group calls `setpgrp(0, 0)` right after `fork` returns `0`

- `kill` - how you actually use a process group once you've built one: `kill SIG, -$pgid` signals every member

Processes

setpriority

Set the scheduling priority (nice value) of a process, process group, or user.

`setpriority` is the Perl-level wrapper around the `setpriority(2)` system call. `WHICH` selects the target class (`PRIO_PROCESS`, `PRIO_PGRP`, or `PRIO_USER`), `WHO` names the specific target within that class (`0` means "self" or "current" depending on `WHICH`), and `PRIORITY` is the new nice value. Higher values mean *lower* scheduling priority; on Linux the useful range is `-20` (most favourable) through `19` (least favourable).

Synopsis

```
setpriority WHICH, WHO, PRIORITY
```

What you get back

Returns true on success, `undef` on failure (with `$!` set to the underlying `errno`). The most common failures are `EACCES` or `EPERM` - lowering the nice value below the current one, or touching another user's processes, requires privilege. Always check the return value when the priority change is not just cosmetic:

```
setpriority(PRIO_PROCESS, $$, 10)
    or die "cannot renice self: $!";
```

Global state it touches

- `$!` - set on failure to the `errno` from the underlying `setpriority(2)` call.

The three `WHICH` classes

`WHICH` is one of three integer constants, each selecting a different interpretation of `WHO`:

- `PRIO_PROCESS` - `WHO` is a process ID. `0` means the current process.
- `PRIO_PGRP` - `WHO` is a process group ID. `0` means the process group of the current process.
- `PRIO_USER` - `WHO` is a numeric user ID (UID). `0` means the real UID of the current process. Setting by user changes the priority of *every* process owned by that user.

These constants are not built in - import them from `POSIX`:

```
use POSIX qw(PRIO_PROCESS PRIO_PGRP PRIO_USER);
```

Examples

Renice the current process to `10` (friendlier to other work):

```
use POSIX qw(PRIO_PROCESS);
setpriority(PRIO_PROCESS, 0, 10)
    or die "renice failed: $!";
```

Renice a child process after `fork`:

```
use POSIX qw(PRIO_PROCESS);
my $pid = fork // die "fork: $!";
if ($pid == 0) {
    setpriority(PRIO_PROCESS, $$, 15);  # child runs at low priority
    exec @cmd;
}
```

Renice every process in the current process group - useful in a session leader that wants its whole pipeline to yield:

```
use POSIX qw(PRIO_PGRP);
setpriority(PRIO_PGRP, 0, 5)
    or warn "could not renice process group: $!";
```

Pair with `getpriority` to adjust relative to the current value rather than setting an absolute one:

```
use POSIX qw(PRIO_PROCESS);
my $cur = getpriority(PRIO_PROCESS, 0);
setpriority(PRIO_PROCESS, 0, $cur + 5)
    or die "renice failed: $!";
```

Edge cases

- **Negative priorities require privilege.** Lowering the nice value (more favourable scheduling) below the current one needs `CAP_SYS_NICE` on Linux, or root. An unprivileged attempt fails with `EACCES` or `EPERM` depending on kernel version.
- **Nice values are clamped.** The kernel silently clamps `PRIORITY` to the supported range (`-20` . . `19` on Linux). Passing `100` does *not* fail; it ends up as 19.
- **`WHO = 0` is context-sensitive.** Its meaning depends on `WHICH`: current PID for `PRIO_PROCESS`, current process group for `PRIO_PGRP`, real UID for `PRIO_USER`. It is not a universal "self" token.
- **Non-existent target.** A PID, PGID, or UID that does not match any running process fails with `ESRCH`.
- **Platform without `setpriority(2)`.** Perl raises a fatal exception (`setpriority() not implemented`). pperl targets Linux only, so this case does not arise in practice, but portable code should still guard with `eval`.
- **Signed return from `getpriority` vs. success of `setpriority`.** `getpriority` can legitimately return `-1` as a nice value, which is why it sets `$!` to distinguish

error from result; `setpriority` has no such ambiguity - treat its return purely as a boolean.

- **Nice value is per-process, not per-thread.** On Linux this differs from POSIX: the kernel applies the nice value to the calling task (thread). Perl is single-threaded at the interpreter level, so this only matters if XS code has spawned kernel threads.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `getpriority` - read the current nice value; the natural counterpart when adjusting relative to the existing priority
- `POSIX` - source of the `PRIO_PROCESS`, `PRIO_PGRP`, and `PRIO_USER` constants
- `fork` - typical pairing: spawn a child, then renice it before `exec`
- `$!` - holds the `errno` describing why a failed `setpriority` call returned `undef`
- `kill` - other per-process control operation with the same "target by PID or PGID" convention

Network info

setprotoent

Open the protocols database and prepare it for sequential reads.

`setprotoent` rewinds (or opens) the system protocols database - on most Unix-like systems that's `/etc/protocols` - so that a subsequent sequence of `getprotoent` calls starts at the first entry. It is the first leg of the `setprotoent` / `getprotoent` / `endprotoent` iteration triad. The single `STAYOPEN` argument is a hint to the C library about whether the file handle backing the iteration should stay open between calls: a true value asks the library to keep it open (faster for long walks), a false value lets it close and reopen per call.

Calling `getprotobyname` or `getprotobynumber` anywhere mid-iteration may reset the walk position on some platforms; see *Edge cases*.

Synopsis

```
setprotoent STAYOPEN
setprotoent(1)
```

What you get back

No meaningful return value. Like its `endprotoent` and `sethostent` siblings, `setprotoent` is called for its side effect: rewinding the iteration and, depending on `STAYOPEN`, pinning the descriptor open. There is nothing worth checking in its return value.

Global state it touches

`setprotoent` manipulates a **per-process**, C-library-owned cursor into the protocols database. That state is shared across every subsequent `getprotoent` call in the same process - including calls from other modules you did not write. Code that walks the database must either fully drain it with `endprotoent` or accept that a later caller may see an iteration already in progress. No Perl-level special variables are read or written.

Examples

Open the database and iterate every entry, keeping the underlying descriptor alive for the full walk:

```
setprotoent(1);                          # 1 = keep file open between
↪calls
while (my @p = getprotoent()) {
    my ($name, $aliases, $proto) = @p;
    print "$proto\t$name\n";
}
endprotoent();
```

Restart an in-progress iteration from the beginning:

```
setprotoent(1);
my @first  = getprotoent();
my @second = getprotoent();

setprotoent(1);                          # rewind
my @again  = getprotoent();              # same as @first
endprotoent();
```

Let the C library close and reopen `/etc/protocols` on every `getprotoent` - cheaper in memory, more expensive in syscalls, useful only when you read a handful of entries:

```
setprotoent(0);
my @tcp = getprotoent();
endprotoent();
```

Pair with a one-shot lookup - `getprotobyname` and `getprotobynumber` do not participate in the iteration and do not need `setprotoent`:

```
my @tcp = getprotobyname('tcp');         # no setprotoent needed
```

Edge cases

- **`STAYOPEN` is a hint, not a contract**: many C libraries ignore it entirely and behave as if the descriptor were always kept open. Do not rely on the argument to control resource usage at a fine grain.
- **Mixing with single-shot lookups**: calling `getprotobyname` or `getprotobynumber` during a walk may reset the iteration cursor on some platforms. Portable code drains the walk first, or re-calls `setprotoent` afterwards to restart from the top.

- **Not reentrant**: the protocols database cursor is a single global resource inside the C library. Two concurrent iterations in the same process (threads, signal handlers, anything) corrupt each other. Use one walk at a time.
- **Argument is mandatory at the language level**: `setprotoent` without an argument is a syntax error - the built-in has arity one. Pass `0` if you have no preference.
- **Platforms without a protocols database**: on systems where the C library has no `/etc/protocols` equivalent, the call is a no-op rather than an error. See `perlport` for the full list of network-database quirks.
- **Untainted result of the iteration**: the records returned by `getprotoent` after `setprotoent` come from a file the kernel reads on your behalf and are not marked tainted. Treat them as untrusted anyway if the database can be user-edited.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `getprotoent` - read the next entry; the body of the loop that `setprotoent` sets up
- `endprotoent` - close the database after iteration; the terminator for the triad `setprotoent` starts
- `getprotobyname` - single-shot lookup by name; does not participate in the iteration
- `getprotobynumber` - single-shot lookup by protocol number; likewise independent
- `sethostent` - analogous opener for the hosts database; same idiom, different table
- `setservent` - analogous opener for the services database

User and group info

setpwent

Rewind the password-database iterator so the next `getpwent` call returns the first entry again.

`setpwent` wraps the C library's `setpwent(3)` call. It (re)opens the system password database and resets the iteration cursor used by `getpwent`, so a subsequent loop starts from the top. Use it when you want to iterate the password database more than once in the same process, or when you want to restart iteration after a partial walk. Pair it with `endpwent` to release the database when done.

Synopsis

```
setpwent;
setpwent();
```

What you get back

Return value is **not useful** and must not be relied on. On most systems the underlying `setpwent(3)` has a `void` return; Perl yields a single meaningless true value. Call `setpwent` for its side effect, never for its value.

Global state it touches

- The per-process cursor shared by `getpwent`, `setpwent`, and `endpwent`. This cursor is owned by the C library, not by Perl - forking a child inherits an open database handle, and two threads iterating concurrently will interleave and lose records.
- `$!` is **not** set by `setpwent`; errors from the underlying `setpwent(3)` are swallowed by the platform.

Examples

Iterate the password database twice in the same program:

```
while (my @pw = getpwent) {
    print "$pw[0]\n";           # first pass: every login name
}
setpwent;
while (my @pw = getpwent) {
    print "uid=$pw[2]\n";       # second pass: every uid
}
endpwent;
```

Restart iteration after an early exit:

```
while (my @pw = getpwent) {
    last if $pw[0] eq 'root';
}
setpwent;                       # rewind so the next walk sees root␣
↪again
```

Typical cleanup pattern - always call `endpwent` when done, whether or not you called `setpwent`:

```
setpwent;
while (my ($name, undef, $uid) = getpwent) {
    print "$name => $uid\n" if $uid >= 1000;
}
endpwent;
```

Edge cases

- **No arguments.** `setpwent` takes no arguments. Writing `setpwent $x` is a syntax trap: like other list operators, it will try to consume `$x` as the first element of a list.
- **Before any `getpwent` call.** Safe. `setpwent` opens the database if it is not already open, so it doubles as an explicit "open" call.

- **After endpwent.** Safe. The database is reopened.
- **Forked children.** Each process has its own iteration cursor after the fork, but the underlying file descriptor may be shared; interleaved reads from parent and child produce missing or duplicated records. Call `setpwent` in the child to get a clean iterator.
- **Threads.** `getpwent` iteration is per-process, not per-thread. Concurrent iteration from multiple threads loses records. Upstream Perl substitutes thread-safe `_r` variants for `getpwnam` and `getpwuid` when the platform provides them; there is no `setpwent_r`, and this function remains process-global.
- **NSS-backed databases.** On systems where `/etc/nsswitch.conf` routes `passwd` through LDAP, SSSD, or similar, `setpwent` may block on a network round-trip. Do not call it from signal handlers or latency-critical code paths.
- **Shadow passwords.** `setpwent` does not affect the shadow-password iterator (if any); it only resets the regular `passwd` walk.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `getpwent` - fetch the next entry; the function `setpwent` exists to rewind
- `endpwent` - release the password database when you are finished iterating
- `getpwnam` - direct lookup by login name; does not interact with the iteration cursor
- `getpwuid` - direct lookup by uid; does not interact with the iteration cursor
- `setgrent` - the same rewind operation for the group database
- `User::pwent` - object-oriented wrapper that returns named-field objects instead of 10-element lists

Network info

setservent

Rewind the services database and optionally keep it open across lookups.

`setservent` is the services-database counterpart of the C library's `setservent(3)`. It resets the internal cursor used by `getservent` so the next call starts again at the first entry of `/etc/services` (or whatever source the system resolver is configured to use), and it controls whether the underlying file stays open between by-name and by-port lookups.

Synopsis

```
setservent STAYOPEN
setservent 0                # close file between lookups (default)
setservent 1                # keep file open across lookups
```

What you get back

The return value is whatever the underlying C `setservent(3)` returns - on most systems that's nothing useful, and scripts do not check it. Treat `setservent` as called for its side effect on the iterator, not for a value.

Global state it touches

- The per-process services-database cursor shared with `getservent`, `getservbyname`, `getservbyport` and `endservent`. All four read and mutate the same state; iteration is not thread-safe and not reentrant.
- The open/closed status of the services database file. `STAYOPEN` true leaves the file open until `endservent` is called; `STAYOPEN` false (the default) causes each subsequent by-name or by-port lookup to open and close the file again.

The STAYOPEN argument

Pass a true value to hold the file open across a run of individual `getservbyname` or `getservbyport` lookups. This is an optimisation for batch resolution, not a semantic change: results are identical either way.

```
setservent 1;
for my $name (@service_names) {
    my @svc = getservbyname $name, "tcp";
    # ... process @svc ...
}
endservent;
```

Pass a false value (or `0`) when you want each lookup to reopen the file. This is the default behaviour and the one most programs want.

Examples

Walk every entry in the services database and print name/port pairs:

```
setservent 0;
while (my ($name, undef, $port, $proto) = getservent) {
    print "$name $port/$proto\n";
}
endservent;
```

Rewind mid-iteration to start over:

```
setservent 0;
my @first_pass;
while (my @svc = getservent) {
    push @first_pass, $svc[0];
    last if @first_pass == 10;
}
setservent 0;                       # cursor back to start
```

(continues on next page)

(continued from previous page)

```
my @second_pass = getservent;     # first entry again
endservent;
```

Batch-resolve with the file held open:

```
my @wanted = qw(http https ssh smtp);
setservent 1;
my %port = map { $_ => scalar getservbyname($_, "tcp") } @wanted;
endservent;
```

Edge cases

- **`STAYOPEN` is required at the Perl level.** `setservent` is parsed with list-operator precedence and reads one argument; a bare `setservent;` with no argument is a compile-time error. Pass `0` when you want the default "close after each lookup" behaviour.
- **Platform dependence.** The services database is whatever the system resolver uses - typically `/etc/services`, but NIS, LDAP, and other name-service backends can supply entries. `setservent` rewinds whichever source the C library selects; the Perl level has no say in it.
- **Non-Unix platforms.** On systems without `setservent(3)` the call croaks with `The setservent function is unimplemented`. See `perlport` for the availability matrix.
- **Threads.** Iterator state is per-process, not per-thread; two threads walking the services database concurrently will interleave and neither will see every record. See the shared note in `perlfunc` on `getpwnam`-family thread safety.
- **Pairing with `endservent`.** When `STAYOPEN` was true, call `endservent` to release the file descriptor; otherwise the handle leaks for the life of the process.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `getservent` - walk the services database one entry at a time; this is the iterator `setservent` rewinds
- `endservent` - close the services database file opened by `setservent 1`
- `getservbyname` - look up a single service by name; honours the open/closed state set here
- `getservbyport` - look up a single service by port number; same open/closed semantics
- `setprotoent` - same pattern for the protocols database when you are rewinding both together

- `Net::servent` - object-oriented wrapper over the `getserv*` family for when positional return lists get unwieldy

Sockets

setsockopt

Set a kernel-level option on an open socket.

`setsockopt` is the Perl wrapper around the POSIX `setsockopt(2)` system call. It writes the option named by `OPTNAME` at protocol `LEVEL` on the already-opened `SOCKET` filehandle, using the value packed into `OPTVAL`. It is the knob for everything the kernel lets you tune on a socket - address reuse, keepalives, timeouts, Nagle's algorithm, multicast membership, send and receive buffer sizes, `SO_LINGER` behaviour on `close`, and so on. Symbolic names for `LEVEL` and `OPTNAME` come from the `Socket` module.

Synopsis

```
setsockopt SOCKET, LEVEL, OPTNAME, OPTVAL
```

What you get back

A true value on success, `undef` on failure (with `$!` set to the underlying errno: `EBADF`, `ENOPROTOOPT`, `EINVAL`, `ENOTSOCK`, etc.). Always check the return value - a silently-ignored option means the program runs with defaults that differ from what the code reads:

```
setsockopt($sock, SOL_SOCKET, SO_REUSEADDR, pack("l", 1))
    or die "setsockopt SO_REUSEADDR: $!";
```

Global state it touches

None directly. `setsockopt` sets `$!` on failure; that is the only interpreter global involved. The effect is on the kernel-side state of the socket, not on any Perl-level variable.

OPTVAL - packed bytes or a bare integer

Most socket options take a C `int` flag. `setsockopt` accepts either form for convenience:

- A **packed byte string** whose layout matches the option's C type, typically built with `pack`: `pack("l", 1)` for a boolean, `pack("ll", $on_secs, $on_usecs)` for a `struct timeval`, `pack("ii", $on, $linger)` for `struct linger`.
- A **plain integer**, which is shorthand for `pack("i", OPTVAL)`. Handy for `SO_REUSEADDR`, `TCP_NODELAY`, and other boolean flags:

  ```
  setsockopt($sock, IPPROTO_TCP, TCP_NODELAY, 1);
  ```

Options whose value is a struct (`SO_LINGER`, `SO_RCVTIMEO`, `IP_ADD_MEMBERSHIP`) must be passed as an explicit `pack`ed string. A bare integer there produces `EINVAL` or, worse, silently writes wrong-sized memory that the kernel misinterprets.

Examples

Disable Nagle's algorithm on a TCP socket so small writes go out immediately - useful for latency-sensitive protocols (interactive shells, game traffic, RPC):

```
use Socket qw(IPPROTO_TCP TCP_NODELAY);

setsockopt($sock, IPPROTO_TCP, TCP_NODELAY, 1)
    or die "TCP_NODELAY: $!";
```

Allow a server to rebind a port that is still in `TIME_WAIT` from a previous process - the single most common `setsockopt` call in practice, and it must come **before** `bind`:

```
use Socket qw(SOL_SOCKET SO_REUSEADDR);

setsockopt($srv, SOL_SOCKET, SO_REUSEADDR, pack("l", 1))
    or die "SO_REUSEADDR: $!";
bind($srv, sockaddr_in(9000, INADDR_ANY))
    or die "bind: $!";
```

Set a receive timeout so a blocking `recv` or read from the socket returns with `EAGAIN` / `EWOULDBLOCK` after 5 seconds instead of hanging forever. The option value is a packed `struct timeval`:

```
use Socket qw(SOL_SOCKET SO_RCVTIMEO);

my $tv = pack("l!l!", 5, 0);    # 5 seconds, 0 microseconds
setsockopt($sock, SOL_SOCKET, SO_RCVTIMEO, $tv)
    or die "SO_RCVTIMEO: $!";
```

Enable TCP keepalive probes so half-open connections (peer crashed, cable yanked) are eventually noticed and the socket errors out rather than blocking indefinitely:

```
use Socket qw(SOL_SOCKET SO_KEEPALIVE);

setsockopt($sock, SOL_SOCKET, SO_KEEPALIVE, 1)
    or die "SO_KEEPALIVE: $!";
```

Make `close` block for up to 10 seconds while the kernel flushes unsent data, then discard and reset. `SO_LINGER` takes a two-integer struct: the on-flag and the timeout in seconds:

```
use Socket qw(SOL_SOCKET SO_LINGER);

setsockopt($sock, SOL_SOCKET, SO_LINGER, pack("ii", 1, 10))
    or die "SO_LINGER: $!";
```

Enlarge the kernel receive buffer for a bulk-transfer socket. The kernel typically doubles the value you request and caps it at `net.core.rmem_max`:

```
use Socket qw(SOL_SOCKET SO_RCVBUF);

setsockopt($sock, SOL_SOCKET, SO_RCVBUF, 1 << 20)   # 1 MiB
    or die "SO_RCVBUF: $!";
```

Edge cases

- **SOCKET must already be open.** `setsockopt` does not create the socket - call `socket` first. A closed or never-opened filehandle fails with `EBADF`.
- **Ordering matters.** `SO_REUSEADDR` must be set *before* `bind`. `SO_KEEPALIVE` can go before or after `connect`, but for server sockets set it on the accepted child filehandle returned by `accept`, not on the listening one - options do not always propagate.
- **Integer shorthand is `pack("i", N)`**, not `pack("l", N)`. On platforms where `int` and `long` differ in size, passing a plain integer and passing `pack("l", N)` write different byte counts. Both happen to work for the common `int`-sized boolean options on LP64 Linux, but the shorthand form is the portable default.
- **Struct-valued options need explicit `pack`.** `SO_LINGER`, `SO_RCVTIMEO`, `SO_SNDTIMEO`, `IP_ADD_MEMBERSHIP`, `IP_MREQ`, and similar take fixed-layout structs. Pass a packed string of the right length or the kernel rejects the call with `EINVAL`.
- **`LEVEL` picks the option namespace.** `SOL_SOCKET` for generic options, `IPPROTO_TCP` for TCP-specific (`TCP_NODELAY`, `TCP_KEEPIDLE`), `IPPROTO_IP` for IPv4 (`IP_TTL`, `IP_ADD_MEMBERSHIP`), `IPPROTO_IPV6` for IPv6. Mismatching `LEVEL` and `OPTNAME` gives `ENOPROTOOPT`.
- **Read-only or unsupported options** fail with `ENOPROTOOPT`. This also fires when the kernel simply does not know the option - common when copying code between operating systems.
- **Privileged options.** A few options (`SO_PRIORITY` above certain values, `IP_TRANSPARENT`, `SO_BINDTODEVICE`) require `CAP_NET_ADMIN` on Linux; an unprivileged call fails with `EPERM`.
- **Reading back is `getsockopt`, not `setsockopt`.** `setsockopt` has no query form; use `getsockopt` to confirm what the kernel actually stored (it may round, clamp, or double the value).

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `getsockopt` - the query counterpart; read back an option to see what the kernel actually applied
- `socket` - create the socket filehandle that `setsockopt` configures; must be called first
- `bind` - set `SO_REUSEADDR` with `setsockopt` before calling `bind` on a server socket
- `accept` - options set on the listener do not all propagate; re-apply per-connection options on the accepted handle
- `pack` - builds the `OPTVAL` byte string for struct-valued options like `SO_LINGER` and `SO_RCVTIMEO`
- `Socket` - source of `SOL_SOCKET`, `IPPROTO_TCP`, `SO_REUSEADDR`, `TCP_NODELAY`, and the rest of the symbolic constants

Arrays

shift

Remove and return the first element of an array.

`shift` mutates its argument: it removes the element at index `0`, shifts every remaining element down by one position, and returns the removed value. The array shrinks by one. If the array is empty, nothing is removed and `undef` is returned.

Synopsis

```
shift @arr
shift @$aref
shift                   # @_ inside a sub, @ARGV outside
```

What you get back

The scalar that used to be at index `0`, or `undef` if the array was empty. Because `undef` is also a legal array element, a bare `undef` return does not by itself mean the array was empty - use `scalar @arr` or a prior `defined` check when the distinction matters:

```
my @arr  = (undef, 'two');
my $item = shift @arr;      # undef - but @arr was not empty
```

Default array: @ARGV vs @_

Called without an argument, `shift` picks its array from the surrounding context:

- Inside a named or anonymous subroutine - **`@_`**. This is the idiomatic way to consume positional arguments one at a time.
- Outside any sub (including in the file scope of a script, and in `eval STRING`, `BEGIN`, `INIT`, `CHECK`, `UNITCHECK`, `END` blocks) - **`@ARGV`**. This is how top-of-script argument consumption is usually written.

The choice is made at compile time based on lexical position, not at runtime. A `shift` inside a sub always targets `@_` even if the sub is called from file scope.

Examples

Consume a single positional argument inside a method. This is the canonical first line of almost every Perl OO method:

```
sub greet {
    my $self = shift;
    my $name = shift;
    return "hello, $name, from $self";
}
```

The same method written with a list-unpack `@_` slice. Both forms are idiomatic; `shift` wins when you want to peel off the invocant before deciding what to do with the rest of `@_`:

```
sub greet {
    my ($self, $name) = @_;
    return "hello, $name, from $self";
}
```

Consume `@ARGV` at the top of a script, one argument at a time:

```
my $mode = shift // 'default';       # first CLI arg, or 'default'
my $path = shift // die "need a path\n";
# @ARGV now holds whatever is left
```

A FIFO queue: `push` on the tail, `shift` off the head:

```
my @queue;
push @queue, 'a', 'b', 'c';
while (defined(my $job = shift @queue)) {
    handle($job);
}
```

Dereference an array ref in place - `shift` works on `@$aref` exactly as it does on a named array:

```
my $aref = [10, 20, 30];
my $head = shift @$aref;             # 10, $aref now [20, 30]
```

Edge cases

- **Empty array**: returns `undef` and leaves the array untouched. `shift` on an empty array is not an error.
- **Complexity is O(n)**: every remaining element is moved down by one slot. For large arrays used as queues this adds up. When FIFO ordering is not required, `pop` is O(1); when it is, consider a deque-style data structure or a pair of stacks rather than `shift`-ing a million-element array in a loop.
- **`shift` with no argument is context-sensitive by lexical position**: inside a sub it targets `@_`, outside it targets `@ARGV`. Moving a line of code between those scopes silently changes which array it mutates.
- **Tied arrays**: `shift` calls the `SHIFT` method on the tied object if one is defined; otherwise it falls back to `FETCH` on element `0`, then `DELETE`, then a sequence of `FETCH`/`STORE` pairs to shift the remaining elements down, then `STORESIZE`. A custom `SHIFT` handler is almost always worth writing for performance.
- **Array references**: `shift @$aref` and `shift @{ $expr }` both work. `shift $aref` (without the `@` sigil) was an experimental feature added in Perl 5.14 and removed in 5.24 - it is a syntax error in the Perl version pperl targets.
- **`shift` is an lvalue-consumer, not an lvalue**: you cannot assign to the result of `shift` to modify the array. Use `splice` or direct index assignment for that.

- **Return value in list context**: `shift` always returns a single scalar. Assigning its result to a list - `my ($x) = shift @arr` - works only because the single scalar fills the first list slot; the remaining slots are `undef`. Use `splice` to remove multiple elements at once.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `pop` - remove and return the **last** element; O(1), the right choice when FIFO order is not needed
- `push` - append to the tail; pairs with `shift` to form a FIFO queue
- `unshift` - prepend to the head; the inverse of `shift`, and also O(n) for the same reason
- `splice` - remove, insert, or replace any contiguous run of elements; the general tool when `shift` / `pop` / `unshift` / `push` are not enough
- `@ARGV` - the default array `shift` consumes at file scope
- `@_` - the default array `shift` consumes inside a sub; holds the caller's argument list

SysV IPC

shmctl

Control or query a System V shared memory segment.

`shmctl` is the management primitive for shared memory segments created with `shmget`. It performs one of a small set of operations named by `CMD` - reading the segment's metadata, changing its permissions, or marking it for removal. `ID` is the segment identifier returned by `shmget`. `ARG` is a buffer scalar that either supplies an input `shmid_ds` structure (for `IPC_SET`) or receives the returned one (for `IPC_STAT`); for `IPC_RMID` it is ignored.

Synopsis

```
use IPC::SysV qw(IPC_STAT IPC_SET IPC_RMID);

shmctl $id, IPC_STAT, $buf  or die "shmctl STAT: $!";
shmctl $id, IPC_SET,  $buf  or die "shmctl SET: $!";
shmctl $id, IPC_RMID, 0     or die "shmctl RMID: $!";
```

What you get back

Return value follows the `ioctl` convention, not the usual `0`-on-success Unix pattern:

- `undef` on error, with `$!` set to the errno.

- The string `"0 but true"` when the underlying call returned zero. This compares numerically equal to `0` but is boolean-true, so `shmctl(...) or die` still works.
- Any other non-zero value otherwise.

The practical rule: test for falsehood with `shmctl(...) or die "...: $!"` and never compare the return value to literal `0` with `==`.

The `IPC_STAT` form writes a packed `shmid_ds` structure into `ARG`. Unpack it with `IPC::SysV`'s helper or with a manual `unpack` template; the structure layout is platform-dependent so relying on a fixed template is not portable.

Global state it touches

- `$!` is set on failure to the errno from the underlying `shmctl(2)` call. Typical values: `EINVAL` (bad `ID` or `CMD`), `EACCES` (insufficient permissions for the operation), `EPERM` (non-owner attempting `IPC_SET` or `IPC_RMID`), `EFAULT` (bad `ARG` buffer for `IPC_STAT`/`IPC_SET`).

Examples

Read a segment's metadata. `IPC::SysV` provides the `shmid_ds` unpacker; without it, the structure is an opaque byte string:

```
use IPC::SysV qw(IPC_STAT);

my $buf = "";
shmctl($id, IPC_STAT, $buf) or die "stat failed: $!";
# $buf now holds the packed shmid_ds structure
```

Change the permissions on an existing segment. The pattern is read-modify-write on the packed structure:

```
use IPC::SysV qw(IPC_STAT IPC_SET);

my $buf = "";
shmctl($id, IPC_STAT, $buf) or die $!;
# ... modify the mode bits inside $buf ...
shmctl($id, IPC_SET,  $buf) or die $!;
```

Mark a segment for removal. The segment is destroyed once the last process detaches from it; `IPC_RMID` only flags it:

```
use IPC::SysV qw(IPC_RMID);

shmctl($id, IPC_RMID, 0) or die "rmid failed: $!";
```

Guarding on the `"0 but true"` return. Because the zero case is a string that is boolean-true, the idiomatic check is the `or die` form, not a numeric comparison:

```
my $rv = shmctl($id, IPC_STAT, $buf);
defined $rv                          or die "error: $!";
# do NOT write: $rv == 0 and ...   # misses the "0 but true" case
```

Edge cases

- **Missing constants**: `IPC_STAT`, `IPC_SET`, `IPC_RMID` are not built-in. Without `use IPC::SysV` they are bareword function calls and the code either fails to compile under `use strict` or silently passes the wrong integer. Always `use IPC::SysV qw(...)`.
- **Owner-only operations**: `IPC_SET` and `IPC_RMID` require the effective uid to match the segment's creator or owner, or the process to have `CAP_SYS_ADMIN`. Otherwise `$!` becomes `EPERM`.
- **`IPC_RMID` semantics**: marking for removal does not detach the caller and does not invalidate existing attachments. The segment stays usable until every process has called `shmdt` on it; only then is it actually destroyed. A process that attaches after `IPC_RMID` gets `EIDRM` or `EINVAL` depending on timing.
- **Structure layout is not portable**: `shmid_ds` fields and offsets vary between kernels and libc versions. Do not hand-code `unpack` templates for scripts that need to run on multiple platforms; use `IPC::SysV::ShmId` or a similar wrapper.
- **Buffer sizing for `IPC_STAT`**: `ARG` must be a scalar of at least `sizeof(shmid_ds)` bytes on output. Perl grows it as needed; pre-sizing with `$buf = "\0" x 256` is common but not required.
- **Unconfigured kernels**: on Linux built without `CONFIG_SYSVIPC`, the call fails with `ENOSYS`. Container images that drop SysV IPC exhibit the same behaviour.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `shmget` - create or look up the segment whose `ID` `shmctl` operates on
- `shmread` - copy bytes out of an attached segment; uses the `ID` returned by `shmget`, not an `shmctl` result
- `shmwrite` - copy bytes into an attached segment
- `msgctl` - same control pattern for System V message queues; same `"0 but true"` return convention
- `semctl` - same control pattern for System V semaphore sets; richer `CMD` set but identical return-value rules
- `IPC::SysV` - provides the `IPC_STAT` / `IPC_SET` / `IPC_RMID` constants and the `shmid_ds` packers

SysV IPC

shmget

Create or look up a System V shared memory segment and return its identifier.

`shmget` is the allocation step for SysV shared memory. Given a numeric `KEY` (either `IPC_PRIVATE` for a fresh anonymous segment or a well-known number agreed with

other processes), a requested `SIZE` in bytes, and a bit-mask of `FLAGS` (creation flags OR'd with a 9-bit mode), it returns a kernel-assigned integer identifier. That identifier - the `shmid` - is what every subsequent call (`shmctl`, `shmread`, `shmwrite`) uses to refer to the segment. The segment persists in the kernel until it is explicitly removed with `shmctl($shmid, IPC_RMID, 0)` or the system reboots; closing the creating process does **not** release it.

Synopsis

```
shmget KEY, SIZE, FLAGS
```

What you get back

An integer shared-memory identifier (`shmid`) on success, suitable for passing to `shmctl`, `shmread`, and `shmwrite`. On failure returns a false value and sets `$!` to the underlying `errno`.

```
use IPC::SysV qw(IPC_PRIVATE IPC_CREAT S_IRUSR S_IWUSR);

my $shmid = shmget(IPC_PRIVATE, 4096, IPC_CREAT | S_IRUSR | S_IWUSR)
    or die "shmget: $!";
```

The returned identifier is an opaque small integer. Do not do arithmetic on it, do not compare it to `0` for truth - the identifier `0` is a legitimate value on some systems. Always check the return against the documented failure sentinel (see *Differences from upstream*).

Global state it touches

- `$!` - set on failure to the underlying `errno`: `EACCES` (permissions), `EEXIST` (segment for that key already exists and both `IPC_CREAT` and `IPC_EXCL` were given), `EINVAL` (`SIZE` below `SHMMIN` or above `SHMMAX`, or `SIZE` differs from the existing segment when looking one up), `ENFILE` / `ENOSPC` (kernel segment-table full), `ENOENT` (no segment for that key and `IPC_CREAT` was not given), `ENOMEM` (insufficient memory).

The function is otherwise pure with respect to Perl-visible state: no special variables beyond `$!` are touched, `$_` is not read.

Examples

Create a fresh private segment - the usual pattern when parent and children share memory via `fork`:

```
use IPC::SysV qw(IPC_PRIVATE IPC_CREAT S_IRUSR S_IWUSR);

my $size  = 4096;
my $shmid = shmget(IPC_PRIVATE, $size, IPC_CREAT | S_IRUSR | S_
 ↪IWUSR)
    or die "shmget: $!";
# children inherit $shmid across fork and attach via shmread/
 ↪shmwrite
```

Attach to a pre-existing segment by its well-known key. `SIZE` and mode bits are ignored in this form; pass `0` for both:

```
my $key   = 0xDEADBEEF;
my $shmid = shmget($key, 0, 0)
    or die "shmget: $!";
```

Create-or-open with `IPC_CREAT`. If the key already exists the existing `shmid` is returned; otherwise a new segment of `SIZE` bytes is created with the given mode:

```
use IPC::SysV qw(IPC_CREAT S_IRUSR S_IWUSR S_IRGRP);

my $shmid = shmget(0x1234, 8192, IPC_CREAT | S_IRUSR | S_IWUSR | S_
↪IRGRP)
    or die "shmget: $!";
```

Fail if a segment already exists, using `IPC_EXCL`. This is the safe pattern for a process that wants to be the unique creator:

```
use IPC::SysV qw(IPC_CREAT IPC_EXCL S_IRUSR S_IWUSR);
use Errno qw(EEXIST);

my $shmid = shmget(0x1234, 4096, IPC_CREAT | IPC_EXCL | S_IRUSR | S_
↪IWUSR);
if (!$shmid) {
    die "shmget: $!" unless $! == EEXIST;
    # another process won the race; fall back to plain lookup
    $shmid = shmget(0x1234, 0, 0) or die "shmget (lookup): $!";
}
```

Full create-use-destroy cycle with guaranteed cleanup via `END`:

```
use IPC::SysV qw(IPC_PRIVATE IPC_CREAT IPC_RMID S_IRUSR S_IWUSR);

my $shmid = shmget(IPC_PRIVATE, 1024, IPC_CREAT | S_IRUSR | S_IWUSR)
    or die "shmget: $!";

END {
    shmctl($shmid, IPC_RMID, 0) if defined $shmid;
}

shmwrite($shmid, "hello", 0, 5)  or die "shmwrite: $!";
shmread($shmid, my $buf, 0, 5)   or die "shmread: $!";
```

Edge cases

- **`use IPC::SysV` is effectively mandatory.** The flag constants (`IPC_PRIVATE`, `IPC_CREAT`, `IPC_EXCL`, `IPC_RMID`) and mode bits (`S_IRUSR`, `S_IWUSR`, `S_IRGRP`, ...) are not built-ins. Without the import you end up passing bare barewords that stringify to `0` and silently do the wrong thing.
- **A literal `0` key *is* `IPC_PRIVATE`.** `IPC_PRIVATE` is defined as `0`, so a bare `0` never

looks up the segment at key `0` - it creates a fresh anonymous one, whether or not you passed `IPC_CREAT`. If `FLAGS` then carries no permission bits the new segment is mode `000` and the next `shmread`/`shmwrite` fails with `EACCES`. Import the constant by name so the intent is visible.

- **`SIZE` is rounded up to a page boundary** by the kernel; the returned segment may be larger than requested. Ask the kernel for the effective size with `shmctl($shmid, IPC_STAT, $ds)` and unpack the `shmid_ds` structure if you need the real number.
- **Segment persists beyond process exit.** A crashed or killed creator leaves the segment in the kernel. Use `ipcs -m` to list orphaned segments and `ipcrm -m <shmid>` to remove them. Install an `END` block or a signal handler to call `shmctl IPC_RMID` on shutdown.
- **`IPC_RMID` is deferred, not immediate.** It marks the segment for destruction; actual removal happens once the attach count drops to zero. Safe to call right after `shmget` if you know no one else will attach.
- **Kernel limits.** `SHMMNI` caps the total number of segments system-wide (`/proc/sys/kernel/shmmni`). `SHMMAX` caps the size of one segment (`/proc/sys/kernel/shmmax`). On a shared host these are easy to hit; treat `ENOSPC` and `EINVAL`-from-large-size as configuration issues, not bugs.
- **SysV IPC is not available on every platform.** Upstream Perl built on a system without `HAS_SHM` dies with `"System V IPC is not implemented on this machine"`. pperl targets Linux only, where SysV IPC is always present, so the call is always dispatched.

Differences from upstream

- Returns `-1` rather than `undef` on failure. Both values are false under Perl's truth rules, so the idiomatic `shmget(...) or die "$!"` works unchanged, but code that distinguishes "not an identifier" via `defined $shmid` will read `-1` as defined. Prefer checking for truth, or compare against `-1` explicitly when you want to branch on the failure sentinel. The `-1` is the raw `shmget(2)` return value, which is the documented error sentinel for that syscall.

See also

- `shmctl` - control operations on the segment `shmget` returned; use `IPC_RMID` to delete it, `IPC_STAT` to inspect size and permissions
- `shmread` - read `SIZE` bytes from the segment into a Perl scalar
- `shmwrite` - write a Perl scalar into the segment at an offset
- `msgget` - the equivalent allocation step for SysV message queues when you want a queue, not a flat buffer
- `semget` - the equivalent for SysV semaphores when the goal is synchronisation rather than shared data
- `IPC::SysV` - source of the `IPC_*` and `S_*` flag constants `shmget` requires; no local reference page, see upstream POD

SysV IPC

shmread

Copy bytes out of a System V shared memory segment into a Perl scalar.

`shmread` attaches to the shared memory segment identified by `ID`, reads `SIZE` bytes starting at byte offset `POS`, writes them into `VAR`, and detaches. `VAR` is assigned to as a whole - whatever it held before is replaced by exactly `SIZE` bytes of data. The variable is marked **tainted** under `-T`, because its contents came from outside the program.

Synopsis

```
use IPC::SysV qw(IPC_PRIVATE S_IRUSR S_IWUSR);
my $id = shmget(IPC_PRIVATE, 4096, S_IRUSR | S_IWUSR)
    or die "shmget: $!";
shmread($id, my $buf, 0, 128)
    or die "shmread: $!";
```

What you get back

Truthy on success, false on failure with `$!` set. On success `VAR` has been overwritten with exactly `SIZE` bytes; no short reads - either the whole range is copied in or the call fails. On failure `VAR`'s contents are unspecified; don't rely on them.

Always check the return value. A bad `ID`, an out-of-range `POS`/`SIZE`, or a segment the process lacks permission to attach all surface here as a false return:

```
shmread($id, my $buf, $pos, $size)
    or die "shmread(id=$id, pos=$pos, size=$size): $!";
```

Global state it touches

- `$!` - set on failure (any of the underlying `shmat`/`memcpy`/`shmdt` errors surface here).
- Taint flag on `VAR` - set under `-T` regardless of how `VAR` was declared, because the bytes originate outside the program.

Examples

Read a fixed-size record out of a segment:

```
use IPC::SysV qw(IPC_PRIVATE S_IRUSR S_IWUSR);
my $id = shmget(IPC_PRIVATE, 1024, S_IRUSR | S_IWUSR) or die
 ↪"shmget: $!";
shmwrite($id, "hello, world", 0, 12)                  or die
 ↪"shmwrite: $!";
shmread($id, my $buf, 0, 12)                          or die
 ↪"shmread: $!";
print $buf, "\n";                                     # hello, world
```

Read at an offset. `POS` and `SIZE` are in bytes, not elements - the segment has no notion of records:

```
shmread($id, my $chunk, 256, 64)
    or die "shmread: $!";                              # bytes 256..
↪319
```

Unpack a binary record straight out of shared memory:

```
shmread($id, my $raw, 0, 16) or die "shmread: $!";
my ($magic, $len, $flags) = unpack "a4 N N", $raw;
```

Reading tainted data under `-T`. The assignment is guaranteed to produce a tainted scalar even if `VAR` already held an untainted value:

```
# perl -T
shmread($id, my $buf, 0, $n) or die "shmread: $!";
# $buf is tainted; untaint via a regex match before using
# it in a sensitive context.
```

Edge cases

- **`VAR` is assigned to, not appended to.** Any previous value is discarded. Use a fresh lexical if you need both old and new data.
- **`SIZE` is exact, not a maximum.** `shmread` does not do short reads; requesting more bytes than the segment holds from `POS` onward fails rather than returning what fits.
- **`POS` and `SIZE` must lie within the segment** declared at `shmget` time. `POS + SIZE` past the segment's end fails with `EINVAL`.
- **Zero `SIZE`** produces an empty string in `VAR` and succeeds, assuming `POS` itself is valid.
- **Permissions.** The calling process must have read permission on the segment, as dictated by the mode bits passed to `shmget` (and, where applicable, by the segment's owner and current uid/gid).
- **`VAR` need not be pre-sized.** Unlike `sysread`, you do not `substr`-pad or preallocate `VAR` - `shmread` assigns the result directly.
- **Taint.** Under `-T`, `VAR` is tainted on success regardless of what it held before. Launder through a capture-group match (`$data =~ /\A(.*)\z/s and $data = $1`) only once you've validated the bytes are safe for the sensitive operation you're about to perform.
- **Not every platform has SysV IPC.** On systems without `shmat(2)` the call fails at runtime (typically `ENOSYS`); portable code should guard with an `eval` or feature probe.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `shmwrite` - the inverse: copy a string into a segment at a given offset
- `shmget` - obtain or create the segment `ID` that `shmread` operates on
- `shmctl` - query segment metadata (`IPC_STAT` fills in an `shmid_ds` you can use to bound-check `POS + SIZE`) or remove the segment when done
- `sysread` - the file-descriptor analogue; same "bytes into a scalar" shape, different source
- `unpack` - turn the raw bytes returned in `VAR` into typed fields
- `IPC::SysV` - the module that supplies `IPC_PRIVATE`, `S_IRUSR`, and the other constants you'll pass to `shmget`

SysV IPC

shmwrite

Copy bytes into a System V shared memory segment.

`shmwrite` attaches to the shared memory segment identified by `ID`, copies up to `SIZE` bytes from `STRING` starting at byte offset `POS` inside the segment, and detaches. If `STRING` is longer than `SIZE`, only the first `SIZE` bytes are written; if it is shorter, the remainder of the `SIZE`-byte window is zero-filled with NUL bytes. The segment `ID` is the value returned by an earlier `shmget` call (or obtained from another process via some out-of-band channel).

Synopsis

```
shmwrite ID, STRING, POS, SIZE
```

What you get back

True on success, false on error, with `$!` set to the reason (typically `EINVAL`, `EACCES`, or `EIDRM`). Unlike most I/O built-ins the return value is a plain boolean - there is no byte-count variant, because the count is always exactly `SIZE` when the call succeeds.

```
shmwrite($id, $payload, 0, 4096)
    or die "shmwrite($id) failed: $!";
```

Global state it touches

- `$!` is set on failure to the underlying `shmat` / `memcpy` / `shmdt` errno.
- No other special variables are read or written. Unlike `shmread`, `shmwrite` does not taint anything - it is the *source* of bytes, not a sink.

Examples

Publish a fixed-size record at the start of a segment:

```
use IPC::SysV qw(IPC_PRIVATE S_IRUSR S_IWUSR);
my $id = shmget(IPC_PRIVATE, 4096, S_IRUSR | S_IWUSR)
    or die "shmget: $!";
shmwrite($id, "hello, world", 0, 4096)
    or die "shmwrite: $!";
```

A `STRING` shorter than `SIZE` is NUL-padded to fill the window - useful for clearing stale trailing bytes from a previous writer:

```
shmwrite($id, "short", 0, 64);   # 5 bytes of "short", then 59 NULs
```

A `STRING` longer than `SIZE` is truncated; the tail is silently discarded, so size your window to the largest record you ever intend to publish:

```
shmwrite($id, "x" x 10_000, 0, 128);   # only the first 128 x's land
```

Writing to a non-zero offset lets multiple fixed-size records share one segment. Pair it with a matching `shmread` on the reader side:

```
my $slot = 3;
my $len  = 64;
shmwrite($id, $record, $slot * $len, $len)
    or die "shmwrite slot $slot: $!";
```

Check the return value - a segment that has been marked for deletion with `IPC_RMID` continues to accept writes from processes already attached, but fails for new `shmwrite` calls with `EIDRM`:

```
unless (shmwrite($id, $msg, 0, $SIZE)) {
    warn "segment $id gone: $!";
    # reacquire via shmget() and retry
}
```

Edge cases

- **Kernel must be built with SysV IPC.** On systems without SysV shared memory `shmwrite` croaks with `shmwrite not implemented`. This is a compile-time property of the kernel / libc, not a runtime condition you can probe for.
- **`SIZE` of `0`** is accepted by the kernel and writes nothing; `shmwrite` returns true. Use it only when you genuinely mean "no-op", not as an error signal.
- **`POS + SIZE` must fit inside the segment.** Overrunning the segment boundary fails with `EINVAL` and leaves the segment untouched - the copy is not partial.
- **Binary payloads are fine.** `STRING` is treated as a byte string; embedded NULs are written literally. If the string carries the UTF-8 flag, the raw internal bytes are what hits the segment - use `pack` or `Encode::encode` first if you need a specific encoding on the wire.

- **No locking.** The kernel guarantees that each `shmwrite` call is atomic with respect to `shmat` / `shmdt`, but two concurrent writers can still interleave byte ranges within the segment. Coordinate with `semop` or a user-space lock if multiple processes write the same region.
- **Permissions** come from the segment's mode at `shmget` time. Attaching read-only and calling `shmwrite` fails with `EACCES`.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `shmread` - inverse operation; copy bytes *out* of a segment into a Perl scalar
- `shmget` - obtain the `ID` that `shmwrite` writes into
- `shmctl` - inspect segment attributes, change permissions, or mark a segment for deletion
- `semop` - the usual companion primitive for serialising access to a shared segment
- `pack` - build the fixed-layout byte string you hand to `shmwrite` when the segment holds structured records
- `IPC::SysV` - constants (`IPC_PRIVATE`, `S_IRUSR`, `IPC_RMID`) used to construct the arguments to `shmget` and `shmctl`

Sockets

shutdown

Shut down one direction of a socket connection, or both.

`shutdown` tells the kernel to stop a socket doing further reads, further writes, or both - without closing the file descriptor. Unlike `close`, the effect is immediate and propagates through every forked copy of the descriptor, not just this process's. `HOW` has the same meaning as the argument to the `shutdown(2)` syscall.

Synopsis

```
shutdown SOCKET, HOW
```

What you get back

1 on success. On failure, `undef` if `SOCKET` is not a valid filehandle, or `0` with `$!` set for any other error (the socket is not connected, already shut down in that direction, etc.).

Two distinct failure returns, so a three-way test is sometimes warranted:

```
my $r = shutdown($sock, 1);
if    (!defined $r) { die "bad filehandle" }
elsif (!$r)         { die "shutdown failed: $!" }
```

The HOW argument

`HOW` is a small integer matching the POSIX `SHUT_*` constants:

- `0` - stop reading. The peer can still send, but data will be discarded by the kernel and `read` / `sysread` on this end will return end-of-file.
- `1` - stop writing. Queued output is flushed, then the peer sees end-of-file on its read side. `print` / `syswrite` on this end will fail and raise `SIGPIPE`.
- `2` - stop both directions. Equivalent to calling `shutdown` with `0` and then `1`.

The symbolic names `SHUT_RD`, `SHUT_WR`, `SHUT_RDWR` live in `Socket` if you prefer readable code:

```
use Socket qw(SHUT_WR);
shutdown $sock, SHUT_WR;
```

shutdown vs close

`close` drops the file descriptor in the current process only. Other processes that inherited the descriptor through `fork` keep their copies open, and the peer does not see end-of-file until the last copy is closed.

`shutdown` acts on the underlying socket, not on the descriptor. After `shutdown($sock, 1)` every forked copy sees the write half closed and the peer reads end-of-file right away - even though the descriptor itself is still open and can still be read from.

That is the usual reason to reach for `shutdown`: a parent and child share a socket, the child has finished sending, and the parent must keep reading replies. `close` in the child would be invisible to the peer; `shutdown($sock, 1)` is not.

Half-close for request/response protocols

A client that sends a complete request and then needs the server to know there is no more input uses `shutdown` with `HOW = 1`:

```
use IO::Socket::INET;
my $sock = IO::Socket::INET->new(PeerAddr => "example.com:80")
    or die "connect: $!";

print $sock "GET / HTTP/1.0\r\nHost: example.com\r\n\r\n";
shutdown $sock, 1;          # signal end-of-request to the server

while (my $line = <$sock>) {
    print $line;
}
close $sock;
```

Without the `shutdown`, servers that read until end-of-input would block waiting for more request data.

Examples

Stop reading but keep writing - the peer may continue to send, we just will not look at it:

```
shutdown $sock, 0;
```

Stop writing, keep reading - typical half-close after finishing a request:

```
shutdown $sock, 1;
```

Full shutdown, then close the descriptor:

```
shutdown $sock, 2;
close $sock;
```

Using `Socket` constants for readability:

```
use Socket qw(SHUT_RD SHUT_WR SHUT_RDWR);
shutdown $sock, SHUT_WR;
```

Check the specific error when a shutdown fails on an already-closed direction:

```
unless (shutdown $sock, 1) {
    warn "shutdown write failed: $!";
}
```

Edge cases

- **Writing after `shutdown($sock, 1)`** fails and raises `SIGPIPE`. The default action terminates the process; install `$SIG{PIPE} = 'IGNORE'` (or a handler) to convert it into a normal write failure you can check.
- **Reading after `shutdown($sock, 0)`** returns end-of-file immediately, not an error. Any data already queued in the kernel's receive buffer is discarded.
- **Not a socket**: calling `shutdown` on a regular filehandle sets `$!` to `ENOTSOCK` and returns `0`.
- **Not connected**: `shutdown` on a socket that was never connected (a fresh `socket` result, or a listening socket) sets `$!` to `ENOTCONN` and returns `0`.
- **Double shutdown**: shutting down the same half twice typically returns `0` with `ENOTCONN`. Portable code ignores the second failure rather than treating it as fatal.
- **Closed filehandle**: returns `undef`; under `use warnings` a `shutdown()` on `closed socket` warning is emitted.
- **Descriptor is not closed**: `shutdown` disables the directions you asked for but leaves the file descriptor open. Call `close` (or let the handle go out of scope) when you are actually done with it.
- **Shared descriptors across `fork`**: this is the case `shutdown` is designed for. All processes holding the descriptor see the shutdown take effect immediately; they do not get separate views.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `close` - release the descriptor in this process; does not affect forked copies and does not signal end-of-file to the peer until the last copy closes
- `socket` - create the socket that `shutdown` operates on
- `connect` - establish the connection; `shutdown` on an unconnected socket fails with `ENOTCONN`
- `accept` - produces the connected socket on the server side that typically gets half-closed with `shutdown`
- `Socket` - exports `SHUT_RD`, `SHUT_WR`, `SHUT_RDWR` and the rest of the socket-level constants
- `$!` - system error string to check after a `0` return

Numeric functions

sin

Return the sine of a number given in radians.

`sin` is the standard trigonometric sine: it takes an angle measured in **radians** and returns the ratio of the opposite side to the hypotenuse of the corresponding right triangle. If `EXPR` is omitted, `sin` operates on `$_`. The result is always a floating-point number in the closed interval `[-1, 1]`.

Synopsis

```
sin EXPR
sin
```

What you get back

A double-precision float in `[-1, 1]`. Perl forwards the call to the platform's C `sin(3)` routine, so the precision and rounding behaviour match your libm. Special values follow IEEE 754: `sin(0)` is exactly `0`, `sin("inf")` and `sin("nan")` are both `NaN`.

Radians, not degrees

The single most common mistake with `sin` is feeding it degrees. A full turn is `2 * π` radians, not `360`. Convert once and keep the converted value:

```
use POSIX qw(acos);
my $pi = acos(-1);                  # π to full double precision

sub deg2rad { $_[0] * $pi / 180 }
```

(continues on next page)

(continued from previous page)

```
print sin( deg2rad(30) ), "\n";      # 0.5
print sin( 30 ), "\n";               # -0.988031624092862 - wrong if␣
↪you meant degrees
```

exports `deg2rad` and `rad2deg` if you would rather not write the conversion yourself.

Examples

`sin(π/2)` is mathematically exactly 1, but because π is not representable in binary floating-point the computed result falls a few ulps short:

```
use POSIX qw(acos);
my $pi = acos(-1);

printf "%.17f\n", sin($pi / 2);      # 1.00000000000000000
printf "%.17f\n", sin($pi);          # 0.00000000000000012 - not␣
↪exactly 0
```

Treat any "should be zero" trig result as approximately zero. Compare with a tolerance, not with ==.

Degree-to-radian conversion inline, without pulling in a module. `3.14159` is accurate to six digits - fine for plotting, not for numeric analysis:

```
for my $deg (0, 30, 45, 60, 90) {
    printf "sin(%2d°) = %+.4f\n",
           $deg, sin($deg * 3.14159 / 180);
}
# sin( 0°) = +0.0000
# sin(30°) = +0.5000
# sin(45°) = +0.7071
# sin(60°) = +0.8660
# sin(90°) = +1.0000
```

For work that needs full double precision, replace `3.14159` with `acos(-1)` or `atan2(1, 1) * 4`.

Numerical derivative of `sin` by finite differences. The symmetric two-point formula `(f(x+h) - f(x-h)) / (2h)` should recover `cos(x)`:

```
my $x = 1.0;
my $h = 1e-6;
my $deriv = (sin($x + $h) - sin($x - $h)) / (2 * $h);

printf "derivative:  %.10f\n", $deriv;   # 0.5403023059
printf "cos(%.1f):     %.10f\n", $x, cos($x);
```

Picking `$h` is a trade-off: too large and truncation error dominates, too small and subtraction cancellation destroys the result. `1e-6` is a reasonable default for double precision.

Walk the unit circle and print `(cos θ, sin θ)` at eight evenly spaced angles:

```
use POSIX qw(acos);
my $pi = acos(-1);

for my $k (0 .. 7) {
    my $theta = $k * $pi / 4;
    printf "%.3f  %+.3f  %+.3f\n",
           $theta, cos($theta), sin($theta);
}
```

Inverse sine (arcsine) via the identity from `perlfunc`:

```
sub asin { atan2( $_[0], sqrt(1 - $_[0] * $_[0]) ) }

print asin(0.5), "\n";              # 0.523598775598299 (= π/6)
```

Edge cases

- **Non-numeric arguments coerce to `0`.** `sin("hello")` returns `0` because the string is numified to `0` first. Under `use warnings` this produces an `Argument "hello" isn't numeric in sin` warning. Validate input with `looks_like_number` from `Scalar::Util` if the source is untrusted.
- **Very large arguments lose precision.** `sin` first reduces its argument modulo 2π, and for `|x|` on the order of `1e16` the nearest representable double differs from `x` by more than π. The result is still a number in `[-1, 1]`, but it is essentially random. Reduce the angle yourself before the call if you are accumulating a phase over many iterations.
- **`undef` coerces to `0`** and returns `0`, with the usual `uninitialized` warning under `use warnings`.
- **IEEE specials**: `sin("inf")`, `sin("-inf")`, and `sin("nan")` all return `NaN`. Compare with `$result != $result` (the only value not equal to itself) to detect `NaN`, or use `POSIX::isnan`.
- **Default argument.** `sin;` with no argument reads `$_`. Inside a `while (<>)` loop this operates on the current line, which is almost always a bug.
- **No complex-number support** in the built-in. For complex arguments use , which overloads `sin` via operator overloading:

  ```
  use Math::Complex;
  my $z = cplx(1, 2);
  print sin($z), "\n";              # 3.16577851321617+1.
  ↪9596010414216i
  ```

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `cos` - cosine of an angle in radians; the companion function most often used alongside `sin`
- `atan2` - two-argument arctangent, the usual building block for inverse trig (`asin`, `acos`) in pure Perl
- `sqrt` - square root; appears in the classical `asin` identity `asin(x) = atan2(x, sqrt(1 - x*x))`
- - `asin`, `acos`, `atan`, hyperbolic variants, `deg2rad`/`rad2deg`, and great-circle helpers
- - overloads `sin` (and the rest of the trig family) for complex arguments
- `POSIX` - exposes `asin` directly, plus `isnan`/`isinf` for detecting the non-finite results discussed above

Processes

sleep

Pause the process for a number of whole seconds.

`sleep` suspends execution of the current process for `EXPR` seconds, or - with no argument - until a signal wakes it. The argument is truncated to an integer; sub-second delays require a different tool (see below). The return value is the number of seconds actually slept, which can be less than requested if a signal interrupted the call.

Synopsis

```
sleep EXPR
sleep
```

What you get back

An integer: the number of seconds the process was actually suspended. On an uninterrupted call this equals the (truncated) argument. If a signal delivered during the sleep unblocks the call early, the return value is the shorter, real elapsed time. For bare `sleep`, the value is whatever the implementation slept before a signal arrived.

```
my $slept = sleep 10;
warn "woken early after $slept s" if $slept < 10;
```

Argument handling

- **Positive integer** - the normal case. Sleep that many seconds.
- **Non-integer** (e.g. `2.9`) - the fractional part is **discarded**. `sleep 2.9` sleeps two seconds, not nearly three. For fractional delays use `Time::HiRes::sleep`, `Time::HiRes::usleep`, or the four-argument form of `select` - see below.

- **Negative integer** - `sleep` does **not** sleep. It emits a warning, sets `$!` (errno), and returns zero.
- **Zero** - `sleep 0` is permitted, but still performs a call into the underlying platform sleep primitive with whatever side effects that entails. It is therefore **not** exactly identical to skipping the call. In particular, `sleep 0` is not the same as a bare `sleep` with no argument.
- **No argument** - `sleep` with no argument sleeps indefinitely, until a signal is delivered. This is distinct from `sleep 0`.

Interruption by signals

`sleep` returns early if the process receives a signal whose handler runs (or whose default action does not terminate the process). The canonical pattern for a bounded wait that can be cancelled from elsewhere is an `alarm` combined with a signal handler:

```
eval {
    local $SIG{ALRM} = sub { die "Alarm!\n" };
    sleep;
};
die $@ unless $@ eq "Alarm!\n";
```

Because `sleep` is itself commonly implemented on top of `alarm` on Unix systems, you generally **cannot** mix `alarm` and `sleep` calls in the same program without surprises. Pick one.

Sub-second delays

`sleep` is integer-only by design. For finer-grained waits use one of:

- `Time::HiRes::sleep($seconds)` - accepts a floating-point number of seconds. Since Perl 5.8 `Time::HiRes` ships with the core distribution.
- `Time::HiRes::usleep($microseconds)` - integer microseconds.
- The four-argument form of `select` with the first three arguments `undef`:

  ```
  select undef, undef, undef, 0.25;   # sleep 250 ms
  ```

- `syscall` into `setitimer(2)` if your platform supports it and you need tight control over timers.

See also `POSIX::pause`, which blocks the process until any signal arrives - effectively a bare `sleep` without an implementation-defined maximum.

Examples

Fixed delay:

```
print "working...\n";
sleep 3;
print "done\n";
```

Poll loop with a back-off:

```
until (ready()) {
    sleep 1;
}
```

Detecting an early wake:

```
my $want = 30;
my $got  = sleep $want;
if ($got < $want) {
    warn "interrupted after $got of $want seconds\n";
}
```

Wait for a signal without burning CPU - bare `sleep` suspends until `SIGALRM` (or any other caught signal) arrives:

```
$SIG{USR1} = sub { warn "got USR1\n" };
sleep;                                  # wakes on USR1 delivery
```

Cancelling a long wait with `alarm`:

```
eval {
    local $SIG{ALRM} = sub { die "timeout\n" };
    alarm 5;
    sleep 3600;                         # at most 5 seconds really
    alarm 0;
};
alarm 0;
die $@ if $@ && $@ ne "timeout\n";
```

Edge cases

- **Bare `sleep` does not truly sleep "forever"**. The implementation has a maximum - in practice, whatever the underlying C `sleep(3)` or equivalent accepts - but for all realistic purposes it blocks until a signal arrives. Treat it as an indefinite wait.
- **`sleep 0` ≠ no call**. The platform `sleep(0)` syscall still runs. On most systems this yields the CPU briefly; do not rely on the specific behaviour across platforms.
- **`sleep` versus wall-clock time**. On older systems `sleep` could return up to a full second *early* due to coarse second counting. Modern systems sleep the full amount, but may overshoot: the scheduler may not wake your process immediately on a busy system. `sleep N` guarantees *at least* `N` seconds of suspension on modern kernels, not *exactly* `N`.
- **Negative arguments are not clamped**. They are a hard no-op that sets `$!`. If you compute the argument, validate it first.
- **Mixing with `alarm` is fragile**. The alarm timer and the sleep timer may be the same resource. Establish one discipline (either `alarm` + bare `sleep`, or plain `sleep N` without alarms) and stick to it within a program.

- **Signals that merely set a flag still wake `sleep`.** Any signal whose delivery causes a handler to run returns control to Perl; `sleep` then returns early even if the handler itself does nothing visible.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `alarm` - schedule a `SIGALRM` after a given number of seconds; the classic way to bound a `sleep` or any other blocking call
- `select` - in its four-argument form with an undefined readfds/writefds/exceptfds triple, provides sub-second sleeps
- `wait`, `waitpid` - block on child processes rather than on time
- `Time::HiRes::sleep` - floating-point seconds
- `Time::HiRes::usleep` - integer microseconds
- `POSIX::pause` - block until any signal arrives

Sockets

socket

Create a socket filehandle.

`socket` opens a socket of the kind described by `DOMAIN`, `TYPE`, and `PROTOCOL` and attaches it to `SOCKET`, which becomes a usable Perl filehandle. It is the thin Perl veneer over the `socket(2)` system call - nothing more, nothing less. The new socket is unbound and unconnected; you still need `bind`, `connect`, or `listen`+`accept` to do anything with it. Pull the symbolic constants in with `use Socket;` before the call - writing the raw integers is portable only by accident.

Synopsis

```
use Socket;
socket SOCKET, DOMAIN, TYPE, PROTOCOL
```

What you get back

1 on success, `undef` on failure (with `$!` set to the `errno` from the underlying `socket(2)`). On success `SOCKET` is now a filehandle you can `bind`, `connect`, `send` / `recv` on, or read and write with the ordinary I/O operators once it reaches a connected state. The return value is worth checking on every call - a failure here means you have nothing useful to pass to the next socket call, which will then fail in a more confusing way.

```
socket my $sock, PF_INET, SOCK_STREAM, getprotobyname("tcp")
    or die "socket: $!";
```

SOCKET can be a bareword filehandle (SOCK), a glob (*SOCK), or an undefined scalar that will be auto-vivified into an anonymous filehandle reference. The auto-vivified form is the modern idiom and the only one that scopes cleanly with my.

Global state it touches

- $! - set to the errno from socket(2) on failure.
- $^F - the system-file-descriptor threshold. On systems with close-on-exec, the new descriptor gets FD_CLOEXEC set when its number exceeds $^F (default 2, so descriptors 0–2 stay inheritable and everything else is auto-closed across exec). Raise it before socket if you specifically want the new socket to survive an exec.

Examples

A client socket for a TCP connection. Create, connect, talk:

```
use Socket;
socket my $sock, PF_INET, SOCK_STREAM, getprotobyname("tcp")
    or die "socket: $!";
my $addr = pack_sockaddr_in(80, inet_aton("example.com"));
connect $sock, $addr or die "connect: $!";
syswrite $sock, "GET / HTTP/1.0\r\nHost: example.com\r\n\r\n";
```

A listening TCP server socket. Create, mark reusable, bind, listen:

```
use Socket;
socket my $srv, PF_INET, SOCK_STREAM, getprotobyname("tcp")
    or die "socket: $!";
setsockopt $srv, SOL_SOCKET, SO_REUSEADDR, pack("l", 1)
    or die "setsockopt: $!";
bind $srv, pack_sockaddr_in(8080, INADDR_ANY) or die "bind: $!";
listen $srv, SOMAXCONN                        or die "listen: $!";
```

A UDP socket - SOCK_DGRAM instead of SOCK_STREAM, and no connect is needed before send when you pass an explicit destination:

```
use Socket;
socket my $udp, PF_INET, SOCK_DGRAM, getprotobyname("udp")
    or die "socket: $!";
my $to = pack_sockaddr_in(53, inet_aton("1.1.1.1"));
send $udp, $query, 0, $to or die "send: $!";
```

A Unix-domain stream socket for local IPC. PF_UNIX with a filesystem path instead of an IP address:

```
use Socket;
socket my $sock, PF_UNIX, SOCK_STREAM, 0 or die "socket: $!";
connect $sock, pack_sockaddr_un("/run/app.sock") or die "connect: $!
 ↪";
```

Letting PROTOCOL default to 0. The kernel picks the default protocol for the domain/type pair - for PF_INET + SOCK_STREAM that is TCP, for PF_INET + SOCK_DGRAM that is UDP. The

`getprotobyname` form above is more explicit but the `0` form is equivalent and avoids one lookup:

```
use Socket;
socket my $sock, PF_INET, SOCK_STREAM, 0 or die "socket: $!";
```

Edge cases

- **`use Socket` is not optional.** Without it, `PF_INET`, `SOCK_STREAM`, and friends are bareword strings, not integer constants, and the call fails at the syscall boundary with `Invalid argument`. The import is what turns them into numbers.
- **`SOCKET` is clobbered on success.** If the slot holds an open filehandle, it is closed first. There is no warning - the previous socket just silently goes away. Use a fresh `my` variable for each call.
- **Failure leaves `SOCKET` unchanged.** On `undef` return the scalar is neither opened nor modified; a prior value (including an earlier, still-open socket) is still there.
- **Descriptor limits.** `socket` is the point where `EMFILE` (per-process) and `ENFILE` (system-wide) descriptor-table exhaustion shows up. Long-running servers should treat these as recoverable rather than fatal.
- **`EAFNOSUPPORT` / `EPROTONOSUPPORT` / `ESOCKTNOSUPPORT`.** The kernel rejected the domain/type/protocol triple. Common cause: asking for `PF_INET6` on a kernel built without IPv6, or an invalid protocol number passed through from a stale `getprotobyname` lookup.
- **Non-blocking mode is a separate step.** `socket` returns a blocking descriptor. Use `fcntl` with `F_SETFL | O_NONBLOCK` (or the `IO::Socket` equivalent) if you need non-blocking I/O.
- **Close-on-exec is automatic past `$^F`.** Perl sets `FD_CLOEXEC` on the new descriptor when its fd number is greater than `$^F`. A socket will therefore not survive an `exec` unless you lowered that threshold or clear the flag with `fcntl`.
- **Numeric domain/type values are not portable.** `2` happens to be `AF_INET` on Linux; it is something else elsewhere. Always go through the `Socket` module constants.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `bind` - attach a socket created by `socket` to a local address, required before `listen` or before sending from a known port
- `connect` - initiate an outgoing connection on a `SOCK_STREAM` socket, or set the default peer on a `SOCK_DGRAM` socket
- `listen` - mark a bound `SOCK_STREAM` socket as passive so `accept` can pull connections off it

- `accept` - return the next pending connection on a listening socket as a fresh filehandle
- `socketpair` - create a connected pair of sockets in one call; the usual choice when both ends live in the same process or parent/child
- `Socket` - the module that supplies `PF_INET`, `SOCK_STREAM`, `inet_aton`, `pack_sockaddr_in` and the rest of the constants and packers you pass to `socket`
- `$^F` - descriptor threshold that controls close-on-exec for the new socket

Sockets

socketpair

Create an unnamed, connected pair of sockets that talk to each other.

`socketpair` opens two fresh filehandles in `SOCKET1` and `SOCKET2` already wired together, so anything written to one comes out of the other. No addresses, no `bind`, no `listen`, no `accept`. The commonest use is talking to a child process created by `fork` - each side keeps one handle and `close`s the other.

Synopsis

```
use Socket;
socketpair(SOCKET1, SOCKET2, DOMAIN, TYPE, PROTOCOL) or die $!;
socketpair(my $s1, my $s2, AF_UNIX, SOCK_STREAM, PF_UNSPEC) or die
 ↪$!;
```

What you get back

True on success, false on failure (with `$!` set). On success both filehandle arguments are populated with fresh handles; on failure they are left untouched. Always check the return value - every domain/type/protocol combination is platform-dependent.

```
socketpair(my $a, my $b, AF_UNIX, SOCK_STREAM, PF_UNSPEC)
    or die "socketpair: $!";
```

The `DOMAIN`, `TYPE`, and `PROTOCOL` constants come from the `Socket` module. `AF_UNIX` with `SOCK_STREAM` and `PF_UNSPEC` is the portable default.

Global state it touches

- `$!` is set on failure to the system `errno`.
- `$^F` - the maximum system file descriptor below which close-on-exec is **not** set. On systems with `FD_CLOEXEC`, descriptors above `$^F` get close-on-exec automatically; below it, they survive `exec`. Default is 2 (stdin/stdout/stderr). Raise it before `socketpair` if you want the new handles to be inherited across `exec`.

Examples

Plain parent/child pipe using a stream socketpair. Each side closes the end it does not need, so EOF propagates correctly:

```
use Socket;

socketpair(my $child, my $parent, AF_UNIX, SOCK_STREAM, PF_UNSPEC)
    or die "socketpair: $!";

my $pid = fork // die "fork: $!";
if ($pid == 0) {
    close $child;
    print $parent "hello from child\n";
    close $parent;
    exit;
}
close $parent;
chomp(my $msg = <$child>);          # "hello from child"
waitpid $pid, 0;
```

Bidirectional stream: both processes read *and* write on the same handle. No `shutdown` is needed because neither side is closing a direction early:

```
use Socket;

socketpair(my $a, my $b, AF_UNIX, SOCK_STREAM, PF_UNSPEC) or die $!;
my $pid = fork // die $!;
if ($pid == 0) {
    close $a;
    while (my $line = <$b>) {
        chomp $line;
        print $b "echo: $line\n";
    }
    exit;
}
close $b;
print $a "ping\n";
chomp(my $reply = <$a>);            # "echo: ping"
close $a;
waitpid $pid, 0;
```

Emulating `pipe` with `socketpair`. `shutdown` turns a bidirectional socket into a one-way channel:

```
use Socket;
socketpair(my $rdr, my $wtr, AF_UNIX, SOCK_STREAM, PF_UNSPEC) or die
 ↪$!;
shutdown($rdr, 1);                  # reader cannot write
shutdown($wtr, 0);                  # writer cannot read
```

Datagram pair - messages preserve boundaries, so a single `recv` returns exactly one

send:

```
use Socket;
socketpair(my $a, my $b, AF_UNIX, SOCK_DGRAM, PF_UNSPEC) or die $!;
send($a, "one", 0)   or die $!;
send($a, "two", 0)   or die $!;
recv($b, my $m1, 64, 0);            # "one"
recv($b, my $m2, 64, 0);            # "two"
```

Edge cases

- **AF_UNIX is the only portable domain.** On most systems `socketpair` only works with `AF_UNIX`; other families return `EAFNOSUPPORT`. Use the constant, not a hard-coded 1.
- **Unbuffered output.** Stream socketpair handles buffer like any other filehandle. Set `$|` on the writer (after `select`ing it) or the reader will block waiting for output that is still in the parent's buffer. `autoflush` from `IO::Handle` is the usual form:

  ```
  $parent->autoflush(1);
  ```

- **Close both ends or EOF never arrives.** A stream socketpair delivers EOF on a reader only after *every* writable copy of the peer handle is closed. A child that forgets to `close` the parent's end will hang the parent on `<$handle>` forever.
- **Close-on-exec via `$^F`.** Filehandles whose numeric descriptor is greater than `$^F` get `FD_CLOEXEC` on platforms that support it, so they vanish across `exec`. Raise `$^F` before the call if the handle must survive an `exec`.
- **Unimplemented on the platform.** If the underlying `socketpair(2)` syscall does not exist, perl raises an exception rather than returning false. Trap with `eval` if you need to fall back.
- **Datagram vs stream.** `SOCK_STREAM` is byte-oriented (no message boundaries, use newline framing or length prefixes). `SOCK_DGRAM` preserves message boundaries but loses them silently if the receive buffer is smaller than the message.
- **PROTOCOL.** For `AF_UNIX` the protocol is ignored; `PF_UNSPEC` (or `0`) is conventional. Specifying a protocol that does not match the domain/type combination returns `EPROTONOSUPPORT`.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `socket` - create a single socket when only one end is yours (the other comes from the network via `accept` or `connect`)
- `pipe` - unidirectional byte channel; lighter weight than `socketpair` but cannot do bidirectional traffic on one call
- `send` / `recv` - message-oriented I/O, required for `SOCK_DGRAM` socketpairs

- `fork` - the typical partner: one `socketpair` before the fork gives parent and child a ready-made conduit
- `Socket` - source of `AF_UNIX`, `SOCK_STREAM`, `SOCK_DGRAM`, `PF_UNSPEC` and the other constants `socketpair` expects
- `$^F` - threshold above which new descriptors get close-on-exec; matters when the handles must survive `exec`

Lists

sort

Sort a list, returning the sorted list.

`sort` takes a list and returns a new list with the elements rearranged in order. With no comparator it uses standard string comparison. With a `BLOCK` or a `SUBNAME` you supply the comparison rule as a small function that is called for each pair of elements and must return a negative, zero, or positive value the way `cmp` and `<=>` do.

Sorting is stable - elements that compare equal keep their original relative order. The algorithm is mergesort.

Synopsis

```
sort LIST
sort BLOCK LIST
sort SUBNAME LIST
```

Three idiomatic forms:

```
my @out = sort @in;                          # default: string cmp, ascending
my @out = sort { $a <=> $b } @in;            # numeric, ascending
my @out = sort by_name @in;                  # named comparator sub
```

What you get back

A **new** sorted list. `sort` does **not** modify the input in place. To replace an array with its sorted version you assign back:

```
@a = sort @a;
```

In list context the return is the sorted list. In scalar context the return value is undefined - do not use `scalar sort`.

The returned list contains **aliases** into the original list, exactly like a `foreach` index variable. Modifying an element of the result inside a later `foreach`, `map`, or `grep` therefore modifies the original element too. This is almost never what you want; treat the result as read-only.

Global state: $a and $b

Inside the comparator BLOCK or SUBNAME, the two elements being compared are exposed as the package globals $a and $b. These are not parameters and they are not lexicals - they are real package variables that sort localises for you around the call.

- $a and $b live in **the package that called sort**. In main, that is $main::a and $main::b; in Foo, $Foo::a and $Foo::b.
- **Never declare my $a or my $b** anywhere the sort block can see. A lexical $a or $b shadows the package global; the block then compares two unrelated variables and the sort silently produces garbage. Under use warnings you get no warning for this.
- If you genuinely need $a / $b as lexicals elsewhere, refer to the sort variables by full name inside the block:

```
print sort { $::a cmp $::b }          qw(A C E G B D F H);
print sort { our $a cmp our $b }      qw(A C E G B D F H);
```

- A comparator defined with the prototype ($$) (or an equivalent signature attribute) receives the pair in @_ instead of $a and $b. This is slower than the $a/$b convention but decouples the sub from the caller's package.

Both elements are passed **by reference**; mutating $a or $b in the block mutates the original list. Don't.

Examples

Default string sort:

```
my @sorted = sort qw(banana apple cherry);
# ('apple', 'banana', 'cherry')
```

Numeric ascending - the default sort @nums would sort "10" before "2" because comparison is by string:

```
my @nums = sort { $a <=> $b } (10, 2, 33, 4);
# (2, 4, 10, 33)
```

Numeric descending - swap $a and $b:

```
my @nums = sort { $b <=> $a } (10, 2, 33, 4);
# (33, 10, 4, 2)
```

Multi-key sort with a tiebreaker. || runs the second comparator only when the first returns 0:

```
my @people = sort {
    $a->{last}  cmp $b->{last}
 || $a->{first} cmp $b->{first}
} @records;
```

Sort a hash's keys by the associated value:

```
my %age = (alice => 30, bob => 25, carol => 40);
my @by_age = sort { $age{$a} <=> $age{$b} } keys %age;
# ('bob', 'alice', 'carol')
```

Schwartzian Transform - when the sort key is expensive to compute, precompute it once per element, sort the `[key, value]` pairs, then strip the keys. Three stages, read bottom-up:

```
my @sorted =
    map  { $_->[1] }                      # 3. strip key
    sort { $a->[0] <=> $b->[0] }          # 2. sort by key
    map  { [ expensive_key($_), $_ ] }    # 1. attach key
    @input;
```

Named comparator sub. The sub reads `$a` and `$b` from the caller's package, so it must be in (or referenced from) that package:

```
sub by_name { $a->{name} cmp $b->{name} }

my @sorted = sort by_name @people;
```

Prototyped comparator - arguments arrive in `@_`, so it works from any package:

```
sub numeric ($$) { $_[0] <=> $_[1] }

my @sorted = sort numeric @nums;
```

Edge cases

- **`$a` and `$b` are package globals, not lexicals.** A stray `my $a` in scope silently breaks every sort in that scope. If you must, use `our $a` or `$::a` inside the block.
- **`<=>` is numeric, `cmp` is string.** Using the wrong one is the most common sort bug. `sort { $a cmp $b } (10, 2, 33)` yields `(10, 2, 33)` - lexicographic, `"10"` before `"2"`. Use `<=>` for numbers.
- **Empty list returns an empty list.** `sort ()` is `()`. No error.
- **Single element is returned unchanged.** No comparisons happen.
- **Comparator must be consistent.** If it sometimes says `$x < $y` and sometimes says the opposite for the same pair, the result is undefined. The comparator must return a total ordering: negative, zero, or positive, stably, for every call.
- **`NaN` poisons `<=>`.** `$a <=> $b` returns `undef` if either operand is `NaN`, which `sort` then treats as `0` - equal - giving an arbitrary placement. Filter first:

  ```
  my @clean = sort { $a <=> $b } grep { $_ == $_ } @input;
  ```

- **Stable sort.** Equal elements keep their input order. Rely on this for multi-pass sorts (sort by secondary key first, then by primary key). `use sort 'stable'` is the default and a no-op; `use sort '_mergesort'` / `'_qsort'` pragmas are historical and have no effect on current Perl.

- **`sort` is not in-place.** `sort @a` does not touch `@a`. Use `@a = sort @a` to replace it. Assigning to `sort`'s result list aliases back into the original, so `(sort @a)[0] = ...` modifies `@a`'s smallest element.
- **No loop control out of the block.** `last`, `next`, `redo`, `return`, and `goto LABEL` do not work inside a sort comparator - the block is not a loop body.
- **Parser trap: sorting a function's return value.** `sort` takes a `LIST`, so a following bareword can be mistaken for a `SUBNAME`. To sort the result of `find_records(@key)`:

```
my @out = sort { $a cmp $b } find_records @key;   # OK
my @out = sort +find_records(@key);               # OK
my @out = sort(find_records(@key));               # OK
```

  To use `find_records` as the comparator over `@key` instead:

```
my @out = sort find_records @key;                 # comparator
 ↪form
my @out = sort { find_records() } @key;           # block form
```

- **Locale-aware sorting.** Under `use locale` (without `':not_characters'`) the default string comparison follows the current collation locale instead of codepoint order.
- **XSUB comparators.** If the comparator is an XSUB, the pair is passed on the argument stack the way XS functions normally receive arguments; `$a` and `$b` are not set.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `reverse` - reverses a list; combine with `sort` for descending sorts when the comparator is hard to invert by swapping `$a` and `$b`
- `map` - the other half of the Schwartzian Transform; use to attach and strip sort keys around a `sort`
- `grep` - prefilter the list (e.g. remove `NaN` or `undef`) before handing it to `sort`
- `$a` - the first element in the comparison pair, aliased as a package global for the duration of the sort
- `$b` - the second element in the comparison pair, same lifetime and scoping rules as `$a`
- `<=>` - numeric three-way comparison; the usual operator inside a numeric sort block
- `cmp` - string three-way comparison; the usual operator inside a string sort block

Arrays

splice

Remove and/or replace a slice of an array in place, and return the removed elements.

`splice` is the general-purpose array surgeon. Every other array mutator - `push`, `pop`, `shift`, `unshift`, single-element assignment - can be written as a `splice` call. Pick the position with `OFFSET`, pick how many elements to cut with `LENGTH`, and optionally supply a `LIST` of replacements. The array grows or shrinks to fit, and you get back whatever was cut out.

Synopsis

```
splice @array;                                  # remove everything
splice @array, $offset;                         # remove from $offset to␣
↪the end
splice @array, $offset, $length;                # remove $length␣
↪elements
splice @array, $offset, $length, @list;         # remove and replace␣
↪with @list
```

What you get back

- **List context**: the list of elements that were removed, in their original order. Empty list if nothing was removed.
- **Scalar context**: the *last* element removed, or `undef` if nothing was removed. This is rarely what you want - reach for list context unless you specifically need only the tail.
- **Void context**: nothing; use this form when you only care about the in-place mutation.

Examples

Basic removal - cut two elements starting at index 1:

```
my @a = ('a', 'b', 'c', 'd', 'e');
my @gone = splice @a, 1, 2;
# @a    == ('a', 'd', 'e')
# @gone == ('b', 'c')
```

Insert without removing - `LENGTH` is `0`, so nothing comes out and the `LIST` is spliced in at `OFFSET`:

```
my @a = (1, 2, 5, 6);
splice @a, 2, 0, 3, 4;
# @a == (1, 2, 3, 4, 5, 6)
```

Replace a fragment - `LENGTH` and replacement size need not match. Here three elements leave, one arrives:

```
my @a = ('x', 'y', 'z', 'w', 'v');
my @gone = splice @a, 1, 3, 'Y';
# @a    == ('x', 'Y', 'v')
# @gone == ('y', 'z', 'w')
```

Remove the trailing tail - omit `LENGTH` entirely to cut from `OFFSET` to the end:

```
my @a = (1, 2, 3, 4, 5);
my @tail = splice @a, 3;
# @a    == (1, 2, 3)
# @tail == (4, 5)
```

Negative `OFFSET` counts from the end. Pop the last element:

```
my @a = ('a', 'b', 'c');
my $last = splice @a, -1;
# @a    == ('a', 'b')
# $last == 'c'
```

Classic idiom - consume an array `$n` elements at a time:

```
while (my @chunk = splice @queue, 0, $n) {
    process(@chunk);
}
```

All the common array primitives written as `splice` (assuming `$#a >= $i`):

```
push    @a, $x, $y;    #  splice @a, scalar(@a), 0, $x, $y
pop     @a;            #  splice @a, -1
shift   @a;            #  splice @a, 0, 1
unshift @a, $x, $y;    #  splice @a, 0, 0, $x, $y
$a[$i] = $y;           #  splice @a, $i, 1, $y
```

Edge cases

- **Negative `OFFSET`** counts from the end: `-1` is the last element, `-2` the one before, and so on. If the magnitude exceeds the array length, Perl issues a warning and clamps to `0`.
- **Negative `LENGTH`** leaves that many elements at the end of the array untouched. `splice @a, 2, -1` removes from index 2 up to but not including the final element.
- **`OFFSET` past the end**: with an explicit `LENGTH`, Perl issues a warning and splices at the end of the array (equivalent to `splice @a, scalar(@a), 0, LIST`). Without a `LENGTH`, nothing is removed.
- **`LENGTH` past the end**: silently clamped. `splice @a, 1, 999` simply removes everything from index 1 onward.
- **Both `OFFSET` and `LENGTH` omitted**: removes every element. The array is left empty.

- **Replacement list size differs from `LENGTH`**: the array grows or shrinks to match. There is no requirement that `scalar(@list)` equal `LENGTH` - that asymmetry is the whole point of `splice`.
- **Array reference**: dereference inline. `splice @$ref, 0, 1` and `splice @{ $obj->{items} }, -2` both work.
- **Splicing a slice is not supported**: `splice @a[1..3], 0, 1` is a syntax error. `splice` requires a named array or dereferenced array, not a list expression. To operate on a range, pass the bounds as `OFFSET` and `LENGTH` instead.
- **Void context is fine**. If the return value is not needed, call `splice` as a statement - no allocation of the removed-elements list happens in that case.
- **Scalar expressions as the first argument**: not allowed. An experimental feature permitted this from 5.14 through 5.22 and was removed in 5.24. The first argument must be an array (or dereferenced arrayref).

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `push` - append to the end; equivalent to `splice @a, scalar(@a), 0, LIST`
- `pop` - remove the last element; equivalent to `splice @a, -1`
- `shift` - remove the first element; equivalent to `splice @a, 0, 1`
- `unshift` - prepend; equivalent to `splice @a, 0, 0, LIST`
- `delete` - superficially similar but semantically different. `delete $a[$i]` leaves a hole (the slot becomes `undef`) and does **not** renumber later indices; the array's length is unchanged unless the deleted slot was the last one. `splice @a, $i, 1` physically removes the slot and shifts every later element down by one. Use `delete` for sparse arrays where index identity matters; use `splice` when you want the array to close up.
- `grep` - filter an array into a new one by predicate; reach for it instead of `splice` when you want "keep only the ones that match" rather than "cut out a contiguous range"

Regular expressions and pattern matching

split

Cut a string into a list of fields using a regex separator.

`split` scans `EXPR` for matches of `PATTERN` and returns the pieces between the matches as a list. The matched text itself is the separator and is **not** included in the result - unless the pattern contains capture groups, in which case each capture becomes an extra element in the output. In scalar context the list size is returned.

If `PATTERN` is omitted, `split` behaves like the `awk` default: runs of whitespace are the separator and any leading whitespace in `EXPR` is stripped. If `EXPR` is omitted, `$_` is split.

Synopsis

```
split /PATTERN/, EXPR, LIMIT
split /PATTERN/, EXPR
split /PATTERN/
split
```

What you get back

A list of substrings (fields) in list context; the count of fields in scalar context. The separator text is never part of a field.

```
my @fields = split /,/, "a,b,c";       # ("a", "b", "c")
my $n      = split /,/, "a,b,c";       # 3
```

Splitting an `EXPR` that is the empty string always yields zero fields, regardless of `LIMIT`:

```
my @x = split /,/, "", -1;             # ()
```

Prior to Perl 5.11, `split` in void or scalar context overwrote `@_`. Modern Perl does not; never rely on that old side effect.

The LIMIT argument

`LIMIT` controls how many fields are produced and, crucially, whether trailing empty fields are kept.

- **Positive `LIMIT`** - upper bound on the number of fields. `EXPR` is split at most `LIMIT - 1` times; the final field holds the rest of the string verbatim. `LIMIT = 1` means no splits at all - you get the whole string back as a single element.

  ```
  my @x = split /,/, "a,b,c", 1;       # ("a,b,c")
  my @x = split /,/, "a,b,c", 2;       # ("a", "b,c")
  my @x = split /,/, "a,b,c", 3;       # ("a", "b", "c")
  my @x = split /,/, "a,b,c", 4;       # ("a", "b", "c")
  ```

- **Negative `LIMIT`** - treated as arbitrarily large. As many fields as possible are produced, including **all** trailing empty fields.

  ```
  my @x = split /,/, "a,b,c,,,", -1;   # ("a", "b", "c", "", "", "
  ↪")
  ```

- **Omitted or zero `LIMIT`** - like negative, **except** trailing empty fields are stripped. Leading empty fields are always kept.

  ```
  my @x = split /,/, "a,b,c,,,";       # ("a", "b", "c")
  my @x = split /,/, ",,a,b";          # ("", "", "a", "b")
  ```

- **Implicit `LIMIT` in list assignment.** When assigning to a fixed list, Perl sets `LIMIT` to one more than the number of targets, so the trailing fields do not need to be scanned. The following gets `LIMIT = 3` automatically:

```
my ($login, $passwd) = split /:/;
```

In time-critical code, pass an explicit `LIMIT` rather than letting the whole string be scanned.

The awk-style whitespace case: `split " "`

A literal single space as the pattern - `split " "`, not `split / /` - triggers a special case: `PATTERN` is treated as `/\s+/` **and** any leading whitespace in `EXPR` is stripped before splitting. This matches classic `awk` behaviour.

```
my @x = split " ", "  Quick brown fox\n";
# ("Quick", "brown", "fox")

my @x = split " ", "RED\tGREEN\tBLUE";
# ("RED", "GREEN", "BLUE")
```

To split on a *single* literal space only, use the regex form `/ /` - it is not special-cased:

```
my @x = split / /, " abc";              # ("", "abc")
```

Since Perl 5.18, the trigger is any expression whose value is the single-character string `" "` (not just a literal), and since Perl 5.28 the rule works correctly under `use feature 'unicode_strings'`. Under Perl 5.39.9+ the `/x` default modifier does **not** affect `split STRING`, so `split " "` still means awk-emulation even inside `use re "/x"`. If you want to split on one literal space under `use re "/x"`, write `split /(?-x: )/` or `split /\x{20}/`.

If `PATTERN` is omitted entirely, it defaults to `" "`, so bare `split` is the awk-style form.

The empty-pattern case: splitting into characters

If `PATTERN` matches the empty string, the split happens at every match position - i.e. between characters.

```
my @x = split //, "abc";                # ("a", "b", "c")
```

As a `split`-specific rule, the bare match operator `//` is **not** the "repeat the last successful match" form here; it is the literal empty pattern. A zero-width match at the very start of `EXPR` never produces an empty leading field, which is why splitting a leading space is handled like this:

```
my @x = split //, " abc";               # (" ", "a", "b", "c")   - 4,␣
↪not 5
my @x = split //, " abc", -1;           # (" ", "a", "b", "c", "") -␣
↪trailing empty with -1
```

A positive-width match at the start *does* produce an empty leading field:

```
my @x = split / /, " abc";              # ("", "abc")
```

Capture groups become extra elements

If PATTERN contains capturing groups, each capture is inserted into the output list for every separator match, in the order the groups are declared. A group that does not participate in the match contributes undef. These extras do **not** count toward LIMIT.

```
my @x = split /-|,/    , "1-10,20", 3;
# ("1", "10", "20")

my @x = split /(-|,)/  , "1-10,20", 3;
# ("1", "-", "10", ",", "20")

my @x = split /-|(,)/  , "1-10,20", 3;
# ("1", undef, "10", ",", "20")

my @x = split /(-)|,/  , "1-10,20", 3;
# ("1", "-", "10", undef, "20")

my @x = split /(-)|(,)/, "1-10,20", 3;
# ("1", "-", undef, "10", undef, ",", "20")
```

Use this when you want the separators preserved alongside the fields - typical for tokenisers where the delimiters are themselves part of the output stream.

Global state it touches

- $_ - EXPR defaults to it when no second argument is given.
- @_ - modern Perl does **not** touch it. Only relevant if you support pre-5.11 perls.
- The regex engine's match variables ($1, $2, ..., $&, $', $`) are **not** set as a side effect of split, even when PATTERN captures - the captures go into the returned list.

Examples

Classic CSV-style line, no embedded commas:

```
my @cells = split /,/, "alice,bob,carol";    # ("alice", "bob",
↪"carol")
```

Parse a /etc/passwd line into known fields; implicit LIMIT stops at the first seven separators:

```
my ($user, $pw, $uid, $gid, $gecos, $home, $shell)
    = split /:/, $line;
```

Awk-style whitespace tokenising, leading whitespace discarded:

```
my @words = split " ", "   one\ttwo  three\n";
# ("one", "two", "three")
```

Characters of a string - the empty pattern:

```
my @chars = split //, "hello";                  # ("h", "e", "l", "l",
↪"o")
```

Keep every trailing empty field for a strict column-count reader:

```
my @cols = split /\t/, $line, -1;
```

Preserve separators by capturing - round-trip reconstructible:

```
my @parts = split /([,;])/, "a,b;c";            # ("a", ",", "b", ";",
↪"c")
my $same  = join "", @parts;                    # "a,b;c"
```

Default form reads `$_` and does awk-style whitespace splitting:

```
for (@lines) {
    my @f = split;                              # split " ", $_
    ...
}
```

Edge cases

- **Empty input** - `split /X/, ""` returns the empty list for every `LIMIT`, including `-1`.
- **`LIMIT = 1`** - no splitting occurs; the whole string is the one and only field. Useful when you want `split` semantics conditionally without losing the input.
- **`/^/` pattern** - treated as if `/^/m` so it matches at every line start, which is the only useful behaviour. Splits a string into lines keeping the newlines.
- **Zero-width match at position 0** - never produces an empty leading field (see `split //, " abc"` above).
- **Positive-width match at position 0** - produces an empty leading field, always.
- **Match at end of string** - produces an empty trailing field, which is then stripped unless `LIMIT` is non-zero.
- **Patterns with modifiers** - the usual `qr//` modifiers (`/i`, `/m`, `/s`, `/x`, `/u`, `/a`, `/l`, `/n`) apply. The pattern need not be a literal; any expression producing a regex or string works, and `qr//` objects are accepted.
- **Single-space string that is not a literal** - from Perl 5.18 on, any expression evaluating to `" "` triggers the awk-style special case, not just the literal `" "`.
- **`split " "` vs `split / /`** - the first is awk-style whitespace (`\s+` with leading-ws stripping), the second is a single literal space. The two are not interchangeable.
- **Unicode whitespace** - under `use feature 'unicode_strings'` (default since 5.28 for the awk-style case), `split " "` treats Unicode whitespace as a separator too. Outside that scope the behaviour is affected by the “Unicode Bug”.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `join` - inverse operation; stitches a list back into a string with a chosen glue
- `m` - the match operator; when you want to *find* something rather than cut the string around it
- `qr` - pre-compile a pattern once for repeated `split` calls in a hot loop
- `index` - locate a fixed substring without building the full list of fields; cheaper when you only need the first split
- `substr` - extract by byte/character offset when the field boundaries are positional, not delimited

SCALARs and strings

sprintf

Build a formatted string from a format template and a list of values.

`sprintf` takes a `FORMAT` string containing literal text interspersed with `%`-introduced conversion specifiers, consumes values from `LIST` to fill each specifier, and returns the resulting string. It is the same machinery that drives `printf`, minus the write to a file-handle. Perl implements its own formatter; it does not call the C library's `sprintf(3)` except for the final floating-point digit generation, so non-standard extensions that happen to exist in your libc are not available here.

Synopsis

```
my $s = sprintf $format, @args;
my $s = sprintf "%-10s %5d", $name, $count;
my $s = sprintf "%.3f", $x;
```

What you get back

A single scalar string. Never a list, regardless of context. If `FORMAT` contains no `%` specifiers, the return value is `FORMAT` unchanged and `LIST` is ignored. If `FORMAT` references more arguments than `LIST` supplies, the missing values are treated as `undef` (numeric zero or the empty string depending on the conversion), and a `Missing argument in sprintf` warning is issued under `use warnings`.

Passing an array as the first argument is almost always a mistake - the array is evaluated in scalar context, so Perl uses its element count as the format. Use `sprintf $format, @rest` with the format held separately, or `sprintf "@array"` for the array-as-string case.

Global state it touches

- `LC_NUMERIC` locale, when `use locale` is in effect and `POSIX::setlocale` has been called, determines the decimal-point character used by %e, %f, %g and their upper-case variants. Without `use locale` the decimal point is always `.`, even if the process locale says otherwise.
- No other special variables are consulted. `sprintf` does not read `$_`; an explicit list is required.

Conversion specifiers

The core set, in the order you will actually reach for:

Spec	Meaning
%s	String. Stringifies the argument.
%d, %i	Signed integer in decimal. Floats are truncated toward zero.
%u	Unsigned integer in decimal.
%f, %F	Fixed-point floating point. Default 6 digits after the decimal.
%e, %E	Scientific notation. Upper-case E selects the upper-case form.
%g, %G	%e or %f, whichever is shorter. Precision is *significant digits*, not digits after the decimal.
%x, %X	Unsigned integer in hexadecimal; %X uses upper-case A–F.
%o	Unsigned integer in octal.
%b, %B	Unsigned integer in binary.
%c	Single character whose codepoint is the given integer.
%%	A literal %. Consumes no argument.
%p	Perl-value address, in hexadecimal. Diagnostic use only.
%n	Stores the number of characters written so far into the next argument (which must be a writable scalar).
%a, %A	Hexadecimal floating point.

Upper-case size synonyms %D %U %O and %F exist for historical compatibility; prefer the lower-case forms.

Flags, width, precision

Between % and the conversion letter, in order:

1. **Argument index** - N$ picks the N-th argument (1-based): `sprintf '%2$s %1$s', 'world', 'hello'` yields `"hello world"`.
2. **Flags** - any combination of:
   - - left-justify within the field (default is right-justify).

- + prefix non-negative numbers with +.
- ` ` (a space) prefix non-negative numbers with a space. When both space and + are given, + wins.
- `0` pad numeric conversions with zeros instead of spaces. Ignored when - is also set or a precision is given for integers.
- # alternate form: `0` prefix for octal, `0x`/`0X` prefix for non-zero hex, `0b`/`0B` prefix for non-zero binary.

3. **Minimum width** - a decimal number, or `*` to take the width from the next argument, or `*N$` for an explicit argument. Negative width (via `*`) is equivalent to the - flag.
4. **Precision** - `.` followed by a decimal number, or `.*` (next argument), or `.*N$`. Meaning depends on the conversion:
   - `%f` / `%e`: digits after the decimal point (default 6).
   - %g: total significant digits.
   - %d / %x / %o / %b: minimum digits; the number is zero-padded to this width. The `0` flag is ignored when a precision is present for integers.
   - `%s`: maximum width; truncates.
5. **Size modifier** - hh, h, `j`, `l`, q, `L`, `ll`, `t`, `z`, `V`. Interprets the argument as a specific C type. Almost never useful from Perl - Perl has one integer type and one float type, and Perl-level values do not overflow into the sizes these modifiers select. `V` is a no-op meaning "Perl's default size".
6. **Conversion letter** - one of the table entries above.

The vector flag

Prefix the conversion letter with `v` (optionally `*v` or `*N$v` to supply a separator) and Perl treats the argument as a vector of codepoints, applying the conversion to each codepoint and joining the results with `.` (or the supplied separator):

```
sprintf "%vd", "AB\x{100}";             # "65.66.256"
sprintf "%vX", "\x01\x02\x1f";          # "1.2.1F"
sprintf "%*vX", ":", "\xde\xad\xbe\xef"; # "DE:AD:BE:EF"
```

Common uses: rendering `$^V`, formatting IPv4 / IPv6 byte sequences, or dumping bitstrings. The argument is always read as a string of codepoints, not as a list.

Examples

Pad and align strings in a fixed-width report column:

```
printf "%-10s %5d\n", "widgets", 42;   # "widgets        42\n"
printf "%-10s %5d\n", "sprockets", 7;  # "sprockets       7\n"
```

Zero-pad a fixed-width integer, e.g. for lexicographic sort keys or line numbers:

```
sprintf "%08d", 1234;                   # "00001234"
sprintf "%05d", -7;                     # "-0007"  (sign consumes a␣
↪slot)
```

Round to a fixed number of decimal places. `sprintf` does the rounding; `printf` is a common way to coerce a display value:

```
sprintf "%.3f", 3.14159265;             # "3.142"
sprintf "%.0f", 2.5;                    # "2" or "3" - banker's␣
↪rounding
                                        # is platform-dependent
```

Scientific notation, with and without a chosen precision:

```
sprintf "%e",    6.022e23;              # "6.022000e+23"
sprintf "%.2e",  6.022e23;              # "6.02e+23"
sprintf "%g",    0.0001234;             # "0.0001234"
sprintf "%g",    0.00001234;            # "1.234e-05"  (switches to
↪%e)
```

Hex, octal, and binary with the # alternate-form prefix:

```
sprintf "%#x",  255;                    # "0xff"
sprintf "%#o",  8;                      # "010"
sprintf "%#b",  10;                     # "0b1010"
sprintf "%08b", 10;                     # "00001010"   (no prefix,␣
↪width 8)
```

Character from a codepoint - `%c` is essentially `chr` routed through the format engine:

```
sprintf "%c", 65;                       # "A"
sprintf "%c", 0x2014;                   # "-"  (em dash)
```

Field width from the argument list - useful when the width is computed at runtime:

```
my $w = 12;
sprintf "%-*s|", "name", $w;            # "name        |"
```

Out-of-order arguments - useful when the same value appears multiple times or when localised formats reorder placeholders:

```
sprintf "%2\$s loves %1\$s", "Alice", "Bob";   # "Bob loves Alice"
```

Build an IPv4 address string:

```
sprintf "%vd", "\x7f\x00\x00\x01";      # "127.0.0.1"
```

Capture length via %n (the receiving argument must be a writable scalar):

```
my $written;
my $s = sprintf "hello%n, world", $written;
```

(continues on next page)

(continued from previous page)

```
# $s       is "hello, world"
# $written is 5
```

Edge cases

- **Integer truncation on %d with floats**: %d converts via integer coercion, which truncates toward zero. `sprintf "%d", 3.9` is `"3"`, not `"4"`. Use `%.0f` if you want banker's-rounded display, or `int` / `sprintf "%.0f"` explicitly first.
- **%s on an object**: stringification runs, which may invoke overloaded `""` or fall back to `"ClassName=HASH(0x...)"`. There is no way to suppress overloading inside `sprintf`; call `overload::StrVal($obj)` first if you need the raw form.
- **Missing arguments**: `sprintf "%s %s", "one"` returns `"one "` and warns `Missing argument in sprintf at ...` under `use warnings`. No exception is raised.
- **Too many arguments**: extras are ignored silently. No warning.
- **%s with precision truncates, %d with precision zero-pads**. `sprintf "%.3s", "abcdef"` is `"abc"`. `sprintf "%.3d", 7` is `"007"`.
- **%0 flag vs precision on integers**: precision wins. `sprintf "%05.3d", 7` is `" 007"`, not `"00007"` - the `0` flag is ignored once you give an explicit integer precision.
- **Negative width via ***: `sprintf "%*s", -6, "x"` is `"x "`. Negative precision via `.*` counts as no precision at all.
- **NaN and Inf**: `sprintf "%f", 9**9**9` yields `"Inf"`; `sprintf "%f", -sin(9**9**9)` yields `"NaN"`. Exact spelling (`"Inf"` vs `"inf"`, `"NaN"` vs `"nan"`) follows the Perl build's convention, not the `%f` / `%F` case distinction.
- **Locale decimal point**: with `use locale` and a de_DE locale, `sprintf "%.2f", 1.5` can produce `"1,50"`. Without `use locale` the result is always `"1.50"`. Code that writes numeric output for consumption by other programs should either avoid `use locale` in that scope or use `use locale ':not_characters'` and format numbers outside locale influence.
- **%p is diagnostic-only**: the hexadecimal pointer value changes from run to run and is meaningless outside the running process. Do not use it as an identity key - two references may share the same address after the first has been freed.
- **Array passed as FORMAT**: `sprintf @a` formats using the scalar count of `@a` as the format string. Almost always a bug. Always keep the format in its own scalar.
- **Unsupported size modifier**: on platforms lacking e.g. long doubles, the `L`/`q`/`ll` size on a float conversion silently falls back to the default size, and a `printf` warning is issued under `use warnings`. To promote this to an exception, use `use warnings FATAL => 'printf'`.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `printf` - same formatting engine, but writes to a filehandle instead of returning the string
- `print` - use with a pre-built `sprintf` result when you want to format once and write to several handles
- `chr` - single codepoint to single character; equivalent to `sprintf "%c", $n`
- `hex`, `oct` - inverse operations: parse a string in hex/octal/binary back into a number
- `pack` - build a binary string from a template; reach for it when the output is bytes, not a human-readable format
- `$_` - *not* consulted by `sprintf`; unlike many built-ins it always needs an explicit list

Numeric functions

sqrt

Return the non-negative square root of EXPR.

`sqrt` computes the **principal square root** - the unique non-negative real number whose square equals EXPR. For any `EXPR >= 0` the result is `>= 0`; `sqrt` never returns the negative root. If EXPR is omitted, `$_` is used.

The computation is performed in double-precision floating point (IEEE 754 `binary64`), so the result is a float even when the input is an integer and even when the mathematical answer is itself an integer.

Synopsis

```
sqrt EXPR
sqrt
sqrt(EXPR)
```

What you get back

A floating-point number: the non-negative square root of EXPR. For negative input the result is `NaN` (and a warning is emitted under `use warnings`); see *Edge cases*. For complex-valued roots load , which overloads `sqrt` so that `sqrt(-1)` returns `i`.

```
my $r = sqrt 2;                    # 1.4142135623731
my $r = sqrt;                      # sqrt of $_
```

The default argument, precedence, and parsing

Three parser details shape every `sqrt` call:

- **No argument uses `$_`.** `sqrt` with no argument and no parentheses reads the topic variable. Handy inside `map` and `grep` blocks that already bind `$_`.
- **Named-unary precedence.** `sqrt` is a named unary operator, so it binds tighter than most binary operators but looser than multiplication and exponentiation. `sqrt 2 + 3` means `sqrt(2) + 3`, not `sqrt(2 + 3)` - parenthesise when in doubt.
- **`sqrt(...)` is a function call.** As with every named unary, writing an opening paren immediately after the name turns the remainder into the argument list: `sqrt(4) * 2` is 4 (the sqrt of 4) times 2, i.e. 4.

```
my @roots = map { sqrt } 1, 4, 9;   # (1, 2, 3); $_ is the topic
my $x = sqrt 2 + 3;                 # 4.41421…  - sqrt(2) + 3
my $y = sqrt(2 + 3);                # 2.23606…  - sqrt(5)
```

Examples

Classic irrational root. The printed decimal is the closest `binary64` approximation, not the exact value:

```
printf "%.15f\n", sqrt(2);          # 1.414213562373095
```

Pythagorean distance between two points:

```
sub distance {
    my ($x1, $y1, $x2, $y2) = @_;
    return sqrt(($x2 - $x1) ** 2 + ($y2 - $y1) ** 2);
}

print distance(0, 0, 3, 4), "\n";   # 5
```

Zero is its own square root, and so is one:

```
print sqrt(0), "\n";                # 0
print sqrt(1), "\n";                # 1
```

Perfect squares round-trip exactly for small integers, because the mathematical result is representable in `binary64`:

```
print sqrt(16), "\n";               # 4
print sqrt(144), "\n";              # 12
print sqrt(1_000_000), "\n";        # 1000
```

Large perfect squares may **not** round-trip exactly - the result is the nearest representable float, which can be slightly off:

```
my $n = 9_007_199_254_740_996;      # 2**53 + 4
printf "%.3f\n", sqrt($n) ** 2 - $n; # non-zero in general
```

Compare to the exponentiation operator, which is the general way to take any real power:

```
print 2 ** 0.5, "\n";                # same as sqrt(2)
print 27 ** (1/3), "\n";             # cube root of 27 ≈ 3
```

Using to get a complex result from a negative input:

```
use Math::Complex;
my $z = sqrt(-1);                    # i
print $z, "\n";                      # "i"
print sqrt(-4), "\n";                # "2i"
```

Edge cases

- **Negative input without** : returns `NaN` and triggers an `Invalid operation` warning under `use warnings`. `NaN` compares unequal to itself, so never test with `==`; use `POSIX::isnan` or check `$x != $x`.

  ```
  my $r = sqrt(-1);                  # NaN
  print "bad\n" if $r != $r;         # NaN self-compare trick
  ```

- **Negative input with** : once is loaded, `sqrt` is overloaded for complex scalars and returns the principal complex root. Real inputs still go through the built-in.

- **Non-numeric input**: coerced to a number using the usual rules - leading whitespace and a numeric prefix are consumed, the rest is ignored. Under `use warnings` an `isn't numeric` warning fires when the string has no numeric prefix at all. `undef` coerces to `0`.

  ```
  print sqrt("9abc"), "\n";          # 3, with a warning under
   ↪warnings
  print sqrt(""), "\n";              # 0, with a warning
  print sqrt(undef), "\n";           # 0, with an uninitialized
   ↪warning
  ```

- **Floating-point imprecision for perfect squares**: for sufficiently large integers, the mathematically exact root may not be representable. `sqrt($n*$n)` is not guaranteed to equal `$n` for large `$n`. If you need an exact integer square root, do not use `sqrt` - use 's `bsqrt` or a dedicated isqrt implementation.

- **Special IEEE values**: `sqrt("Inf")` is `Inf`; `sqrt("NaN")` is `NaN`; `sqrt(-0.0)` is `-0.0` (negative zero, which compares equal to `0`). `sqrt("-Inf")` is `NaN`.

- **Integer overflow is not an issue**: because the result is always a float, `sqrt` never overflows for any finite numeric input.

- **List context is irrelevant**: `sqrt` always returns a single scalar. In list context that scalar is the only element of the returned list.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `abs` - absolute value; pair with `sqrt` when you want `sqrt(abs($x))` to sidestep negative input
- `**` - exponentiation operator; `$x ** 0.5` is `sqrt`, and `$x ** (1/$n)` generalises to other roots
- `hypot` - from `POSIX`, computes `sqrt($x*$x + $y*$y)` without intermediate overflow
- - overloads `sqrt` and friends so that `sqrt(-1)` returns `i` instead of `NaN`
- , - arbitrary-precision square roots via `bsqrt` when `binary64` is not enough

Numeric functions

srand

Seed the pseudo-random number generator.

`srand` sets the internal state of the PRNG that `rand` draws from. Call it with an explicit integer to get a reproducible stream, or call it with no argument to reseed from the best entropy source the platform offers. Since Perl 5.14 `srand` **returns the seed it used**, so you can log it and replay the same run later.

Synopsis

```
srand EXPR
srand
```

What you get back

The seed that was installed, as an integer. For `srand($n)` the return value is `$n` (after the usual integer truncation). For argument-less `srand()` the return value is the auto-chosen seed drawn from system entropy - capture it if you ever want to reproduce the run.

```
my $seed = srand();                  # auto-seed, remember what we␣
↪used
warn "seed for this run: $seed\n";
```

Before Perl 5.14 `srand` returned nothing useful. Code that relies on the seed return should declare the minimum version:

```
use v5.14;                           # so srand returns the seed
```

Global state

`srand` mutates a single process-wide PRNG. Every subsequent call to `rand` in the same process - from any package, any module, any thread-free context - reads from that one state. There is no per-package or per-scope RNG. Consequences:

- Calling `srand($k)` anywhere in the program affects *every* later `rand` call, including those inside modules you did not write.
- Two processes that call `srand($k)` with the same `$k` produce identical `rand` streams. This is the basis of reproducible tests and the reason you must reseed after `fork`.
- If `srand` is never called explicitly, it is called implicitly **without argument** the first time `rand` is invoked.

Examples

Reproducible test case with an explicit seed - same input, same sequence, every run:

```
srand(42);
my @sample = map { rand() } 1..5;   # identical on every invocation
```

Seed from `time()` for rare-collision randomness across separate runs started at different wall-clock seconds. This is the classical pattern; it is **not** cryptographic-grade:

```
srand(time() ^ $$);                 # time XOR pid, old-school␣
↪spread
```

Save-seed, restore-seed pattern for a test that picks a random subset of its cases but logs enough to replay any failure:

```
my $seed = srand();                 # auto-seed, capture it
eval { run_randomised_tests() };
if ($@) {
    warn "FAILED with seed=$seed - reproduce with: srand($seed)\n";
    die $@;
}
```

Reseed after `fork` so parent and child do not share a stream:

```
my $pid = fork();
die "fork: $!" unless defined $pid;
if ($pid == 0) {
    srand();                        # child gets fresh entropy
    exec_child_work();
}
```

Two independent streams from the same seed - useful when you want to checkpoint and resume, or diff two runs that diverged after a decision point:

```
srand(12345);
my @first  = map { rand() } 1..10;
```

(continues on next page)

(continued from previous page)

```
srand(12345);
my @second = map { rand() } 1..10;  # identical to @first
```

Edge cases

- **No-argument form auto-seeds with the best available entropy.** On Linux this draws from `/dev/urandom` (or `getrandom(2)`). The seed is wide enough that you should treat it as opaque, not as a small integer.
- **Do not call `srand()` without arguments more than once per process.** The PRNG's internal state already carries more entropy than any single seed can restore, so re-seeding *loses* randomness rather than adding it. The two legitimate reasons to call it repeatedly are (a) with an explicit seed for reproducibility, and (b) once in each child after `fork`.
- **Decimal arguments are silently truncated to integer.** `srand(42)` and `srand(42.9)` install the same seed. Always pass an integer so intent is obvious.
- **Same seed ⇒ identical `rand` stream.** That is the whole point for tests; it is the whole problem for security.
- **Not cryptographically secure.** `rand`/`srand` use a fast non-cryptographic PRNG. Do not use them to generate session tokens, nonces, keys, password salts, or anything an adversary must not be able to predict. Use `Crypt::URandom` or read from `/dev/urandom` directly.
- **`PERL_RAND_SEED` environment variable.** If set to a non-negative integer at process startup, argument-less `srand()` (including the implicit call triggered by the first `rand`) installs a deterministic seed derived from that value. The derivation is deliberately unspecified; only same-value-same-binary-same-code reproducibility is guaranteed. Intended for debugging and performance analysis. The variable is read **once** at startup; mutating `%ENV` later has no effect on the current process.
- **Threads** (`use threads`): each interpreter clone gets its own PRNG state. Seeding in one thread does not affect another.
- **Scope of the seed**: there is no way to `local`-ise the PRNG state. If a library you call in between does an `srand`, your stream is perturbed. Capture and restore manually if that matters.

Differences from upstream

Fully compatible with upstream Perl 5.44. `PERL_RAND_SEED` is honoured with the same "deliberately unspecified but reproducible" contract as perl5.

See also

- `rand` - the consumer of the state `srand` installs; draws the next value from the seeded stream
- `time` - seconds since the epoch; the classic quick-and-dirty seed source for non-security code (`srand(time() ^ $$)`)

- `Crypt::URandom` - cryptographically secure random bytes from the OS entropy pool; use this, not `rand`, for tokens and keys
- `Math::Random::MT` - Mersenne Twister PRNG with its own independent state, when you need a second stream that is not perturbed by library calls to `rand`
- `perlrun` - documents the `PERL_RAND_SEED` environment variable and other startup knobs

Filehandles, files, directories

stat

Get a file's status information.

`stat` asks the operating system for the metadata record of a file - size, ownership, permissions, timestamps, inode - and returns it as a 13-element list. It is the underlying primitive behind the `-X` file tests (`-e`, `-f`, `-r`, ...), behind modules like `File::stat`, and behind any script that needs to inspect a file without opening it. `stat` dereferences symlinks and reports on the target; use `lstat` to get the link itself.

Synopsis

```
stat FILEHANDLE
stat EXPR
stat DIRHANDLE
stat
stat _
```

What you get back

In list context, a 13-element list of numeric fields. In scalar context, a boolean: true on success, false on failure. Either way, on success the kernel's stat buffer is cached in the special filehandle `_`, which any subsequent `stat`, `lstat`, or `-X` test can re-use without a new syscall.

On failure, list context returns the empty list and `$!` is set to the `errno` value from the failed `stat(2)`.

The fields, in order:

Index	Field	Meaning
0	`dev`	device number of the filesystem holding the file
1	`ino`	inode number
2	`mode`	file mode - type bits **and** permission bits combined
3	`nlink`	number of hard links to the file
4	`uid`	numeric user ID of the owner
5	`gid`	numeric group ID of the owner
6	`rdev`	device identifier, for character/block special files
7	`size`	total size in bytes
8	`atime`	last access time, seconds since the epoch (1970-01-01 00:00 GMT)
9	`mtime`	last modify time, seconds since the epoch
10	`ctime`	inode change time, seconds since the epoch - **not** creation time
11	`blksize`	preferred I/O block size for reads/writes against this file
12	`blocks`	number of filesystem blocks actually allocated (often 512 B each)

Field 2 (`mode`) packs both the file type and the permission bits into one number. Mask with `07777` to see just the permissions; use the `S_IF*` constants and `S_IS*` helpers from `Fcntl` to test the type portably.

```
my $mode = (stat($filename))[2];
printf "permissions are %04o\n", $mode & 07777;
```

Not every filesystem populates every field. `atime`, `blksize`, and `blocks` may come back as `0` on filesystems that do not track them (for instance some FUSE mounts or network filesystems); `ctime` is not a portable "creation time" - it tracks the last change to the inode itself (permissions, ownership, link count), not when the file was first created.

Global state it touches

- `$_` - read when `stat` is called with no argument. `stat` with no EXPR stats the filename held in `$_`, **not** the cached _ handle.
- `$!` - set to the `errno` of the failed `stat(2)` syscall when the call fails.
- The **special _ filehandle** - a per-interpreter cache of the most recent successful `stat`, `lstat`, or `-X` result. Passing _ as the argument reuses that cached buffer and issues no syscall. Successful calls refresh it; failed calls leave the previous contents in place.

Examples

Basic list-context unpack:

```
my ($dev, $ino, $mode, $nlink, $uid, $gid, $rdev, $size,
    $atime, $mtime, $ctime, $blksize, $blocks) = stat($filename);
```

Pick out a single field with a list slice:

```
my $size  = (stat($filename))[7];
my $mtime = (stat($filename))[9];
```

Scalar context as an existence-plus-readable-metadata probe:

```
if (stat($path)) {
    my $size = (stat _)[7];          # reuse the cached buffer
    print "size = $size\n";
} else {
    warn "stat $path: $!";
}
```

Reusing the cache across an `-X` test and a `stat`:

```
if (-x $file && (($d) = stat(_)) && $d < 0) {
    print "$file is executable NFS file\n";
}
```

Named-accessor access through `File::stat`:

```
use File::stat;
my $sb = stat($filename);
printf "file %s, size %s, perm %04o, mtime %s\n",
       $filename, $sb->size, $sb->mode & 07777,
       scalar localtime $sb->mtime;
```

Decoding the mode with `Fcntl`:

```
use Fcntl ':mode';
my $mode = (stat($filename))[2];
printf "permissions %04o\n", S_IMODE($mode);
print "is a directory\n" if S_ISDIR($mode);
```

Edge cases

- **No argument**: `stat;` stats `$_`, **not** the cached _ handle. To re-read the cache you must write `stat(_)` with the underscore as an explicit bareword.
- **The _ bareword is special**: it names the stat cache, not a file. Quoting it (`stat("_")`) stats a file literally called _ in the current directory.
- **Symlinks are followed**: `stat` reports on the target of a symlink. For the link itself, use `lstat`. A broken symlink makes `stat` fail with `ENOENT`; `lstat` on the same path succeeds.
- **DIRHANDLE form**: passing a directory handle from `opendir` returns the stat of the open directory itself. Not every platform supports this; on those that do not, the call fails and `$!` is set.
- **Inode numbers may overflow integers**: on filesystems with 64-bit inode numbers beyond Perl's integer range, `ino` is returned as a decimal string to preserve the full value. Compare inode numbers with eq, not ==, to stay correct on those filesystems. eq works fine on numeric inodes too.
- **`ctime` is not creation time**: it is the inode-change time - updated by `chmod`, `chown`, `rename`, link-count changes, and the file's own writes. Linux exposes a true creation time (`btime`) via `statx(2)`, but that is not part of `stat`'s return list.

- **Zero fields on some filesystems**: `atime` (on `noatime` mounts), `blksize`, and `blocks` may be reported as `0`. Treat `0` as "unavailable", not as a meaningful value.
- **Scalar context does not populate _ on failure**: a failed `stat` leaves the previous cached buffer untouched. Always check the return value before a follow-up `stat(_)` or `-X _`.
- **Race windows**: the metadata returned is a snapshot. Anything that acts on a path based on `stat`'s result (permission checks, TOCTOU patterns) must be written to tolerate the file changing between the `stat` and the follow-up operation - or better, open the file first and `stat` the filehandle.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `lstat` - like `stat` but does **not** follow symlinks; reports on the link itself
- `-X` file-test operators (`-e`, `-f`, `-r`, `-w`, `-x`, ...) - built on top of the same stat buffer; share the _ cache with `stat` and `lstat`
- `chmod` - change the permission bits reported in field 2 (`mode`)
- `chown` - change the `uid` and `gid` reported in fields 4 and 5
- `File::stat` - named accessors (`$sb->size`, `$sb->mtime`, ...) over the same 13-field list; `use File::stat` overrides `stat` in the current scope
- `Fcntl` - `:mode` tag exports the `S_I*` constants and `S_IS*` helpers for decoding field 2

Scoping

state

Declare a lexically scoped variable whose value persists across calls to its enclosing subroutine.

A `state` variable has the same visibility rules as a `my` variable - it is visible only inside the block that declares it - but it is **initialised exactly once** per enclosing closure, not on every entry to the block. This is Perl's built-in way to write persistent private variables: counters, memoisation caches, one-time-computed lookup tables, anything you would otherwise hide inside a file-scoped lexical above a `sub`.

Synopsis

```
state $scalar
state $scalar = EXPR
state ($a, $b, undef, $c)
state @array
state %hash
```

(continues on next page)

(continued from previous page)

```
state TYPE $var
state $var : ATTRS
```

What you get back

`state` is a declaration, not a function. Like `my` it returns the variable(s) it declares, so it can be used in any expression position where the declared variable would appear:

```
(state $n //= 0)++;                # declare-and-use in one␣
↪expression
print ++(state $calls), "\n";      # count calls to this line
```

The initialiser on the right of = is evaluated **only the first time control flows through the declaration** in that particular closure instance. On every subsequent entry, the declaration re-exposes the already-initialised variable and the initialiser is skipped.

Persistence scope - what "once" means

"Once per enclosing closure" is the precise rule. A `state` variable lives as long as the CV (code value) that contains its declaration:

- In a **named sub**, the CV is created once at compile time. The `state` variable is initialised on the first call and retains its value across every later call for the life of the process.
- In an **anonymous sub** / **closure**, each `sub { ... }` evaluation produces a fresh CV with its own fresh `state` slot. Two closures made from the same source do **not** share state.
- In a **nested block** inside a sub, the `state` still belongs to the surrounding CV - it is not re-created on each entry to the inner block.

```
sub counter { state $n = 0; ++$n }
counter(); counter(); counter();    # returns 1, 2, 3

my $make = sub { sub { state $n = 0; ++$n } };
my $a = $make->();
my $b = $make->();
$a->(); $a->(); $b->();             # $a sees 1, 2; $b sees 1
```

Feature gate and availability

`state` has always been feature-gated. Two ways to enable it:

- `use feature 'state';` - turns on just this feature.
- `use v5.10;` (or any later version bundle, including `use v5.36` and `use v5.44`) - implicit via the version feature bundle. Every modern program already has `state` available through its `use vX.Y` line.

Without the feature in scope, `state` is parsed as an ordinary bareword. To reach the built-in unconditionally, write `CORE::state`.

```
use v5.36;                              # 'state' feature is on by␣
↪default
sub hits { state $n = 0; ++$n }
```

List declarations and initialisers

`state` supports the parenthesised list form for declaring several variables at once, with `undef` as a placeholder:

```
state ($x, $y, undef, $z);
```

What it does **not** yet support is **initialising a list** of `state` variables. Upstream explicitly notes this: initialisation of `state` variables in a parenthesised list is not currently possible, so the list form is useful only for declaration.

Aggregates - `state @array` and `state %hash` - have historically had the same restriction on initialisers (Perl emitted an experimental warning, and in several versions a syntax error, for `state @a = (1, 2, 3)`). Build the aggregate inside the body instead:

```
sub primes_below_100 {
    state @p;
    unless (@p) {
        @p = _sieve(100);               # fill on first call only
    }
    return @p;
}
```

The `unless (@p)` / `unless (%h)` idiom above is the portable replacement for an aggregate initialiser.

Declaration placement and same-statement semantics

Like `my`, `our`, and `local`, a `state` declaration can appear anywhere an expression is allowed (except inside string interpolation). The new binding takes effect for **subsequent statements**, not for other mentions of the same variable in the same statement:

```
package main;
use feature 'state';
our $x = 2;
foo($x, state $x = $x + 1, $x);     # foo() receives (2, 3, 2)
foo($x, $main::x);                  # foo() receives (3, 2)
```

The first `$x` and the trailing `$x` in the same call still refer to `our $x`; only the next statement sees the `state $x`.

Examples

A hit counter - the canonical one-liner:

```
sub hits { state $n = 0; ++$n }
hits(); hits(); hits();             # returns 1, 2, 3
```

Memoisation of an expensive pure function:

```
sub fib {
    my ($n) = @_;
    state %cache;
    return $cache{$n} //= $n < 2 ? $n : fib($n-1) + fib($n-2);
}
```

Lazy one-time setup of a read-only table:

```
sub months {
    state @m = qw(Jan Feb Mar Apr May Jun Jul Aug Sep Oct Nov Dec);
    return @m;
}
```

Here the initialiser is a simple list, which works because the RHS of `state @m = ...` is constant-folded to a list literal and current Perl permits this form; the more general case of a computed list still wants the `unless (@m) { ... }` pattern above for portability.

Per-closure state (fresh slot per `sub { ... }` evaluation):

```
sub make_counter {
    return sub { state $n = 0; ++$n };
}
my $a = make_counter();
my $b = make_counter();
$a->(); $a->();                         # 1, 2
$b->();                                 # 1 - independent of $a
```

Declare-and-use in a single expression:

```
while (my $line = <$fh>) {
    warn "first line was: $line" if (state $first //= $line) eq
 ↪$line;
}
```

Edge cases

- **Aggregate initialisers.** `state @a = (1, 2, 3)` and `state %h = (k => 1)` have a long history of being restricted or experimental. When in doubt, declare the aggregate and fill it under `unless (@a) { ... }` on the first call. Scalar initialisers (`state $x = EXPR`) have always been fine.
- **Same-statement reuse.** A fresh `state` declaration does **not** apply to other mentions of the same name within the same statement; those still resolve to whatever was in scope before the declaration. See the `foo($x, state $x = $x + 1, $x)` example above.
- **Shadowing warning.** Redeclaring the same name in the same scope - `state $n; state $n;` - shadows the first. Under `use warnings` this emits a warning in the `shadow` category. Almost always a bug.
- **Anonymous-sub multiplicity.** Every evaluation of `sub { ... }` produces a new CV with its own `state` slot. If you build many closures from the same source, each

has its own independent `state` - that is a feature, but it surprises people expecting file-scoped persistence.

- **Threads and forks.** `state` lives in the CV, which is cloned on `fork` (copy-on-write in the OS sense - each process continues with its own copy) and on `threads->create` (deep-cloned). Two processes or threads do not share a `state` counter.
- **`local` does not apply.** `state` variables are lexicals, not package variables, so `local` cannot save and restore them. Wrap the whole sub in its own scope or use a different mechanism if you need dynamic scoping.
- **Access via `CORE::state`.** When writing code that must parse even without the feature enabled, prefix the keyword: `CORE::state $n = 0;`.
- **Destruction.** `state` variables live as long as the CV. For a named sub in the main program that means "until global destruction." Do not put a file-handle or a large buffer in a `state` variable expecting it to be freed at sub exit - it will not be.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `my` - ordinary lexical; reinitialised on every block entry, the natural contrast to `state`
- `our` - lexical alias for a package variable; use when callers need to see or `local`-ise the value
- `local` - dynamic scoping for package variables; orthogonal to `state` and cannot be applied to it
- `sub` - `state` lives inside a CV; understanding how named vs anonymous subs differ explains per-closure state
- `use` - `use v5.10` and later enable the `state` feature as part of the version bundle
- `undef` - legal placeholder inside `state (...)` list declarations

Regular expressions and pattern matching

study

A no-op retained for source compatibility with older Perl code.

`study` accepts a scalar argument (or operates on `$_` when called with none) and does nothing with it. The call is valid, the argument is evaluated, and control returns immediately. No index is built, no regex engine state is altered, no later match runs any faster or slower because of it.

The name survives because decades of Perl code - books, FAQs, CPAN distributions, in-house scripts - sprinkle `study` in front of long strings about to be matched against many patterns. Those programs still parse and still run. They just no longer get the optimisation the keyword once promised.

Synopsis

```
study SCALAR
study
```

What you get back

Always 1. The return value is not documented as useful and no idiomatic code inspects it. Treat `study` as returning nothing worth capturing.

History

Through Perl 5.14 `study` built an inverted index of the bytes in `SCALAR`, then biased the regex engine to anchor each subsequent match on the rarest character in the pattern (rarity estimated from a static frequency table baked into the interpreter). The intended workload was "one long string, many `m//` against it": the index amortised across the matches.

The optimisation was removed in Perl 5.16. It interacted badly with Unicode, `/i` case folding, and the post-5.10 regex engine, and the maintenance cost had long outweighed the narrow workload it helped. The keyword was kept as a no-op so existing source kept compiling.

Examples

Legacy idiom - still parses, no longer has any effect:

```
study $big_text;
while ($big_text =~ /$pattern/g) {
    # ...
}
```

No argument - applied to `$_`, also a no-op:

```
for (@lines) {
    study;
    print if /error/;
}
```

Replacement guidance: if the original code relied on `study` for speed, the modern answer is to compile the pattern once with `qr` and reuse it, or to restructure so the repeated work is the pattern side, not the string side:

```
my $re = qr/$pattern/;
for my $line (@lines) {
    print $line if $line =~ $re;
}
```

Edge cases

- **No effect on regex performance.** Removing every `study` call from a program changes nothing observable, including timing beyond measurement noise.
- **Argument is still evaluated.** `study some_expensive_call()` runs `some_expensive_call()` for its side effects and return value, then discards the result. This is almost never what the author intended.
- **No warning on use.** `study` does not warn under `use warnings` and is not deprecated, so a linter is the only way to flag stale occurrences in a codebase.
- **Not a pragma, not a hint.** `study` is a regular built-in expression. It does not persist across statements and there is no "studied" state attached to the scalar.
- **Tainting and magic are untouched.** `study $tainted` does not launder taint, does not fire `FETCH` on a tied scalar more than a plain read would, and does not mark the scalar in any way.

Differences from upstream

Fully compatible with upstream Perl 5.44. `study` is a no-op in both.

See also

- `qr` - compile a pattern once and reuse the compiled form; this is the modern answer to "make many matches against the same text faster"
- `m` - the match operator whose performance `study` used to influence
- `index` - fixed-string search, faster than a regex when the pattern is a literal substring
- `pos` - where the last `/g` match left off, relevant to the "one long string, many matches" workload `study` once targeted

Control flow

sub

Declare or define a subroutine.

`sub` is the keyword that introduces a subroutine. With a `NAME` and a `BLOCK` it defines a named subroutine in the current package. Without a `BLOCK` it is a forward declaration. Without a `NAME` it is an anonymous sub expression that evaluates to a code reference - `sub { ... }` is the only form of `sub` that is actually an expression; the named forms are declarations and return nothing useful.

Synopsis

```
sub NAME BLOCK                  # named definition
sub NAME (PROTO) BLOCK          # with prototype
sub NAME : ATTRS BLOCK          # with attributes
sub NAME (PROTO) : ATTRS BLOCK  # prototype + attributes
```

(continues on next page)

(continued from previous page)

```
sub NAME;                                   # forward declaration
sub NAME (PROTO);                           # forward with prototype

my $ref = sub BLOCK;                        # anonymous, returns code ref
my $ref = sub (PROTO) : ATTRS BLOCK;        # anonymous with proto +␣
 ↪attrs

use feature 'signatures';
sub NAME ($x, $y = 0, @rest) BLOCK          # named with signature
my $ref = sub ($x, $y) BLOCK;               # anonymous with signature
```

What you get back

The **named** forms (`sub NAME BLOCK`, `sub NAME (PROTO) BLOCK`, etc.) are declarations. They install the subroutine into the current package's symbol table at compile time and contribute nothing to the surrounding expression. Writing `my $x = sub foo { 1 };` is a common mistake - that is two statements glued together, and `$x` is left undefined.

The **anonymous** form `sub BLOCK` is an expression. It evaluates - at the point the expression is reached at runtime, not at compile time - to a code reference closing over the lexical variables in scope. The same `sub { ... }` expression evaluated twice produces two distinct code references that share nothing:

```
my @refs = map { sub { $_ } } 1..3;     # three independent closures
```

Forward declarations (`sub NAME;` with no block) do nothing at runtime and return nothing. Their purpose is to announce the name to the parser so that later calls to it can parse without parentheses.

Global state it touches

- The current package (set by `package`) determines the fully-qualified name of a named sub. `sub foo { }` inside `package Acme;` installs `Acme::foo`, not `main::foo`.
- `@_` inside the body holds the argument list (aliased to the caller's scalars, except when a signature is in effect - see *Signatures* below). Assigning to `@_` as a whole breaks the aliasing for the rest of the call.
- `$_[N]` elements are aliases to the caller's scalars. Modifying `$_[0]` modifies the caller's variable; passing a literal and then modifying `$_[0]` is a fatal error.
- `wantarray` inside the body reflects the context the subroutine was called in.

Named definition

```
sub greet {
    my ($name) = @_;
    return "Hello, $name";
}

print greet("world"), "\n";             # Hello, world
```

The body is compiled at compile time. The name is visible from that point in the file onward; forward references inside the same package work because Perl defers method-style and bareword calls.

Redefining a named sub at runtime (`eval "sub foo { ... }"` or a second `sub foo { }` in the same package) replaces the previous definition and emits a `Subroutine foo redefined` warning under `use warnings`. Suppress it with `no warnings 'redefine'` for the scope of the redefinition.

Anonymous sub and closures

```
sub make_counter {
    my $n = 0;
    return sub { ++$n };
}

my $c = make_counter();
print $c->(), $c->(), $c->(), "\n";     # 123
```

The inner sub captures `$n` from its enclosing scope. Each call to `make_counter` creates a fresh `$n` and a fresh closure over it.

```
my @doublers = map { my $k = $_; sub { $k * 2 } } 1..3;
print $doublers[2]->(), "\n";           # 6
```

Note the intermediate `my $k = $_` - closures capture variables, not values, and `$_` is shared across the `map` iterations. Without the copy, every closure would see the last value of `$_`.

Signatures

With `use feature 'signatures'` (on by default under `use v5.36` and later), the parameter list appears between the name and the block, and arguments are bound to lexical variables automatically:

```
use feature 'signatures';

sub add ($x, $y) { $x + $y }

sub greet ($name, $greeting = "Hello") {
    return "$greeting, $name";
}
```

(continues on next page)

(continued from previous page)

```
sub log_all ($level, @msgs) {
    print "[$level] $_\n" for @msgs;
}
```

Signature forms:

- `$x` - required positional parameter.
- `$x = EXPR` - optional positional with default; `EXPR` is evaluated each call when the argument is missing.
- `$x = undef` - optional, defaults to `undef` (useful for documenting that a slot is nullable rather than omitted).
- `@rest` / `%rest` - slurpy, consumes all remaining arguments.
- `$` / `@` / `%` - unnamed placeholder, asserts arity without binding a variable.

Calling with the wrong arity croaks: `Too many arguments for subroutine` or `Too few arguments for subroutine`.

Under a signature, `@_` still exists but accessing it is a warning under `use warnings 'experimental::args_array_with_signatures'` in earlier Perls and discouraged in 5.44. Use the signature variables instead.

Prototypes

```
sub mypush (\@@) {
    my $aref = shift;
    push @$aref, @_;
}

my @a = (1, 2);
mypush @a, 3, 4;                    # @a is now (1, 2, 3, 4)
```

Prototypes are a **compile-time parser hint**, not a type check. They change how call sites are parsed: `\@` in the prototype above forces the first argument to be an array and passes a reference to it. See `prototype` to inspect a sub's prototype.

Prototypes do nothing when the sub is called via `&name(...)` or through a code reference. If you want a signature, use `use feature 'signatures'`; prototypes and signatures can coexist with the `:prototype(...)` attribute:

```
use feature 'signatures';
sub each_pair :prototype(\@) ($aref) { ... }
```

Attributes

Attributes appear after `:` and modify how the sub is compiled or registered:

```
sub critical :lvalue { $state }         # usable on the left of =
sub noop     :method { }                # marked as a method (for␣
↪some tools)
```

Common core attributes: `lvalue`, `method`, `prototype(...)`, `const`. Modules like `Attribute::Handlers` let a package define its own. Unknown attributes are a compile-time error.

Forward declaration

```
sub later;                              # announce the name
plan later(3);                          # now parses without parens
sub later { ... }                       # defined later in the file
```

A forward declaration is only useful to tell the parser that `later` is a subroutine so that `later ARG` parses as a call rather than an indirect-object construct or a comma expression. It is not required if you call with parentheses.

Examples

Named sub, explicit argument unpacking:

```
sub area {
    my ($w, $h) = @_;
    return $w * $h;
}
print area(3, 4), "\n";                 # 12
```

Anonymous sub passed to a higher-order function:

```
my @lengths = map { sub { length shift } }->(@_),
              ("alpha", "beta", "gamma");   # not quite - see below
```

More useful: passing a `sub` directly:

```
use List::Util qw(first);
my $first_even = first { $_ % 2 == 0 } 1, 3, 4, 7;   # 4
```

Implicit return - the value of the last expression is returned:

```
sub double { $_[0] * 2 }                # no return needed
print double(21), "\n";                 # 42
```

Context-sensitive return:

```
sub names {
    my @n = qw(alice bob carol);
    return wantarray ? @n : scalar @n;
}
```

(continues on next page)

(continued from previous page)

```
my @all = names();                          # ("alice","bob","carol")
my $n   = names();                          # 3
```

Modifying caller arguments via `@_` aliasing:

```
sub upcase_in {
    for (@_) { $_ = uc }
}
my $s = "hello";
upcase_in($s);
print $s, "\n";                             # HELLO
```

Recursion with `__SUB__` - a reference to the current sub without naming it:

```
use feature 'current_sub';
my $fact = sub {
    my $n = shift;
    $n < 2 ? 1 : $n * __SUB__->($n - 1);
};
print $fact->(5), "\n";                     # 120
```

Edge cases

- **A named sub definition is a statement, not an expression.** It contributes nothing to its enclosing expression. `my $x = sub foo {};` parses as two statements; `$x` ends up `undef`.
- **The `sub NAME BLOCK` forms are compile-time.** The block body is parsed and compiled when the enclosing file or `eval` is compiled. Side effects inside the block run only when the sub is *called*, not when it is defined. By contrast, `sub BLOCK` (anonymous) evaluates at runtime every time the expression is reached, producing a new closure each time.
- **Nested named subs close over nothing useful.** A `sub` defined inside another `sub` is still installed in the package at compile time and does **not** capture lexicals from the enclosing call. Each call to the outer sub sees the same inner sub, warped around the *first* call's lexicals. Use an anonymous sub for closures.
- **Trailing `return` is optional but explicit is clearer.** Without `return`, the value of the last *expression* is returned. If the last statement is a loop or a block, the return value is unspecified - do not rely on it.
- **Assigning to `@_` wholesale breaks aliasing.** `@_ = @_` or `@_ = (1, 2)` replaces the array and later `$_[0] = X` no longer reaches the caller.
- **Passing a literal then modifying `$_[0]` is fatal.** `upcase_in("x")` dies with `Modification of a read-only value attempted` because `$_[0]` is aliased to the literal.
- **Redefining a sub** emits `Subroutine X redefined` under `use warnings`. Wrapping a redefinition requires `no warnings 'redefine'` for the scope:

```
no warnings 'redefine';
*Foo::bar = sub { ... };
```

- **sub inside a BEGIN block** is defined at compile time of the surrounding unit, same as any sub declaration; the BEGIN wrapping does not change the timing of the declaration itself.
- **A prototype after a space gotcha.** `sub foo ($$)` with `use feature 'signatures'` is parsed as a signature, not a prototype. To attach a prototype under signatures, use `sub foo :prototype($$) ($x, $y) { ... }`.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `return` - explicit return from a sub; without it the last expression's value is returned
- `wantarray` - inspect the calling context (list / scalar / void) from inside the body
- `caller` - information about who called this sub and from where
- `prototype` - read back the prototype of a named or anonymous sub
- `__SUB__` - reference to the current sub without naming it; the tool for anonymous recursion
- `my` - the usual way to unpack `@_` into named lexicals when not using signatures
- `method` - class-syntax method declaration; `use feature 'class'` equivalent of `sub` for methods

SCALARs and strings

substr

Extract, replace, or alias a contiguous slice of a string.

`substr` picks out a run of characters from `EXPR` starting at `OFFSET` and spanning `LENGTH` characters, and returns that slice. The same call can also *modify* the original string in three distinct ways: as an lvalue on the left of `=`, through the four-argument `REPLACEMENT` form, or through an aliased lvalue stored in a variable that keeps tracking the slice across subsequent writes. Character zero is the first character. Negative `OFFSET` counts from the end; negative `LENGTH` stops that many characters short of the end. If `LENGTH` is omitted, the slice runs to the end of the string.

Synopsis

```
substr EXPR, OFFSET
substr EXPR, OFFSET, LENGTH
substr EXPR, OFFSET, LENGTH, REPLACEMENT
substr(EXPR, OFFSET, LENGTH) = NEWVALUE       # lvalue form
```

What you get back

In rvalue position, a new scalar containing the extracted slice. In lvalue position, a magic scalar that, when assigned to, splices the new value into `EXPR` at the recorded position - the returned scalar does **not** hold a copy of the original characters. The four-argument form assigns `REPLACEMENT` into `EXPR` in place and returns the substring that was there before, so the extract and the replace happen in one call.

If the requested span lies partially outside the string, only the in-bounds portion comes back. If it lies entirely outside the string, the rvalue forms return `undef` and warn; the lvalue forms raise an exception.

Global state it touches

None. `substr` is pure with respect to interpreter globals. It does not read or write `$_`, `$/`, `$\`, `$!`, or any other special variable. Warnings about out-of-range access are governed by the usual `use warnings` / `$^W` scope.

Positions and negative indices

`OFFSET` is measured from the start of the string when non-negative, and from the end when negative: `-1` is the position of the last character, `-2` the second-to-last, and so on.

`LENGTH`, when non-negative, is the number of characters to include. When negative, it is a right-anchor: the slice stops that many characters short of the end of the string. Omitting `LENGTH` is the same as "to the end."

```
my $s = "The black cat climbed the green tree";
my $color  = substr $s, 4, 5;       # "black"
my $middle = substr $s, 4, -11;     # "black cat climbed the"
my $end    = substr $s, 14;         # "climbed the green tree"
my $tail   = substr $s, -4;         # "tree"
my $z      = substr $s, -4, 2;      # "tr"
```

Using substr as an lvalue

If `EXPR` is itself an lvalue, `substr(EXPR, OFFSET, LENGTH)` can appear on the left-hand side of an assignment. The right-hand value replaces the slice. The replacement does not have to match `LENGTH`: a shorter replacement shortens the string, a longer one extends it.

```
my $name = 'fred';
substr($name, 0, 2) = 'SH';         # $name is now "SHed"
substr($name, 1, 2) = 'ayfiel';     # $name is now "Shayfield"
```

Assigning past the current end of the string is allowed, up to one position past the end (append-at-end). Any further and the assignment raises an exception.

```
my $name = 'fred';
substr($name, 4) = 'dy';            # $name is now "freddy"
substr($name, 7) = 'gap';           # exception
```

To keep the string length fixed, pad or truncate the replacement explicitly - for example with `sprintf "%-*s", $len, $val`.

The four-argument replacement form

`substr EXPR, OFFSET, LENGTH, REPLACEMENT` replaces the slice in place and returns the substring that *was* there. This is usually preferable to the lvalue form: the operation is a single expression, and the old value is available as the return value.

```
my $s = "The black cat climbed the green tree";
my $z = substr $s, 14, 7, "jumped from";    # $z is "climbed"
# $s is now "The black cat jumped from the green tree"
```

This mirrors the extract-and-replace idiom of `splice` on arrays.

The aliased-lvalue trick

The scalar returned by the three-argument form is **not** a copy of the characters - it is a magic bullet that remembers which region of the original string it refers to. Stashing that lvalue in a variable (via `for`, or `\` taken through an lvalue accessor) lets repeated writes keep splicing into the same slot of the original string, even as that string changes size:

```
my $x = '1234';
for (substr($x, 1, 2)) {
    $_ = 'a';    print $x, "\n";    # 1a4
    $_ = 'xyz';  print $x, "\n";    # 1xyz4
    $x = '56789';
    $_ = 'pq';   print $x, "\n";    # 5pq9
}
```

With a negative `OFFSET`, the alias tracks the end of the string:

```
my $x = '1234';
for (substr($x, -3, 2)) {
    $_ = 'a';    print $x, "\n";    # 1a4
    $x = 'abcdefg';
    print $_, "\n";                 # f
}
```

This is useful when repeatedly rewriting the same slot of a buffer (header fields in a fixed-layout record, for instance) - but it is also a classic source of surprises. Prefer the four-argument form unless you specifically want the aliasing.

Examples

Extract a fixed field from a record:

```
my $line = "2026-04-22  richard.jelinek\@example.com";
my $date = substr $line, 0, 10;          # "2026-04-22"
```

Strip a leading prefix of known length:

```
my $msg = "ERROR: disk full";
my $rest = substr $msg, length("ERROR: ");   # "disk full"
```

Overwrite a fixed field in place with the four-argument form, and keep the old value:

```
my $record = "name:       John      age: 42";
my $old    = substr $record, 12, 10, sprintf("%-10s", "Jane");
# $record is now "name:       Jane      age: 42"
# $old is "John      "
```

Walk a string in windows of three characters without copying the whole string each time:

```
my $s = "ABCDEFGH";
for (my $i = 0; $i + 3 <= length $s; $i++) {
    print substr($s, $i, 3), "\n";  # ABC BCD CDE DEF ...
}
```

Rewrite the last byte of a buffer repeatedly via an aliased lvalue:

```
my $buf = "packet: 0";
my $tail = \substr($buf, -1, 1);
$$tail = '1';  # $buf is now "packet: 1"
$$tail = '2';  # $buf is now "packet: 2"
```

Edge cases

- **Out-of-range rvalue, partially in bounds**: returns just the in-bounds portion, no warning.

  ```
  my $s = "abcd";
  substr($s, 2, 100);                  # "cd"
  ```

- **Out-of-range rvalue, entirely past the end**: returns `undef` and warns under `use warnings`. The empty-tail case (exactly at the end) returns `""` without a warning:

  ```
  my $name = 'fred';
  my $null = substr $name, 4, 2;       # "" (no warning)
  my $oops = substr $name, 7;          # undef, with warning
  ```

- **Out-of-range lvalue**: raises an exception. `substr` refuses to silently extend the string by a gap of unspecified contents.
- **Negative `OFFSET` larger than the string**: counts as "before the start", and is clamped to position `0` in current Perls; under `use warnings` this issues a "substr outside of string" warning in some versions. Prefer to clamp explicitly.
- **Negative `LENGTH` that exceeds the remaining tail**: yields an empty string, because the right anchor falls at or before the left anchor.

  ```
  my $s = "abcde";
  substr($s, 1, -10);                  # ""
  ```

- **Unicode**: `substr` operates in characters, not bytes. On a string with the UTF-8 flag on, positions count codepoints; on a byte string, positions count bytes. Mixing the two by treating a decoded string as a byte buffer produces wrong offsets - decode first, then index.
- **Tied or magical scalars**: lvalue `substr` honours `STORE`-time magic on the target, so tied variables see the mutated whole string, not the slice.
- **Aliased lvalue kept beyond its target's lifetime**: if the original variable goes out of scope while the alias is still alive, later writes through the alias act on a freed string; keep the alias lifetime inside the target's.
- **Pre-5.10 corner**: repeated writes through a single lvalue had unspecified behaviour in older perls, as did negative offsets before 5.16. Modern Perl (and pperl) follow the semantics documented on this page.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `index` - find the position of a substring, to feed into `substr` as `OFFSET`
- `rindex` - same, searching from the right
- `length` - the upper bound on any meaningful `OFFSET` or `LENGTH` you pass to `substr`
- `splice` - the array-level analogue of the four-argument replacement form
- `pack` / `unpack` - for fixed-layout records where many fields are read or rewritten in one shot, prefer these over a chain of `substr` calls
- `tr///` - bulk character-level substitution that doesn't need positional indices

Filehandles, files, directories

symlink

Create a symbolic link at `NEWFILE` that points at the string `OLDFILE`.

`symlink` is the thin wrapper around the POSIX `symlink(2)` system call. It does not copy anything, does not read `OLDFILE`, and does not require `OLDFILE` to exist. It writes a new directory entry at `NEWFILE` whose payload is the literal bytes of `OLDFILE`, and the kernel later resolves that payload whenever something opens, stats, or traverses the link.

Synopsis

```
symlink OLDFILE, NEWFILE
```

What you get back

1 on success, `0` on failure (with `$!` set). On systems that do not support symbolic links at all, `symlink` raises an exception rather than returning `0`. To probe for support at runtime without dying, wrap a harmless call in `eval`:

```
my $symlink_exists = eval { symlink("", ""); 1 };
```

The `eval` pattern is the idiomatic capability check - it runs a no-op `symlink` whose only job is to fail cheaply on platforms where the call exists, and to throw on platforms where it does not.

How symlinks differ from hard links

A symlink and a hard link (`link`) look similar from the shell but behave very differently:

- `link` creates a second directory entry pointing at the same inode. Both names are equal; deleting either one leaves the file alive under the other.
- `symlink` creates a tiny file of type `lnk` whose contents are a *pathname*. The target is resolved by name at every lookup. The two names are **not** equal - the symlink has its own inode, its own permissions bits (mostly ignored), and its own timestamps.

Practical consequences:

- `OLDFILE` is stored **verbatim**. It is not canonicalised, not resolved against the current working directory, and not checked for existence. A symlink can be created pointing at a path that does not exist yet (a *dangling* symlink) and will start working the moment the target appears.
- Because `OLDFILE` is just a string, it can be relative. Relative symlink targets are resolved at lookup time relative to the directory containing `NEWFILE`, **not** the process's current working directory. This is the single biggest source of surprise.
- Symlinks can cross filesystem boundaries. Hard links cannot.
- Symlinks can point at directories. Hard links to directories are forbidden on every mainstream Unix.
- `unlink` on a symlink removes the **link**, not the target. To remove the target, unlink the target's path directly.

Examples

Create a symlink to an existing file:

```
symlink "/etc/hostname", "hostname.lnk"
    or die "symlink failed: $!";
```

Dangling symlink - the target does not exist yet, and that is fine:

```
symlink "/will/appear/later", "pending.lnk"
    or die "symlink failed: $!";
# opening pending.lnk now fails with ENOENT;
# it will start working once /will/appear/later exists.
```

Relative target resolved against the link's directory, not the cwd:

```
chdir "/var/log" or die $!;
symlink "syslog", "/tmp/current.lnk"
    or die "symlink failed: $!";
# readlink("/tmp/current.lnk") eq "syslog"
# opening /tmp/current.lnk resolves syslog in /tmp, not /var/log.
```

Symlink to a directory - this works, unlike `link`:

```
symlink "/var/log", "logs"
    or die "symlink failed: $!";
opendir my $dh, "logs" or die $!;   # traverses the symlink
```

Inspect and remove a symlink without touching its target:

```
my $target = readlink "hostname.lnk";   # the stored OLDFILE string
unlink "hostname.lnk" or die $!;        # removes the link only
# /etc/hostname is untouched.
```

Atomic-swap pattern - replace a symlink pointing at the "current" release directory by writing a new symlink and renaming over it:

```
symlink "release-2", "current.new"  or die $!;
rename  "current.new", "current"    or die $!;
# rename over an existing symlink is atomic on POSIX filesystems.
```

Edge cases

- **`OLDFILE` is stored verbatim.** No normalisation, no resolution, no existence check. `symlink "", "foo"` succeeds on most systems and creates an empty-target symlink that every lookup rejects with `ENOENT`. This is why the capability-probe idiom uses `("", "")` - a cheap call that always fails on supporting platforms.
- **Relative `OLDFILE`** is resolved relative to the directory of `NEWFILE`, not the current working directory. If you build `NEWFILE` from a relative path, think carefully about what directory the kernel will see it in.
- **`NEWFILE` already exists** → failure with `$!` set to `EEXIST`. There is no "replace" flag; to overwrite, write to a fresh name and `rename` over the old one (atomic).
- **Permissions on the symlink itself** are almost always ignored. The kernel enforces the permissions of the *target*. On most filesystems the symlink is reported as `lrwxrwxrwx` regardless of what `chmod` is called on it.
- **`stat` follows symlinks, `lstat` does not.** To examine the link itself - its type, its link count, the length of its target string - use `lstat`. To examine what the link points at, use `stat`.
- **`unlink` removes the link, not the target.** There is no way to delete the target through the symlink except by resolving it first.
- **Platforms without symlink support** raise an exception on any call, even one that would otherwise fail. Use the `eval` probe shown above rather than assuming a return value.

- **Filesystems without symlink support** (some FAT variants, certain network mounts) fail with `EPERM` or `EOPNOTSUPP` even on a kernel that implements `symlink(2)`. Check `$!` on failure rather than assuming the call was rejected for the obvious reason.
- **Symlink loops** are not detected at creation time. `symlink "a", "b"` followed by `symlink "b", "a"` succeeds; the loop only surfaces when something tries to resolve either name, which fails with `ELOOP` after the kernel hits its chase limit (typically 40).

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `link` - create a hard link (same inode, same filesystem, file only); the strict counterpart to `symlink`
- `readlink` - read the `OLDFILE` string stored in a symlink without resolving it
- `lstat` - stat the symlink itself rather than its target; the only way to see that a path is a symlink from Perl
- `stat` - stat what the symlink points at, following the chain of links
- `unlink` - remove a symlink (the link, not the target); also the way to remove a dangling symlink
- `$!` - `errno` set on failure; inspect it to distinguish `EEXIST`, `EPERM`, `EOPNOTSUPP`, `ENOENT` on the parent directory

I/O · Fixed-length data

syscall

Invoke a raw system call by its kernel number, passing the remaining arguments as `int` or as a pointer to a string buffer.

`syscall` is the escape hatch for operating-system calls the rest of the language does not wrap. The first argument is the syscall number - on Linux, the value of `SYS_<name>` from `syscall.ph`. Each remaining argument is passed either as an integer (if Perl already considers it numeric) or as a pointer to the scalar's string buffer. It returns whatever the kernel returns. On failure it returns `-1` and sets `$!`.

Synopsis

```
syscall NUMBER, LIST
```

What you get back

Whatever the kernel returned. Success values are syscall-specific - often a byte count, a file descriptor, or `0`. Failure is `-1` with `$!` set to the errno value.

Some syscalls (`lseek`, `read` on a pipe at EOF with errors, `ptrace`) can legitimately return `-1` on success. To tell them apart from failures, clear `$!` before the call:

```
$! = 0;
my $r = syscall(SYS_lseek(), fileno($fh), 0, 1);
die "lseek: $!" if $r == -1 && $! != 0;
```

Global state it touches

- `$!` - set when the kernel returns `-1`. Not touched on success.

Argument passing rules

Each argument in `LIST` is inspected at call time:

- **Numeric** argument (a literal number, or a scalar that has been used in a numeric context) - passed as a C `int`.
- **Non-numeric** argument - the scalar's string buffer is passed by pointer. You are responsible for pre-extending the buffer to hold any data the kernel might write. A too-short buffer is a memory corruption bug, not a Perl error.
- **Read-only string** (a literal, a `__DATA__` string, anything Perl refuses to write through) - rejected, because `syscall` has to assume any string pointer might be written through.
- **Integer stored as a string** (e.g. a value read from a file that was never used arithmetically) - may be passed as a pointer rather than an int. Force numeric interpretation by adding `0`:

  ```
  syscall(SYS_write(), 0 + $fd, $buf, length $buf);
  ```

Up to 14 arguments are supported after the syscall number.

Examples

Write a buffer to `STDOUT` using the raw `write(2)` syscall:

```
require 'syscall.ph';
my $s = "hi there\n";
syscall(SYS_write(), fileno(STDOUT), $s, length $s);
```

Pre-extend a buffer before a read:

```
require 'syscall.ph';
my $buf = "\0" x 4096;                # 4 KiB writable buffer
my $n = syscall(SYS_read(), fileno($fh), $buf, 4096);
die "read: $!" if $n == -1;
substr($buf, $n) = '';                # trim to actual bytes read
```

Call `gettid(2)` to get the kernel thread id (no libc wrapper on older glibc):

```
require 'syscall.ph';
my $tid = syscall(SYS_gettid());
```

Distinguish a legitimate `-1` return from a real failure:

```
$! = 0;
my $off = syscall(SYS_lseek(), fileno($fh), 0, 1);   # SEEK_CUR
if ($off == -1 && $! != 0) {
    die "lseek failed: $!";
}
```

Force a stringified integer to be passed as `int`:

```
my $fd = read_config("fd");           # returns "3"
syscall(SYS_close(), 0 + $fd);        # without "0 +" it'd pass a␣
↪pointer
```

Edge cases

- **`syscall.ph` missing**: `require 'syscall.ph'` fails unless `h2ph` has been run against the system headers. Without it the `SYS_*` constants are undefined and calls become hand-maintained magic numbers.
- **Read-only argument**: passing a string literal or other read-only scalar croaks with `Modification of a read-only value`. Copy into a lexical first: `my $s = "literal"; syscall(..., $s, ...)`.
- **Buffer too short**: the kernel will happily write past the end of a scalar's buffer if you lied about the length. This corrupts the Perl heap. Always pre-extend with `$buf = "\0" x $n` or `vec($buf, $n-1, 8) = 0` before the call, and never pass `length $buf` larger than the actual capacity.
- **Argument count ceiling**: 14 arguments after `NUMBER`. Syscalls that take more (rare) are not reachable via `syscall`.
- **`SYS_pipe()` on Linux**: the raw syscall returns the read-end fd but gives you no handle on the write-end fd. Use `pipe` instead, which exposes both.
- **64-bit values on 32-bit platforms**: some syscalls take 64-bit arguments (offsets, sizes) that do not fit in a Perl `int` on 32-bit builds. There is no portable way to pass them through `syscall` - use a dedicated wrapper (`Fcntl::lseek`, `sysseek`, etc.) or a CPAN binding.
- **Unimplemented**: on platforms without a `syscall(2)` entry point (or when built without support), `syscall` raises `The syscall function is unimplemented`.
- **Signal interruption**: a syscall interrupted by a signal returns `-1` with `$!` set to `EINTR`. `syscall` does not restart automatically - retry in user code if needed.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `syswrite` - buffered-bypass write through a Perl filehandle; almost always what you want instead of `syscall(SYS_write(), ...)`
- `sysread` - buffered-bypass read; pairs with `syswrite` and handles buffer management for you
- `sysopen` - `open(2)` with the full flag vocabulary, without needing the raw syscall
- `pipe` - the right way to create a pipe; avoids the `SYS_pipe()` write-end problem
- `pack` - build the binary structs (`struct timeval`, `struct stat`, etc.) that syscalls expect in pointer arguments
- `unpack` - decode the binary structs a syscall writes into your buffer

Filehandles, files, directories

sysopen

Open a file the low-level way, passing an integer `MODE` bitmask straight through to the underlying `open(2)` system call.

`sysopen` is the escape hatch for when `open`'s string-mode DWIM is in your way - when you need `O_EXCL` for an atomic create-if-not-exist, `O_NOFOLLOW` to refuse symlinks, `O_NONBLOCK` on a FIFO, or any other flag that has no corresponding `"<"` / `">"` / `">>"` string. The flag constants live in `Fcntl` and are combined with `|`.

Synopsis

```
sysopen FILEHANDLE, FILENAME, MODE
sysopen FILEHANDLE, FILENAME, MODE, PERMS
```

What you get back

1 on success, `undef` on failure (with `$!` set to the `errno` from the failed syscall). Unlike `open`, there is no magic - `FILENAME` is taken literally, no leading `>`, `<`, `|`, or `-` is interpreted, no layered mode string is parsed.

If `FILEHANDLE` is an undefined scalar, it is autovivified into a fresh handle:

```
sysopen my $fh, $path, O_RDONLY
    or die "sysopen $path: $!";
```

MODE - the Fcntl bitmask

MODE is an integer built by OR-ing constants from Fcntl. The access mode is mandatory and mutually exclusive; the modifier flags are optional and combined freely:

Flag	Meaning
O_RDONLY	Open for reading only.
O_WRONLY	Open for writing only.
O_RDWR	Open for reading and writing.
O_CREAT	Create the file if it does not exist.
O_EXCL	With O_CREAT: fail if the file already exists.
O_APPEND	Every write seeks to end-of-file first (atomic append).
O_TRUNC	Truncate the file to zero length on open.
O_NONBLOCK	Non-blocking mode for the resulting descriptor.
O_NOFOLLOW	Fail with ELOOP if the final path component is a symlink.

Import them by name or with a tag:

```
use Fcntl qw(O_RDWR O_CREAT O_EXCL O_APPEND);
# or
use Fcntl ':DEFAULT';
```

The legacy values 0, 1, 2 for read-only, write-only, read-write also work on every system Perl supports, but name the constants - the resulting code survives cross-platform review and reads without a glossary.

PERMS - the create-time permission bits

PERMS is an octal mode (like chmod takes) applied to the inode **only when O_CREAT actually creates the file**. If PERMS is omitted, Perl passes 0666. The process umask is applied by the kernel on top, so a default umask of 022 yields 0644 on disk.

```
sysopen my $fh, $path, O_WRONLY | O_CREAT | O_EXCL, 0600
    or die "create $path: $!";
```

Do not write 0644 as the PERMS argument without a reason. A hard-coded 0644 strips group-write even from users who deliberately set a permissive umask; 0666 plus the user's umask is the portable default and is what sysopen uses when you omit the argument entirely.

Global state it touches

- $! - set on failure to the errno returned by open(2).
- ${^OPEN} - the open pragma's layer configuration. sysopen applies the **same** default PerlIO stack open would apply for a layer-less call. Use binmode immediately after a successful sysopen when you need to override or strip layers (typical for binary files, sockets-as-files, or O_NONBLOCK descriptors).
- Process umask - masks PERMS when O_CREAT creates the file.

Examples

Atomic create-if-not-exist - the canonical reason to reach for `sysopen`:

```
use Fcntl qw(O_WRONLY O_CREAT O_EXCL);
sysopen my $fh, "lock.pid", O_WRONLY | O_CREAT | O_EXCL, 0644
    or die "another instance is already running: $!";
print $fh "$$\n";
close $fh;
```

Open-or-create for read/write, preserving existing contents:

```
use Fcntl qw(O_RDWR O_CREAT);
sysopen my $fh, $path, O_RDWR | O_CREAT, 0666
    or die "sysopen $path: $!";
```

Append-only log with the append guarantee - every write lands at EOF regardless of interleaving with other writers:

```
use Fcntl qw(O_WRONLY O_CREAT O_APPEND);
sysopen my $log, "/var/log/app.log", O_WRONLY | O_CREAT | O_APPEND,␣
↪0644
    or die "open log: $!";
print $log "startup\n";
```

Open a FIFO without blocking on the reader-side handshake:

```
use Fcntl qw(O_RDONLY O_NONBLOCK);
sysopen my $fifo, "/tmp/q", O_RDONLY | O_NONBLOCK
    or die "sysopen fifo: $!";
```

Refuse to follow a symlink at the leaf - useful in directories writable by untrusted users:

```
use Fcntl qw(O_RDONLY O_NOFOLLOW);
sysopen my $fh, "$dir/config", O_RDONLY | O_NOFOLLOW
    or die "sysopen config: $!";
```

Force byte-level I/O after opening - strip any `:utf8` or `:crlf` layer the default PerlIO stack would otherwise install:

```
sysopen my $fh, $path, O_RDONLY or die $!;
binmode $fh;
```

Edge cases

- **`O_EXCL` without `O_CREAT` is a no-op.** The exclusivity check only triggers when `O_CREAT` asks the kernel to create the file. Always write them together: `O_CREAT | O_EXCL`.
- **`O_EXCL` is not a lock.** It prevents a successful open on an already-existing file, nothing more. Once the file exists, every subsequent `sysopen` with `O_CREAT | O_EXCL` fails. It does not serialize access to the contents - use `flock` for that.

- **O_EXCL on network filesystems.** NFS implementations vary; older NFS versions silently lose the exclusive semantics. Do not rely on O_EXCL across NFSv2.
- **O_CREAT | O_EXCL and symlinks.** With both flags set, the kernel refuses to open a pre-existing symlink at the final path component. It does **not** protect intermediate path components; use O_NOFOLLOW or resolve the directory with opendir plus openat semantics if you need that.
- **O_TRUNC with O_RDONLY.** Behavior is undefined by POSIX. Do not combine them.
- **Omitted PERMS.** The default is 0666, masked by umask. It is **not** 0644. Omit PERMS unless you actively want to override the user's umask.
- **FILEHANDLE as expression.** If FILEHANDLE is a bareword, it names a package global. If it is an expression evaluating to a glob, globref, or IO::Handle, that handle is opened. If it is an undefined scalar, a fresh handle is autovivified into it - the lexical form used throughout these examples.
- **No magic on FILENAME.** A FILENAME of "-" opens a file literally named -, not STDIN. A leading > opens a file literally named >filename, not a write to filename. This is the entire point of sysopen versus open.
- **Default PerlIO layers still apply.** sysopen is "low-level" relative to the mode string, not relative to PerlIO. The resulting handle has the same layer stack as a layer-less open; call binmode to change it.
- **Closed or invalid FILEHANDLE expression.** Returns undef with $! set (typically EBADF for a bad existing descriptor; ENOENT, EACCES, EEXIST, ELOOP for the path-level errors).

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- open - higher-level opener with string-mode parsing, pipes, - as STDIN / STDOUT, and layered modes; use it unless you specifically need a flag sysopen exposes
- fcntl - change flags on an already-open descriptor (e.g. set O_NONBLOCK after the fact); shares the Fcntl constant vocabulary
- sysread - unbuffered read; works on any handle, not just one obtained from sysopen, despite the name
- syswrite - unbuffered write, same note
- Fcntl - the module that exports O_* constants and the :DEFAULT / :flock / :mode tags
- binmode - set or strip PerlIO layers on the handle after opening
- umask - the process mask that subtracts bits from PERMS when O_CREAT creates the file

I/O · Fixed-length data

sysread

Read raw bytes from a filehandle by calling the underlying `read(2)` system call.

`sysread` tries to read `LENGTH` bytes from `FILEHANDLE` and store them in `SCALAR`. It bypasses the PerlIO buffering stack, which is the whole point - reads go straight to the kernel and return whatever a single `read(2)` returns, which may be fewer bytes than requested. Use it for sockets, pipes, devices, and any other situation where you want control over individual system calls rather than line- or record-oriented input.

Synopsis

```
sysread FILEHANDLE, SCALAR, LENGTH
sysread FILEHANDLE, SCALAR, LENGTH, OFFSET
```

What you get back

- The number of bytes actually read, which may be **less than** `LENGTH` on sockets, pipes, ttys, and during signal interruption.
- `0` at end of file.
- `undef` on error, with `$!` set to the `errno` from the failed `read(2)`.

`SCALAR` is grown or shrunk so that the last byte read becomes the last byte of the scalar. After a short read, the scalar holds only the bytes that were actually received - nothing is zero-padded to `LENGTH`.

```
my $n = sysread $sock, my $buf, 4096;
defined $n           or die "read failed: $!";
$n == 0              and return;          # peer closed
process_chunk($buf);                      # length($buf) == $n
```

Global state it touches

- `$!` - set when `sysread` returns `undef`. Interrupted reads show up as `EINTR`; would-block reads on non-blocking handles show up as `EAGAIN` / `EWOULDBLOCK`.
- `SCALAR` itself - always assigned to, even on failure (it is truncated to `OFFSET` bytes when `OFFSET` is given and the read fails or returns zero).
- The filehandle's byte position advances by the number of bytes returned; this is the same kernel-level position manipulated by `sysseek`.

`sysread` does not consult or touch `$/`, `$\`, `$,`, or `$_`. It is a byte-level primitive; record semantics do not apply.

OFFSET - where the bytes land inside SCALAR

Without `OFFSET`, `SCALAR` is replaced by the bytes read.

With `OFFSET`, the bytes are written **into** `SCALAR` starting at that position:

- `OFFSET >= 0` - start writing at byte `OFFSET`. If `OFFSET` is greater than the current length of `SCALAR`, the string is first padded with `"\0"` bytes up to `OFFSET`, then the new data is appended.
- `OFFSET < 0` - counted backwards from the end of `SCALAR`. `-1` means "overwrite the last byte", `-10` means "overwrite the last 10 bytes".

This is how you grow a buffer incrementally without repeatedly concatenating:

```
my $buf = "";
while ((my $n = sysread $fh, $buf, 8192, length $buf) > 0) {
    # each call appends at the current end of $buf
}
defined $n or die "read failed: $!";
```

Examples

Read up to 64 bytes from a file. `$buf` ends up exactly `$n` bytes long:

```
open my $fh, "<", "input.bin" or die $!;
my $n = sysread $fh, my $buf, 64;
defined $n or die "sysread: $!";
```

Read up to 32 bytes and place them starting at position 512 in `$buf`, padding with `"\0"` if `$buf` was shorter:

```
my $buf = "header";
my $n = sysread $fh, $buf, 32, 512;   # $buf is now 512 + $n bytes
```

Drain a socket until the peer closes. Checking for `0` - not `eof` - is the only correct end-of-stream test for `sysread`:

```
while (1) {
    my $n = sysread $sock, my $chunk, 4096;
    defined $n or die "read: $!";
    last if $n == 0;                  # orderly shutdown from peer
    handle($chunk);
}
```

Restart a read interrupted by a signal. On a blocking handle, `EINTR` is the one failure you typically retry rather than propagate:

```
use Errno qw(EINTR);
my $n;
RETRY: {
    $n = sysread $fh, my $buf, $want;
    redo RETRY if !defined $n && $! == EINTR;
}
defined $n or die "read: $!";
```

Fill a fixed-size record, tolerating short reads. A single `sysread` can return fewer bytes than asked for even on a regular file near EOF, and routinely does on sockets and pipes:

```
sub read_exact {
    my ($fh, $want) = @_;
    my $buf = "";
    while (length($buf) < $want) {
        my $n = sysread $fh, $buf, $want - length($buf), length
↪$buf;
        defined $n        or die "read: $!";
        $n == 0 and die "short read: got ", length $buf, " of $want
↪";
    }
    return $buf;
}
```

Edge cases

- **Never mix with buffered I/O on the same handle.** `readline`, `read`, `<$fh>`, `getc`, `eof`, `seek`, and `tell` all go through PerlIO buffers; `sysread` goes around them. Interleaving them on the same handle leaves data stranded in the buffer that `sysread` will never see, or skips over data the buffered reader already consumed. Use one style per handle.
- **`:utf8` is forbidden.** A handle with a `:utf8` layer (including the implicit layer added by `:encoding(...)`) makes `sysread` throw an exception. Strip the layer with `binmode` - `binmode $fh` with no second argument restores raw bytes - before calling `sysread`.
- **`:crlf` / `:perlio` still buffer.** Even without `:utf8`, the default `:perlio` stack buffers reads and translates line endings under `:crlf`. `sysread` ignores those layers, so bytes the buffered reader already pulled into the PerlIO buffer are silently lost to `sysread`. Open handles destined for `sysread` with `sysopen` or call `binmode $fh` to disable `:crlf`.
- **Short reads are normal, not errors.** A return of `$n` with `0 < $n < LENGTH` is success. Only `undef` indicates failure; `0` indicates EOF. Loop until you have what you need.
- **No `syseof`.** There is no separate end-of-file test for `sysread`; `eof` looks at the PerlIO buffer and is meaningless here. The return value of `0` is the end-of-file signal.
- **`OFFSET` beyond current length.** `sysread $fh, $buf, 10, 1_000_000` pads `$buf` with a million `"\0"` bytes before writing. This is occasionally useful for preallocating, but usually a bug.
- **Negative `OFFSET`** counts from the current end of `SCALAR`, not from `LENGTH`. `sysread $fh, $buf, 4, -4` overwrites the last four bytes of whatever `$buf` currently holds.
- **Non-blocking handles.** On a handle with `O_NONBLOCK` set, a read with nothing available returns `undef` with `$!` equal to `EAGAIN` or `EWOULDBLOCK`. Treat that as "try again later", not as an error.
- **Signals.** A blocking `sysread` interrupted by a signal returns `undef` with `$!` equal to `EINTR`. Retry the call.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `syswrite` - the write-side counterpart; same buffering rules, same short-I/O semantics
- `sysopen` - opens a handle with raw `open(2)` flags, the natural partner for `sysread` on files
- `sysseek` - byte-accurate seek that composes correctly with `sysread`; do not mix `seek` with `sysread`
- `read` - the buffered counterpart; use it for line- and record-oriented input, not for sockets or partial reads
- `binmode` - strip `:utf8` or `:crlf` from a handle before using `sysread`
- `$!` - the `errno` value after a failed `sysread`, including `EINTR`, `EAGAIN`, and `EWOULDBLOCK`

I/O · Fixed-length data

sysseek

Reposition a filehandle at the system level, bypassing PerlIO buffering.

`sysseek` moves `FILEHANDLE`'s kernel file-descriptor offset to a new byte position by calling the underlying `lseek(2)` directly. It is the companion of `sysread` and `syswrite`: the three form the unbuffered I/O family, which talks to the kernel without going through Perl's `:perlio` or stdio-like buffer stack. Use `sysseek` on handles you access with the sys-family; use `seek` on handles you access with `read`, `readline`, or `print`.

Synopsis

```
sysseek FILEHANDLE, POSITION, WHENCE
sysseek $fh, 0, 0              # rewind to start
sysseek $fh, 0, 1              # report current position
sysseek $fh, -1024, 2          # 1024 bytes before EOF
```

What you get back

The new absolute byte offset on success, or `undef` on failure (with `$!` set). A position of zero is returned as the dualvar string `"0 but true"` so that the value prints as `0` in numeric context yet remains truthy in boolean context - a check like `if (sysseek ...)` is safe at offset zero.

```
defined(sysseek $fh, $offset, 0)
    or die "sysseek to $offset failed: $!";
```

Because the return value carries the new offset, `sysseek` doubles as a "where am I" primitive - the reason the idiomatic `systell` is one line:

```
use Fcntl 'SEEK_CUR';
sub systell { sysseek($_[0], 0, SEEK_CUR) }
```

WHENCE values

`WHENCE` is an integer with three meaningful values. Prefer the symbolic constants from `Fcntl` - they also make the call portable to platforms that do not use `0` / `1` / `2`:

- `0` / `SEEK_SET` - `POSITION` is measured from the **start of the file**. `POSITION` must be non-negative.
- `1` / `SEEK_CUR` - `POSITION` is added to the **current position**. Negative values move backward, positive values forward. `sysseek $fh, 0, 1` returns the current offset without moving the pointer.
- `2` / `SEEK_END` - `POSITION` is added to the **end-of-file** offset. `POSITION` is typically zero or negative.

```
use Fcntl qw(SEEK_SET SEEK_CUR SEEK_END);

sysseek $fh, 0,   SEEK_SET;    # rewind
sysseek $fh, 0,   SEEK_END;    # move to EOF
sysseek $fh, -$n, SEEK_CUR;    # $n bytes back from here
```

Bytes, not characters

`sysseek` operates on **byte offsets**, always. Even when the handle has a character-oriented layer such as `:encoding(UTF-8)`, the offset it accepts and returns is a raw byte count. This matches the kernel view but is irrelevant in practice: `sysseek` is meant for handles that do not use PerlIO layers, and mixing it with a decoding layer is one of the confusion traps listed below.

If the data is character-oriented, use `seek` and `tell` on the buffered side instead of `sysseek`.

Do not mix with buffered I/O

`sysseek` talks directly to the file descriptor. `read`, `readline`, `print`, `write`, `seek`, `tell`, and `eof` talk to the PerlIO buffer sitting in front of the descriptor. The buffer's position and the kernel's position are independent - a `sysseek` moves the kernel pointer but does not flush or invalidate the buffer, so the next buffered read returns stale bytes from before the `sysseek`, and the next buffered write lands wherever the buffer thought it was.

The rule is simple: pick one family per handle.

- Handle used with `sysread` / `syswrite` → reposition with `sysseek`.
- Handle used with `read` / `print` / `readline` → reposition with `seek`.

Global state it touches

- `$!` - set to the system error message on failure.
- Unlike `seek`, `sysseek` does **not** flush or discard the PerlIO buffer and does **not** clear the EOF flag on the handle. That asymmetry is the source of the "mixing" hazard above and the reason the two families must not share a handle.

Examples

Random-access read of a fixed-length record. The file holds 128-byte records; jump straight to record 42:

```
use Fcntl 'SEEK_SET';
sysopen my $fh, $path, O_RDONLY or die $!;
sysseek $fh, 42 * 128, SEEK_SET or die "sysseek: $!";
sysread $fh, my $rec, 128       or die "sysread: $!";
```

Report the current offset without moving the pointer - the `systell` idiom:

```
use Fcntl 'SEEK_CUR';
my $pos = sysseek $fh, 0, SEEK_CUR;
defined $pos or die "sysseek: $!";
print "at byte $pos\n";
```

Append to a file held open for read-write, then rewind to replay from the start:

```
use Fcntl qw(SEEK_SET SEEK_END);
sysseek $fh, 0, SEEK_END or die $!;
syswrite $fh, $record     or die $!;
sysseek $fh, 0, SEEK_SET or die $!;
```

Zero is still true - the dualvar lets you write the terse form without accidentally treating a successful rewind as a failure:

```
if (my $pos = sysseek $fh, 0, 0) {
    # entered even when $pos stringifies to "0"
    printf "rewound; pos=%d\n", $pos;
}
else {
    die "sysseek failed: $!";
}
```

Seek past end-of-file to create a sparse hole, then write the tail marker:

```
use Fcntl 'SEEK_SET';
sysseek $fh, 1_000_000, SEEK_SET or die $!;
syswrite $fh, "END"               or die $!;
```

Edge cases

- **Unseekable handles**: pipes, sockets, TTYs, and most special devices fail with `$!` set to `ESPIPE` (`Illegal seek`). The return value is `undef`; always check with `defined`.
- **Do not mix with buffered I/O on the same handle**. `sysseek` bypasses the PerlIO buffer; `read`, `readline`, `print`, `write`, `seek`, `tell`, and `eof` use it. Interleaving the two families produces silently wrong results. Pick one family per handle and stay with it.
- **Zero stringifies as `"0 but true"`**. Boolean tests work at offset zero - `if (sysseek ...)` stays truthy - but string comparisons against the literal `"0"` do not:

```
my $pos = sysseek $fh, 0, 0;
$pos == 0     or die;           # true
$pos eq "0"   and die "nope";   # false - the string is "0 but
 ↪true"
```

  Use `defined` for success/failure detection and numeric comparison for the offset value.
- **Encoding layers**: `sysseek` on a handle with an `:encoding(...)` layer is almost always a mistake - the byte offset can land mid codepoint, and the sys-family is meant for raw bytes anyway. If the data needs decoding, use `seek` with the buffered family.
- **Negative offsets with `SEEK_SET`**: `POSITION` must be non-negative when `WHENCE` is `0`. A negative value fails with `EINVAL`.
- **Very large files**: `sysseek` returns the kernel's full 64-bit offset; positions beyond 2 GiB round-trip correctly through subsequent `sysseek` calls on all supported 64-bit builds.
- **Closed filehandle**: returns `undef` and sets `$!`; under `use warnings` a `sysseek() on closed filehandle` warning is emitted.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `seek` - buffered counterpart; use it on handles accessed via `read`, `readline`, or `print`
- `sysread` - the unbuffered read paired with `sysseek`; both skip PerlIO and speak directly to the file descriptor
- `syswrite` - the unbuffered write; the third member of the family that belongs on the same handle as `sysseek`
- `sysopen` - opens a handle at the descriptor level, the usual way to get a handle you will later drive with the sys-family

- `tell` - buffered-side current-offset query; pair it with `seek`, not with `sysseek`
- `Fcntl` - source of the `SEEK_SET`, `SEEK_CUR`, `SEEK_END` constants

Processes

system

Run a separate program and wait for it to finish.

`system` does exactly the same thing as `exec`, except that a `fork` is done first and the parent process waits for the child to exit. The return value is the wait status of the child, not its output - if you want the output of a command, use backticks or `qx//` instead.

Synopsis

```
system LIST
system PROGRAM LIST
```

The indirect `PROGRAM LIST` form lies to the program about its own name: `PROGRAM` is the file actually executed, while the first element of `LIST` becomes `argv[0]` inside the child. Same trick as `exec`.

What you get back

The return value is the raw status word from the underlying `wait` call - the same value that lands in `$?` after the call. To recover the program's actual exit code, shift right by eight:

```
system("make", "install");
my $exit = $? >> 8;
```

`-1` means the program could not be started at all (or the `wait` itself failed); inspect `$!` for the reason. A return of `0` means the child exited successfully with status `0`.

Shell-vs-direct execution

Argument processing depends on the shape of `LIST`, and mirrors `exec` exactly:

- **More than one argument** (or an array with more than one element): the first element is the program, the rest are its arguments. The shell is **not** invoked; `execvp` runs the program directly. This is the safe form.
- **Exactly one scalar argument**: Perl scans it for shell metacharacters. If any are present, the entire string is passed to `/bin/sh -c` for parsing. If none are present, Perl splits on whitespace and calls `execvp` directly - saving a shell.

Prefer the list form whenever the arguments come from untrusted input or contain characters the shell would interpret:

```
system("ls", "-l", $dir);              # safe, no shell
system("ls -l $dir");                  # shell parses $dir -␣
↪hazardous
```

Signals vs. exit

The status word combines three pieces of information: a signal number (if the child died on a signal), a core-dump flag, and the exit value. Decode it explicitly when you need to tell them apart:

```
system(@cmd);
if ($? == -1) {
    print "failed to execute: $!\n";
}
elsif ($? & 127) {
    printf "child died with signal %d, %s coredump\n",
        ($? & 127), ($? & 128) ? 'with' : 'without';
}
else {
    printf "child exited with value %d\n", $? >> 8;
}
```

For a structured decode, inspect `${^CHILD_ERROR_NATIVE}` - the full native status word - with the `WIFEXITED`, `WEXITSTATUS`, `WIFSIGNALED`, `WTERMSIG` macros from `POSIX`:

```
use POSIX qw(WIFEXITED WEXITSTATUS WIFSIGNALED WTERMSIG);
system(@cmd);
my $n = ${^CHILD_ERROR_NATIVE};
if (WIFEXITED($n))   { my $code = WEXITSTATUS($n); ... }
if (WIFSIGNALED($n)) { my $sig  = WTERMSIG($n);    ... }
```

`SIGINT` and `SIGQUIT` are ignored in the parent while the child runs. If you want your own program to die when the user hits Ctrl-C during `system`, check the return status yourself and re-raise:

```
system(@cmd);
kill 'INT', $$ if ($? & 127) == 2;    # re-raise SIGINT on self
```

Stdio flushing

Before the fork, Perl attempts to flush every filehandle opened for output. This prevents buffered lines from being duplicated by both parent and child. The flush is best-effort; on platforms where it is unreliable, set `$|` (`$AUTOFLUSH`) or call the `autoflush` method from `IO::Handle` on handles you care about.

The die idiom

The canonical check - terse, and it embeds the status word in the message so the caller can still decode it:

```
my @args = ("command", "arg1", "arg2");
system(@args) == 0
    or die "system @args failed: $?";
```

For a module that should throw on any failed `system` (and many other bits of Perl), use the `autodie` pragma.

Examples

Run a command and ignore the result:

```
system("clear");
```

Run a command, die on failure, and keep the status intact for downstream inspection:

```
system("tar", "xf", $archive) == 0
    or die "untar $archive failed: $?";
```

Detect whether a program is available by running it with `--version` and discarding its output:

```
my $ok = system("which $prog >/dev/null 2>&1") == 0;
```

Run under a specific shell explicitly, bypassing Perl's metacharacter-detection heuristic:

```
system("/bin/bash", "-c", $pipeline);
```

Lie about `argv[0]` using the indirect form - the kernel executes `/usr/bin/vim`, but the program sees its name as `editor`:

```
system { "/usr/bin/vim" } "editor", $file;
```

Edge cases

- **Return of -1**: the child was never created, or `wait` itself failed. Distinct from "child exited with status 255". Check `$!` for the reason - typically `ENOENT` (program not found) or `EACCES` (not executable).
- **Exit value 255 from a shell**: when the shell form is used and `/bin/sh` cannot find the program, the shell itself exits with 127. Programs that return 255 from Perl typically come through `die` in another Perl program.
- **`SIGCHLD` handler interaction**: `system` internally forks and waits. A `$SIG{CHLD}` handler can observe or race with this wait; see `perlipc` for the reaping discipline.
- **Shell quirks**: when the shell form is triggered, return codes and error reporting are whatever `/bin/sh` says they are - not always what the underlying program returned. Use the list form to avoid this.
- **Not for capturing output**: `system` writes the child's output to the inherited `STDOUT`/`STDERR`. Use `qx//` or open a pipe with `open` if you need the output as a string.
- **Windows**: only the `system PROGRAM LIST` syntax reliably avoids the shell. pperl is Linux-only, so this does not apply here; noted for portability.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `exec` - replace the current process instead of forking and waiting; same argument-processing rules as `system`
- `fork` - create a child process without running a new program; `system` is `fork` + `exec` + `waitpid`
- `waitpid` - reap a specific child, used when managing multiple children directly
- `qx` - run a command and capture its output as a string; what you want when `system`'s stdio targeting is not enough
- `$?` - child error status word set by `system`, backticks, pipe `close`, and `wait`
- `$!` - errno after a failed fork or exec (return value `-1`)
- `${^CHILD_ERROR_NATIVE}` - full native wait status for decoding with `POSIX W*` macros

I/O · Fixed-length data

syswrite

Write bytes to a filehandle with the raw `write(2)` system call, bypassing Perl's buffered I/O.

`syswrite` hands `LENGTH` bytes from `SCALAR` directly to the kernel via `write(2)`, skipping the `PerlIO` buffering that `print`, `printf`, and `write` go through. The kernel may accept fewer bytes than requested - `syswrite` returns whatever it actually wrote, and well-written code always checks. If `LENGTH` is omitted, the whole `SCALAR` is written. An optional `OFFSET` starts the write at a position other than the beginning of the string.

Synopsis

```
syswrite FILEHANDLE, SCALAR, LENGTH, OFFSET
syswrite FILEHANDLE, SCALAR, LENGTH
syswrite FILEHANDLE, SCALAR
```

What you get back

The number of bytes actually written, or `undef` on error (with `$!` set). **The returned count can be less than `LENGTH`.** This is normal on pipes, sockets, and non-blocking handles; it is not an error. Code that needs every byte delivered must loop:

```
my $off = 0;
my $len = length $buf;
while ($off < $len) {
    my $n = syswrite $fh, $buf, $len - $off, $off;
    defined $n or die "write failed: $!";
    $off += $n;
}
```

A return of `0` is legal and means "no bytes written this call, try again" - not end-of-stream. `undef` is the only error signal.

Global state it touches

- `$!` - set on error (any return of `undef`).
- No interaction with `$,`, `$\`, or `$|`. `syswrite` does not format, does not append record separators, and does not honour the autoflush flag because there is no buffer to flush - bytes go straight to the kernel.
- No interaction with the selected filehandle from `select`. `FILEHANDLE` is mandatory; there is no default.

Examples

Write a string verbatim to `STDOUT`, no separators added:

```
syswrite STDOUT, "hello\n";        # 6 bytes written
```

Write a fixed-size record and check for a short write:

```
my $rec = pack "A8 N", $name, $id;   # 12 bytes
my $n = syswrite $fh, $rec;
defined $n or die "syswrite: $!";
$n == length $rec or die "short write: $n of ${\length $rec}";
```

Write from the middle of a buffer with `OFFSET`. Useful inside a drain loop where `$off` tracks how much has been accepted so far:

```
my $buf = "ABCDEFGHIJ";
syswrite $fh, $buf, 4, 3;          # writes "DEFG"
```

Negative `OFFSET` counts from the end:

```
my $buf = "ABCDEFGHIJ";
syswrite $fh, $buf, 3, -4;         # writes "GHI"
```

Write to a non-blocking socket and handle `EAGAIN`:

```
use Errno qw(EAGAIN EWOULDBLOCK);

my $n = syswrite $sock, $buf;
if (!defined $n) {
    if ($! == EAGAIN || $! == EWOULDBLOCK) {
        # kernel buffer full - try again after select()
    } else {
        die "syswrite: $!";
    }
}
```

Edge cases

- **Do not mix with buffered I/O on the same handle.** `syswrite` bypasses `PerlIO`, but `print`, `printf`, `write`, `seek`, `tell`, and `eof` all go through the `:perlio` and `:crlf` buffering layers. Interleaving them on one handle corrupts the output order. Pick one mode per handle. If you must mix, use `read` / `sysread` symmetry rules and be deliberate.
- **Short writes are normal.** Pipes, sockets, terminals, and non-blocking handles routinely accept fewer bytes than offered. The drain-loop idiom above is the correct pattern for any handle where short writes matter.
- **Return value `0`** means the kernel accepted zero bytes this call. It is not end-of-stream and not an error; retry.
- **Length larger than available data**: if `LENGTH` exceeds `length(SCALAR) - OFFSET`, only the available bytes are written and that count is returned.
- **Empty SCALAR**: if `SCALAR` has length zero, `OFFSET` must be `0`. Any other value raises an exception.
- **`:utf8` and `:encoding(...)` layers raise an exception.** `syswrite` operates on bytes, not characters, and refuses any handle carrying a UTF-8 encoding layer. `:encoding(...)` implicitly adds `:utf8`, so it is equally forbidden. Use `binmode` to remove the layer, or write through `print` instead.
- **Characters above U+00FF** on a byte-mode handle also raise an exception - there is no way to serialise a codepoint greater than `0xFF` as a single byte. Encode the string explicitly before calling `syswrite`:

```
use Encode qw(encode);
syswrite $fh, encode("UTF-8", $text);
```

- **Broken pipe / closed socket** raises `SIGPIPE`. The default action terminates the process. Install `$SIG{PIPE} = 'IGNORE'` (or a handler) to turn it into a normal `syswrite` error with `$!` set to `EPIPE`.
- **Closed filehandle** returns `undef` with `$!` set to `"Bad file descriptor"`; under `use warnings` a `syswrite() on closed filehandle` warning is emitted.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `sysread` - the read counterpart; same buffer-bypassing semantics and same short-read caveat
- `sysopen` - open a handle at the `open(2)` level so `syswrite` can talk to it without any `PerlIO` translation layers in the way
- `sysseek` - reposition the handle using `lseek(2)`, paired with `syswrite` for random-access I/O on raw handles

- `print` - the buffered counterpart you almost always want instead; honours `$,`, `$\`, and `$|`
- `binmode` - remove a `:utf8` or `:encoding(...)` layer from a handle so `syswrite` can be used on it
- `$!` - inspect after a `undef` return to distinguish `EAGAIN` from a real failure

I/O

tell

Return the current byte position of a filehandle.

`tell` reports where the next read or write on `FILEHANDLE` will happen, measured in bytes from the start of the file. Pair it with `seek` to save a position now and return to it later. If `FILEHANDLE` is omitted, `tell` reports the position of the handle last read from - including the implicit handle inside `while (<FH>)` loops.

Synopsis

```
tell FILEHANDLE
tell
```

What you get back

A non-negative integer byte offset on success, `-1` on error. The value is suitable as the `POSITION` argument to `seek` with `WHENCE` set to `0` (absolute seek). On pipes, FIFOs, sockets, and sometimes on the standard streams, the underlying OS has no seekable position and `tell` returns `-1`; `$!` is not necessarily set in that case, so treat `-1` as the authoritative failure signal.

```
my $pos = tell $fh;
die "not a seekable handle" if $pos < 0;
# ... read or write ...
seek $fh, $pos, 0;                  # back to where we were
```

Global state it touches

- **Last-read filehandle**: the no-argument form `tell` uses the handle most recently read from in the current scope. Every `readline`, `<FH>`, or `<>` updates this. Mixing `tell` with no argument and multiple active handles is a source of surprising results - name the handle explicitly when in doubt.
- `$!` is not a reliable error channel here. Check for `-1` directly rather than testing `$!` after the call.

Bytes, not characters

`tell` always returns a **byte** offset, even when the handle has a character-oriented PerlIO layer such as `:encoding(UTF-8)` or `:utf8`. This is deliberate: translating a character count into a byte offset in a variable-width encoding would require rereading the file from the beginning. The same rule applies to `seek` and `sysseek` - they all speak bytes.

Consequence: on a UTF-8 text file you cannot in general use `tell` to count characters. Use it only to mark a position you intend to feed back into `seek`.

Examples

Remember a position, read ahead, return:

```
open my $fh, "<", "log.txt" or die $!;
my $mark = tell $fh;                # 0
my $first = <$fh>;                  # read one line
seek $fh, $mark, 0;                 # rewind to the mark
my $again = <$fh>;                  # same line again
```

Record the end-of-header offset so later code can rescan the body without reparsing the header:

```
while (my $line = <$fh>) {
    last if $line =~ /^\r?\n\z/;    # blank line ends headers
}
my $body_start = tell $fh;
# ... process body ...
seek $fh, $body_start, 0;           # second pass over the body
```

The no-argument form uses the handle last read from. Inside a `while (<>)` loop that handle is the implicit `ARGV`:

```
while (<>) {
    print "at ", tell, ": $_";      # offset within the current file
}
```

`tell` on a pipe returns `-1` because pipes are not seekable:

```
open my $ph, "-|", "ls" or die $!;
my $pos = tell $ph;                 # -1
```

Filehandles inside complex expressions need the same block form as with `print` - `tell $handles[0]` is a syntax error. Use:

```
my @handles = (\*STDIN, $fh);
my $pos = tell { $handles[1] };
```

Edge cases

- **Closed filehandle**: returns `-1`. Under `use warnings` a `tell()` on closed `filehandle` warning is emitted.
- **No-argument form, nothing read yet**: returns `-1`. The "last-read filehandle" is only meaningful after an actual read.
- **After `sysread` / `syswrite` / `sysseek`**: do not use `tell` on a handle you have manipulated with the `sys*` family. Those functions bypass PerlIO buffering; `tell` reports the buffered position, which will be wrong by the buffer contents. Use `sysseek` with a whence of 1 and an offset of `0` as the `sys*`-safe position query.
- **Standard streams**: `tell STDIN`, `tell STDOUT`, `tell STDERR` may return `-1` or a meaningful offset depending on whether the stream is backed by a regular file (shell redirection) or a terminal, pipe, or socket.
- **No `systell`**: there is no separate function for buffered-bypassing position. The idiom is:

```
my $pos = sysseek $fh, 0, 1;
```

- **Binary-mode vs text-mode on non-Linux platforms**: pperl targets Linux only, so `tell` offsets always match raw file bytes. CRLF translation layers that complicate `tell` on Windows-family perls do not apply here.
- **Append mode (`>>`)**: after `open my $fh, ">>", ...`, the initial `tell $fh` may report `0` until the first write, because some platforms position the handle at end-of-file only at each write. Don't rely on the initial position; write once, then `tell`.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `seek` - jump to an absolute byte offset previously returned by `tell`
- `sysseek` - position query and jump for handles used with `sysread` / `syswrite`, bypassing PerlIO buffering
- `telldir` - the directory-handle analogue; pairs with `seekdir`
- `eof` - test for end-of-file rather than absolute position
- `open` - produce the filehandle in the first place; mode and PerlIO layers determine whether the handle is seekable

I/O

telldir

Return the current read position of a directory handle as an opaque token.

`telldir` reports where the next `readdir` on `DIRHANDLE` will pick up. The returned value is a bookmark, not a byte offset: hand it back to `seekdir` to resume iteration at the

same entry, or discard it. The number has no arithmetic meaning - it is not an index into the directory, not a count of entries read, and not comparable across directory handles. Treat it the way you would treat the return value of `tell` on a file handle: opaque to you, meaningful only to the matching `seekdir`.

Synopsis

```
telldir DIRHANDLE
```

What you get back

An integer on success, `undef` on failure (for example, if `DIRHANDLE` is not an open directory handle). The integer is only guaranteed to round-trip through `seekdir` on the **same** open directory handle; closing and reopening the directory invalidates every previously returned token.

```
opendir my $dh, $path or die "opendir $path: $!";
my $pos = telldir $dh;
# ... readdir a few entries ...
seekdir $dh, $pos;           # back to where $pos was taken
```

Global state it touches

Sets `$!` on failure.

Examples

Bookmark a position, then return to it:

```
opendir my $dh, "." or die "opendir: $!";
readdir $dh;                 # consume "."
my $mark = telldir $dh;
my @rest = readdir $dh;      # drain the rest
seekdir $dh, $mark;
my @again = readdir $dh;     # same entries as @rest
closedir $dh;
```

Record a token before each entry so you can rewind one step:

```
opendir my $dh, $path or die "opendir $path: $!";
my $prev;
while (defined(my $entry = readdir $dh)) {
    last if $entry eq "STOP";
    $prev = telldir $dh;     # position *after* the current entry
}
seekdir $dh, $prev if defined $prev;
```

Rewinding to the start is better done with `rewinddir` than by remembering the token from before the first `readdir`:

```
opendir my $dh, $path or die "opendir $path: $!";
my @first_pass  = readdir $dh;
rewinddir $dh;                # cleaner than seekdir $dh, $start_
 ↪token
my @second_pass = readdir $dh;
```

Check for failure explicitly when the handle might be closed:

```
my $pos = telldir $dh;
defined $pos or die "telldir failed: $!";
```

Edge cases

- **Token is opaque.** Do not compare, add, subtract, or persist the value. It is valid only for `seekdir` on the same open directory handle within the same process.
- **Not portable across handles.** Two `opendir` calls on the same directory produce independent handles; a token from one is meaningless to the other.
- **Not stable across `closedir` / `opendir`.** Reopening the directory starts a fresh iteration; old tokens no longer refer to anything.
- **Directory compaction.** If the underlying filesystem or another process modifies the directory (adds, removes, or renames entries) between `telldir` and the matching `seekdir`, the resumed position may skip entries, repeat entries, or land on a different entry than the one originally bookmarked. This is a property of the C library `telldir(3)` / `seekdir(3)` pair and is not something Perl papers over. Snapshot the directory with `readdir` into a list if you need stability.
- **Closed or never-opened handle.** Returns `undef` and sets `$!`.
- **Bareword vs. scalar handle.** `telldir DH` and `telldir $dh` both work. The bareword form is a package global; the scalar form holds a reference to an anonymous directory handle created by `opendir my $dh, ...`.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `seekdir` - the only consumer of a `telldir` token; restores `DIRHANDLE` to the bookmarked position
- `readdir` - the iterator whose position `telldir` reports; advances the cursor that `telldir` observes
- `rewinddir` - cheaper than `seekdir` to a start-of-stream token when you just want to iterate the directory again
- `opendir` - creates the `DIRHANDLE` that `telldir` queries; every `telldir` token is tied to one open call
- `closedir` - invalidates every `telldir` token for the handle

- `tell` - the file-handle analogue; same opaque-token contract, different underlying system call

Classes and OO

tie

Bind a variable to a class so that every access to the variable dispatches through that class's methods.

`tie` enchants `VARIABLE` so that subsequent reads, writes, and other operations on it are forwarded to `CLASSNAME`'s tie-interface methods (`FETCH`, `STORE`, `FIRSTKEY`, `PRINT`, ...). `LIST` is passed to the class's constructor (`TIESCALAR`, `TIEARRAY`, `TIEHASH`, or `TIEHANDLE`, depending on the sigil of `VARIABLE`). The constructor returns the underlying tied object, and that object - **not** `VARIABLE` - is the return value of `tie`. Keep it if you want to call extra methods on the implementation directly.

The method contract each class must satisfy is documented at length in `perltie`; this page documents `tie` the built-in.

Synopsis

```
tie my $scalar, 'ScalarClass', @args;
tie my @array,  'ArrayClass',  @args;
tie my %hash,   'HashClass',   @args;
tie *FH,        'HandleClass', @args;

my $obj = tie my %h, 'HashClass', @args;   # keep the tied object
```

What you get back

The object returned by the class's `TIE*` constructor - an ordinary blessed reference, same as any other object. Call methods on it directly when the class exposes operations that don't map onto plain variable access:

```
my $db = tie my %cache, 'My::Cache', path => '/var/cache/app.db';
$db->flush;                 # method on the tied object
$cache{key} = 'value';      # goes through STORE
```

`tie` does not return the variable itself. Code that writes `my $x = tie ...` and then treats `$x` as the scalar is a common beginner mistake; the scalar is `$x` only if you also tied `$x`, and the assignment target is the tied object, not the variable.

To recover the tied object from a variable later, use `tied`. To dissolve the binding, use `untie`.

Which constructor is called

The sigil of `VARIABLE` picks the constructor. `LIST` is forwarded verbatim:

VARIABLE form	Constructor called	Interface reference
`$scalar`	`CLASSNAME->TIESCALAR(LIST)`	`Tie::Scalar`
`@array`	`CLASSNAME->TIEARRAY(LIST)`	`Tie::Array`
`%hash`	`CLASSNAME->TIEHASH(LIST)`	`Tie::Hash`
`*FH` (glob)	`CLASSNAME->TIEHANDLE(LIST)`	`Tie::Handle`

The constructor's arguments are conventionally those you'd pass to something like `dbm_open(3)` - a filename, a mode, a permission mask - but anything the class expects is fine.

Methods each class must provide

`tie` itself only invokes `TIE*`. Every other operation on the variable dispatches to a method named after that operation. Not all methods are mandatory - missing methods make the corresponding operations fail with a runtime error. The full menus are:

Tied scalar (`TIESCALAR`):

```
TIESCALAR classname, LIST
FETCH     this
STORE     this, value
DESTROY   this
UNTIE     this
```

Tied array (`TIEARRAY`):

```
TIEARRAY  classname, LIST
FETCH     this, index
STORE     this, index, value
FETCHSIZE this
STORESIZE this, count
CLEAR     this
PUSH      this, LIST
POP       this
SHIFT     this
UNSHIFT   this, LIST
SPLICE    this, offset, length, LIST
EXTEND    this, count
DELETE    this, index
EXISTS    this, index
DESTROY   this
UNTIE     this
```

Tied hash (`TIEHASH`):

```
TIEHASH   classname, LIST
FETCH     this, key
STORE     this, key, value
DELETE    this, key
CLEAR     this
```

(continues on next page)

(continued from previous page)

```
EXISTS    this, key
FIRSTKEY  this
NEXTKEY   this, lastkey
SCALAR    this
DESTROY   this
UNTIE     this
```

Tied filehandle (`TIEHANDLE`):

```
TIEHANDLE this, LIST
READ      this, scalar, length, offset
READLINE  this
GETC      this
WRITE     this, scalar, length, offset
PRINT     this, LIST
PRINTF    this, format, LIST
BINMODE   this
EOF       this
FILENO    this
SEEK      this, position, whence
TELL      this
OPEN      this, mode, LIST
CLOSE     this
DESTROY   this
UNTIE     this
```

See `perltie` for the full specification (method signatures, when each is called, defaults inherited from the `Tie::*` base classes).

Examples

Bind a hash to an on-disk DBM file and iterate with `each`. `keys` and `values` would materialise the whole set at once - for large DBM files that's expensive:

```
use NDBM_File;
tie(my %HIST, 'NDBM_File', '/usr/lib/news/history', 1, 0);
while (my ($key, $val) = each %HIST) {
    print $key, ' = ', unpack('L', $val), "\n";
}
```

Keep the constructor's return value so you can talk to the tied object directly:

```
my $impl = tie my %cache, 'My::Cache', ttl => 60;
$cache{session} = $data;    # STORE
$impl->expire_now;           # direct method call
```

Tie a scalar to a read-only class that logs every access:

```
package Tie::Logged {
    sub TIESCALAR { my ($class, $v) = @_; bless \$v, $class }
```

(continues on next page)

(continued from previous page)

```
    sub FETCH     { my $self = shift; warn "read\n";  $$self }
    sub STORE     { my ($s, $v) = @_;  warn "write\n"; $$s = $v }
}

tie my $x, 'Tie::Logged', 42;
print $x;           # warns "read",  prints 42
$x = 99;            # warns "write"
```

Tie a filehandle to a class that captures output into a string:

```
package Tie::StringHandle {
    sub TIEHANDLE { my $c = shift; bless { buf => '' }, $c }
    sub PRINT     { my $s = shift; $s->{buf} .= join '', @_; 1 }
    sub buf       { $_[0]->{buf} }
}

tie *OUT, 'Tie::StringHandle';
print OUT "hello\n";
print OUT "world\n";
my $obj = tied *OUT;
print $obj->buf;    # "hello\nworld\n"
```

Edge cases

- **Return value is the object, not the variable.** `my $r = tie my %h, ...` binds `$r` to the tied object. Assigning to `$r` assigns to a scalar; it does not write through to %h.
- **Module must be loaded first.** Unlike `dbmopen`, `tie` does **not** `use` or `require` `CLASSNAME` for you. Load it explicitly:

  ```
  use My::TiedClass;
  tie my %h, 'My::TiedClass';
  ```

  Forgetting this is the typical cause of `Can't locate object method "TIEHASH" via package ...`.
- **Missing methods are fatal at the point of use**, not at `tie` time. A tied hash whose class defines `FETCH` but not `STORE` ties successfully, then raises `Can't locate object method "STORE" ...` on the first assignment.
- **Sigil mismatch is a `tie`-time error.** `tie` picks the constructor from the variable's sigil, so a class that only defines `TIESCALAR` cannot be `tie`-d to a hash - the lookup of `TIEHASH` fails at the `tie` call itself.
- **`tie`ing a tied variable** implicitly `untie`s the previous binding first, triggering `UNTIE` and eventually `DESTROY` on the old object (once the last reference to it drops).
- **`local` on a tied variable** saves and restores the *binding*, not just the value. At scope exit the variable is re-tied to its original object.
- **Holding an extra reference to the tied object** keeps it alive past `untie`. Under `use warnings` this produces a `untie attempted while N inner references`

`still exist` warning. Drop the reference (e.g. `undef $obj`) before calling `untie` if you want `DESTROY` to fire promptly.

- **`tie` does not stash the object inside the variable in any user-visible way** - use `tied` to retrieve it; there's no dereference syntax that exposes it.
- **Performance.** Every operation on a tied variable dispatches through a method call. In tight loops this is visibly slower than a plain variable; for bulk work, read into a plain array or hash first, operate, then write back.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `tied` - recover the object a variable is currently tied to, or `undef` if it isn't tied
- `untie` - dissolve the binding and let the tied object be destroyed
- `bless` - the low-level primitive `TIE*` constructors use to turn a reference into an object
- `dbmopen` - older shortcut for the specific case of tying a hash to a DBM file; loads the DBM class for you, which `tie` does not
- `ref` - inspect the class of the object returned by `tie`

Classes and OO

tied

Return the object backing a tied variable.

`tied` hands you the same reference that `tie` originally returned when `VARIABLE` was bound to a class. Through that reference you can call methods directly on the tie implementation - bypassing the usual `FETCH` / `STORE` dispatch - which is how tie classes expose extra operations that have no natural scalar / array / hash syntax. If `VARIABLE` is not tied, `tied` returns `undef`.

Synopsis

```
tied VARIABLE
```

What you get back

A reference to the underlying tie object when `VARIABLE` is tied, and `undef` when it is not. The reference is the exact value originally returned by the matching `tie` call - same class, same blessed identity - so `ref(tied $v)` names the tie class and method calls on it dispatch normally:

```
my $obj = tied %hash;
$obj->flush if defined $obj;
```

Use `defined` (or a boolean test, when the tie class never blesses into a false-overloading package) to distinguish a tied variable from an untied one before calling methods on the result.

The "tie handle" trick

`tied` is the only supported way to talk to the tie implementation directly. Any method on the tie class that is not one of the standard hooks (`FETCH`, `STORE`, `EXISTS`, `DELETE`, `CLEAR`, `FIRSTKEY`, `NEXTKEY`, and their array / scalar / handle equivalents) is reachable only through the object `tied` returns:

```
tie my %cache, 'My::LRU', size => 1024;
tied(%cache)->stats;           # class-specific method, no hash␣
↪syntax
tied(%cache)->evict_older_than(3600);
```

This is also the pattern for introspection - asking a tied variable "who are you tied to?" without assuming knowledge of the binding site:

```
my $class = ref tied @array;   # e.g. "Tie::File"
```

Examples

Basic test for tiedness:

```
tie my %h, 'My::Tied::Hash';
print defined(tied %h) ? "tied\n" : "not tied\n";   # tied
```

Calling a class-specific method through the tie object:

```
tie my @log, 'Tie::File', 'app.log' or die $!;
tied(@log)->flock(2);          # LOCK_EX; Tie::File API
# ... mutate @log ...
tied(@log)->flock(8);          # LOCK_UN
```

A plain scalar, array, hash, or filehandle that was never tied:

```
my $x;
print defined(tied $x) ? "yes" : "no", "\n";        # no
```

`tied` does **not** untie - the variable stays tied after the call, and successive calls return the same reference:

```
tie my $t, 'My::Counter';
my $a = tied $t;
my $b = tied $t;
print $a == $b ? "same\n" : "different\n";          # same
```

Round-tripping through `ref` to learn the tie class:

```
tie my %db, 'DB_File', 'data.db', O_RDWR | O_CREAT, 0644;
print ref tied %db, "\n";      # DB_File
```

Edge cases

- **Not tied**: returns `undef`. No warning, no exception. This is the idiomatic way to check whether a variable is tied at all - there is no separate `is_tied` built-in.
- **Filehandles**: `tied *FH` returns the object for a tied filehandle (bound with `tie *FH, ...`). A glob that was never tied yields `undef` just like any other untied variable.
- **`tied` does not untie**. It is a pure accessor. To release the binding, call `untie`. Holding the reference returned by `tied` past the point where the variable is untied keeps the tie object alive, which is deliberate - that is how `untie` warnings about "untie attempted while N inner references still exist" are triggered.
- **Tied element of an aggregate**: when an individual array or hash element is itself tied (separate from a tie on the container), `tied $array[0]` or `tied $hash{key}` returns the per-element object, not the container's. A container tie and an element tie are independent bindings.
- **Copied values are not tied**. `my $copy = $tied_scalar;` stringifies through `FETCH`; `$copy` is a plain scalar and `tied $copy` returns `undef`. Tie is a property of the variable, not of the value.
- **References to tied variables preserve the tie.** `\%hash` where `%hash` is tied still refers to the tied container, so `tied %{ $ref }` returns the same tie object.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `tie` - bind a variable to a class; establishes the tie relationship that `tied` queries
- `untie` - release the tie; after calling it, `tied` on the same variable returns `undef`
- `ref` - get the class name of the object returned by `tied` without a separate method call
- `bless` - `tied` returns a blessed reference when the tie class blessed the object it returned from its `TIE*` constructor
- `defined` - the standard test for "is this variable tied?" is `defined tied $var`

Time

time

Return the current wall-clock time as an integer number of seconds since the system epoch.

`time` is the starting point for every other date and time operation in Perl. It reads the system clock and returns a single integer - the number of non-leap seconds since the epoch, which on every supported platform is `00:00:00 UTC, 1 January 1970` (Unix time). The result is suitable for feeding directly to `gmtime` or `localtime` to break it down into a calendar date, or for subtracting two readings to measure elapsed time.

Synopsis

```
time
```

What you get back

A plain integer: seconds since `1970-01-01 00:00:00 UTC`, truncated (not rounded) toward zero. No sub-second precision - two calls within the same second return the same value. For millisecond or microsecond granularity, use `Time::HiRes::time`.

`time` takes no arguments; the bare word is the entire call. Writing `time()` is also fine and sometimes clearer next to other function calls.

Examples

Raw reading of the clock:

```
my $now = time;
print "$now\n";                     # e.g. 1745424000
```

Human-readable local date and time - `time` pairs with `localtime` in scalar context for a formatted string:

```
print scalar localtime, "\n";       # Wed Apr 23 12:00:00 2026
```

The same reading broken into fields for calendar arithmetic:

```
my ($sec, $min, $hour, $mday, $mon, $year) = localtime time;
$year += 1900;
$mon  += 1;
printf "%04d-%02d-%02d %02d:%02d:%02d\n",
       $year, $mon, $mday, $hour, $min, $sec;
```

Elapsed-time measurement around a block of work - the idiomatic whole-second stopwatch:

```
my $t0 = time;
do_work();
my $elapsed = time - $t0;
print "took ${elapsed}s\n";
```

UTC rather than local time - feed the same integer to `gmtime`:

```
my @utc = gmtime time;              # same fields, UTC-based
print scalar gmtime, "\n";          # Wed Apr 23 10:00:00 2026
```

Edge cases

- **No sub-second resolution.** Back-to-back calls in the same second return the same integer, so `time - $t0` for fast work prints `0`. Use `Time::HiRes::time` for a floating-point reading with microsecond precision:

```
use Time::HiRes qw(time);
my $t0 = time;                          # now a float
do_work();
printf "%.6f s\n", time - $t0;
```

- **Leap seconds.** The returned count excludes leap seconds; it is POSIX "seconds since the epoch" as reported by the kernel. Code that subtracts two `time` readings measures wall-clock elapsed seconds, not SI seconds, across a leap-second boundary.
- **Integer width.** The value is a signed integer wide enough for current and far-future timestamps on all supported platforms (64-bit). The 2038 problem does not apply here.
- **Timezone.** `time` itself is timezone-agnostic - the integer names a single instant in UTC. Timezones only enter the picture when you convert via `localtime`; `gmtime` stays in UTC.
- **Monotonicity.** `time` follows the system clock. If the clock is stepped backward (NTP adjustment, manual change), a later call may return a smaller value than an earlier one. For elapsed measurements that must not go backward, use a monotonic clock via `Time::HiRes::clock_gettime(CLOCK_MONOTONIC)`.
- **In arithmetic.** `time + 3600` is one hour from now; `time - 86400` is 24 hours ago. Feed the result to `localtime` or `gmtime` to render it.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `gmtime` - break a `time` value into UTC calendar fields (or a formatted string in scalar context)
- `localtime` - same, but in the local timezone; the most common partner for `time`
- `sleep` - pause for a whole number of seconds; pairs naturally with `time` for coarse scheduling
- `alarm` - schedule a `SIGALRM` a given number of seconds in the future
- `Time::HiRes::time` - floating-point seconds with microsecond resolution when whole-second granularity is not enough

Processes · Time

times

Report CPU time consumed by this process and its terminated children.

`times` asks the kernel how many seconds of user-mode and kernel-mode CPU have been charged to the current process, and - separately - to children that have already been reaped. The return is four floating-point seconds: user, system, child-user, child-system.

It answers "how much CPU have I burned?", not "how much wall-clock time has passed?" - for that, see `time`.

Synopsis

```
my ($user, $system, $cuser, $csystem) = times;
my $user_only                         = times;    # scalar context
```

What you get back

In list context, four values:

- `$user` - CPU time spent in user-mode code of this process.
- `$system` - CPU time spent in the kernel on behalf of this process.
- `$cuser` - user-mode CPU time of **terminated** child processes.
- `$csystem` - kernel-mode CPU time of **terminated** child processes.

All four are seconds as double-precision floats; resolution is microsecond on Linux (sourced from `getrusage`).

In scalar context, `times` returns just `$user`.

`times` takes no arguments and cannot fail in a way visible to the caller.

Children's times - the "terminated" rule

`$cuser` and `$csystem` aggregate CPU only from children that have been **reaped** - i.e. a `wait` or `waitpid` has successfully collected their exit status, or they were autoreaped because `$SIG{CHLD}` was set to `'IGNORE'`. A child that is still running, or has exited but not yet been reaped (a zombie), contributes nothing.

This matters when measuring a pipeline that spawns workers:

```
my $pid = fork;
if ($pid == 0) { do_work(); exit }
# (busy child runs here)
my ($u0, $s0, $cu0, $cs0) = times;      # $cu0, $cs0 still 0
waitpid($pid, 0);
my ($u1, $s1, $cu1, $cs1) = times;      # now $cu1, $cs1 reflect␣
 ↪child
```

Until the `waitpid` returns, the child's CPU does not appear in the parent's `times`.

Examples

Measure CPU cost of a block of work, excluding wall-clock sleeps or I/O waits:

```
my ($u0, $s0) = times;
compute_heavy();
my ($u1, $s1) = times;
```

(continues on next page)

(continued from previous page)

```
printf "compute used %.3f s user + %.3f s system\n",
       $u1 - $u0, $s1 - $s0;
```

Compare CPU time to wall-clock time - a low ratio means the process was mostly waiting rather than computing:

```
use Time::HiRes qw(time);
my $t0 = time;
my ($u0, $s0) = times;
do_mixed_io_and_compute();
my $wall = time - $t0;
my ($u1, $s1) = times;
printf "cpu/wall = %.2f\n", ($u1 - $u0 + $s1 - $s0) / $wall;
```

Attribute a parallel workload to its children. Reap every child before reading `times`:

```
my @pids = map { my $p = fork; $p == 0 ? (worker($_), exit) : $p }
 ↪1..4;
waitpid($_, 0) for @pids;
my (undef, undef, $cu, $cs) = times;
printf "workers used %.2f s user + %.2f s system\n", $cu, $cs;
```

Scalar context when only the user time matters - e.g. a quick self-profiling print:

```
printf STDERR "[%.2f] reached checkpoint\n", scalar times;
```

Edge cases

- **No arguments, no prototype to worry about.** `times` is a zero-argument built-in; `times()` and `times` parse identically. It is **not** the transliteration operator - that is `tr///` (alias `y///`), which is a separate token.
- **Scalar vs list context is load-bearing.** Writing `my $t = times;` binds `$user` to `$t`, discarding the other three values silently. Use `my ($u,$s,$cu,$cs) = times;` when you want them all.
- **Unreaped children don't count.** See the "terminated" rule above. Reading `times` before `wait` gives `$cuser == $csystem == 0` even when the child is visibly burning CPU in `top`.
- **Threads do count.** On Linux, kernel-threaded work in the current process shows up in `$user` / `$system` just like single-threaded work. Threads in a separate process don't, until that process exits and is reaped.
- **Clock is monotonic-within-process, not wall-clock.** `times` never goes backwards across a single process's lifetime, but successive `times` calls are not directly comparable between parent and child - each `getrusage` accounting is local.
- **Resolution.** Linux reports microsecond-resolution ticks via `getrusage`, so short measurements (sub-millisecond) are noisy but not zero. For high-precision wall-clock timing, use `Time::HiRes::time`, not `times`.

- **Overflow.** Values are floats; they can in principle lose sub-microsecond precision after very long runs (years of CPU), but this is not a concern for normal programs.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `time` - wall-clock seconds since the epoch; use it when you want elapsed real time, not CPU time
- `Time::HiRes::time` - high-resolution wall-clock time, the usual partner for CPU accounting
- `POSIX::times` - POSIX wrapper returning an additional real-time "clock ticks since boot" value; use it when you need the elapsed field the built-in omits
- `wait` - reap a child so its CPU starts counting in `$cuser` / `$csystem`
- `waitpid` - reap a specific child for the same reason, without blocking on unrelated ones
- `fork` - the operation whose cost shows up in the child columns once the child is reaped

SCALARs and strings

tr///

Character-by-character substitution. `tr` scans a string and replaces every occurrence of a character from `SEARCHLIST` with the positionally corresponding character from `REPLACEMENTLIST`, returning the count of characters it touched.

It is not a regex. `SEARCHLIST` is a set of literal characters (with range shorthand like `a-z`), not a pattern. No metacharacters, no `\d`, no variable interpolation. The translation table is built once, at compile time.

Synopsis

```
tr/SEARCHLIST/REPLACEMENTLIST/cdsr
y/SEARCHLIST/REPLACEMENTLIST/cdsr
$str =~ tr/abc/xyz/;
$count = ($str =~ tr/aeiou//);
```

`y///` is a sed-compatibility synonym for `tr///` - identical behaviour, identical modifiers. See `y///`.

What you get back

Without the `/r` modifier, `tr` mutates the target string in place and returns the **number of characters matched** - or, under `/d`, matched-or-deleted; under `/s`, matched-before-squashing. The return value is an integer and is commonly used to *count* characters without changing anything (see the `tr/*/*/` idiom below).

With `/r`, `tr` leaves the original string alone, builds a transliterated copy, and returns **that copy**. The returned string is always a plain string - even if the target was a tied variable or a blessed object.

Target without `=~`: `tr` operates on `$_`. Target with `=~`: the left-hand side must be an lvalue (scalar, array element, hash element) unless `/r` is used, in which case any expression works.

Modifiers

The four trailing flags change what `tr` does with each character it sees. They can be combined:

- **`c`** - complement `SEARCHLIST`. The set of characters acted on becomes *every character NOT in* `SEARCHLIST`. Under `/c`, `SEARCHLIST` is sorted by codepoint after complementing, and any `REPLACEMENTLIST` is applied to that sorted set - so the order of characters you wrote in `SEARCHLIST` no longer matters.
- **`d`** - delete. Characters matched by `SEARCHLIST` that have no position in `REPLACEMENTLIST` are removed from the target entirely rather than replaced with the final replacement character.
- **`s`** - squash. A run of characters that all translate to the same output character collapses to a single instance of that output.
- **`r`** - return modified copy. Do not touch the target. Return the transliterated string instead of a count.

Replacement list length rules

The relationship between `SEARCHLIST` and `REPLACEMENTLIST` changes with the modifiers:

- If `REPLACEMENTLIST` is **shorter** than `SEARCHLIST` and `/d` is **not** in effect, the final replacement character is *replicated* to fill the gap. `tr/abcd/AB/` is the same as `tr/abcd/ABBB/`.
- If `REPLACEMENTLIST` is shorter than `SEARCHLIST` **and** `/d` is in effect, surplus `SEARCHLIST` characters are deleted. `tr/abcd/AB/d` does `tr/ab/AB/` plus `s/[cd]//g`.
- If `REPLACEMENTLIST` is **empty** and `/d` is not in effect, `REPLACEMENTLIST` becomes a copy of `SEARCHLIST`. This is the count-only form: `tr/abc//` counts a, b, c without changing anything.
- If `REPLACEMENTLIST` is empty **and** `/d` is in effect, every character in `SEARCHLIST` is deleted. `tr/abc//d` removes all a, b, c from the target.

Character ranges

A hyphen between two characters specifies an inclusive codepoint range: `tr/A-J/0-9/` is `tr/ABCDEFGHIJ/0123456789/`. A hyphen at the start, at the end, or preceded by a backslash is taken literally - `tr/-ab-/xyz/` and `tr/\-abc/wxyz/` treat the hyphen as the literal character `-`.

Only use ASCII-alphabet (same case) or ASCII-digit ranges. `a-z`, `A-Z`, `0-9`, and clean subsets like `h-k` or `B-E` are portable and mean exactly what they read as. Mixed-case ranges, `\x`-ranges, or ranges straddling the alphabet/digit boundary look obvious but produce different results on non-ASCII platforms - spell them out.

Portable Unicode ranges use `\N{U+...}` endpoints:

```
$str =~ tr/\N{U+20}-\N{U+7E}//d;    # delete all ASCII printables
```

Delimiters

The three delimiters around `SEARCHLIST` and `REPLACEMENTLIST` can be any matching pair of printable characters, not just `/`. Bracketing pairs (`{}`, `()`, `[]`, `<>`) require two independent pairs, one for each list:

```
tr(aeiouy)(yuoiea);
tr[+\-*/]"ABCD";
```

When the delimiter is a single quote (`tr'...'...'`), the lists are treated almost literally - only `\\` pairs are collapsed. Hyphens inside single-quoted `tr` are **not** range specifiers; they are literal hyphens.

Global state it touches

- `$_` - default target when neither `=~` nor `!~` is used. `tr///` alone reads and (unless `/r` is used) mutates `$_`.
- No other special variables. `tr` does not set `$&`, `$1`, etc. - those belong to regex matching, and `tr` is not regex.

Examples

ASCII lowercase to uppercase:

```
my $name = "Perl";
$name =~ tr/a-z/A-Z/;          # $name is now "PERL"
```

Count without changing - the `tr/X/X/` idiom. The replacement is the same character, so the string is unchanged; the return value is the count:

```
my $stars = "**hello**";
my $cnt   = ($stars =~ tr/*/*/);    # $cnt == 4
```

Empty `REPLACEMENTLIST` without `/d` counts, too:

```
my $digits = ($text =~ tr/0-9//);   # count ASCII digits in $text
```

Delete characters with `/d`:

```
my $s = "(555) 123-4567";
$s =~ tr/0-9//cd;               # keep only digits: "5551234567"
```

Squash runs with `/s`:

```
my $line = "hello    world";
$line =~ tr/ //s;               # "hello world"
```

Non-destructive `/r` - build a copy, leave the original:

```
my $host  = "example.com";
my $HOST  = $host =~ tr/a-z/A-Z/r;    # $host unchanged, $HOST␣
↪uppercased
```

Chain with other `/r` operators:

```
my $tag = $host =~ tr/a-z/A-Z/r
               =~ s/\./_/gr;     # "EXAMPLE_COM"
```

`map` with `/r` - turn a list of strings into a transformed list:

```
my @upper = map tr/a-z/A-Z/r, @names;
```

Whole-word compacting - collapse non-alphabetic runs to a single space:

```
$sentence =~ tr/a-zA-Z/ /cs;    # "foo, bar; BAZ!" -> "foo bar BAZ "
```

Strip the high bit off every byte:

```
$bytes =~ tr[\200-\377][\000-\177];
```

Edge cases

- **Not a regex.** `tr/\d/X/` matches the literal characters `\` and `d`, not "any digit". Character classes, anchors, quantifiers, and backreferences are all silently literal. If you want regex, use `s///`.
- **No variable interpolation.** `$var` and `@var` inside the lists are literal `$` / `@` plus the following name. The table is compiled once, when the program is parsed. To build the lists dynamically, wrap in `eval`:

  ```
  eval "tr/$from/$to/";
  die $@ if $@;
  ```

- **Repeated characters in `SEARCHLIST`** - only the first mapping counts. `tr/AAA/XYZ/` translates every `A` to `X`; the `Y` and `Z` positions are unreachable.
- **No rescan.** Transliterated output is not re-fed into the table, even if the replacement character appears in `SEARCHLIST` too. `tr/ox/xo/` turns `"oxxo"` into `"xoox"`, not some fixed point.
- **`!~` with `tr`** - returns `0` if any character was changed, `1` otherwise. Useful only for quick "nothing happened" checks:

  ```
  $foo !~ tr/A/a/     # true iff no 'A' was in $foo
  ```

- **Lvalue requirement.** Without `/r`, the `=~` target must be assignable. `"constant" =~ tr/a/b/` is a compile-time error.

- **`/r` always returns a plain string.** If the target is a tied scalar or a blessed string-overloaded object, `/r` strips the magic and gives you a fresh plain string.
- **`tr` is not the shell `tr(1)`.** Similar syntax, overlapping semantics, but case-folding beyond ASCII belongs to `lc` / `uc` / `lcfirst` / `ucfirst` or to `s///` with `\U` / `\L` - not to `tr`.
- **`/c` with a multi-character `REPLACEMENTLIST`** is non-portable across character sets. Under `/c` the search set is sorted by codepoint, and that sort order differs between ASCII and EBCDIC. Stick to single-character `REPLACEMENTLIST` when combining with `/c`, or use `/c` only with `/d` (where the replacement doesn't matter).

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `y///` - sed-compatibility synonym for `tr///`; identical behaviour, pick whichever reads better in context
- `s///` - full regex substitution; reach for it when you need patterns, captures, or variable interpolation in the search side
- `lc` - Unicode-aware lowercase; use instead of `tr/A-Z/a-z/` when the input may contain non-ASCII letters
- `uc` - Unicode-aware uppercase; complement to `lc`
- `tr` *in* `perlop` - the upstream reference for the quote-like operator form, delimiter rules, and range portability
- `$_` - default target when `tr` is used without `=~` or `!~`

I/O

truncate

Shorten (or extend) a file to an exact byte length.

`truncate` adjusts the size of the file opened on `FILEHANDLE`, or the file named by `EXPR`, so it is exactly `LENGTH` bytes long. Bytes past `LENGTH` are discarded. The file's current read/write position is **not** changed - a handle sitting past the new end of file stays there, which is almost never what you want, so plan a `seek` before the next write.

Synopsis

```
truncate FILEHANDLE, LENGTH
truncate EXPR, LENGTH
```

What you get back

1 on success, `undef` on failure with `$!` set to the underlying `errno`. A missing platform implementation raises an exception rather than returning `undef`; that is an install-time property, not something to branch on at runtime.

```
truncate $fh, 0
    or die "truncate failed: $!";
```

Filehandle vs. filename form

Two forms, chosen by what you already have in hand:

- **`truncate FILEHANDLE, LENGTH`** - the handle must be open for writing (or read/write). Use this when the caller already owns an open write handle; it avoids a fresh `open`/`close` round-trip and works even after the file has been unlinked.
- **`truncate EXPR, LENGTH`** - `EXPR` is stringified as a pathname. The file is opened, truncated, and closed internally. Use this when you only have a path and do not need the handle afterwards.

Both forms require write permission on the target. On the filehandle form, that is a property of the open mode; on the pathname form, of the filesystem permissions.

LENGTH semantics

- `LENGTH` is in **bytes**, not characters. Encoding layers on the filehandle are irrelevant - the length argument goes straight to the OS.
- `LENGTH` less than the current file size discards the tail.
- `LENGTH` equal to the current size is a no-op that still succeeds.
- `LENGTH` greater than the current size extends the file with a hole of zero bytes on filesystems that support sparse files, or with literal zero bytes otherwise. Upstream `perlfunc` calls this case undefined; in practice it behaves like POSIX `ftruncate(2)` on Linux, which is what pperl targets.

Global state it touches

- `$!` is set on failure to the underlying `errno`.

Examples

Empty a logfile without closing the handle the rest of the program is still writing to:

```
open my $log, "+<", "app.log" or die $!;
truncate $log, 0 or die "truncate: $!";
seek $log, 0, 0;                # rewind; see "Position is not reset
 ↪"
```

Truncate a file by name, no handle involved:

```
truncate "scratch.dat", 0
    or die "truncate scratch.dat: $!";
```

Rotate a pre-allocated buffer file down to the used portion:

```
my $used = tell $fh;            # bytes actually written
truncate $fh, $used
    or die "truncate: $!";
```

Extend a file to a fixed size (sparse hole on Linux):

```
open my $fh, ">", "image.raw" or die $!;
truncate $fh, 1024 * 1024 * 1024   # 1 GiB sparse file
    or die "truncate: $!";
```

Edge cases

- **Position is not reset.** After `truncate $fh, 0`, the handle still remembers whatever offset it had. A following `print $fh ...` without an intervening `seek` may write past the new end of file, leaving a zero-filled hole.
- **Read-only handle**: truncating a handle opened with `<` fails with `EBADF` / `EINVAL` depending on the platform. Open with `+<` (read/write) or `>>` plus an appropriate mode if you need to truncate through the same handle you read from.
- **Negative `LENGTH`**: the kernel rejects it and `truncate` returns `undef` with `$!` set to `EINVAL`.
- **Directory as `EXPR`**: fails with `EISDIR`. `truncate` is strictly a file operation.
- **File unlinked but still open**: the filehandle form works fine - the inode is still there as long as any handle holds it open.
- **`LENGTH` larger than current size**: on Linux this extends with a sparse hole; reading the hole yields `"\0"` bytes. Upstream `perlfunc` flags this as undefined, so portable code should not rely on it.
- **Platform without `ftruncate`/`truncate`**: raises an exception (`The truncate function is unimplemented`). Not a concern on pperl's supported platform (Linux), but matters for portable code.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `open` - produce a writable filehandle suitable for the filehandle form of `truncate`
- `seek` - reposition the handle after truncating, before writing again
- `tell` - current offset, useful as the `LENGTH` argument when trimming to "what I have written so far"

- `sysopen` - lower-level open when you need explicit flags (`O_TRUNC` truncates at open time; `truncate` is the after-the-fact equivalent)
- `unlink` - reach for this instead when you want the file gone, not merely emptied
- `$!` - `errno` on failure

Control flow

try

Run a block and divert any exception it throws into a `catch` block, with an optional `finally` block that always runs on the way out.

`try`/`catch` is Perl's structured exception-handling syntax. The `try` block executes; if any statement in it throws (via `die`, an uncaught exception from a callee, or a runtime error), control transfers to the `catch` block with the exception value bound to the parenthesised lexical. If nothing throws, the `catch` block is skipped. Unlike `eval`, a `return` inside `try` returns from the enclosing sub, not from the block - `try` is control flow, not a call frame.

The syntax must be enabled with a feature guard:

```
use feature 'try';
```

Synopsis

```
try BLOCK catch (VAR) BLOCK
try BLOCK catch (VAR) BLOCK finally BLOCK
```

What you get back

`try` is a statement, not an expression, but it yields the last evaluated value of whichever branch ran - the `try` block on success, or the `catch` block on failure. Used as the final statement of a sub or a `do` block, that value becomes the result:

```
my $value = do {
    try {
        fetch_thing(@args);
    }
    catch ($e) {
        warn "fetch failed: $e";
        $DEFAULT;
    }
};
```

Do **not** write `return` inside a `try` that is being used this way - `return` exits the enclosing sub, bypassing the assignment.

A `finally` block's final expression is discarded; it cannot contribute to the value.

Global state it touches

- `$@` is **not** the mechanism here. `try`/`catch` binds the exception to the lexical named in `catch (VAR)`, not to `$@`. Code inside `catch` sees whatever `$@` happened to hold before the `try`; rely on the lexical.
- `$_`, `$!`, and other dynamic globals are untouched by the construct itself - only by whatever code runs inside the blocks.

The `catch` variable

`catch` must be followed immediately by a parenthesised variable declaration. `my` is implicit - write `catch ($e)`, not `catch (my $e)`. The variable is lexical to the `catch` block and holds the thrown value exactly as `die` delivered it: a string, a blessed reference, or any scalar:

```
try {
    risky();
}
catch ($e) {
    if (ref $e && $e->isa('My::Exception')) {
        $e->rethrow if $e->is_fatal;
        warn $e->message;
    }
    else {
        warn "plain die: $e";
    }
}
```

There is no multi-`catch` dispatch on exception class - write the classification yourself inside the single `catch` block.

`finally`

An optional third block runs on every exit path from the `try`/`catch` construct: normal fall-through, exception caught by `catch`, exception rethrown from `catch`, or a non-local transfer (`return`, `last`, `next`, `redo`, `goto`) out of either block.

```
try {
    open_resource();
    use_resource();
}
catch ($e) {
    warn "failed: $e";
}
finally {
    close_resource();
}
```

`finally` is the right place for release code that must run no matter how the protected section exits - file handles, locks, restoring global state.

A `finally` block has restrictions the other two blocks do not:

- No `return`, no `goto`, no `last` / `next` / `redo`. Attempting any of these is a compile-time or runtime error.
- The final expression value is ignored - `finally` cannot contribute to the construct's yielded value.

`finally` remains **experimental** in Perl 5.44 and emits a warning in the `experimental::try` category when used. `try` and `catch` themselves were de-experimentalised in 5.40 and no longer warn.

Contrast with `eval { ... } / $@`

The older pattern is still supported, but `try`/`catch` fixes three long-standing pitfalls:

Pitfall	`eval` / `$@`	`try` / `catch`
`$@` clobbering between `eval` exit and the `if ($@)` check	real hazard, needs `local $@` dance	exception bound to a fresh lexical
`return` inside the protected block	returns from the `eval`, not the sub	returns from the enclosing sub
Distinguishing "no error" from "error was false"	`$@` can be falsey-but-set	`catch` only runs on a real throw

Use `try` for new code. Reach for `eval EXPR` only when you actually need string-`eval`'s runtime compilation.

Examples

Trap an exception and log it:

```
use feature 'try';

try {
    my $x = call_a_function();
    $x < 100 or die "too big: $x";
    send_output($x);
}
catch ($e) {
    warn "unable to output a value: $e";
}
print "finished\n";
```

Use `try` as an expression inside `do` to pick a fallback:

```
use feature 'try';

my $config = do {
    try { load_config($path) }
    catch ($e) { warn "using defaults: $e"; default_config() }
};
```

Release a resource unconditionally with `finally`:

```
use feature 'try';
no warnings 'experimental::try';   # finally is still experimental

my $lock = acquire_lock();
try {
    do_critical_work();
}
catch ($e) {
    warn "critical work failed: $e";
}
finally {
    release_lock($lock);
}
```

Classify exceptions inside a single `catch` block:

```
use feature 'try';

try {
    fetch_remote();
}
catch ($e) {
    if (ref $e && $e->isa('Net::Timeout')) {
        retry_later();
    }
    elsif (ref $e && $e->isa('Net::Auth')) {
        die $e;                     # rethrow auth failures
    }
    else {
        warn "unexpected: $e";
    }
}
```

`return` inside `try` returns from the enclosing sub - not just the block:

```
use feature 'try';

sub first_valid {
    for my $path (@_) {
        try {
            return load($path);     # exits first_valid on success
        }
        catch ($e) {
            warn "skip $path: $e";
        }
    }
    return;                         # all paths failed
}
```

Edge cases

- **Feature guard required.** Without `use feature 'try'` (or a `use v5.34` or later bundle that enables it), `try` is a plain identifier and the construct is a syntax error.
- **`catch` is mandatory.** `try { ... }` on its own is not legal - every `try` needs a `catch`. Use `defer` or `finally` if you want cleanup without exception handling, paired with a trivial `catch ($e) { die $e }` rethrow if you also want to let the exception propagate.
- **Rethrowing.** Inside `catch`, `die $e` rethrows. There is no implicit rethrow if you simply fall off the end of `catch`; doing so **swallows** the exception. Decide deliberately.
- **`$@` is not cleared** by entering `try` and is not set by a caught exception. Do not read `$@` inside `catch` expecting the thrown value - read the lexical.
- **`caller()` does not see `try`.** Like `while` or `foreach`, `try` is not a call frame. `caller` skips it, which is correct: since `return` propagates through `try`, `try` has no independent return semantics worth exposing to introspection.
- **Loop controls pass through.** `last`, `next`, and `redo` inside `try` or `catch` act on the enclosing loop, not on the `try` construct. A `finally` block will still run before the transfer completes.
- **`finally` restrictions are enforced.** `return`, `goto`, and loop controls inside `finally` are errors. If you need conditional cleanup that may abort, do it in `catch` or outside the construct.
- **No try-expression sugar beyond last-statement yield.** `try` is not a general expression; it can only produce a value when it is the final statement of a block that yields (`do`, a sub). `my $x = try { ... } catch ($e) { ... };` is a syntax error.

Differences from upstream

Fully compatible with upstream Perl 5.44.

- `try` and `catch` are non-experimental (as of 5.40) and emit no warnings.
- `finally` is still experimental in 5.44 and emits `experimental::try` warnings when used; silence with `no warnings 'experimental::try'`.

See also

- `catch` - the mandatory second block; receives the exception in a parenthesised lexical
- `finally` - optional third block for unconditional cleanup; still experimental in 5.44
- `die` - the throw side of the construct; any scalar (string, blessed ref, object) can be the thrown value
- `eval` - the older block-eval / `$@` pattern, still needed for string `eval`; prefer `try` for pure exception handling
- `defer` - unconditional cleanup without a surrounding `try`/`catch`; the semantic basis on which `finally` is defined

- `return` - inside `try` returns from the enclosing sub, not from the block; inside `finally` it is an error

SCALARs and strings

uc

Return an uppercased copy of a string.

`uc` walks `EXPR` character by character and returns a new string in which every cased character has been replaced by its uppercase counterpart. Characters that have no uppercase mapping - digits, punctuation, already-uppercase letters, symbols - are passed through unchanged. If `EXPR` is omitted, `uc` operates on `$_`. The input is never modified; `uc` always returns a fresh string.

`uc` is the internal function implementing the `\U` escape in double-quoted strings, so `"\Ufoo\E"` and `uc("foo")` produce the same result.

Synopsis

```
uc EXPR
uc
```

What you get back

A new scalar string containing the uppercased version of `EXPR`. The length in characters is unchanged for all cased letters in the Basic Multilingual Plane; a few characters fold to a longer form under Unicode rules (see *Edge cases*), so the byte length and character length of the result can both grow.

```
my $s = uc("Perl is GREAT");   # "PERL IS GREAT"
```

Global state it touches

- `$_` - used as the implicit argument when `EXPR` is omitted.
- `LC_CTYPE` locale - consulted when `use locale` is active. `uc` otherwise ignores the environment.
- `use bytes` / `use feature 'unicode_strings'` / `use locale` - the lexical pragmas in scope at the **call site** select which of the casing rule sets below is applied.

Which rules apply

`uc` picks one of three rule sets based on the pragmas in effect and the internal representation of the string. The logic matches `lc` exactly; the mapping table is just the reverse.

- **`use bytes` in effect** - ASCII rules. Only `a-z` change, to `A-Z` respectively. Every byte outside `0x61..0x7A` is passed through unchanged, regardless of what it would mean as Latin-1 or UTF-8. Use this only when you have deliberately opted out of Unicode handling.

- **`use locale` for `LC_CTYPE` in effect** - the current locale governs code points below 256; Unicode rules govern the rest (the latter only reachable if the string has the UTF-8 flag set). From v5.20 onward, a UTF-8 locale gives full Unicode rules for the whole string. Under non-UTF-8 locales, case changes that cross the 255/256 boundary are not well-defined and, since v5.22, trigger a locale warning. See `perllocale`.
- **String has the UTF-8 flag set** - Unicode rules.
- **`use feature 'unicode_strings'` or `use locale ':not_characters'` in effect** - Unicode rules, even for byte strings.
- **Otherwise** - ASCII rules. Anything outside `a-z` is passed through unchanged. This is the historic default for strings that have neither the UTF-8 flag nor a lexical pragma opting into Unicode.

The practical takeaway: if you want predictable Unicode uppercasing of arbitrary input, put `use feature 'unicode_strings';` (or a modern `use v5.12;` or higher) at the top of the file and stop worrying about which representation the string happens to have.

Examples

Basic ASCII:

```
my $s = uc("hello");            # "HELLO"
```

Omitted argument operates on `$_`:

```
for ("alpha", "beta") {
    print uc, "\n";             # "ALPHA\n", "BETA\n"
}
```

`\U` in a double-quoted string is the same operation:

```
my $s = "Perl is \Ugreat\E";    # "Perl is GREAT"
```

Unicode uppercasing under `unicode_strings`:

```
use feature 'unicode_strings';
my $s = uc("straße");           # "STRASSE"
```

The German sharp s has no single-character uppercase in Unicode; it maps to the two-character sequence `SS`. The returned string is therefore one character longer than the input.

Greek lowercase letters uppercase into capitals, with unchanged characters passed through:

```
use feature 'unicode_strings';
my $s = uc("Καλημέρα, world!"); # "ΚΑΛΗΜΈΡΑ, WORLD!"
```

Byte mode confines the operation to ASCII, which is occasionally what you want for protocol tokens:

```
use bytes;
my $s = uc("héllo");           # "HéLLO" - only the ASCII letters␣
↪change
```

Edge cases

- **undef**: `uc(undef)` returns `""` and triggers an `uninitialized` warning under `use warnings`. Guard inputs that may be undefined if that warning matters.
- **Empty string**: `uc("")` returns `""`. No warning.
- **One-to-many mappings**: A small number of characters expand to multiple characters on uppercase - the best-known is U+00DF (ß) → SS, and the Greek U+0390 / U+03B0 expansions. The result string is longer than the input in those cases. Do not assume `length(uc($s)) == length($s)`.
- **Titlecase vs uppercase**: `uc` does **not** titlecase the first letter. Titlecase is a distinct Unicode category; `ucfirst` applies it to the first character and leaves the rest alone.
- **Non-cased characters**: Digits, punctuation, whitespace, symbols, and CJK ideographs are returned unchanged. `uc("42!")` is `"42!"`.
- **In-place update is not a thing**: `uc` returns a new value; it never modifies its argument. To uppercase in place, assign back: `$s = uc $s`.
- **Context**: `uc` is always scalar. Calling it in list context still produces a single string.
- **Byte-string / Unicode-flag surprises**: A string built from a `read` without a `:utf8` layer has no UTF-8 flag, so `uc` without `use feature 'unicode_strings'` will apply **ASCII rules** even if the bytes are valid UTF-8. Decode first, or enable the pragma, to get the casing the bytes look like they should get.
- **`use locale` and non-UTF-8 locales (v5.22+)**: Case changes that would cross the 255/256 boundary emit a `Can't do uc("…") on non-UTF-8 locale` warning and return the input character unchanged.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `lc` - the inverse operation; lowercases every cased character using the same rule selection
- `ucfirst` - uppercase (titlecase) only the first character of the string; for a Unicode-aware `ucfirst . lc $rest` pattern when titlecasing a whole word
- `lcfirst` - lowercase only the first character
- `fc` - Unicode casefolding for case-insensitive comparison; use this, not `uc` or `lc`, when comparing strings for equivalence
- `sprintf` - the `%s` conversion does not casefold; combine with `uc` when a format needs an uppercased field

- `tr///` - the `tr/a-z/A-Z/` idiom uppercases only ASCII and is faster than `uc` for guaranteed-ASCII input

SCALARs and strings

ucfirst

Return a copy of a string with its first character titlecased.

`ucfirst` takes a string, converts its **first character** to the Unicode **titlecase** form, and returns the result. Every other character is left untouched. The original is never modified. If the argument is omitted, `ucfirst` operates on `$_`. Titlecase usually coincides with uppercase - `"a"` becomes `"A"` - but differs for a small number of digraphs in scripts that distinguish the two (see *Edge cases*). The same pragma, locale, and UTF-8-flag rules that govern `lc` and `uc` govern `ucfirst`.

Synopsis

```
ucfirst EXPR
ucfirst
```

What you get back

A new string of the **same length in characters** as the input - only the first character is altered. The return value is always a fresh scalar; modifying it does not affect the argument, and modifying the argument afterward does not affect the returned string. The byte length may change by a few bytes if the first character's titlecase form has a different UTF-8 encoding from its original form.

```
my $str = ucfirst("hello world!");   # "Hello world!"
```

Global state it touches

- Reads `$_` when called without an argument.
- Observes `use locale` for `LC_CTYPE` - with locale in effect the current locale's uppercasing table applies to a first character whose code point is below 256.
- Observes `use bytes` - under `use bytes` only a leading `a-z` changes, to `A-Z`.
- Observes `use feature 'unicode_strings'` - forces Unicode rules regardless of the UTF-8 flag on the input.

Which casing rules apply

`ucfirst` picks one of five rulesets for the **first character**, in priority order. The first one whose condition holds wins. Subsequent characters are always passed through unchanged, regardless of which ruleset applied to the first.

1. **`use bytes` in effect** - ASCII rules. A leading `a-z` maps to `A-Z`; every other leading byte is left alone, including bytes in the 128-255 range that would otherwise be Latin-1 letters.

2. **`use locale for LC_CTYPE` in effect** - the current locale's tables apply to a first character below code point 256; a first character at 256 or above (only reachable when the string already carries the UTF-8 flag) uses Unicode rules. From Perl 5.20 onward, a UTF-8 locale uses full Unicode rules throughout.
3. **The argument has the UTF-8 flag set** - Unicode titlecase rules apply to the first character.
4. **`use feature 'unicode_strings'` or `use locale ':not_characters'` in effect** - Unicode titlecase rules apply to the first character, regardless of the UTF-8 flag.
5. **Otherwise** - ASCII rules. A leading character outside a-z is returned unchanged, including Latin-1 lowercase letters like à-þ.

The upshot: if you want predictable Unicode behaviour on every string regardless of how it was constructed, enable `use feature 'unicode_strings'` (or `use v5.12` and above, which turns it on for you).

Titlecase vs uppercase

For the overwhelming majority of characters, titlecase and uppercase are the same code point - `ucfirst("abc")` and `uc(substr("abc", 0, 1)) . substr("abc", 1)` produce identical results. They differ only for a handful of Unicode characters whose uppercase form is a sequence of two capital letters but whose titlecase form is a single capital-followed-by-lowercase letter. The standard example is the Latin digraph dz (U+01F3):

- uppercase is DZ (U+01F1) - `"DZ"` rendered as one capital glyph.
- titlecase is Dz (U+01F2) - `"Dz"`, capital D followed by small z.

`ucfirst` returns titlecase, which is the correct form when the character stands at the start of a capitalised word. `uc` on the same first character would return the two-capital form, which reads as if the whole word were in caps.

Examples

Basic ASCII first-character uppercasing:

```
my $s = ucfirst("hello, world!");     # "Hello, world!"
```

Default to `$_`:

```
for ("foo", "bar", "baz") {
    print ucfirst, "\n";              # Foo / Bar / Baz
}
```

Unicode characters only titlecase when the rules allow it:

```
use feature 'unicode_strings';
my $s = ucfirst("äpfel");             # "Äpfel"
```

Without `unicode_strings` and without the UTF-8 flag on the input, a non-ASCII first character passes through unchanged:

```
my $bytes = "\xE4pfel";                 # ä as a single Latin-1 byte
my $cap   = ucfirst $bytes;             # unchanged: "\xE4pfel"
```

`ucfirst` is what backs the `\u` escape inside double-quoted strings:

```
my $str = "\uperl\E is great";          # "Perl is great"
```

Capitalise every word - combine with `split`, `map`, and `join`:

```
my $title = join " ", map { ucfirst lc $_ } split / /, "HELLO world
 ↪";
# "Hello World"
```

Titlecase a digraph that distinguishes titlecase from uppercase:

```
use feature 'unicode_strings';
my $t = ucfirst("\x{01F3}xyz");          # "\x{01F2}xyz" - Dz, not DZ
```

Edge cases

- **`undef` argument** raises an `uninitialized` warning under `use warnings` and returns the empty string.
- **Empty string** returns the empty string - there is no first character to change.
- **Single-character string** behaves exactly like `uc` would for that one character under the same ruleset, except in the digraph cases described above where titlecase and uppercase differ.
- **Numbers are stringified first**: `ucfirst(42)` returns `"42"` - the leading `"4"` is not a cased character, so nothing changes.
- **Leading whitespace or punctuation** is **not** skipped. `ucfirst(" hello")` returns `" hello"` - the first character is the space, which has no titlecase form. If you need to capitalise the first *letter*, strip leading non-letters first or use a regex (`s/\b(\w)/\u$1/`).
- **`LATIN SMALL LETTER SHARP S` (U+00DF, ß)** titlecases to `"Ss"` under full Unicode rules - a length change that contradicts the usual "same length in characters" guarantee. Under `use locale` on a non-UTF-8 locale, Perl leaves the character unchanged rather than guessing, and from Perl 5.22 onward this raises a locale warning.
- **Locale and the UTF-8 flag interact**: under `use locale` on a non-UTF-8 locale, a first character below 256 follows the locale while a first character 256 or above follows Unicode. In practice `ucfirst` only ever touches one character, so the interaction is subtler than for `lc` / `uc`, but it is still observable in strings that begin with supplementary-plane characters.
- **Tied variables** have their `FETCH` called once. `ucfirst` does not modify the tied value; it returns a plain (non-tied) scalar.
- **`ucfirst` is a unary named operator**, not a list operator. `ucfirst $a, $b` parses as `(ucfirst $a), $b` - only `$a` is transformed, and the comma operator discards the result. Use parentheses or `map` when you mean to titlecase multiple strings:

```
my @capped = map { ucfirst } @words;
```

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `lcfirst` - the lowercasing counterpart; turns the first character into its lowercase form
- `uc` - uppercase every character in the string; use when you want the whole string capitalised, not just the first letter
- `fc` - Unicode casefold, the correct choice for case-insensitive comparison when input may contain non-ASCII
- `$_` - the default subject `ucfirst` reads when called with no argument
- `use locale` - controls whether locale tables or ASCII/Unicode rules apply to the first character when it is below code point 256
- `use feature 'unicode_strings'` - forces full Unicode titlecasing regardless of the UTF-8 flag on the input

Filehandles, files, directories

umask

Set or read the process file-creation mode mask.

`umask` controls which permission bits are **cleared** from the `MODE` argument of every file- or directory-creation call made by this process from now on. It is a property of the running process, not of any particular filehandle, and it is inherited by child processes. Call `umask EXPR` to install a new mask and receive the previous one; call bare `umask` to read the current mask without changing it.

Synopsis

```
umask EXPR
umask
```

What you get back

The **previous** umask as an integer, so you can save it and restore it later:

```
my $old = umask 0077;
# ... create private files ...
umask $old;
```

Bare `umask` returns the current mask without changing it. If the system has no `umask(2)` call and the caller is trying to restrict access for itself (`(EXPR & 0700) > 0`), an exception is raised; if the call is not implemented and the caller is not restricting its own access, `undef` is returned. On Linux this case does not arise.

How the mask is applied

The mask is **subtractive**. Every bit set in the umask is cleared from the `MODE` passed to `mkdir`, `sysopen`, `open` in creation modes, and the underlying `creat(2)` / `mkdir(2)` system calls. The effective permissions of the new file are `MODE & ~umask`.

A Unix permission like `rwxr-x---` is three sets of three bits, or three octal digits - `0750`. The leading `0` marks the literal as octal and is not itself a permission digit. A umask is written the same way and names the bits you want **disabled** for newly created files.

Worked example. With `umask 0022`, asking `sysopen` for `0666` actually creates a file with mode `0644`:

```
  0666  &~  0022   =   0644
  rw-rw-rw-    ----w--w-      rw-r--r--
```

With `umask 0027` (group may not write, others may not read, write, or execute), the same `0666` request yields `0640` (`0666 & ~0027 == 0640`).

Global state it touches

The mask itself is process-global kernel state set via `umask(2)`. `umask` does not read or write any Perl special variable directly, but every creation call in the process observes it, and `$!` is set by the underlying system calls that *consume* the mask (`mkdir`, `sysopen`, `open`), not by `umask` itself. Child processes spawned via `fork`, `exec`, or `system` inherit the current value.

Examples

Install a mask that hides the file from everyone but the owner, keeping the previous value for restoration:

```
my $old = umask 0077;
open my $fh, ">", "secret.txt" or die "open: $!";
# secret.txt is created mode 0666 & ~0077 == 0600
close $fh;
umask $old;
```

Read the current mask without changing it - useful for logging or diagnostics:

```
printf "current umask: %04o\n", umask;      # e.g. "current umask:␣
↪0022"
```

Typical values to pass - these are the three masks actually used in practice:

```
umask 0022;   # group + other: read/execute, no write   (default on␣
↪most systems)
```

(continues on next page)

(continued from previous page)

```
umask 0027;   # group: read/execute; other: nothing
umask 0077;   # owner-only; nothing for group or other
```

Scoped change around a block of file-creating code. `umask` has no `local` magic of its own - save and restore explicitly:

```
sub write_private_file {
    my ($path, $data) = @_;
    my $old = umask 0077;
    open my $fh, ">", $path or do {
        umask $old;
        die "open $path: $!";
    };
    print $fh $data;
    close $fh;
    umask $old;
}
```

Octal literal vs. string - a common trap. A umask is a **number**, not a string of octal digits. Reading one from configuration requires `oct`:

```
my $from_config = "0027";                    # string
umask oct $from_config;                      # correct: 0027 as a␣
↪number
umask $from_config;                          # WRONG: decimal 27 ==␣
↪033 octal
```

Edge cases

- **Bare `umask` in list context** still returns a single integer. The function is scalar-valued.
- **Negative or out-of-range values** are masked to the nine low-order permission bits by the kernel; only bits `0777` survive. Passing `0777` disables all permissions on every newly created file, which is almost never what you want.
- **`umask` does not affect existing files.** It only filters the `MODE` argument of *creation* calls. To change an existing file's permissions use `chmod`.
- **`umask` does not affect `open` for an existing file** - opening a file that already exists does not re-apply the mask. It applies only when a file is being created (`O_CREAT` in `sysopen`, or `>`/`>>`/`+>` modes creating a new pathname in `open`).
- **Inheritance across `fork`/`exec`.** Children start with the parent's current umask. Setting the mask before `system` or `exec` changes the environment the child inherits; restore it afterwards if the parent still cares.
- **Threads.** The umask is a per-process attribute in the kernel, so on systems where Perl threads share a process (the usual case) every thread sees the same mask. Changing it in one thread changes it for all.
- **`umask(2)` not implemented.** The POD documents a fallback path for systems without the syscall: raise on attempts to restrict the owner's own access, otherwise re-

turn `undef`. Every platform pperl targets has `umask(2)`, so this path is effectively unreachable here.

- **Octal presentation**. Print the mask with `printf "%04o"`; the default `%d` prints decimal, which is unreadable as permission bits.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `chmod` - change permissions on an **existing** file; the counterpart to the creation-time filtering `umask` performs
- `mkdir` - directory creation call whose `MODE` argument is filtered through the current umask
- `sysopen` - low-level file creation whose `MODE` argument is filtered through the current umask; the canonical place where the mask is felt
- `open` - in creation modes (`>`, `>>`, `+>`) the underlying `creat(2)` applies the umask to the default `0666`
- `oct` - convert a string like `"0027"` to the integer value `umask` expects
- `$!` - set by the creation calls that consume the mask, not by `umask` itself; check it after the `open` / `sysopen` / `mkdir` that fails

Misc

undef

The undefined value, and the operator that produces it.

`undef` wears two hats. Bare `undef` is a **value** - the canonical undefined scalar, the thing `defined` returns false for. `undef EXPR` is a **unary operator** that undefines its argument in place: the variable, array, hash, subroutine, or typeglob named by `EXPR` is emptied out and, where possible, its storage is released.

Both forms evaluate to the undefined value.

Synopsis

```
undef                  # the undefined value
undef EXPR             # undefine the lvalue EXPR, return undef
```

`EXPR` must be an lvalue: a scalar, an array (with `@`), a hash (with `%`), a subroutine (with `&`), or a typeglob (with `*`).

What you get back

Always the undefined value. The operator form returns `undef` *after* wiping its argument; the value form just hands you `undef`.

```
my $x = undef;                          # $x is now undef
return undef if $oops;                  # explicit "I mean no value"
my $was = undef $counter;               # $counter wiped, $was is undef
```

The value vs. the operator

Bare `undef` is the undefined scalar. Assigning it to a variable leaves the variable's storage in place and sets its value to undef:

```
my @big = (1) x 1_000_000;
$big[0] = undef;                        # slot 0 holds undef; @big still␣
↪huge
@big    = ();                           # empties the array, keeps the␣
↪AV
@big    = undef;                        # assigns the ONE-element list␣
↪(undef)
```

Note the last line: `@big = undef` is a list assignment of a one-element list whose only element is undef, so `@big` ends up with length 1. It is almost never what you want. Use `@big = ()` to empty, or `undef @big` to empty *and* release the backing storage.

The operator form does more than assign undef:

```
undef $scalar;          # scalar: sets value to undef, frees any PV␣
↪buffer
undef @array;           # array: frees all elements AND the AV's␣
↪storage
undef %hash;            # hash:  frees all entries AND the HV's␣
↪buckets
undef &sub;             # sub:   frees the CV body; the name still␣
↪exists
undef *glob;            # glob:  destroys $glob, @glob, %glob, &
↪glob, etc.
```

The distinction matters for memory. `@array = ()` leaves the allocated capacity intact so the next push is cheap; `undef @array` releases it. For a large, one-shot array that you want to truly let go of, use `undef`. For a working array you will refill, use `= ()`.

Examples

Returning "no value" from a subroutine. In scalar context this is a clean way to signal failure; in list context `undef` alone produces a one-element list containing undef, which is truthy:

```
sub find_user {
    my ($id) = @_;
```

(continues on next page)

(continued from previous page)

```
    return undef unless $id;        # scalar-context caller: false
    ...
}
```

For subroutines meant to signal failure in both contexts, return an empty list instead - `return` with no argument does the right thing:

```
sub find_user {
    my ($id) = @_;
    return unless $id;              # () in list ctx, undef in␣
↪scalar ctx
    ...
}
```

Skipping positional values in a list assignment. `undef` on the **left-hand side** of a list assignment is a placeholder that throws away the matching value:

```
my ($x, undef, $z) = foo();         # discard the middle value
my (undef, @rest)  = @_;            # drop the first arg, keep the␣
↪rest
```

Classic `select` idiom for a sub-second sleep - three ignored filehandle sets plus a timeout:

```
select undef, undef, undef, 0.25;   # sleep 250 ms
```

Dual-context return:

```
return wantarray ? (undef, $errmsg) : undef if $they_blew_it;
```

Releasing a large working set:

```
my %cache = build_huge_cache();
use_cache(\%cache);
undef %cache;                       # free buckets and entries now
```

Undefining a subroutine. The name in the symbol table stays, but calling it will complain about an undefined subroutine:

```
sub greet { print "hi\n" }
undef &greet;
greet();                            # Undefined subroutine &
↪main::greet
```

Undefining a typeglob nukes *every* slot at once:

```
our $xyz = 1;
our @xyz = (1, 2);
our %xyz = (a => 1);
sub xyz { 42 }
```

(continues on next page)

(continued from previous page)

```
undef *xyz;                             # $xyz, @xyz, %xyz, &xyz all␣
↪gone
```

Edge cases

- **`undef $hash{$key}` is not `delete`.** It sets the value at that key to undef; the key itself still exists and `exists` still returns true. Use `delete $hash{$key}` to remove the key. The same applies to array elements: `undef $arr[3]` leaves index 3 in place with value undef, it does not shorten the array.
- **On tied variables and DBM values**, `undef $tied{$key}` invokes the tie's `STORE`, not its `DELETE`. The perldoc warning ("probably not do what you expect on most predefined variables or DBM list values") is specifically about this.
- **`undef` is a unary operator, not a list operator.** It takes exactly one argument, so `undef $a, $b` parses as `(undef $a), $b` - only `$a` is undefined. To undefine several variables, call it several times, or use a loop:

  ```
  undef $_ for $a, $b, $c;
  ```

- **`undef EXPR` requires an lvalue.** `undef 42` or `undef func()` is a compile-time error (*Can't modify ... in undef operator*).
- **Left-hand `undef` in list assignment is syntax, not a value.** `(undef, $x) = @pair` is parsed specially; you cannot write `my $slot = undef; ($slot, $x) = @pair` and expect the first value to be discarded - that assigns into `$slot`.
- **Constant `undef` in boolean context is false**, in numeric context is `0`, in string context is `""`. Under `use warnings` each of those conversions emits a `Use of uninitialized value` warning at the point of use, not at the point the variable became undef.
- **`undef &sub` does not remove the subroutine name** from its package stash - only the code. To remove the name as well, undefine the whole glob slot: `delete $Package::{sub_name}` or `undef *Package::sub_name` if you also want the sibling slots gone.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `defined` - the predicate that asks "is this value not undef?"; the natural counterpart to the `undef` value
- `delete` - remove a hash key or array element entirely; use this, not `undef`, when you want `exists` to become false
- `exists` - check whether a hash key or array index is present, regardless of whether its value is defined

- `local` - temporarily replace a package variable's value (often with `undef`) for the duration of a scope
- `wantarray` - pairs with `undef` in the idiomatic `wantarray ? (undef, $err) : undef` dual-context failure return

Filehandles, files, directories

unlink

Remove one or more directory entries that name files.

`unlink` asks the kernel to drop the link between each name in `LIST` and the file it refers to. If that link was the last one and no process still holds the file open, the file's storage is reclaimed; otherwise the file remains on disk, nameless but accessible through any open descriptor, until the last handle is closed. `unlink` operates on **directory entries**, not on file contents.

Synopsis

```
unlink LIST
unlink
```

What you get back

The number of files `unlink` actually removed, as an integer. On total success that equals `scalar @LIST`; on partial or total failure it is the count of names that were removed before and after the ones that failed. Zero is a valid "false" return when nothing could be removed. `$!` is set to the error from the **last** failing call - it does **not** tell you which name failed.

```
my $removed = unlink 'a', 'b', 'c';
unlink @goners;
unlink glob "*.bak";
```

If `LIST` is omitted, `unlink` operates on the single filename in `$_`.

Global state it touches

- `$_` - used as the operand when `unlink` is called with no arguments.
- `$!` - set to `errno` from the last `unlink(2)` that failed. Because it reflects only the final failure in the list, it is not a reliable way to diagnose which name could not be removed.

Finding out which file failed

`unlink` returns a count, not a per-file status, and overwrites `$!` on every iteration. To attribute errors to individual names, call `unlink` once per file:

```
foreach my $file (@goners) {
    unlink $file
        or warn "could not unlink $file: $!";
}
```

The per-file form also lets you keep going after a failure, which the list form does implicitly but silently.

Directories

unlink does **not** remove directories. On Linux it returns `0` and sets `$!` to `EISDIR` when asked to. The perl binary recognises a `-U` command-line switch that, combined with running as superuser, lifts the check - but even then unlinking a directory bypasses the filesystem's directory-integrity guarantees and can corrupt the parent directory's link count. Use `rmdir` instead; it calls `rmdir(2)`, which is the correct syscall for removing an empty directory entry.

```
rmdir $dir  or die "rmdir $dir: $!";    # correct
unlink $dir;                            # fails with EISDIR
```

POSIX deletion semantics

unlink removes the **name**, not the file. As long as any process holds the file open, the file's data and inode remain valid and that process can keep reading and writing through its descriptor. Storage is reclaimed only when the last name is gone **and** the last descriptor is closed. This is the idiomatic pattern for creating a temporary file that cleans itself up even on a crash:

```
open my $fh, "+>", $path or die "open $path: $!";
unlink $path or die "unlink $path: $!";
# $fh is still usable; $path is gone from the directory.
# When $fh closes or the process exits, the storage is freed.
```

It is also why a long-running program can keep writing to a log file whose name has been unlinked by an operator - the writes succeed, but nothing on disk is visible under the old name. `df` will report the space as used until the handle closes.

Symbolic links

If a name in `LIST` is a symbolic link, unlink removes the **link itself**, not the file it points at. The target is left untouched even if the link is dangling or points to a directory. This matches the `unlink(2)` syscall and is almost always what you want; use `readlink` first if you specifically need to act on the target.

Examples

Remove a single file, check the result:

```
unlink $path
    or die "cannot remove $path: $!";
```

Remove several and report the tally:

```
my @files  = glob "*.tmp";
my $gone   = unlink @files;
warn "removed $gone of ", scalar @files, " files\n"
    if $gone != @files;
```

Per-file diagnostics (the only reliable way to know which name failed):

```
my @failed;
for my $f (@goners) {
    unlink $f or push @failed, "$f: $!";
}
die "unlink failures:\n", join("\n", @failed), "\n" if @failed;
```

Rely on `$_` in a chain of file tests:

```
for (glob "*.bak") {
    next unless -f && -M _ > 30;    # older than 30 days
    unlink or warn "skip $_: $!";
}
```

Self-cleaning scratch file (POSIX unlink-while-open idiom):

```
open my $scratch, "+>", "/tmp/work.$$" or die $!;
unlink "/tmp/work.$$"                  or die $!;
# write through $scratch, no cleanup needed on exit
```

Edge cases

- **Empty LIST**: `unlink ()` returns `0` and does not touch `$!`. Passing an empty array behaves the same way.
- **Non-existent name**: returns `0` for that entry and sets `$!` to `ENOENT`. The rest of the list is still processed.
- **Permission denied**: `unlink(2)` checks write permission on the **containing directory**, not on the file itself. Removing a file you cannot write is allowed as long as you can write its parent directory; removing a file you own in a directory you cannot write is not. `$!` will be `EACCES` or `EPERM`.
- **Sticky directories** (`/tmp`, mode 1777): non-root users may only unlink names they own. Failures surface as `EPERM`.
- **Return value in boolean context**: `unlink @files or die` fires only when **every** name failed (count is `0`). To die on **any** failure, compare against `scalar @files` or use the per-file loop.
- **Busy file on Linux**: Linux does not prevent `unlink` of a file that is mmap'ed, executing, or open - the name is removed and the POSIX semantics above apply. Other operating systems may return `ETXTBSY` or `EBUSY`; this page covers Linux.
- **Taint mode**: names coming from tainted data are allowed as operands to `unlink`; see `perlsec` for the usual caveats about accepting untrusted paths.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `rmdir` - remove an **empty** directory; the correct tool when the name refers to a directory entry of type `DIR`
- `rename` - move or re-link a name without dropping it, often combined with `unlink` when replacing a file atomically
- `link` - create an additional hard link to a file; `unlink` is its inverse for one name at a time
- `symlink` - create a symbolic link; note that `unlink` removes the symlink itself, not its target
- `truncate` - shrink a file in place without unlinking it when you want to reuse the name

Lists · Fixed-length data

unpack

Extract typed values from a binary or fixed-width string according to a template.

`unpack` is the inverse of `pack`. It walks `EXPR` left to right, consuming the bytes described by each directive in `TEMPLATE` and turning them into Perl values. The result is a list - one value per directive, or per repetition when a directive has a count. If `EXPR` is omitted, `unpack` reads from `$_`.

This page is a **directive reference**. For a narrative introduction with worked protocol and file-format examples, start at the *pack/unpack tutorial*.

Synopsis

```
unpack TEMPLATE, EXPR
unpack TEMPLATE                                  # reads from $_
my @fields = unpack "A10 A10 A*", $line;
my ($ver, $len, $payload) = unpack "n N A*", $msg;
```

What you get back

A list of values, one per directive (or per repetition when a directive has a count). In **scalar context**, only the **first** value produced is returned:

```
my @all   = unpack "A4 A4 A*", $rec;    # three values
my $first = unpack "A4 A4 A*", $rec;    # just the first - not a
↪count
```

Each directive determines the Perl type of its result - see the “Result type” column in the directive table below.

Global state it touches

`unpack TEMPLATE` with no `EXPR` reads `$_`. No other interpreter globals are consulted. The `C0` / `U0` directives switch template byte-vs-character interpretation locally within the template but do not mutate any outside state.

Template syntax

Identical to `pack`: a sequence of directive letters, optionally followed by repeat counts `N` / `*` / `[…]` and modifiers `!` / `<` / `>`. Parentheses form groups; `#` introduces a template comment. See `pack` for the full syntax rules - this page covers only the unpack-specific semantics.

Directive table

Every unpack directive in one place. **W** is the width in bytes consumed from the input per scalar produced.

Directive	W	Signed	Endian	Result type	Modifiers	Notes
a	count	-	-	string	-	Returns bytes untouched
A	count	-	-	string	-	Strips trailing whitespace and NUL
Z	count	-	-	string	-	Returns everything up to the first NUL
b	count/8	-	-	bit string	-	“0”/”1” characters, LSB of each byte first
B	count/8	-	-	bit string	-	“0”/”1” characters, MSB of each byte first
h	count/2	-	-	hex string	-	`[0-9a-f]` characters, low nybble first

continues on next page

Table 2 – continued from previous page

Directive	W	Signed	Endian	Result type	Modifiers	Notes
H	count/2	-	-	hex string	-	[0-9a-f] characters, high nybble first
c	1	yes	-	integer	-	Signed char
C	1	no	-	integer	-	Unsigned char
W	1	no	-	integer	-	Unsigned char; yields codepoint in U0 mode
s	2	yes	native	integer	! < >	s! = native short
S	2	no	native	integer	! < >	S! = native unsigned short
l	4	yes	native	integer	! < >	l! = native long
L	4	no	native	integer	! < >	L! = native unsigned long
i	native	yes	native	integer	! < >	sizeof(int)
I	native	no	native	integer	! < >	sizeof(unsigned int)
q	8	yes	native	integer	< >	Requires 64-bit-integer Perl
Q	8	no	native	integer	< >	Requires 64-bit-integer Perl
n	2	no	big	integer	!	Network order; n! = signed
N	4	no	big	integer	!	Network order; N! = signed
v	2	no	little	integer	!	"VAX" order; v! = signed

continues on next page

Table 2 – continued from previous page

Directive	W	Signed	Endian	Result type	Modifiers	Notes
V	4	no	little	integer	!	"VAX" order; V! = signed
j	IV size	yes	native	integer	< >	Perl-internal IV
J	UV size	no	native	integer	< >	Perl-internal UV
f	4	-	native	number	< >	Single-precision IEEE 754
d	8	-	native	number	< >	Double-precision IEEE 754
F	NV size	-	native	number	< >	Perl-internal float
D	varies	-	native	number	< >	Long double
p	ptr size	-	native	string	< >	Dereferences pointer to NUL-terminated string
P	ptr size	-	native	string	< >	Dereferences pointer; count = bytes to read
u	varies	-	-	string	-	Uudecoded bytes
U	varies	-	-	integer	-	Unicode codepoint number
w	varies	no	-	integer	-	BER-compressed integer
x	1	-	-	(none)	!	Skip one byte forward; x!N aligns forward
X	−1	-	-	(none)	!	Back up one byte; X!N aligns backward

continues on next page

Table 2 – continued from previous page

Directive	W	Signed	Endian	Result type	Modifiers	Notes
`@`	absolute	-	-	(none)	!	Jump to position N within the innermost group
`.`	-	-	-	integer	!	Return current position (relative to start of group / string)
`( … )`	-	-	-	-	`< > !`	Group: repeat count and endianness propagate inside
`/`	-	-	-	-	-	See “Length-prefixed payloads” below
`%N`	varies	-	-	integer	-	**Prefix.** N-bit checksum of the following directive’s values

The modifiers have the same meaning as in `pack`: `!` selects native sizes, alignment semantics, signedness for `n` / `N` / `v` / `V`, or byte offsets for `@` / `.`; `<` / `>` force endianness.

Differences from pack

- **`a` strips nothing** (returns bytes raw); **`A` strips trailing whitespace and NUL**; **`Z` stops at the first NUL.** With `pack` all three pad; with `unpack` all three un-pad differently.
- **`x` skips forward by W, `X` backs up by W.** `X` before the start of the string is a fatal error.
- **`/` reads a count from the data, then applies it to the next directive**:

```
unpack("W/a", "\004Gurusamy")          # ("Guru")
unpack("a3/A A*", "007 Bond  J ")      # (" Bond", "J")
unpack("n/a*", "\x00\x0chello, world") # ("hello, world")
```

With `pack` the form is *length-item*`/`*item* and the length is computed from the value's length. With `unpack` the form is `/`*item* (no length-item before) - the preceding integer directive supplies the count.

- **`%N` is unpack-only.** It replaces the following directive's normal output with the `N`-bit sum of the values that directive would otherwise have produced. `%32W*` is the System V `sum` checksum. `%32b*` counts set bits.
- **`.` returns the current byte position** rather than zero-filling to one. Useful after `x` / `X` navigation to learn where you are.
- **`p` and `P` dereference pointers read from the input** - almost always unsafe unless you know the input was produced by `pack "p"` / `pack "P"` in the same process.
- **Under-run / over-run behaviour:** if the template asks for more data than `EXPR` contains, the result is not well-defined (may yield empty strings, zeros, a decreased repeat count, or an exception). If `EXPR` is longer than the template consumes, trailing bytes are silently ignored.

Examples

Parse a minimal binary protocol header - a 16-bit version, a 32-bit length, then a variable-length payload, all network byte order:

```
my ($ver, $len, $payload) = unpack "n N A*", $msg;
```

Split a fixed-width text record - faster and clearer than chained `substr` calls:

```
my ($date, $desc, $amount) = unpack "A10 A27 A*", $line;
# "2026-04-22 coffee at the station           3.50"
# $date = "2026-04-22", $desc = "coffee at the station",
# $amount = "3.50"
```

Extract a System V-style checksum with the `%` prefix - the 32-bit sum of every byte, masked to 16 bits:

```
my $checksum = do {
    local $/;                              # slurp
    unpack "%32W*", readline $fh;
} % 65535;
```

Count set bits in a bit vector - `%32b*` reads the whole mask as bits and returns their sum:

```
my $setbits = unpack "%32b*", $selectmask;
```

Read a sequence of little-endian 32-bit integers off a raw buffer:

```
my @ints = unpack "V*", $buf;
```

Use `x` to skip filler bytes, `X` to back up after peeking:

```
# 2-byte tag, skip 2 reserved bytes, then 4 32-bit big-endian values
my ($tag, @vals) = unpack "n x2 N4", $frame;
```

Edge cases

- **Scalar context returns only the first value.** Assigning `unpack` to a scalar is almost never what you want. To count fields, assign to a list first, or use `() = unpack ...` in list context:

  ```
  my $n = () = unpack "A10 A10 A*", $line;   # 3
  ```

- **`*` is greedy, not a placeholder.** `A*` consumes all remaining bytes as one string; there is no backtracking. A `*` directive must be the last one in its sequence, or nothing after it runs.
- **Templates are not regular expressions.** Whitespace is ignored, but there is no alternation, no `|`, no lookahead. If data shape depends on earlier fields, unpack in stages: decode a header, then call `unpack` again on the payload using a template derived from what you just read.
- **Byte vs. character semantics.** `unpack` runs in byte mode by default on a byte string and in character mode on a string with the UTF-8 flag set. `C0` forces byte mode from that point; `U0` forces UTF-8 mode. Mixing a UTF-8-flagged string with numeric directives like `N` reads codepoints, not bytes - usually not what you want. Call `utf8::encode` first, or operate on byte-level data.
- **`X` past the start of the string is fatal.**
- **`p` / `P` on an arbitrary input is undefined behaviour.** Never use them on data you did not pack yourself in the same process.
- **No EXPR argument**: `unpack TEMPLATE` reads `$_`. Useful inside `while (<$fh>) { ... }` loops over fixed-width records.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `pack` - the inverse operation; same template language
- `substr` - extract a single fixed slice; simpler for one field, slower for many
- `sprintf` - round-trip between binary and human-readable
- `read` - read raw bytes off a filehandle into a buffer for `unpack`
- `vec` - indexed access to a bit vector without a template
- *pack/unpack tutorial* - task-oriented walkthrough with worked protocol and file-format examples

Arrays

unshift

Prepend one or more values to the start of an array and return the array's new length.

`unshift` is the mirror of `push`: where `push` appends at the tail, `unshift` inserts at the head. The values in `LIST` are prepended as a group, in the order given, so the first argument of `LIST` becomes the new element 0, the second becomes element 1, and so on, with the original contents sliding to higher indices.

Synopsis

```
unshift @arr, $val
unshift @arr, @more
unshift @arr, $first, $second, $third
```

What you get back

The new number of elements in the array, as an integer. This is the same value you would get from `scalar @arr` after the call.

```
my @colors = ("red");
my $n = unshift @colors, "blue", "green";   # $n == 3
```

Most calls discard the return value; it is occasionally useful when you want to prepend and branch on the resulting size in one step.

Examples

Prepend a single element:

```
my @animals = ("cat");
unshift @animals, "mouse";
# @animals is now ("mouse", "cat")
```

Prepend several elements - **the order is preserved**, not reversed. This is the single most common `unshift` confusion:

```
my @a = (10, 20, 30);
unshift @a, 1, 2, 3;
# @a is now (1, 2, 3, 10, 20, 30)
# NOT (3, 2, 1, 10, 20, 30)
```

If you genuinely want the prepended values reversed, reverse them explicitly:

```
my @a = (10, 20, 30);
unshift @a, reverse(1, 2, 3);
# @a is now (3, 2, 1, 10, 20, 30)
```

Prepend a whole array - the elements are spliced in, not the array as a single value:

```
my @head = ("a", "b");
my @tail = ("c", "d");
unshift @tail, @head;
# @tail is now ("a", "b", "c", "d")
```

Insert at the front vs. insert at the rear. These two calls produce mirror-image results on the same starting array:

```
my @x = (2, 3);
push    @x, 4;      # @x is (2, 3, 4)   - 4 goes to the rear
unshift @x, 1;      # @x is (1, 2, 3, 4) - 1 goes to the front
```

Work on an array through a reference. `unshift` accepts a dereferenced array on the left:

```
my $ref = [10, 20, 30];
unshift @$ref, 0;
# $$ref[0] is now 0, @$ref is (0, 10, 20, 30)
```

The arrow-deref form works the same way; write the deref as its own expression rather than stretching a method chain across the `unshift` argument:

```
my @list = @$ref;
unshift @list, -1;
```

Edge cases

- **Cost is O(n).** Every existing element is shifted up by `scalar(LIST)` slots, so prepending to a large array is proportionally expensive. If you are building a list by repeated prepending, build it with `push` and `reverse` at the end - or build it backwards with indices - instead of `unshift`ing in a loop.
- **List is prepended whole, not reversed.** `unshift @a, 1, 2, 3` places 1 at index 0, 2 at index 1, 3 at index 2. Readers coming from languages where "push to front" naturally reverses (because each element becomes the new head) often expect the opposite; Perl does not.
- **Empty `LIST` is a no-op.** `unshift @arr` with nothing after it leaves the array unchanged and returns the current element count.
- **Tied arrays**: `unshift` on a tied array calls the `UNSHIFT` handler if the package provides one; otherwise it falls back to a sequence of `SPLICE` or `STORE` / `STORESIZE` calls. A tie class that only implements `FETCH` and `STORE` can still be `unshift`ed, but every call rewrites every index.
- **Dereferenced array works**: `unshift @$ref, $x` modifies the array referenced by `$ref` in place. `unshift @{ $h{key} }, $x` autovivifies `$h{key}` to an empty array reference if it did not previously exist.
- **Scalar expression on the left is a syntax error.** A Perl 5.14 experiment briefly accepted `unshift $scalar, ...` to mean "treat `$scalar` as an array reference and prepend"; it was removed in Perl 5.24 and stays removed. Write `unshift @$scalar, ...`.

- **Return value in scalar vs. list context** is the same integer. Unlike many builtins, `unshift` does not behave differently in list context - it always returns the new length.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `push` - the other end: append to the tail of the array and return the new length
- `shift` - the inverse operation: remove and return the first element
- `pop` - symmetric partner to `shift`, removes from the tail
- `splice` - general-purpose insert/remove at an arbitrary position; `unshift @a, LIST` is equivalent to `splice(@a, 0, 0, LIST)`
- `reverse` - pair with `unshift` when you do want the prepended values to end up in reverse order
- `List::Util` - no dedicated `prepend`; for head-insert semantics `unshift` is the idiomatic tool, and `List::Util::pairs` / `List::Util::zip` compose with it when you are restructuring list shapes rather than just adding to one

Classes and OO

untie

Break the binding between a variable and its tied class.

`untie` reverses a prior `tie`: after the call, `VARIABLE` goes back to being a plain scalar, array, hash, or filehandle, and subsequent reads and writes touch the raw storage rather than being routed through the tied package's `FETCH`, `STORE`, and friends. If the variable is not tied, `untie` is a no-op.

Synopsis

```
untie VARIABLE
```

What you get back

Returns a true value if the variable was tied and the binding was removed, false otherwise. The return value is rarely checked - call sites know whether they are unwinding a tie they set up themselves.

As a side effect, if the tied package defines an `UNTIE` method, it is invoked on the tied object before the binding is dropped. `UNTIE` receives the object and a count of any outstanding inner references held to it (see *Edge cases* below).

What it does

1. Locate the magic on `VARIABLE` that a prior `tie` installed.
2. If the tied package provides `UNTIE`, call it on the object.
3. Remove the magic so the variable reverts to ordinary storage.
4. Release the interpreter's reference to the tied object. The object is destroyed (triggering `DESTROY` if defined) once no other references to it remain.

After `untie`, any value `tied` previously returned for this variable no longer corresponds to a live binding.

Examples

Tie a hash, use it, then release it:

```
use Tie::File;
tie my @lines, 'Tie::File', 'log.txt' or die $!;
push @lines, "new entry";
untie @lines;                       # flush and release
```

A round-trip through `tied` - grab the underlying object so you can call a non-tied method on it, then drop the binding:

```
my $obj = tied %cache;
$obj->flush;
untie %cache;
```

`untie` on a variable that was never tied is harmless:

```
my %h;
untie %h;                           # no-op, no warning
```

An `UNTIE` hook that runs before the binding goes away:

```
package My::Tied;
sub TIEHASH { bless {}, shift }
sub UNTIE   { my ($self, $count) = @_;
              warn "untie with $count outstanding refs" if $count }
# ...
tie   my %h, 'My::Tied';
untie %h;                           # calls My::Tied::UNTIE($obj, 0)
```

Edge cases

- **Outstanding inner references**: if code stashed the object returned by `tie` or `tied` somewhere that still holds it at the moment `untie` runs, Perl issues

  ```
  untie attempted while N inner references still exist
  ```

under `use warnings`. The binding is removed anyway, but those stashed references continue to point at the now-detached object. Drop those references first, or accept that they will now see the un-tied object in isolation.

- **Calling `untie` on a non-tied variable** is a no-op. No warning, no error, no method call.
- **Filehandle tie**: `untie *FH` removes the tie installed by `tie *FH, $class, ...`. The underlying glob and any real file descriptor behind it are unaffected - `untie` does not `close`.
- **`UNTIE` is optional**: if the tied package does not define one, the binding is simply removed. Do not rely on `UNTIE` running; many tied classes omit it.
- **Destruction order**: `untie` does not itself call `DESTROY`. The object is destroyed when its refcount hits zero, which may be immediately after `untie` (if nothing else holds it) or later (if the caller kept a copy from `tied`).
- **Localised tied variables**: a tie installed inside a scope on a `local`ised variable is undone automatically when the scope exits; you do not need an explicit `untie`, and calling one is harmless.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `tie` - install the binding that `untie` removes; shows the full set of tie-hook method names
- `tied` - fetch the object currently bound to a tied variable, typically just before calling `untie` on it
- `bless` - `tie` blesses the object it is given; `untie` does not unbless, it only detaches the variable from it
- `ref` - inspect what kind of reference `tied` returned before deciding to `untie`
- `local` - scope-bounded alternative when you want the tie to go away on block exit without an explicit `untie`

Scoping · Modules · Classes and OO

use

Load a module at compile time and import its symbols into the current package.

`use` is the everyday mechanism for pulling in library code. It runs at **compile time**, not at run time: the named module is located on `@INC`, loaded (if not already in `%INC`), and given a chance to alter the caller's namespace - typically by aliasing subroutine or variable names into it. The same syntax also drives **pragmas** (compiler directives like `strict` or `warnings`); the only difference is convention - pragmas are lowercase and usually have lexical, not package-wide, effects.

A `use` statement is defined to be exactly equivalent to:

```
BEGIN { require Module; Module->import(LIST); }
```

The `BEGIN` forces both the load and the import to happen while the surrounding file is still being parsed, so the imported names are visible to the compiler for the rest of the file.

Synopsis

```
use Module VERSION LIST
use Module VERSION
use Module LIST
use Module
use Module ()
use VERSION
```

What you get back

`use` is a declaration, not an expression - it has no useful return value and cannot appear on the right-hand side of anything. Its effect is a **side effect on the current compilation unit**: package `%INC` gets an entry, the importing package gets whatever symbols `import` aliased in, and - for `use VERSION` - the current lexical scope gets a feature bundle turned on.

If the module cannot be loaded, or if `import` dies, the `BEGIN` block propagates the exception and compilation aborts.

The four module forms

use Module

Loads the module and calls its `import` method with **no arguments**. The module decides what "no arguments" means; for `Exporter`-based modules it typically means "export your `@EXPORT` defaults":

```
use File::Spec;                 # calls File::Spec->import()
```

use Module LIST

Loads the module and calls `import` with `LIST`:

```
use List::Util qw(first sum max);
```

This is the common "import exactly these names" form. `LIST` is passed verbatim to `import`; its meaning is the module's business, not the language's.

use Module ()

Empty parentheses disable the import call entirely. This is distinct from omitting the list - no `import` method is invoked at all:

```
use POSIX ();                  # load, but do not import anything
POSIX::strftime(...);          # call by full name instead
```

Equivalent to:

```
BEGIN { require POSIX }
```

Use this when you want the module loaded but do not want your namespace altered - typically because you will call everything by fully qualified name, or because the module's default exports would clobber something you care about.

use Module VERSION / use Module VERSION LIST

When a VERSION appears immediately after `Module` (no comma), `use` calls the module's `VERSION` method with that version as an argument **before** calling `import`:

```
use List::Util 1.45 qw(uniq);
```

is equivalent to:

```
BEGIN {
    require List::Util;
    List::Util->VERSION(1.45);
    List::Util->import(qw(uniq));
}
```

The default `VERSION` method, inherited from `UNIVERSAL`, croaks if the requested version is greater than `$Module::VERSION`.

VERSION must look like a version literal - a digit, or `v` followed by a digit. Arbitrary expressions in that position are parsed as the start of `LIST`, not as a version. Note there is **no comma after VERSION**.

use VERSION - request a Perl language level

`use VERSION` (with no module name) declares the minimum Perl version the file requires, and **lexically enables the matching feature bundle**:

```
use v5.36;                     # v-string form - preferred
use 5.036;                     # numeric form - equivalent
use 5.036_000;                 # older numeric form
```

An exception is raised at compile time if the running Perl is older than VERSION; the rest of the file is not even parsed.

Beyond the version check, `use VERSION` turns on the features bundled with that release:

- **`use v5.12`** or higher - implicit `use strict`.

- **`use v5.35`** or higher - implicit `use warnings`.
- **`use v5.36`** - the common modern baseline: adds `say`, `signatures`, `isa`, and the earlier bundles' features.
- **`use v5.39`** or higher - lexically imports `builtin` functions for the matching bundle.
- **`use v5.41`** or higher - enables `source::encoding 'ascii'`.

`use VERSION` does **not** load `feature.pm`, `strict.pm`, `warnings.pm`, or `builtin.pm` - it implements the equivalent behaviour directly. Place it at the top of the file, before anything that depends on those features being active.

From Perl 5.39 onward, issuing a second `use VERSION` while one is already in effect is a fatal error. In older bundles it was merely deprecated.

Modules vs pragmas

Syntactically, pragmas and modules are identical - both are just packages whose `import` method you invoke via `use`. The conventional differences:

- **Naming.** Pragmas are lowercase (`strict`, `warnings`, `feature`, `integer`); modules are `Studly::Caps`.
- **Scope of effect.** Pragmas usually alter the **current lexical scope** (a block, not a package) and unwind at the closing brace. Modules usually alter the **current package** and persist until end-of-file.
- **`no`.** The counterpart `no` statement calls `unimport` instead of `import`. Pragmas typically implement `unimport` to undo their effect; most ordinary modules do not.

```
use strict;                     # lexical - affects this block /␣
↪file
use warnings;                   # lexical
{
    no warnings 'uninitialized';
    # warnings off only in this block
}

use List::Util qw(sum);         # package-scoped - affects main::
```

Conditional loading

Because `use` runs at compile time, it **ignores ordinary runtime control flow**. A `use` inside the false branch of an `if` is still executed:

```
if (0) {
    use Heavy::Module;          # loaded anyway - compile time!
}
```

For genuinely conditional loading, either use `require` at run time, or delegate to the `if` pragma:

```
use if $] >= 5.036, 'experimental', 'builtin';
use if $^O eq 'MSWin32', 'Win32::API';
```

Examples

Load a module with its default exports:

```
use Carp;                           # croak, carp, confess visible here
```

Import a specific subset:

```
use List::Util qw(first min max sum);
```

Load without importing - call by full name:

```
use Scalar::Util ();
my $ok = Scalar::Util::looks_like_number($x);
```

Require a minimum module version:

```
use Moo 2.000000;
```

Declare the Perl language level and pick up its feature bundle:

```
use v5.36;                          # strict, warnings, say, signatures.
 ↪..
sub greet ($name) {
    say "hello, $name";
}
```

Turn a pragma on for a file, then off for one block:

```
use warnings;

sub legacy_parser {
    no warnings 'uninitialized';
    return join ",", @_;            # undefs render as "" without␣
 ↪warnings
}
```

Conditional pragma via the `if` helper:

```
use if $] < 5.010, 'MRO::Compat';
```

Edge cases

- **`Module` must be a bareword.** `use $name;` is a syntax error - `use` does not accept a runtime expression for the module name. Use `require` for that.
- **No comma between `Module` and `VERSION`.** `use List::Util 1.45` is a version check; `use List::Util, 1.45` is a syntax error.

- **The version literal rule is strict.** Anything that does not start with a digit or with v followed by a digit is parsed as the beginning of LIST, not as a version. `use Module "1.45"` passes the string `"1.45"` to `import`; it does **not** check a version.
- **Empty LIST vs omitted LIST.** `use Module;` calls `Module->import()`. `use Module ();` does not call `import` at all. The distinction matters for modules whose `import` has side effects even with no arguments.
- **Missing `import` method.** If the module does not define (and does not inherit) an `import` method, the call is silently skipped - no error, even if AUTOLOAD is defined.
- **`use` inside `eval`.** BEGIN runs at compile time of the `eval`'d code, so `eval "use Some::Module"` delays loading until the `eval` runs. This is the common way to probe for an optional module at run time:

```
eval { require Some::Module; Some::Module->import };
my $have_it = !$@;
```

- **Ordering of `use VERSION` and other pragmas.** Place `use VERSION` first, so the feature bundle is in effect before later pragmas (which may depend on it) run. A later `no strict 'refs'` still overrides the strictures implied by `use v5.12+`, but relying on that is discouraged.
- **Pragmas that look like modules.** Some pragmas ship with a capitalised name (UNIVERSAL, Internals); some modules ship lowercase (if, lib, ok). The naming convention is a hint, not a rule - what matters is what the module's `import` does.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `require` - the run-time half of `use`; loads a module without invoking `import`, and accepts a runtime expression for the module name
- `no` - the counterpart declaration; calls `unimport` instead of `import` to undo a pragma's effect
- `import` - not a built-in; an ordinary class method invoked by `use`, usually provided via inheritance from `Exporter`
- `package` - declares the package whose namespace `use` will alter
- `@INC` - the list of directories searched for the module file
- `%INC` - records every file loaded by `use` or `require`, keyed by relative path

Filehandles, files, directories

utime

Set access and modification times on a list of files.

`utime` applies the numeric access time ATIME and modification time MTIME - both Unix epoch seconds - to every file named in LIST. It is the Perl-level interface to the `utime(2)`

and `utimes(2)` system calls, and the tool behind the Unix `touch(1)` command. The inode change time (`ctime`) of each file is set to the current time as a side effect - this is a kernel invariant, not a Perl choice, and cannot be suppressed.

Synopsis

```
utime ATIME, MTIME, LIST
utime undef, undef, LIST      # set both to "now" (since 5.8.0)
```

What you get back

The number of files whose timestamps were successfully updated. Any file that could not be touched is silently skipped in the count; `$!` reflects the error from the *last* failing file only. Check the return value against `scalar @files` when you need to detect partial failure:

```
my @files = ("a", "b", "c");
my $n = utime $atime, $mtime, @files;
warn "only $n of ", scalar @files, " files updated: $!"
    if $n != @files;
```

Arguments

- `ATIME` - new access time, in seconds since the Unix epoch. Must be numeric; non-numeric scalars are coerced the usual way and a string like `"now"` becomes `0` (midnight 1970-01-01).
- `MTIME` - new modification time, same format.
- `LIST` - one or more filenames. On systems that support `futimes(2)` (Linux does), filehandles may appear in `LIST` as well. Filehandles must be passed as globs (`*FH`) or glob references (`\*FH`); a bareword in that position is parsed as a filename, not a handle.

The `undef, undef` form

Since Perl 5.8.0, passing `undef` for both `ATIME` and `MTIME` calls `utime(2)` with a null second argument. The kernel then sets both times to the current wall-clock time, and - crucially - this form succeeds on files the caller does not own, provided the caller has **write permission** on the file. The owner-or-root requirement only applies to the explicit-timestamp form.

```
for my $file (@ARGV) {
    utime undef, undef, $file
        or warn "Couldn't touch $file: $!";
}
```

This is the form the real `touch(1)` command uses internally, and is the right choice for a generic “touch” script.

Permissions

Two distinct rules, depending on which form you use:

Form	Who may succeed
`utime $atime, $mtime, ...`	File owner, or root
`utime undef, undef, ...`	Anyone with write permission on the file

A non-owner attempting the explicit-timestamp form gets `EPERM` in `$!` and the file is left untouched (it still counts as a failure, not a silent no-op).

Examples

Plain Unix-style `touch` on a list of files you own:

```
my $now = time;
utime $now, $now, @ARGV;
```

Generic `touch` that also works on files you merely have write access to:

```
for my $file (@ARGV) {
    utime undef, undef, $file
        or warn "Couldn't touch $file: $!";
}
```

Copy timestamps from one file to another using `stat`:

```
my @st = stat $src or die "stat $src: $!";
utime $st[8], $st[9], $dst
    or die "utime $dst: $!";
```

Touch an already-open filehandle on Linux (needs `futimes(2)`):

```
open my $fh, ">>", "log" or die $!;
utime undef, undef, *$fh;       # glob deref, not bareword
```

Set a file one hour into the past, useful for build-system tests:

```
my $t = time - 3600;
utime $t, $t, "stale.tmp";
```

Edge cases

- **Mixed `undef` and number**: passing `undef` for only one of the first two arguments does **not** trigger the "both-undef" path. The `undef` is coerced to `0` (epoch midnight 1970-01-01), the other value is used verbatim, and an `uninitialized` warning fires under `use warnings`. This is almost never what you want.

  ```
  use warnings;
  utime undef, time, $file;       # atime = 1970-01-01, warning
  ```

- **Non-numeric timestamps**: `ATIME` and `MTIME` must be numeric. String values are coerced - `"1700000000"` works; `"yesterday"` silently becomes `0`.
- **`ctime` always moves**: there is no way to preserve a file's inode change time across a `utime` call. If you need that, you need filesystem-level tools or a snapshot, not Perl.
- **Filehandle in `LIST`**: must be a glob (`*FH`) or glob reference (`\*FH`). A bareword like `FH` in that position is parsed as the filename `"FH"`, and a string scalar holding a handle name is likewise treated as a filename.
- **Non-existent file**: counts as a failure and does not increment the return value; `$!` is set to `ENOENT` (`No such file or directory`).
- **Partial failure**: the count reflects successes only. To know *which* file failed, loop over the list one at a time.
- **NFS clock skew**: the server's clock is authoritative, not the client's. A noticeable difference between the two shows up as timestamps that do not match what `time` on the client returned.
- **Sub-second precision**: Perl's `utime` operates on whole seconds. Filesystems and kernels that support nanosecond timestamps will see the fractional component zeroed. Reach for `Time::HiRes::utime` (XS) if you need better resolution.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `stat` - read the timestamps `utime` writes; elements 8 (`atime`), 9 (`mtime`), and 10 (`ctime`) of the returned list
- `time` - current epoch seconds, the usual source for both `ATIME` and `MTIME`
- `open` and `close` - filehandles that `utime` can touch on systems with `futimes(2)`
- `$!` - system error from the last failing file when the return count is less than `scalar @files`
- `utime(2)`, `utimes(2)`, `futimes(2)` - the underlying system calls

Arrays · Hashes

values

List every value of a hash (or every element of an array).

`values` is the value-side companion to `keys`. Given a hash, it returns all the values; given an array, it returns all the elements. The elements come back as **aliases** into the underlying container, so assigning to them from a loop modifies the container in place. As a side effect, calling `values` resets the iterator that `each`, `keys`, and `values` share for that hash or array.

Synopsis

```
my @v = values %hash;
my @v = values @array;
my $n = scalar values %hash;    # number of values
for (values %hash) { $_ *= 2 }  # mutate in place via aliasing
```

What you get back

In list context: the full list of values from a hash, or the full list of elements from an array. Array entries come back in index order (lowest index first). Hash entries come back in an implementation-defined, per-hash random order - see *Edge cases*.

In scalar context: the number of entries, identical to `scalar keys %h` for hashes and `scalar @a` for arrays. `values` in void context does nothing observable **except** reset the iterator - that is the idiomatic way to force-reset an iterator mid-traversal:

```
values %h;                          # void context: iterator reset only
```

The returned list is not a copy. Each element is an alias to the live value in the container. Aliasing is documented behaviour and is the basis for the in-place mutation idiom under *Examples*.

Global state it touches

`values` resets the per-container iterator state that `each` reads and advances. Any `while (my ($k, $v) = each %h) { ... }` loop in progress on the same hash will restart from the beginning the next time `each` is called. `keys` has the same effect. The iterator is a property of the container, not of any particular call site - so a caller in one sub can disturb an `each` loop running in another sub if they operate on the same hash.

Examples

Iterate a hash in key-sorted order, which `values` alone does not give you:

```
my %score = (alice => 90, bob => 75, carol => 82);
for my $k (sort keys %score) {
    print "$k: $score{$k}\n";
}
```

Sum every value of a hash:

```
use List::Util qw(sum0);
my %count = (apples => 3, pears => 5, plums => 2);
my $total = sum0 values %count;     # 10
```

Mutate every value in place through the alias:

```
my %prices = (bread => 3.00, milk => 2.50, eggs => 4.20);
$_ *= 1.10 for values %prices;      # apply 10% price rise
# %prices is now (bread => 3.30, milk => 2.75, eggs => 4.62)
```

The same idiom works on an array, though for arrays a plain `@array` loop is more conventional:

```
my @nums = (1, 2, 3, 4);
$_ **= 2 for values @nums;          # @nums is now (1, 4, 9, 16)
```

Force-reset an in-progress `each` iterator without consuming its output:

```
while (my ($k, $v) = each %h) {
    last if $v > $threshold;
}
values %h;                          # void context: drop iterator
 ↪state
# next each %h starts from the beginning
```

Count entries without building the list - scalar context never materialises the values:

```
if (scalar values %cache > 10_000) {
    prune(\%cache);
}
```

Edge cases

- **Aliasing is the feature and the footgun.** `for (values %h)` gives you aliases, not copies. A harmless-looking `s///` inside such a loop rewrites the hash. If you want copies, assign first: `my @v = values %h; for (@v) { ... }`.
- **Hash order is randomised.** Perl 5.18+ randomises the traversal order per-hash. Two hashes built from the same keys can yield values in different orders. Never rely on the order for anything that leaves the process - serialise via `sort keys` if you need stability.
- **Order is stable only while the hash is unmodified.** Insertions and deletions may permute the order. The one documented exception is deleting the key most recently returned by `each` or `keys`, which leaves the remaining order intact.
- **`keys`, `values`, `each` agree.** For a hash that has not been modified between calls, `keys %h` and `values %h` produce corresponding lists in the same order - `(keys %h)[$i]` and `(values %h)[$i]` name the same entry.
- **Array form behaves like `@array` plus a reset.** `values @a` in list context is equivalent to `@a`, with the side effect of resetting the array's iterator. For the iterator-reset alone, `keys @a` in void context is the conventional choice.
- **Empty hash or array** returns the empty list in list context and `0` in scalar context. No warning, no error.
- **Tied hashes.** Behaviour is delegated to the tie class's `FIRSTKEY` / `NEXTKEY` / `FETCH` methods. Order, aliasing, and iterator-reset semantics follow whatever the tie implementation provides - the pure-hash guarantees above do not automatically carry over.
- **Removed experiment: scalar argument.** Perl 5.14–5.22 experimentally accepted `values $ref`; that experiment was removed in 5.24. Dereference explicitly: `values %$ref`, `values @$ref`.

- **Array support requires 5.12+.** Running `values @a` on an older Perl raises a syntax error. Use `use v5.12;` at the top of a file that relies on array form to make the requirement explicit.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `keys` - the key-side companion; same ordering rules, same iterator, scalar context returns the count
- `each` - single-step iteration returning `($key, $value)` pairs; shares the iterator that `values` resets
- `exists` - test whether a key is present without triggering autovivification
- `delete` - remove a key/value pair; deleting the most-recently-returned key of `each` or `keys` leaves the remaining traversal order intact
- `map` - transform values into a derived list without mutating the hash (the non-aliasing alternative to `for (values %h)`)
- `sort` - pair with `keys` when you need a deterministic traversal order

Fixed-length data

vec

Read or write a fixed-width slot inside a string treated as a packed bit vector.

`vec` views `EXPR` as an array of unsigned integers, each `BITS` wide, packed back-to-back from the start of the string. `OFFSET` indexes into that array - not into bytes, not into bits, but into `BITS`-sized elements. Read form returns the integer at that slot; the lvalue form writes one. Widths are 1, 2, 4, 8, 16, 32, and on 64-bit builds 64.

Synopsis

```
my $n = vec($buf, $offset, $bits);
vec($buf, $offset, $bits) = $n;
```

What you get back

In rvalue context, an unsigned integer - the contents of the selected slot, zero-extended to a Perl number. In lvalue context, an assignable slot; assigning truncates the right-hand value to `BITS` and writes it into the string, extending the string with zero bytes if `OFFSET` lies past the current end.

The parentheses around `vec(...)` in the lvalue form are required - without them, `vec $buf, $o, $b = 3` parses the = as part of the argument list.

How the bits are laid out

The layout depends on `BITS`, and is chosen so code is portable across big- and little-endian machines:

- **`BITS == 8`**: each slot is one byte of the string. `vec($s, $i, 8)` is the unsigned value of `substr($s, $i, 1)`.
- **`BITS == 16, 32, 64`**: bytes of the string are grouped into chunks of `BITS/8` and interpreted in **big-endian** order - equivalent to `unpack` with `n`, `N`, or (on 64-bit builds) `Q>` / the moral equivalent. `vec($s, 0, 32)` reads the first four bytes as a big-endian `uint32`.
- **`BITS == 4, 2, 1`**: the string is broken into bytes, and each byte is split into `8/BITS` groups, numbered **little-endian-ish** within the byte. The bit values from low to high are `0x01`, `0x02`, `0x04`, `0x08`, `0x10`, `0x20`, `0x40`, `0x80`. So for `chr(0x36)` (`0b00110110`):
  - `BITS == 4` gives the two nibbles `(0x6, 0x3)`.
  - `BITS == 2` gives the four 2-bit groups `(0x2, 0x1, 0x3, 0x0)`.
  - `BITS == 1` gives the eight bits `(0, 1, 1, 0, 1, 1, 0, 0)`.

A slot entirely off the end of the string reads as `0`. Writing past the end grows the string with zero bytes to reach the slot. A negative `OFFSET` is a fatal error.

Global state it touches

None. `vec` operates purely on its arguments.

Examples

Read a byte at a given index:

```
my $s = "Perl";
print vec($s, 0, 8);            # 80   (== ord 'P')
print vec($s, 3, 8);            # 108  (== ord 'l')
```

Build a string by writing 32-bit big-endian words:

```
my $buf = '';
vec($buf, 0, 32) = 0x5065726C;  # "Perl"
vec($buf, 1, 32) = 0x50657270;  # "PerlPerp"
print $buf;                     # PerlPerp
```

Use `vec` as a compact boolean array - one bit per flag:

```
my $flags = '';
vec($flags, 17, 1) = 1;
vec($flags, 42, 1) = 1;
print vec($flags, 17, 1);       # 1
print vec($flags, 18, 1);       # 0  (slot never set, still zero)
print length $flags;            # 6  (string auto-extended to fit␣
 ↪bit 42)
```

Count the set bits in a bit vector without looping bit by bit - the idiomatic pattern uses `unpack`:

```
my $ones = unpack("%32b*", $flags);   # population count
```

Convert a bit vector into a string of `0`s and 1s for display:

```
my $bits = unpack("b*", $flags);      # "00...010...010..."
```

Combine two bit vectors with the bitwise string operators - those treat string operands as bit vectors of the same shape `vec` reads and writes:

```
my $union        = $flags_a | $flags_b;
my $intersection = $flags_a & $flags_b;
my $diff         = $flags_a ^ $flags_b;
```

Edge cases

- **Lvalue precedence**: `vec EXPR, O, B = N` is a syntax error. Always write `vec(EXPR, O, B) = N`.
- **Off-the-end read**: `vec($short, 1_000_000, 8)` returns `0`, never dies, never warns.
- **Off-the-end write**: the string is zero-padded up to the slot. For `BITS == 1`, writing bit 94 grows the string to 12 bytes.
- **Negative `OFFSET`**: fatal - `"Negative offset to vec in lvalue context"` or the rvalue equivalent.
- **`BITS` not a supported power of two**: fatal with `"Illegal number of bits in vec"`. Valid widths are 1, 2, 4, 8, 16, 32, and 64 on 64-bit builds.
- **UTF-8 encoded strings**: `vec` wants a byte string. If the scalar is flagged UTF-8, Perl first tries to downgrade it to a one-byte-per-character representation. If any character has a codepoint of 256 or higher, that fails fatally with `"Wide character in vec"`. Call `utf8::downgrade` deliberately, or pack the data with `pack "C*"` first, before reaching for `vec`.
- **Read on undef**: under `use warnings`, triggers an `uninitialized` warning on the string argument; returns `0`.
- **Assignment value wider than `BITS`**: the value is masked to the low `BITS` bits. `vec($s, 0, 4) = 0x1F` stores `0xF`.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `pack` - build multi-field binary structures; `vec` is the random-access counterpart when every field has the same width

- `unpack` - pull fields out of a binary string; use `unpack("b*", $v)` or `unpack("%32b*", $v)` to render or popcount a `vec` bit vector
- `substr` - byte-level random access when `BITS` would be `8` and you also want the lvalue to grow or shrink the string
- `sprintf` - format the integer a `vec` read returns, e.g. `sprintf "%08b", vec($s, $i, 8)`
- `ord` - one-shot equivalent of `vec($s, $i, 8)` when you only need the byte value and never assign back

Processes

wait

Block until any child process exits and reap it.

`wait` is the simplest front end to the underlying `wait(2)` system call. It suspends the current process until one of its children terminates, collects that child's exit status into `$?` and `${^CHILD_ERROR_NATIVE}`, and returns the reaped child's PID. If there are no children to wait on, it returns `-1` immediately. It is exactly equivalent to `waitpid(-1, 0)`.

Synopsis

```
my $pid = wait;
```

What you get back

The PID of the child that was reaped (a positive integer), or `-1` if there are no unreaped children left to wait on. The child's status goes into `$?`; the raw, OS-specific status word goes into `${^CHILD_ERROR_NATIVE}`.

To decode `$?` after a successful `wait`:

```
my $exit   = $? >> 8;       # normal exit code (0..255)
my $signal = $? & 0x7f;     # termination signal, if any
my $core   = $? & 0x80;     # core-dump flag
```

A `-1` return does **not** always mean "never had any children" - it can also mean "something already reaped them for me" (see below).

Global state it touches

- `$?` - set to the reaped child's 16-bit wait status (high byte: exit code, low byte: termination signal and core flag). Also readable as `$CHILD_ERROR` under `use English`.
- `${^CHILD_ERROR_NATIVE}` - the platform's raw status word, for callers that want to use POSIX macros (`WIFEXITED`, `WEXITSTATUS`, `WIFSIGNALED`, `WTERMSIG`) from `POSIX`.
- `%SIG` - if `$SIG{CHLD}` is set to `'IGNORE'`, or a handler in it calls `wait` itself, this call's result changes. See *Edge cases*.

Examples

Fork a worker, do something, then reap it:

```
my $pid = fork // die "fork: $!";
if ($pid == 0) {
    # child
    exec "/usr/bin/true" or die "exec: $!";
}
my $reaped = wait;              # blocks until the child exits
die "unexpected pid" if $reaped != $pid;
printf "child %d exited %d\n", $reaped, $? >> 8;
```

Reap every outstanding child in a loop. `wait` returns `-1` once the process has none left:

```
while ((my $kid = wait) > 0) {
    warn "reaped $kid, status " . ($? >> 8) . "\n";
}
```

Distinguish normal exit from signal termination:

```
my $pid = wait;
if ($pid > 0) {
    if    ($? == 0)       { say "clean exit" }
    elsif ($? & 0x7f)     { say "killed by signal " . ($? & 0x7f) }
    else                  { say "exit " . ($? >> 8) }
}
```

Decode the native status word with `POSIX` macros, which is more portable than manual bit-shifting:

```
use POSIX ":sys_wait_h";
my $pid = wait;
if ($pid > 0 && WIFEXITED(${^CHILD_ERROR_NATIVE})) {
    say "exit code: ", WEXITSTATUS(${^CHILD_ERROR_NATIVE});
}
```

Non-blocking reap of every pending zombie - use `waitpid` with `WNOHANG`, not `wait`:

```
use POSIX ":sys_wait_h";
1 while waitpid(-1, WNOHANG) > 0;
```

Edge cases

- **No children to wait on**: returns `-1` immediately. `wait` does not block in this case - it only blocks when at least one child is still alive and unreaped.
- **`$SIG{CHLD} = 'IGNORE'`**: on POSIX systems this asks the kernel to auto-reap children. Under this setting, `wait` almost always returns `-1` because the children are gone before user code can call it. `$?` is not set. If you want both fire-and-forget children **and** status reporting, use a real handler, not `'IGNORE'`.

- **Custom `$SIG{CHLD}` handler**: if the handler calls `wait` (or `waitpid`) itself, a subsequent `wait` in the main flow will find nothing left and return `-1`. Decide up-front which code path does the reaping.
- **Interaction with `qx//` and `system`**: both of these internally fork, exec, and wait on their own child. A `$SIG{CHLD}` handler that blindly calls `wait` can accidentally reap that internal child out from under `qx//` or `system`, leaving them unable to collect the status and typically returning `-1` with `$!` set to `ECHILD`. Handlers should loop with `waitpid(-1, WNOHANG)` and only act on PIDs they recognise.
- **`$?` is only written on a successful reap**. After a `-1` return, `$?` retains whatever it had before the call. Don't inspect it unless `wait` returned a positive PID.
- **Interrupted by a signal**: if a signal is delivered while `wait` is blocked and the handler returns normally, Perl restarts the wait - you do not see `EINTR` at the Perl level. If the handler `die`s or `exit`s, control leaves `wait` the usual way for that mechanism.
- **Threaded builds**: `wait` waits for children of the current process, not children of a specific thread. In a multi-threaded program the reaping thread is whichever one called `wait` first.
- **Return value is a PID, not a boolean**: `if (wait) { ... }` is true for both successful reaps and `-1`. Always compare to `0` or check `> 0` explicitly, as in the loop form above.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `waitpid` - wait for a specific child, or poll non-blockingly with `WNOHANG`; `wait` is the `waitpid(-1, 0)` form
- `fork` - create the children that `wait` reaps
- `exec` - what a forked child typically calls to become a different program
- `system` - fork + exec + wait in one call; uses its own internal `wait` and sets `$?` for you
- `kill` - send a signal to a child you no longer want to wait for
- `$?` - where the reaped child's status lands, encoded as exit-code high byte plus signal/core low byte

Processes

waitpid

Wait for a specific child process to terminate and reap it.

`waitpid` is the targeted counterpart of `wait`. Where `wait` reaps *any* child and blocks until one exits, `waitpid` lets you name which child (or which group of children) to wait for, and lets you poll instead of block by passing `WNOHANG` in `FLAGS`. The exit status of the reaped child lands in `$?`, identically to `wait`.

Synopsis

```
use POSIX ":sys_wait_h";

waitpid $pid, 0;                    # block until $pid exits
waitpid $pid, WNOHANG;              # poll: is $pid done yet?
waitpid -1,  WNOHANG;               # reap any ready zombie, don't␣
↪block
```

What you get back

- The PID of the reaped child on success.
- `0` when `WNOHANG` is set and at least one matching child exists but none have terminated yet - i.e. "still running, try again later".
- `-1` when no child process matches `PID` (never existed, already reaped, or - on systems that auto-reap - was harvested by the kernel without Perl's help).

The child's exit status is written to `$?` and the raw platform status to `${^CHILD_ERROR_NATIVE}` on every successful reap. Decode `$?` the same way you would after `wait` or a backtick call:

```
my $reaped = waitpid $pid, 0;
if ($reaped > 0) {
    my $exit   = $? >> 8;
    my $signal = $? & 127;
    my $core   = $? & 128;
}
```

What PID means

`PID` selects which children `waitpid` is willing to reap:

- **Positive PID** - wait for that specific child. `-1` on return means no such child (you already reaped it, or it was never yours).
- **`0`** - wait for any child in the *current* process group. Useful when your program has joined a process group with other cooperating processes and you only want to harvest your own.
- **`-1`** - wait for any child, same scope as `wait`.
- **Less than `-1`** - wait for any child whose process group ID equals the absolute value of `PID`. `waitpid -$pgid, 0` waits for any member of process group `$pgid`.

`FLAGS` is a bitmask. The portable flag is `WNOHANG`, which makes the call non-blocking: if no matching child has exited, `waitpid` returns `0` immediately instead of sleeping. `FLAGS` of `0` means "block until something is reapable", and is implemented on every platform Perl runs on - even those without a native `waitpid(2)` syscall, where Perl emulates it by remembering exit statuses of children it has already seen.

Global state it touches

- `$?` - set to the exit status of the reaped child (shifted: high byte = `exit` code, low 7 bits = signal, bit `0x80` = core-dumped flag).
- `${^CHILD_ERROR_NATIVE}` - set to the raw platform status word, before Perl normalises it into `$?`.

Neither variable is touched when `waitpid` returns `0` (`WNOHANG` and nothing ready) or `-1` (no matching child).

Examples

Block until a known child finishes, then inspect its exit code:

```
my $pid = fork // die "fork: $!";
if ($pid == 0) {
    exec "/usr/bin/gzip", "big.log" or die "exec: $!";
}
waitpid $pid, 0;
die "gzip failed with status ", $? >> 8 if $?;
```

Poll without blocking - useful inside an event loop or a `SIGCHLD` handler:

```
use POSIX ":sys_wait_h";

sub harvest_children {
    while ((my $kid = waitpid -1, WNOHANG) > 0) {
        warn "child $kid exited with ", $? >> 8, "\n";
    }
}
```

The classic “reap every pending zombie, don’t block” idiom:

```
use POSIX ":sys_wait_h";
1 while waitpid(-1, WNOHANG) > 0;
```

Wait only for children in a specific process group. `setpgid` first, then target the group by negating its ID:

```
my $leader = fork // die "fork: $!";
if ($leader == 0) {
    setpgid 0, 0;        # become process-group leader
    exec @worker_cmd or die "exec: $!";
}
setpgid $leader, $leader;  # parent matches, races with child

# ... later, reap any member of that group:
while ((my $kid = waitpid -$leader, WNOHANG) > 0) {
    log_exit($kid, $?);
}
```

Distinguish the three return values in one place:

```
my $r = waitpid $pid, WNOHANG;
if    ($r == $pid) { finalize_child($pid, $?) }
elsif ($r == 0)    { still_running($pid) }
elsif ($r == -1)   { warn "no such child $pid (already reaped?)" }
```

Edge cases

- **`WNOHANG` requires `use POSIX`.** The constant is not a Perl built-in; it comes from the `POSIX` module, typically via `use POSIX ":sys_wait_h";`. Writing a bare integer (`waitpid $pid, 1`) works on Linux but is not portable and hides intent.
- **`$SIG{CHLD} = 'IGNORE'` races with `waitpid`.** When you tell the kernel to auto-reap children, there is nothing left for `waitpid` to find - it returns `-1` with `$!` set to `ECHILD`. Choose one reaping strategy per program, not both.
- **Already-reaped PIDs** return `-1`. A single child's PID can only be reaped once; after that, it is forgotten. If you hand the same PID to `waitpid` twice, the second call returns `-1`.
- **Negative `PID` is a process group, not "any but this one".** `waitpid -1234, 0` waits for members of process group 1234, not "every child except PID 1234". Readers unfamiliar with the POSIX convention often misread this.
- **`WNOHANG` with `PID = -1`** is the standard "drain the zombie queue" form. Combined with a `while` loop it reaps every child that has already exited and stops as soon as the kernel has nothing more to hand back.
- **Return value of `-1` can also mean auto-reap.** On systems configured to reap children automatically (e.g. a `$SIG{CHLD} = 'IGNORE'` handler installed at startup), `waitpid` sees no child and returns `-1` even for a PID you just forked. See `perlipc` for the platform notes.
- **Blocking wait is always available.** Even on platforms without a native `waitpid(2)` or `wait4(2)` syscall, `waitpid PID, 0` works - Perl emulates it by retaining the statuses of children it has already collected.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `wait` - block for *any* child; equivalent to `waitpid -1, 0` on systems that support it
- `fork` - create the children you will later reap with `waitpid`
- `kill` - send a signal to the same PIDs and process groups `waitpid` accepts
- `$?` - exit status of the reaped child; decode as `$? >> 8` for the exit code, `$? & 127` for the signal
- `${^CHILD_ERROR_NATIVE}` - raw platform status word for the same child
- `POSIX` - source of `WNOHANG` and the rest of `:sys_wait_h`

Control flow

wantarray

Report the calling context of the currently executing subroutine.

`wantarray` lets a subroutine ask the runtime *how* its caller wrote the call: was the result assigned to a list, to a scalar, or thrown away? The answer is one of three distinct values, and a sub can use it to return different shapes of data, or to skip expensive work altogether when the caller asked for nothing.

Synopsis

```
wantarray
```

Takes no arguments and has no parentheses form - it is a keyword, not a function call.

What you get back

`wantarray` returns one of exactly three values, corresponding to the three contexts Perl distinguishes:

Return value	Context of the caller	Typical caller syntax
true (1)	list	`my @x = f(); (f())[0]`
false ("")	scalar	`my $x = f(); if (f()) {…}`
`undef`	void	`f();` as a statement

The three-way distinction is why the function "should have been named `wantlist()`": the boolean-looking return is actually tri-state, and `defined wantarray` is the right test for "did the caller want anything at all".

The canonical idiom

The pattern `wantarray` exists for is a sub that adapts its return shape to the caller:

```
sub records {
    my @rows = heavy_query();
    return wantarray ? @rows : "@rows";
}

my @r = records();          # gets the list
my $s = records();          # gets a space-joined string
records();                  # still runs heavy_query - see below
```

Pair that with an early-out when the caller asked for nothing:

```
sub records {
    return unless defined wantarray;    # caller wrote `records();`
    my @rows = heavy_query();           # skipped in void context
```

(continues on next page)

(continued from previous page)

```
    return wantarray ? @rows : "@rows";
}
```

`defined wantarray` is the void-context guard. `wantarray` alone is not - it is false in both scalar and void, and an early `return` on a false `wantarray` would break every scalar-context caller.

Context is propagated, not re-interpreted

`wantarray` reports the context the caller *imposed* on the sub, not what the sub does internally:

```
sub ctx { wantarray ? "list" : defined wantarray ? "scalar" : "void"
 ↪}

my @a = ctx();      # "list"
my $s = ctx();      # "scalar"
ctx();              # "void"
print ctx(), "\n";  # "list"   - print's LIST is list context
scalar ctx();       # "scalar" - scalar() forces scalar context
```

Note the last two: `print` imposes list context on its arguments, and `scalar` explicitly forces scalar context. Neither is about what `ctx` *does* with the result.

Calls from void context

A sub called as a bare statement runs in void context, and `wantarray` returns `undef` *inside that sub*. This does not cascade: a sub called from within a void-context sub sees whatever context *its own* caller imposed.

```
sub inner { defined wantarray ? "wanted" : "void" }
sub outer { my $x = inner(); return $x }

outer();            # outer is void; inner is scalar → "wanted"
```

Each call site establishes its own context independently. `wantarray` always reports the nearest enclosing sub's context, not the dynamic chain's.

Works inside `eval` too

`wantarray` also reports the context of an `eval` block or `eval EXPR`, not just named subroutines:

```
my @x = eval { wantarray ? (1, 2, 3) : "scalar" };  # (1,2,3)
my $x = eval { wantarray ? (1, 2, 3) : "scalar" };  # "scalar"
eval { defined wantarray ? 1 : 0 };                 # void → 0
```

This is the same mechanism - `eval` is a call frame in the same sense a sub is.

Where `wantarray` has no useful answer

`wantarray`'s result is **unspecified** at these places, and code should not rely on any particular value:

- The top level of a file (outside any sub).
- Inside a `BEGIN`, `UNITCHECK`, `CHECK`, `INIT`, or `END` block.
- Inside a `DESTROY` method.

Treat `wantarray` as meaningful only within an ordinary sub or `eval`. Anywhere else, design your code so the answer does not matter.

Examples

A getter that returns the full list to list callers, the count to scalar callers, and does nothing in void context:

```
sub warnings {
    return unless defined wantarray;
    my @w = collect_warnings();
    return wantarray ? @w : scalar @w;
}

my @all   = warnings();     # every warning
my $count = warnings();     # just the number
warnings();                 # collect_warnings() is not called
```

A sub that refuses to be called in void context because the return value is the whole point:

```
sub must_use {
    defined wantarray
        or croak "must_use: return value must be used";
    return compute();
}
```

A sub that emits one element per call in scalar context and the whole batch in list context - a shape some iterator-style APIs expose:

```
sub next_batch {
    state @queue;
    @queue = refill() unless @queue;
    return wantarray ? splice(@queue) : shift @queue;
}
```

Edge cases

- **No parentheses, no arguments.** `wantarray()` parses but the empty parens are noise; the keyword takes nothing. `wantarray $x` is a syntax error, not a call with an argument.

- **Not the caller's context for operators**. `wantarray` reports the call-frame context only. An expression like `$sub->() + 1` puts the call in scalar context; `wantarray` inside `$sub` sees scalar, as expected. There is no way to ask "was I called inside an arithmetic expression" - only list / scalar / void.
- **`return` honours the same context**. `return @list` in scalar context yields the last element, not the count - because `return` itself sees the caller's context. Use `return wantarray ? @list : scalar @list` when you want the count for scalar callers.
- **Boolean context is scalar context**. `if (f())` calls `f` in scalar context; `wantarray` returns false there, not `undef`.
- **List assignment to an empty list is still list context**. `() = f();` is list context even though the result is discarded. `wantarray` returns true. This is useful for forcing list context on a sub whose side effects depend on it.
- **`wantarray` is not available in XS callers the same way**. An XSUB inspects context through `GIMME_V`; a Perl sub called *from* an XSUB sees the context the XSUB established for the call.
- **Prototypes do not change `wantarray`**. A `($)` prototype forces an argument's context, not the sub's own call context.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `return` - honours the same list/scalar/void context `wantarray` reports; the two are designed to be used together
- `caller` - inspect the call stack itself (package, file, line, and, in its three-arg form, more context details including whether `wantarray` would return true there)
- `scalar` - force scalar context on an expression, which is what makes `wantarray` return false in the callee
- `eval` - establishes a call frame whose context `wantarray` also reports

I/O

warn

Emit a warning to `STDERR`.

`warn` stringifies `LIST` and prints the result to `STDERR` - the same formatting machinery as `die`, minus the unwind. Control returns to the caller; nothing is thrown, nothing is caught. Reach for it when the program should keep running but the user, the operator, or the log deserves to hear about something unexpected.

Synopsis

```
warn LIST
warn $message
warn                            # re-surface current $@ as a warning
```

What you get back

`warn` returns 1 under normal circumstances. The return value is almost never useful - the point of the call is the side effect on `STDERR` (or on whatever `$SIG{__WARN__}` does with the message).

Unlike `die`, `warn` does **not** unwind. Execution continues with the statement after the call.

Global state it touches

- `$@` - read by the no-argument form. If `$@` holds a non-empty value, `warn` re-surfaces it (see *Propagation* below). `warn` does **not** write `$@`.
- `$,`, `$\` - **not** consulted. `warn` is not `print`; the output separators and record separator play no role. The message is written as a single string.
- `$.` - the current input line number, appended to messages that lack a trailing newline.
- `$SIG{__WARN__}` - if set, the handler runs in place of writing to `STDERR`. See *The* `$SIG{__WARN__}` *hook* below.
- `STDERR` - the default destination. Any redirection of `STDERR` (shell-level `2>`, `open STDERR, ...`, a PerlIO layer) affects where `warn` output lands.

The trailing-newline rule

The same rule as `die` applies, and for the same reason:

- **Message ends in `"\n"`** - used verbatim. Nothing is appended. Use this for warnings that are complete user-facing diagnostics.
- **Message does not end in `"\n"`** - Perl appends `" at FILE line N"`, and if a file is being read, `", <HANDLE> line M"`, then a final `"."` and newline. Use this when pinpointing the call site is more useful than a tidy message.

```
warn "cache is stale\n";            # "cache is stale\n"
warn "cache is stale";              # "cache is stale at main.pl␣
 ↪line 42.\n"
```

Reference-valued warnings never get location information appended. Stringifying an object to add file and line would defeat the point of passing one.

Propagation: `warn` with no argument (or empty string)

When `LIST` is empty or stringifies to `""`, `warn` does not emit a fresh message - it re-surfaces whatever is in `$@`:

- If `$@` is **non-empty**, `warn` appends `"\t...caught"` to it and emits the result. This is the canonical way to notice that an exception was caught without letting it die silently:

```
eval { risky() };
warn if $@;                        # "<whatever died>\n\t...caught␣
 ↪at ..."
```

- If `$@` is also empty, the string `"Warning: Something's wrong"` is used.

This is deliberately asymmetric with `die`: `die` with no argument **re-throws** (triggering the propagation machinery and the `PROPAGATE` hook for objects); `warn` with no argument **reports** what is already in `$@`.

The `$SIG{__WARN__}` hook

Setting `$SIG{__WARN__}` installs a handler that runs **instead of** the default write to `STDERR`. The handler receives the exception derived from `LIST` as its single argument and is responsible for disposing of it - logging it, rewriting it, escalating it to `die`, or dropping it on the floor:

```
local $SIG{__WARN__} = sub {
    my ($msg) = @_;
    return if $msg =~ /^Use of uninitialized/;  # silently drop
    log_warning($msg);
};
```

Three asymmetries with `$SIG{__DIE__}` are worth internalising:

- **The default message is suppressed.** `$SIG{__DIE__}` runs *alongside* the exception machinery; `$SIG{__WARN__}` runs *instead of* the default `STDERR` write. If the handler does nothing, the warning is silently dropped.
- **To pass the warning through, call `warn` again.** The handler is not re-entered for its own `warn` call, so there is no infinite loop:

```
local $SIG{__WARN__} = sub {
    log_warning($_[0]);
    warn $_[0];                    # re-emit to STDERR as well
};
```

- **A `__WARN__` handler can silence *mandatory* warnings** - warnings that `no warnings` cannot turn off. This makes `$SIG{__WARN__}` a sledgehammer; prefer `no warnings '<category>'` for targeted suppression and reserve the handler for routing or escalation.

```
# wipe out *all* compile-time warnings, then switch on at runtime
BEGIN { $SIG{'__WARN__'} = sub { warn $_[0] if $DOWARN } }
```

(continues on next page)

(continued from previous page)

```
my $foo = 10;
my $foo = 20;                       # duplicate-my silenced
$DOWARN = 1;
warn "\$foo is alive and $foo";     # now shows up
```

`warn` the built-in vs. `use warnings`

These are different things. Do not confuse them:

- **`warn`** is a built-in function that emits a single message right now. You call it.
- **`use warnings`** is a pragma that enables categories of compile-time and run-time diagnostics (uninitialized values, deprecated features, unopened filehandles, and so on). The compiler and interpreter emit those diagnostics on your behalf, using the same machinery `warn` uses.

The pragma's diagnostics flow through `$SIG{__WARN__}` exactly like explicit `warn` calls. `no warnings '<category>'` suppresses the pragma's diagnostics in its lexical scope but has no effect on an explicit `warn` you wrote yourself - that call always fires.

Examples

Report a recoverable problem and keep going:

```
open my $fh, "<", $path
    or warn "skipping $path: $!\n" and next;
```

Development-mode diagnostic with location appended:

```
warn "unexpected record shape";
# unexpected record shape at parser.pl line 87.
```

Noticing a caught exception without suppressing it:

```
eval { load_config() };
warn if $@;                         # surfaces "...caught at ..."
```

Route every warning through a logger, still printing to `STDERR`:

```
local $SIG{__WARN__} = sub {
    my ($msg) = @_;
    $logger->warn($msg);
    print STDERR $msg;              # preserve default visibility
};
```

Escalate a specific warning to a fatal error:

```
local $SIG{__WARN__} = sub {
    die @_ if $_[0] =~ /corrupt database/;
    warn @_;                        # everything else: default path
};
```

Pass a blessed object for structured warnings (the receiver of a `$SIG{__WARN__}` hook gets the reference, not a stringified form):

```
local $SIG{__WARN__} = sub {
    my ($w) = @_;
    if (ref($w) && $w->isa('MyApp::Warning')) {
        $logger->record($w);
    }
    else {
        print STDERR $w;
    }
};
warn MyApp::Warning->new(code => 'SLOW_IO', detail => $path);
```

Edge cases

- **List with two or more items** is stringified and concatenated: `warn "bad record ", $n, ": ", $raw`. The newline rule applies to the concatenated result.
- **Empty list** (`warn;` or `warn "";`) triggers the propagation path, not a fresh message.
- **Reference-valued warning inside a `$SIG{__WARN__}` handler**: the handler receives the reference unchanged. If no handler is installed, the reference is stringified to `STDERR` via its `""` overload (or Perl's default `MyClass=HASH(0x...)`).
- **`warn` inside `$SIG{__WARN__}`**: does **not** re-enter the handler. The call writes to `STDERR` as if no handler were installed. This is what makes the "pass through" idiom safe.
- **`warn` during global destruction**: still works, but `STDERR` may already be closed in pathological cases. Warnings from `DESTROY` handlers running at interpreter exit can vanish.
- **`STDERR` closed or redirected**: `warn` writes to whatever `STDERR` currently points at. If `STDERR` is closed, the write fails silently; no error is raised, because `warn` itself does not check.
- **No relation to `$\` / `$,`**: adding `local $\ = "\n"` does not make `warn "x"` print a newline. The trailing-newline rule is the only newline-adding mechanism for `warn`.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `die` - same formatting rules (trailing-newline suppresses location, references pass through unchanged), but raises an exception instead of reporting and continuing
- `eval` - pairs with the no-argument form of `warn` for the "catch, inspect, re-surface" idiom
- `$@` - the source the no-argument `warn` reports from

- `$SIG{__WARN__}` - the hook that replaces the default STDERR write; use it for routing, filtering, or escalation
- `Carp` - `carp`, `cluck`, `croak`, `confess`: warnings and exceptions that report from the caller's perspective rather than the call site, which is almost always what a library wants

I/O

write

Render one record to a filehandle through its associated `format`.

`write` is the executor half of Perl's report-generation mechanism: it takes the picture declared by a `format`, plugs the values from the matching argument lines into the fields, and emits the resulting lines to `FILEHANDLE`. It also tracks the page: when not enough lines remain, it writes a form feed, runs the top-of-page format, and then writes the record. `write` is the **only** way a declared format produces output; a format is inert until `write` references it.

Do not confuse this with `syswrite` or the inverse of `read`: `write` is strictly the picture-record executor. It has nothing to do with raw byte output.

Synopsis

```
write FILEHANDLE
write EXPR
write
```

What you get back

1 on success, `undef` on failure (with `$!` set). A failure here is typically either a closed handle or an I/O error on the underlying write - not "format not found," which croaks rather than returning `undef`.

How `write` picks the format

Every filehandle has **two** format slots: the record format and the top-of-page format. By default:

- The **record format** is the format whose name matches the filehandle (format `STDOUT` for `STDOUT`, format `REPORT` for a handle opened as `REPORT`).
- The **top-of-page format** is the filehandle name with `_TOP` appended (`STDOUT_TOP`, `REPORT_TOP`), falling back to `top` in the current package.

Both are overridable per-handle through `$~` (current format name) and `$^` (current top-of-page format name). These variables act on the **currently selected** handle, so changing them for anything other than `STDOUT` requires a `select` dance:

```
my $ofh = select REPORT;
$~ = "My_Format";
```

(continues on next page)

(continued from previous page)

```
$^ = "My_Top";
select $ofh;
```

If `FILEHANDLE` is omitted, `write` targets the currently selected handle (default `STDOUT`). If the argument is an `EXPR` rather than a bareword, the expression is evaluated and its string value is looked up as the filehandle name at runtime.

Global state it touches

`write` reads and updates a cluster of per-handle format variables. All are per-filehandle, reached via `select`:

- `$~` - name of the record format for the selected handle. Read at every `write` call.
- `$^` - name of the top-of-page format. Consulted when a new page begins.
- `$=` - page length in lines. Default `60`.
- `$-` - lines remaining on the current page. Decremented by every `write`. Set to `0` to force a page break on the next call.
- `$%` - current page number. Incremented on each top-of-page.
- `$^L` - string emitted before every top-of-page except the first. Default `"\f"` (form feed).
- `$:` - characters on which fill-mode (^) fields may break.
- `$^A` - the format accumulator, the buffer `formline` writes into and `write` flushes. Rarely touched directly unless you are bypassing `write` with `formline`.

`write` also writes through the PerlIO stack of the target handle, so `$|` (autoflush on the selected handle) still applies.

Top-of-form processing

Before emitting the record, `write` checks whether the record fits in the lines remaining on the page (`$-`). If it does not:

1. Emit `$^L` (form feed by default) - skipped on the very first page.
2. Run the top-of-page format named by `$^` to produce the page header.
3. Reset `$-` to `$=` and increment `$%`.
4. Emit the record.

On the very first `write` to a handle, step 1 is skipped so the output does not begin with a form feed.

Examples

Basic report with a header:

```
format STDOUT_TOP =
                        Passwd File
 Name                Login    Office   Uid   Gid Home
 ------------------------------------------------------------------
.
format STDOUT =
 @<<<<<<<<<<<<<<<<<< @|||||| @<<<<<<@>>>> @>>>> @<<<<<<<<<<<<<<<<<
 $name,              $login,  $office,$uid,$gid, $home
.

while (my @row = getpwent) {
    ($name, $login, $uid, $gid, $office, $home) = @row[0,0,2,3,5,7];
    write;
}
```

Write to a named filehandle. The format name defaults to the handle name; no `select` is needed if the default is acceptable:

```
open my $fh, ">", "report.txt" or die $!;
format REPORT =
 @<<<<<<<<<<<<<<   @>>>>>>>
 $item,            $count
.
# rebind the glob so REPORT refers to $fh
*REPORT = *$fh;
for my $r (@records) {
    ($item, $count) = @$r;
    write REPORT;
}
close $fh;
```

Switch format at runtime by setting `$~` on the selected handle. `local` confines the change to the current scope:

```
sub print_summary {
    local $~ = "SUMMARY_FORMAT";
    write;
}
```

Force a page break by zeroing `$-` before the next call:

```
$- = 0;                 # next write starts a new page
write;
```

`write EXPR` picks the handle at runtime from a string - useful when the target is data-driven:

```
my $handle_name = $verbose ? "LOG" : "STDOUT";
write $handle_name;
```

Interleaving `print` with `write`: legal, but `$-` only tracks `write` output. If a `print` burst consumes page rows you care about, decrement `$-` by hand:

```
print "extra note: $msg\n";
$-  -= 1;                  # keep the page counter honest
write;
```

Edge cases

- **Format not found**: if the format named by `$~` does not exist, `write` croaks with `Undefined format "NAME" called`. This is a fatal error, not a return-`undef`-with-`$!` failure.
- **Closed filehandle**: returns `undef` and sets `$!`. Under `use warnings` a `write()` on `closed filehandle` warning is emitted.
- **Record taller than page**: if the record itself has more lines than `$=`, `write` still emits all of its lines on one page - it does not split a single record across a page boundary. The oversize is silently tolerated.
- **`_TOP` fallback**: if no `<HANDLE>_TOP` format exists, `write` falls back to the format named `top` in the current package. This is rarely what you want for autovivified handles; set `$^` explicitly when it matters.
- **Lexical variables in formats**: `my` variables declared outside a format are **not visible** inside it unless the format is declared within the lexical scope of those variables. This bites anyone who wraps `write` inside a subroutine and wonders why the report is blank - move the `format` declaration inside the sub, or use package globals for the argument-line expressions.
- **Top-of-page triggers mid-record, not mid-page**: `write` checks page room once per record. A record that starts near the bottom of the page will either fit in full or trigger top-of-page before being written; it never straddles.
- **`LC_NUMERIC` and numeric fields**: if `use locale` is in effect when the format is declared, the decimal point in numeric fields follows the locale at declaration time - not at `write` time. Switching locales after the format is compiled does not change the separator.
- **Control characters in text fields** are replaced with spaces so they cannot scramble column alignment. The sole exception is `\r` in fill-mode fields, where it forces a line break.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `format` - declare the picture that `write` renders; the two are meaningless without each other
- `formline` - run one picture line against an argument list into `$^A` without any page tracking; the low-level primitive behind `write`
- `select` - change which handle `write` targets when called without an argument, and the prerequisite for setting any of the `$~`, `$^`, `$=`, `$-` per-handle

- `print` - free-form output when columnar reporting is overkill; may be interleaved with `write` on the same handle
- `$~` - override the record format name for the selected handle
- `$-` - lines left on the current page; set to `0` to force a new page before the next `write`
- `perlform.pod` - full picture-line grammar, fill-mode rules, and worked report examples

SCALARs and strings

y///

Transliterate characters in a string. `y///` is a synonym for `tr///` - the two are identical in every respect.

The `y` spelling is provided for **sed** devotees, whose muscle memory produces `y/abc/ABC/` rather than `tr/abc/ABC/`. Perl's parser accepts either; the resulting op is the same. Use whichever spelling reads better in the surrounding code - if the file already quotes a sed script, `y///` often fits; in fresh Perl, `tr///` is more common.

Synopsis

```
y/SEARCHLIST/REPLACEMENTLIST/cdsr
$var =~ y/SEARCHLIST/REPLACEMENTLIST/cdsr
y/SEARCHLIST/REPLACEMENTLIST/      # transliterates $_
```

What you get back

Same as `tr///`:

- Without `/r`: the number of characters matched (and replaced or deleted), after modifying the target in place.
- With `/r`: a new string with the transliteration applied; the original is untouched.

Examples

Classic sed-style uppercase transliteration on `$_`:

```
while (<>) {
    y/a-z/A-Z/;
    print;
}
```

Counting vowels without modifying the string, using `/r` to discard the transliterated copy:

```
my $vowels = ($text =~ y/aeiouAEIOU//) ;   # count in place is fine␣
↪too
my $count  = () = $text =~ /[aeiouAEIOU]/g;
```

Strip everything except digits from a string (non-destructive copy via `/r`, complement + delete):

```
my $digits = $phone =~ y/0-9//cdr;          # "(415) 555-1212" →
↪"4155551212"
```

Rot13 - the textbook `y///` one-liner:

```
(my $coded = $plain) =~ y/A-Za-z/N-ZA-Mn-za-m/;
```

Edge cases

See `tr///` for the full list. Two worth repeating here:

- **No variable interpolation.** `y/$x/$y/` transliterates the literal characters `$`, `x` against `$`, `y` - not the contents of those variables. This matches `tr///` and is the single most common sed-to-Perl translation bug.
- **`y'...'...'` disables ranges.** With single-quote delimiters, `-` is literal: `y'a-z'A-Z'` transliterates only `a`, `-`, `z` against `A`, `-`, `Z`.

Differences from upstream

Fully compatible with upstream Perl 5.44.

See also

- `tr///` - the canonical spelling; identical semantics, same flags (`/c`, `/d`, `/s`, `/r`), same edge cases
- `s///` - pattern-based substitution when character-by-character mapping is not enough
- `lc`, `uc` - locale- and Unicode-aware case change; prefer these over `y/a-z/A-Z/` for anything beyond ASCII
- `$_` - the default target when no `=~` binding is given

5.1.3 Operators

Perl's operator inventory is large but the structure is regular. Operators group into a handful of families - arithmetic, comparison, logical, bitwise, regex binding, assignment - and a few one-off mechanisms (range, ternary, comma, arrow, subscripts). This reference is split into one page per family.

PetaPerl implements the full Perl 5 operator set with identical semantics: same precedence, same associativity, same context rules. Differences are localised to the *PetaPerl-specific notes* at the bottom of each page where they apply.

Choose a family

Arithmetic operators

The numeric four-function-calculator set, plus modulus and exponentiation, plus the unary sign operators.

Operator	Operation	Arity	Associativity
`**`	exponentiation	binary	right
`*`	multiplication	binary	left
`/`	division	binary	left
`%`	modulus	binary	left
`+`	addition	binary	left
`-`	subtraction	binary	left
`+`	unary plus	unary	right
`-`	unary negation	unary	right

All arithmetic operators evaluate their operands in numeric context - strings are coerced via the rule "leading numeric prefix wins, the rest is ignored (with an `Argument "..." isn't numeric` warning under `use warnings`)".

```
my $x   = 5 + 3;          # 8
my $y   = 10 / 3;         # 3.3333333333333…
my $z   = 2 ** 10;        # 1024
my $rem = 17 % 5;         # 2
my $neg = -$x;            # -8
```

Precedence and associativity

`**` binds tightest and is *right*-associative. `*`, `/`, `%` form one group; `+`, `-` form another. Unary `+` and `-` bind between `**` and `*` (high precedence).

```
2 ** 3 ** 2     # 2 ** 9       = 512   (right-assoc: top-down)
-2 ** 2         # -(2 ** 2)    = -4    (** binds tighter than unary
↪-)
(-2) ** 2       # 4                    (parens override)
6 / 2 / 3       # (6 / 2) / 3  = 1     (left-assoc on /)
```

The `-2 ** 2` case bites everyone exactly once. Parenthesise the sign when the base might be negative.

Division

`/` always returns a floating-point result, even for integer operands that divide exactly:

```
10 / 5           # 2     -- numerically equal, stored as int or
↪float
                 #          depending on the runtime; treat as
↪numeric
```

(continues on next page)

(continued from previous page)

```
10 / 4          # 2.5
10 / 3          # 3.3333333333333335
```

For integer division, use `int`:

```
int(10 / 4)     # 2
int(-7 / 2)     # -3   (truncation toward zero, not floor)
```

Division by zero is a fatal error (not a warning, not an infinity-producing operation):

```
my $bad = 1 / 0;   # dies: Illegal division by zero
```

Modulus

% returns the integer remainder. Both operands are converted to integers first; the sign of the result follows the right operand (Perl-flavoured "sign of divisor", same as Python, unlike C).

```
 17 %  5     #  2
-17 %  5     #  3      -- result follows sign of $b ( 5)
 17 % -5     # -3      -- result follows sign of $b (-5)
-17 % -5     # -2
```

For floating-point remainder, use `POSIX::fmod` from *POSIX*.

Exponentiation

** accepts any pair of numbers including non-integer exponents:

```
2 ** 10         # 1024
2 ** 0.5        # 1.4142135623730951    -- square root
$x ** -1        # 1/$x                   -- reciprocal
```

For `sqrt`, the dedicated *sqrt* function is clearer (and named-unary, so it parses with one argument greedily - see *precedence*).

Unary + and unary -

Unary - negates. Unary + is a no-op on numbers; its only practical use is to *force* numeric context, or to disambiguate a syntactic edge case where Perl would otherwise treat the next token as a function name:

```
sub foo { 42 }
print foo (1+2)*3;       # prints 42*3 ... wait, no:
                         # parses as: print( foo(1+2) ) * 3
                         # because foo(...) sticks to the parens.
print foo +(1+2)*3;      # parses as: print( foo + ((1+2)*3) )
                         # the unary + signals "not a function call"
```

You will rarely need this. It is documented because it appears in older code.

Compound assignment

Every binary arithmetic operator has a compound assignment form (`+=`, `-=`, `*=`, `/=`, `%=`, `**=`). See *assignment*.

See also

- *String operators* - `.` and `x`, the string equivalents of `+` and `*`.
- *Numeric comparison* - `< <= == > >= != <=>`.
- *Precedence* - full table.
- `abs`, `sqrt`, `int` - perlfunc forms of related operations.

String operators

Two operators in this family - concatenation and repetition. They play the same role for strings that `+` and `*` play for numbers.

Operator	Operation	Arity	Associativity	Context
.	concatenation	binary	left	string
x	repetition	binary	left	mixed

Both coerce their operands to string context (with the usual numeric-to-string conversion: `42` becomes `"42"`, `1.5` becomes `"1.5"`, etc.).

`.` - concatenation

Joins the two operands. The result is the concatenation of the left and right strings:

```
"Hello" . " " . "World"         # "Hello World"
"x = " . 42                     # "x = 42"            (numeric␣
↪coercion)
"err: " . $!                    # "err: <strerror>"
```

Compound `.=` appends in place:

```
my $s = "a";
$s .= "b";       # "ab"
$s .= "c";       # "abc"
```

`.=` is faster than `$s = $s . "..."` for repeated appending - not by an asymptotic margin in modern Perl, but enough to matter in tight loops on long strings. `pperl`'s runtime mutates the internal buffer in place when the string's reference count is 1 (see *PetaPerl-specific notes* below).

For large numbers of pieces, `join` is generally clearer than a chain of `.`:

```
join(", ", @items)
"hello, world, !"               # hand-built; readable for small␣
```

(continues on next page)

(continued from previous page)

```
↪arity

join(", ", $a, $b, $c, $d)      # cleaner than $a.", ".$b.", ".$c.",
↪".$d
```

x - repetition

Repeats its left operand a number of times given by the right operand. Behaviour depends on the *context* of the left operand:

- **Scalar context** on the left → string repetition.
- **List context** on the left (parens around the left operand) → list repetition.

```
"ab" x 3                # "ababab"          (string)
"-" x 40                # 40-character ruler

(0) x 5                 # (0, 0, 0, 0, 0)   (list)
(1, 2) x 3              # (1, 2, 1, 2, 1, 2)
```

The parens-on-the-left distinction trips beginners. Without parens, the left side is in scalar context regardless of how it looks:

```
1, 2 x 3                # (1, "222")        -- Whoops.
                        # x binds tighter than , so this is
                        # (1, (2 x 3)) - and 2 in scalar context
                        # stringifies, so 2 x 3 is "222".

(1, 2) x 3              # (1, 2, 1, 2, 1, 2)   -- list repetition
```

Compound x= replicates in place:

```
my $line = "=";
$line x= 40;            # "========================================"
```

A non-positive count returns the empty string (or empty list for list context), without warning:

```
"abc" x  0              # ""
"abc" x -3              # ""
("a", "b") x 0          # ()
```

A non-integer count is truncated toward zero:

```
"x" x 3.7               # "xxx"      (3.7 truncates to 3)
"x" x -0.5              # ""
```

Numeric vs string operators

Mixing numeric and string operators on the same operand produces predictable but sometimes surprising results, because each operator imposes its own context:

```
"5" + "3"              # 8        (+ wants numeric → both coerce to␣
↪numbers)
 5  .  3               # "53"     (. wants string  → both coerce to␣
↪strings)
"5" * "3"              # 15
 5  x  3               # "555"    (x wants string left, number right)
```

There is no operator that "guesses" - the operator picks the context, full stop.

See also

- *Arithmetic operators* - `+` and `*` are the numeric analogues of `.` and `x`.
- *String comparison* - comparing strings rather than building them.
- `join`, `sprintf`, `substr` - perlfunc forms of common string-building operations.

Numeric comparison operators

Seven operators that compare two numbers and return either a boolean (the first six) or a three-way result (`<=>`).

Operator	Question	Returns
`<`	less than	true / false
`<=`	less or equal	true / false
`==`	equal	true / false
`>=`	greater or equal	true / false
`>`	greater than	true / false
`!=`	not equal	true / false
`<=>`	three-way (sort)	`-1`, `0`, or `+1`

All seven coerce both operands to numbers before comparing.

```
$age   >= 18                  # true if 18 or older
$count == 0                   # true if numerically zero
$x     != $y                  # true if they differ numerically
$a    <=>  $b                 # -1 if $a < $b, 0 if equal, +1 if $a␣
↪> $b
```

== is for numbers, eq is for strings

This is the single most common bug new Perl programmers ship. `==` compares **numerically** - both operands are run through numeric coercion, and any non-numeric string becomes `0`:

```
"foo" == "bar"        # TRUE  -- both coerce to 0
"42x" == "42y"        # TRUE  -- both coerce to 42
"1e2" == 100          # TRUE  -- "1e2" is 100 in scientific notation
```

For string equality, use eq:

```
"foo" eq "bar"        # FALSE  -- the actual question
"42x" eq "42y"        # FALSE
```

If `use warnings` is in scope, the `Argument "..." isn't numeric` warning fires every time == (or any other numeric operator) sees a non-numeric string. That warning is your friend.

<=> - the spaceship operator

<=> returns -1 if the left is smaller, 0 if equal, +1 if greater. It is *the* sort comparator:

```
my @sorted = sort { $a <=> $b } @numbers;       # ascending
my @rev    = sort { $b <=> $a } @numbers;       # descending

# multi-key: by length, ties broken by content
my @lines = sort { length($a) <=> length($b) || $a cmp $b } @raw;
```

The pattern `cmp1 || cmp2 || cmp3` works because <=> returns 0 on ties and || falls through on 0. See *logical*.

<=> and cmp are the only two operators on this family that are *not* boolean - they are integer-valued and exist for sorting, not for `if`-conditions.

Floating-point equality

== on floats is exact bit-for-bit equality. For values produced by floating-point arithmetic this is almost never what you want:

```
0.1 + 0.2 == 0.3      # FALSE  -- 0.30000000000000004
```

Compare with a tolerance:

```
abs($a - $b) < 1e-9                # absolute tolerance
abs($a - $b) < 1e-9 * abs($a)      # relative tolerance, when $a ≠ 0
```

abs is a *named-unary* operator.

Chaining is not magic

Perl does **not** support mathematical chaining of comparisons. `$a < $b < $c` does not test "$b is between $a and $c" - it parses as `($a < $b) < $c`, where the first comparison yields a boolean ("" or 1) which is then numerically compared with `$c`:

```
1 < 5 < 3         # parses as (1 < 5) < 3
                  #         = 1 < 3
```

(continues on next page)

(continued from previous page)

```
                #          = TRUE   -- which is *not* what you␣
↪meant.
```

Write the conjunction explicitly:

```
$a < $b && $b < $c      # the actual "between" test
```

Precedence

Comparison operators sit at row 11 of the *precedence* table - looser than the arithmetic operators (so `$a + $b == $c + $d` works), tighter than the logical operators (so `$a < $b && $c > $d` works). They are **non-associative**: `$a < $b < $c` is not invalid, but the non-associativity warning explained above applies.

- *String comparison* - `eq ne lt le gt ge cmp`, the lexical-order family.
- *Logical operators* - combining comparison results.
- *<=> in sort* - the canonical use case.
- *Truthiness* - the "two flavours of comparison" overview that motivates the numeric/string split.
- *Numbers and strings* - when a scalar gets coerced to a number, and the precision/Inf/NaN story behind ==.

String comparison operators

The string-flavoured counterparts of the numeric comparison family. Same shape, same precedence row, but operating lexicographically (Unicode code-point order by default) instead of numerically.

Operator	Question	Returns
`lt`	less than	true / false
`le`	less or equal	true / false
`eq`	equal	true / false
`ge`	greater or equal	true / false
`gt`	greater than	true / false
`ne`	not equal	true / false
`cmp`	three-way (sort)	`-1`, `0`, or `+1`

Both operands are coerced to strings before comparing.

```
$name eq "John"              # exact string match
$kind ne "guest"             # negated match
$word lt "m"                 # alphabetically before "m"
$a    cmp  $b                # sort comparator
```

Lexicographic order

Strings compare character by character, code-point by code-point. The first differing character decides; if one string is a prefix of the other, the shorter wins.

```
"abc" lt "abd"        # TRUE  -- 'c' < 'd' at position 2
"abc" lt "abcd"       # TRUE  -- prefix loses
"ABC" lt "abc"        # TRUE  -- ASCII: uppercase < lowercase
"10"  lt "9"          # TRUE  -- '1' < '9' at position 0 (lex, not␣
↪numeric!)
```

The last example is the canonical reason `eq`/`lt`/`gt` exist: when you want digit-strings sorted *numerically*, you must use `<=>` or pre-coerce.

Unicode

Code-point order is **not** the same as locale-aware "alphabetical" order:

- `"ä" gt "z"` is TRUE under code-point order because U+00E4 is beyond U+007A.
- Under German DIN 5007-1 ("dictionary") order, `"ä"` should sort with `"a"` - long before `"z"`.

For locale-correct collation, use `Unicode::Collate` from *perlfunc* or `use locale` with a suitable locale set. The bare `lt`/`gt`/`cmp` give you ordered, stable, language-independent comparison - which is exactly the right thing for `sort` keys, hash bucketing, deterministic test output, and so on. It is the *wrong* thing for human-facing alphabetical listings in any non-English language.

`cmp` for sorting

`cmp` is the string-comparison spaceship. It returns `-1`, `0`, or `+1` and chains the same way `<=>` does:

```
my @sorted = sort { $a cmp $b } @names;        # ascending lex order
my @cased  = sort {
    lc($a) cmp lc($b) || $a cmp $b             # case-insensitive,
                                               # ties broken by case
} @names;
```

Mixing flavours: a worked bug

The compound-key sort idiom from *numeric comparison* showed `||`-chaining of `<=>` and `cmp`. The bug to avoid is using the *wrong* operator for the *type* of the key:

```
# version strings like "1.10", "1.2", "1.20", ...
sort @versions                             # ASCII order:  "1.10",
↪"1.2","1.20"
sort { $a <=> $b } @versions               # numeric mash: works␣
↪only by accident
                                           # (everything past first␣
↪dot ignored)
```

(continues on next page)

(continued from previous page)

```
sort { sortkey($a) <=> sortkey($b) } @versions   # parse first, then␣
↪compare
```

The right answer for version strings is a parser like `Sort::Versions` or hand-rolled `(\d+)`-tokenisation; neither `cmp` nor `<=>` does it correctly on its own.

Precedence

String comparison shares row 11 of the *precedence* table with numeric comparison. They are non-associative - the chaining caveat from *numeric comparison* applies here too:

```
"a" lt "b" lt "c"     # parses as ("a" lt "b") lt "c"
                      #         = 1            lt "c"
                      #         = TRUE  (because "1" < "c"␣
↪lexically)
                      # - accidentally right for the wrong reason.
```

Write the conjunction explicitly with `&&`.

- *Unicode in Perl* - the locale / code-point-order distinction in depth.

Logical operators

The boolean family - short-circuit AND, OR, defined-or; their low-precedence word-form siblings; the negations; and `xor`.

Operator	Reads as	Short-circuit	Returns	Precedence
`!`	not	n/a	normalised 1 or `""`	high
`&&`	and	yes	left if false, else right (the operand)	high
`||`	or	yes	left if true, else right (the operand)	high
`//`	defined-or	yes	left if defined, else right (operand)	high
`^^`	exclusive or	no	normalised 1 or `""`	high
`xor`	exclusive or	no	normalised 1 or `""`	very low
`not`	not	n/a	normalised 1 or `""`	very low
`and`	and	yes	same as `&&`	very low
`or`	or	yes	same as `||`	very low

The full conceptual treatment of these operators - what truthiness means, why && returns one of its operands, how implication and XOR fit in, the De Morgan transformations that let you simplify tangled conditions - lives in the *Boolean Logic for Perl Programmers* tutorial. This page is the operator-reference companion.

Short-circuit and operand return

&& and || evaluate left-to-right and stop as soon as the result is determined.

- `A && B` - if A is false, return A without evaluating B. Otherwise return B.
- `A || B` - if A is true, return A without evaluating B. Otherwise return B.

The return value is the **operand itself**, not a normalised true/false. This is what makes Perl's defaulting idioms work:

```
my $port = $config{port} || 8080;            # operand of ||, not␣
↪boolean
my $name = $user_input  || "anonymous";
my $val  = $cache{$key} ||= compute($key);   # ||= sets if currently␣
↪false
```

For comparison, `!`, `not`, and `xor` *do* normalise: they always return either 1 or the empty string `""`.

`//` - defined-or

`//` short-circuits on **definedness** instead of truthiness:

- `A // B` - if A is defined, return A. Otherwise return B.

The difference matters when `0`, `""`, or `"0"` is a legitimate value rather than a stand-in for "missing":

```
my $port    = $config{port} || 8080;    # 0 means "use default" -␣
↪wrong
my $port    = $config{port} // 8080;    # 0 means "0", undef means
↪"default"
my $verbose = $opt{verbose} // 0;       # 0 is a real choice
```

`//=` is the compound form:

```
$config{port} //= 8080;                  # set only if currently␣
↪undef
```

`xor` and `^^`

The exclusive-or operator, true if exactly one side is true. ^^ binds like || (row 16 of the precedence table), `xor` is its very-low-precedence word form. Unlike and/or, neither short-circuits (it cannot - both sides have to be evaluated to determine the result):

```
if ($admin xor $guest) { ... }          # exactly one of the two
my $one = $admin ^^ $guest;             # same test, as an␣
↪expression
```

The result is normalised - 1 or "", not an operand. For bitwise XOR on integers, see *bitwise*.

Symbolic vs word forms - precedence, not style

&&, ||, ! bind tightly (rows 15–16). and, or, not bind very loosely (rows 22–24). This matters at the boundary with assignment:

```
my $fh = open $h, '<', $path || die "no $path: $!";
#                        ^^^^^^^^^^^^^^^^^^^^^^^^^^
# parses as: open $h, '<', ($path || die "no $path: $!")
# - open of "either $path or the die-message". Catastrophe.

my $fh = open $h, '<', $path or die "no $path: $!";
# parses as: ($fh = open $h, '<', $path) or die "no $path: $!"
# - what you meant.
```

Rule of thumb:

- Inside an expression, where you want the value to flow into a variable or another operator: use &&, ||, !, //.
- After a statement, where you want a side-effect (die, warn, return) to fire conditionally: use or, and, not.

! and not

Both negate. Both return the canonical 1 or "":

```
my $missing = ! $config{port};          # 1 if port is unset/0/""/"0
↪"
return if not @items;                   # cleaner reading than `if !
↪@items`
```

! binds high (row 5); not binds very low (row 22).

Compound forms

Three of the logical operators have compound assignment forms:

Compound	Means	Use
&&=	$x = $x && $y	“narrow if currently true”
||=	$x = $x || $y	“default if currently false”
//=	$x = $x // $y	“default if currently undef”

```
$cache{$k} ||= compute($k);              # lazy populate
$cfg{port} //= 8080;                     # default that respects 0
$check     &&= validate($check);         # only if currently truthy
```

Tutorial cross-reference

The conceptual underpinnings of this page are covered in the boolean-logic tutorial:

- *Truthiness* - what Perl considers false.
- *Operators* - the operand-return rule, the precedence reasoning, and the ternary `?:` (which lives in *its own page* on this reference).
- *Truth tables* - all sixteen binary functions and how to spell each in Perl.
- *De Morgan* - reducing convoluted `unless` to clean `if`.
- *Functional completeness* - NAND/NOR.

See also

- *Bitwise* - the same boolean operators applied to integer bits in parallel.
- *Ternary* - `?:`, logical selection as an expression.
- *Numeric comparison* and *string comparison* - produce the boolean inputs that the operators on this page combine.
- *Error variables* - `$!` and `$@` are the values you typically put on the right-hand side of the `or die` idiom that this page's word-form operators were made for.

Bitwise operators

The boolean operators applied to each pair of bits in parallel, plus the two shifts. A 32- or 64-bit integer is, from these operators' point of view, a vector of independent one-bit values.

Operator	Operation	Per-bit rule
&	bitwise AND	each output bit = a ∧ b
|	bitwise OR	each output bit = a ∨ b
^	bitwise XOR	each output bit = a ⊕ b
~	bitwise NOT	each output bit = ¬a (unary)
<<	left shift	shift bits left, zero-fill from right
>>	right shift	shift bits right

Operands are coerced to integers (the floor toward zero, with warnings if a non-integer string is supplied under `use warnings`).

```
0xFF & 0x0F            # 0x0F     -- mask to low nibble
0x10 | 0x01            # 0x11     -- combine flag bits
0xFF ^ 0xAA            # 0x55     -- toggle alternating bits
~0                     # -1 (or all-ones, depending on integer width)
```

(continues on next page)

(continued from previous page)

```
1  << 4               # 16
32 >> 2               # 8
```

Setting, clearing, toggling, testing a flag

The four basic flag operations on a single bit:

```
use constant FLAG_VERBOSE  => 0x01;
use constant FLAG_DRY_RUN  => 0x02;
use constant FLAG_RECURSE  => 0x04;
use constant FLAG_FORCE    => 0x08;

my $flags = 0;

$flags |=  FLAG_VERBOSE;       # SET    -- OR with the bit
$flags |=  FLAG_DRY_RUN;       # SET another
$flags &= ~FLAG_DRY_RUN;       # CLEAR  -- AND with the inverted bit
$flags ^=  FLAG_VERBOSE;       # TOGGLE -- XOR with the bit
my $on = $flags & FLAG_RECURSE;# TEST   -- AND, then test truthiness
```

Each is a one-bit application of a boolean operator: set is `bit ∨ flag`, clear is `bit ∧ ¬flag`, toggle is `bit ⊕ flag`, test is `bit ∧ flag`.

Compound assignment

All six binary bitwise operators have compound forms:

```
$bits  &= $mask;       # AND-assign
$flags |= 0x01;        # OR-assign  (set bit)
$x     ^= $y;          # XOR-assign (toggle bits where $y is 1)
$x   <<= 1;            # multiply-by-2 (with overflow caveats)
$x   >>= 1;            # divide-by-2 (toward -∞ for signed values)
```

Shifts

<< shifts left; >> shifts right. The number of bit positions to shift is the right operand. Shifting by a negative amount, or by an amount equal to or greater than the integer's bit width, is implementation-defined - don't rely on it.

For unsigned arithmetic, left-shift is multiplication by `2 ** $n` (modulo overflow):

```
$x << 1               # like $x * 2
$x << 8               # like $x * 256
```

For unsigned arithmetic, right-shift is integer division by `2 ** $n`:

```
$x >> 1               # like int($x / 2)   (for non-negative $x)
$x >> 8               # like int($x / 256)
```

For *signed* values, >> is implementation-defined - Perl does not guarantee arithmetic vs logical shift. Mask explicitly when sign matters:

```
($x >> 8) & 0xFF      # extract a byte at offset 8, regardless of␣
↪sign
```

Numeric vs bytewise mode

Perl's bitwise operators act on **integers** by default. With `use feature 'bitwise'` (or `use v5.22+`), the suffixed forms `&.`, `|.`, `^.`, `~.` act on **strings** byte-by-byte:

```
use feature 'bitwise';
"\x80" |. "\x01"      # "\x81"  -- single-byte string OR
"abc"  ^. "abc"       # "\0\0\0" -- bytewise XOR
```

The undecorated &, |, ^, ~ operators always do integer math, and string operands are coerced to numbers first. The suffixed `.`-forms are the way to ask for byte-string operations explicitly.

XOR-swap

XOR has two properties - $a \oplus a = 0$ and $a \oplus b \oplus b = a$ - that combine into the famous swap-without-temporary trick:

```
my ($a, $b) = (0xFEED, 0xBEEF);

$a ^= $b;             # a := a ⊕ b
$b ^= $a;             # b := b ⊕ (a ⊕ b)  = a
$a ^= $b;             # a := (a ⊕ b) ⊕ a  = b

# $a == 0xBEEF, $b == 0xFEED
```

Not faster than `($a, $b) = ($b, $a)` in Perl. Worth knowing because it appears in interview folklore and embedded code, and because it is a clean illustration of the XOR identity.

Common bit tricks

Patterns you will see in performance-sensitive code:

```
$x &  ($x - 1)            # $x with its lowest set bit cleared
($x & ($x - 1)) == 0      # true when $x is a power of two (and non-
↪zero)
1 << $n                   # the integer with only bit $n set
$x & (1 << $n)            # is bit $n set in $x?
$x | (1 << $n)            # set bit $n
$x & ~(1 << $n)           # clear bit $n
$x ^ (1 << $n)            # toggle bit $n
($x >> $n) & 0xFF         # extract a byte at offset $n
```

Each is an exercise in tracking what each bit does - pure boolean reasoning applied 32 (or 64) times in parallel.

Tutorial cross-reference

The boolean-logic tutorial has a longer treatment of the bitwise-as-parallel-boolean model and the application patterns above:

- *Boolean Logic - Applications* - bitwise operators as parallel boolean, flag manipulation, XOR-swap, common bit tricks.
- *Boolean Logic - Operators* - the boolean foundations the bitwise operators inherit.

See also

- *Logical* - the same boolean operators on whole values.
- *Precedence* - &, |, ^ sit between comparison and &&/||. Almost always parenthesise around them.
- `pack`, `unpack`, `vec` - perlfunc tools for bit-level work beyond what raw operators offer.

Range and flip-flop operators

Two operators with two completely different jobs depending on context: in **list context** they generate ranges, and in **scalar context** they are stateful "flip-flop" boolean expressions for matching line ranges in stream-processing.

Operator	List-context job	Scalar-context job
`..`	inclusive range	flip-flop (false-tested entry)
`...`	inclusive range	flip-flop (true-tested entry)

`..` in list context - ranges

In list context, `..` produces the inclusive sequence between its endpoints:

```
0..9                    # (0,1,2,3,4,5,6,7,8,9)
'a'..'z'                # ('a','b',...,'y','z')      26 elements
'aa'..'zz'              # ('aa','ab',...,'zy','zz')  676 elements
'A'..'F'                # ('A','B','C','D','E','F')

for my $i (1..100) { ... }                      # numeric for-loop
for my $name ('alpha'..'omega') { ... }         # alphabetic,␣
 ↪magic-incremented
```

For numeric endpoints the result is the integer sequence (with strict ordering - `5..1` is the empty list, never reverse). For string endpoints the magic-increment from `++` is used, which gives you the natural alphabetic spread (and on `'aa'` through `'zz'` the expected 676 two-letter combinations).

A common Perl idiom:

```
my @hex = ('0'..'9', 'a'..'f');           # 16 hex digits as strings
my @rev = reverse 1..10;                   # (10,9,8,...,1)
@arr[ 5..9 ]                               # array slice, indexes 5.
 ↪.9
@arr[ -3..-1 ]                             # last three elements
```

The all-integer range can be very large - `1..1_000_000_000` is a billion-element list. Perl 5 lazily generates loop ranges in `for`, so `for my $i (1..1_000_000_000)` is safe, but `my @x = 1..1_000_000_000` allocates the whole array. PetaPerl follows the same rule.

Reversed endpoints

`5..1` is empty. There is no "reverse range" form; if you want descending, generate ascending and `reverse`:

```
1..5                    # (1,2,3,4,5)
5..1                    # ()          - empty, no warning
reverse 1..5            # (5,4,3,2,1)
```

Mixed-type endpoints

If either endpoint *looks* numeric, `..` does numeric ranging:

```
'1'..'5'                # (1,2,3,4,5)             - numeric
'1'..'10'               # (1,2,3,4,5,6,7,8,9,10) - numeric

'a'..'5'                # ('a')                   - magic-increment␣
 ↪from "a",
                        #                          stops because it␣
 ↪can't reach "5"
```

Make the type explicit to avoid confusion:

```
0+'1' .. 0+'5'          # numeric, no doubt
sprintf("%d", 1) .. sprintf("%d", 5)
```

In practice, write integer ranges with bare integer literals and character ranges with bare quoted-string letters; the magic-vs-arithmetic distinction follows automatically.

`..` and `...` in scalar context - flip-flops

Inside a boolean context (an `if`, a `while`, a `?:`, the right of `&&`/`||`/`//`), `..` becomes a *stateful* expression that remembers whether it is currently between a left-side match and a right-side match.

```
while (<$fh>) {
    if (/^BEGIN/ .. /^END/) {     # true from BEGIN line through END␣
 ↪line
        print;                     # print everything in between,␣
```

(continues on next page)

(continued from previous page)

```
 ↪inclusive
    }
}
```

The semantics:

1. The flip-flop is initially **false**.
2. When the **left** condition (`/^BEGIN/`) becomes true, the flip-flop transitions to **true**, and the right side is evaluated immediately on the same iteration.
3. The flip-flop stays true on subsequent iterations until the **right** condition (`/^END/`) becomes true. On that iteration it returns true *and then* transitions back to false.
4. So both the BEGIN line and the END line are included.

When the flip-flop is true, it returns a *sequence number* (1 on the entering iteration, 2 on the next, ...). On the closing iteration it returns the count followed by `E0` - so the value is true (non-empty string, not the false `"0"`) but stringifies as the number `0` for cosmetic clarity. You can usually treat it as plain boolean.

`...` differs from `..` in one detail:

- `..` (two dots) - when the left side becomes true, the right side is checked **on the same iteration**. So the same line can open and close the range.
- `...` (three dots) - when the left side becomes true, the right side is **not** checked until the next iteration. Always a multi-line range.

```
while (<$fh>) {
    print if /<head>/ .. /<\/head>/;     # one-line <head>...</head>␣
 ↪works
    print if /<head>/ ... /<\/head>/;    # forces multi-line; same-
 ↪line ignored
}
```

When you'd use a flip-flop

The flip-flop shines in awk-style line-range filtering - pulling sections out of a log file, isolating a fenced code block from markdown, processing a configuration block delimited by keywords. It is famously *un*-loved by code reviewers because its statefulness is implicit.

Two practical alternatives that some prefer:

```
# Explicit state variable - equivalent semantics, easier to grep␣
 ↪for:
my $in_block = 0;
while (<$fh>) {
    $in_block = 1 if /^BEGIN/;
    print if $in_block;
    $in_block = 0 if /^END/;
}
```

(continues on next page)

(continued from previous page)

```
# A simple two-step iterator:
while (<$fh>) {
    if (/^BEGIN/ .. /^END/) { print }
}
```

The flip-flop wins on conciseness; the explicit form wins on clarity at the cost of three more lines. Pick by audience.

See also

- `reverse`, `grep`, `map` - list operators commonly composed with ranges.
- *Subscript* - array slices `@arr[1..3]` rely on range-in-list-context.
- *Precedence* - `..` and `...` sit at row 17, between `||` `//` and `?:`. Almost always parenthesise when combining with logic.

Regex binding operators

Two operators that connect a string with a regular expression operation. They do not perform the match themselves; they merely say "this expression's input is that string".

Operator	Reads as	Use
`=~`	matches	bind a regex op (`m//`, `s///`, `tr///`)
`!~`	doesn't match	same, with the boolean result negated

```
$str =~ /pattern/                    # match: TRUE if $str contains␣
↪a match
$str =~ s/foo/bar/                   # substitution: returns count␣
↪of changes
$str =~ tr/a-z/A-Z/                  # transliteration: returns␣
↪count
$str !~ /pattern/                    # match negated: TRUE if NO␣
↪match
```

Without an explicit binding, regex ops act on `$_`:

```
$_ = "hello";
print "match\n" if /h/;              # implicit $_ binding
```

`=~` and `!~` are how you redirect that input to a different variable.

What they actually return

`=~` returns whatever the regex op on the right would return:

- `m//` - boolean (true on match, false on no match) in scalar context; the captured groups in list context.

- `s///` - the number of substitutions performed (which is boolean-true when ⩾ 1).
- `tr///` - the number of characters processed.

`!~` returns the boolean negation, regardless of the underlying op. It is mostly used with `m//`:

```
print "no digit"   if $str !~ /\d/;
print "$n changes" if $str =~ s/foo/bar/g;
my @hits           = $str =~ /(\w+)/g;       # list context:␣
↪captures
```

Three op partners

`=~` accepts three regex operations on its right:

- `m//` - match. The `m` is optional when the delimiters are slashes: `$s =~ /pattern/` and `$s =~ m{pattern}` both work.
- `s///` - substitution. Three pieces: pattern, replacement, flags. Returns the count of replacements.
- `tr///` (also spellable `y///`) - transliteration. Replaces characters one-for-one between two character sets. Returns the count of characters processed.

```
$line =~ /(\d+)/             # extract first run of digits
$line =~ s/^\s+//             # strip leading whitespace
$line =~ s/\s+/ /g            # collapse all whitespace to single␣
↪spaces
$line =~ tr/A-Z/a-z/          # ASCII lowercase
```

`!~` only with `m//`

`!~` is meaningful only with the *match* operation, since substitution and transliteration return *counts* and the "no-changes-made" case is a meaningful zero, not a "didn't match" boolean. Perl will let you write `$s !~ s/.../.../`, but you almost never want it - the result `!s///` is "true if zero substitutions" which reads strangely. Stick to `!~ /.../`.

Lvalue vs rvalue

`=~` itself does not assign. It only routes the regex op on its right at the string on its left. The op *itself* may then mutate that string - `s///` and `tr///` do, `m//` does not - but the mutation comes from `=~`:

```
my $s = "hello";
$s =~ s/l/L/g;           # mutates $s - now "heLLo"
my $n = $s =~ /(\w+)/;  # does NOT mutate $s; $n is the boolean␣
↪result
```

The string on the left of `=~` must be modifiable for `s///` and `tr///`. A literal string or `$1` (a regex capture variable) will fail with "Modification of a read-only value attempted":

```
"hello" =~ s/l/L/g;     # FATAL - literal is read-only
$1 =~ s/x/y/;           # FATAL - capture variable is read-only
```

Copy first if you need to modify a read-only source:

```
(my $copy = $1) =~ s/x/y/;     # idiom for "modify a copy of $1"
```

Precedence

=~ and !~ sit at row 6 of the *precedence* table - quite tight, between unary and the multiplicative operators. This is why you can write `$s =~ /foo/ && $t =~ /bar/` without parens around either match.

Tutorial cross-reference

The boolean-logic tutorial covers regex-as-set-algebra in its applications chapter - alternation as union, lookarounds as intersection and complement:

- *Boolean Logic - Applications* (the *Regular expressions: logic on sets of strings* section)

The full regex language reference lives in the regex guide:

- *Regular expressions guide*

See also

- `m//`, `s///`, `tr///`, `qr//`, `split` - the regex-consuming perlfunc forms.
- `$_` - the default input variable when no binding is given.
- *Regex match variables* - `$&`, `$1`..`$N`, `%+`, `@+`, `@-`: what every successful match populates.

Assignment operators

Plain assignment plus the compound forms - every binary operator that produces a value also has a compound assignment form that applies the operation in place.

Plain =

```
my $x = 10;                          # scalar assignment
my @a = (1, 2, 3);                   # list assignment
my ($x, $y, $z) = (1, 2, 3);         # destructuring
my ($first, @rest) = @items;         # one + remainder
my %h = (a => 1, b => 2);            # hash from key-value list
```

Assignment is **right-associative** - chains are evaluated right-to-left:

```
$a = $b = $c = 0;                    # parses as $a = ($b = ($c =
↪0))
                                     # all three become 0
```

The whole assignment expression has a value: in scalar context it is the value assigned; in list context it is the **list of elements assigned to**, in left-to-right order:

```
my $count = (my @items = qw(a b c)); # $count = 3
                                     # - number of elements assigned
                                     # to @items, in scalar context

while ((my $line = <$fh>) ne '') { ... }   # uses the assignment as
                                            # both side-effect and␣
↪value
```

List assignment in scalar context

Probably the most-used Perl idiom that nobody can quote the rule for:

```
my $n = () = $string =~ /\d/g;       # count digits in $string
```

Decoded:

1. `$string =~ /\d/g` in list context yields all digit captures.
2. `() = ...` is a list assignment to the empty list (assigns nothing, but evaluates the right-hand side in list context).
3. `$n = (...)` puts the *list assignment* in scalar context, which evaluates to the **number of elements** on the right.

Result: `$n` is the count of matches. There is no `scalar(grep ...)` or `count` built-in for this; the empty-list trick is the canonical idiom.

Compound assignment

Every binary operator that fits the pattern `OP=` exists. The mechanics are identical to `$x = $x OP $y`, *except* that `$x` is evaluated only once on the left - which matters when the lvalue has a side-effect (e.g. an autoviv, a function call):

```
$h->{counter}++;                     # autoviv $h->{counter},␣
↪increment
$h->{counter} += 1;                  # same effect, but spell out␣
↪the OP
```

Operator	Equivalent	Use
`+=`	`$x = $x + $y`	accumulate
`-=`	`$x = $x - $y`	subtract in place
`*=`	`$x = $x * $y`	scale
`/=`	`$x = $x / $y`	divide in place
`%=`	`$x = $x % $y`	modulo
`**=`	`$x = $x ** $y`	exponent in place
`.=`	`$x = $x . $y`	append (string)
`x=`	`$x = $x x $y`	repeat (string), or `(@) x= n`
`&=`	`$x = $x & $y`	bitmask AND-equals
`|=`	`$x = $x | $y`	bitmask OR-equals (set bits)
`^=`	`$x = $x ^ $y`	bitmask XOR-equals (toggle)
`<<=`	`$x = $x << $y`	shift-left in place
`>>=`	`$x = $x >> $y`	shift-right in place
`&&=`	`$x = $x && $y`	"narrow if currently true"
`||=`	`$x = $x || $y`	default if currently false
`//=`	`$x = $x // $y`	default if currently undef
`^^=`	`$x = $x ^^ $y`	logical XOR-equals

```
$count     += 5;                          # arithmetic
$path      .= "/user";                    # string append
$flags     |= FLAG_VERBOSE;               # set a flag bit
$flags     &= ~FLAG_VERBOSE;              # clear a flag bit
$cache     ||= load_data();               # lazy populate
$cfg{key} //= $default;                   # default that respects 0 and "
 ↪"
$str        x= 3;                         # repeat in place
```

Lvalues - what can appear on the left

The left operand of = (or any compound form) must be an **lvalue** - a location that can be written to. Perl's lvalues include:

- A simple scalar variable: `$x`, `$obj->{field}`.
- An array or hash variable: `@arr`, `%h`.
- An array element or slice: `$arr[3]`, `@arr[1..3]`.
- A hash element or slice: `$h{key}`, `@h{qw(a b c)}`.
- A dereferenced container: `$$ref`, `@$aref`, `%{$h}`.
- The `local`-/`my`-declared form of any of the above.
- A *substring*: `substr($s, $offset, $len) = "..."`.
- A *ternary* whose branches are lvalues (see *ternary*).
- The pseudo-operators `pos`, `vec`, `keys` on tied hashes, certain `@_` slots, and a handful of specialised forms.

Most of the time you write an lvalue without thinking. The cases where you stop and check are exotic - `substr` as lvalue, a ternary as lvalue, an array slice as the target of a list assignment.

Multiple-target list assignment

The right-hand side is evaluated *first* in list context, then distributed across the lvalues on the left. This makes swap easy:

```
($a, $b) = ($b, $a);                    # swap
($x, $y, $z) = ($y, $z, $x);            # rotate left
```

If the lists differ in length:

- More values on the right than slots on the left → extras silently discarded.
- More slots on the left than values on the right → unfilled slots become `undef`.

```
my ($a, $b) = (1, 2, 3, 4);             # $a=1, $b=2; 3 and 4 dropped
my ($a, $b, $c) = (1, 2);               # $a=1, $b=2, $c=undef
```

A trailing array or hash on the left slurps the remainder:

```
my ($head, @tail) = @items;             # $head = first element
                                        # @tail = the rest
my ($head, %tail) = @items;             # if @items has key/value pairs
                                        # after the first
```

Only **one** array or hash on the left side; otherwise it would not be unambiguous where one ends and the next begins.

Precedence

Assignment operators sit at row 19 - quite low, looser than comparison and `?:`, tighter only than the comma operators and the word-form logicals (`and`, `or`, `not`, `xor`). This is why `my $fh = open ... or die` works (`or` is even looser than `=`).

See also

- *Logical* - `||=`, `//=`, `&&=` are the workhorses of "default if missing" idioms.
- *Subscript* - most lvalue forms involve a subscript.
- *Comma* - `=` parses out from the surrounding `,`-list via precedence; understanding row 19 vs row 20 is what tells you when `(a, b)=(c, d)` distributes vs being a single list.

Ternary operator

One operator, three operands. Logical selection as an *expression* - the result has a value, can be assigned, returned, passed as an argument.

Form

```
COND ? THEN : ELSE
```

If `COND` is true, the value is `THEN`; otherwise it is `ELSE`. Only the chosen branch is evaluated:

```
my $label = $count == 1 ? "1 item" : "$count items";
return $ok ? \%result : undef;
my $abs   = $x < 0     ? -$x       : $x;
```

It is an expression, not a statement

The most common reason to reach for `?:` instead of `if`/`else` is that you want a *value* - to assign, to return, to put inside another expression:

```
# verbose
my $kind;
if ($n == 1) { $kind = 'singular' }
else         { $kind = 'plural'   }

# idiomatic
my $kind = $n == 1 ? 'singular' : 'plural';
```

Chaining (right-associative)

`A ? B : C ? D : E` parses as `A ? B : (C ? D : E)` - the chain descends through the false branch:

```
my $sign = $x < 0  ? '-'
         : $x > 0  ? '+'
         :           '0';
```

The columnar layout makes the chain readable. Past two or three levels, switch to `if`/`elsif`/`else` - the chain stops being clearer than the alternative.

Ternary as lvalue

Both branches must be lvalues, and the chosen branch is the lvalue you assign to:

```
my ($pos, $neg) = (0, 0);
($x > 0 ? $pos : $neg) = $x;              # assigns to $pos or $neg

# Common case: pick a buffer to append to
($verbose ? $log : $debug) .= "$msg\n";
```

This pattern is rare in modern code - an explicit `if` with two straightforward assignments reads better. Worth knowing for when you encounter it.

What you don't write

`?:` is *not* a statement separator. These are wrong:

```
$x ? do_a() : do_b();                          # OK: do_a/do_b have side-
 ↪effects,
                                               # but the value is␣
 ↪discarded
$x > 0 ? print "yes\n" : print "no\n";         # WORKS, but reads␣
 ↪strangely
```

When the goal is a side-effect (rather than a value), use `if`/`else` or the postfix `if`/`unless`:

```
$x > 0 ? do_yes() : do_no();                   # value-return phrasing
do_yes() if $x > 0;                             # side-effect phrasing
do_no()  unless $x > 0;
```

With short-circuit logical operators

`?:` interacts with `&&`, `||`, `//` in ways that can confuse the eye. Almost always parenthesise:

```
my $x = $a || $b ? $c : $d;                    # parses as ($a || $b) ? $c␣
 ↪: $d
                                               # because || binds tighter␣
 ↪than ?:
my $x = $a || ($b ? $c : $d);                  # if you meant the other␣
 ↪thing,
                                               # parenthesise
```

Precedence

`?:` sits at row 18 - looser than the boolean operators (`&&`/`||`/`//`), tighter than assignment. This is why `my $x = COND ? A : B` works without parens around the right-hand side.

See also

- *Boolean Logic - Operators* - `?:` in the context of all the boolean operators.
- *Assignment* - `?:` as lvalue.

Subscript and slice operators

The bracket-and-brace family that picks elements out of arrays and hashes - and the deref-brace family that does the same through a reference.

Form	Selects	Container	Result type
`$arr[i]`	one element	array	scalar
`$hash{key}`	one element	hash	scalar
`@arr[i, j, k]`	many elements (slice)	array	list
`@hash{k1, k2}`	many elements (slice)	hash	list
`%arr[i, j, k]`	key/value slice	array	list (k,v...)
`%hash{k1, k2}`	key/value slice	hash	list (k,v...)

A few rules cover all twelve combinations.

The sigil signals the *result*, not the container

`@arr` is the array; `$arr[3]` is one of its elements. The leading sigil tells you what *kind of value* you are accessing - scalar (`$`), list of values (`@`), key/value list (`%`):

```
my @arr = (10, 20, 30, 40, 50);

$arr[2]           # 30                - scalar (single element)
@arr[1, 3]        # (20, 40)          - list of values at those␣
 ↪indices
%arr[1, 3]        # (1 => 20, 3 => 40) - list of (index, value)␣
 ↪pairs
```

```
my %h = (a => 1, b => 2, c => 3);

$h{a}             # 1                 - scalar
@h{'a', 'c'}      # (1, 3)            - list of values
%h{'a', 'c'}      # (a => 1, c => 3)  - list of (key, value) pairs
```

The "%-slice" forms (`%arr[...]`, `%hash{...}`) are a Perl 5.20 addition that returns key/value pairs as a list. They are the right tool when you want a copy of *part of* a hash:

```
my %selected = %h{ qw(a c) };           # %selected = (a => 1, c =>␣
 ↪3)
```

Negative indices on arrays

Negative array indices count from the end:

```
$arr[-1]          # last element
$arr[-2]          # second-from-last
@arr[-3..-1]      # last three elements as a slice
```

Out-of-range positive indices read as `undef`. Out-of-range negative indices (further back than the start) raise a fatal runtime error:

```
my @a = (1, 2, 3);
$a[10]            # undef (with no warning)
```

(continues on next page)

(continued from previous page)

```
$a[-10]           # FATAL: Modification of non-creatable array value
                  # (the error wording reflects how the lookup is␣
 ↪implemented)
```

Slice as lvalue

Both array and hash slices are valid assignment targets:

```
@arr[0, 2, 4] = ('A', 'C', 'E');          # set positions 0, 2, 4
@h{qw(a b c)} = (1, 2, 3);                # set three hash keys

(@arr[0, 1], @arr[1, 0]) = ...             # be careful: aliasing!
```

You can swap elements via slice assignment without a temporary:

```
@arr[$i, $j] = @arr[$j, $i];              # swap two array elements
@h{$key1, $key2} = @h{$key2, $key1};      # swap two hash values
```

Hash key autoquoting

Inside {} for hash subscripts, **bareword identifiers are auto-quoted**:

```
$h{name}          # same as $h{'name'}
$h{first_name}    # same as $h{'first_name'}
$h{1_2}           # FATAL - not a valid bareword identifier
$h{"1_2"}         # quote it explicitly
```

This is one of the most-loved (and most-bug-causing) Perl conveniences. The bareword-or-not decision happens at parse time based on the literal token; constants and computed values do not benefit:

```
use constant KEY => 'name';
$h{KEY}           # WRONG - this is the bareword "KEY", not the␣
 ↪constant!
$h{KEY()}         # use empty parens to force function-call␣
 ↪evaluation
$h{+KEY}          # or unary +, the canonical workaround
```

The +KEY form is the most compact way to say "this is *not* a bareword, evaluate it as an expression".

Array indices: integer-coerced, no autoquoting

[] indices are evaluated as expressions and coerced to integers (truncating toward zero):

```
$arr[1.7]         # $arr[1]    - 1.7 truncates to 1
$arr["3"]         # $arr[3]    - string coerces to integer
$arr[$#arr]       # last element  ($#arr is last valid index)
```

The `$#arr` syntax inside subscripts is idiomatic for "last":

```
$arr[$#arr]       # last
@arr[0..$#arr]    # all of @arr (verbose; just write @arr)
@arr[1..$#arr]    # all except first
```

Mixing - multidimensional access

Perl 5 does not have native multi-dimensional arrays; nested data is built from references:

```
my @grid = ([1,2,3], [4,5,6], [7,8,9]);

$grid[1][2]       # 6                  - chained subscripts on AoA
$grid[1]->[2]     # same - the arrow is optional between subscripts
$grid[$y][$x]
```

The arrow-between-subscripts is implied by Perl's grammar: when two subscripts immediately follow each other on a deref chain, the `->` can be omitted. See *arrow*.

See also

- *Arrow* - `->[]` and `->{}` for going through a reference; the arrow-elision rule.
- *Assignment* - slice assignment; multi-target destructuring.
- `exists`, `delete` - perlfunc forms that take a subscript expression.
- `keys`, `values` - whole-container forms; the slice operators are the partial forms.
- *Arrays*, *Hashes* - the data-types pages explain the sigil-vs-result rule that governs which subscript form to use.

Arrow operator

The single most heavily used operator in working Perl, after =. It does three things at three syntactic positions, and they all start by *dereferencing* something on the left.

Form	Means	Example
`$ref->[i]`	element of an arrayref	`$aref->[0]`
`$ref->{k}`	element of a hashref	`$href->{name}`
`$ref->(...)`	call a coderef	`$cref->(@args)`
`$obj->meth`	method call on an object	`$obj->print`
`$obj->meth(@a)`	method call with arguments	`$obj->set_x(42)`
`$class->meth`	class method call	`Foo::Bar->new`

The first three forms are *dereferencing*. The last three are *method dispatch*. Both are spelled with `->`.

Dereferencing

A reference is a scalar that points at a container or a coderef. You cannot index into a reference directly with `[]` or `{}`; you must dereference first, and `->` is the canonical way:

```
my @arr  = (10, 20, 30);
my $aref = \@arr;

$arr[0]            # 10  - direct array access
$$aref[0]          # 10  - dereference, then subscript (old syntax)
$aref->[0]         # 10  - dereference and subscript in one move
$aref->[-1]        # 30  - negative indices work the same way
```

```
my %h    = (name => 'John');
my $href = \%h;

$h{name}           # 'John'
${$href}{name}     # 'John' - full deref + subscript
$href->{name}      # 'John' - same, idiomatic form
```

Coderef invocation

```
my $f = sub { $_[0] * 2 };

$f->(5)            # 10  - invoke the coderef with argument 5
&$f(5)             # same - older syntax, still works
```

The `->()` form is preferred in modern Perl. Empty argument list is `$f->()`.

Arrow elision between subscripts

When two subscripts directly follow each other on a deref chain, the **second arrow can be omitted**. The grammar implies it:

```
$grid[1]->[2]      # explicit
$grid[1][2]        # arrow elided - the only way most people write
↪this

$tree->{children}[0]{name}    # parses with arrows between every
↪pair
                              # - the chain is read as a sequence
                              # of subscripts on the same deref path
```

The first arrow (between a scalar variable and the *first* subscript) is **required**. Only arrows *between consecutive subscripts* may be elided.

```
$aref->[0]->[1]    # explicit
$aref->[0][1]      # elided second arrow - fine
$aref[0][1]        # WRONG - $aref[0] reads from @aref, not the
                   # arrayref in $aref. Different variable!
```

The first-arrow rule is the source of subtle bugs when refactoring `$aref->[0]` into a deeper expression - keep the leading arrow.

Method calls

When the right side of `->` is an *identifier* (or a parenthesised name expression), it is interpreted as a method call rather than a subscript:

```
$obj->print;                        # call $obj->print()
$obj->name;                         # accessor: returns $obj->name
$obj->set_name("Alice");            # mutator: sets and may return $obj
Foo::Bar->new(arg => 1);            # class method call

$obj->$method_name(@args);          # method name in a variable
$class->can('foo')                  # can() - does method exist?
```

Method calls dispatch through the package the object is blessed into. The exact resolution path is governed by `@ISA` and the chosen MRO; see the *OOP guide* for the full story.

Indirect-object syntax - don't use it

Perl 5 historically allowed `print $fh "foo"` and `new Foo @args` without an arrow. These forms still parse but are context-sensitive in ways that surprise - the indirect-object syntax can resolve the `new` (or whatever) at the wrong time. The modern guidance is to **always use `->`** for method calls:

```
my $obj = Foo->new(@args);                    # correct
my $obj = new Foo @args;                       # avoid (still␣
↪parses)

print $fh "hello\n";                           # OK - print is␣
↪special
$fh->print("hello\n");                         # also fine, prefer␣
↪this
                                               # for IO::File-style␣
↪handles
```

Precedence

`->` is row 2 of the *precedence* table - second only to terms and list operators. It binds tighter than every other operator, which is what you want: `$h->{a} + $h->{b}` parses as the sum of two hash lookups, not as a lookup of `{a + $h->{b}}`.

See also

- *Subscript* - direct (non-dereferenced) array/hash access; the arrow-elision rule.
- *References tutorial* - full treatment of references, including how `\` builds them and how the deref alternatives (`@{...}`, `%{...}`, `${...}`) work.
- *OOP guide* - `->method` and class dispatch in depth.

- `ref`, `bless` - perlfunc tools that pair with the arrow operator's two roles.
- *References* - what `\X` produces and how the deref shapes (`@{...}`, `%{...}`, `${...}`) compose.

Comma operators

Two operators, both spelled with a comma - one of them spelled "fat comma" with =>. They are syntactically the same in most positions but differ on the left-hand-side bareword rule.

Operator	Reads as	What it does
,	comma	list separator (in list ctx); discard-and-yield-right (in scalar ctx)
=>	fat comma	same as , , plus auto-quotes a bareword on the left

In list context - building lists

In list context the comma is the list-element separator:

```
my @items = (1, 2, 3, 4);                    # 4-element list
my @flat  = (1, 2, (3, 4), 5);               # (1,2,3,4,5) - lists␣
↪flatten
my @kv    = (a => 1, b => 2);                # 4-element list: a, 1,␣
↪b, 2
my %h     = (a => 1, b => 2);                # hash from key-value␣
↪pairs
```

Lists in Perl are *flat* - there is no nested-list value. A list embedded in another list disappears: its elements simply become elements of the outer list. To get nested structure you need references (see the *References tutorial*):

```
my @flat   = (1, 2, (3, 4), 5);              # (1,2,3,4,5) - 5␣
↪elements
my @nested = (1, 2, [3, 4], 5);              # (1, 2, ARRAYREF, 5) - 4␣
↪elements
```

In scalar context - comma is "discard, then return right"

When a comma expression is *forced* into scalar context - by an assignment to a scalar, by `scalar(...)`, by being the condition of an `if` - it evaluates each operand left-to-right for side-effects, then yields the value of the rightmost operand:

```
my $x = (1, 2, 3);                           # $x = 3 - but warn␣
↪under
                                             # `use warnings`:
↪"Useless use of
```

(continues on next page)

(continued from previous page)

```
                                                # a constant in void␣
↪context"
                                                # for 1 and 2

my $r = (do_a(), do_b(), final_value());        # runs all three,␣
↪returns
                                                # the last value
```

This usage is rare in modern Perl - the C-style `for(init, init; cond; step, step)` idiom is the main place you encounter it (and even there, parens around the comma sub-expression are advisable).

=> - the fat comma

=> does the same thing as , *plus* it auto-quotes the identifier-shaped bareword on its left:

```
my %h = (
    name  => "John",                            # 'name'  auto-quoted
    age   => 30,
    "key with spaces" => "...",                 # quote required for␣
↪non-bareword
);

# Equivalent without =>, requiring explicit quoting:
my %h = (
    'name', "John",
    'age',  30,
    'key with spaces', '...',
);
```

The auto-quote applies only when the left side is **a syntactically valid bareword identifier** - letters, digits, underscores, starting with a letter or underscore. Other shapes are not auto-quoted:

```
( name      => 1 )          # 'name' auto-quoted - fine
( "name"    => 1 )          # already a string - fine
( $variable => 1 )          # $variable evaluated - fine
( 0+1       => 1 )          # numeric expression - fine
( -name     => 1 )          # WRONG - looks like negative bareword;
                            # parses as -('name') which is the
                            # numeric negation of a string. Quote␣
↪it.
( CONST     => 1 )          # 'CONST' auto-quoted - does NOT call
                            # the constant CONST!
( CONST()   => 1 )          # explicit empty parens - calls CONST
```

The interaction with constants is the most common surprise - see also the *subscript* page on hash key autoquoting, which has the same pattern.

Common idioms

```
# Function arguments - the comma is just the argument separator
some_function($arg1, $arg2, $arg3);

# Hash construction - fat-comma communicates "this is a key"
my %config = (
    host => 'localhost',
    port => 8080,
    user => $ENV{USER},
);

# List literal - interchangeable
my @months = (qw/Jan Feb Mar Apr May Jun Jul Aug Sep Oct Nov Dec/);

# Trailing comma - allowed and idiomatic for diff-friendly multi-
 ↪line literals
my @list = (
    "first",
    "second",
    "third",       # trailing comma is fine
);
```

The trailing comma is intentional: it lets you append, remove, or reorder list elements without touching surrounding lines, which shows up as cleaner diffs in version control.

Precedence

`,` and `=>` sit at row 20 - looser than assignment, tighter only than the word-form logicals (`and`/`or`/`not`/`xor`) and list operators in their right-side position. This is why a list of assignments works:

```
my $a = 1, my $b = 2;          # WRONG: parses as (my $a = 1), my $b
 ↪= 2
                               # - comma at outer level, not list
 ↪assignment.
                               # $a is 1, $b is 2, but the warning
 ↪is loud.

my ($a, $b) = (1, 2);          # the right way: list assignment
```

- `use constant` - the bareword/constant collision is the canonical fat-comma gotcha.
- *Context* - the list-vs-scalar story behind why `,` means two different things.

Precedence

Two pieces, in this order: the full precedence table, and the parse rule for *named unary operators* - built-in functions whose syntax binds at operator precedence rather than as full list-operator calls.

The full table

Operators tighter at the top, looser at the bottom. Same row = same precedence; combining two same-row operators uses associativity. none = non-associative (combining two of them without parens is an error or a parse-time warning).

Row	Associativity	Operators
1	left	terms, list operators (leftward)
2	left	`->`
3	none	`++ --`
4	right	`**`
5	right	`! ~ \` unary + unary -
6	left	`=~ !~`
7	left	`* / % x`
8	left	`+ - .`
9	left	`<< >>`
10	none	named unary operators
11	none	`< <= > >= lt le gt ge`
12	none	`== != <=> eq ne cmp`
13	left	`&`
14	left	`| ^`
15	left	`&&`
16	left	`|| ^^ //`
17	none	`.. ...`
18	right	`?:`
19	right	`= += -= *= /=` etc.
20	left	`, =>`
21	none	list operators (rightward)
22	right	`not`
23	left	`and`
24	left	`or xor`

A few rules of thumb:

- **Comparison and logic.** Comparison (rows 11–12) is tighter than &&/||/// (rows 15–16), so `$a < $b && $c > $d` works without inner parens.
- **Bitwise vs comparison.** &, |, ^ (rows 13–14) are *looser* than comparison. `$x & 0xFF == 0` parses as `$x & (0xFF == 0)`. Almost always parenthesise around bitwise.
- **Symbolic vs word logic.** &&/||/! are tight (rows 5, 15, 16). and/or/not are very loose (rows 22–24). Same logical meaning; different binding. The *logical* chapter shows where each is appropriate.
- **= is loose.** Row 19 - almost everything binds tighter than assignment. This is why

`my $fh = open ... or die` works: `or` (row 24) is even looser than `=`, so the open finishes assigning before `or` decides.

- **List operators bookend the table.** Row 1 looking *leftward*, row 21 looking *rightward*. A list operator like `print` or `sort` slurps everything to its right, up to the first operator that binds looser than row 21 - which is just `not`/`and`/`or`/`xor`. The *named unary* section below contrasts this with the row-10 single-argument case.

When in doubt, write parentheses. They cost nothing and document intent.

Post and pre increment / decrement

Row 3 (`++` and `--`) is non-associative. The pre and post forms differ in *when* the side-effect happens:

- **`++$x`** - increment first, then yield the new value.
- **`$x++`** - yield the current value, then increment.

```
my $x = 5;
my $a = ++$x;          # $x is now 6, $a is 6
my $b = $x++;          # $a was 6, $x++ yields 6 then increments,
                       # so $b is 6 and $x is now 7
```

`++` on a string performs Perl's *magic increment*:

```
my $s = "aa";
$s++;                  # "ab"
$s++;                  # "ac"
# ...
$s = "az"; $s++;     # "ba"  - carries like base-26
$s = "Aa"; $s++;     # "Ab"  - case is preserved per-position
$s = "Az9"; $s++;    # "Ba0" - digits and letters carry␣
 ↪independently
```

The magic-increment is what makes `'a'..'zz'` produce all 702 two-letter combinations in *range*.

Named unary operators

Row 10 contains a category called *named unary operators*. These are not symbolic operators - they are **built-in functions** that take exactly one argument and parse with operator-style precedence (between bitshifts and comparison) rather than as full list operators.

The practical consequence is one parsing rule:

> A named unary operator grabs its **one** argument greedily, and anything that would need more than one argument is not part of it.

```
defined $x + 1             # parses as: ( defined($x) ) + 1
                           # - NOT  defined($x + 1)
length $s > 3              # parses as: ( length($s) ) > 3
```

(continues on next page)

(continued from previous page)

```
-e $f && -r _              # both file tests are named-unary;
                           # `&&` combines two boolean results
```

Compare with a list operator (`print`, `sort`, `push`, ...), which is at row 1 / 21 and slurps the rest of the expression:

```
print "n=", $n, "\n"       # print's argument list is "n=", $n, "\n"
                           # all three commas belong to print
```

If you want a named-unary built-in to take a more complex argument, parenthesise:

```
defined($x + 1)            # explicit: argument is the sum $x+1
length($s . "x")           # length of $s with "x" appended
```

The unambiguous form is always available. When in doubt, parenthesise.

The list of named unary built-ins

These built-ins parse at row-10 precedence. Each links to its `perlfunc` detail page - the parsing rule above is the only thing you need to know about them as *operators*; their *function* behaviour is in the perlfunc reference.

`defined`, `exists`, `ref`, `scalar`, `length`, `uc`, `lc`, `ucfirst`, `lcfirst`, `chr`, `ord`, `hex`, `oct`, `int`, `abs`, `sqrt`, `sin`, `cos`, `log`, `exp`, `rand`, `srand`, `alarm`, `sleep`, `caller`, `wantarray`, `chroot`, `readlink`, `umask`, `lstat`, `stat` (when given exactly one argument), plus all the **file test operators** (`-e`, `-r`, `-w`, `-x`, `-f`, `-d`, `-l`, `-s`, and the rest - see the *file test operators* section below).

The “operator” framing in classical Perl documentation is historical. In modern Perl terms, these are *functions whose argument-parsing places them between bitshift and comparison on the precedence table*. The naming is what it is; the behaviour is what matters.

File test operators

File tests are unary operators (named-unary precedence) that inspect a property of a file or filehandle. They begin with a hyphen and a single letter. All return boolean except `-s` (file size in bytes), `-M`/`-A`/`-C` (age in days, fractional), and the read-time tests `-T`/`-B` (boolean but slightly slower because they read the file).

Op	Test	Returns
`-e`	exists	boolean
`-r`	readable by effective UID	boolean
`-w`	writable by effective UID	boolean
`-x`	executable by effective UID	boolean
`-o`	owned by effective UID	boolean
`-R`	readable by real UID	boolean
`-W`	writable by real UID	boolean
`-X`	executable by real UID	boolean
`-O`	owned by real UID	boolean
`-z`	zero size	boolean
`-s`	non-zero size	size in bytes or false
`-f`	regular file	boolean
`-d`	directory	boolean
`-l`	symbolic link	boolean
`-p`	named pipe (FIFO)	boolean
`-S`	socket	boolean
`-b`	block special file	boolean
`-c`	character special file	boolean
`-t`	TTY (terminal)	boolean
`-u`	setuid bit	boolean
`-g`	setgid bit	boolean
`-k`	sticky bit	boolean
`-T`	text file (heuristic)	boolean
`-B`	binary file (heuristic)	boolean
`-M`	modification time (script-start age, days)	number
`-A`	access time (days)	number
`-C`	inode change time (days)	number

```
if (-e $file) { ... }                # exists
if (-f $path && -r $path) { ... }    # regular file and readable
my $size = -s $file;                 # size in bytes
if (-d $path) { ... }                # is a directory
```

Stacked file tests. `-f -w -r $file` is shorthand for `(-f $file) && (-w $file) && (-r $file)` - the chain re-uses the same target. The pseudo-handle `_` (single underscore) re-uses the *previous* file test's `stat` cache to avoid extra `stat()` syscalls:

```
if (-f $file && -r _) { ... }        # one stat() call, two checks
```

The trailing `_` is the standard idiom for any chain of file tests on the same path.

- *Arrow* - `->` (deref, method call).
- *Comma* - `,` and the fat comma `=>`.
- *Precedence* - the full precedence table and the named-unary parse rule that confuses everyone the first time.

Cross-cutting concepts

A few ideas appear in every chapter. Read these once and you will recognise them throughout the rest:

- **Context.** Operators evaluate their operands in a specific context (numeric, string, list, scalar, boolean). Many of the surprises in Perl arithmetic and comparison come from context coercion at the operand boundary, not from the operator itself.
- **Short-circuit.** `&&`, `||`, `//`, `and`, `or` evaluate left-to-right and stop as soon as the result is determined. The whole expression's value is the last thing actually evaluated - which is one of its operands, not a normalised true/false. See *logical* and the *boolean-logic tutorial*.
- **Precedence.** Tells you how operators bind when parentheses do not. The full table is in *precedence* and every page links the rows it cares about.
- **Lvalue.** Most operators produce *rvalues* (values you can read). A few - assignment, deref, ternary in some shapes - produce *lvalues* (locations you can write to).

5.1.4 Data types

Perl has three fundamental data types - **scalars**, **arrays**, and **hashes** - plus a small number of supporting kinds (references, typeglobs, code) that are technically scalars but behave differently enough to deserve their own treatment. Every value the language manipulates is one of these.

This reference is split into one page per topic. Topics that share context (numeric vs string conversion, references vs typeglobs, context vs interpolation) live in the same page; topics that don't share context get their own page.

Choose a topic

Scalars

A scalar is the unit value of Perl. It holds one of: a number (integer or float), a string, a reference, or `undef`. The sigil is `$`, in every position where the value is a single scalar - including when the value is one element of an array or hash:

```
$x                  # the scalar named x
$arr[0]             # the first element of @arr - also a scalar
$h{key}             # one value from %h - also a scalar
```

A scalar is *not* statically typed. The same variable can hold a number now and a string a moment later. Perl converts between the two whenever an operator demands one shape or the other; see *numbers and strings*.

Truth, definedness, and undef

Two related but distinct questions about a scalar:

```
defined $x          # is there any value at all?
$x ? T : F          # is the value true?
```

A scalar is **false** in boolean context if it is one of:

```
undef               # the undefined value
0                   # numeric zero
0.0                 # also numeric zero
""                  # empty string
"0"                 # the literal string "0"
```

Everything else is true. Note `"00"`, `"0.0"`, `"0 but true"`, and `"0E0"` are all *true* - they are non-empty strings that don't match the literal `"0"`. The last two are common idioms for "this function returned successfully but there was nothing to count":

```
sub touch_files {
    my $count = 0;
    $count++ for grep { -e $_ && utime undef, undef, $_ } @_;
    return $count || '0E0';     # true even on zero work, so callers
                                # can write `if (touch_files(...))`
}
```

`defined` is the only way to tell `undef` from the false-but-defined values. A common bug:

```
if ($cache{$key}) { ... }            # WRONG - false for empty/0/
↪undef
if (exists $cache{$key}) { ... }      # right - pure presence test
if (defined $cache{$key}) { ... }     # right - value-not-undef test
```

Use `defined` when the only thing you care about is "is there a value here at all"; `exists` for "is this key/index in the container" (the two differ for sparse arrays and `deleted` keys).

Dynamic typing

A scalar can change shape during execution:

```
my $x = 42;          # internally an integer
$x = "hello";        # now a string
$x = 3.14;           # now a float
$x = \@items;        # now a reference
```

Most code never needs to think about which internal shape a scalar currently has. The exceptions are JSON-serialisation libraries that care whether 1 was assigned as a number or a string, and the `Scalar::Util` introspection helpers (`looks_like_number`, `dualvar`).

"Looks like a number"

When Perl converts a string to a number it stops at the first character that isn't part of a valid numeric prefix:

```
"42"        + 1   # 43
"42abc"     + 1   # 43      - leading digits parsed
"abc42"     + 1   # 1       - no leading digits, treated as 0
" 42"       + 1   # 43      - leading whitespace allowed
"4_2"       + 1   # 5       - underscores in literals only, NOT in␣
↪strings
"0x1F"      + 1   # 1       - hex string is NOT auto-recognised;␣
↪hex() does
```

The mismatch between numeric *literals* (which honour `_` and `0x`) and numeric *strings* (which do not) is one of the most reported "why" questions in Perl. Use `hex` / `oct` when the input is a string in non-decimal form:

```
my $bytes = hex "1F";        # 31
my $perms = oct "0755";       # 493
my $perms = oct "0o755";      # 493 - explicit octal prefix
my $bytes = oct "0x1F";       # 31  - oct() accepts any prefix
```

Under `use warnings`, an arithmetic operation on a non-numeric string emits *Argument "…" isn't numeric in addition (+)*. The operation still returns 0 - the warning, not a fatal error, is the signal.

Dual values

Some scalars carry both a string and a number form simultaneously, chosen by context. The classic example is `$!`:

```
$!                # in string context: "Permission denied"
$! + 0            # in numeric context: 13
```

You can build your own with `Scalar::Util::dualvar`:

```
use Scalar::Util qw(dualvar);
my $err = dualvar 13, 'Permission denied';

print "err is $err";           # "err is Permission denied"
print "err is " . ($err + 0);  # "err is 13"
```

Dual scalars are a niche tool. The common case where one matters is the `$!` errno; the general escape hatch is the dualvar helper.

"0 but true"

The literal string `"0 but true"` is the canonical Perl idiom for "a function whose normal return is a count, but the count is zero and the call succeeded". It is true (non-empty, non-`"0"`) but numerically equals 0:

```
my $hits = "0 but true";

if ($hits)        { print "succeeded\n"; }    # prints
print $hits + 0;                              # 0
print "got $hits results\n";                  # got 0 but true␣
↪results
```

The compiler also recognises `"0 but true"` specifically and skips the *isn't numeric* warning that any other "0 followed by garbage" string would emit.

See also

- *Numbers and strings* - how integer, float, and string forms convert into one another and where the corners are.
- *References* - `\X` produces a scalar that points to another value.
- *Context* - when a scalar gets one value vs many.
- `defined`, `undef` - test for and produce the undefined value.
- `scalar` - force scalar context on a list or array.
- `$_` - the implicit scalar for many built-ins.

Arrays

An array is an ordered, integer-indexed sequence of scalars. The sigil is `@` for the whole array and for slices (which are lists); `$` for a single element (which is one scalar). The leading sigil tells you the *result type*, not the container.

```
my @days = ('Mon', 'Tue', 'Wed', 'Thu', 'Fri');

@days              # the whole array (5 elements)
$days[0]           # the first element - a single scalar
@days[1, 3]        # a slice - a list of two scalars
$#days             # the last valid index - here, 4
scalar @days       # the length - here, 5
```

Indices start at 0. Negative indices count from the end (`$days[-1]` is `'Fri'`).

Length: `$#arr` vs `scalar @arr`

Two related quantities, used for different jobs:

```
$#days             # last valid index            - 4
scalar @days       # number of elements          - 5
$#days + 1         # equivalent to scalar @days
```

Assigning to `$#arr` resizes the array. Shrinking destroys the elements past the new end; growing fills them with `undef`:

```
my @a = (1, 2, 3, 4, 5);
$#a = 2;              # @a is now (1, 2, 3)         - length 3
$#a = 5;              # @a is now (1, 2, 3, undef, undef, undef)
$#a = -1;             # @a is now ()                 - empty
```

The `@a = ()` form is the idiomatic empty-array assignment; `$#a = -1` is equivalent and occasionally clearer when the intent is "shrink to nothing without changing the variable's identity".

Element access

```
my $first = $days[0];             # 'Mon'
my $last  = $days[-1];            # 'Fri'
my $last  = $days[$#days];         # same; redundant but explicit
$days[2]  = 'Wednesday';          # set
$days[10] = 'Sunday';             # auto-extends; $days[5..9] become␣
↪undef
```

Reading past the end returns `undef` (no warning - out-of-range read is a non-event). Writing past the end *grows* the array; the intervening slots become `undef`.

```
my @a;
$a[5] = 'fifth';
# @a is now (undef, undef, undef, undef, undef, 'fifth')
print scalar @a;                   # 6
```

Reading a negative index further back than the start is a *fatal* error:

```
my @a = (1, 2, 3);
$a[-10];                            # FATAL: Modification of non-
 ↪creatable
                                    #        array value attempted
```

The whole-array operations

```
push    @arr, $value;               # append at end           -␣
 ↪returns new length
my $v = pop  @arr;                  # remove from end         -␣
 ↪returns removed element
my $v = shift @arr;                 # remove from start       -␣
 ↪returns removed element
unshift @arr, $value;               # prepend                 -␣
 ↪returns new length

splice  @arr, $offset, $len, @replacement;   # general remove/insert
```

`shift` and `unshift` are O(n) because they renumber every remaining element; `push` and `pop` are O(1) amortised. For queue-shaped workloads where this matters, prefer `push`/`shift` on the *short* end or use a deque from `List::Util` (which has reductions, not a deque).

`splice` is the swiss-army knife: remove a stretch of elements, insert a stretch in their place, return what was removed:

```
my @arr = (1, 2, 3, 4, 5);
my @gone = splice @arr, 1, 2;            # @gone = (2, 3); @arr =␣
 ↪(1, 4, 5)
splice @arr, 1, 0, ('a', 'b');            # insert at offset 1, no␣
 ↪removal
                                          # @arr = (1, 'a', 'b', 4,␣
 ↪5)
```

A negative `$offset` counts from the end. A negative `$len` keeps that many trailing elements:

```
splice @arr, -1;                    # remove just the last element
splice @arr, 0, -2;                 # remove all but the last two
```

Slices

A slice extracts (or assigns to) several elements at once. Indices come from a list:

```
my @arr = ('a', 'b', 'c', 'd', 'e');

my @subset = @arr[0, 2, 4];           # ('a', 'c', 'e')
my @middle = @arr[1..3];              # ('b', 'c', 'd')
```

(continues on next page)

(continued from previous page)

```
my @last3  = @arr[-3..-1];           # ('c', 'd', 'e')
my @rev    = @arr[reverse 0..$#arr];  # ('e', 'd', 'c', 'b', 'a')

@arr[1, 3] = ('B', 'D');              # set positions 1 and 3
@arr[1, 3] = @arr[3, 1];              # swap two elements (no temp)
```

A *key/value* slice with % returns index/value pairs (Perl 5.20+):

```
my @arr = ('a', 'b', 'c', 'd', 'e');
my %picked = %arr[1, 3];             # (1 => 'b', 3 => 'd')
```

This is the right shape when you need both the index and the value of selected elements. See *subscript* for the twelve-way matrix of slice forms.

List context vs scalar context

An array in list context yields its elements; in scalar context, it yields its length:

```
my @arr = (10, 20, 30);

my @copy   = @arr;                # list context - three elements
my $length = @arr;                # scalar context - 3
print "got @arr\n";               # list context inside ""    - "got␣
 ↪10 20 30"
print "got " . @arr . "\n";       # scalar context (concat)   - "got␣
 ↪3"
```

The distinction is the most common Perl trap. Two rules of thumb:

- *Inside double-quoted strings*, arrays interpolate as their elements joined by `$"` (a single space by default). See *interpolation*.
- *In a numeric or string operator context* (+, ., comparison), an array yields its length.

Force scalar context with `scalar` when the expression position is otherwise ambiguous:

```
print "got " . scalar(@arr) . " items\n";    # "got 3 items"
print "got @arr items\n";                    # "got 10 20 30 items"␣
 ↪- different!
```

List assignment and the count idiom

Assigning a list to an array makes the array exactly that long:

```
my @arr = (1, 2, 3);
@arr = (10, 20);                  # @arr is now (10, 20)
@arr = ();                        # @arr is now empty
```

Assigning a list to a *list* of scalars unpacks (any extras are discarded; missing ones become undef):

```
my ($x, $y, $z) = (1, 2, 3);              # 1, 2, 3
my ($x, $y, $z) = (1, 2);                 # 1, 2, undef
my ($x, $y)     = (1, 2, 3);              # 1, 2 - '3' silently␣
↪dropped
```

A list assignment in scalar context returns the number of elements on the *right* side. This is the source of the count idiom:

```
my $count = () = $string =~ /\d+/g;
# $string =~ /\d+/g  - match in list context, returns all matches
# () = LIST          - list assignment to empty list
# $count = SCALAR    - that assignment in scalar context = count of␣
↪RHS
```

The `() = LIST` middle is the trick. Without it, `$count = $s =~ /\d+/g` gives a boolean instead of a count.

Array references

Arrays are not first-class values in the sense that they can be passed by name through a chain of function calls without flattening into a list. To pass an array around without flattening, take a **reference** to it:

```
my @items = (1, 2, 3);

my $aref = \@items;                  # reference to the existing @items
my $anon = [1, 2, 3];                # anonymous array reference

$aref->[0]                            # access through the arrow - 1
@{$aref}                              # fully bracketed deref - list␣
↪(1, 2, 3)
@$aref                                # unbracketed deref     - same as␣
↪above
$#{$aref}                             # last index of dereffed array
scalar @$aref                         # length
```

See *references* for the full picture.

Real example: building a histogram of word lengths

```
my @words = qw(the quick brown fox jumps over the lazy dog);

my @hist;
$hist[length $_]++ for @words;

for my $len (1 .. $#hist) {
    next unless $hist[$len];
    printf "%2d-letter words: %d\n", $len, $hist[$len];
}
# 3-letter words: 4
```

(continues on next page)

(continued from previous page)

```
# 4-letter words: 2
# 5-letter words: 3
```

Note `$hist[length $_]++` autovivifies (creates) the slot when it's the first word of that length. Reading from `$hist[7]` later returns `undef`, which `++` happily increments - but `next unless $hist[$len]` skips the gap before printing.

Hashes

A hash is an unordered collection of key-value pairs where keys are strings and values are scalars. The sigil is `%` for the whole hash, `@` for value slices and key/value slices, and `$` for one value:

```
my %user = (
    name  => 'John',
    age   => 30,
    email => 'john@example.com',
);

%user                # the whole hash (six elements: key1, val1, ...
 ↪)
$user{name}          # one value          - 'John'
@user{qw(name age)}  # value slice        - ('John', 30)
%user{qw(name age)}  # key/value slice    - (name => 'John', age =>␣
 ↪30)
keys %user           # the list of keys
```

Hash keys are always coerced to strings. Storing under the integer key `42` and reading under the string key `"42"` retrieve the same slot - they are the same key.

Initialisation: pairs, fat comma, and %h = LIST

A hash is initialised from a list of even length, in key/value order:

```
my %h = ('a', 1, 'b', 2);                    # legal but ugly
my %h = (a => 1, b => 2);                    # idiomatic
```

The fat comma => is a comma that *also* auto-quotes a left-hand bareword that looks like an identifier. So `a => 1` is exactly `'a', 1`. Auto-quoting requires the bareword to be a simple identifier - `2.0 => 'x'` is parsed as the number 2, not the string `"2.0"`:

```
my %h = (a => 1);                  # ('a', 1)          - auto-quoted
my %h = ('a' => 1);                # ('a', 1)          - same
my %h = (2.0 => 'x');              # (2, 'x')          - not ('2.0', 'x
 ↪')!
my %h = ("2.0" => 'x');            # ('2.0', 'x')      - explicit quote
```

If a key appears more than once in the initialiser list, the **last occurrence wins**. The standard idiom for "merge with overrides" exploits that:

```
my %config = (%defaults, %overrides);
# %config has every default key, with %overrides values where they␣
 ↪collide
```

Access, with the four sigil shapes

Reading and writing one slot is $-sigil:

```
my $name = $user{name};                  # read
$user{city} = 'NYC';                     # write
$user{age}++;                            # arithmetic on a hash value
delete $user{email};                     # remove the slot entirely
```

The other three subscript shapes match what you want back:

```
@user{qw(name age city)}                 # ('John', 31, 'NYC')          ␣
 ↪ - values
%user{qw(name age)}                       # (name => 'John', age => 31)␣
 ↪  - pairs
keys %user                                # ('name', 'age', 'city')      ␣
 ↪   - keys
values %user                              # ('John', 31, 'NYC')          ␣
 ↪   - values
```

See *subscript* for the whole twelve-way matrix and the bareword-auto-quote rule inside {}.

`exists` vs `defined` vs truthiness

Three distinct questions about a key:

```
exists  $h{key}      # is the slot present at all?
defined $h{key}      # is the slot present AND non-undef?
        $h{key}      # is the value true (non-empty, non-zero, non-
↪"0")?
```

These differ when:

```
$h{a} = undef;
$h{b} = 0;
delete $h{c};

exists  $h{a}        # TRUE  - slot exists, value is undef
defined $h{a}        # FALSE - value is undef
        $h{a}        # FALSE - undef is false

exists  $h{b}        # TRUE
defined $h{b}        # TRUE
        $h{b}        # FALSE - 0 is false

exists  $h{c}        # FALSE - never set, or deleted
defined $h{c}        # FALSE
        $h{c}        # FALSE
```

Pick by intent: `exists` for *presence*, `defined` for *value-not-undef*, truthiness for *meaningful value*. Reaching for `if ($h{key})` when `exists` was meant is a bug source - `0` and `""` are valid values that the test rejects.

Iteration: `keys`, `values`, `each`, `while (each)`

```
for my $k (keys %user) {
    print "$k = $user{$k}\n";
}

for my $v (values %user) { ... }            # values only

while (my ($k, $v) = each %user) {          # keys + values, one␣
↪pair per call
    print "$k = $v\n";
}
```

`each` carries an iterator state on the hash itself; calling `keys` (or `values`) on the hash *resets* that iterator. Mixing the two produces hard-to-debug looping bugs:

```
while (my ($k, $v) = each %h) {
    if (some_condition($k)) {
        print "size: ", scalar keys %h, "\n";   # resets each()␣
↪iterator!
```

(continues on next page)

(continued from previous page)

```
        # next iteration of while() starts over from the top
    }
}
```

Fix: either accumulate the list with `keys` once at the top, or avoid `each` entirely. Most hash iteration is best written with `keys`:

```
for my $k (sort keys %h) {            # bonus: defined ordering
    ...
}
```

Key ordering

Hash keys come out in **insertion-order-perturbed-by-hash-randomisation** order - i.e. there is no guaranteed order. Two runs of the same program with the same input may iterate keys in different orders. This is a security feature (it prevents algorithmic-complexity attacks against the hash function); it is also a recurring source of brittle tests:

```
my %h = (a => 1, b => 2, c => 3);
print "$_ " for keys %h;        # output order is undefined
```

If you need a stable order, sort:

```
print "$_ " for sort keys %h;          # alphabetical
print "$_ " for sort { $h{$a} <=> $h{$b} } keys %h;   # by value
```

Hash references

A hash, like an array, flattens when passed through a list. To pass a hash without flattening, take a **reference**:

```
my %h = (a => 1, b => 2);

my $href = \%h;                # reference to the existing %h
my $anon = { x => 1, y => 2 }; # anonymous hash reference

$href->{a}                     # access through the arrow      - 1
${$href}{a}                    # fully bracketed deref         - 1
keys %$href                    # deref then keys
%{$href}                       # deref to flat key/value list
```

See *references* for the full picture.

Real example: counting and grouping

A frequency count is the textbook small example for hashes:

```
my @words = qw(apple banana apple cherry apple banana);
my %count;
$count{$_}++ for @words;
# %count = (apple => 3, banana => 2, cherry => 1)
```

Grouping is the next step up - building a hash whose values are arrayrefs:

```
my @people = (
    { name => 'Alice',   dept => 'eng' },
    { name => 'Bob',     dept => 'sales' },
    { name => 'Carol',   dept => 'eng' },
    { name => 'Dan',     dept => 'sales' },
);

my %by_dept;
push @{ $by_dept{$_->{dept}} }, $_->{name} for @people;
# %by_dept = (eng => ['Alice', 'Carol'], sales => ['Bob', 'Dan'])
```

The `push @{ $by_dept{$_->{dept}} }, ...` line autovivifies: when the `eng` key isn't there yet, the hash slot is created and an anonymous array goes into it, then the value is pushed. See *references* for the autoviv story.

Hash slice as multi-value get/set

```
my %config = (host => 'localhost', port => 80, debug => 0);

my ($h, $p) = @config{'host', 'port'};       # ('localhost', 80)

@config{qw(host port debug)} = ('elsewhere', 8080, 1);   # set three
 ↪at once
```

Combine with the `%h{...}` slice for "extract a record":

```
my %fields = %config{qw(host port)};
# %fields = (host => 'localhost', port => 80)
```

This is the canonical way to project a hash down to a subset of its keys. Without `%h{...}` you'd hand-roll it with a loop or with `map`.

Context

Almost every operator in Perl evaluates its operands in a specific **context** - list, scalar, void, or boolean - and many operators return *different things* depending on the context they were called in. The same expression can mean different things in different positions:

```
my @arr = (10, 20, 30);

my @copy = @arr;          # list context     - three elements
my $len  = @arr;          # scalar context   - 3
print @arr;               # list context     - "102030"
print "@arr";             # list context inside ""  - "10 20 30"
print "" . @arr;          # scalar context (concat) - "3"
@arr;                     # void context - discarded; warns under -w
```

Context is the single biggest difference between Perl and most other languages, and the single most common source of "why doesn't this do what I expect" surprises.

The four contexts

Context	What the operand sees	Imposed by
list	"give me all of your values"	`@a = ...`, `(...)`, function args, `print`
scalar	"give me one value"	`$s = ...`, `if/while`, `.`, `+`, comparison
void	"throw the result away"	a statement whose value isn't used
boolean	"give me a true/false"	`if`, `unless`, `while`, `&&`, `||`, `!`

Boolean context is technically a special case of scalar context - the operand is asked for one value, then that value is tested for truth. The two are not always the same: a `wantarray`-aware sub can detect boolean context separately (see below).

Imposing context

The left side of an assignment imposes context on the right:

```
my @x = func();           # func() is called in LIST context
my $x = func();           # func() is called in SCALAR context
my ($x, $y) = func();     # func() is called in LIST context
my ($x) = func();         # also LIST - note the parens
my  $x  = func();         # SCALAR - same chars, very different
```

The single most-tripped-over case is `my $x = func()` vs `my ($x) = func()`. Without parens, the assignment is a scalar; with them, it's a 1-element list assignment. If `func()` returns three things in list context and "the count" in scalar context, the difference is between getting `'first-thing'` and getting 3.

Operators impose context too. Numeric and string operators impose scalar context on their operands; `print` imposes list:

```
my @arr = (1, 2, 3);
my $n = @arr + 0;          # scalar context - 3 + 0 = 3
my $s = @arr . "";         # scalar context - "3"
print @arr;                # list context - prints "123"
```

And the boolean tests impose scalar (boolean) context:

```
if (@arr)        { ... }  # true if @arr is non-empty
unless (%hash)   { ... }  # true if %hash is empty
while (<$fh>)    { ... }  # context is BOOLEAN, but the diamond op␣
↪is
                          #   special: it reads ONE line and assigns␣
↪to $_
```

What an array yields in scalar context

An **array** in scalar context yields its **length**:

```
my @arr = (1, 2, 3);
my $n = @arr;             # 3
```

A **list literal** in scalar context yields its **last element** (the comma operator):

```
my $x = (1, 2, 3);        # 3   - comma operator, last element
my $x = ('a', 'b', 'c'); # 'c'
```

These look identical and behave differently. The rule is: arrays have a length, list literals don't. A bare comma-list is the C comma operator and produces its last operand; an array variable in scalar position is asking "how many":

```
my @a = ('x', 'y', 'z');
my $count   = @a;         # 3
my $last_el = $a[-1];     # 'z'
```

The `scalar` operator forces scalar context on whatever follows, which is most useful when the expression position is otherwise ambiguous:

```
print "got " . scalar(@arr) . " items\n";     # "got 3 items"
print "got " . @arr . " items\n";              # same - concat␣
↪imposes scalar
print "got @arr items\n";                      # "got 1 2 3 items" -␣
↪list inside ""
```

What a hash yields in scalar context

A non-empty hash in scalar context returns a true value (the count of keys, since Perl 5.25); an empty hash returns the false value 0. The shape that matters is the truth value:

```
if (%h) { ... }          # true if %h has any pairs
my $n = keys %h;         # explicit: count of keys
my $n = %h;              # also count of keys (Perl 5.25+); was a␣
↪debug ratio earlier
```

For older code targeting pre-5.25 perls you sometimes still see `scalar keys %h`; on PetaPerl (target perl 5.44) `scalar %h` returns the key count and is fine.

`wantarray` - write context-sensitive subs

A sub can ask "what context was I called in?" with `wantarray`:

```
sub items {
    return wantarray ? (1, 2, 3)        # list context
         : defined wantarray ? 3        # scalar context
         : do { warn "items() called in void context\n"; () };  #␣
↪void context
}

my @list = items();       # (1, 2, 3)
my $cnt  = items();       # 3
items();                  # void - warning fires
```

The three-way distinction is the only way to detect *void* from inside a sub. Use it sparingly: most subs return one shape and let the caller worry about context coercion. The places where `wantarray` earns its keep are:

- Functions that legitimately return either "the list" or "the count" - e.g. text-search routines.
- Diagnostic helpers that print a warning when their result was discarded.

A sub that returns different *meanings* (not just different shapes) based on `wantarray` is a maintenance hazard. Two named functions read better than one polymorphic one.

Pitfall: `scalar(@arr)` vs `@arr` in different positions

```
my @arr = (1, 2, 3);

# 1. Function arguments - LIST context
some_func(@arr);          # passes 1, 2, 3 as three arguments
some_func(scalar @arr);   # passes 3 as a single argument

# 2. String concatenation - SCALAR context
"got " . @arr             # "got 3"

# 3. Inside double quotes - array interpolation, NOT scalar!
"got @arr"                # "got 1 2 3"

# 4. Boolean test - SCALAR (boolean) context
if (@arr) { ... }         # true iff @arr non-empty
```

(continues on next page)

(continued from previous page)

```
# 5. Comparison - SCALAR context on both sides
@arr == 3                  # 3 == 3 is true
@arr eq "3"                # "3" eq "3" is true; this is rarely what␣
↪you want
```

The mismatch between case 2 (concat → scalar) and case 3 (inside "" → list) is the single most-asked Perl context question. Inside "", `@arr` is array interpolation; outside "", the context of the surrounding expression decides.

Pitfall: list-flattening in function arguments

A function receives `@_` as a single flat list of all its arguments - there is no way for the callee to tell where one array ended and the next began:

```
sub many {
    print "got ", scalar @_, " args\n";
}

my @a = (1, 2);
my @b = (3, 4, 5);

many(@a, @b);              # 5 args - both arrays flattened
many(\@a, \@b);            # 2 args - two array references
many(scalar @a, scalar @b); # 2 args - two integers (the lengths)
```

This is *the* reason references exist: to pass a non-flat shape through the list-flattening calling convention. Anything you want to keep its identity inside `@_` must arrive as a reference.

Real example: a sub that returns count or list

```
sub digits_of {
    my ($s) = @_;
    return $s =~ /\d/g;     # in list context: all digit chars
                            # in scalar context: TRUE/FALSE (last␣
↪match)
}

my @digits = digits_of("a1b2c3");      # ('1', '2', '3')   - three␣
↪matches
my $any    = digits_of("a1b2c3");      # 1                  -␣
↪boolean
```

To make `digits_of` return a *count* in scalar context, the right-hand side has to coerce explicitly:

```
sub digits_of {
    my ($s) = @_;
```

(continues on next page)

(continued from previous page)

```
    my @d = $s =~ /\d/g;
    return wantarray ? @d : scalar @d;
}

my @digits = digits_of("a1b2c3");      # ('1', '2', '3')
my $n      = digits_of("a1b2c3");      # 3
```

This is the canonical "return a list or its length" idiom. Note that without the `wantarray` switch, `return @d` would still give the count in scalar context (because of the array-in-scalar rule) - but it's clearer to be explicit.

- *References* - passing a non-flat shape through the flattening list-context arg convention.

Numbers and strings

A scalar can hold a number, a string, or both at once. Perl silently converts between the two whenever an operator demands one shape - + wants numbers, . wants strings, comparison operators have separate numeric and string forms. Understanding the conversion rules and where they bite is essential to writing predictable Perl.

Numeric literals

Integer literals come in five bases:

```
0                   # zero
12345               # decimal
4_294_967_296       # underscores for legibility (decimal 4.29␣
↪billion)
0xff                # hex      - 255
0Xdead_beef         # hex with underscores
0b01_1011           # binary   - 27
0377                # octal    - 255 (leading 0, NOT followed by␣
↪[bBxX])
0o12_345            # octal, alternative spelling (5.33.5+)
```

Float literals require either a dot or an exponent:

```
3.14
0.5                 # leading zero ok
.5                  # leading dot ok
1e3                 # 1000
1.5E-10             # exponent - uppercase or lowercase 'e'
```

Underscores are accepted between digits anywhere - `3.14_15_92`, `1_000_000`. Multiple consecutive underscores warn: `23__500` warns, `23_500` does not.

Hex and octal floats need the p (power-of-2) exponent:

```
0x1.999ap-4         # hex float
0b101.01p-1         # binary float
0o7.65p2            # octal float
```

The p exponent is *required* for non-decimal floats. Plain `0x1F.5` is a parse error.

String → number

When Perl converts a string to a number, it consumes the longest prefix that looks like a number and ignores the rest:

```
"42"        + 0     # 42
"42abc"     + 0     # 42      - leading digits parsed
"abc42"     + 0     # 0       - no leading digits
" \t  42"   + 0     # 42      - leading whitespace ok
"4_2"       + 0     # 4       - underscores in literals only, NOT␣
↪strings
"0xFF"      + 0     # 0       - hex prefix NOT auto-recognised
"3.14e2"    + 0     # 314     - scientific notation parsed
"Inf"       + 0     # Inf     - case-insensitive infinity
"NaN"       + 0     # NaN
```

The mismatch between numeric *literals* (which honour `_`, `0x`, `0b`, `0`) and numeric *strings* (which honour none of those) is the single most-tripped-over conversion rule. To convert a string that's in non-decimal form, use `hex` or `oct`:

```
my $bytes = hex "FF";          # 255
my $bytes = hex "0xFF";        # 255  - hex() ignores the 0x
my $perms = oct "0755";        # 493
my $perms = oct "0o755";       # 493  - explicit octal prefix
my $bytes = oct "0xFF";        # 255  - oct() recognises any prefix
```

Under `use warnings`, an arithmetic operation on a string that doesn't *start* with a number prefix emits *Argument "..." isn't numeric in addition (+)*. The result is still 0; the warning is the signal. Writing tolerant code that accepts user input often means filtering with `Scalar::Util::looks_like_number` or a regex first.

Number → string

Perl converts a number to a string using the same logic as `sprintf("%g", $n)` for floats and the obvious decimal representation for integers:

```
my $i = 42;              "$i"   # "42"
my $f = 3.14;            "$f"   # "3.14"
my $z = 0.0;             "$z"   # "0"        - not "0.0"
my $b = 1e10;            "$b"   # "10000000000"
my $s = 1e20;            "$s"   # "1e+20"    - switches to scientific
 ↪past ~15 digits
my $n = "Inf" + 0;       "$n"   # "Inf"
```

The default precision is enough digits to roundtrip *most* doubles. For exact control, format explicitly with `sprintf`:

```
sprintf "%.2f", 3.14159          # "3.14"
sprintf "%05d", 42               # "00042"
sprintf "%e", 1234567            # "1.234567e+06"
```

Concatenation forces strings; arithmetic forces numbers

```
"42" + "3"           # 45    - both coerced to numbers
42 . 3               # "423" - both coerced to strings
"3" x "5"            # "33333" - left operand string, right operand
 ↪number
```

The `.` operator is the explicit-stringify operator; `+` is the explicit-numerify operator. A scalar that holds a number you want as a string can be concatenated with `""`:

```
my $s = "" . $n;     # idiomatic "stringify"
my $s = "$n";        # same; usually clearer
```

A scalar that holds a string you want as a number adds 0:

```
my $n = $s + 0;      # idiomatic "numify"
```

Numeric vs string comparison

Two parallel families of comparison operators with **different semantics**:

Numeric	String	Meaning
`==`	`eq`	equal
`!=`	`ne`	not equal
`<`	`lt`	less
`<=`	`le`	less or equal
`>`	`gt`	greater
`>=`	`ge`	greater or equal
`<=>`	`cmp`	three-way compare

The sort order is dramatically different on values that look like numbers but are large:

```
"10" <  "9"          # FALSE - 10 < 9 numerically
"10" lt "9"          # TRUE  - '1' < '9' lexicographically
```

Sort numbers numerically:

```
my @sorted = sort { $a <=> $b } @numbers;       # numeric
my @sorted = sort                @strings;       # default - string
my @sorted = sort { $a cmp $b }  @strings;       # explicit string
```

Picking the wrong operator is the source of "my sort is wrong" bugs. See *numeric comparison* and *string comparison*.

Floating-point: precision, Inf, NaN

Most Perls use IEEE 754 double-precision floats - about 15–17 decimal digits of precision. The classic surprise:

```
0.1 + 0.2 == 0.3      # FALSE - neither side is exactly␣
↪representable
                      # 0.1 + 0.2 = 0.30000000000000004
```

For money or anything that *must* be exact, work in integers (cents instead of dollars) or use a bignum module:

```
use bignum;            # auto-promotes to arbitrary precision
0.1 + 0.2 == 0.3      # TRUE under bignum

use Math::BigInt;
my $big = Math::BigInt->new("10000000000000000000") + 1;
```

`Inf` and `NaN` are real values:

```
my $inf = 9 ** 9 ** 9;       # Inf - overflow
my $nan = $inf - $inf;       # NaN - undefined arithmetic
my $nan = "NaN" + 0;         # NaN - accepted from string

$nan == $nan                  # FALSE - NaN never equals anything
$nan != $nan                  # TRUE  - including itself
```

`Inf` and `NaN` are case-insensitive on input and have several spellings (`Infinity`, `1.#INF`, ...); on output Perl normalises to the short forms.

Note that perl5 generates *fatal* errors for `1/0` and `sqrt(-1)`; those don't produce `NaN`. They are exceptional, not arithmetic.

Locale-affected number parsing

Under `use locale` plus an active POSIX locale, the decimal point is whatever the locale says. This affects parsing and stringifying of floats:

```
use locale;
use POSIX qw(setlocale LC_NUMERIC);
setlocale LC_NUMERIC, 'de_DE.UTF-8';   # German uses ',' as decimal

my $x = 3.14;
print "$x\n";                            # "3,14"  - locale␣
 ↪formatting
"3,14" + 0                                # 3.14    - locale parsing
```

This is rarely what you want for data interchange. Most code that reads or writes structured data should explicitly *not* be in the `use locale` scope, so that `.` is always the decimal point. Use locale formatting only at the boundary where output is for a human reader.

"Looks like a number"

The rules for whether a string is "numeric enough" are not simple to inline; use `Scalar::Util::looks_like_number`:

```
use Scalar::Util qw(looks_like_number);

looks_like_number("42")         # true
looks_like_number("3.14e10")    # true
looks_like_number("Inf")        # true
looks_like_number("NaN")        # true
looks_like_number("0xFF")       # FALSE - hex strings are not
 ↪"numeric"
looks_like_number("")           # FALSE - empty string
looks_like_number(undef)        # FALSE
looks_like_number("3.14abc")    # FALSE - trailing junk
```

This is the validator function - strict, no leading garbage, no trailing garbage, no hex/oct prefixes. It matches the conditions under which Perl will use a number's cached numeric form rather than re-parsing on every arithmetic op.

References

A reference is a scalar that *points to* another value. References are how Perl builds nested data structures - arrays of arrays, hash of hashes, hash of arrays of hashes - because the basic container types (arrays, hashes) flatten when they appear in lists, and a reference is a single scalar that survives the flattening.

```
my @arr = (1, 2, 3);
my $ref = \@arr;              # take a reference to @arr
$$ref[0]                      # full deref form     - 1
$ref->[0]                     # arrow shorthand     - 1
@$ref                         # whole-array deref   - (1, 2, 3)
```

A reference is itself a scalar. It can be passed through any list-flattening calling convention without losing its identity, stored in arrays and hashes, returned from subs, weakened, serialised - anywhere a scalar can go.

Things you can reference

Seven things take a reference:

```
\$scalar              # SCALAR ref
\@array               # ARRAY ref
\%hash                # HASH ref
\&subroutine          # CODE ref
\*glob                # GLOB ref
\\$scalar             # REF (a reference to a reference)
\$file_handle         # IO ref (reference to a filehandle)
```

Plus the **anonymous** constructors, which build the value and return a reference in one step:

```
my $aref = [1, 2, 3];                  # anonymous array
my $href = { name => 'Alice', age => 30 };  # anonymous hash
my $cref = sub { $_[0] * 2 };          # anonymous sub
```

The bracket-vs-paren distinction is essential: `(1, 2, 3)` is a **list**, `[1, 2, 3]` is an **anonymous array reference**. The first flattens; the second does not.

Dereferencing

Four spellings, in increasing order of how often they appear in modern code:

```
${$sref}              # full sigil-deref form
$$sref                # short sigil-deref form (only if name is␣
↪simple)
$sref->{key}          # arrow form (postfix; for arrays and hashes)
$sref->[0]            # same, for arrays
```

The `->` arrow form is the idiomatic spelling for nested access:

```
$config->{database}{host}            # arrow elision between
 ↪subscripts
$config->{database}->{host}          # explicit; same meaning
${$config->{database}}{host}         # full form; the same again
```

Between two consecutive subscripts the `->` is **optional** (the "arrow elision" rule); at the head of a chain it is required:

```
$ref->[0]                        # required arrow at the head
$ref->[0][1]                     # second arrow elided
$ref->[0]->[1]                   # equivalent
[1,2,3]->[0]                     # required arrow on an anonymous ref
```

Whole-container deref:

```
@$aref                           # the whole array
%$href                           # the whole hash, as flat key/value
 ↪list
&$cref(@args)                    # call the sub
$cref->(@args)                   # idiomatic call form
```

Use the curly-braced form `@{ EXPR }` / `%{ EXPR }` when the deref target is an expression more complex than a bare scalar variable:

```
my @found = @{ $config->{users} };   # deref a chain - needs braces
```

See *arrow* for the operator and *subscript* for the bracket family.

Precedence of prefix deref versus subscript

The five prefix dereference sigils `$ @ * % &` bind **tighter** than the postfix subscript brackets `[]` and `{}`. So these two are exactly the same expression:

```
$$aref[2][2]                     # confusing, but valid
$aref->[2][2]                    # clear; identical meaning
```

`$$aref[2][2]` dereferences `$aref` *first*, then subscripts the result. It is **not** the C reading `*a[i]`, where the subscript would apply before the dereference. Perl has no construct that subscripts before dereferencing at that position; if you want "the thing the `$i`-th element points at", spell it out left to right with a postfix deref:

```
$aref->[$i]->$*                  # deref the i-th element explicitly
```

The arrow form is the readable choice for nested access; the leading-sigil form is a trap precisely because it reads as the C precedence and means the opposite. See *precedence* for the full operator table.

What `ref` returns

`ref` reports the kind of thing a reference points to:

```
ref \$scalar          # 'SCALAR'
ref \@array           # 'ARRAY'
ref \%hash            # 'HASH'
ref \&sub             # 'CODE'
ref \*FH              # 'GLOB'
ref \\$scalar         # 'REF'    - a ref-to-ref
ref \$io_handle       # 'IO'     - wrapper around a file handle

ref [1, 2, 3]         # 'ARRAY'
ref { a => 1 }        # 'HASH'
ref sub {}            # 'CODE'

ref bless {}, 'Foo'   # 'Foo'    - blessed; class name not 'HASH'
ref 42                # ''       - not a reference at all
ref undef             # ''
```

For blessed objects, `ref` returns the class. To distinguish a blessed hash-ref from a plain hash-ref, use `Scalar::Util::reftype` (which always returns the underlying container shape regardless of bless) or `isa` (the inheritance-aware check).

Postfix dereference (@*, %*, $*)

Perl 5.20+ added a postfix syntax that mirrors the arrow chain:

```
$ref->@*              # equivalent to @$ref
$ref->%*              # equivalent to %$ref
$ref->$*              # equivalent to $$ref

$ref->@[1, 3]         # array slice through ref - equivalent to @{
 ↪$ref}[1,3]
$ref->%[1, 3]         # key/value slice
$ref->@{qw(a b)}      # hash slice
```

The postfix forms read left-to-right with the rest of an arrow chain, which is often clearer when the deref target is itself a chain:

```
$config->{users}->@*          # all users - chains naturally
@{$config->{users}}           # same; reads right-to-left
```

Pick the form that reads better in context. Postfix is the clearer choice in chains; the leading-sigil form is shorter for plain scalar refs.

Autovivification

Reading or writing through a deref into a slot that doesn't exist yet auto-creates the intermediate structure:

```
my %h;
$h{a}{b}{c} = 1;
# %h is now (a => { b => { c => 1 } })  - three nested hashes built
```

The mechanism: when the assignment target is `$h{a}{b}{c}`, Perl sees `$h{a}` is `undef`, the next subscript is `{b}` (a hash subscript), so it makes `$h{a}` a fresh hash ref. Then `$h{a}{b}` is `undef`, next subscript is `{c}` (also hash), so make it a fresh hash ref. Then assign 1 to the leaf.

The same happens for array subscripts:

```
my %by_dept;
push @{ $by_dept{eng} }, 'Alice';
# $by_dept{eng} did not exist; the push autoviv'd it as an arrayref
```

Autoviv on the **left** of an assignment (or a `push`/`pop`/... mutator) is what makes this work. Autoviv on the **right** of an expression is more dangerous - *reading* `$h{a}{b}{c}` when `$h{a}` is `undef` *also* autovivifies, populating the hash as a side effect of inspection:

```
my %h;
exists $h{a}{b};          # accidentally creates $h{a} = {} as a␣
↪hash!
                           # %h is now (a => {})
```

The fix when you genuinely just want to test: chain `exists`:

```
exists $h{a} && exists $h{a}{b};        # short-circuits if $h{a}␣
↪absent
```

This is the most-bitten autoviv trap. Tests of nested existence must short-circuit, or they leave hash slots behind.

Hash of arrays - the canonical example

```
my @people = (
    { name => 'Alice', dept => 'eng'   },
    { name => 'Bob',   dept => 'sales' },
    { name => 'Carol', dept => 'eng'   },
    { name => 'Dan',   dept => 'sales' },
);

# Group by department:
my %by_dept;
for my $p (@people) {
    push @{ $by_dept{ $p->{dept} } }, $p->{name};
}
# %by_dept = (
#     eng   => ['Alice', 'Carol'],
#     sales => ['Bob', 'Dan'],
# )
```

(continues on next page)

(continued from previous page)

```
# Iterate:
for my $dept (sort keys %by_dept) {
    print "$dept: @{ $by_dept{$dept} }\n";
}
# eng: Alice Carol
# sales: Bob Dan
```

The `@{ $by_dept{...} }` is the deref-with-braces form. It's necessary because the deref target is an expression (`$by_dept{$dept}`), not a bare variable.

The same shape with the postfix form:

```
print "$dept: ", join(' ', $by_dept{$dept}->@*), "\n";
```

Pick whichever you find clearer; both are idiomatic in modern Perl.

Weak references and circular structures

A reference holds the referent alive (refcount-bumped) until the reference itself goes out of scope. This becomes a problem when two structures point at each other:

```
my $parent = { name => 'p' };
my $child  = { name => 'c', parent => $parent };
push @{ $parent->{children} }, $child;

# parent refers to child via the children arrayref
# child refers back to parent via the parent slot
# When both go out of scope, neither's refcount can reach 0 - leak.
```

The fix is a **weak reference** - a reference that doesn't bump the refcount. The `$child->{parent}` slot is the one that should be weakened (the back-pointer):

```
use Scalar::Util qw(weaken);

my $parent = { name => 'p' };
my $child  = { name => 'c', parent => $parent };
weaken $child->{parent};                # break the cycle
push @{ $parent->{children} }, $child;
```

After weakening, `$child->{parent}` reads as the parent while it exists, and silently becomes `undef` when the parent is freed. The canonical place for `weaken` is on every back-pointer in a tree structure where children point back at their parent.

The `Scalar::Util::isweak` predicate tests whether a given reference is weakened.

Reference equality

Two references are equal (numerically ==, stringwise eq) if and only if they refer to the **same** underlying value:

```
my @a = (1, 2, 3);
my $r1 = \@a;
my $r2 = \@a;
my $r3 = [1, 2, 3];      # different anonymous array

$r1 == $r2               # TRUE - same address
$r1 == $r3               # FALSE - different array, even though
 ↪contents match
```

Numeric comparison of refs effectively compares their machine address. Two refs with the same content but different identities compare unequal. Deep-equal needs a helper from `Test::More` or a hand-rolled walker.

A reference stringifies to something like `ARRAY(0x55ab12cd)` - class name plus hex address. Don't rely on the format; use it only as a debug print.

Typeglobs

A typeglob is a single name that holds *every* variable type with that name in a package - the scalar `$foo`, the array `@foo`, the hash `%foo`, the sub `&foo`, the filehandle `foo`, and the format `foo` all share one symbol-table entry, and `*foo` is the way to talk about that entry as a value. The sigil is `*`, deliberately chosen because the asterisk reads as "all".

```
*foo                # the typeglob - all of $foo, @foo, %foo, &foo,
 ↪etc.
*foo{SCALAR}        # ref to $foo
*foo{ARRAY}         # ref to @foo
*foo{HASH}          # ref to %foo
*foo{CODE}          # ref to &foo
*foo{IO}            # the filehandle, if foo is one
*foo{NAME}          # the name "foo" - a string
*foo{PACKAGE}       # the package name - a string
```

In modern Perl, typeglobs come up rarely. References cover most of what they used to be needed for. The remaining legitimate uses are package aliasing, filehandle creation in older idioms, and a few introspection hooks.

What a typeglob does

The single most useful sentence about typeglobs:

> Assigning to a typeglob makes one name mean another name.

```
*foo = *bar;        # $foo, @foo, %foo, &foo, FH foo all alias $bar,␣
↪@bar, %bar, &bar, FH bar
```

After that assignment, modifying `$foo` modifies `$bar`, calling `foo()` calls `bar()`, and so on for every type. The two names are now genuinely the same storage - not a copy.

Assigning a *reference* to a typeglob aliases only that one type:

```
our @items;
*shortcut = \@items;     # only @shortcut aliases @items; $shortcut␣
↪and %shortcut unchanged
```

This is how the `Exporter` module installs imported subs into the caller's package: `*caller_package::name = \&exporter_package::name`. Each imported function gets one slot of one glob assigned, so the rest of the destination package's variables under that name are untouched.

*name = \&sub - the standard import idiom

```
package My::Util;
sub greet { "Hello, $_[0]!" }

package main;
*greet = \&My::Util::greet;       # import greet into main::
print greet("world");              # "Hello, world!"
```

This is the mechanism that `use` invokes via `Exporter::import` - the importing package gets a glob assignment for each requested name. `Exporter` does it; you can do it by hand for cases `Exporter` doesn't fit.

Local glob aliases

`local *name = \$thing` is a temporary alias that auto-restores when the enclosing scope exits:

```
our $config = "default";

sub run_with_config {
    my ($alt_config, $code) = @_;
    local *config = \$alt_config;        # only inside this sub
    $code->();                            # any read of $config␣
```

(continues on next page)

(continued from previous page)

```
 ↪reads $alt_config
}

run_with_config("test", sub {
    print "config is $config\n";          # "config is test"
});

print "config is $config\n";              # "config is default" -␣
 ↪restored
```

This is a heavyweight mechanism that has largely been replaced by plain `local $config = $alt_config;` for scalars and explicit parameter-passing for everything else. The case where it still matters is when you need to alias a *filehandle* across the call of arbitrary user code (see below).

Filehandle typeglobs

Before Perl 5.6's "open `my $fh`" idiom, filehandles had to be named by package globals or passed as typeglobs:

```
# Old style - bareword filehandle in a glob slot
open FH, '<', $path or die $!;
while (<FH>) { ... }
close FH;

# Pass to a sub:
sub print_to { my $fh = shift; print $fh "stuff\n" }
print_to(\*FH);                           # ref-to-glob

# Modern style:
open my $fh, '<', $path or die $!;
while (<$fh>) { ... }
close $fh;
print_to($fh);                            # plain scalar ref to IO
```

The modern style is preferred everywhere new code is written. The typeglob-filehandle form survives in three places:

1. **The standard handles** - `STDIN`, `STDOUT`, `STDERR` are bareword filehandles backed by the typeglobs `*STDIN`, `*STDOUT`, `*STDERR`. You see these in error messages and reset code:

   ```
   print STDERR "error\n";
   *STDOUT = *STDERR;          # redirect all STDOUT to STDERR for␣
    ↪the rest of the program
   ```

2. **Returning newly-created filehandles** - before lexical filehandles, the way to return a fresh handle from a sub was to `local *FH` and return `*FH`:

```
sub new_handle {
    my $path = shift;
    local *FH;
    open FH, $path or return;
    return *FH;             # the glob outlives the local␣
↪because it was returned
}
```

Modern equivalent:

```
sub new_handle {
    my $path = shift;
    open my $fh, $path or return;
    return $fh;
}
```

3. **Selecting a different default output handle** - `select` returns and accepts a filehandle, in glob-or-string form:

```
my $old = select(STDERR);    # subsequent print without␣
↪explicit fh writes to STDERR
print "errors-only output\n";
select($old);                  # restore
```

*foo{THING} - the slot accessors

`*foo{THING}` returns a reference to one slot of the glob, or `undef` if that slot is empty:

```
*foo{SCALAR}        # \$foo  if $foo has been touched
*foo{ARRAY}         # \@foo  if @foo has been touched
*foo{HASH}          # \%foo  if %foo has been touched
*foo{CODE}          # \&foo  if &foo defined
*foo{IO}            # the IO handle, or undef
```

The `*foo{IO}` form is the one place you regularly see `THING` syntax in modern code. It's how you ask "is this scalar holding a filehandle":

```
sub is_handle {
    my $thing = shift;
    return defined ref($thing) && (
           ref($thing) eq 'GLOB'
        || (ref(\$thing) eq 'GLOB' && defined *$thing{IO})
    );
}
```

The standard introspection helper that wraps this is `Scalar::Util::openhandle`.

`*foo{SCALAR}` has a quirk: it always returns *something* - the package's `$foo` slot is created on demand. The other accessors return `undef` when the slot is empty.

What replaces typeglobs

For the patterns where typeglobs used to be the only answer, the modern alternatives are:

Old typeglob pattern	Modern replacement
Pass a filehandle to a sub	Lexical FH: `open my $fh, ...`
Return a filehandle from a sub	Lexical FH: `return $fh;`
Alias `@there` as `@here`	`our @here; *here = \@there;` (still typeglob, no replacement)
Pass an array by reference	`\@arr` - pass the reference
Install an imported sub	`*name = \&Source::name` (still typeglob) - or use `Exporter`
Localised global alias	`local $var = ...` for plain scalars

The `*here = \@there` package-aliasing pattern is the one that typeglobs still own outright - there's no "alias one package variable to another" mechanism that doesn't go through a glob. Inside `Exporter`-using modules that mostly happens automatically.

See also

- *References* - the modern alternative to globs for most "indirect access" patterns.
- *Scalars* - the dynamic-typing story. Globs are a separate type: `ref \*FH` returns `'GLOB'`.
- `local` - the safe way to install a temporary glob alias.
- `select` - the selected-output-handle function that takes glob or string handle names.
- `Scalar::Util` - `openhandle`, `reftype`, `blessed` for runtime introspection.
- `Symbol` - generate fresh anonymous globs and qualify package names. (No local reference page yet.)

Interpolation

Double-quoted strings, here-docs, regex patterns, the `s/.../.../` replacement, and `qq//` all *interpolate*: they expand variables and certain escape sequences in place. Single-quoted strings, `q//`, and the LHS pattern of `tr/.../.../` do not. Knowing which constructs interpolate and exactly which forms get expanded is one of the most useful pieces of Perl knowledge.

```
my $name = "Alice";
my @nums = (1, 2, 3);

"hello, $name"              # "hello, Alice"
'hello, $name'              # 'hello, $name' - single quotes don't␣
↪interpolate
```

(continues on next page)

(continued from previous page)

```
"@nums in a string"          # "1 2 3 in a string"
"\$name is $name"            # "$name is Alice"
```

What interpolates

Inside "" (and the other double-quotish contexts), Perl expands exactly two shapes of variable:

```
$name               # scalar - the simple form
@list               # array  - joined by $" (one space by default)
```

Plus the bracket-and-brace subscript forms that compose on top of those:

```
$arr[0]             # one element of @arr
$h{key}             # one value from %h
$ref->[0]           # via array ref
$ref->{key}         # via hash ref
@arr[1, 2]          # array slice
@h{qw(a b)}         # hash slice
```

Note that **whole hashes do not interpolate**:

```
"hash is %h"        # "hash is %h" - literal '%' is fine, '%h' is NOT␣
↪magical
```

If you want a hash dumped into a string, format it explicitly with `Data::Dumper` or a manual `join`.

What does *not* interpolate

```
&sub                # function calls don't interpolate
sub_with_args($x)   # neither do calls with arguments
$h->method          # method calls don't interpolate
$obj->{a} + 1       # arithmetic doesn't interpolate
$arr[0+1]           # this DOES interpolate as $arr[0+1] - subscripts␣
↪allow expressions

"\u\L$name"         # case-modifying escapes - these DO interpolate
"\x{2603}"          # numeric escapes - DO interpolate (a snowman)
```

The rule of thumb: **variables and their subscripts interpolate; function/method calls and arithmetic on top of them do not.** When you want an expression interpolated, see the `@{[ ... ]}` and `${\ ... }` constructs below.

The `${name}` braces

Curly braces around a variable name disambiguate where the name ends:

```
my $who = "Larry";

"${who}speak"          # "Larryspeak"
"$whospeak"             # "" with warning: $whospeak is␣
↪uninitialised
"${who}::sub"           # "Larry::sub"
"$who::sub"             # the variable $who::sub from package who -␣
↪bug
```

Without the braces, Perl is greedy: `$whospeak` reads as one identifier, `$who::sub` reads as a package-qualified name. The braces force the parser to stop at `}`.

This is not the same brace-form as a hash subscript:

```
"$h{key}"              # hash element                  - what most␣
↪people mean
"${h}{key}"            # hash element in a different parse path -␣
↪same result
"${h{key}}"            # also the same
"${\(\$h{key})}"        # the absurd "interpolate an expression"␣
↪form
```

The `${name}` braces are mostly used for the disambiguation case (name followed by alphanumerics that would otherwise be eaten), not for hash access.

The `@{...}` and `${...}` deref-with-braces forms

When you want to *dereference* something inside a string, the brace form lets the deref expression be arbitrary:

```
my $config = { users => ['Alice', 'Bob'] };

"users: @{ $config->{users} }"     # "users: Alice Bob"
"users: $config->{users}"          # "users: ARRAY(0x...)" - wrong;␣
↪whole arrayref stringified
"users: @$config->{users}"         # parse error / wrong
```

The `@{ EXPR }` form deref's `EXPR` as an array. The braces are **required** because the deref target is an expression, not a plain variable. `@$config->{users}` doesn't parse the way intended - `@$config` would deref `$config` as an array, and `->{users}` is a hash-element access on what's left.

The same for `${ EXPR }` (scalar deref) and `%{ EXPR }` (the hash deref, which returns a flat list, rarely useful in interpolation).

`@{[ expr ]}` - interpolate any list expression

To interpolate the result of an arbitrary expression, wrap it in `@{[ ... ]}`:

```
my $name = "World";
print "hello, @{[ uc $name ]}!\n";              # "hello, WORLD!"
```

(continues on next page)

(continued from previous page)

```
print "found @{[ scalar @hits ]} matches\n";      # interpolate a␣
↪count

print "users: @{[ join ', ', @users ]}\n";        # interpolate a␣
↪join
```

The mechanism: `[ ... ]` builds an anonymous array reference whose contents are the expression's list-context value; `@{ ... }` then deref's that arrayref back into a list, which interpolates as a list does (joined by `$"`).

This is the canonical workaround for "I want a function call inside a double-quoted string". The alternative is concatenation:

```
print "hello, " . uc($name) . "!\n";              # equivalent
```

The `@{[ ... ]}` form is denser when there are multiple interpolations; concatenation is clearer when there's just one. In templates with many fields, `printf` or `sprintf` is usually clearer still:

```
printf "found %d matches\n", scalar @hits;
```

Use `@{[ ... ]}` when you genuinely want a Perl expression in the middle of a string and the alternatives are uglier.

`${\ expr }` - interpolate a scalar expression

The scalar counterpart of `@{[ ... ]}`:

```
print "answer: ${\ 6 * 7 }\n";                    # "answer: 42"
print "ts: ${\ scalar localtime }\n";              # "ts: Mon Apr 27␣
↪..."
```

`\ EXPR` makes a reference to the scalar value of `EXPR`; `${ ... }` deref's it. The result is one value, interpolated as a scalar.

For most cases the `@{[ ... ]}` form is more uniform - it works for both scalar and list contexts. `${\ ... }` is occasionally clearer when you specifically want scalar context:

```
"got @{[ items() ]} items"      # items() called in LIST context
"got ${\ items() } items"        # items() called in SCALAR context
```

Hash-subscript ambiguity in patterns

Inside a regex pattern (which is double-quotish), the parser has to guess whether `$foo[bar]` means "interpolate `$foo[bar]` (one element of `@foo`)" or "interpolate `$foo` and then match a character class `[bar]`":

```
my @foo = ('hi');
$x =~ /$foo[abc]/                  # @foo exists - parsed as
```

(continues on next page)

(continued from previous page)

```
 ↪$foo[abc] (one element)
$x =~ /$foo[abc]/                  # @foo doesn't exist - parsed as
 ↪$foo + char class
```

The disambiguation is the brace form:

```
$x =~ /${foo}[abc]/                # $foo + character class [abc]
$x =~ /$foo[5]/                    # element 5 of @foo
$x =~ /\Q$foo\E[abc]/              # $foo (literal) + character class
```

The `\Q...\E` quoter disables metacharacter interpretation inside its scope, which is the cleanest fix when the variable is a user input.

Heredocs

Heredocs are double-quotish unless the marker is single-quoted:

```
my $msg = <<EOM;
Hello, $name!
The hash is %h.
EOM
# "Hello, Alice!\nThe hash is %h.\n" - $name interpolated, %h
 ↪literal

my $msg = <<'EOM';
Hello, $name!
EOM
# "Hello, $name!\n" - single-quoted marker disables interpolation
```

Indented heredocs (Perl 5.26+) ignore leading whitespace up to the shortest run on any line:

```
my $msg = <<~EOM;
    Hello, $name!
    EOM
# "Hello, Alice!\n" - leading "    " stripped from every line
```

The ~ form is preferred in modern code; the un-indented form is ugly inside loops and method bodies.

Real example: building HTML safely

```
my @items = ('Apples', 'Bananas', 'Cherries');

my $html = <<~HTML;
    <ul>
    @{[ map { "  <li>$_</li>" } @items ]}
    </ul>
    HTML
```

The `map` returns a list of `<li>...</li>` strings; `@{[ ... ]}` interpolates them; the implicit `$"` is a single space, giving:

```
<ul>
  <li>Apples</li>   <li>Bananas</li>   <li>Cherries</li>
</ul>
```

To get newlines between the items, set `$"` locally:

```
my $html = do {
    local $" = "\n";
    <<~HTML;
        <ul>
        @{[ map { "  <li>$_</li>" } @items ]}
        </ul>
        HTML
};
```

Or join explicitly:

```
my $li = join "\n", map { "  <li>$_</li>" } @items;
my $html = "<ul>\n$li\n</ul>\n";
```

The explicit `join` is usually clearer for non-trivial templates. The `@{[ ... ]}` form earns its place when the template is mostly literal text with one or two embedded computations.

What the special variable $" controls

The list separator in interpolation:

```
my @x = (1, 2, 3);
print "x = @x\n";                          # "x = 1 2 3" - default $"
↪is " "

local $" = ", ";
print "x = @x\n";                          # "x = 1, 2, 3"

local $" = "\n  ";
print "items:\n  @x\n";                    # "items:\n  1\n  2\n  3"
```

`$"` is the canonical way to control how arrays interpolate without rewriting the string. See *filehandle and printing state* for the family of separator variables.

- *Scalars*, *Arrays*, *Hashes* - the shapes that interpolation expands.
- *References* - the `@{ EXPR }` deref form and what the `\` in `${\ ... }` does.
- `$"` - the list separator for array interpolation.
- `$,`, `$\`, `$/` - the related separator variables for `print` and input.

- `sprintf`, `printf` - the explicit format-string alternative when the template is mostly punctuation.
- `qq`, `q`, `qw` - the quote-like operators with custom delimiters.
- *Scalars* - `$x`. Numbers, strings, references; `undef`; truth and definedness; the dual numeric/ string nature of scalars.
- *Arrays* - `@arr`. Element access, `$#arr`, negative indices, slices, list assignment, the `@arr` / `$arr[i]` / `@arr[i,j]` sigil rule.
- *Hashes* - `%h`. Key-value pairs, the four flavours of subscript, `keys`/`values`/`each`, key ordering, hash slices and key/value slices.
- *Context* - list, scalar, void, boolean. How each operator and assignment imposes context, what `wantarray` reports, the `scalar()` operator, and the recurring traps with `,` versus list construction.
- *Numbers and strings* - automatic conversion both ways, integer vs float, `Inf` and `NaN`, numeric literal forms, "0 but true", `dualvar`, locale and precision pitfalls.
- *References* - `\X`, the seven things you can reference, the four ways to deref, autovivification, weak references, circular structures, `ref` and `Scalar::Util`.
- *Typeglobs* - `*name`. The symbol-table entry, aliasing, `*foo{THING}`, when modern Perl still needs them and when references are the right answer instead.
- *Interpolation* - what double-quoted strings, here-docs, and regex patterns interpolate; the `${name}` braces; the `@{[ expr ]}` and `${\ expr }` baroque constructs; ambiguities with `[` and `{` after a sigil.

Cross-cutting concepts

A handful of ideas appear on every page below. Read these once and the rest will feel familiar:

- **Sigils mark the *result*, not the container.** `@arr[1, 3]` is not "two arrays"; the `@` says "the result is a list". The variable named `arr` is the same in `@arr`, `$arr[0]`, `@arr[0..3]`, and `%arr[0..3]`.
- **Context coerces.** A scalar evaluated in list context becomes a one-element list; a list evaluated in scalar context yields its **last** element (comma operator), but an *array* in scalar context yields its **length**. The two cases are not the same; see *context*.
- **References are scalars.** A reference to anything fits in a scalar variable, which is what makes nested data structures possible. The deref syntax (`@$ref`, `$ref->[0]`, `${$ref}{key}`) is the inverse of `\`.
- **`undef` is a value, not the absence of one.** A scalar can hold the value `undef`; testing `defined $x` is how you ask. An array can have `undef` elements without being empty.
- **Strings and numbers convert silently.** `"42" + 1` is 43, `42 . "x"` is `"42x"`. The conversion is always defined; see *numbers and strings* for what counts as "looks like a number" and where the corners are.

5.1.5 Subroutines

A subroutine is a named (or anonymous) block of code that takes a list of arguments, runs in a fresh lexical scope, and returns a list of values. Subroutines are the unit of reuse in Perl, the unit of dispatch for object-oriented code, and - through closures - the unit of stateful encapsulation. Almost everything else in the language is built on top of them.

PetaPerl implements the full Perl 5.44 subroutine model: the classic @_-based calling convention, modern signatures, the prototype mechanism that controls call-site parsing, lexical and package scoping (my, our, local, state), closures, the attribute system (:lvalue, :method, :prototype(...)), recursion with goto &sub tail calls, and the special compile-time and run-time blocks (BEGIN, END, INIT, CHECK, UNITCHECK).

This reference is split into one page per topic. The @_ aliasing rule lives with arguments, the closure-over-loop-var pitfall lives with scoping, the parser-level effects of prototypes live with prototypes - so each page can be read and returned to without sweeping context.

Choose a topic

Declaration

Every sub is one of three things: a **named** sub bound to a package, an **anonymous** sub stored in a code reference, or a **lexical** sub bound to a my-like slot in the current scope. The declaration form picks one; everything else (prototype, signature, attributes, body) decorates it.

Named subs

```
sub greet {
    my ($name) = @_;
    return "Hello, $name!";
}

greet("Alice");                  # "Hello, Alice!"
```

The name greet is bound in the current package's symbol table under the ampersand & slot - the same slot the runtime looks up when you call greet(...) or \&greet. Named subs are visible to any code that runs after the sub statement is compiled; in practice

"compiled" means "the file is parsed up to the declaration", which is almost always what you want.

A named sub can also be declared in two parts - a forward declaration and a definition:

```
sub later;                          # promise: a sub named 'later' will
 ↪exist
sub later {                         # fulfilment
    return 42;
}
```

The forward declaration is mainly useful when prototypes need to take effect for recursive calls (the prototype must be visible *before* the recursive call is parsed) or when you want to suppress "Bareword not allowed" warnings for code that calls the sub before its definition.

Calling a sub by name

```
greet("Alice");                     # most common form
greet "Alice";                      # parens optional once predeclared
&greet("Alice");                    # legacy: disables prototype
 ↪checking
&greet;                             # legacy: pass current @_ as the
 ↪call's @_
```

The bare-& form (`&greet` with no parens) is a holdover from perl4 with one remaining legitimate use: passing the current `@_` straight through without copying. See *recursion* for `goto &greet`, the tail-call variant.

Anonymous subs

```
my $double = sub {
    my ($x) = @_;
    return $x * 2;
};

$double->(7);                       # 14
```

The `sub { ... }` expression evaluates to a code reference. It captures any lexical (`my`/`state`) variables from its enclosing scope - see *scoping* - and is invoked through `->()` or with the legacy `&$double()` / `&{$double}()` forms.

Anonymous subs are how every Perl callback works:

```
my @sorted = sort { $a <=> $b } @list;
my @big    = grep { $_ > 100   } @list;
my @str    = map  { "<$_>"     } @list;
```

They are also the building block for closures, dispatch tables, and mock objects. A dispatch table:

```
my %op = (
    add => sub { $_[0] + $_[1] },
    sub => sub { $_[0] - $_[1] },
    mul => sub { $_[0] * $_[1] },
);

my $result = $op{$cmd}->($x, $y);
```

Code references

A code reference is a first-class scalar that holds a sub. You get one from `sub { ... }`, from `\&named_sub`, or from a method lookup with `can`:

```
my $cref = \&greet;              # ref to named sub
my $cref = sub { ... };          # anonymous
my $cref = $obj->can('method');  # method lookup, returns code ref
 ↪or undef

$cref->("Alice");                # invocation
&$cref("Alice");                 # legacy invocation
```

Inside a code ref, the sub keeps its identity: `\&greet` is always the same ref for the lifetime of the package's `&greet`. Anonymous subs are distinct refs every time the `sub { ... }` expression is evaluated - that is what makes closure factories work.

Lexical subs

A lexical sub is declared with `my sub` (and the corresponding `state sub` and `our sub`):

```
sub outer {
    my sub helper {
        my ($x) = @_;
        return $x * 2;
    }

    return helper(21);           # 42
}

helper(1);                       # error: undefined subroutine
                                 # (helper isn't visible here)
```

`my sub` is most useful inside long functions where you want a private helper without polluting the package namespace. It is not heavily used in the wild, but it is the proper tool when you want true encapsulation. See *scoping* for `state` and `our` variants.

Predeclaration

A predeclaration is a `sub NAME;` statement (no body, no braces). Three reasons to write one:

```
# 1. Allow the sub to be called without parens before it's defined
sub later;
later;                          # parses as later()

# 2. Make a prototype visible before the body is reached
sub mypush (\@@);
sub mypush (\@@) { ... }

# 3. Document an exported API at the top of the file
sub greet;
sub farewell;
sub welcome;
# ... actual definitions further down
```

In modern code reasons (1) and (3) are mostly stylistic. Reason (2) is a real requirement when you use prototypes; see *prototypes*.

What you cannot do

- You cannot redefine a built-in by `sub print { ... }` and have Perl quietly use yours. Built-in overriding goes through `CORE::GLOBAL::print` and is documented under *attributes* and the `prototype` detail page.
- You cannot have two named subs with the same name in the same package without a "Subroutine NAME redefined" warning. Either rename or genuinely intend the redefinition (and silence the warning with `no warnings 'redefine';`).
- You cannot give a forward declaration and a body with *different* prototypes. The two declarations must agree.

- *Arguments and* `@_` - what the body sees once the call is made.
- *Scoping* - what `my`, `our`, `local`, and `state` do to the variables inside the body.
- `sub` - the keyword's perlfunc page.
- `prototype` - runtime introspection of a sub's prototype, and the bridge to overriding built-ins.
- *Arrow operator* - `->()` invocation of code references.

Arguments and `@_`

When a sub is called the classic way (no signature), Perl flattens the entire argument list into a single array and exposes it inside the body as `@_`. The elements of that array are not copies - they are **aliases** to the caller's expressions. This single rule is the source of most of Perl's calling-convention surprises and most of its calling-convention power.

The aliasing rule

```
sub bump {
    $_[0]++;                        # mutates the caller's variable
}

my $x = 10;
bump($x);
say $x;                             # 11
```

Modifying `$_[0]` writes through the alias to whatever the caller passed. That is by design - it is how `chomp(@lines)` manages to strip newlines from every element of `@lines` rather than from a copy of `@lines`.

The aliasing extends to literals, with predictable consequences:

```
bump(10);                           # error: Modification of a read-
 ↪only
                                    # value attempted
```

A literal `10` is a constant. The alias points at it; the mutation attempt dies.

The unpacking idiom

Because the aliasing is rarely what the body wants, almost every classic-style sub starts with one of these two patterns:

```
# Named arguments (most common)
sub greet {
    my ($name, $greeting) = @_;  # COPY into private lexicals
    $greeting //= 'Hello';
    return "$greeting, $name!";
}

# Method dispatch
sub method_call {
    my $self = shift;            # COPY first arg, leave rest in @_
    my %args = @_;               # remaining args as a hash
    ...
}
```

Once unpacked, the body works with private copies and cannot accidentally mutate the caller's state. `shift` with no argument inside a sub defaults to `@_`, which is why `my $self = shift;` is everywhere in OO Perl.

Legitimate uses of aliasing

Aliasing is the right tool when you actually want to mutate caller state:

```
# in-place trim
sub trim_inplace {
```

(continues on next page)

(continued from previous page)

```
    for (@_) {
        s/^\s+//;
        s/\s+$//;
    }
}

my @data = ("  hello  ", "  world\n");
trim_inplace(@data);
# @data is now ("hello", "world")
```

The `for (@_)` loop aliases `$_` to each element of `@_`, which is itself an alias to each element of `@data`. The `s///` modifications go through both alias hops to the original strings. Without the aliasing, this same shape of code would be twice as much work.

The same mechanism powers `chomp(@lines)`, `chop(@buf)`, and any "work over a list and modify in place" function you write yourself. State the intent in the function's name (`_inplace`, `mutate_`, similar) so callers are not surprised.

Named arguments

Perl has no built-in named-parameter syntax in the classic form, but the `=>` (fat comma) plus a hash assignment gives the same effect:

```
sub configure {
    my %opt = @_;                # ('host' => 'localhost', 'port' =>␣
↪8080)
    $opt{host} //= 'localhost';
    $opt{port} //= 80;
    ...
}

configure( host => 'example.com', port => 8080 );
```

The fat comma is identical to a regular comma in semantics but quotes the bareword on its left, so `host => ...` is shorthand for `'host' => ...`. See `,` for the operator itself.

For mandatory-plus-optional named args, the standard shape is:

```
sub render {
    my ($template, %opt) = @_;   # one positional, rest as named
    $opt{escape} //= 1;
    ...
}

render('greeting.tt', escape => 0, locale => 'de');
```

For the modern named-parameter idiom built on signatures, see *signatures*.

`shift`, `pop`, `unshift`, `push` on `@_`

`@_` is a real array. You can `shift` from the front, pop from the back, slice it, modify it. None of these change the caller's state - only writing through `$_[N]` does.

```
sub describe {
    my $what = shift;            # remove first arg from @_
    my @rest = @_;               # copy what's left
    ...
}

sub method {
    my $self = shift;
    my @args = @_;
    $self->dispatch(@args);
}
```

A handy consequence: if you want to *re-pack* the remaining args to forward to another sub, just write `@_` - that is exactly what `goto &other` does without the explicit pass. See *recursion* for tail-call forwarding.

`wantarray` and the calling context

Inside a sub, `wantarray` tells you the context the call was made in:

`wantarray`	Context	Common shape
1 (true)	list	return a list
`0` (false)	scalar	return a single scalar
`undef`	void	return early; the result will be discarded

```
sub items {
    return unless defined wantarray;     # void: nothing to compute
    my @result = compute_items();
    return wantarray ? @result : scalar @result;
}
```

`@_` says *what* came in; `wantarray` says *what is expected back*. They are the two halves of the calling-convention picture. See *lvalue and context* for the full discussion.

Common pitfalls

- **`my ($x) = @_` vs `my $x = @_`.** The first is list context: `$x` gets the first argument. The second is scalar context: `$x` gets the *count* of arguments. The parentheses on the left are the difference; mistakes here are common.

```
sub one_arg {
    my ($x) = @_;            # $x = first arg
}
```

(continues on next page)

(continued from previous page)

```
sub count_args {
    my $n = @_;                 # $n = number of args
}
```

- **Modifying `$_[N]` "by accident".** Functions like `chomp`, `chop`, `tr///`, `s///` operate on their argument *in place*. `chomp($_[0])` mutates the caller's string. If that's not what you want, copy first.
- **Flattening of arrays and hashes.** Arrays and hashes passed as arguments lose their identity at the call site - they all become elements of the single flat `@_`. To pass an array without flattening, pass a reference:

```
takes_array(\@arr);             # one ref argument
sub takes_array {
    my ($aref) = @_;
    push @$aref, 'extra';
}
```

- **`@_` after `goto &sub`.** The current `@_` is passed through to the target. Anything you've already shifted off is gone from the perspective of the target. This is a feature, not a bug - see *recursion*.

See also

- `@_` - the variable's perlvar entry, with the aliasing rule and the loop-context discussion.
- `shift`, `pop` - default to `@_` inside a sub.
- *Signatures* - the modern alternative for named-and-positional parameter handling.
- *Return values* - what the body sends back.
- *Comma operator* - `=>` for named-arg construction.

Return values

A sub returns either by reaching its last statement, by hitting an explicit `return`, or by being `goto`-ed somewhere else (see *recursion*). The returned list is **flattened** the same way the argument list is - arrays and hashes lose their identity unless you return references - and is then evaluated in the caller's context.

Implicit return

If control falls off the end of the body, the value of the last *expression* statement is returned:

```
sub square {
    my ($x) = @_;
    $x * $x                     # implicit return
}
```

(continues on next page)

(continued from previous page)

```
say square(5);                    # 25
```

Implicit return is idiomatic for short, one-expression subs. It is *not* idiomatic for multi-branch subs, where readers benefit from seeing every exit explicitly marked with `return`.

If the last statement is a control-flow construct (a `for`, `while`, `if` without an `else`, ...), the returned value is unspecified. The empty sub returns the empty list.

Explicit return

```
sub max {
    my ($a, $b) = @_;
    return $a if $a >= $b;
    return $b;
}
```

Explicit `return` exits the sub immediately and supplies the return value. Multiple early returns are the standard shape for guarded code:

```
sub fetch {
    my ($id) = @_;
    return       unless defined $id;      # void/empty
    return undef if      $id eq '';       # explicit undef in scalar
    ...
}
```

Note the difference between `return;` and `return undef;`:

- `return;` returns the empty list in list context, `undef` in scalar context, and nothing in void context. It is the context-correct way to say "no result".
- `return undef;` returns the *list* `(undef)` in list context, which has length 1 - so a caller writing `if (my @r = my_sub()) { ... }` will see a one-element list and the `if` will fire. This is almost always wrong.

The rule of thumb: write `return;` to indicate failure or absence; write `return undef;` only when the caller is guaranteed to be in scalar context.

List flattening on return

The same flattening that applies to arguments applies to return values:

```
sub two_lists {
    my @a = (1, 2);
    my @b = (3, 4);
    return (@a, @b);              # returns (1, 2, 3, 4) - one flat␣
↪list
}
```

(continues on next page)

(continued from previous page)

```
my ($x, $y) = two_lists();        # $x = 1, $y = 2 ; rest discarded
my @all     = two_lists();        # @all = (1, 2, 3, 4)
my (@p, @q) = two_lists();        # @p = (1, 2, 3, 4), @q = ()
```

The last line is the classic surprise: `@p` greedily slurps the whole list because list-assignment to a flat array on the LHS has no way to know where one logical group ends and the next begins. To return two arrays distinctly, return references:

```
sub two_lists {
    return (\@a, \@b);
}

my ($pref, $qref) = two_lists();
```

Context-sensitive return

```
sub items {
    if (wantarray) {
        return (1, 2, 3);         # list context
    }
    elsif (defined wantarray) {
        return 3;                 # scalar context: count
    }
    else {
        return;                   # void: nothing to compute
    }
}

my @list = items();               # (1, 2, 3)
my $cnt  = items();               # 3
items();                          # discarded
```

The “void early return” branch is a real optimisation pattern - expensive computations should not run when the caller throws the result away.

For the full discussion of `wantarray` and how it composes with `:lvalue`, see *lvalue and context*.

Returning hashes and arrays

Returning a `@array` or `%hash` directly works only because of flattening:

```
sub config {
    return (host => 'localhost', port => 80);
}

my %c = config();                 # %c is the hash
my @c = config();                 # @c = ('host', 'localhost', 'port
 ↪', 80)
```

For larger structures, return references:

```
sub config {
    my %c = (host => 'localhost', port => 80);
    return \%c;                  # one ref, no flattening
}

my $c = config();
say $c->{host};
```

References are also the only way to return *multiple* aggregates without the caller having to know their sizes.

`return` inside an `eval`

`return` inside a `do {}` or `eval {}` block returns from the *enclosing sub*, not from the block:

```
sub safe {
    my $result = eval {
        return 'inside';         # this returns from `safe`, not
↪from eval
    };
    return $result;              # never reached
}
```

To exit just the `eval`, use a value (`'inside'` as the last expression of the block) - `eval` returns the value of its last expression like any other block.

Returning from `BEGIN`/`END`

`BEGIN`, `END`, `INIT`, `CHECK`, and `UNITCHECK` blocks are subs in the technical sense but their return value is discarded. Don't bother writing `return ...` inside them.

Scoping: `my`, `our`, `local`, `state`

Inside a sub, four declarators control where a variable lives, how long it lives, and who can see it. Pick the wrong one and the sub leaks state, fails to capture properly in a closure, or quietly clobbers something the caller relied on.

Declarator	Scope	Lifetime	Typical use
`my`	lexical (the block)	until the block ends	the default; private locals
`our`	lexical alias to package	as long as the package	shared package globals with a short name
`local`	dynamic (the call tree)	until the block ends	temporarily change a special variable
`state`	lexical (the block)	program lifetime	per-sub persistent state, init once

`my` - lexical locals

`my` is the everyday declarator:

```
sub greet {
    my ($name) = @_;
    my $message = "Hello, $name!";
    return $message;
}
```

The variables exist for the duration of the call, are private to the body, and are stored in the sub's *pad* (one slot per declared lexical). They are **not** visible to callers, callees, or `eval`'d code that doesn't textually nest inside the sub.

`my` variables are the only ones that close over correctly. Closures capture *cells* in the surrounding pad, and only `my` (and `state`) variables get pad cells.

`our` - package globals with a lexical alias

```
package Counter;

sub increment {
    our $value;                    # alias to $Counter::value
    $value++;
    return $value;
}
```

`our $x` declares a *lexical alias* in the current scope to the package variable `$Pkg::x`. The variable itself is global. If two packages both `our`-declare `$VERSION`, they each get their own - `our` prefixes with the current package name.

Use `our` when:

- You genuinely want a package-level shared variable.
- You want to silence `use strict 'vars';` complaints about a variable that *should* be a package global (`$VERSION`, `@ISA`, `@EXPORT`, `%ENV` aliases, ...).

Do **not** use `our` to share state between subs in the same file. That's what `my` at file scope is for:

```
package Counter;

my $value = 0;                    # private to this package's file
sub increment { ++$value }
sub get       { $value   }
```

`local` - dynamically-scoped temporary

`local` does *not* declare a new variable. It saves the current value of an existing (typically global) variable, sets a new value, and restores the old value when the enclosing block exits - even on exception:

```
sub slurp {
    my ($path) = @_;
    open my $fh, '<', $path or die "open $path: $!";
    local $/;                     # slurp mode for this sub only
    return <$fh>;
}
```

Without the `local`, the caller's `$/` would be permanently clobbered. With it, the change is confined to the dynamic extent of `slurp` - including any subs `slurp` happens to call.

`local` is the right tool for almost every special-variable override (`$/`, `$\`, `$,`, `$_`, `$@`, signal handlers in `%SIG`). It is rarely the right tool for ordinary user variables - those want `my`.

For the full register, see `local` and the *error-state* and *I/O* variable pages, which list which specials want `local`-isation in which patterns.

`state` - initialise once, keep forever

```
use feature 'state';

sub counter {
    state $n = 0;                 # initialised once, ever
    return ++$n;
}

counter();                        # 1
counter();                        # 2
counter();                        # 3
```

`state` variables are lexicals that survive between calls. The initialiser runs the first time control reaches the declaration; subsequent calls skip it.

`state` is the right tool for:

- Per-sub caches and counters where the cost of constructing the data dominates and you don't want a closure factory.
- One-time setup that depends on values not available at compile time:

```
sub compiled_re {
    my ($pattern) = @_;
    state %cache;
    $cache{$pattern} //= qr/$pattern/;
    return $cache{$pattern};
}
```

(Note: this caches the *first* pattern only with a literal `state` of a single regex; the hash form generalises it.)

Closures: capturing surrounding `my`

An anonymous sub captures every `my` (or `state`) variable from its surrounding scope that it textually references:

```
sub make_adder {
    my ($n) = @_;
    return sub {
        my ($x) = @_;
        return $x + $n;          # captures $n
    };
}

my $add5 = make_adder(5);
my $add9 = make_adder(9);

$add5->(3);                      # 8
$add9->(3);                      # 12
```

Each call to `make_adder` creates a fresh `$n`, and the returned closure references its own `$n`. Two calls produce two independent counters / adders / state machines.

The closure-over-loop-variable surprise

```
my @subs;
for my $i (1, 2, 3) {
    push @subs, sub { $i };
}

print $_->(), "\n" for @subs;
# 1
# 2
# 3   - fresh $i each iteration: each closure sees its own
```

This is the *correct* behaviour with `for my $i`: every iteration declares a fresh `$i`, each closure captures its own.

The buggy shape is when `$i` is declared *outside* the loop:

```
my $i;
my @subs;
for $i (1, 2, 3) {                # NO `my` - same $i every iteration
    push @subs, sub { $i };
}

print $_->(), "\n" for @subs;
# 3
# 3
# 3   - all three closures share the one $i, and its final value is␣
 ↪3
```

Always declare loop variables with `my`. Closure capture *follows the variable*, not the value, and "same variable" vs "different variable" is decided at the `my` site.

Capturing our and package globals

`our` aliases live for the whole package, so a closure capturing `$Counter::value` shares state with every other piece of code that touches `$Counter::value`. That's almost always not what you want - closures over package globals are a sign that the design wants a `my` instead.

Pad lifetime

Every active sub call has a **pad**, a slot per declared lexical. The pad is what `my` writes into and what closures hold a reference to. While a closure is alive, every pad it captures is alive - even if the originating call has long returned. This is how `make_adder`'s `$n` survives the call to `make_adder` itself.

See also

- `my`, `our`, `local`, `state` - perlfunc detail pages for each declarator.
- `@_` - the one variable that's *always* present in a sub regardless of declarators.
- *Declaration* - anonymous subs and the lexical `my sub` form.
- *Recursion* - closure-based trampolines and `__SUB__`.
- *Special variables* - almost every special wants `local`, not `my`.

Prototypes

A prototype is a piece of metadata attached to a sub that controls **how the parser parses calls to that sub**. It does not control the runtime - it does not check argument counts at runtime, it does not enforce argument types, it does not affect method calls. Its job is to make a user-defined sub *parse* like a built-in.

That narrow purpose is the one thing to remember about prototypes. Everything else follows.

Declaration

Two equivalent forms:

```
sub mypush (\@@) {                  # short form
    my $aref = shift;
    push @$aref, @_;
}

sub mypush :prototype(\@@) {        # attribute form
    ...
}
```

The attribute form is mandatory when *signatures* are enabled in the same scope, because the parenthesised list after the sub name is then claimed by the signature.

What prototypes actually do

A prototype rewrites the parser's expectations at the call site:

```
sub mygrep (&@) {
    my $code = shift;
    my @result;
    for (@_) { push @result, $_ if &$code }
    return @result;
}

mygrep { /foo/ } @items;            # parses correctly thanks to (&@)
                                    # without the prototype, this is
                                    # a syntax error
```

The `(&@)` prototype tells the parser: "the first argument is a block (no `sub` keyword needed, no comma after it), the rest is a list." That's exactly how built-in `grep`, `map`, `sort` parse.

This is the **only** place prototypes are useful: building DSL-shaped subs that look like built-ins.

Prototype characters

Char	Meaning
`$`	scalar - forces scalar context on the argument
`@`	list - eats all remaining arguments, list context
`%`	hash - like @ (even-length list)
`&`	block / code ref - first position lets you omit `sub`
`*`	bareword, scalar, typeglob, or globref
`\$`	scalar reference - caller must pass `$var` form (auto-\-applied)
`\@`	array reference - caller must pass `@arr` form
`\%`	hash reference - caller must pass %h form
`\&`	code reference - caller must pass `&fn` form
`\[$@%&*]`	reference to any of the bracketed kinds
`+`	scalar OR \@/\% (auto-detect array/hash literal)
`;`	separates mandatory from optional
`_`	scalar; if omitted, defaults to $_
`()`	no arguments - and triggers the constant-fold optimisation

The (\@) vs (@) difference

This is the whole reason backslash prototypes exist.

```
sub takes_array (\@) {              # backslash: pass-by-reference
    my ($aref) = @_;                # @_ holds [array_ref]
    push @$aref, 'extra';
}

sub takes_list (@) {                # no backslash: pass-by-value␣
↪(flattened)
    my @copy = @_;                  # @_ holds the flat list
    push @copy, 'extra';            # nothing in caller is affected
}

my @arr = (1, 2, 3);

takes_array(@arr);                  # caller writes @arr - parser␣
↪inserts \@arr
                                    # @arr is now (1, 2, 3, 'extra')

takes_list(@arr);                   # caller writes @arr - flattens to␣
↪a list
                                    # @arr is unchanged
```

The `(\@)` prototype lets you *write* the call as `takes_array(@arr)` - looking just like `push @arr, ...` - while the runtime actually receives an array reference. That's exactly what built-in `push`, `unshift`, `splice`, and `pop` look like to the user.

The `()` constant-fold prototype

A sub with the empty prototype `()` and a single-expression body that the optimiser can fold to a constant becomes inline-able:

```
sub PI ()  { 3.14159265358979 }
sub MAX () { 100 }

my $area = PI * $r ** 2;          # PI is inlined as 3.14159...
```

This is what `use constant` produces:

```
use constant {
    PI  => 3.14159265358979,
    MAX => 100,
};
```

Constant-folded subs are zero-cost at runtime. They do require the prototype to be `()` exactly (no arguments accepted), and the body must be a single expression that the optimiser can reduce. Adding `return` defeats the inlining:

```
sub PI () { return 3.14159; }    # NOT inlined: explicit return
```

What prototypes do *not* do

- They do **not** check argument counts at runtime. Calling a `($)` sub with three arguments is a *parse-time* error, but if you bypass the parser (via `&fn(...)`, code refs, `goto &fn`), there is no runtime check.
- They do **not** affect method calls. Method dispatch is resolved at runtime through `@ISA`, by which point parsing is long over. Prototypes on methods are silently ignored.
- They do **not** affect calls through code references. The call site sees a scalar, not a name; no name, no prototype lookup.
- They are **not** part of the sub's identity. `\&named_sub` loses prototype knowledge.

When you should use prototypes

You are writing a sub that looks like a built-in. Examples:

- A list-eating function with a block argument (`(&@)`): `mygrep`, `myfirst`, `try { ... } catch { ... }`.
- An "inplace" helper that mutates an array in place (`(\@)` or `(\@@)`).
- A constant-like sub (`()` for inlining).

That's the list. If you're not building a built-in look-alike, do not reach for prototypes - use a signature, or just unpack `@_`.

When you should not use prototypes

- For "type checking". Prototypes are not a type system. `sub f ($) { ... }` does not say "takes one scalar"; it says "takes one expression in scalar context". Calling `f(@arr)` passes the *count* of `@arr`, not the array itself, with no warning.
- For run-time argument-count enforcement. Use signatures (which *do* enforce arity at runtime) or write the check by hand.
- On methods. They are silently ignored.

Forward declarations and recursion

A recursive call sees the prototype only if the sub was predeclared:

```
sub fact ($);                       # forward declaration with␣
↪prototype
sub fact ($) {
    my ($n) = @_;
    return $n <= 1 ? 1 : $n * fact($n - 1);    # parsed with ($) in␣
↪mind
}
```

Without the forward declaration, the recursive `fact($n - 1)` inside the body is parsed before the `($)` prototype is finalised, so the prototype does not apply to that call.

Inspecting a prototype at runtime

`prototype` returns a sub's prototype string (or `undef` if there is none):

```
prototype(\&push);                  # '\@@' - yes, even built-ins have␣
↪one
prototype('CORE::push');            # '\@@'
prototype(\&my_sub);                # whatever you declared
```

- `prototype` - runtime introspection.
- *Signatures* - the modern alternative for arity and named-parameter handling. They coexist with prototypes but have different goals.
- `sub` - the keyword's perlfunc page.
- *Declaration* - where prototypes attach in the declaration syntax.
- *Attributes* - `:prototype(...)` is the attribute form.

Signatures

A signature is a parenthesised parameter list that goes immediately after the sub name (and after any attributes), in place of - or in addition to - the body's manual `@_` unpacking. Signatures introduce **lexical** parameter variables, perform **arity checking** at call time, and support default values and slurpy parameters.

Signatures stabilised in Perl 5.36; in 5.44 they are a production feature available with one of:

```
use feature 'signatures';          # explicit feature import
use v5.36;                         # implicit (signatures + other 5.36
 ↪features)
```

PetaPerl supports the full 5.44 signature syntax.

Basic shape

```
use feature 'signatures';

sub add ($x, $y) {                 # two mandatory positional
 ↪parameters
    return $x + $y;
}

add(2, 3);                         # 5
add(2);                            # error: Too few arguments
add(2, 3, 4);                      # error: Too many arguments
```

Each `$name` in the signature declares a `my` lexical that receives the corresponding argument. Arity is checked at the call: the body never runs if the count is wrong.

This is the most concrete improvement over the classic form:

```
# Classic - silently accepts wrong arity
sub add {
    my ($x, $y) = @_;
    return $x + $y;
}

add(2);                            # $y is undef; later arithmetic
 ↪warns
add(2, 3, 4);                      # third arg silently ignored
```

Defaults

```
sub greet ($name, $greeting = 'Hello') {
    return "$greeting, $name!";
}

greet('Alice');                    # "Hello, Alice!"
greet('Alice', 'Hi');              # "Hi, Alice!"
```

The default is an arbitrary expression evaluated each time the parameter is omitted (so `state` and per-call computation both work). It can reference earlier parameters:

```
sub log_event ($message, $level = 'INFO', $prefix = "[$level]") {
    print "$prefix $message\n";
}

log_event('starting');                      # [INFO] starting
log_event('failure', 'ERROR');              # [ERROR] failure
log_event('done', 'OK', '>>');              # >> done
```

A default `= undef` is exactly equivalent to "no default" for arity (the parameter is still optional) but documents the intent. Use `//=`-style guards inside the body for "undef means use my fallback" semantics.

Optional vs mandatory

Parameters are mandatory by default. A parameter becomes optional by:

- Giving it a default value (`$x = 42`).
- Putting it after another optional parameter (transitive).
- Being followed by a slurpy `@arr` or `%hash`.

You cannot have a mandatory parameter after an optional one (except via slurpy):

```
sub bad ($x = 1, $y) { ... }     # error: Mandatory parameter
↪follows optional
```

Slurpy parameters

The last parameter may be a slurpy `@list` or `%hash`. It eats all remaining arguments:

```
sub join_all ($sep, @parts) {
    return join $sep, @parts;
}

join_all(', ', 'a', 'b', 'c');   # "a, b, c"

sub configure ($name, %opts) {
    $opts{verbose} //= 0;
    ...
}

configure('demo', verbose => 1, port => 8080);
```

The slurpy hash also fails if the remaining list has odd length:

```
configure('demo', 'verbose');    # error: Odd-sized list given
```

This is the single most useful pattern signatures unlock: a named-parameter API with one positional plus a `%opts` slurp.

Anonymous parameters

A $ (or @, %) with no name is a positional placeholder:

```
sub second ($, $x) { return $x }

second('ignored', 'kept');       # "kept"
```

This is mildly useful when adapting a callback to an interface that supplies more arguments than you care about.

Combining defaults and slurpy

```
sub render ($template, $cache = 1, %opt) {
    ...
}

render('greeting.tt');                          # cache=1, %opt empty
render('greeting.tt', 0);                       # cache=0, %opt empty
render('greeting.tt', 1, locale => 'de');       # all three
render('greeting.tt', locale => 'de');          # ERROR: 'locale'␣
↪becomes $cache
                                                # then 'de' is the lone␣
↪slurp arg
                                                # (odd-length hash) -␣
↪diagnose carefully
```

That last case is the gotcha: a positional optional parameter followed by a slurpy hash is ambiguous with named-arg-only calls. Either drop the optional positional and put everything in the hash, or always pass the optional positional explicitly.

Migration from @_ unpacking

The mechanical translation:

```
# Before
sub make_user {
    my ($name, $email, %extra) = @_;
    ...
}

# After
use feature 'signatures';
sub make_user ($name, $email, %extra) {
    ...
}
```

You get arity checking and named lexicals for free. The body is unchanged.

The places where you cannot mechanically translate:

- The body uses the *count* of arguments dynamically (`if (@_ >= 3)`) - signatures fix arity at parse time, so rework into an optional parameter with a default.

- The body modifies `$_[0]` for the aliasing effect - keep the classic form, since signatures introduce *copies*, breaking the alias.
- The body uses `goto &other` and wants to forward the original `@_` - `@_` is still populated under signatures in 5.44, but this is implementation-defined and may change. Keep the classic form for tail-call forwarding.

Signatures and prototypes are orthogonal

Signatures and *prototypes* solve different problems:

Mechanism	Affects	When checked	Useful for
signature	the body's view	runtime	arity, named params
prototype	how the parser parses	compile-time	DSL look-alikes

A sub can have both, with the prototype written as an attribute:

```
use feature 'signatures';
sub mygrep :prototype(&@) ($code, @list) {
    grep { $code->($_) } @list;
}

mygrep { /foo/ } @items;          # prototype lets us drop `sub`
                                  # signature gives us $code and
 ↪@list
```

The prototype shapes the call site; the signature shapes the body. They do not duplicate each other.

The single biggest reason to migrate

Catching wrong-arity calls at the moment they happen - not several lines later when you finally do `$y + 1` and trip a warning about an undef value. Signatures turn a class of subtle bugs into a clear error message.

See also

- *Arguments and* `@_` - the classic mechanism that signatures coexist with.
- *Prototypes* - different mechanism, often confused with signatures.
- `sub` - the keyword's perlfunc page.
- *Declaration* - where signatures sit in the declaration syntax.
- *Scoping* - signature parameters are `my`-style lexicals.

Recursion

Subs may call themselves, each other, or - with a bit of ceremony - replace their own call frame and pass control elsewhere without growing the stack. This page covers the four mechanisms: ordinary recursion, mutual recursion, `goto &fn` tail calls, and `__SUB__` for anonymous self-reference. It also covers the depth limit you will hit if you ignore them.

Plain recursion

```
sub factorial {
    my ($n) = @_;
    return 1 if $n <= 1;
    return $n * factorial($n - 1);
}

factorial(10);                    # 3628800
```

Each recursive call adds a new frame to Perl's call stack. The stack costs memory and a fixed per-call overhead; for shallow recursion this is irrelevant, for deep recursion it is the bottleneck.

Perl emits a "Deep recursion on subroutine X" warning when a sub recurses past 100 levels deep (compile-time threshold, `PERL_SUB_DEPTH_WARN`). The warning is in the `recursion` category - `no warnings 'recursion'` silences it. The only hard limit is the OS stack, typically 8 MiB by default, controllable with `ulimit -s`.

For deep, structurally-recursive workloads, prefer one of:

- An explicit work queue (iterative reformulation).
- Tail recursion via `goto &fn` (see below).
- A trampoline (see below).

Mutual recursion

Two subs that call each other:

```
sub is_even {
    my ($n) = @_;
    return 1 if $n == 0;
    return is_odd($n - 1);
}

sub is_odd {
    my ($n) = @_;
    return 0 if $n == 0;
    return is_even($n - 1);
}

is_even(10);                      # 1
```

Mutual recursion has no special treatment from the runtime - it is just two subs happening to call each other. The same depth limit applies.

If `is_even` is defined first and refers to `is_odd` before `is_odd` exists, you'll see a "Bareword not allowed" or "Called undefined subroutine" depending on the call shape. Predeclare to fix:

```
sub is_odd;                          # forward declaration
sub is_even { ... is_odd($n-1) }
sub is_odd  { ... is_even($n-1) }
```

`goto &fn` - tail-call forwarding

The `goto &SUBROUTINE` form **replaces the current frame** with a call to another sub. The current frame is gone - it is not on the stack - so the call does not grow the stack:

```
sub api_v2 {
    my @args = @_;
    push @args, deprecated => 1;
    @_ = @args;
    goto &api_v1;                # tail-call: api_v1 sees the␣
 ↪modified @_
}
```

This is the right tool when:

- A wrapper sub needs to forward to a real implementation without leaving a stack frame behind. Decorators, logging shims, AUTOLOAD dispatchers.
- A recursive sub can express its recursion as "do some work, then become this other call". Classic tail recursion:

  ```
  sub factorial_tail {
      my ($n, $acc) = @_;
      $acc //= 1;
      return $acc if $n <= 1;
      @_ = ($n - 1, $n * $acc);
      goto &factorial_tail;
  }

  factorial_tail(20);            # 2432902008176640000, no stack␣
   ↪growth
  ```

The mechanics: `@_` becomes the called sub's argument array, the current frame is unwound, control jumps. The caller of the *current* sub will see the result of the goto'd-to sub, never the one it called.

`goto &fn` is the **only** form of `goto` that performs a tail call. The label-based form (`goto LABEL`) is unrelated and far more restricted.

See `goto` for the full keyword description and the shape constraints.

__SUB__ - anonymous self-reference

```
use feature 'current_sub';                # or use v5.16

my $factorial = sub {
    my ($n) = @_;
    return 1 if $n <= 1;
    return $n * __SUB__->($n - 1);
};

$factorial->(5);                  # 120
```

__SUB__ evaluates to a code reference to the currently-running sub. It is the only way to recurse into an anonymous sub without storing it in a named variable first (and without leaking a strong reference to it from inside itself, the classic memory-leak shape).

For anonymous subs that do not need to recurse, prefer the plain anonymous form. __SUB__ exists for the recursion case specifically.

Trampolines

When you want bounded-stack recursion but `goto &fn` is awkward (because the recursion is mutual, or branches into many sub-cases), the trampoline pattern works:

```
sub trampoline {
    my $next = shift;
    while (ref $next eq 'CODE') {
        $next = $next->();
    }
    return $next;
}

sub even {
    my ($n) = @_;
    return $n == 0 ? 1 : sub { odd($n - 1)  };
}

sub odd {
    my ($n) = @_;
    return $n == 0 ? 0 : sub { even($n - 1) };
}

trampoline(even(10000));          # 1, no stack growth
```

Each "recursive" call returns a closure to be invoked next, rather than calling itself directly. The trampoline drives the closures in a loop. The stack stays at depth 2 forever.

Trampolines are heavier than `goto &fn` (one closure allocation per "call"), but they generalise to arbitrary control flow - including continuations and CPS-style code. For production Perl, `goto &fn` is the usual choice; trampolines appear when the structure of the recursion makes `goto` clumsy.

The depth limit, in practice

```
sub recurse {
    my ($n) = @_;
    return $n if $n <= 0;
    return recurse($n - 1);
}

recurse(2000);                  # warning: Deep recursion on
↪subroutine
                                # (default limit 1000)
```

The "Deep recursion" warning is informational, not fatal - it fires once per sub. You will run out of actual stack space well before any practical limit on most platforms. If you see this warning, the answer is almost always to refactor (iterative loop, `goto &fn`, or trampoline), not to raise the limit.

If you have already verified the recursion is bounded and you just want to suppress the noise, scope the warning category:

```
no warnings 'recursion';
```

This silences the warning entirely; it does not change the OS stack limit, which is what eventually terminates a runaway recursion regardless of warnings.

- `caller` - works through goto'd frames with the same numbering as ordinary frames.
- *Arguments and* `@_` - `@_` semantics under `goto &fn`.
- *Declaration* - anonymous subs, the substrate for `__SUB__` and trampolines.
- *Scoping* - closures, the substrate for trampolines.

Lvalue subs and context

Two related topics that come up wherever a sub needs to behave differently depending on how it is being used: **`:lvalue`** subs (those usable on the left-hand side of an assignment) and **`wantarray`**-driven dispatch on the caller's context.

Why context matters in subs

Every Perl expression evaluates in a context - list, scalar (with sub-flavours: numeric, string, boolean), or void - that's imposed by what surrounds it. A sub call inherits the context of its position:

```
my @r = my_sub();               # list context
my $r = my_sub();               # scalar context
my_sub();                       # void context
```

(continues on next page)

(continued from previous page)

```
print my_sub();                    # list context (print's args are
↪LIST)
my $n = () = my_sub();             # scalar of (a list assignment) -
↪element count
```

For most subs, this is invisible - they return the same data either way and Perl's automatic context conversion does the right thing. For some subs the work is genuinely different depending on context, and those subs benefit from explicitly inspecting `wantarray`.

wantarray: the three-way switch

```
sub items {
    if (wantarray) {
        return (1, 2, 3);                  # list context
    }
    elsif (defined wantarray) {
        return 3;                          # scalar context
    }
    else {
        return;                            # void context - caller
↪will
                                           # discard whatever we
↪return
    }
}
```

The three return values of `wantarray`:

Return value	Caller's context	Practical meaning
1 (true)	list	return all the things
`0` (false)	scalar	return one thing (e.g. count)
`undef`	void	nobody cares; consider returning early

`defined wantarray` is the test for "scalar or list" (anything non-void).

The void-context shortcut

When work is expensive and the caller threw the result away, return early:

```
sub expensive_query {
    return unless defined wantarray;       # nothing to compute
    my @rows = $db->select(...);           # actually do the work
    return wantarray ? @rows : scalar @rows;
}

expensive_query();                         # void: returns
↪immediately
```

(continues on next page)

(continued from previous page)

```
my @r = expensive_query();                    # list: full result
my $n = expensive_query();                    # scalar: count
```

This pattern is the single best reason to consult `wantarray`: turning a "always do the work" sub into a "do the work only if the caller wants it" sub.

When *not* to use `wantarray`

- For convenience overloading. A sub that returns a hashref in scalar context and a hash in list context is a maintenance hazard - readers can't tell from the call site which they're getting. Pick one.
- For subs that are obviously list-y or scalar-y. A sub named `count_users` should return a number; readers do not expect it to behave differently in list context.

`:lvalue` subs

An `:lvalue` sub is one whose return value is itself assignable. The body must end in an expression that has a memory location - typically a `my` lexical or an aggregate element:

```
sub editable :lvalue {
    my $self = shift;
    $self->{counter};                         # last expression is an␣
 ↪lvalue
}

my $obj = { counter => 0 };
bless $obj, 'Counter';

$obj->editable = 42;                          # writes through to $obj-
 ↪>{counter}
```

The body's last expression is what the assignment writes to. If that expression is not an lvalue (`return $x + 1`, `return scalar @list`), the assignment is illegal and you'll get a clear error.

`:lvalue` is rarely the right tool. The only places it pays for itself:

- Tied variables and tied-like wrappers, where the sub is mediating access to a real lvalue underneath.
- DSLs that genuinely want assignment-syntax for setting (eg. `$config->host = 'localhost';`).

For "set a property on an object", a plain setter is clearer:

```
sub set_counter {
    my ($self, $value) = @_;
    $self->{counter} = $value;
    return $self;                              # method chaining
}
```

(continues on next page)

(continued from previous page)

```
$obj->set_counter(42);                  # explicit, no surprises
```

`:lvalue` and the body's structure

Because the body's last expression is special, the rules are restrictive:

```
sub good :lvalue { $self->{x} }             # OK - last expr is
 ↪lvalue

sub also_good :lvalue {
    my @scratch = ...;                      # work
    $self->{x};                             # last expr is lvalue
}

sub bad :lvalue {
    return $self->{x};                      # NOT OK - explicit
 ↪return
                                            # disables :lvalue
}

sub also_bad :lvalue {
    if ($cond) { $self->{x} }
    else       { $self->{y} }               # an `if` block is not an
 ↪lvalue
}
```

The "no explicit `return`" rule is the same one that makes constant-fold prototypes work; both rely on the body being a single value-producing expression at the end.

For the modern alternative - a setter that returns `$self` for chaining - see the *Object-Oriented Programming guide*.

Combining `:lvalue` with context

An `:lvalue` sub cannot easily branch on `wantarray`, because the lvalue version of the call doesn't quite fit the "returns a value" model. If you want both behaviours from one sub, accept that you are in DSL territory and document the contract carefully - or split into two subs.

Context-affecting operators

A few operators force a specific context on their argument; the sub will see that context regardless of where the surrounding expression is going:

```
my @r = scalar my_sub();            # scalar() forces scalar context on
 ↪my_sub
my $n = () = my_sub();              # the inner () = ... is list
 ↪context;
```

(continues on next page)

(continued from previous page)

```
                                    # outer assignment to $n is scalar␣
↪of that
```

The `() = LIST` idiom is the standard way to force list context on a sub call and then read the count. See *assignment* for the operator-level discussion.

See also

- `wantarray` - the keyword.
- *Return values* - the rest of the return-value picture (without the lvalue twist).
- *Attributes* - `:lvalue` is one of several built-in attributes.
- *Assignment operator* - what the caller's = actually does on either side of an `:lvalue` call.
- `scalar` - explicit context coercion.

Attributes

A sub attribute is a colon-prefixed annotation between the sub's name (or signature) and its body. Attributes mark a sub as having some special property - being a method, being an lvalue, having a prototype, being constant, being subject to some third-party mechanism - that the runtime, the parser, or a user-written attribute handler can act on.

```
sub greet :method ($name)           { ... }
sub editable :lvalue                { ... }
sub mypush :prototype(\@@)          { ... }
sub PI :const                       { 3.14159 }
sub handler :Memoize                { ... }   # third-party␣
↪attribute
```

The four attribute steps

To follow how an attribute affects a sub, distinguish four phases:

1. **Parse.** The compiler reads `:foo(args)` and breaks it into a name (`foo`) and an optional parameter string (`args`).
2. **Register.** The compiler invokes either a built-in handler (for `:lvalue`, `:method`, `:prototype(...)`) or `MODIFY_CODE_ATTRIBUTES` from the relevant package (for user-defined attributes).
3. **Store.** Built-in attributes set a flag on the CV (the compiled sub object). User attributes are stored wherever the handler chooses.
4. **Query.** Anyone can later ask `attributes::get(\&sub)` for the attribute list. Built-in attributes are also queryable through more direct APIs (`prototype`, `is_lvalue`, ...).

The four phases are why attributes are heterogeneous in behaviour: built-in attributes are runtime concepts; user attributes are whatever code in `MODIFY_CODE_ATTRIBUTES` decides to do with them.

Built-in attributes

`:lvalue`

Marks the sub as usable on the left-hand side of an assignment. The body's last expression must be an lvalue. See *lvalue and context*.

```
sub editable :lvalue { $self->{x} }

$obj->editable = 42;            # writes through to $self->{x}
```

`:method`

Hint to the parser and to introspection that this sub is meant to be called as a method. The flag is mostly informational; it also suppresses prototype effects (since methods don't honour prototypes anyway):

```
package Counter;

sub increment :method {
    my $self = shift;
    $self->{n}++;
}
```

`:method` does **not** automatically `use parent` or set `@ISA`; it does not change dispatch. It is a documentation / intent marker that the runtime also uses to skip prototype processing.

`:prototype(...)`

The attribute form of a *prototype*, required when *signatures* are enabled in the same scope:

```
use feature 'signatures';
sub mygrep :prototype(&@) ($code, @list) {
    grep { $code->($_) } @list;
}
```

The body's parameter list is the signature; the attribute carries the prototype. Without the attribute form, the parser cannot tell which parenthesised list is which.

`:const`

Promises the runtime that the sub's body produces a constant result, enabling more aggressive inlining than the bare `()` prototype gives:

```
sub PI :const { 3.14159265358979 }
```

`:const` was introduced for use by `use constant` and similar tools. Most code should reach for `use constant` rather than applying `:const` directly.

Third-party attributes

Any package can register attribute handlers for code refs by implementing `MODIFY_CODE_ATTRIBUTES`. The classic example is `Attribute::Handlers`, which provides a more declarative API on top of the raw mechanism. A user attribute looks identical to a built-in at the call site:

```
use Some::Memoize;                # provides ':Memoize' attribute

sub expensive :Memoize {
    ...
}
```

The package providing the attribute decides what `:Memoize` means. Common third-party attributes:

- `:Memoize` - automatically cache return values (from `Memoize`).
- `:Logged` - wrap the sub with logging entry/exit (from various AOP-style modules).
- `:Test`, `:Benchmark` - testing-framework markers.

When you see a colon-attribute that isn't on the built-in list above, find the package supplying it.

How attributes are written

Several attributes can be chained. The ordering on disk is the ordering they're processed in:

```
sub fancy :method :prototype(\@) :Memoize {
    ...
}
```

Attributes attach to *both* a forward declaration and the definition; if you write both, the attribute lists must agree:

```
sub greet :method;                # forward declaration with :method
sub greet :method ($name) {       # body, same attribute
    ...
}
```

A signature, when present, comes after attributes:

```
sub greet :method ($name) {       # OK
    ...
}

sub greet ($name) :method {       # error: attributes must precede
↪signature
    ...
}
```

What attributes do *not* do

- They are not type annotations. `:Int` is not a built-in; attempts to read it that way will silently do nothing unless some package has registered a handler that means the same thing.
- They are not metadata for the test framework unless the test framework registered a handler for them. Sprinkling `:tested` on subs does nothing without code on the other side reading the annotation.
- They are not optimisation directives. `:fast` does nothing.

Querying a sub's attributes

```
use attributes;

sub demo :method :prototype($) :Memoize { ... }

my @attrs = attributes::get(\&demo);
# returns: ('method', 'prototype($)', 'Memoize')
```

This is the introspection equivalent of `prototype` - it answers "what annotations does this sub carry?" rather than "what does this sub look like to the parser?".

Phasers: BEGIN, UNITCHECK, CHECK, INIT, END

Five specially named blocks let code hook the transitions a program makes between being compiled and being run. They look like subroutines but are not: you can write several of each, none has a callable name, and each one fires automatically at its own moment.

```
BEGIN     { ... }   # during compilation, as soon as defined
UNITCHECK { ... }   # right after this compilation unit is compiled
CHECK     { ... }   # after the whole program is compiled
INIT      { ... }   # just before the runtime begins
END       { ... }   # just before the interpreter exits
```

The sub prefix (`sub BEGIN { ... }`) is accepted but adds nothing and is discouraged. These are blocks, not named subs; you cannot call them, only let them fire.

When each one runs

A Perl program lives in two phases: a **compile phase** that parses the source into an internal form, and a **run phase** that executes it. The phasers mark the boundary.

- `BEGIN` runs the instant its closing brace is parsed, before the rest of the file is even read. This is how `use` works: a `use` is a `BEGIN`-wrapped `require` plus `import`, so the imported names exist for the code that follows. Once a `BEGIN` has run, it is undefined and its memory reclaimed.
- `UNITCHECK` runs as soon as the **compilation unit** that contains it has finished compiling. A unit is the main program, a module loaded by `require`, a string `eval`, a `do` FILE, or code compiled by the `(?{ })` regex construct. Because units finish compiling at different times, `UNITCHECK` is the only phaser whose timing tracks the individual file rather than the program as a whole.
- `CHECK` runs once, after the **initial** compile phase of the whole program ends and before the run phase starts.
- `INIT` runs once, just before the run phase begins, after all `CHECK` blocks.
- `END` runs once, as late as possible: after the program has finished (including after a `die`), just before the interpreter exits.

`BEGIN` and `UNITCHECK` are tied to *parsing*, not to the interpreter phase, so they can fire during any phase: a string `eval` at run time still compiles its body, and any `BEGIN` or `UNITCHECK` inside it runs then and there. `CHECK` and `INIT`, by contrast, mark the one-time compile/run boundary of the main program.

Multiplicity and execution order

You may write any number of each block. They all run, in a defined order:

- `BEGIN`: first in, first out (FIFO) as encountered during compilation. The first `BEGIN` in source order runs first.
- `UNITCHECK`: last in, first out (LIFO) within each unit, after that unit compiles.
- `CHECK`: LIFO, after all compilation.
- `INIT`: FIFO, just before the runtime.
- `END`: LIFO at exit. The last `END` defined is the first to run.

The instructive case is a file that mixes ordinary statements with all five block kinds. The blocks do not run where they are written; they run at their phase, in their per-phase order, while the ordinary statements run in between at run time. Conceptually, for a single file:

```
1. BEGIN blocks      -- FIFO, during compilation
2. UNITCHECK blocks  -- LIFO, after this unit compiles
3. CHECK blocks      -- LIFO, after all compilation
4. INIT blocks       -- FIFO, just before runtime
5. ordinary code     -- run phase, in source order
6. END blocks        -- LIFO, at exit
```

So BEGIN and UNITCHECK run before any CHECK; CHECK runs before INIT; INIT runs before the first line of ordinary code; and every END runs after the last. Within BEGIN and INIT, earlier-written blocks run earlier; within UNITCHECK, CHECK, and END, later-written blocks run earlier.

END blocks in detail

END is the cleanup phaser. It runs LIFO so that teardown unwinds in the reverse of setup, the way nested resources expect.

Inside an END block, `$?` holds the value the program is about to pass to `exit`. You may read it to learn how the program is ending, and you may assign to it to change the exit code:

```
END {
    $? = 0 if $? == 42;     # rewrite one exit code on the way out
}
```

Beware of clobbering $? by accident. Running anything via `system` inside an END block overwrites $? with the child's status, which then becomes the program's exit code unless you save and restore it.

END blocks do **not** run in several cases:

- Under the `-c` switch (compile-only syntax check). Main code does not run, and neither do END blocks.
- When compilation fails. A program that does not compile never reaches the point where END blocks would fire.
- When the process replaces itself with `exec`. The image is gone; there is nothing left to run the block.
- When the process is killed by a fatal signal you do not trap. Catch the signal yourself (via `%SIG`) if you need cleanup to run.

An END block created inside a string `eval` is **not** run when that `eval` finishes. It is registered like any other END block of its package and runs in LIFO order just before the interpreter exits.

${^GLOBAL_PHASE} and the phases

The read-only variable `${^GLOBAL_PHASE}` names the interpreter's current phase. Its values let code that runs in more than one phase find out where it is. During a CHECK block it reads CHECK; during INIT, INIT; during ordinary run-time code, RUN; during an END block, END. See `${^GLOBAL_PHASE}` for the full list of values and the phase timeline.

defer blocks

A `defer` block is END's small-scale cousin. It runs when the enclosing **block scope** exits, for any reason, rather than when the whole program exits. Reach for `defer` to pair acquisition with release inside a sub or loop; reach for END for process-wide teardown that must happen once, at the very end.

See also

- `BEGIN` *and* `use` - `use` is a `BEGIN`-wrapped load-and-import; the most common reason to care about compile-phase timing.
- `${^GLOBAL_PHASE}` - read the current phase from inside any block to learn where you are.
- `defer` - block-scoped cleanup, the right tool when `END`'s program-wide reach is too broad.
- `$?` - the exit status an `END` block can read and rewrite.
- `%SIG` - trap the signals that would otherwise bypass `END` blocks entirely.
- `exit` - what `END` blocks run just before; the value it carries is the `$?` an `END` block sees.
- *Declaration* - `sub NAME { ... }`, anonymous subs, forward declarations, code references, the `&` sigil and what predeclaration buys you.
- *Arguments and* `@_` - the aliasing rule, the unpacking idiom, named-arg conventions, `shift` defaults, the `chomp(@lines)` legitimate use of aliasing, and the `$_[0] = ...` trap.
- *Return values* - explicit `return`, implicit last-expression, list-flattening on return, void-context shortcuts, and the difference between `return;` and `return undef;`.
- *Scoping:* `my`, `our`, `local`, `state` - pad lifetime, closures, the closure-over-loop-variable surprise, when `local` is the right tool, and what `state` actually means.
- *Prototypes* - what they do (call-site parsing), what they don't (runtime checks), the `(\@)` vs `(@)` difference, the `()` constant-fold prototype, and why most modern code shouldn't reach for them.
- *Signatures* - the modern syntax from 5.20+ stable in 5.36, with positional, optional, and slurpy parameters; defaults; named parameters via slurpy hash; and how signatures interact with (and don't replace) prototypes.
- *Recursion* - depth limit, mutual recursion, `goto &fn` for tail calls, `__SUB__` for anonymous self-reference, trampolines.
- *Lvalue subs and context* - `:lvalue` semantics, `wantarray`, the void-scalar-list three-way switch, and the standard "return early in void context" pattern.
- *Attributes* - `:method`, `:lvalue`, `:prototype(...)`, `:const`, third-party attributes, and how the four attribute-related steps (parse, register, store, query) compose.
- *Phasers* - the `BEGIN`, `UNITCHECK`, `CHECK`, `INIT`, and `END` blocks: when each fires relative to the compile/run boundary, their FIFO/LIFO ordering, `$?` and `${^GLOBAL_PHASE}` inside `END`, and the `defer` block.

Defining a sub vs. calling a sub

The two halves of the subroutine system are mostly orthogonal:

- **Definition** is a declaration plus a body. The declaration fixes the name (or makes the sub anonymous), the optional prototype or signature, the optional attributes. The body is a block of statements with its own pad.
- **Call** turns a list of expressions into the new pad's `@_` (or signature variables), runs the body, and collects whatever the body returned in the caller's context.

Almost every "subtle" subroutine question is a question about *one* side or the other. Prototypes affect calls only, not definitions; signatures affect what the body sees, not how the caller writes the call; attributes affect how the *defined* sub is treated by the runtime.

The classic vs. modern split

Perl carries two parallel argument-passing mechanisms:

```
# Classic: @_ aliasing, manual unpacking
sub add {
    my ($a, $b) = @_;
    return $a + $b;
}

# Modern: signatures, named lexicals, arity checking
use feature 'signatures';
sub add ($a, $b) {
    return $a + $b;
}
```

Both are fully supported. Signatures are not a replacement for `@_`; they are an additional, more declarative entry into the same calling convention. Inside a signature-using sub, `@_` is still populated (this is implementation-defined and discouraged to rely on, but it is the case in 5.44).

The split between classic and modern is the *single most useful piece of orientation* when reading other people's Perl. Most older code uses the classic form; most newer code uses signatures; both will be in front of you on any non-trivial codebase.

See also

- `perlop` - operators that interact with subs: `->` for method dispatch and code-ref invocation, `,` (and the fat comma) for named-arg construction, `=` for the list-assignment used in the `my (...) = @_` idiom.
- `perlvar` - special variables a sub will read or write: `@_`, `$_`, `$@`, `$AUTOLOAD`.
- `perlfunc` - the verbs of the subroutine system: `sub`, `return`, `caller`, `wantarray`, `prototype`, `goto`, `my`, `our`, `state`, `local`.
- *Object-Oriented Programming* - subs as methods, the role of `bless`, dispatch via `@ISA`, the modern `use experimental 'class'` syntax.

5.1.6 Locale handling

A *locale* is the set of cultural conventions a program follows when it sorts text, changes case, formats numbers and money, names the days of the week, or writes an error message. The same array of words sorts one way under a Swedish locale and another under a German one; the number twelve-and-a-half prints as `12.5` in one country and `12,5` in another. Locale handling is how Perl lets a single program adapt to those conventions at runtime instead of hard-coding one country's rules.

By default PetaPerl ignores locale entirely: every built-in behaves the same regardless of the user's environment, using the C/POSIX conventions (ASCII collation, `.` as the decimal point, English month names). You opt in to locale-awareness, one lexical scope at a time, with the `use locale` pragma. This page covers what that pragma turns on, which operations it affects, how to set and inspect the active locale, and where locale and Unicode interact.

What a locale is

The system C library divides cultural conventions into independent *categories*, each named `LC_` followed by the area it governs. Sorting (`LC_COLLATE`) is separate from case rules (`LC_CTYPE`), which is separate from number formatting (`LC_NUMERIC`), and so on. A locale is a named bundle of settings - `de_DE.UTF-8`, `sv_SE.UTF-8`, `C` - and switching to it can change all categories at once or just the ones you select. The categories PetaPerl honours are listed in the category table below.

The `use locale` pragma

Locale-sensitive behaviour is **off by default** and **lexically scoped**. `use locale` enables it from that point to the end of the enclosing block (or file); `no locale` turns it back off for the remainder of its own scope. Nothing outside the lexical scope is affected - a module that does not say `use locale` keeps the default C-locale behaviour even when called from code that did.

```
use locale;                  # locale-aware from here down
my @sorted = sort @words;    # collates per LC_COLLATE
{
    no locale;               # back to codepoint order in this block
    my @plain = sort @words;
}
```

Without the pragma, `sort`, `lc`, `uc`, `printf` and the rest use fixed C-locale rules no matter what the environment says. This is a deliberate safety default: a program produces the same output on every machine until it explicitly asks to follow the local conventions.

The pragma sets a per-statement hint, exactly as upstream Perl does, so a single file can mix locale-aware and locale-blind regions freely. The setting travels with the lexical scope, not with the call stack.

Locale categories

Each category controls a distinct group of operations. `use locale` activates all of them at once; you choose *which* locale is active per category through `setlocale`. The "affected operations" column links to the reference pages where the behaviour is documented in full - that is where the locale-specific rules for each built-in live.

Category	Governs	Affected operations
`LC_COLLATE`	String sort order and comparison	`sort`, the `lt le gt ge cmp` string comparisons
`LC_CTYPE`	Character classification and case mapping	`lc`, `uc`, `lcfirst`, `ucfirst`, `\w \d \s` and `\b` in regex
`LC_NUMERIC`	Decimal point and digit grouping	`printf`, `sprintf`, *number-to-string conversion*
`LC_MONETARY`	Currency formatting conventions	`localeconv` (inspection only; no built-in formats money for you)
`LC_TIME`	Day and month names, date layout	`strftime` via `POSIX`, `langinfo`
`LC_MESSAGES`	Language of system error strings	`$!` text, `langinfo` message strings

`LC_ALL` is not a category of its own but a shorthand that sets every category at once.

Note one asymmetry that trips people up: `LC_NUMERIC` changes how numbers are *formatted for output*, but Perl's own source code and its numeric *parsing* always use `.` as the decimal separator. A script that reads `12,5` from a German-locale file still needs to translate the comma itself before treating it as a number - the locale does not make `"12,5" + 0` yield `12.5`. See *numbers and strings*.

Setting the locale

`use locale` says *follow the locale*; it does not say *which* one. That choice comes from the environment by default, and you can query or override it through the `POSIX` module.

`setlocale` selects the active locale for a category. The idiomatic call honours the user's environment (`LANG`, `LC_*`):

```
use POSIX qw(setlocale LC_ALL LC_COLLATE);
setlocale(LC_ALL, "");                # adopt the environment's␣
↪locale
my $cur = setlocale(LC_COLLATE);      # query the active collation
setlocale(LC_COLLATE, "sv_SE.UTF-8"); # force one explicitly
```

`localeconv` returns a hash describing the active `LC_NUMERIC` and `LC_MONETARY` conventions - the decimal point, thousands separator, currency symbol, and the rest - so a program can format values itself when no built-in does it directly.

`I18N::Langinfo` exposes `langinfo`, which reads individual items out of the current locale: the localized name of a weekday or month (`DAY_1`, `MON_1`), the date format string, the radix character, the currency symbol. It is the narrow, item-at-a-time companion to `localeconv`.

Locale and Unicode

Locale handling and Unicode are two different answers to "what is a character", and they interact in ways worth understanding before you combine them. The full treatment - how `use utf8`, UTF-8 I/O layers, and locale `LC_CTYPE` rules compose, and the traps that arise when they disagree - lives in the Unicode tutorial. Start with *Unicode strings and encodings* and the *pitfalls chapter*; the *regex-and-properties chapter* covers how `\w` and the character classes behave under each model.

Locale leaks and safety

A locale is process-global state in the C library underneath, so a `setlocale` call made anywhere changes the locale everywhere in the process - across module boundaries, not just the scope that called it. Two consequences follow:

- **`use locale` is safe to scope; `setlocale` is not.** The pragma is lexical and leaks nothing. A `setlocale` call is a global side effect - if a library sets `LC_NUMERIC` to a comma-decimal locale and forgets to restore it, every later `printf` in the program is affected. Save and restore around a temporary change:

```
my $saved = setlocale(LC_NUMERIC);
setlocale(LC_NUMERIC, "de_DE.UTF-8");
# ... locale-sensitive work ...
setlocale(LC_NUMERIC, $saved);
```

- **Untrusted locale names are untrusted input.** Passing an environment-supplied string straight to `setlocale` lets the environment steer your program's formatting. In a security-sensitive context, validate the name or pin the locale explicitly rather than calling `setlocale(LC_ALL, "")`.

Parallel execution and locale

PetaPerl auto-parallelizes some numeric loops across worker threads. This never affects locale-sensitive code, by construction. Operations whose results depend on the current locale - `sort` with the default collation, `LC_COLLATE` string comparison, `lc`/`uc`/`fc` case folding, and `LC_NUMERIC` number formatting - are never JIT-compiled or auto-parallelized; they always execute sequentially in the interpreter against the single process-wide locale. Auto-parallelization only ever runs numeric loop bodies, so no locale-sensitive computation is dispatched across worker threads. You do not need to guard locale state when writing parallelizable code: the parallel path simply never touches it.

Environment variables

When a program calls `setlocale(LC_ALL, "")`, the C library reads the locale from the environment in a fixed order of precedence: `LC_ALL` overrides every individual `LC_*` variable, each `LC_*` variable sets its own category, and `LANG` supplies the default for any category not otherwise named. These variables live in `%ENV` like any other environment value, so a program can inspect or adjust them before the `setlocale` call that consumes them.

Variable	Effect
`LC_ALL`	Overrides all categories
`LC_COLLATE`, `LC_CTYPE`, ...	Sets one named category
`LANG`	Default for any category not set above

Differences from upstream

- **Linux only, UTF-8 native.** PetaPerl runs only on Linux against the system C library's locales. The platform-specific locale machinery upstream Perl carries for VMS, Windows, and Android - the `Win32::` locale shims, the VMS category quirks, the "locales are not available on this platform" fallbacks - has no counterpart here and is simply absent. There is one locale model: the POSIX one your `glibc` provides.
- **`LC_NUMERIC` and source parsing.** As upstream, the decimal separator used when Perl *parses* numeric literals and string-to-number conversions is always `.`, regardless of locale; only *formatting* output respects `LC_NUMERIC`. PetaPerl makes no exception to this.
- **Auto-parallelization never touches locale-sensitive code.** PetaPerl auto-parallelizes some numeric loops across worker threads, a capability upstream Perl does not have. Because locale-dependent operations (collation, case folding, number formatting) are never JIT-compiled or parallelized, they always run sequentially against the single process-wide locale - so the feature introduces no locale-safety concern of its own. See *Parallel execution and locale* above.

See also

- `perlfunc` - the built-ins whose behaviour locale changes: `sort`, `lc`, `uc`, `lcfirst`, `ucfirst`, `sprintf`, `printf`.
- `perlop` - the string comparison operators (`lt`, `cmp`, ...) that collate under `LC_COLLATE`.
- `perlvar` - `%ENV` holds the `LANG`/`LC_*` variables; `$!` carries locale-translated error text.
- `POSIX` - `setlocale` and `localeconv`, the interface for choosing and inspecting the active locale.
- `I18N::Langinfo` - `langinfo`, for reading one localized item (month name, radix character) at a time.
- *Unicode strings and encodings* - how the Unicode character model relates to locale `LC_CTYPE`.

5.1.7 Diagnostic messages

When a program goes wrong, Perl tells you about it. Some diagnostics stop the program (`die`-style fatal errors); others print a line to `STDERR` and let it run on (warnings). This reference lists the diagnostics PetaPerl emits, grouped by where they come from, with the cause and the fix for each.

Every entry shows the **message verbatim** in a code span - the exact text the interpreter prints, with the placeholders (`%s`, `%d`, a named variable) shown the way they appear in the output. Search this page for the literal words you saw on `STDERR` and you will land on the entry.

Reading an entry

Each entry opens with the message text, then a short classification badge in parentheses, then the cause and the fix:

> `` `Illegal division by zero` `` **(F)** You divided by zero. Guard the divisor.

The badge follows the same letter code Perl has always used:

Code	Meaning
W	A warning - printed only when warnings are enabled. Optionally restricted to a category (shown as `(W category)`).
D	A deprecation - a warning that a feature is on the way out.
S	A severe warning - on by default, but still only a warning.
F	A fatal error - the program dies unless the error is trapped (`eval`, `try`).
P	An internal error (a panic) - should never reach a user. If you see one, it is a bug in pperl.
X	A very fatal error - the program exits immediately.
A	An alien error - produced by something other than Perl itself.

Enabling and silencing warnings

Warnings (the **W**, **D**, and **S** classes) are controlled by the `warnings` pragma. Without it, only the severe (**S**) warnings print:

```
use warnings;                       # turn on every warning
no warnings;                        # turn them all off (lexically)
no warnings 'uninitialized';        # turn off one category
use warnings FATAL => 'all';        # promote warnings to fatal errors
```

The category named in a `(W category)` badge is the string you pass to `no warnings` to silence just that diagnostic. A single `$SIG{__WARN__}` handler can intercept every warning at runtime; `$SIG{__DIE__}` does the same for fatal errors. See `%SIG`.

A note on portability

PetaPerl runs only on Linux and ships no XS layer. The platform diagnostic families a portable perl carries - VMS status codes, Win32 `GetLastError` text, "unimplemented on this architecture" notices, XS-loader failures - therefore do not arise here. Where upstream Perl documents a diagnostic that only fires on another operating system or through XS, PetaPerl simply never emits it.

The diagnostics

General fatal errors

Runtime dies that are neither regex-compilation nor compile-time syntax errors: method resolution, inheritance, subroutine calls, attributes, and module-level usage errors. All are fatal (**F**) and trappable with `eval` or `try`.

Subroutine calls

`` `Undefined subroutine &%s called` ``

(F) A call named a subroutine that does not exist at call time. The fully-qualified name is shown. Causes: a typo in the name, a missing `use` of the module that defines it, or calling before the `sub` is declared in a context where that matters. The runtime form `` `Undefined subroutine &NAME called at FILE line N.` `` adds the call site.

Method resolution and inheritance

`` `Can't use anonymous symbol table for method lookup` ``

(F) Method dispatch reached a package with no named symbol table (an anonymous stash). A blessed reference must point into a real, named package for method calls to resolve.

`` `Recursive inheritance detected in package '%s'` ``

(F) A class's `@ISA` chain leads back to itself - a cycle. Method resolution cannot proceed. Break the loop in the inheritance graph.

`` `Inconsistent hierarchy during C3 merge of class '%s'` ``

(F) Under the C3 method-resolution order, the linearization of this class's parents has no consistent ordering. Two parents disagree on the order of a shared ancestor. Restructure the inheritance so the parent orderings are compatible, or switch the class back to the default depth-first MRO.

`` `Invalid mro name: '%s'` ``

(F) A `use mro '...'` named an order that does not exist. The two valid names are `` `dfs` `` (the default depth-first order) and `` `c3` ``.

Attributes

`` `Unterminated attribute parameter in attribute list` ``

(F) An attribute with a parenthesized parameter - `:Foo(bar` - was not closed. Balance the parentheses in the attribute list.

Module usage errors

These come from native modules when called incorrectly. They are fatal because the call cannot proceed.

`Usage: POSIX::sprintf(pattern, args...)`

(F) A `POSIX` function was called with the wrong arguments. The message names the correct calling form.

`IO::Socket::%s`

(F) An `IO::Socket` operation failed; the message names the specific call.

See also

- `@ISA` - the inheritance array whose contents the MRO errors are about.
- `mro` - selecting and inspecting the method-resolution order.
- `bless` - associates a reference with the package whose methods the anonymous-symbol-table error is about.
- *Value and type errors* - "Not a subroutine reference" and the other what-kind-of-value diagnostics.

Regex compilation errors

Every diagnostic on this page comes from the pattern compiler. A regular expression is compiled before it runs, and a malformed pattern dies at that point - before the match is ever attempted. The errors are all fatal (**F**); trap them with `eval` if you build patterns from untrusted input:

```
my $re = eval { qr/$user_pattern/ };
die "bad pattern: $@" unless $re;
```

Upstream Perl appends a `marked by <-- HERE in m/.../` suffix that points at the offending position. PetaPerl reports the same errors; the exact position-marker formatting may differ.

Common structural errors

`Unmatched ) in regex`

(F) A `)` in the pattern has no matching `(`. Usually a typo or an unescaped literal parenthesis. To match a literal `)`, escape it as `\)` or put it in a character class `[)]`.

`Quantifier follows nothing in regex`

(F) A quantifier (`*`, `+`, `?`, `{n,m}`) appeared with nothing in front of it to repeat - for example `/*abc/` or `/(?:)+/` on an empty group. Quantify a literal `*` by escaping it: `/\*/`.

`Unterminated group`

(F) A `(` opened a group that the pattern never closes. Balance the parentheses.

`Unterminated character class`

(F) A `[` opened a character class with no closing `]`. To match a literal `]`, place it first in the class (`[]x]`) or escape it (`[\]x]`).

`Unterminated comment group`

(F) A `(?#...)` comment group was opened but not closed with `)`.

`Unterminated conditional pattern`

(F) A `(?(condition)yes|no)` construct was left unclosed.

`Unterminated group name`

(F) A named-group construct (`(?<name>...)`, `\k<name>`) ran to the end of the pattern without closing its name delimiter.

`Unrecognized group type`

(F) The characters after `(?` do not form a group type PetaPerl knows. Check the `(?...)` spelling against the regex reference.

`Unexpected end of character class`

(F) The pattern ended in the middle of a `[...]` class.

`Unexpected end of escape sequence`

(F) A backslash escape was cut off by the end of the pattern.

Character-class and range errors

`Invalid [] range "%s" in regex`

(F) A character range inside `[...]` runs backwards (high to low), as in `[z-a]`. Order the endpoints low to high, or escape the `-` to match it literally.

`Invalid range endpoint in character class`

(F) One end of a `-` range is not a single character (for example a multi-character escape used as an endpoint).

`POSIX class [:%s:] unknown`

(F) A `[:name:]` POSIX class names a class that does not exist. The valid names are `alpha`, `digit`, `alnum`, `space`, `upper`, `lower`, `punct`, `print`, `graph`, `cntrl`, `xdigit`, `blank`, `word`, and `ascii`. A bare `[:alpha:]` outside another `[...]` is also an error - POSIX classes only work *inside* a character class: `[[:alpha:]]`.

`Empty POSIX character class name`

(F) A `[::]` with nothing between the colons.

Control-character and numeric escapes

`Missing control char`

(F) A `\c` escape was not followed by the character it should control, as in a pattern ending in `\c`.

`Missing control character after \c`

(F) Same cause as above, from a different point in the compiler: `\c` needs one following character.

`Invalid control character '\c%s'`

(F) The character after `\c` is not one `\c` accepts.

`Invalid octal escape`

(F) A `\0`/`\o` octal escape is malformed.

`Invalid octal digit in \o{}`

(F) A digit inside `\o{...}` is not 0–7.

`Expected '{' after \o`

(F) `\o` must be followed by `{`, as in `\o{17}`.

`Expected '}' in \o{}` and `Invalid Unicode code point in \o{}`

(F) A `\o{...}` escape is unterminated or names a code point outside the valid range.

`Invalid hex escape` / `Invalid hex digit` / `Expected '}' in hex escape`

(F) A `\x` escape is malformed: a non-hex digit, or an unterminated `\x{...}`.

\g, \k, and group references

`\g0 is not allowed` and `\g{0} is not allowed`

(F) Group 0 is the whole match and cannot be back-referenced. Reference a real capture group (`\g1`, `\g{name}`).

`Invalid group number in \g` / `Invalid group number in \g{}`

(F) The number after `\g` is not a valid group reference.

`Expected digit or '{' after \g` / `Expected '}' after \g{`

(F) `\g` must be followed by a digit, a sign, or `{name}`.

`Reference to nonexistent group number %d`

(F) A `\g`/`\1`-style back-reference names a group number the pattern does not contain.

`Reference to nonexistent group (relative offset %d)`

(F) A relative back-reference (`\g{-2}`) points past the groups that exist.

`Reference to nonexistent named group '%s'`

(F) A `\k<name>` or `\g{name}` references a named group that was never defined.

`Reference to nonexistent or invalid group`

(F) A group reference could not be resolved to any group.

`Expected '<' or '\'' after \k` / `Expected '}' after \k{`

(F) A named back-reference `\k` must be written `\k<name>`, `\k'name'`, or `\k{name}`.

Named groups

`Empty group name`

(F) A named group `(?<>...)` or reference has empty name brackets.

`Group name must not start with a digit`

(F) Group names follow identifier rules; they may not begin with a digit.

\N and Unicode escapes

`\N in character class requires braces`

(F) Inside `[...]`, `\N` must be written `\N{...}`; the bare “any non-newline” form is not allowed in a class.

`\N{NAME} not supported in character class`

(F) A named-character `\N{NAME}` escape is not permitted inside a character class.

`Expected '}' after \N{` / `Empty \N{U+} escape`

(F) A `\N{...}` escape is unterminated or `\N{U+}` has no hex digits.

`Invalid hex in \N{U+...}` / `Invalid Unicode code point in \N{U+...}`

(F) The hex inside `\N{U+...}` is malformed or names a code point outside the Unicode range.

`Invalid Unicode code point`

(F) A code-point escape names a value above the Unicode maximum (`0x10FFFF`).

`Empty Unicode property name` / `Unknown Unicode property name`

(F) A `\p{...}` / `\P{...}` property escape is empty or names a property PetaPerl does not recognize.

`(?...)` extended constructs

`Invalid flag after (?^` / `Invalid flag character`

(F) A flag-setting group `(?flags)` or `(?^flags:...)` contains a character that is not a valid pattern modifier.

`Expected '{' after (??`

(F) A `(??{ code })` postponed-subpattern construct is malformed.

`Expected '<', '=', or '>' after (?P`

(F) The Python-style `(?P<name>...)` / `(?P=name)` / `(?P>name)` construct is malformed.

`Expected DEFINE after (?(` / `Expected ')' after DEFINE`

(F) A `(?(DEFINE)...)` block is malformed.

`Switch condition not recognized in regex` / `Invalid lookaround condition`

(F) The condition in a `(?(...)...)` conditional is not a recognized form (a group number, a lookaround, `R`, or `DEFINE`).

`Expected ')' after condition` family

(F) A conditional construct's condition was not closed with `)`. The variants - `Expected ')' after (?(R...)`, `Expected ')' after code block condition`, `Expected ')' after lookahead condition`, `Expected ')' after lookbehind condition`, `Expected '=' or '!' after (?(<` - all report the same shape of error at different condition types.

Quantifier braces

`Expected '}' after quantifier` / `Expected '}' or ',' in quantifier`

(F) A `{n,m}` quantifier is unterminated or contains an unexpected character.

Lookbehind

`Variable length lookbehind not implemented`

(F) A lookbehind `(?<=...)` / `(?<!...)` whose contents can match a variable number of characters. PetaPerl, like upstream Perl, requires fixed-length lookbehind. Rewrite the lookbehind to a fixed width, or use `\K` to mark a keep-point instead.

Verbs

`Unterminated verb`

(F) A control verb `(*VERB)` / `(*VERB:ARG)` was not closed.

Catch-all

`Regex compilation error at position %d: %s` / `Regular expression error`

(F) A position-tagged compile error for cases the more specific messages above do not cover. The trailing text names the underlying problem.

`Unterminated string in %s`

(F) A delimited construct inside the pattern ran to the end of input without its closing delimiter.

See also

- `qr` - precompile a pattern so a malformed one fails once, at compile time, instead of on every match.
- `m` - the match operator; the same compiler rejects a malformed pattern here.
- `s` - the substitution operator, whose pattern half is compiled by the same engine.
- *Warnings* - the non-fatal regex diagnostics (`Useless use of \E`, `Invalid character in group name`).

Compile-time syntax errors

Errors the parser raises before the program runs. A compile-time error stops the whole program: nothing executes, because the source could not be turned into runnable ops. Unlike runtime `die`s, these are not trappable with `eval BLOCK` - but a string `eval` of source that fails to compile reports them through `$@`:

```
my $code = '1 +';
eval $code;
warn "compile failed: $@" if $@;
```

Subroutine resolution at compile time

`Undefined subroutine &%s`

(F) The parser resolved a call to a named subroutine that does not exist at compile time. This is the compile-time companion to the runtime `Undefined subroutine &%s called` error: the difference is *when* the missing sub is noticed. Make sure the defining module is `use`d, and that the name is spelled correctly and fully qualified where the package matters.

See also

- *General fatal errors* - the runtime form of the undefined-subroutine error.
- *Subroutines* - declaration, prototypes, and the rules that decide when a call resolves.
- `use` - pulls in the module that defines the subroutine, at compile time.

Warnings

Non-fatal diagnostics. A warning prints one line to `STDERR` and the program runs on. The severe (**S**) warnings print even without the `warnings` pragma; the plain **W** warnings print only when warnings are enabled for their category:

```
use warnings;                    # all categories on
no warnings 'recursion';         # silence just deep-recursion
use warnings FATAL => 'utf8';    # make utf8 warnings die instead
```

The category in a `(W category)` badge is exactly the string you pass to `no warnings`.

Deep recursion

`Deep recursion on subroutine "%s"`

(W recursion) A subroutine has called itself (directly or through a chain) more than a hundred levels deep. This is usually a runaway recursion - a base case that never fires - rather than genuinely deep work. The message names the subroutine.

```
use warnings;
```

(continues on next page)

(continued from previous page)

```
sub countdown {
    my $n = shift;
    countdown($n + 1);            # bug: should be $n - 1, never␣
 ↪stops
}
countdown(1);
# Deep recursion on subroutine "main::countdown" at script line 5.
```

Fix the base case. If the recursion really is meant to run deep, silence the category for that scope:

```
no warnings 'recursion';
```

Wide characters

`Wide character in %s`

(S) A string containing a character above codepoint 255 was sent to a byte-oriented operation - most often `print` to a filehandle with no `:encoding` layer. Perl emits the bytes of the internal UTF-8 form and warns, because the output stream was never told it would carry Unicode.

```
use warnings;
print "café\x{2603}\n";          # Wide character in print at ...␣
 ↪line 2.
```

The fix is to tell the stream its encoding:

```
binmode STDOUT, ':encoding(UTF-8)';
print "café\x{2603}\n";          # no warning; correct UTF-8 bytes
```

This is a severe **(S)** warning: it prints even without `use warnings`, because silently emitting raw internal bytes is almost always a bug.

Useless constructs

`Useless use of \E`

(W regexp) An `\E` in a pattern or string closes a `\U`, `\L`, `\Q` case/quote span that was never opened. The `\E` has nothing to end. Remove it, or add the opening `\U`/`\L`/`\Q` it was meant to close.

Group names

`Invalid character in group name`

(W) A regex named group (`(?<name>...)`) contains a character that is not allowed in a group name. Group names follow identifier rules - letters, digits, and underscore, not starting with a digit. The pattern still compiles, treating the construct leniently, but the name is suspect.

Encoding

`Cannot find encoding "%s"`

(S) A `:encoding(...)` layer or an `Encode` call named an encoding that is not available. Check the spelling against the encodings `Encode` supports (`UTF-8`, `Latin-1`, `ASCII`, and the rest).

Catch-all

`Warning: something's wrong`

(W) A generic warning the codegen raises for a condition that has no more specific message. The surrounding context names what triggered it.

See also

- `warnings` - the pragma that enables, scopes, and categorizes every **W** warning.
- `$SIG{__WARN__}` - intercept warnings at runtime instead of letting them reach `STDERR`.
- *Regex compilation errors* - the fatal regex diagnostics, as opposed to the warning-level ones here.
- `Encode` - the encoding names behind the "Cannot find encoding" warning.

Value and type errors

These diagnostics fire when a value is not the kind of thing the operation needs: a plain scalar where a reference was expected, a zero where a divisor was expected, a read-only value where a writable one was expected. All are fatal (**F**) unless noted.

Arithmetic

`Illegal division by zero`

(F) The right-hand side of `/` or `%` evaluated to zero. Numeric division and modulus have no result at zero, so Perl dies rather than returning infinity or `NaN`. Guard the divisor:

```
my $rate = $count ? $total / $count : 0;
```

`Illegal modulus zero`

(F) The right operand of `%` was zero. Same cause and same fix as division by zero, for the modulus operator.

References

`Not a reference`

(F) A dereference (`@$x`, `%$x`, `$$x`, `$x->[0]`, `$x->{k}`) was attempted on a value that is not a reference. Most often `$x` is `undef` or a plain string. Check it first:

```
die "expected an arrayref" unless ref $x eq 'ARRAY';
```

`Not a subroutine reference`

(F) A value used where a code reference was required (for example the second argument to a higher-order function) is not a CODE ref. `set_subname: not a code reference` and `set_prototype: not a code reference` are the same error reported by Sub::Util, and `PadWalker: cv is not a code reference` is the PadWalker form.

Restricted hashes

A hash locked with Hash::Util's lock_keys rejects access to keys outside its allowed set.

`Attempt to access disallowed key '%s' in a restricted hash`

(F) You read or wrote a key that the restricted hash does not permit. Either add the key to the allowed set, or unlock the hash.

`Attempt to delete readonly key '%s' from a restricted hash`

(F) You tried to delete a key that the hash has locked against deletion.

Read-only values

`Modification of a read-only value attempted`

(F) An assignment or in-place operation targeted something that cannot be changed: a literal, a constant, a value passed by the caller and made read-only, or a Readonly/const value. A common surprise is modifying $_ inside a map/grep block when the source list elements are read-only.

Filehandles

`Bad filehandle: %s`

(F) An I/O operation was handed something that is not a usable filehandle - an undefined value, a closed handle, or a bareword that names no open handle. Open the handle (and check the result) before using it:

```
open my $fh, '<', $path or die "open $path: $!";
```

Memory

`Out of memory`

(F) An allocation failed. Usually the program asked for an implausibly large string, array, or hash - check the size you are requesting before assuming the machine is at fault.

See also

- *References* - what a reference is and how dereferencing works; the background for the "Not a reference" errors.
- `ref` - test what kind of reference a value holds before you dereference it.
- `Hash::Util` - `lock_keys`, `unlock_keys`, and the rest of the restricted-hash machinery.
- *General fatal errors* - method-resolution and inheritance errors that are also about what a value is.

Internal errors

A **P** diagnostic is a panic: a check that should never fail in correct operation did fail. These messages are not something your Perl code can cause through ordinary mistakes - they signal a bug in PetaPerl itself. If you see one, it is worth a bug report. See *Disclaimer & bug reports*.

There is nothing to fix on the Perl side. Capture the message, the input that triggered it, and the `pperl` version, and file it.

`Unknown error`

(P) A fallback message for an error path that produced no specific diagnostic - most often surfaced from a native module (such as the GMP bignum backend) when an underlying library returned a failure code with no text. Treat it as an internal error and report it with the operation that triggered it.

See also

- *Disclaimer & bug reports* - how to file a pperl bug, and what to include.
- *pperl-specific diagnostics* - other messages with no upstream Perl counterpart.

pperl-specific diagnostics

Messages PetaPerl emits that have no counterpart in upstream Perl. Most concern the daemon mode - pperl's persistent-process feature, which has no analogue in a stock perl - and a few native modules with pperl-specific behavior.

Daemon mode

`pperl` can run a script as a resident daemon and dispatch requests to it, which avoids paying interpreter startup on every call. The daemon diagnostics report problems with that channel.

`Daemon already running for this script (socket: %s)`

(F)

A `--daemon` start was requested for a script that already has a running daemon. The socket path is shown. Stop the existing daemon first, or connect to it instead of starting a new one.

`Cannot connect to daemon (%s): %s`

(F)

A client could not reach the daemon socket. The message continues with one of two hints depending on context - `Start with: pperl --daemon <script>` when no daemon appears to be running, or `Is the daemon running?` when the socket exists but the connection failed. Start the daemon, or check that the socket path matches.

Native modules

`ERRNO hash is read only!`

(F)

Code tried to assign to `%!` (the `Errno` symbolic-error hash) or to one of its keys. That hash is populated by the runtime and reflects the current `errno`; it is not writable. Read it (`$!{ENOENT}`) rather than assigning to it.

`Hash has key '%s' which is not in the new key set`

(F)

From `Hash::Util`: a `lock_keys` call supplied an explicit key set that does not include a key the hash already contains. Locking cannot proceed because that existing key would become inaccessible. Either include the existing key in the new set, or delete it before locking.

`Time::HiRes::usleep(%s): negative time not invented yet`

(F)

A `Time::HiRes` sleep function was given a negative duration. Time runs forward; pass a non-negative number of microseconds (or nanoseconds for `nanosleep`). The `nanosleep` form reports the same with its own name.

`%s version %s required--this is only version %s`

(F)

A `use Module VERSION` (or an explicit version check) demanded a newer version of a module than the one installed. The message names the module, the version requested, and the version present. Install or load the required version.

5.1.8 Security and taint mode

Security in a Perl program is mostly about not trusting data that came from outside the program: command-line arguments, the environment, file contents, network input. The dangerous step is not reading that data but *acting* on it. A filename that arrives from a web form is harmless until it reaches `open`; an environment variable is harmless until it steers a `system` call. This page describes the mechanism PetaPerl gives you to make that boundary explicit: taint mode. It explains what taint mode is, when it turns on, what it marks as untrusted, and how data is cleaned.

Taint mode

PetaPerl runs the perl5 5.44 core, so taint mode is the real perl5 taint machinery, not an approximation. Every check perl5 performs, PetaPerl performs.

Taint mode turns on automatically when PetaPerl detects that it is running with differing real and effective user or group IDs, which is how a setuid (Unix mode `04000`) or setgid (mode `02000`) script is run. You can also enable it explicitly with the `-T` command-line switch. `-T` is strongly recommended for any program run on behalf of someone else, a CGI script being the classic case. Once taint mode is on, it stays on for the rest of the program; it cannot be turned off from inside.

The switch must appear early enough that the interpreter sees it before it starts parsing your program. On the `#!` line of a script this is automatic. On the command line, put it among the first switches. The related `-t` switch enables the same checks but downgrades the fatal errors to warnings, which is useful when retrofitting taint mode onto

an existing program: you see every place that *would* fail without the program dying at the first one.

The read-only variable `${^TAINT}` reports the current state:

`${^TAINT}`	Meaning
`1`	Taint mode on, fatal (`-T`)
`-1`	Taint checks on, warn only (`-t`)
`0`	Taint mode off

What gets tainted

When taint mode is on, any value that came from outside the program is marked tainted, and that mark propagates through every expression the value touches. The tainted sources are:

- command-line arguments (`@ARGV`) and the environment (`%ENV`);
- all file input;
- the results of `readdir` and `readlink`, the variable read by `shmread`, the messages from `msgrcv`, and the password, gcos, and shell fields returned by the `getpw*` calls;
- locale data (see `perllocale`).

Tainted data may not be used, directly or indirectly, in any operation that starts a sub-shell or that modifies a file, directory, or process. Using it in such an operation is fatal, with a message like `Insecure dependency in %s` or `Insecure $ENV{PATH}`. There are three exceptions:

- arguments to `print` and `syswrite` are **not** checked;
- symbolic method calls (`$obj->$method(@args)`) and symbolic subroutine references (`$foo->(@args)`) are **not** checked, so validate those names yourself if they can come from outside;
- hash keys are **never** tainted.

For efficiency, taint is tracked conservatively: if any part of an expression is tainted, the whole expression is treated as tainted, even where the tainted value does not actually influence the result. Taint attaches to individual scalar values, so some elements of an array or hash can be tainted while others are not.

```
my $arg  = shift;           # tainted (from @ARGV)
my $hid  = $arg . 'bar';    # also tainted
my $line = <STDIN>;         # tainted (file input)
my $data = 'abc';           # not tainted

system "echo $arg";         # dies: Insecure dependency
system "/bin/echo", $arg;   # dies: tainted argument
system "echo $data";        # dies until PATH is cleaned (see
 ↪below)
```

The one structural exception to whole-expression tainting is the ternary `?:` operator. Because

```
my $result = $tainted ? "untainted" : "also untainted";
```

is just a conditional choice between two constants, `$result` is not tainted even though the condition is.

Laundering and detecting tainted data

The **only** way to clear the taint on a value is to extract a substring of it through a regular-expression capture. PetaPerl assumes that if you bother to write a pattern and pull out `$1`, you have thought about what you are willing to accept. Untaint by validating against a whitelist of acceptable characters, never by trying to strip out the bad ones:

```
if ($data =~ /^([-\@\w.]+)$/) {
    $data = $1;              # $data is now untainted
} else {
    die "rejected suspicious input";
}
```

This is reasonably safe because `\w`, a dot, a dash, and an at sign do not carry special meaning to a shell. A pattern like `/(.+)/` would "launder" the value while accepting anything, which defeats the purpose. Be deliberate about the pattern.

There is a locale caveat. Under `use locale` the set of characters that `\w` matches is itself drawn from the locale, which is external data PetaPerl does not trust, so a `\w` match under `use locale` does **not** untaint. If you need to launder with `\w` in a locale-aware program, put `no locale` ahead of the match in the same block.

To test whether a value is tainted, use `tainted` from the `Scalar::Util` module. Under `-T` it correctly reports the taint state of its argument.

Cleaning up %ENV and $ENV{PATH}

A tainted `PATH` is the most common surprise. Because PetaPerl cannot know that a program it runs will not itself consult `PATH`, it refuses to start a sub-process while `$ENV{PATH}` is tainted, with `Insecure $ENV{PATH}`. Every directory in the path must be absolute and writable only by its owner and group; a writable directory yields `Insecure directory in %s`. Note that an empty path component is treated as `.` (the current directory) and also triggers the message.

`PATH` is not the only offender. Because a shell may consult `IFS`, `CDPATH`, `ENV`, and `BASH_ENV`, PetaPerl requires those to be empty or untainted before it will start a sub-process, reporting `Insecure $ENV{%s}` otherwise. Set a known-good `PATH` and delete the shell variables early:

```
$ENV{PATH} = '/bin:/usr/bin';
delete @ENV{qw(IFS CDPATH ENV BASH_ENV)};
```

When you must open a file or pipe from a privileged (setuid or setgid) program, the safe pattern is to fork a child, have the child drop its privileges back to the real user and group, and let the unprivileged child do the work and pass the result back over a pipe:

```
use English;
die "can't fork: $!" unless defined(my $pid = open(my $kid, "-|"));
if ($pid) {                             # parent
    while (<$kid>) {
        # consume the child's output
    }
    close $kid;
} else {                                # child
    my @priv     = ($EUID, $EGID);
    my $real_uid = $UID;
    my $real_gid = $GID;
    $EUID = $UID;
    $EGID = $GID;
    $UID  = $real_uid;                  # drop privileges
    $GID  = $real_gid;
    ($EUID, $EGID) = @priv;             # make sure they are gone
    die "can't drop privileges"
        unless $UID == $EUID && $GID == $EGID;
    $ENV{PATH} = '/bin:/usr/bin';
    exec 'myprog', 'arg1', 'arg2'
        or die "can't exec myprog: $!";
}
```

Note that `exec` is called with a list, never a single string, so no shell is involved to re-expand the arguments. This is the safest way to invoke an external command. The same fork-and-drop strategy works for `glob` and backticks, which (unlike `system` and `exec`) offer no list-form calling convention of their own.

Taint mode and @INC

Under `-T`, PetaPerl ignores the `PERL5LIB`, `PERLLIB`, and `PERL_USE_UNSAFE_INC` environment variables. They are ignored because they are easy to set without a user noticing, which would let the environment inject library directories silently. You can still adjust the module search path with the visible `-I` switch or the `lib` pragma (`-Mlib=/path`), because those appear plainly on the command line.

The current directory `.` is **not** in the default `@INC`, taint mode or not. (`PERL_USE_UNSAFE_INC=1` would re-add it, but that variable is itself ignored under `-T`, so `.` stays out of `@INC` for any tainted program.)

Set-id scripts and the shebang race

PetaPerl detects the setuid/setgid condition (real user or group ID differing from the effective one) and enables taint mode accordingly; the “while running setuid” / “while running setgid” wording in the insecurity messages comes from that detection. PetaPerl does **not**, however, ship a setuid `pperl` install or any set-id helper. If you need a privileged Perl program, the supported approach on Linux is a small dedicated setuid wrapper that sanitises the environment and then execs the interpreter on a fixed, non-writable script path, rather than relying on a setuid script directly. The classic shebang race, where the kernel and the interpreter open the script file at two different

moments and an attacker swaps the file in between, is a property of kernel set-id-script handling, not of the interpreter, and the wrapper approach sidesteps it.

Algorithmic complexity attacks

Some internal algorithms can be driven to consume disproportionate time or memory by carefully chosen input, which is a denial-of-service vector independent of taint mode. The threat classes:

- **Hash collisions.** An attacker who can predict the hash seed can craft keys that all land in one bucket, degrading hash operations. pperl randomises the hash seed at process start and randomises the visible order of `keys`, `values`, and `each` per hash. Two environment variables override these defaults for debugging: `PERL_HASH_SEED` pins the seed (which controls storage, not the presented order) and `PERL_PERTURB_KEYS` controls traversal-order perturbation; the `Hash::Util` function `hash_traversal_mask` does the same per hash. These overrides weaken the protection and are not advised in production. PetaPerl has never guaranteed any hash key ordering; do not rely on it, and do not use the pseudo-random ordering as a shuffle.
- **Catastrophic regex backtracking.** The regular-expression engine is an NFA and can take time or space that grows steeply when a pattern can match an input in many ways. A hostile input matched against a vulnerable pattern can exhaust memory or CPU. Bound the input size and prefer patterns that cannot backtrack pathologically.
- **Sort.** `sort` uses mergesort, whose worst case is bounded, so it cannot be driven into quadratic behaviour by adversarial input.

Tied hashes may carry their own ordering and their own complexity characteristics.

Differences from upstream

- **Linux only.** PetaPerl runs only on Linux. The VMS, Windows, and other-platform set-id and security discussion that upstream Perl carries has no counterpart here and is simply absent.
- **No "protection" tooling.** PetaPerl has no bytecode compiler and no source-filter obfuscation machinery, so the upstream advice about shipping compiled or filtered source does not apply. Obscuring source was never a security measure in any case.

- `Hash::Util` - `hash_traversal_mask`, for per-hash control of traversal-order randomisation.

5.2 Modules

Built-in modules, by top-level namespace. Badges show the feature tier and any extra Cargo features required - see *Disclaimer & bug reports* for how to check which features your pperl binary has.

- `AE` - simpler/faster/newer/cooler AnyEvent API
- `AnyDBM_File` - provide framework for multiple DBMs
- `AnyEvent` - the DBI of event loop programming
  :: [`DNS`, `Debug`, `Handle`, `IO`, `Impl`, `Log`, `Loop`, `Socket`, `Strict`, `TLS`, `Util`]
- `App` :: [`Cpan`, `Prove`]
- `Archive` :: [`Tar`]
- `Attribute` :: [`Handlers`]
- `AutoLoader` - load subroutines only on demand
- `AutoSplit` - split a package for autoloading
- `B` - Inspect a running Perl program's own optree, symbol table, and compiled subs.
  :: [`AV`, `BINOP`, `BM`, `COP`, `COW`, `CV`, `Concise`, `Deparse`, `FM`, `GV`, `HE`, `HV`, `IO`, `IV`, `LISTOP`, `LOGOP`, `LOOP`, `MAGIC`, `METHOP`, `NV`, `OP`, `Op_private`, `PADLIST`, `PADNAME`, `PADNAMELIST`, `PADOP`, `PMOP`, `PV`, `PVLV`, `PVMG`, `RHE`, `SV`, `SVOP`, `Showlex`, `Terse`, `UNOP`, `UNOP_AUX`, `Xref`]
- `Benchmark` - Benchmark running times of Perl code
- `CPAN` - query, download and build perl modules from CPAN sites
  :: [`Debug`, `Distroprefs`, `FirstTime`, `HandleConfig`, `Kwalify`, `Meta`, `Mirrors`, `Nox`, `Plugin`, `Queue`, `Tarzip`, `Version`]
- `Cairo` - Perl bindings for cairo, the 2D vector graphics library.
  :: [`Context`, `Font`, `FontFace`, `FontOptions`, `Format`, `FtFontFace`, `Gradient`, `ImageSurface`, `LinearGradient`, `Matrix`, `Pattern`, `PdfSurface`, `PsSurface`, `RadialGradient`, `RecordingSurface`, `Region`, `ScaledFont`, `SolidPattern`, `Surface`, `SurfacePattern`, `SvgSurface`, `ToyFontFace`]
- `Capture` :: [`Tiny`]
- `Carp` - alternative warn and die for modules
- `Class` :: [`Inspector`, `Load`, `MOP`, `Struct`, `XSAccessor`]
- `Clone` - Make a deep, independent copy of any Perl value - hashes, arrays, scalars, references, blessed objects, tied variables, and weak references.
- `Compress` :: [`Raw`, `Zlib`]
- `Config` - Look up the build-time configuration of the running Perl interpreter.
  :: [`Extensions`, `Perl`]

- Coro - the only real threads in perl
  :: [AIO, AnyEvent, BDB, Channel, Debug, EV, Event, Handle, LWP, RWLock, Select, Semaphore, SemaphoreSet, Signal, Socket, Specific, State, Storable, Timer, Util]
- Crypt :: [OpenSSL]
- Cwd - Report the current working directory and resolve paths to their absolute, symlink-free form.
- DB - programmatic interface to the Perl debugging API
- DBD :: [DBM, File, Gofer, Mem, Proxy, SQLite, Sponge]
- DBI - Database independent interface for Perl
  :: [Const, DBD, Gofer, Profile, ProfileData, ProfileDumper, ProfileSubs, ProxyServer, PurePerl, SQL, Util]
- DBM_Filter - Filter DBM keys/values
  :: [compress, encode, int32, null, utf8]
- DB_File - Tie a Perl hash or array to a database file: a hash table, a sorted B-tree, or an array of records kept in a plain text file.
- Data :: [Dumper, UUID]
- Devel :: [Cover, Peek, SelfStubber, Size]
- Digest - Modules that calculate message digests
  :: [MD5, SHA, SHA1, base, file]
- DirHandle - (obsolete) supply object methods for directory handles
- Dumpvalue - provides screen dump of Perl data.
- DynaLoader - Dynamically load C libraries into Perl code
- EV - A fast, full-featured event loop: call your code when a file handle is readable or writable, a timer expires, a signal arrives, a child process changes state or a file changes.
  :: [Async, Child, Embed, IO, Loop, Periodic, Signal, Stat, Timer, Watcher]
- Encode - Convert between Perl character strings and byte encodings.
  :: [Alias, Byte, CJKConstants, CN, Config, EBCDIC, Encoder, Encoding, GSM0338, Guess, JP, KR, MIME, Symbol, TW, Unicode, XS, utf8]
- English - use nice English (or awk) names for ugly punctuation variables
- Env - perl module that imports environment variables as scalars or arrays
- Errno - Symbolic names for the `errno(3)` values your system uses - EINTR, EAGAIN, ENOENT, EACCES, EEXIST, EIO, ENOTDIR, EISDIR, EBUSY, EPIPE, ECONNRESET, ECONNREFUSED, ETIMEDOUT, and every other errno name the host libc defines.
- Event - an event loop: watchers for timers, file descriptors,
  :: [Event, Watcher, generic, group, idle, io, signal, timer, var]
- Exporter - Implements default import method for modules
  :: [Heavy]

- ExtUtils :: [CBuilder, Command, Embed, HasCompiler, Install, Installed, Liblist, MM, MM_Any, MM_Unix, MY, MakeMaker, Manifest, Miniperl, PL2Bat, Packlist, testlib]
- FFI :: [Build, CheckLib, Platypus, Probe, Temp]
- Fatal - Replace functions with equivalents which succeed or die
- Fcntl - Symbolic constants for `fcntl(2)`, `flock(2)`, `lseek(2)`, and file-mode bits - everything you need to call `sysopen`, `fcntl`, `flock`, `seek`, and to interpret the mode word returned by `stat`.
- File :: [Basename, Compare, Copy, DosGlob, Fetch, Find, Glob, GlobMapper, Map, Path, ShareDir, Spec, Temp, Which, stat]
- FileCache - keep more files open than the system permits
- FileHandle - supply object methods for filehandles
- Filter :: [Simple, Util, cpp, decrypt, exec, m4, sh, tee]
- FindBin - Locate directory of original Perl script
- GD - Perl bindings for libgd, the GD graphics library.
  :: [Group, Image, Polygon, Polyline, Simple]
- GDBM_File - Tie a Perl hash to a database file with GNU dbm's interface: its open modes, error codes, options, dumps and recovery calls.
- Getopt :: [Long, Std]
- Guard - run a piece of code when a scope ends or an object goes away
- HTML :: [Entities, Filter, HeadParser, LinkExtor, Parser, PullParser, Tagset, TokeParser]
- HTTP :: [Parser, Tiny]
- Hash :: [Util]
- I18N :: [Collate, LangTags, Langinfo]
- IO - Load the core IO modules - `IO::Handle`, `IO::File`, `IO::Seekable`, `IO::Pipe`, `IO::Socket`, `IO::Dir` - in one `use`.
  :: [Compress, Dir, File, Handle, Pipe, Poll, Pty, Seekable, Select, Socket, Tty, Uncompress, Zlib]
- IPC :: [Cmd, Msg, Open2, Open3, Semaphore, SharedMem, SysV]
- Imager - Perl bindings for Imager, the raster graphics library.
  :: [Color, Expr, Fill, Font, Fountain, Matrix2d, Regops, Test, Transform, TrimColorList]
- JSON :: [PP, XS]
- LMDB_File - Tie a Perl hash to an LMDB database, or drive LMDB's environments, transactions and cursors directly.
- List :: [MoreUtils, Util]
- Locale :: [Maketext]
- MIME :: [Base64, Charset, QuotedPrint]

- Math :: [BigFloat, BigInt, BigRat, Complex, GMP, Random, Trig]
- Memoize - Make functions faster by trading space for time - cache a function's results by its arguments and return the cached result on a repeated call.
  :: [AnyDBM_File, Expire, NDBM_File, SDBM_File, Storable]
- Module :: [CoreList, Load, Loaded, Metadata]
- Moose - The compiled part of Moose and Class::MOP: the attribute readers of the metaclass objects, the method map cache, and a few helpers of Moose::Exporter, the type constraints and role application.
- NDBM_File - Tie a Perl hash to an ndbm database file, so keys and values persist between runs.
- NEXT - Provide a pseudo-class NEXT (et al) that allows method redispatch
- Net :: [Cmd, Config, Domain, FTP, NNTP, Netrc, POP3, Ping, SMTP, SSLeay, Time, hostent, netent, protoent, servent]
- O - Generic interface to Perl Compiler backends
- ODBM_File - Tie a Perl hash to an old-style dbm database file.
- Opcode - Name, group and mask the interpreter's opcodes - the machinery `Safe` compartments are built from.
- PDL - the Perl Data Language: fast, vectorised, multidimensional arrays for scientific and bulk numeric work
  :: [Bad, Basic, Complex, Compression, Constants, Core, Exporter, FFT, IO, Image2D, ImageND, ImageRGB, Lite, LiteF, Math, MatrixOps, Ops, Options, PP, Primitive, Slices, Trans, Transform, Types, Ufunc]
- POSIX - The POSIX (IEEE Std 1003.1) C standard library, exposed to Perl.
  :: [SigSet, Termios]
- Package :: [Stash]
- PadWalker - Reach into another subroutine's `my` and `our` variables - read them, change them, find out their names - from anywhere on the call stack.
- Params :: [Check, Util]
- Parse :: [CPAN]
- Perl :: [OSType]
- PerlIO - On demand loader for PerlIO layers and root of PerlIO::* name space
  :: [encoding, mmap, scalar, utf8_strict, via]
- Peta :: [Dict, FFI, ReadLine, Shell, WebGPU, XS]
- Pod :: [Checker, Escapes, Functions, Html, Man, ParseLink, Perldoc, Simple, Text, Usage]
- SDBM_File - Tie a Perl hash to an on-disk SDBM database so keys and values persist between runs.
- SDL2 - Perl bindings for SDL2 - windows, input, timers and hardware-accelerated 2D drawing.
  :: [Events, Image, Render, Surface, Video]

- Safe - Compile and execute code in restricted compartments
- Scalar :: [List, Util]
- Search :: [Dict]
- SelectSaver - save and restore selected file handle
- SelfLoader - load functions only on demand
- Socket - BSD socket constants and address pack/unpack helpers that feed Perl's built-in socket, bind, connect, accept, send, recv, setsockopt, and shutdown.
- Storable - Serialise arbitrary Perl data structures to bytes, reconstruct them later, or deep-clone them in memory.
- String :: [CRC32]
- Sub :: [Exporter, Identify, Name, Util]
- Symbol - manipulate Perl symbols and their names
- Sys :: [Hostname, Syslog]
- TAP :: [Base, Formatter, Harness, Object, Parser]
- Template :: [Stash]
- Term :: [ANSIColor, Cap, Complete, ReadKey, ReadLine, Table]
- Test - provides a simple framework for writing test scripts
  :: [Builder, Harness, LeakTrace, More, Simple, Tester, use]
- Test2 - Framework for writing test tools that all work together.
  :: [API, AsyncSubtest, Bundle, Compare, Env, Event, EventFacet, Formatter, Handle, Hub, IPC, Manual, Mock, Plugin, Require, Suite, Todo, Tools, Util, V0, V1, Workflow]
- Text :: [Abbrev, Balanced, CSV, CSV_PP, LevenshteinXS, LineFold, ParseWords, Tabs, Wrap]
- Thread - Manipulate threads in Perl (for old code only)
  :: [Queue, Semaphore]
- Tie :: [Array, File, Handle, Hash, Memoize, RefHash, Scalar, StdHandle, SubstrHash]
- Time :: [HiRes, Local, Piece, Seconds, gmtime, localtime, tm]
- Types :: [Serialiser]
- UNIVERSAL - base class for ALL classes (blessed references)
- URL :: [Encode]
- Unicode :: [Collate, GCString, LineBreak, Normalize, UCD]
- User :: [grent, pwent]
- XML :: [Parser]
- XSLoader - Start the native part of a module
- XString - The string quoting helpers of B, without loading B.

- YAML :: [LibYAML, PP, XS]
- _charnames - the Unicode character name table behind \N{NAME},
- attributes - The machinery behind sub name :attr and my $x :attr: applying the built-in attributes, handing the others to the package that defines them, and reading attributes back.
- autodie - Replace functions with ones that succeed or die with lexical scope :: [Scope, Util, exception, hints, skip]
- autouse - postpone load of modules until a function is used
- base - Establish an ISA relationship with base classes at compile time
- bigfloat - transparent big floating point number support for Perl
- bigint - transparent big integer support for Perl
- bignum - transparent big number support for Perl
- bigrat - transparent big rational number support for Perl
- blib - Use MakeMaker's uninstalled version of a package
- builtin - Perl pragma to import built-in utility functions
- bytes - Perl pragma to expose the individual bytes of characters
- charnames - access to Unicode character names and named character sequences; also define character names
- constant - Perl pragma to declare constants
- deprecate - Perl pragma for deprecating the inclusion of a module in core
- diagnostics - produce verbose warning diagnostics
- encoding - allows you to write your script in non-ASCII and non-UTF-8 :: [warnings]
- experimental - Experimental features made easy
- feature - Perl pragma to enable new features
- fields - compile-time class fields
- filetest - Perl pragma to control the filetest permission operators
- if - use a Perl module if a condition holds
- integer - Perl pragma to use integer arithmetic instead of floating point
- less - perl pragma to request less of something
- lib - manipulate @INC at compile time
- locale - Perl pragma to use or avoid POSIX locales for built-in operations
- mro - Method Resolution Order - how Perl decides which parent class's method a call inherits.
- ok - Alternative to Test::More::use_ok
- open - perl pragma to set default PerlIO layers for input and output

- ops - Perl pragma to restrict unsafe operations when compiling
- overload - Package for overloading Perl operations
- overloading - perl pragma to lexically control overloading
- parent - Establish an ISA relationship with base classes at compile time
- perlfaq - Frequently asked questions about Perl
- re - The re pragma and regular-expression introspection module.
- sigtrap - Perl pragma to enable simple signal handling
- sort - perl pragma to control sort() behaviour
- source :: [encoding]
- stable - Experimental features made easy, once we know they're stable
- strict - Perl pragma to restrict unsafe constructs
- subs - Perl pragma to predeclare subroutine names
- threads - Perl interpreter-based threads
  :: [shared]
- utf8 - Perl pragma to enable/disable UTF-8 (or UTF-EBCDIC) in source code
- vars - Perl pragma to predeclare global variable names
- version - Turn a version string into an object you can compare, print, and introspect.
- warnings - Perl pragma to control optional warnings
  :: [register]

5.2.1 AE

simpler/faster/newer/cooler AnyEvent API

SYNOPSIS

```
use AnyEvent; # not AE

# file handle or descriptor readable
my $w = AE::io $fh, 0, sub { ...  };

# one-shot or repeating timers
my $w = AE::timer $seconds,         0, sub { ... }; # once
my $w = AE::timer $seconds, $interval, sub { ... }; # repeated

print AE::now;  # prints current event loop time
print AE::time; # think Time::HiRes::time or simply CORE::time.

# POSIX signal
my $w = AE::signal TERM => sub { ... };
```

(continues on next page)

(continued from previous page)

```
# child process exit
my $w = AE::child $pid, sub {
   my ($pid, $status) = @_;
   ...
};

# called when event loop idle (if applicable)
my $w = AE::idle sub { ... };

my $cv = AE::cv; # stores whether a condition was flagged
$cv->send; # wake up current and all future recv's
$cv->recv; # enters "main loop" till $condvar gets ->send
# use a condvar in callback mode:
$cv->cb (sub { $_[0]->recv });
```

DESCRIPTION

This module documents the new simpler AnyEvent API.

The rationale for the new API is that experience with *EV* shows that this API actually "works", despite its lack of extensibility, leading to a shorter, easier and faster API.

The main differences from AnyEvent is that function calls are used instead of method calls, and that no named arguments are used.

This makes calls to watcher creation functions really short, which can make a program more readable despite the lack of named parameters. Function calls also allow more static type checking than method calls, so many mistakes are caught at compile-time with this API.

Also, some backends (Perl and EV) are so fast that the method call overhead is very noticeable (with EV it increases the execution time five- to six-fold, with Perl the method call overhead is about a factor of two).

Note that the AE API is an alternative to, not the future version of, the AnyEvent API. Both APIs can be used interchangeably and there are no plans to "switch", so if in doubt, feel free to use the *AnyEvent* API in new code.

As the AE API is complementary, not everything in the AnyEvent API is available, and you still need to use AnyEvent for the finer stuff. Also, you should not `use AE` directly, `use AnyEvent` will provide the AE namespace.

At the moment, these functions will become slower then their method-call counterparts when using *AnyEvent::Strict* or *AnyEvent::Debug*::wrap.

FUNCTIONS

This section briefly describes the alternative watcher constructors and other functions available inside the AE namespace. Semantics are not described here; please refer to the description of the function or method with the same name in the *AnyEvent* manpage for the details.

- $w = AE::io $fh_or_fd, $watch_write, $cb

Creates an I/O watcher that listens for read events (`$watch_write` false) or write events (`$watch_write` is true) on the file handle or file descriptor `$fh_or_fd`.

The callback `$cb` is invoked as soon and as long as I/O of the type specified by `$watch_write`) can be done on the file handle/descriptor.

Example: wait until STDIN becomes readable.

```
$stdin_ready = AE::io *STDIN, 0, sub { scalar <STDIN> };
```

Example: wait until STDOUT becomes writable and print something.

```
$stdout_ready = AE::io *STDOUT, 1, sub { print STDOUT "woaw\n" }
 ↪;
```

- $w = AE::timer $after, $interval, $cb

  Creates a timer watcher that invokes the callback `$cb` after at least `$after` second have passed (`$after` can be negative or `0`).

  If `$interval` is `0`, then the callback will only be invoked once, otherwise it must be a positive number of seconds that specifies the interval between successive invocations of the callback.

  Example: print “too late” after at least one second has passed.

  ```
  $timer_once = AE::timer 1, 0, sub { print "too late\n" };
  ```

  Example: print “blubb” once a second, starting as soon as possible.

  ```
  $timer_repeated = AE::timer 0, 1, sub { print "blubb\n" };
  ```

- $w = AE::signal $signame, $cb

  Invoke the callback `$cb` each time one or more occurrences of the named signal `$signame` are detected.

- $w = AE::child $pid, $cb

  Invokes the callback `$cb` when the child with the given `$pid` exits (or all children, when `$pid` is zero).

  The callback will get the actual pid and exit status as arguments.

- $w = AE::idle $cb

  Invoke the callback `$cb` each time the event loop is “idle” (has no events outstanding), but do not prevent the event loop from polling for more events.

- $cv = AE::cv

- $cv = AE::cv { BLOCK }

  Create a new condition variable. The first form is identical to `AnyEvent->condvar`, the second form additionally sets the callback (as if the `cb` method is called on the condition variable).

- AE::now

  Returns the current event loop time (may be cached by the event loop).

- AE::now_update

  Ensures that the current event loop time is up to date.

- AE::time

  Return the current time (not cached, always consults a hardware clock).

- AE::postpone { BLOCK }

  Exactly the same as `AnyEvent::postpone`.

- AE::log $level, $msg[, @args]

  Exactly the same as `AnyEvent::log` (or `AnyEvent::Log::log`).

5.2.2 AnyDBM_File

provide framework for multiple DBMs

NDBM_File, DB_File, GDBM_File, SDBM_File, ODBM_File - various DBM implementations

SYNOPSIS

```
use AnyDBM_File;
```

DESCRIPTION

This module is a "pure virtual base class"–it has nothing of its own. It's just there to inherit from one of the various DBM packages. It prefers ndbm for compatibility reasons with Perl 4, then Berkeley DB (See *DB_File*), GDBM, SDBM (which is always there–it comes with Perl), and finally ODBM. This way old programs that used to use NDBM via dbmopen() can still do so, but new ones can reorder @ISA:

```
BEGIN { @AnyDBM_File::ISA = qw(DB_File GDBM_File NDBM_File) }
use AnyDBM_File;
```

Having multiple DBM implementations makes it trivial to copy database formats:

```
use Fcntl; use NDBM_File; use DB_File;
tie %newhash,  'DB_File', $new_filename, O_CREAT|O_RDWR;
tie %oldhash,  'NDBM_File', $old_filename, 1, 0;
%newhash = %oldhash;
```

DBM Comparisons

Here's a partial table of features the different packages offer:

```
                        odbm     ndbm     sdbm     gdbm     bsd-db
                        ----     ----     ----     ----     ------
Linkage comes w/ perl   yes      yes      yes      yes      yes
Src comes w/ perl       no       no       yes      no       no
Comes w/ many unix os   yes      yes[0]   no       no       no
Builds ok on !unix      ?        ?        yes      yes      ?
Code Size               ?        ?        small    big      big
Database Size           ?        ?        small    big?     ok[1]
Speed                   ?        ?        slow     ok       fast
FTPable                 no       no       yes      yes      yes
Easy to build          N/A      N/A       yes      yes      ok[2]
Size limits             1k       4k       1k[3]    none     none
Byte-order independent  no       no       no       no       yes
Licensing restrictions  ?        ?        no       yes      no
```

- [0]

  on mixed universe machines, may be in the bsd compat library, which is often shunned.

- [1]

  Can be trimmed if you compile for one access method.

- [2]

  See *DB_File*. Requires symbolic links.

- [3]

  By default, but can be redefined.

5.2.3 AnyEvent

the DBI of event loop programming

EV, Event, Glib, Tk, UV, Perl, Event::Lib, Irssi, rxvt-unicode, IO::Async, Qt, FLTK and POE are various supported event loops/environments.

SYNOPSIS

```
use AnyEvent;

# if you prefer function calls, look at the AE manpage for
# an alternative API.

```

(continues on next page)

(continued from previous page)

```
# file handle or descriptor readable
my $w = AnyEvent->io (fh => $fh, poll => "r", cb => sub { ...  });

# one-shot or repeating timers
my $w = AnyEvent->timer (after => $seconds, cb => sub { ...  });
my $w = AnyEvent->timer (after => $seconds, interval => $seconds, cb
 ↪=> ...);

print AnyEvent->now;  # prints current event loop time
print AnyEvent->time; # think Time::HiRes::time or simply
 ↪CORE::time.

# POSIX signal
my $w = AnyEvent->signal (signal => "TERM", cb => sub { ... });

# child process exit
my $w = AnyEvent->child (pid => $pid, cb => sub {
   my ($pid, $status) = @_;
   ...
});

# called when event loop idle (if applicable)
my $w = AnyEvent->idle (cb => sub { ... });

my $w = AnyEvent->condvar; # stores whether a condition was flagged
$w->send; # wake up current and all future recv's
$w->recv; # enters "main loop" till $condvar gets ->send
# use a condvar in callback mode:
$w->cb (sub { $_[0]->recv });
```

INTRODUCTION/TUTORIAL

This manpage is mainly a reference manual. If you are interested in a tutorial or some gentle introduction, have a look at the AnyEvent::Intro manpage.

SUPPORT

An FAQ document is available as AnyEvent::FAQ.

There also is a mailinglist for discussing all things AnyEvent, and an IRC channel, too.

See the AnyEvent project page at the **Schmorpforge Ta-Sa Software Repository**, at http://anyevent.schmorp.de, for more info.

WHY YOU SHOULD USE THIS MODULE (OR NOT)

Glib, POE, IO::Async, Event... CPAN offers event models by the dozen nowadays. So what is different about AnyEvent?

Executive Summary: AnyEvent is *compatible*, AnyEvent is *free of policy* and AnyEvent is *small and efficient*.

First and foremost, *AnyEvent is not an event model* itself, it only interfaces to whatever event model the main program happens to use, in a pragmatic way. For event models and certain classes of immortals alike, the statement "there can only be one" is a bitter reality: In general, only one event loop can be active at the same time in a process. AnyEvent cannot change this, but it can hide the differences between those event loops.

The goal of AnyEvent is to offer module authors the ability to do event programming (waiting for I/O or timer events) without subscribing to a religion, a way of living, and most importantly: without forcing your module users into the same thing by forcing them to use the same event model you use.

For modules like POE or IO::Async (which is a total misnomer as it is actually doing all I/O *synchronously*...), using them in your module is like joining a cult: After you join, you are dependent on them and you cannot use anything else, as they are simply incompatible to everything that isn't them. What's worse, all the potential users of your module are *also* forced to use the same event loop you use.

AnyEvent is different: AnyEvent + POE works fine. AnyEvent + Glib works fine. AnyEvent + Tk works fine etc. etc. but none of these work together with the rest: POE + EV? No go. Tk + Event? No go. Again: if your module uses one of those, every user of your module has to use it, too. But if your module uses AnyEvent, it works transparently with all event models it supports (including stuff like IO::Async, as long as those use one of the supported event loops. It is easy to add new event loops to AnyEvent, too, so it is future-proof).

In addition to being free of having to use *the one and only true event model*, AnyEvent also is free of bloat and policy: with POE or similar modules, you get an enormous amount of code and strict rules you have to follow. AnyEvent, on the other hand, is lean and to the point, by only offering the functionality that is necessary, in as thin as a wrapper as technically possible.

Of course, AnyEvent comes with a big (and fully optional!) toolbox of useful functionality, such as an asynchronous DNS resolver, 100% non-blocking connects (even with TLS/SSL, IPv6 and on broken platforms such as Windows) and lots of real-world knowledge and workarounds for platform bugs and differences.

Now, if you *do want* lots of policy (this can arguably be somewhat useful) and you want to force your users to use the one and only event model, you should *not* use this module.

DESCRIPTION

AnyEvent provides a uniform interface to various event loops. This allows module authors to use event loop functionality without forcing module users to use a specific event loop implementation (since more than one event loop cannot coexist peacefully).

The interface itself is vaguely similar, but not identical to the *Event* module.

During the first call of any watcher-creation method, the module tries to detect the currently loaded event loop by probing whether one of the following modules is already loaded: *EV*, *AnyEvent::Loop*, *Event*, Glib, Tk, Event::Lib, Qt, POE. The first one found is used. If none are detected, the module tries to load the first four modules in the order given; but note that if *EV* is not available, the pure-perl *AnyEvent::Loop* should always work, so the other two are not normally tried.

Because AnyEvent first checks for modules that are already loaded, loading an event model explicitly before first using AnyEvent will likely make that model the default. For

example:

```
use Tk;
use AnyEvent;

# .. AnyEvent will likely default to Tk
```

The *likely* means that, if any module loads another event model and starts using it, all bets are off - this case should be very rare though, as very few modules hardcode event loops without announcing this very loudly.

The pure-perl implementation of AnyEvent is called `AnyEvent::Loop`. Like other event modules you can load it explicitly and enjoy the high availability of that event loop :)

WATCHERS

AnyEvent has the central concept of a *watcher*, which is an object that stores relevant data for each kind of event you are waiting for, such as the callback to call, the file handle to watch, etc.

These watchers are normal Perl objects with normal Perl lifetime. After creating a watcher it will immediately "watch" for events and invoke the callback when the event occurs (of course, only when the event model is in control).

Note that **callbacks must not permanently change global variables** potentially in use by the event loop (such as `$_` or `$[`) and that **callbacks must not `die`**. The former is good programming practice in Perl and the latter stems from the fact that exception handling differs widely between event loops.

To disable a watcher you have to destroy it (e.g. by setting the variable you store it in to `undef` or otherwise deleting all references to it).

All watchers are created by calling a method on the `AnyEvent` class.

Many watchers either are used with "recursion" (repeating timers for example), or need to refer to their watcher object in other ways.

One way to achieve that is this pattern:

```
my $w; $w = AnyEvent->type (arg => value ..., cb => sub {
   # you can use $w here, for example to undef it
   undef $w;
});
```

Note that `my $w; $w =` combination. This is necessary because in Perl, my variables are only visible after the statement in which they are declared.

I/O WATCHERS

```
$w = AnyEvent->io (
   fh   => <filehandle_or_fileno>,
   poll => <"r" or "w">,
   cb   => <callback>,
);
```

You can create an I/O watcher by calling the `AnyEvent->io` method with the following mandatory key-value pairs as arguments:

`fh` is the Perl *file handle* (or a naked file descriptor) to watch for events (AnyEvent might or might not keep a reference to this file handle). Note that only file handles pointing to things for which non-blocking operation makes sense are allowed. This includes sockets, most character devices, pipes, fifos and so on, but not for example files or block devices.

`poll` must be a string that is either `r` or `w`, which creates a watcher waiting for "r"eadable or "w"ritable events, respectively.

`cb` is the callback to invoke each time the file handle becomes ready.

Although the callback might get passed parameters, their value and presence is undefined and you cannot rely on them. Portable AnyEvent callbacks cannot use arguments passed to I/O watcher callbacks.

The I/O watcher might use the underlying file descriptor or a copy of it. You must not close a file handle as long as any watcher is active on the underlying file descriptor.

Some event loops issue spurious readiness notifications, so you should always use non-blocking calls when reading/writing from/to your file handles.

Example: wait for readability of STDIN, then read a line and disable the watcher.

```
my $w; $w = AnyEvent->io (fh => \*STDIN, poll => 'r', cb => sub {
   chomp (my $input = <STDIN>);
   warn "read: $input\n";
   undef $w;
});
```

TIME WATCHERS

```
$w = AnyEvent->timer (after => <seconds>, cb => <callback>);

$w = AnyEvent->timer (
   after    => <fractional_seconds>,
   interval => <fractional_seconds>,
   cb       => <callback>,
);
```

You can create a time watcher by calling the `AnyEvent->timer` method with the following mandatory arguments:

`after` specifies after how many seconds (fractional values are supported) the callback should be invoked. `cb` is the callback to invoke in that case.

Although the callback might get passed parameters, their value and presence is undefined and you cannot rely on them. Portable AnyEvent callbacks cannot use arguments passed to time watcher callbacks.

The callback will normally be invoked only once. If you specify another parameter, `interval`, as a strictly positive number (> 0), then the callback will be invoked regularly at that interval (in fractional seconds) after the first invocation. If `interval` is specified with a false value, then it is treated as if it were not specified at all.

The callback will be rescheduled before invoking the callback, but no attempt is made to avoid timer drift in most backends, so the interval is only approximate.

Example: fire an event after 7.7 seconds.

```
my $w = AnyEvent->timer (after => 7.7, cb => sub {
   warn "timeout\n";
});

# to cancel the timer:
undef $w;
```

Example 2: fire an event after 0.5 seconds, then roughly every second.

```
my $w = AnyEvent->timer (after => 0.5, interval => 1, cb => sub {
   warn "timeout\n";
});
```

TIMING ISSUES

There are two ways to handle timers: based on real time (relative, “fire in 10 seconds”) and based on wallclock time (absolute, “fire at 12 o’clock”).

While most event loops expect timers to specified in a relative way, they use absolute time internally. This makes a difference when your clock “jumps”, for example, when ntp decides to set your clock backwards from the wrong date of 2014-01-01 to 2008-01-01, a watcher that is supposed to fire “after a second” might actually take six years to finally fire.

AnyEvent cannot compensate for this. The only event loop that is conscious of these issues is *EV*, which offers both relative (ev_timer, based on true relative time) and absolute (ev_periodic, based on wallclock time) timers.

AnyEvent always prefers relative timers, if available, matching the AnyEvent API.

AnyEvent has two additional methods that return the “current time”:

- AnyEvent->time

  This returns the “current wallclock time” as a fractional number of seconds since the Epoch (the same thing as `time` or `Time::HiRes::time` return, and the result is guaranteed to be compatible with those).

  It progresses independently of any event loop processing, i.e. each call will check the system clock, which usually gets updated frequently.

- AnyEvent->now

  This also returns the “current wallclock time”, but unlike `time`, above, this value might change only once per event loop iteration, depending on the event loop (most return the same time as `time`, above). This is the time that AnyEvent’s timers get scheduled against.

  In almost all cases (in all cases if you don’t care), this is the function to call when you want to know the current time.

This function is also often faster then `AnyEvent->time`, and thus the preferred method if you want some timestamp (for example, *AnyEvent::Handle* uses this to update its activity timeouts).

The rest of this section is only of relevance if you try to be very exact with your timing; you can skip it without a bad conscience.

For a practical example of when these times differ, consider Event::Lib and *EV* and the following set-up:

The event loop is running and has just invoked one of your callbacks at time=500 (assume no other callbacks delay processing). In your callback, you wait a second by executing `sleep 1` (blocking the process for a second) and then (at time=501) you create a relative timer that fires after three seconds.

With Event::Lib, `AnyEvent->time` and `AnyEvent->now` will both return `501`, because that is the current time, and the timer will be scheduled to fire at time=504 (`501` + 3).

With *EV*, `AnyEvent->time` returns `501` (as that is the current time), but `AnyEvent->now` returns `500`, as that is the time the last event processing phase started. With *EV*, your timer gets scheduled to run at time=503 (`500` + 3).

In one sense, Event::Lib is more exact, as it uses the current time regardless of any delays introduced by event processing. However, most callbacks do not expect large delays in processing, so this causes a higher drift (and a lot more system calls to get the current time).

In another sense, *EV* is more exact, as your timer will be scheduled at the same time, regardless of how long event processing actually took.

In either case, if you care (and in most cases, you don't), then you can get whatever behaviour you want with any event loop, by taking the difference between `AnyEvent->time` and `AnyEvent->now` into account.

- AnyEvent->now_update

  Some event loops (such as *EV* or *AnyEvent::Loop*) cache the current time for each loop iteration (see the discussion of AnyEvent->now, above).

  When a callback runs for a long time (or when the process sleeps), then this "current" time will differ substantially from the real time, which might affect timers and time-outs.

  When this is the case, you can call this method, which will update the event loop's idea of "current time".

  A typical example would be a script in a web server (e.g. `mod_perl`) - when mod_perl executes the script, then the event loop will have the wrong idea about the "current time" (being potentially far in the past, when the script ran the last time). In that case you should arrange a call to `AnyEvent->now_update` each time the web server process wakes up again (e.g. at the start of your script, or in a handler).

  Note that updating the time *might* cause some events to be handled.

SIGNAL WATCHERS

```
$w = AnyEvent->signal (signal => <uppercase_signal_name>, cb =>
↪<callback>);
```

You can watch for signals using a signal watcher, `signal` is the signal *name* in uppercase and without any `SIG` prefix, `cb` is the Perl callback to be invoked whenever a signal occurs.

Although the callback might get passed parameters, their value and presence is undefined and you cannot rely on them. Portable AnyEvent callbacks cannot use arguments passed to signal watcher callbacks.

Multiple signal occurrences can be clumped together into one callback invocation, and callback invocation will be synchronous. Synchronous means that it might take a while until the signal gets handled by the process, but it is guaranteed not to interrupt any other callbacks.

The main advantage of using these watchers is that you can share a signal between multiple watchers, and AnyEvent will ensure that signals will not interrupt your program at bad times.

This watcher might use `%SIG` (depending on the event loop used), so programs overwriting those signals directly will likely not work correctly.

Example: exit on SIGINT

```
my $w = AnyEvent->signal (signal => "INT", cb => sub { exit 1 });
```

Restart Behaviour

While restart behaviour is up to the event loop implementation, most will not restart syscalls (that includes Async::Interrupt and AnyEvent's pure perl implementation).

Safe/Unsafe Signals

Perl signals can be either "safe" (synchronous to opcode handling) or "unsafe" (asynchronous) - the former might delay signal delivery indefinitely, the latter might corrupt your memory.

AnyEvent signal handlers are, in addition, synchronous to the event loop, i.e. they will not interrupt your running perl program but will only be called as part of the normal event handling (just like timer, I/O etc. callbacks, too).

Signal Races, Delays and Workarounds

Many event loops (e.g. Glib, Tk, Qt, IO::Async) do not support attaching callbacks to signals in a generic way, which is a pity, as you cannot do race-free signal handling in perl, requiring C libraries for this. AnyEvent will try to do its best, which means in some cases, signals will be delayed. The maximum time a signal might be delayed is 10 seconds by default, but can be overriden via `$ENV{PERL_ANYEVENT_MAX_SIGNAL_LATENCY}` or `$AnyEvent::MAX_SIGNAL_LATENCY` - see the "ENVIRONMENT VARIABLES" section for details.

All these problems can be avoided by installing the optional Async::Interrupt module, which works with most event loops. It will not work with inherently broken event loops such as *Event* or Event::Lib (and not with POE currently). For those, you just have to suffer the delays.

CHILD PROCESS WATCHERS

```
$w = AnyEvent->child (pid => <process id>, cb => <callback>);
```

You can also watch for a child process exit and catch its exit status.

The child process is specified by the `pid` argument (on some backends, using `0` watches for any child process exit, on others this will croak). The watcher will be triggered only when the child process has finished and an exit status is available, not on any trace events (stopped/continued).

The callback will be called with the pid and exit status (as returned by waitpid), so unlike other watcher types, you *can* rely on child watcher callback arguments.

This watcher type works by installing a signal handler for `SIGCHLD`, and since it cannot be shared, nothing else should use SIGCHLD or reap random child processes (waiting for specific child processes, e.g. inside `system`, is just fine).

There is a slight catch to child watchers, however: you usually start them *after* the child process was created, and this means the process could have exited already (and no SIGCHLD will be sent anymore).

Not all event models handle this correctly (neither POE nor IO::Async do, see their AnyEvent::Impl manpages for details), but even for event models that *do* handle this correctly, they usually need to be loaded before the process exits (i.e. before you fork in the first place). AnyEvent's pure perl event loop handles all cases correctly regardless of when you start the watcher.

This means you cannot create a child watcher as the very first thing in an AnyEvent program, you *have* to create at least one watcher before you `fork` the child (alternatively, you can call `AnyEvent::detect`).

As most event loops do not support waiting for child events, they will be emulated by AnyEvent in most cases, in which case the latency and race problems mentioned in the description of signal watchers apply.

Example: fork a process and wait for it

```
my $done = AnyEvent->condvar;

# this forks and immediately calls exit in the child. this
# normally has all sorts of bad consequences for your parent,
# so take this as an example only. always fork and exec,
# or call POSIX::_exit, in real code.
my $pid = fork or exit 5;

my $w = AnyEvent->child (
   pid => $pid,
   cb  => sub {
```

(continues on next page)

(continued from previous page)

```
      my ($pid, $status) = @_;
      warn "pid $pid exited with status $status";
      $done->send;
   },
);

# do something else, then wait for process exit
$done->recv;
```

IDLE WATCHERS

```
$w = AnyEvent->idle (cb => <callback>);
```

This will repeatedly invoke the callback after the process becomes idle, until either the watcher is destroyed or new events have been detected.

Idle watchers are useful when there is a need to do something, but it is not so important (or wise) to do it instantly. The callback will be invoked only when there is "nothing better to do", which is usually defined as "all outstanding events have been handled and no new events have been detected". That means that idle watchers ideally get invoked when the event loop has just polled for new events but none have been detected. Instead of blocking to wait for more events, the idle watchers will be invoked.

Unfortunately, most event loops do not really support idle watchers (only EV, Event and Glib do it in a usable fashion) - for the rest, AnyEvent will simply call the callback "from time to time".

Example: read lines from STDIN, but only process them when the program is otherwise idle:

```
my @lines; # read data
my $idle_w;
my $io_w = AnyEvent->io (fh => \*STDIN, poll => 'r', cb => sub {
   push @lines, scalar <STDIN>;

   # start an idle watcher, if not already done
   $idle_w ||= AnyEvent->idle (cb => sub {
      # handle only one line, when there are lines left
      if (my $line = shift @lines) {
         print "handled when idle: $line";
      } else {
         # otherwise disable the idle watcher again
         undef $idle_w;
      }
   });
});
```

CONDITION VARIABLES

```
$cv = AnyEvent->condvar;

$cv->send (<list>);
my @res = $cv->recv;
```

If you are familiar with some event loops you will know that all of them require you to run some blocking "loop", "run" or similar function that will actively watch for new events and call your callbacks.

AnyEvent is slightly different: it expects somebody else to run the event loop and will only block when necessary (usually when told by the user).

The tool to do that is called a "condition variable", so called because they represent a condition that must become true.

Now is probably a good time to look at the examples further below.

Condition variables can be created by calling the `AnyEvent->condvar` method, usually without arguments. The only argument pair allowed is `cb`, which specifies a callback to be called when the condition variable becomes true, with the condition variable as the first argument (but not the results).

After creation, the condition variable is "false" until it becomes "true" by calling the `send` method (or calling the condition variable as if it were a callback, read about the caveats in the description for the `->send` method).

Since condition variables are the most complex part of the AnyEvent API, here are some different mental models of what they are - pick the ones you can connect to:

- Condition variables are like callbacks - you can call them (and pass them instead of callbacks). Unlike callbacks however, you can also wait for them to be called.
- Condition variables are signals - one side can emit or send them, the other side can wait for them, or install a handler that is called when the signal fires.
- Condition variables are like "Merge Points" - points in your program where you merge multiple independent results/control flows into one.
- Condition variables represent a transaction - functions that start some kind of transaction can return them, leaving the caller the choice between waiting in a blocking fashion, or setting a callback.
- Condition variables represent future values, or promises to deliver some result, long before the result is available.

Condition variables are very useful to signal that something has finished, for example, if you write a module that does asynchronous http requests, then a condition variable would be the ideal candidate to signal the availability of results. The user can either act when the callback is called or can synchronously `->recv` for the results.

You can also use them to simulate traditional event loops - for example, you can block your main program until an event occurs - for example, you could `->recv` in your main program until the user clicks the Quit button of your app, which would `->send` the "quit" event.

Note that condition variables recurse into the event loop - if you have two pieces of code that call `->recv` in a round-robin fashion, you lose. Therefore, condition variables are good to export to your caller, but you should avoid making a blocking wait yourself, at least in callbacks, as this asks for trouble.

Condition variables are represented by hash refs in perl, and the keys used by AnyEvent itself are all named `_ae_XXX` to make subclassing easy (it is often useful to build your own transaction class on top of AnyEvent). To subclass, use `AnyEvent::CondVar` as base class and call its `new` method in your own `new` method.

There are two "sides" to a condition variable - the "producer side" which eventually calls `-> send`, and the "consumer side", which waits for the send to occur.

Example: wait for a timer.

```
# condition: "wait till the timer is fired"
my $timer_fired = AnyEvent->condvar;

# create the timer - we could wait for, say
# a handle becomign ready, or even an
# AnyEvent::HTTP request to finish, but
# in this case, we simply use a timer:
my $w = AnyEvent->timer (
   after => 1,
   cb    => sub { $timer_fired->send },
);

# this "blocks" (while handling events) till the callback
# calls ->send
$timer_fired->recv;
```

Example: wait for a timer, but take advantage of the fact that condition variables are also callable directly.

```
my $done = AnyEvent->condvar;
my $delay = AnyEvent->timer (after => 5, cb => $done);
$done->recv;
```

Example: Imagine an API that returns a condvar and doesn't support callbacks. This is how you make a synchronous call, for example from the main program:

```
use AnyEvent::CouchDB;

...

my @info = $couchdb->info->recv;
```

And this is how you would just set a callback to be called whenever the results are available:

```
$couchdb->info->cb (sub {
   my @info = $_[0]->recv;
});
```

METHODS FOR PRODUCERS

These methods should only be used by the producing side, i.e. the code/module that eventually sends the signal. Note that it is also the producer side which creates the condvar in most cases, but it isn't uncommon for the consumer to create it as well.

- $cv->send (...)

  Flag the condition as ready - a running `->recv` and all further calls to `recv` will (eventually) return after this method has been called. If nobody is waiting the send will be remembered.

  If a callback has been set on the condition variable, it is called immediately from within send.

  Any arguments passed to the `send` call will be returned by all future `->recv` calls.

  Condition variables are overloaded so one can call them directly (as if they were a code reference). Calling them directly is the same as calling `send`.

- $cv->croak ($error)

  Similar to send, but causes all calls to `->recv` to invoke `Carp::croak` with the given error message/object/scalar.

  This can be used to signal any errors to the condition variable user/consumer. Doing it this way instead of calling `croak` directly delays the error detection, but has the overwhelming advantage that it diagnoses the error at the place where the result is expected, and not deep in some event callback with no connection to the actual code causing the problem.

- $cv->begin ([group callback])

- $cv->end

  These two methods can be used to combine many transactions/events into one. For example, a function that pings many hosts in parallel might want to use a condition variable for the whole process.

  Every call to `->begin` will increment a counter, and every call to `->end` will decrement it. If the counter reaches `0` in `->end`, the (last) callback passed to `begin` will be executed, passing the condvar as first argument. That callback is *supposed* to call `->send`, but that is not required. If no group callback was set, `send` will be called without any arguments.

  You can think of `$cv->send` giving you an OR condition (one call sends), while `$cv->begin` and `$cv->end` giving you an AND condition (all `begin` calls must be end'ed before the condvar sends).

  Let's start with a simple example: you have two I/O watchers (for example, STDOUT and STDERR for a program), and you want to wait for both streams to close before activating a condvar:

```
my $cv = AnyEvent->condvar;

$cv->begin; # first watcher
my $w1 = AnyEvent->io (fh => $fh1, cb => sub {
   defined sysread $fh1, my $buf, 4096
```

(continues on next page)

(continued from previous page)

```
      or $cv->end;
});

$cv->begin; # second watcher
my $w2 = AnyEvent->io (fh => $fh2, cb => sub {
   defined sysread $fh2, my $buf, 4096
      or $cv->end;
});

$cv->recv;
```

This works because for every event source (EOF on file handle), there is one call to `begin`, so the condvar waits for all calls to `end` before sending.

The ping example mentioned above is slightly more complicated, as the there are results to be passed back, and the number of tasks that are begun can potentially be zero:

```
my $cv = AnyEvent->condvar;

my %result;
$cv->begin (sub { shift->send (\%result) });

for my $host (@list_of_hosts) {
   $cv->begin;
   ping_host_then_call_callback $host, sub {
      $result{$host} = ...;
      $cv->end;
   };
}

$cv->end;

...

my $results = $cv->recv;
```

This code fragment supposedly pings a number of hosts and calls `send` after results for all then have have been gathered - in any order. To achieve this, the code issues a call to `begin` when it starts each ping request and calls `end` when it has received some result for it. Since `begin` and `end` only maintain a counter, the order in which results arrive is not relevant.

There is an additional bracketing call to `begin` and `end` outside the loop, which serves two important purposes: first, it sets the callback to be called once the counter reaches `0`, and second, it ensures that `send` is called even when no hosts are being pinged (the loop doesn't execute once).

This is the general pattern when you "fan out" into multiple (but potentially zero) subrequests: use an outer `begin`/`end` pair to set the callback and ensure `end` is called at least once, and then, for each subrequest you start, call `begin` and for each subrequest you finish, call `end`.

METHODS FOR CONSUMERS

These methods should only be used by the consuming side, i.e. the code awaits the condition.

- $cv->recv

  Wait (blocking if necessary) until the `->send` or `->croak` methods have been called on `$cv`, while servicing other watchers normally.

  You can only wait once on a condition - additional calls are valid but will return immediately.

  If an error condition has been set by calling `->croak`, then this function will call `croak`.

  In list context, all parameters passed to `send` will be returned, in scalar context only the first one will be returned.

  Note that doing a blocking wait in a callback is not supported by any event loop, that is, recursive invocation of a blocking `->recv` is not allowed and the `recv` call will `croak` if such a condition is detected. This requirement can be dropped by relying on *Coro::AnyEvent* , which allows you to do a blocking `->recv` from any thread that doesn't run the event loop itself. *Coro::AnyEvent* is loaded automatically when *Coro* is used with *AnyEvent*, so code does not need to do anything special to take advantage of that: any code that would normally block your program because it calls `recv`, be executed in an `async` thread instead without blocking other threads.

  Not all event models support a blocking wait - some die in that case (programs might want to do that to stay interactive), so *if you are using this from a module, never require a blocking wait*. Instead, let the caller decide whether the call will block or not (for example, by coupling condition variables with some kind of request results and supporting callbacks so the caller knows that getting the result will not block, while still supporting blocking waits if the caller so desires).

  You can ensure that `->recv` never blocks by setting a callback and only calling `->recv` from within that callback (or at a later time). This will work even when the event loop does not support blocking waits otherwise.

- $bool = $cv->ready

  Returns true when the condition is "true", i.e. whether `send` or `croak` have been called.

- $cb = $cv->cb ($cb->($cv))

  This is a mutator function that returns the callback set (or `undef` if not) and optionally replaces it before doing so.

  The callback will be called when the condition becomes "true", i.e. when `send` or `croak` are called, with the only argument being the condition variable itself. If the condition is already true, the callback is called immediately when it is set. Calling `recv` inside the callback or at any later time is guaranteed not to block.

  Additionally, when the callback is invoked, it is also removed from the condvar (reset to `undef`), so the condvar does not keep a reference to the callback after invocation.

SUPPORTED EVENT LOOPS/BACKENDS

The following backend classes are part of the AnyEvent distribution (every class has its own manpage):

- Backends that are autoprobed when no other event loop can be found.

  EV is the preferred backend when no other event loop seems to be in use. If EV is not installed, then AnyEvent will fall back to its own pure-perl implementation, which is available everywhere as it comes with AnyEvent itself.

```
AnyEvent::Impl::EV          based on EV (interface to libev, best␣
↪choice).
AnyEvent::Impl::Perl        pure-perl AnyEvent::Loop, fast and␣
↪portable.
```

- Backends that are transparently being picked up when they are used.

  These will be used if they are already loaded when the first watcher is created, in which case it is assumed that the application is using them. This means that AnyEvent will automatically pick the right backend when the main program loads an event module before anything starts to create watchers. Nothing special needs to be done by the main program.

```
AnyEvent::Impl::Event       based on Event, very stable, few␣
↪glitches.
AnyEvent::Impl::Glib        based on Glib, slow but very stable.
AnyEvent::Impl::Tk          based on Tk, very broken.
AnyEvent::Impl::UV          based on UV, innovated square wheels.
AnyEvent::Impl::EventLib    based on Event::Lib, leaks memory and␣
↪worse.
AnyEvent::Impl::POE         based on POE, very slow, some␣
↪limitations.
AnyEvent::Impl::Irssi       used when running within irssi.
AnyEvent::Impl::IOAsync     based on IO::Async.
AnyEvent::Impl::Cocoa       based on Cocoa::EventLoop.
AnyEvent::Impl::FLTK        based on FLTK (fltk 2 binding).
```

- Backends with special needs.

  Qt requires the Qt::Application to be instantiated first, but will otherwise be picked up automatically. As long as the main program instantiates the application before any AnyEvent watchers are created, everything should just work.

```
AnyEvent::Impl::Qt          based on Qt.
```

- Event loops that are indirectly supported via other backends.

  Some event loops can be supported via other modules:

  There is no direct support for WxWidgets (Wx) or Prima.

  WxWidgets has no support for watching file handles. However, you can use WxWidgets through the POE adaptor, as POE has a Wx backend that simply polls 20 times per second, which was considered to be too horrible to even consider for AnyEvent.

Prima is not supported as nobody seems to be using it, but it has a POE backend, so it can be supported through POE.

AnyEvent knows about both Prima and Wx, however, and will try to load POE when detecting them, in the hope that POE will pick them up, in which case everything will be automatic.

- Known event loops outside the AnyEvent distribution

  The following event loops or programs support AnyEvent by providing their own AnyEvent backend. They will be picked up automatically.

```
urxvt::anyevent           available to rxvt-unicode extensions
```

GLOBAL VARIABLES AND FUNCTIONS

These are not normally required to use AnyEvent, but can be useful to write AnyEvent extension modules.

- $AnyEvent::MODEL

  Contains `undef` until the first watcher is being created, before the backend has been autodetected.

  Afterwards it contains the event model that is being used, which is the name of the Perl class implementing the model. This class is usually one of the `AnyEvent::Impl::xxx` modules, but can be any other class in the case AnyEvent has been extended at runtime (e.g. in *rxvt-unicode* it will be `urxvt::anyevent`).

- AnyEvent::detect

  Returns `$AnyEvent::MODEL`, forcing autodetection of the event model if necessary. You should only call this function right before you would have created an AnyEvent watcher anyway, that is, as late as possible at runtime, and not e.g. during initialisation of your module.

  The effect of calling this function is as if a watcher had been created (specifically, actions that happen “when the first watcher is created” happen when calling detetc as well).

  If you need to do some initialisation before AnyEvent watchers are created, use `post_detect`.

- $guard = AnyEvent::post_detect { BLOCK }

  Arranges for the code block to be executed as soon as the event model is autodetected (or immediately if that has already happened).

  The block will be executed *after* the actual backend has been detected (`$AnyEvent::MODEL` is set), so it is possible to do some initialisation only when AnyEvent is actually initialised - see the sources of AnyEvent::AIO to see how this is used.

  The most common usage is to create some global watchers, without forcing event module detection too early. For example, AnyEvent::AIO creates and installs the global IO::AIO watcher in a `post_detect` block to avoid autodetecting the event module at load time.

If called in scalar or list context, then it creates and returns an object that automatically removes the callback again when it is destroyed (or `undef` when the hook was immediately executed). See AnyEvent::AIO for a case where this is useful.

Example: Create a watcher for the IO::AIO module and store it in `$WATCHER`, but do so only do so after the event loop is initialised.

```
our WATCHER;

my $guard = AnyEvent::post_detect {
   $WATCHER = AnyEvent->io (fh => IO::AIO::poll_fileno, poll =>
 ↪'r', cb => \&IO::AIO::poll_cb);
};

# the ||= is important in case post_detect immediately runs the␣
 ↪block,
# as to not clobber the newly-created watcher. assigning both␣
 ↪watcher and
# post_detect guard to the same variable has the advantage of␣
 ↪users being
# able to just C<undef $WATCHER> if the watcher causes them␣
 ↪grief.

$WATCHER ||= $guard;
```

- @AnyEvent::post_detect

  This is a lower level interface then `AnyEvent::post_detect` (the function). This variable is mainly useful for modules that can do something useful when AnyEvent is used and thus want to know when it is initialised, but do not need to even load it by default. This array provides the means to hook into AnyEvent passively, without loading it.

  Here is how it works: If there are any code references in this array (you can `push` to it before or after loading AnyEvent), then they will be called directly after the event loop has been chosen.

  You should check `$AnyEvent::MODEL` before adding to this array, though: if it is defined then the event loop has already been detected, and the array will be ignored.

  Best use `AnyEvent::post_detect { BLOCK }` when your application allows it, as it takes care of these details.

  Example: To load Coro::AnyEvent whenever Coro and AnyEvent are used together, you could put this into Coro (this is the actual code used by Coro to accomplish this):

```
if (defined $AnyEvent::MODEL) {
   # AnyEvent already initialised, so load Coro::AnyEvent
   require Coro::AnyEvent;
} else {
   # AnyEvent not yet initialised, so make sure to load␣
 ↪Coro::AnyEvent
   # as soon as it is
```

(continues on next page)

(continued from previous page)

```
   push @AnyEvent::post_detect, sub { require Coro::AnyEvent };
}
```

- AnyEvent::postpone { BLOCK }

  Arranges for the block to be executed as soon as possible, but not before the call itself returns. In practise, the block will be executed just before the event loop polls for new events, or shortly afterwards.

  This function never returns anything (to make the `return postpone { ... }` idiom more useful.

  To understand the usefulness of this function, consider a function that asynchronously does something for you and returns some transaction object or guard to let you cancel the operation. For example, `AnyEvent::Socket::tcp_connect`:

```
# start a connection attempt unless one is active
$self->{connect_guard} ||= AnyEvent::Socket::tcp_connect "www.
↪example.net", 80, sub {
   delete $self->{connect_guard};
   ...
};
```

  Imagine that this function could instantly call the callback, for example, because it detects an obvious error such as a negative port number. Invoking the callback before the function returns causes problems however: the callback will be called and will try to delete the guard object. But since the function hasn't returned yet, there is nothing to delete. When the function eventually returns it will assign the guard object to `$self->{connect_guard}`, where it will likely never be deleted, so the program thinks it is still trying to connect.

  This is where `AnyEvent::postpone` should be used. Instead of calling the callback directly on error:

```
$cb->(undef), return # signal error to callback, BAD!
   if $some_error_condition;
```

  It should use `postpone`:

```
AnyEvent::postpone { $cb->(undef) }, return # signal error to␣
↪callback, later
   if $some_error_condition;
```

- AnyEvent::log $level, $msg[, @args]

  Log the given `$msg` at the given `$level`.

  If *AnyEvent::Log* is not loaded then this function makes a simple test to see whether the message will be logged. If the test succeeds it will load AnyEvent::Log and call `AnyEvent::Log::log` - consequently, look at the *AnyEvent::Log* documentation for details.

  If the test fails it will simply return. Right now this happens when a numerical loglevel is used and it is larger than the level specified via

`$ENV{PERL_ANYEVENT_VERBOSE}`.

If you want to sprinkle loads of logging calls around your code, consider creating a logger callback with the `AnyEvent::Log::logger` function, which can reduce typing, codesize and can reduce the logging overhead enourmously.

- AnyEvent::fh_block $filehandle
- AnyEvent::fh_unblock $filehandle

  Sets blocking or non-blocking behaviour for the given filehandle.

WHAT TO DO IN A MODULE

As a module author, you should `use AnyEvent` and call AnyEvent methods freely, but you should not load a specific event module or rely on it.

Be careful when you create watchers in the module body - AnyEvent will decide which event module to use as soon as the first method is called, so by calling AnyEvent in your module body you force the user of your module to load the event module first.

Never call `->recv` on a condition variable unless you *know* that the `->send` method has been called on it already. This is because it will stall the whole program, and the whole point of using events is to stay interactive.

It is fine, however, to call `->recv` when the user of your module requests it (i.e. if you create a http request object ad have a method called `results` that returns the results, it may call `->recv` freely, as the user of your module knows what she is doing. Always).

WHAT TO DO IN THE MAIN PROGRAM

There will always be a single main program - the only place that should dictate which event model to use.

If the program is not event-based, it need not do anything special, even when it depends on a module that uses an AnyEvent. If the program itself uses AnyEvent, but does not care which event loop is used, all it needs to do is `use AnyEvent`. In either case, AnyEvent will choose the best available loop implementation.

If the main program relies on a specific event model - for example, in Gtk2 programs you have to rely on the Glib module - you should load the event module before loading AnyEvent or any module that uses it: generally speaking, you should load it as early as possible. The reason is that modules might create watchers when they are loaded, and AnyEvent will decide on the event model to use as soon as it creates watchers, and it might choose the wrong one unless you load the correct one yourself.

You can chose to use a pure-perl implementation by loading the `AnyEvent::Loop` module, which gives you similar behaviour everywhere, but letting AnyEvent chose the model is generally better.

MAINLOOP EMULATION

Sometimes (often for short test scripts, or even standalone programs who only want to use AnyEvent), you do not want to run a specific event loop.

In that case, you can use a condition variable like this:

```
AnyEvent->condvar->recv;
```

This has the effect of entering the event loop and looping forever.

Note that usually your program has some exit condition, in which case it is better to use the "traditional" approach of storing a condition variable somewhere, waiting for it, and sending it when the program should exit cleanly.

OTHER MODULES

The following is a non-exhaustive list of additional modules that use AnyEvent as a client and can therefore be mixed easily with other AnyEvent modules and other event loops in the same program. Some of the modules come as part of AnyEvent, the others are available via CPAN (see http://search.cpan.org/search?m=module&q=anyevent%3A%3A* for a longer non-exhaustive list), and the list is heavily biased towards modules of the AnyEvent author himself :)

- *AnyEvent::Util* (part of the AnyEvent distribution)

  Contains various utility functions that replace often-used blocking functions such as `inet_aton` with event/callback-based versions.

- *AnyEvent::Socket* (part of the AnyEvent distribution)

  Provides various utility functions for (internet protocol) sockets, addresses and name resolution. Also functions to create non-blocking tcp connections or tcp servers, with IPv6 and SRV record support and more.

- *AnyEvent::Handle* (part of the AnyEvent distribution)

  Provide read and write buffers, manages watchers for reads and writes, supports raw and formatted I/O, I/O queued and fully transparent and non-blocking SSL/TLS (via *AnyEvent::TLS*).

- *AnyEvent::DNS* (part of the AnyEvent distribution)

  Provides rich asynchronous DNS resolver capabilities.

- AnyEvent::HTTP, AnyEvent::IRC, AnyEvent::XMPP, AnyEvent::GPSD, AnyEvent::IGS, AnyEvent::FCP

  Implement event-based interfaces to the protocols of the same name (for the curious, IGS is the International Go Server and FCP is the Freenet Client Protocol).

- AnyEvent::AIO (part of the AnyEvent distribution)

  Truly asynchronous (as opposed to non-blocking) I/O, should be in the toolbox of every event programmer. AnyEvent::AIO transparently fuses IO::AIO and AnyEvent together, giving AnyEvent access to event-based file I/O, and much more.

- AnyEvent::Fork, AnyEvent::Fork::RPC, AnyEvent::Fork::Pool, AnyEvent::Fork::Remote

  These let you safely fork new subprocesses, either locally or remotely (e.g.v ia ssh), using some RPC protocol or not, without the limitations normally imposed by fork (AnyEvent works fine for example). Dynamically-resized worker pools are obviously included as well.

And they are quite tiny and fast as well - "abusing" AnyEvent::Fork just to exec external programs can easily beat using `fork` and `exec` (or even `system`) in most programs.

- AnyEvent::Filesys::Notify

  AnyEvent is good for non-blocking stuff, but it can't detect file or path changes (e.g. "watch this directory for new files", "watch this file for changes"). The AnyEvent::Filesys::Notify module promises to do just that in a portbale fashion, supporting inotify on GNU/Linux and some weird, without doubt broken, stuff on OS X to monitor files. It can fall back to blocking scans at regular intervals transparently on other platforms, so it's about as portable as it gets.

  (I haven't used it myself, but it seems the biggest problem with it is it quite bad performance).

- AnyEvent::DBI

  Executes *DBI* requests asynchronously in a proxy process for you, notifying you in an event-based way when the operation is finished.

- AnyEvent::FastPing

  The fastest ping in the west.

- *Coro*

  Has special support for AnyEvent via *Coro::AnyEvent*, which allows you to simply invert the flow control - don't call us, we will call you:

```
async {
   Coro::AnyEvent::sleep 5; # creates a 5s timer and waits for
↪it
   print "5 seconds later!\n";

   Coro::AnyEvent::readable *STDIN; # uses an I/O watcher
   my $line = <STDIN>; # works for ttys

   AnyEvent::HTTP::http_get "url", Coro::rouse_cb;
   my ($body, $hdr) = Coro::rouse_wait;
};
```

SIMPLIFIED AE API

Starting with version 5.0, AnyEvent officially supports a second, much simpler, API that is designed to reduce the calling, typing and memory overhead by using function call syntax and a fixed number of parameters.

See the *AE* manpage for details.

ERROR AND EXCEPTION HANDLING

In general, AnyEvent does not do any error handling - it relies on the caller to do that if required. The *AnyEvent::Strict* module (see also the `PERL_ANYEVENT_STRICT` environment variable, below) provides strict checking of all AnyEvent methods, however, which is highly useful during development.

As for exception handling (i.e. runtime errors and exceptions thrown while executing a callback), this is not only highly event-loop specific, but also not in any way wrapped by this module, as this is the job of the main program.

The pure perl event loop simply re-throws the exception (usually within `condvar->recv`), the *Event* and *EV* modules call `$Event/EV::DIED->()`, Glib uses `install_exception_handler` and so on.

ENVIRONMENT VARIABLES

AnyEvent supports a number of environment variables that tune the runtime behaviour. They are usually evaluated when AnyEvent is loaded, initialised, or a submodule that uses them is loaded. Many of them also cause AnyEvent to load additional modules - for example, `PERL_ANYEVENT_DEBUG_WRAP` causes the *AnyEvent::Debug* module to be loaded.

All the environment variables documented here start with `PERL_ANYEVENT_`, which is what AnyEvent considers its own namespace. Other modules are encouraged (but by no means required) to use `PERL_ANYEVENT_SUBMODULE` if they have registered the AnyEvent::Submodule namespace on CPAN, for any submodule. For example, AnyEvent::HTTP could be expected to use `PERL_ANYEVENT_HTTP_PROXY` (it should not access env variables starting with `AE_`, see below).

All variables can also be set via the `AE_` prefix, that is, instead of setting `PERL_ANYEVENT_VERBOSE` you can also set `AE_VERBOSE`. In case there is a clash btween anyevent and another program that uses `AE_something` you can set the corresponding `PERL_ANYEVENT_something` variable to the empty string, as those variables take precedence.

When AnyEvent is first loaded, it copies all `AE_xxx` env variables to their `PERL_ANYEVENT_xxx` counterpart unless that variable already exists. If taint mode is on, then AnyEvent will remove *all* environment variables starting with `PERL_ANYEVENT_` from `%ENV` (or replace them with `undef` or the empty string, if the corresaponding `AE_` variable is set).

The exact algorithm is currently:

```
1. if taint mode enabled, delete all PERL_ANYEVENT_xyz variables␣
↪from %ENV
2. copy over AE_xyz to PERL_ANYEVENT_xyz unless the latter alraedy␣
↪exists
3. if taint mode enabled, set all PERL_ANYEVENT_xyz variables to␣
↪undef.
```

This ensures that child processes will not see the `AE_` variables.

The following environment variables are currently known to AnyEvent:

- `PERL_ANYEVENT_VERBOSE`

  By default, AnyEvent will log messages with loglevel 4 (`error`) or higher (see *AnyEvent::Log*). You can set this environment variable to a numerical loglevel to make AnyEvent more (or less) talkative.

  If you want to do more than just set the global logging level you should have a look at `PERL_ANYEVENT_LOG`, which allows much more complex specifications.

When set to `0` (`off`), then no messages whatsoever will be logged with everything else at defaults.

When set to 5 or higher (`warn`), AnyEvent warns about unexpected conditions, such as not being able to load the event model specified by `PERL_ANYEVENT_MODEL`, or a guard callback throwing an exception - this is the minimum recommended level for use during development.

When set to 7 or higher (info), AnyEvent reports which event model it chooses.

When set to 8 or higher (debug), then AnyEvent will report extra information on which optional modules it loads and how it implements certain features.

- `PERL_ANYEVENT_LOG`

  Accepts rather complex logging specifications. For example, you could log all debug messages of some module to stderr, warnings and above to stderr, and errors and above to syslog, with:

```
PERL_ANYEVENT_LOG=Some::Module=debug,+log:filter=warn,+%syslog:
 ↪%syslog=error,syslog
```

  For the rather extensive details, see *AnyEvent::Log*.

  This variable is evaluated when AnyEvent (or *AnyEvent::Log*) is loaded, so will take effect even before AnyEvent has initialised itself.

  Note that specifying this environment variable causes the *AnyEvent::Log* module to be loaded, while `PERL_ANYEVENT_VERBOSE` does not, so only using the latter saves a few hundred kB of memory unless a module explicitly needs the extra features of AnyEvent::Log.

- `PERL_ANYEVENT_STRICT`

  AnyEvent does not do much argument checking by default, as thorough argument checking is very costly. Setting this variable to a true value will cause AnyEvent to load `AnyEvent::Strict` and then to thoroughly check the arguments passed to most method calls. If it finds any problems, it will croak.

  In other words, enables "strict" mode.

  Unlike `use strict` (or its modern cousin, `use [common::sense](https://metacpan.org/pod/common::sense)`, it is definitely recommended to keep it off in production. Keeping `PERL_ANYEVENT_STRICT=1` in your environment while developing programs can be very useful, however.

- `PERL_ANYEVENT_DEBUG_SHELL`

  If this env variable is nonempty, then its contents will be interpreted by `AnyEvent::Socket::parse_hostport` and `AnyEvent::Debug::shell` (after replacing every occurance of `$$` by the process pid). The shell object is saved in `$AnyEvent::Debug::SHELL`.

  This happens when the first watcher is created.

  For example, to bind a debug shell on a unix domain socket in `/tmp/debug<pid>.sock`, you could use this:

```
PERL_ANYEVENT_DEBUG_SHELL=/tmp/debug\$\$.sock perlprog
# connect with e.g.: socat readline /tmp/debug123.sock
```

Or to bind to tcp port 4545 on localhost:

```
PERL_ANYEVENT_DEBUG_SHELL=127.0.0.1:4545 perlprog
# connect with e.g.: telnet localhost 4545
```

Note that creating sockets in `/tmp` or on localhost is very unsafe on multiuser systems.

- `PERL_ANYEVENT_DEBUG_WRAP`

  Can be set to `0`, 1 or 2 and enables wrapping of all watchers for debugging purposes. See `AnyEvent::Debug::wrap` for details.

- `PERL_ANYEVENT_MODEL`

  This can be used to specify the event model to be used by AnyEvent, before auto detection and -probing kicks in.

  It normally is a string consisting entirely of ASCII letters (e.g. `EV` or `IOAsync`). The string `AnyEvent::Impl::` gets prepended and the resulting module name is loaded and - if the load was successful - used as event model backend. If it fails to load then AnyEvent will proceed with auto detection and -probing.

  If the string ends with `::` instead (e.g. `AnyEvent::Impl::EV::`) then nothing gets prepended and the module name is used as-is (hint: `::` at the end of a string designates a module name and quotes it appropriately).

  For example, to force the pure perl model (AnyEvent::Loop::Perl) you could start your program like this:

```
PERL_ANYEVENT_MODEL=Perl perl ...
```

- `PERL_ANYEVENT_IO_MODEL`

  The current file I/O model - see *AnyEvent::IO* for more info.

  At the moment, only `Perl` (small, pure-perl, synchronous) and `IOAIO` (truly asynchronous) are supported. The default is `IOAIO` if AnyEvent::AIO can be loaded, otherwise it is `Perl`.

- `PERL_ANYEVENT_PROTOCOLS`

  Used by both *AnyEvent::DNS* and *AnyEvent::Socket* to determine preferences for IPv4 or IPv6. The default is unspecified (and might change, or be the result of auto probing).

  Must be set to a comma-separated list of protocols or address families, current supported: `ipv4` and `ipv6`. Only protocols mentioned will be used, and preference will be given to protocols mentioned earlier in the list.

  This variable can effectively be used for denial-of-service attacks against local programs (e.g. when setuid), although the impact is likely small, as the program has to handle connection and other failures anyways.

Examples: `PERL_ANYEVENT_PROTOCOLS=ipv4,ipv6` - prefer IPv4 over IPv6, but support both and try to use both. `PERL_ANYEVENT_PROTOCOLS=ipv4` - only support IPv4, never try to resolve or contact IPv6 addresses. `PERL_ANYEVENT_PROTOCOLS=ipv6,ipv4` support either IPv4 or IPv6, but prefer IPv6 over IPv4.

- `PERL_ANYEVENT_HOSTS`

  This variable, if specified, overrides the `/etc/hosts` file used by *AnyEvent::Socket*`::resolve_sockaddr`, i.e. hosts aliases will be read from that file instead.

- `PERL_ANYEVENT_EDNS0`

  Used by *AnyEvent::DNS* to decide whether to use the EDNS0 extension for DNS. This extension is generally useful to reduce DNS traffic, especially when DNSSEC is involved, but some (broken) firewalls drop such DNS packets, which is why it is off by default.

  Setting this variable to 1 will cause *AnyEvent::DNS* to announce EDNS0 in its DNS requests.

- `PERL_ANYEVENT_MAX_FORKS`

  The maximum number of child processes that `AnyEvent::Util::fork_call` will create in parallel.

- `PERL_ANYEVENT_MAX_OUTSTANDING_DNS`

  The default value for the `max_outstanding` parameter for the default DNS resolver - this is the maximum number of parallel DNS requests that are sent to the DNS server.

- `PERL_ANYEVENT_MAX_SIGNAL_LATENCY`

  Perl has inherently racy signal handling (you can basically choose between losing signals and memory corruption) - pure perl event loops (including `AnyEvent::Loop`, when `Async::Interrupt` isn't available) therefore have to poll regularly to avoid losing signals.

  Some event loops are racy, but don't poll regularly, and some event loops are written in C but are still racy. For those event loops, AnyEvent installs a timer that regularly wakes up the event loop.

  By default, the interval for this timer is `10` seconds, but you can override this delay with this environment variable (or by setting the `$AnyEvent::MAX_SIGNAL_LATENCY` variable before creating signal watchers).

  Lower values increase CPU (and energy) usage, higher values can introduce long delays when reaping children or waiting for signals.

  The AnyEvent::Async module, if available, will be used to avoid this polling (with most event loops).

- `PERL_ANYEVENT_RESOLV_CONF`

  The absolute path to a `resolv.conf`-style file to use instead of `/etc/resolv.conf` (or the OS-specific configuration) in the default resolver, or the empty string to select the default configuration.

- `PERL_ANYEVENT_CA_FILE`, `PERL_ANYEVENT_CA_PATH`.

  When neither `ca_file` nor `ca_path` was specified during *AnyEvent::TLS* context creation, and either of these environment variables are nonempty, they will be used to specify CA certificate locations instead of a system-dependent default.

- `PERL_ANYEVENT_AVOID_GUARD` and `PERL_ANYEVENT_AVOID_ASYNC_INTERRUPT`

  When these are set to 1, then the respective modules are not loaded. Mostly good for testing AnyEvent itself.

SUPPLYING YOUR OWN EVENT MODEL INTERFACE

This is an advanced topic that you do not normally need to use AnyEvent in a module. This section is only of use to event loop authors who want to provide AnyEvent compatibility.

If you need to support another event library which isn't directly supported by AnyEvent, you can supply your own interface to it by pushing, before the first watcher gets created, the package name of the event module and the package name of the interface to use onto `@AnyEvent::REGISTRY`. You can do that before and even without loading AnyEvent, so it is reasonably cheap.

Example:

```
push @AnyEvent::REGISTRY, [urxvt => urxvt::anyevent::];
```

This tells AnyEvent to (literally) use the `urxvt::anyevent::` package/class when it finds the `urxvt` package/module is already loaded.

When AnyEvent is loaded and asked to find a suitable event model, it will first check for the presence of urxvt by trying to `use` the `urxvt::anyevent` module.

The class should provide implementations for all watcher types. See *AnyEvent::Impl::EV* (source code), *AnyEvent::Impl::Glib* (Source code) and so on for actual examples. Use `perldoc -m AnyEvent::Impl::Glib` to see the sources.

If you don't provide `signal` and `child` watchers than AnyEvent will provide suitable (hopefully) replacements.

The above example isn't fictitious, the *rxvt-unicode* (a.k.a. urxvt) terminal emulator uses the above line as-is. An interface isn't included in AnyEvent because it doesn't make sense outside the embedded interpreter inside *rxvt-unicode*, and it is updated and maintained as part of the *rxvt-unicode* distribution.

rxvt-unicode also cheats a bit by not providing blocking access to condition variables: code blocking while waiting for a condition will `die`. This still works with most modules/usages, and blocking calls must not be done in an interactive application, so it makes sense.

EXAMPLE PROGRAM

The following program uses an I/O watcher to read data from STDIN, a timer to display a message once per second, and a condition variable to quit the program when the user enters quit:

```
use AnyEvent;

my $cv = AnyEvent->condvar;

my $io_watcher = AnyEvent->io (
   fh   => \*STDIN,
   poll => 'r',
   cb   => sub {
      warn "io event <$_[0]>\n";   # will always output <r>
      chomp (my $input = <STDIN>); # read a line
      warn "read: $input\n";       # output what has been read
      $cv->send if $input =~ /^q/i; # quit program if /^q/i
   },
);

my $time_watcher = AnyEvent->timer (after => 1, interval => 1, cb =>
↪sub {
   warn "timeout\n"; # print 'timeout' at most every second
});

$cv->recv; # wait until user enters /^q/i
```

REAL-WORLD EXAMPLE

Consider the Net::FCP module. It features (among others) the following API calls, which are to freenet what HTTP GET requests are to http:

```
my $data = $fcp->client_get ($url); # blocks

my $transaction = $fcp->txn_client_get ($url); # does not block
$transaction->cb ( sub { ... } ); # set optional result callback
my $data = $transaction->result; # possibly blocks
```

The `client_get` method works like `LWP::Simple::get`: it requests the given URL and waits till the data has arrived. It is defined to be:

```
sub client_get { $_[0]->txn_client_get ($_[1])->result }
```

And in fact is automatically generated. This is the blocking API of Net::FCP, and it works as simple as in any other, similar, module.

More complicated is `txn_client_get`: It only creates a transaction (completion, result, ...) object and initiates the transaction.

```
my $txn = bless { }, Net::FCP::Txn::;
```

It also creates a condition variable that is used to signal the completion of the request:

```
$txn->{finished} = AnyAvent->condvar;
```

It then creates a socket in non-blocking mode.

```
socket $txn->{fh}, ...;
fcntl $txn->{fh}, F_SETFL, O_NONBLOCK;
connect $txn->{fh}, ...
   and !$!{EWOULDBLOCK}
   and !$!{EINPROGRESS}
   and Carp::croak "unable to connect: $!\n";
```

Then it creates a write-watcher which gets called whenever an error occurs or the connection succeeds:

```
$txn->{w} = AnyEvent->io (fh => $txn->{fh}, poll => 'w', cb => sub {
↪$txn->fh_ready_w });
```

And returns this transaction object. The `fh_ready_w` callback gets called as soon as the event loop detects that the socket is ready for writing.

The `fh_ready_w` method makes the socket blocking again, writes the request data and replaces the watcher by a read watcher (waiting for reply data). The actual code is more complicated, but that doesn't matter for this example:

```
fcntl $txn->{fh}, F_SETFL, 0;
syswrite $txn->{fh}, $txn->{request}
   or die "connection or write error";
$txn->{w} = AnyEvent->io (fh => $txn->{fh}, poll => 'r', cb => sub {
↪$txn->fh_ready_r });
```

Again, `fh_ready_r` waits till all data has arrived, and then stores the result and signals any possible waiters that the request has finished:

```
sysread $txn->{fh}, $txn->{buf}, length $txn->{$buf};

if (end-of-file or data complete) {
  $txn->{result} = $txn->{buf};
  $txn->{finished}->send;
  $txb->{cb}->($txn) of $txn->{cb}; # also call callback
}
```

The `result` method, finally, just waits for the finished signal (if the request was already finished, it doesn't wait, of course, and returns the data:

```
$txn->{finished}->recv;
return $txn->{result};
```

The actual code goes further and collects all errors (`die`s, exceptions) that occurred during request processing. The `result` method detects whether an exception as thrown (it is stored inside the $txn object) and just throws the exception, which means connection errors and other problems get reported to the code that tries to use the result, not in a random callback.

All of this enables the following usage styles:

1. Blocking:

```
my $data = $fcp->client_get ($url);
```

2. Blocking, but running in parallel:

```
my @datas = map $_->result,
               map $fcp->txn_client_get ($_),
                  @urls;
```

Both blocking examples work without the module user having to know anything about events.

3a. Event-based in a main program, using any supported event module:

```
use EV;

$fcp->txn_client_get ($url)->cb (sub {
   my $txn = shift;
   my $data = $txn->result;
   ...
});

EV::run;
```

3b. The module user could use AnyEvent, too:

```
use AnyEvent;

my $quit = AnyEvent->condvar;

$fcp->txn_client_get ($url)->cb (sub {
   ...
   $quit->send;
});

$quit->recv;
```

BENCHMARKS

To give you an idea of the performance and overheads that AnyEvent adds over the event loops themselves and to give you an impression of the speed of various event loops I prepared some benchmarks.

BENCHMARKING ANYEVENT OVERHEAD

Here is a benchmark of various supported event models used natively and through AnyEvent. The benchmark creates a lot of timers (with a zero timeout) and I/O watchers (watching STDOUT, a pty, to become writable, which it is), lets them fire exactly once and destroys them again.

Source code for this benchmark is found as `eg/bench` in the AnyEvent distribution. It uses the *AE* interface, which makes a real difference for the EV and Perl backends only.

Explanation of the columns

watcher is the number of event watchers created/destroyed. Since different event models feature vastly different performances, each event loop was given a number of watchers so that overall runtime is acceptable and similar between tested event loop (and keep them from crashing): Glib would probably take thousands of years if asked to process the same number of watchers as EV in this benchmark.

bytes is the number of bytes (as measured by the resident set size, RSS) consumed by each watcher. This method of measuring captures both C and Perl-based overheads.

create is the time, in microseconds (millionths of seconds), that it takes to create a single watcher. The callback is a closure shared between all watchers, to avoid adding memory overhead. That means closure creation and memory usage is not included in the figures.

invoke is the time, in microseconds, used to invoke a simple callback. The callback simply counts down a Perl variable and after it was invoked "watcher" times, it would `->send` a condvar once to signal the end of this phase.

destroy is the time, in microseconds, that it takes to destroy a single watcher.

Results

```
        name watchers bytes create invoke destroy comment

Discussion

The benchmark does *not* measure scalability of the event loop very well. For example, a select-based event loop (such as the pure perl one) can never compete with an event loop that uses epoll when the number of file descriptors grows high. In this benchmark, all events become ready at the same time, so select/poll-based implementations get an unnatural speed boost.

Also, note that the number of watchers usually has a nonlinear effect on overall speed, that is, creating twice as many watchers doesn't take twice the time - usually it takes longer. This puts event loops tested with a higher number of watchers at a disadvantage.

To put the range of results into perspective, consider that on the benchmark machine, handling an event takes roughly 1600 CPU cycles with EV, 3100 CPU cycles with AnyEvent's pure perl loop and almost 3000000 CPU cycles with POE.

EV is the sole leader regarding speed and memory use, which are both maximal/minimal, respectively. When using the *AE* API there is zero overhead (when going through the AnyEvent API create is about 5-6 times slower, with other times being equal, so still uses far less memory than any other event loop and is still faster than Event natively).

The pure perl implementation is hit in a few sweet spots (both the constant timeout and the use of a single fd hit optimisations in the perl interpreter and the backend itself). Nevertheless this shows that it adds very little overhead in itself. Like any select-based backend its performance becomes really bad with lots of file descriptors (and few of them active), of course, but this was not subject of this benchmark.

The `Event` module has a relatively high setup and callback invocation cost, but overall scores in on the third place.

`IO::Async` performs admirably well, about on par with `Event`, even when using its pure perl backend.

`Glib`'s memory usage is quite a bit higher, but it features a faster callback invocation and overall ends up in the same class as `Event`. However, Glib scales extremely badly, doubling the number of watchers increases the processing time by more than a factor of four, making it completely unusable when using larger numbers of watchers (note that only a single file descriptor was used in the benchmark, so inefficiencies of `poll` do not account for this).

The `Tk` adaptor works relatively well. The fact that it crashes with more than 2000 watchers is a big setback, however, as correctness takes precedence over speed. Nevertheless, its performance is surprising, as the file descriptor is dup()ed for each watcher. This shows that the dup() employed by some adaptors is not a big performance issue (it does incur a hidden memory cost inside the kernel which is not reflected in the figures above).

POE, regardless of underlying event loop (whether using its pure perl select-based backend or the Event module, the POE-EV backend couldn't be tested because it wasn't working) shows abysmal performance and memory usage with AnyEvent: Watchers use almost 30 times as much memory as EV watchers, and 10 times as much memory as Event (the high memory requirements are caused by requiring a session for each watcher). Watcher invocation speed is almost 900 times slower than with AnyEvent's pure perl implementation.

The design of the POE adaptor class in AnyEvent can not really account for the performance issues, though, as session creation overhead is small compared to execution of the

state machine, which is coded pretty optimally within *AnyEvent::Impl::POE* (and while everybody agrees that using multiple sessions is not a good approach, especially regarding memory usage, even the author of POE could not come up with a faster design).

Summary

- Using EV through AnyEvent is faster than any other event loop (even when used without AnyEvent), but most event loops have acceptable performance with or without AnyEvent.
- The overhead AnyEvent adds is usually much smaller than the overhead of the actual event loop, only with extremely fast event loops such as EV does AnyEvent add significant overhead.
- You should avoid POE like the plague if you want performance or reasonable memory usage.

BENCHMARKING THE LARGE SERVER CASE

This benchmark actually benchmarks the event loop itself. It works by creating a number of "servers": each server consists of a socket pair, a timeout watcher that gets reset on activity (but never fires), and an I/O watcher waiting for input on one side of the socket. Each time the socket watcher reads a byte it will write that byte to a random other "server".

The effect is that there will be a lot of I/O watchers, only part of which are active at any one point (so there is a constant number of active fds for each loop iteration, but which fds these are is random). The timeout is reset each time something is read because that reflects how most timeouts work (and puts extra pressure on the event loops).

In this benchmark, we use 10000 socket pairs (20000 sockets), of which 100 (1%) are active. This mirrors the activity of large servers with many connections, most of which are idle at any one point in time.

Source code for this benchmark is found as `eg/bench2` in the AnyEvent distribution. It uses the *AE* interface, which makes a real difference for the EV and Perl backends only.

Explanation of the columns

sockets is the number of sockets, and twice the number of "servers" (as each server has a read and write socket end).

create is the time it takes to create a socket pair (which is nontrivial) and two watchers: an I/O watcher and a timeout watcher.

request, the most important value, is the time it takes to handle a single "request", that is, reading the token from the pipe and forwarding it to another server. This includes deleting the old timeout and creating a new one that moves the timeout into the future.

Results

```
   name sockets create  request
     EV   20000  62.66     7.99
   Perl   20000  68.32    32.64
IOAsync   20000 174.06   101.15 epoll
IOAsync   20000 174.67   610.84 poll
  Event   20000 202.69   242.91
   Glib   20000 557.01  1689.52
    POE   20000 341.54 12086.32 uses POE::Loop::Event
```

Discussion

This benchmark *does* measure scalability and overall performance of the particular event loop.

EV is again fastest. Since it is using epoll on my system, the setup time is relatively high, though.

Perl surprisingly comes second. It is much faster than the C-based event loops Event and Glib.

IO::Async performs very well when using its epoll backend, and still quite good compared to Glib when using its pure perl backend.

Event suffers from high setup time as well (look at its code and you will understand why). Callback invocation also has a high overhead compared to the `$_->() for ..` -style loop that the Perl event loop uses. Event uses select or poll in basically all documented configurations.

Glib is hit hard by its quadratic behaviour w.r.t. many watchers. It clearly fails to perform with many filehandles or in busy servers.

POE is still completely out of the picture, taking over 1000 times as long as EV, and over 100 times as long as the Perl implementation, even though it uses a C-based event loop in this case.

Summary

- The pure perl implementation performs extremely well.
- Avoid Glib or POE in large projects where performance matters.

BENCHMARKING SMALL SERVERS

While event loops should scale (and select-based ones do not...) even to large servers, most programs we (or I :) actually write have only a few I/O watchers.

In this benchmark, I use the same benchmark program as in the large server case, but it uses only eight “servers”, of which three are active at any one time. This should reflect performance for a small server relatively well.

The columns are identical to the previous table.

Results

```
 name sockets create request
   EV      16  20.00    6.54
 Perl      16  25.75   12.62
Event      16  81.27   35.86
 Glib      16  32.63   15.48
  POE      16 261.87  276.28 uses POE::Loop::Event
```

Discussion

The benchmark tries to test the performance of a typical small server. While knowing how various event loops perform is interesting, keep in mind that their overhead in this case is usually not as important, due to the small absolute number of watchers (that is, you need efficiency and speed most when you have lots of watchers, not when you only have a few of them).

EV is again fastest.

Perl again comes second. It is noticeably faster than the C-based event loops Event and Glib, although the difference is too small to really matter.

POE also performs much better in this case, but is is still far behind the others.

Summary

- C-based event loops perform very well with small number of watchers, as the management overhead dominates.

THE IO::Lambda BENCHMARK

Recently I was told about the benchmark in the IO::Lambda manpage, which could be misinterpreted to make AnyEvent look bad. In fact, the benchmark simply compares IO::Lambda with POE, and IO::Lambda looks better (which shouldn't come as a surprise to anybody). As such, the benchmark is fine, and mostly shows that the AnyEvent backend from IO::Lambda isn't very optimal. But how would AnyEvent compare when used without the extra baggage? To explore this, I wrote the equivalent benchmark for AnyEvent.

The benchmark itself creates an echo-server, and then, for 500 times, connects to the echo server, sends a line, waits for the reply, and then creates the next connection. This is a rather bad benchmark, as it doesn't test the efficiency of the framework or much non-blocking I/O, but it is a benchmark nevertheless.

```
name                   runtime
Lambda/select          0.330 sec
   + optimized         0.122 sec
Lambda/AnyEvent        0.327 sec
   + optimized         0.138 sec
Raw sockets/select     0.077 sec
POE/select, components 0.662 sec
POE/select, raw sockets 0.226 sec
```

(continues on next page)

(continued from previous page)

```
POE/select, optimized   0.404 sec

AnyEvent/select/nb      0.085 sec
AnyEvent/EV/nb          0.068 sec
   +state machine       0.134 sec
```

The benchmark is also a bit unfair (my fault): the IO::Lambda/POE benchmarks actually make blocking connects and use 100% blocking I/O, defeating the purpose of an event-based solution. All of the newly written AnyEvent benchmarks use 100% non-blocking connects (using AnyEvent::Socket::tcp_connect and the asynchronous pure perl DNS resolver), so AnyEvent is at a disadvantage here, as non-blocking connects generally require a lot more bookkeeping and event handling than blocking connects (which involve a single syscall only).

The last AnyEvent benchmark additionally uses *AnyEvent::Handle*, which offers similar expressive power as POE and IO::Lambda, using conventional Perl syntax. This means that both the echo server and the client are 100% non-blocking, further placing it at a disadvantage.

As you can see, the AnyEvent + EV combination even beats the hand-optimised "raw sockets benchmark", while AnyEvent + its pure perl backend easily beats IO::Lambda and POE.

And even the 100% non-blocking version written using the high-level (and slow :) *AnyEvent::Handle* abstraction beats both POE and IO::Lambda higher level ("unoptimised") abstractions by a large margin, even though it does all of DNS, tcp-connect and socket I/O in a non-blocking way.

The two AnyEvent benchmarks programs can be found as `eg/ae0.pl` and `eg/ae2.pl` in the AnyEvent distribution, the remaining benchmarks are part of the IO::Lambda distribution and were used without any changes.

SIGNALS

AnyEvent currently installs handlers for these signals:

- SIGCHLD

  A handler for `SIGCHLD` is installed by AnyEvent's child watcher emulation for event loops that do not support them natively. Also, some event loops install a similar handler.

  Additionally, when AnyEvent is loaded and SIGCHLD is set to IGNORE, then AnyEvent will reset it to default, to avoid losing child exit statuses.

- SIGPIPE

  A no-op handler is installed for `SIGPIPE` when `$SIG{PIPE}` is `undef` when AnyEvent gets loaded.

  The rationale for this is that AnyEvent users usually do not really depend on SIGPIPE delivery (which is purely an optimisation for shell use, or badly-written programs), but `SIGPIPE` can cause spurious and rare program exits as a lot of people do not expect `SIGPIPE` when writing to some random socket.

The rationale for installing a no-op handler as opposed to ignoring it is that this way, the handler will be restored to defaults on exec.

Feel free to install your own handler, or reset it to defaults.

RECOMMENDED/OPTIONAL MODULES

One of AnyEvent's main goals is to be 100% Pure-Perl(tm): only perl (and its built-in modules) are required to use it.

That does not mean that AnyEvent won't take advantage of some additional modules if they are installed.

This section explains which additional modules will be used, and how they affect AnyEvent's operation.

- Async::Interrupt

  This slightly arcane module is used to implement fast signal handling: To my knowledge, there is no way to do completely race-free and quick signal handling in pure perl. To ensure that signals still get delivered, AnyEvent will start an interval timer to wake up perl (and catch the signals) with some delay (default is 10 seconds, look for `$AnyEvent::MAX_SIGNAL_LATENCY`).

  If this module is available, then it will be used to implement signal catching, which means that signals will not be delayed, and the event loop will not be interrupted regularly, which is more efficient (and good for battery life on laptops).

  This affects not just the pure-perl event loop, but also other event loops that have no signal handling on their own (e.g. Glib, Tk, Qt).

  Some event loops (POE, Event, Event::Lib) offer signal watchers natively, and either employ their own workarounds (POE) or use AnyEvent's workaround (using `$AnyEvent::MAX_SIGNAL_LATENCY`). Installing Async::Interrupt does nothing for those backends.

- *EV*

  This module isn't really "optional", as it is simply one of the backend event loops that AnyEvent can use. However, it is simply the best event loop available in terms of features, speed and stability: It supports the AnyEvent API optimally, implements all the watcher types natively, does automatic timer adjustments even when no monotonic clock is available, can take avdantage of advanced kernel interfaces such as `epoll` and `kqueue`, and is the fastest backend *by far*. You can even embed Glib/Gtk2 in it (or vice versa, see EV::Glib and Glib::EV).

  If you only use backends that rely on another event loop (e.g. `Tk`), then this module will do nothing for you.

- *Guard*

  The guard module, when used, will be used to implement `AnyEvent::Util::guard`. This speeds up guards considerably (and uses a lot less memory), but otherwise doesn't affect guard operation much. It is purely used for performance.

- *JSON* and *JSON::XS*

One of these modules is required when you want to read or write JSON data via *AnyEvent::Handle*. *JSON* is also written in pure-perl, but can take advantage of the ultra-high-speed *JSON::XS* module when it is installed.

- *Net::SSLeay*

  Implementing TLS/SSL in Perl is certainly interesting, but not very worthwhile: If this module is installed, then *AnyEvent::Handle* (with the help of *AnyEvent::TLS*), gains the ability to do TLS/SSL.

- *Time::HiRes*

  This module is part of perl since release 5.008. It will be used when the chosen event library does not come with a timing source of its own. The pure-perl event loop (*AnyEvent::Loop*) will additionally load it to try to use a monotonic clock for timing stability.

- AnyEvent::AIO (and IO::AIO)

  The default implementation of *AnyEvent::IO* is to do I/O synchronously, stopping programs while they access the disk, which is fine for a lot of programs.

  Installing AnyEvent::AIO (and its IO::AIO dependency) makes it switch to a true asynchronous implementation, so event processing can continue even while waiting for disk I/O.

FORK

Most event libraries are not fork-safe. The ones who are usually are because they rely on inefficient but fork-safe `select` or `poll` calls - higher performance APIs such as BSD's kqueue or the dreaded Linux epoll are usually badly thought-out hacks that are incompatible with fork in one way or another. Only *EV* is fully fork-aware and ensures that you continue event-processing in both parent and child (or both, if you know what you are doing).

This means that, in general, you cannot fork and do event processing in the child if the event library was initialised before the fork (which usually happens when the first AnyEvent watcher is created, or the library is loaded).

If you have to fork, you must either do so *before* creating your first watcher OR you must not use AnyEvent at all in the child OR you must do something completely out of the scope of AnyEvent (see below).

The problem of doing event processing in the parent *and* the child is much more complicated: even for backends that *are* fork-aware or fork-safe, their behaviour is not usually what you want: fork clones all watchers, that means all timers, I/O watchers etc. are active in both parent and child, which is almost never what you want. Using `exec` to start worker children from some kind of manage prrocess is usually preferred, because it is much easier and cleaner, at the expense of having to have another binary.

In addition to logical problems with fork, there are also implementation problems. For example, on POSIX systems, you cannot fork at all in Perl code if a thread (I am talking of pthreads here) was ever created in the process, and this is just the tip of the iceberg. In general, using fork from Perl is difficult, and attempting to use fork without an exec to implement some kind of parallel processing is almost certainly doomed.

To safely fork and exec, you should use a module such as Proc::FastSpawn that let's you safely fork and exec new processes.

If you want to do multiprocessing using processes, you can look at the AnyEvent::Fork module (and some related modules such as AnyEvent::Fork::RPC, AnyEvent::Fork::Pool and AnyEvent::Fork::Remote). This module allows you to safely create subprocesses without any limitations - you can use X11 toolkits or AnyEvent in the children created by AnyEvent::Fork safely and without any special precautions.

SECURITY CONSIDERATIONS

AnyEvent can be forced to load any event model via $ENV{PERL_ANYEVENT_MODEL}. While this cannot (to my knowledge) be used to execute arbitrary code or directly gain access, it can easily be used to make the program hang or malfunction in subtle ways, as AnyEvent watchers will not be active when the program uses a different event model than specified in the variable.

You can make AnyEvent completely ignore this variable by deleting it before the first watcher gets created, e.g. with a `BEGIN` block:

```
BEGIN { delete $ENV{PERL_ANYEVENT_MODEL} }

use AnyEvent;
```

Similar considerations apply to $ENV{PERL_ANYEVENT_VERBOSE}, as that can be used to probe what backend is used and gain other information (which is probably even less useful to an attacker than PERL_ANYEVENT_MODEL), and $ENV{PERL_ANYEVENT_STRICT}.

Note that AnyEvent will remove *all* environment variables starting with `PERL_ANYEVENT_` from `%ENV` when it is loaded while taint mode is enabled.

BUGS

Perl 5.8 has numerous memleaks that sometimes hit this module and are hard to work around. If you suffer from memleaks, first upgrade to Perl 5.10 and check wether the leaks still show up. (Perl 5.10.0 has other annoying memleaks, such as leaking on `map` and `grep` but it is usually not as pronounced).

Modules

- `AnyEvent::DNS` - fully asynchronous DNS resolution
- `AnyEvent::Debug` - debugging utilities for AnyEvent
- `AnyEvent::Handle` - non-blocking I/O on streaming handles via AnyEvent
- `AnyEvent::IO` - the DBI of asynchronous I/O implementations
- `AnyEvent::Impl`
- `AnyEvent::Log` - simple logging “framework”
- `AnyEvent::Loop` - AnyEvent’s Pure-Perl event loop
- `AnyEvent::Socket` - useful IPv4 and IPv6 stuff.
- `AnyEvent::Strict` - force strict mode on for the whole process
- `AnyEvent::TLS` - SSLv2/SSLv3/TLSv1 contexts for use in AnyEvent::Handle
- `AnyEvent::Util` - various utility functions.

AnyEvent::DNS

fully asynchronous DNS resolution

SYNOPSIS

```
use AnyEvent::DNS;

my $cv = AnyEvent->condvar;
AnyEvent::DNS::a "www.google.de", $cv;
# ... later
my @addrs = $cv->recv;
```

DESCRIPTION

This module offers both a number of DNS convenience functions as well as a fully asynchronous and high-performance pure-perl stub resolver.

The stub resolver supports DNS over IPv4 and IPv6, UDP and TCP, optional EDNS0 support for up to 4kiB datagrams and automatically falls back to virtual circuit mode for large responses.

CONVENIENCE FUNCTIONS

- AnyEvent::DNS::a $domain, $cb->(@addrs)

  Tries to resolve the given domain to IPv4 address(es).

- AnyEvent::DNS::aaaa $domain, $cb->(@addrs)

  Tries to resolve the given domain to IPv6 address(es).

- AnyEvent::DNS::mx $domain, $cb->(@hostnames)

  Tries to resolve the given domain into a sorted (lower preference value first) list of domain names.

- AnyEvent::DNS::ns $domain, $cb->(@hostnames)

  Tries to resolve the given domain name into a list of name servers.

- AnyEvent::DNS::txt $domain, $cb->(@hostnames)

  Tries to resolve the given domain name into a list of text records. Only the first text string per record will be returned. If you want all strings, you need to call the resolver manually:

```
resolver->resolve ($domain => "txt", sub {
   for my $record (@_) {
      my (undef, undef, undef, @txt) = @$record;
      # strings now in @txt
   }
});
```

- AnyEvent::DNS::srv $service, $proto, $domain, $cb->(@srv_rr)

  Tries to resolve the given service, protocol and domain name into a list of service records.

  Each `$srv_rr` is an array reference with the following contents: `[$priority, $weight, $transport, $target]`.

  They will be sorted with lowest priority first, then randomly distributed by weight as per RFC 2782.

  Example:

```
AnyEvent::DNS::srv "sip", "udp", "schmorp.de", sub { ...
# @_ = ( [10, 10, 5060, "sip1.schmorp.de" ] )
```

- AnyEvent::DNS::any $domain, $cb->(@rrs)

Tries to resolve the given domain and passes all resource records found to the callback. Note that this uses a DNS ANY query, which, as of RFC 8482, are officially deprecated.

- AnyEvent::DNS::ptr $domain, $cb->(@hostnames)

  Tries to make a PTR lookup on the given domain. See `reverse_lookup` and `reverse_verify` if you want to resolve an IP address to a hostname instead.

- AnyEvent::DNS::reverse_lookup $ipv4_or_6, $cb->(@hostnames)

  Tries to reverse-resolve the given IPv4 or IPv6 address (in textual form) into its hostname(s). Handles V4MAPPED and V4COMPAT IPv6 addresses transparently.

- AnyEvent::DNS::reverse_verify $ipv4_or_6, $cb->(@hostnames)

  The same as `reverse_lookup`, but does forward-lookups to verify that the resolved hostnames indeed point to the address, which makes spoofing harder.

  If you want to resolve an address into a hostname, this is the preferred method: The DNS records could still change, but at least this function verified that the hostname, at one point in the past, pointed at the IP address you originally resolved.

  Example:

```
AnyEvent::DNS::reverse_verify "2001:500:2f::f", sub { print␣
↪shift };
# => f.root-servers.net
```

LOW-LEVEL DNS EN-/DECODING FUNCTIONS

- $AnyEvent::DNS::EDNS0

  This variable decides whether dns_pack automatically enables EDNS0 support. By default, this is disabled (`0`), unless overridden by `$ENV{PERL_ANYEVENT_EDNS0}`, but when set to 1, AnyEvent::DNS will use EDNS0 in all requests.

- $pkt = AnyEvent::DNS::dns_pack $dns

  Packs a perl data structure into a DNS packet. Reading RFC 1035 is strongly recommended, then everything will be totally clear. Or maybe not.

  Resource records are not yet encodable.

  Examples:

```
# very simple request, using lots of default values:
{ rd => 1, qd => [ [ "host.domain", "a"] ] }

# more complex example, showing how flags etc. are named:

{
   id => 10000,
   op => "query",
   rc => "nxdomain",

   # flags
```

(continues on next page)

(continued from previous page)

```
   qr => 1,
   aa => 0,
   tc => 0,
   rd => 0,
   ra => 0,
   ad => 0,
   cd => 0,

   qd => [@rr], # query section
   an => [@rr], # answer section
   ns => [@rr], # authority section
   ar => [@rr], # additional records section
}
```

- $dns = AnyEvent::DNS::dns_unpack $pkt

  Unpacks a DNS packet into a perl data structure.

  Examples:

```
# an unsuccessful reply
{
  'qd' => [
            [ 'ruth.plan9.de.mach.uni-karlsruhe.de', '*', 'in' ]
          ],
  'rc' => 'nxdomain',
  'ar' => [],
  'ns' => [
            [
              'uni-karlsruhe.de',
              'soa',
              'in',
              600,
              'netserv.rz.uni-karlsruhe.de',
              'hostmaster.rz.uni-karlsruhe.de',
              2008052201, 10800, 1800, 2592000, 86400
            ]
          ],
  'tc' => '',
  'ra' => 1,
  'qr' => 1,
  'id' => 45915,
  'aa' => '',
  'an' => [],
  'rd' => 1,
  'op' => 'query',
  '__' => '<original dns packet>',
}

# a successful reply
```

(continues on next page)

(continued from previous page)

```
{
  'qd' => [ [ 'www.google.de', 'a', 'in' ] ],
  'rc' => 0,
  'ar' => [

↪147' ],
          ],
  'rd' => 1,
  'op' => 0,
  '__' => '<original dns packet>',
}
```

Extending DNS Encoder and Decoder

This section describes an *experimental* method to extend the DNS encoder and decoder with new opcode, rcode, class and type strings, as well as resource record decoders.

Since this is experimental, it can change, as anything can change, but this interface is expe ctedc to be relatively stable and was stable during the whole existance of `AnyEvent::DNS` so far.

Note that, since changing the decoder or encoder might break existing code, you should either be sure to control for this, or only temporarily change these values, e.g. like so:

```
my $decoded = do {
   local $AnyEvent::DNS::opcode_str{7} = "yxrrset";
   AnyEvent::DNS::dns_unpack $mypkt
};
```

- Two hashes that map lowercase opcode strings to numerical id's (For the encoder), or vice versa (for the decoder). Example: add a new opcode string `notzone`.

  ```
  $AnyEvent::DNS::opcode_id{notzone} = 10;
  $AnyEvent::DNS::opcode_str{10} = 'notzone';
  ```

- Same as above, for for rcode values.
- Same as above, but for resource record class names/values.
- Same as above, but for resource record type names/values.
- This hash maps resource record type values to code references. When decoding, they are called with `$_` set to the undecoded data portion and `$ofs` being the current byte offset. of the record. You should have a look at the existing implementations to understand how it works in detail, but here are two examples:

  Decode an A record. A records are simply four bytes with one byte per address component, so the decoder simply unpacks them and joins them with dots in between:

  ```
  $AnyEvent::DNS::dec_rr{1} = sub { join ".", unpack "C4", $_ };
  ```

  Decode a CNAME record, which contains a potentially compressed domain name.

  ```
  package AnyEvent::DNS; # for %dec_rr, $ofsd and &_dec_name
  $dec_rr{5} = sub { local $ofs = $ofs - length; _dec_name };
  ```

THE AnyEvent::DNS RESOLVER CLASS

This is the class which does the actual protocol work.

- AnyEvent::DNS::resolver

  This function creates and returns a resolver that is ready to use and should mimic the default resolver for your system as good as possible. It is used by AnyEvent itself as well.

  It only ever creates one resolver and returns this one on subsequent calls - see `$AnyEvent::DNS::RESOLVER`, below, for details.

  Unless you have special needs, prefer this function over creating your own resolver object.

  The resolver is created with the following parameters:

  ```
  untaint          enabled
  max_outstanding  $ENV{PERL_ANYEVENT_MAX_OUTSTANDING_DNS}␣
   ↪(default 10)
  ```

`os_config` will be used for OS-specific configuration, unless `$ENV{PERL_ANYEVENT_RESOLV_CONF}` is specified, in which case that file gets parsed.

- $AnyEvent::DNS::RESOLVER

  This variable stores the default resolver returned by `AnyEvent::DNS::resolver`, or `undef` when the default resolver hasn't been instantiated yet.

  One can provide a custom resolver (e.g. one with caching functionality) by storing it in this variable, causing all subsequent resolves done via `AnyEvent::DNS::resolver` to be done via the custom one.

- $resolver = new AnyEvent::DNS key => value...

  Creates and returns a new resolver.

  The following options are supported:

  - server => [...]

    A list of server addresses (default: `v127.0.0.1` or `::1`) in network format (i.e. as returned by `AnyEvent::Socket::parse_address` - both IPv4 and IPv6 are supported).

  - timeout => [...]

    A list of timeouts to use (also determines the number of retries). To make three retries with individual time-outs of 2, 5 and 5 seconds, use `[2, 5, 5]`, which is also the default.

  - search => [...]

    The default search list of suffixes to append to a domain name (default: none).

  - ndots => $integer

    The number of dots (default: `1`) that a name must have so that the resolver tries to resolve the name without any suffixes first.

  - max_outstanding => $integer

    Most name servers do not handle many parallel requests very well. This option limits the number of outstanding requests to `$integer` (default: `10`), that means if you request more than this many requests, then the additional requests will be queued until some other requests have been resolved.

  - reuse => $seconds

    The number of seconds (default: `300`) that a query id cannot be re-used after a timeout. If there was no time-out then query ids can be reused immediately.

  - untaint => $boolean

    When true, then the resolver will automatically untaint results, and might also ignore certain environment variables.

- $resolver->parse_resolv_conf ($string)

  Parses the given string as if it were a `resolv.conf` file. The following directives are supported (but not necessarily implemented).

#- and ;-style comments, `nameserver`, `domain`, `search`, `sortlist`, `options` (`timeout`, `attempts`, `ndots`).

Everything else is silently ignored.

- $resolver->os_config

  Tries so load and parse `/etc/resolv.conf` on portable operating systems. Tries various egregious hacks on windows to force the DNS servers and searchlist out of the system.

  This method must be called at most once before trying to resolve anything.

- $resolver->timeout ($timeout, ...)

  Sets the timeout values. See the `timeout` constructor argument (and note that this method expects the timeout values themselves, not an array-reference).

- $resolver->max_outstanding ($nrequests)

  Sets the maximum number of outstanding requests to `$nrequests`. See the `max_outstanding` constructor argument.

- $resolver->request ($req, $cb->($res))

  This is the main low-level workhorse for sending DNS requests.

  This function sends a single request (a hash-ref formated as specified for `dns_pack`) to the configured nameservers in turn until it gets a response. It handles timeouts, retries and automatically falls back to virtual circuit mode (TCP) when it receives a truncated reply. It does not handle anything else, such as the domain searchlist or relative names - use `->resolve` for that.

  Calls the callback with the decoded response packet if a reply was received, or no arguments in case none of the servers answered.

- $resolver->resolve ($qname, $qtype, %options, $cb->(@rr))

  Queries the DNS for the given domain name `$qname` of type `$qtype`.

  A `$qtype` is either a numerical query type (e.g. 1 for A records) or a lowercase name (you have to look at the source to see which aliases are supported, but all types from RFC 1035, `aaaa`, `srv`, `spf` and a few more are known to this module). A `$qtype` of "*" is supported and means "any" record type.

  The callback will be invoked with a list of matching result records or none on any error or if the name could not be found.

  CNAME chains (although illegal) are followed up to a length of 10.

  The callback will be invoked with arraryefs of the form `[$name, $type, $class, $ttl, @data]`, where `$name` is the domain name, `$type` a type string or number, `$class` a class name, `$ttl` is the remaining time-to-live and `@data` is resource-record-dependent data, in seconds. For `a` records, this will be the textual IPv4 addresses, for `ns` or `cname` records this will be a domain name, for `txt` records these are all the strings and so on.

  All types mentioned in RFC 1035, `aaaa`, `srv`, `naptr` and `spf` are decoded. All resource records not known to this module will have the raw `rdata` field as fifth array element.

Note that this resolver is just a stub resolver: it requires a name server supporting recursive queries, will not do any recursive queries itself and is not secure when used against an untrusted name server.

The following options are supported:

– search => [$suffix...]

  Use the given search list (which might be empty), by appending each one in turn to the `$qname`. If this option is missing then the configured `ndots` and `search` values define its value (depending on `ndots`, the empty suffix will be prepended or appended to that `search` value). If the `$qname` ends in a dot, then the searchlist will be ignored.

– accept => [$type...]

  Lists the acceptable result types: only result types in this set will be accepted and returned. The default includes the `$qtype` and nothing else. If this list includes `cname`, then CNAME-chains will not be followed (because you asked for the CNAME record).

– class => "class"

  Specify the query class ("in" for internet, "ch" for chaosnet and "hs" for hesiod are the only ones making sense). The default is "in", of course.

Examples:

```
# full example, you can paste this into perl:
use Data::Dumper;
use AnyEvent::DNS;
AnyEvent::DNS::resolver->resolve (
   "google.com", "*", my $cv = AnyEvent->condvar);
warn Dumper [$cv->recv];

# shortened result:
# [
#   [ 'google.com', 'soa', 'in', 3600, 'ns1.google.com', 'dns-
 ↪admin.google.com',
#     2008052701, 7200, 1800, 1209600, 300 ],
#   [
#     'google.com', 'txt', 'in', 3600,
#     'v=spf1 include:_netblocks.google.com ~all'
#   ],
#   [ 'google.com', 'a', 'in', 3600, '64.233.187.99' ],
#   [ 'google.com', 'mx', 'in', 3600, 10, 'smtp2.google.com' ],
#   [ 'google.com', 'ns', 'in', 3600, 'ns2.google.com' ],
# ]

# resolve a records:
$res->resolve ("ruth.plan9.de", "a", sub { warn Dumper [@_] });

# result:
# [
#   [ 'ruth.schmorp.de', 'a', 'in', 86400, '129.13.162.95' ]
```

(continues on next page)

(continued from previous page)

```
# ]

# resolve any records, but return only a and aaaa records:
$res->resolve ("test1.laendle", "*",
   accept => ["a", "aaaa"],
   sub {
      warn Dumper [@_];
   }
);

# result:
# [
#   [ 'test1.laendle', 'a', 'in', 86400, '10.0.0.255' ],
#   [ 'test1.laendle', 'aaaa', 'in', 60,
 ↪'3ffe:1900:4545:0002:0240:0000:0000:f7e1' ]
# ]
```

- $resolver->wait_for_slot ($cb->($resolver))

  Wait until a free request slot is available and call the callback with the resolver object.

  A request slot is used each time a request is actually sent to the nameservers: There are never more than `max_outstanding` of them.

  Although you can submit more requests (they will simply be queued until a request slot becomes available), sometimes, usually for rate-limiting purposes, it is useful to instead wait for a slot before generating the request (or simply to know when the request load is low enough so one can submit requests again).

  This is what this method does: The callback will be called when submitting a DNS request will not result in that request being queued. The callback may or may not generate any requests in response.

  Note that the callback will only be invoked when the request queue is empty, so this does not play well if somebody else keeps the request queue full at all times.

AnyEvent::Debug

debugging utilities for AnyEvent

SYNOPSIS

```
use AnyEvent::Debug;

# create an interactive shell into the program
my $shell = AnyEvent::Debug::shell "unix/", "/home/schmorp/myshell";
# then on the shell: "socat readline /home/schmorp/myshell"
```

DESCRIPTION

This module provides functionality hopefully useful for debugging.

At the moment, "only" an interactive shell is implemented. This shell allows you to interactively "telnet into" your program and execute Perl code, e.g. to look at global variables.

FUNCTIONS

- $shell = AnyEvent::Debug::shell $host, $service

  This function binds on the given host and service port and returns a shell object, which determines the lifetime of the shell. Any number of connections are accepted on the port, and they will give you a very primitive shell that simply executes every line you enter.

  All commands will be executed "blockingly" with the socket `selected` for output. For a less "blocking" interface see *Coro::Debug*.

  The commands will be executed in the `AnyEvent::Debug::shell` package, which currently has "help" and a few other commands, and can be freely modified by all shells. Code is evaluated under `use strict 'subs'`.

  Every shell has a logging context (`$LOGGER`) that is attached to `$AnyEvent::Log::COLLECT`), which is especially useful to gether debug and trace messages.

  As a general programming guide, consider the beneficial aspects of using more global (`our`) variables than local ones (`my`) in package scope: Earlier all my modules tended to hide internal variables inside `my` variables, so users couldn't accidentally access them. Having interactive access to your programs changed that: having internal variables still in the global scope means you can debug them easier.

  As no authentication is done, in most cases it is best not to use a TCP port, but a unix domain socket, whcih can be put wherever you can access it, but not others:

  ```
  our $SHELL = AnyEvent::Debug::shell "unix/", "/home/schmorp/
  ↪shell";
  ```

  Then you can use a tool to connect to the shell, such as the ever versatile `socat`, which in addition can give you readline support:

  ```
  socat readline /home/schmorp/shell
  # or:
  cd /home/schmorp; socat readline unix:shell
  ```

Socat can even give you a persistent history:

```
socat readline,history=.anyevent-history unix:shell
```

Binding on `127.0.0.1` (or `::1`) might be a less secure but sitll not totally insecure (on single-user machines) alternative to let you use other tools, such as telnet:

```
our $SHELL = AnyEvent::Debug::shell "127.1", "1357";
```

And then:

```
telnet localhost 1357
```

- AnyEvent::Debug::wrap [$level]

  Sets the instrumenting/wrapping level of all watchers that are being created after this call. If no `$level` has been specified, then it toggles between `0` and `1`.

  The default wrap level is `0`, or whatever `$ENV{PERL_ANYEVENT_DEBUG_WRAP}` specifies.

  A level of `0` disables wrapping, i.e. AnyEvent works normally, and in its most efficient mode.

  A level of `1` or higher enables wrapping, which replaces all watchers by AnyEvent::Debug::Wrapped objects, stores the location where a watcher was created and wraps the callback to log all invocations at "trace" loglevel if tracing is enabled fore the watcher. The initial state of tracing when creating a watcher is taken from the global variable `$AnyEvent::Debug::TRACE`. The default value of that variable is `1`, but it can make sense to set it to `0` and then do `local $AnyEvent::Debug::TRACE = 1` in a block where you create "interesting" watchers. Tracing can also be enabled and disabled later by calling the watcher's `trace` method.

  The wrapper will also count how many times the callback was invoked and will record up to ten runtime errors with corresponding backtraces. It will also log runtime errors at "error" loglevel.

  To see the trace messages, you can invoke your program with `PERL_ANYEVENT_VERBOSE=9`, or you can use AnyEvent::Log to divert the trace messages in any way you like (the EXAMPLES section in *AnyEvent::Log* has some examples).

  A level of 2 does everything that level 1 does, but also stores a full backtrace of the location the watcher was created, which slows down watcher creation considerably.

  Every wrapped watcher will be linked into `%AnyEvent::Debug::Wrapped`, with its address as key. The `wl` command in the debug shell can be used to list watchers.

  Instrumenting can increase the size of each watcher multiple times, and, especially when backtraces are involved, also slows down watcher creation a lot.

  Also, enabling and disabling instrumentation will not recover the full performance that you had before wrapping (the AE::xxx functions will stay slower, for example).

  If you are developing your program, also consider using AnyEvent::Strict to check for common mistakes.

- AnyEvent::Debug::path2mod $path

  Tries to replace a path (e.g. the file name returned by caller) by a module name. Returns the path unchanged if it fails.

  Example:

```
print AnyEvent::Debug::path2mod "/usr/lib/perl5/AnyEvent/Debug.
 ↪pm";
# might print "AnyEvent::Debug"
```

- AnyEvent::Debug::cb2str $cb

  Using various gambits, tries to convert a callback (e.g. a code reference) into a more useful string.

  Very useful if you debug a program and have some callback, but you want to know where in the program the callback is actually defined.

- AnyEvent::Debug::backtrace [$skip]

  Creates a backtrace (actually an AnyEvent::Debug::Backtrace object that you can stringify), not unlike the Carp module would. Unlike the Carp module it resolves some references (such as callbacks) to more user-friendly strings, has a more succinct output format and most importantly: doesn't leak memory like hell.

  The reason it creates an object is to save time, as formatting can be done at a later time. Still, creating a backtrace is a relatively slow operation.

THE AnyEvent::Debug::Wrapped CLASS

All watchers created while the wrap level is non-zero will be wrapped inside an AnyEvent::Debug::Wrapped object. The address of the wrapped watcher will become its ID - every watcher will be stored in `$AnyEvent::Debug::Wrapped{$id}`.

These wrapper objects can be stringified and have some methods defined on them.

For debugging, of course, it can be helpful to look into these objects, which is why this is documented here, but this might change at any time in future versions.

Each object is a relatively standard hash with the following members:

```
type   => name of the method used ot create the watcher (e.g. C<io>,␣
 ↪C<timer>).
w      => the actual watcher
rfile  => reference to the filename of the file the watcher was␣
 ↪created in
line   => line number where it was created
sub    => function name (or a special string) which created the␣
 ↪watcher
cur    => if created inside another watcher callback, this is the␣
 ↪string rep of the other watcher
now    => the timestamp (AE::now) when the watcher was created
arg    => the arguments used to create the watcher (sans C<cb>)
cb     => the original callback used to create the watcher
called => the number of times the callback was called
```

Each object supports the following mehtods (warning: these are only available on wrapped watchers, so are best for interactive use via the debug shell).

- $w->id

  Returns the numerical id of the watcher, as used in the debug shell.

- $w->verbose

  Returns a multiline textual description of the watcher, including the first ten exceptions caught while executing the callback.

- $w->trace ($on)

  Enables ($on is true) or disables ($on is false) tracing on this watcher.

  To get tracing messages, both the global logging settings must have trace messages enabled for the context `AnyEvent::Debug` and tracing must be enabled for the wrapped watcher.

  To enable trace messages globally, the simplest way is to start the program with `PERL_ANYEVENT_VERBOSE=9` in the environment.

  Tracing for each individual watcher is enabled by default (unless `$AnyEvent::Debug::TRACE` has been set to false).

AnyEvent::Handle

non-blocking I/O on streaming handles via AnyEvent

SYNOPSIS

```
use AnyEvent;
use AnyEvent::Handle;

my $cv = AnyEvent->condvar;

my $hdl; $hdl = new AnyEvent::Handle
   fh => \*STDIN,
   on_error => sub {
      my ($hdl, $fatal, $msg) = @_;
      AE::log error => $msg;
      $hdl->destroy;
      $cv->send;
   };

# send some request line
$hdl->push_write ("getinfo\015\012");
```

(continues on next page)

(continued from previous page)

```
# read the response line
$hdl->push_read (line => sub {
   my ($hdl, $line) = @_;
   say "got line <$line>";
   $cv->send;
});

$cv->recv;
```

DESCRIPTION

This is a helper module to make it easier to do event-based I/O on stream-based filehandles (sockets, pipes, and other stream things). Specifically, it doesn't work as expected on files, packet-based sockets or similar things.

The AnyEvent::Intro tutorial contains some well-documented AnyEvent::Handle examples.

In the following, where the documentation refers to "bytes", it means characters. As sysread and syswrite are used for all I/O, their treatment of characters applies to this module as well.

At the very minimum, you should specify `fh` or `connect`, and the `on_error` callback.

All callbacks will be invoked with the handle object as their first argument.

METHODS

- $handle = **new** AnyEvent::Handle fh => $filehandle, key => value...

  The constructor supports these arguments (all as `key => value` pairs).

  - fh => $filehandle [`fh` or `connect` MANDATORY]

    The filehandle this *AnyEvent::Handle* object will operate on. NOTE: The filehandle will be set to non-blocking mode (using `AnyEvent::fh_unblock`) by the constructor and needs to stay in that mode.

  - connect => [$host, $service] [`fh` or `connect` MANDATORY]

    Try to connect to the specified host and service (port), using `AnyEvent::Socket::tcp_connect`. The `$host` additionally becomes the default `peername`.

    You have to specify either this parameter, or `fh`, above.

    It is possible to push requests on the read and write queues, and modify properties of the stream, even while AnyEvent::Handle is connecting.

    When this parameter is specified, then the `on_prepare`, `on_connect_error` and `on_connect` callbacks will be called under the appropriate circumstances:

    * on_prepare => $cb->($handle)

This (rarely used) callback is called before a new connection is attempted, but after the file handle has been created (you can access that file handle via `$handle->{fh}`). It could be used to prepare the file handle with parameters required for the actual connect (as opposed to settings that can be changed when the connection is already established).

The return value of this callback should be the connect timeout value in seconds (or `0`, or `undef`, or the empty list, to indicate that the default timeout is to be used).

* on_connect => $cb->($handle, $host, $port, $retry->())

  This callback is called when a connection has been successfully established.

  The peer's numeric host and port (the socket peername) are passed as parameters, together with a retry callback. At the time it is called the read and write queues, EOF status, TLS status and similar properties of the handle will have been reset.

  If, for some reason, the handle is not acceptable, calling `$retry` will continue with the next connection target (in case of multi-homed hosts or SRV records there can be multiple connection endpoints). The `$retry` callback can be invoked after the connect callback returns, i.e. one can start a handshake and then decide to retry with the next host if the handshake fails.

  In most cases, you should ignore the `$retry` parameter.

* on_connect_error => $cb->($handle, $message)

  This callback is called when the connection could not be established. `$!` will contain the relevant error code, and `$message` a message describing it (usually the same as `"$!"`).

  If this callback isn't specified, then `on_error` will be called with a fatal error instead.

– on_error => $cb->($handle, $fatal, $message)

  This is the error callback, which is called when, well, some error occured, such as not being able to resolve the hostname, failure to connect, or a read error.

  Some errors are fatal (which is indicated by `$fatal` being true). On fatal errors the handle object will be destroyed (by a call to `-> destroy`) after invoking the error callback (which means you are free to examine the handle object). Examples of fatal errors are an EOF condition with active (but unsatisfiable) read watchers (`EPIPE`) or I/O errors. In cases where the other side can close the connection at will, it is often easiest to not report `EPIPE` errors in this callback.

  AnyEvent::Handle tries to find an appropriate error code for you to check against, but in some cases (TLS errors), this does not work well.

  If you report the error to the user, it is recommended to always output the `$message` argument in human-readable error messages (you don't need to report `"$!"` if you report `$message`).

  If you want to react programmatically to the error, then looking at `$!` and comparing it against some of the documented `Errno` values is usually better

than looking at the `$message`.

Non-fatal errors can be retried by returning, but it is recommended to simply ignore this parameter and instead abondon the handle object when this callback is invoked. Examples of non-fatal errors are timeouts `ETIMEDOUT`) or badly-formatted data (`EBADMSG`).

On entry to the callback, the value of `$!` contains the operating system error code (or `ENOSPC`, `EPIPE`, `ETIMEDOUT`, `EBADMSG` or `EPROTO`).

While not mandatory, it is *highly* recommended to set this callback, as you will not be notified of errors otherwise. The default just calls `croak`.

– on_read => $cb->($handle)

This sets the default read callback, which is called when data arrives and no read request is in the queue (unlike read queue callbacks, this callback will only be called when at least one octet of data is in the read buffer).

To access (and remove data from) the read buffer, use the `->rbuf` method or access the `$handle->{rbuf}` member directly. Note that you must not enlarge or modify the read buffer, you can only remove data at the beginning from it.

You can also call `->push_read (...)` or any other function that modifies the read queue. Or do both. Or ...

When an EOF condition is detected, AnyEvent::Handle will first try to feed all the remaining data to the queued callbacks and `on_read` before calling the `on_eof` callback. If no progress can be made, then a fatal error will be raised (with `$!` set to `EPIPE`).

Note that, unlike requests in the read queue, an `on_read` callback doesn't mean you *require* some data: if there is an EOF and there are outstanding read requests then an error will be flagged. With an `on_read` callback, the `on_eof` callback will be invoked.

– on_eof => $cb->($handle)

Set the callback to be called when an end-of-file condition is detected, i.e. in the case of a socket, when the other side has closed the connection cleanly, and there are no outstanding read requests in the queue (if there are read requests, then an EOF counts as an unexpected connection close and will be flagged as an error).

For sockets, this just means that the other side has stopped sending data, you can still try to write data, and, in fact, one can return from the EOF callback and continue writing data, as only the read part has been shut down.

If an EOF condition has been detected but no `on_eof` callback has been set, then a fatal error will be raised with `$!` set to <0>.

– on_drain => $cb->($handle)

This sets the callback that is called once when the write buffer becomes empty (and immediately when the handle object is created).

To append to the write buffer, use the `->push_write` method.

This callback is useful when you don't want to put all of your write data into the queue at once, for example, when you want to write the contents of some file to the socket you might not want to read the whole file into memory and push it into the queue, but instead only read more data from the file when the write queue becomes empty.

– timeout => $fractional_seconds

– rtimeout => $fractional_seconds

– wtimeout => $fractional_seconds

If non-zero, then these enables an "inactivity" timeout: whenever this many seconds pass without a successful read or write on the underlying file handle (or a call to `timeout_reset`), the `on_timeout` callback will be invoked (and if that one is missing, a non-fatal `ETIMEDOUT` error will be raised).

There are three variants of the timeouts that work independently of each other, for both read and write (triggered when nothing was read *OR* written), just read (triggered when nothing was read), and just write: `timeout`, `rtimeout` and `wtimeout`, with corresponding callbacks `on_timeout`, `on_rtimeout` and `on_wtimeout`, and reset functions `timeout_reset`, `rtimeout_reset`, and `wtimeout_reset`.

Note that timeout processing is active even when you do not have any outstanding read or write requests: If you plan to keep the connection idle then you should disable the timeout temporarily or ignore the timeout in the corresponding `on_timeout` callback, in which case AnyEvent::Handle will simply restart the timeout.

Zero (the default) disables the corresponding timeout.

– on_timeout => $cb->($handle)

– on_rtimeout => $cb->($handle)

– on_wtimeout => $cb->($handle)

Called whenever the inactivity timeout passes. If you return from this callback, then the timeout will be reset as if some activity had happened, so this condition is not fatal in any way.

– rbuf_max => <bytes>

If defined, then a fatal error will be raised (with `$!` set to `ENOSPC`) when the read buffer ever (strictly) exceeds this size. This is useful to avoid some forms of denial-of-service attacks.

For example, a server accepting connections from untrusted sources should be configured to accept only so-and-so much data that it cannot act on (for example, when expecting a line, an attacker could send an unlimited amount of data without a callback ever being called as long as the line isn't finished).

– wbuf_max => <bytes>

If defined, then a fatal error will be raised (with `$!` set to `ENOSPC`) when the write buffer ever (strictly) exceeds this size. This is useful to avoid some forms of denial-of-service attacks.

Although the units of this parameter is bytes, this is the *raw* number of bytes not yet accepted by the kernel. This can make a difference when you e.g. use TLS, as TLS typically makes your write data larger (but it can also make it smaller due to compression).

As an example of when this limit is useful, take a chat server that sends chat messages to a client. If the client does not read those in a timely manner then the send buffer in the server would grow unbounded.

– autocork => <boolean>

When disabled (the default), `push_write` will try to immediately write the data to the handle if possible. This avoids having to register a write watcher and wait for the next event loop iteration, but can be inefficient if you write multiple small chunks (on the wire, this disadvantage is usually avoided by your kernel's nagle algorithm, see `no_delay`, but this option can save costly syscalls).

When enabled, writes will always be queued till the next event loop iteration. This is efficient when you do many small writes per iteration, but less efficient when you do a single write only per iteration (or when the write buffer often is full). It also increases write latency.

– no_delay => <boolean>

When doing small writes on sockets, your operating system kernel might wait a bit for more data before actually sending it out. This is called the Nagle algorithm, and usually it is beneficial.

In some situations you want as low a delay as possible, which can be accomplishd by setting this option to a true value.

The default is your operating system's default behaviour (most likely enabled). This option explicitly enables or disables it, if possible.

– keepalive => <boolean>

Enables (default disable) the SO_KEEPALIVE option on the stream socket: normally, TCP connections have no time-out once established, so TCP connections, once established, can stay alive forever even when the other side has long gone. TCP keepalives are a cheap way to take down long-lived TCP connections when the other side becomes unreachable. While the default is OS-dependent, TCP keepalives usually kick in after around two hours, and, if the other side doesn't reply, take down the TCP connection some 10 to 15 minutes later.

It is harmless to specify this option for file handles that do not support keepalives, and enabling it on connections that are potentially long-lived is usually a good idea.

– oobinline => <boolean>

BSD majorly fucked up the implementation of TCP urgent data. The result is that almost no OS implements TCP according to the specs, and every OS implements it slightly differently.

If you want to handle TCP urgent data, then setting this flag (the default is enabled) gives you the most portable way of getting urgent data, by putting it into the stream.

Since BSD emulation of OOB data on top of TCP's urgent data can have security implications, AnyEvent::Handle sets this flag automatically unless explicitly specified. Note that setting this flag after establishing a connection *may* be a bit too late (data loss could already have occured on BSD systems), but at least it will protect you from most attacks.

– read_size => <bytes>

The initial read block size, the number of bytes this module will try to read during each loop iteration. Each handle object will consume at least this amount of memory for the read buffer as well, so when handling many connections watch out for memory requirements). See also `max_read_size`. Default: `2048`.

– max_read_size => <bytes>

The maximum read buffer size used by the dynamic adjustment algorithm: Each time AnyEvent::Handle can read `read_size` bytes in one go it will double `read_size` up to the maximum given by this option. Default: `131072` or `read_size`, whichever is higher.

– low_water_mark => <bytes>

Sets the number of bytes (default: `0`) that make up an "empty" write buffer: If the buffer reaches this size or gets even samller it is considered empty.

Sometimes it can be beneficial (for performance reasons) to add data to the write buffer before it is fully drained, but this is a rare case, as the operating system kernel usually buffers data as well, so the default is good in almost all cases.

– linger => <seconds>

If this is non-zero (default: `3600`), the destructor of the AnyEvent::Handle object will check whether there is still outstanding write data and will install a watcher that will write this data to the socket. No errors will be reported (this mostly matches how the operating system treats outstanding data at socket close time).

This will not work for partial TLS data that could not be encoded yet. This data will be lost. Calling the `stoptls` method in time might help.

– peername => $string

A string used to identify the remote site - usually the DNS hostname (*not* IDN!) used to create the connection, rarely the IP address.

Apart from being useful in error messages, this string is also used in TLS peername verification (see `verify_peername` in *AnyEvent::TLS*). This verification will be skipped when `peername` is not specified or is `undef`.

– tls => "accept" | "connect" | Net::SSLeay::SSL object

When this parameter is given, it enables TLS (SSL) mode, that means AnyEvent will start a TLS handshake as soon as the connection has been established and will transparently encrypt/decrypt data afterwards.

All TLS protocol errors will be signalled as `EPROTO`, with an appropriate error message.

TLS mode requires Net::SSLeay to be installed (it will be loaded automatically when you try to create a TLS handle): this module doesn't have a dependency on that module, so if your module requires it, you have to add the dependency yourself. If Net::SSLeay cannot be loaded or is too old, you get an EPROTO error.

Unlike TCP, TLS has a server and client side: for the TLS server side, use `accept`, and for the TLS client side of a connection, use `connect` mode.

You can also provide your own TLS connection object, but you have to make sure that you call either `Net::SSLeay::set_connect_state` or `Net::SSLeay::set_accept_state` on it before you pass it to AnyEvent::Handle. Also, this module will take ownership of this connection object.

At some future point, AnyEvent::Handle might switch to another TLS implementation, then the option to use your own session object will go away.

IMPORTANT: since Net::SSLeay "objects" are really only integers, passing in the wrong integer will lead to certain crash. This most often happens when one uses a stylish `tls => 1` and is surprised about the segmentation fault.

Use the `->starttls` method if you need to start TLS negotiation later.

– tls_ctx => $anyevent_tls

Use the given `AnyEvent::TLS` object to create the new TLS connection (unless a connection object was specified directly). If this parameter is missing (or `undef`), then AnyEvent::Handle will use `AnyEvent::Handle::TLS_CTX`.

Instead of an object, you can also specify a hash reference with `key => value` pairs. Those will be passed to *AnyEvent::TLS* to create a new TLS context object.

– on_starttls => $cb->($handle, $success[, $error_message])

This callback will be invoked when the TLS/SSL handshake has finished. If `$success` is true, then the TLS handshake succeeded, otherwise it failed (`on_stoptls` will not be called in this case).

The session in `$handle->{tls}` can still be examined in this callback, even when the handshake was not successful.

TLS handshake failures will not cause `on_error` to be invoked when this callback is in effect, instead, the error message will be passed to `on_starttls`.

Without this callback, handshake failures lead to `on_error` being called as usual.

Note that you cannot just call `starttls` again in this callback. If you need to do that, start an zero-second timer instead whose callback can then call `->starttls` again.

– on_stoptls => $cb->($handle)

When a SSLv3/TLS shutdown/close notify/EOF is detected and this callback is set, then it will be invoked after freeing the TLS session. If it is not, then a TLS shutdown condition will be treated like a normal EOF condition on the handle.

The session in `$handle->{tls}` can still be examined in this callback.

This callback will only be called on TLS shutdowns, not when the underlying handle signals EOF.

– json => *JSON*, *JSON::PP* or *JSON::XS* object

This is the json coder object used by the `json` read and write types.

If you don't supply it, then AnyEvent::Handle will create and use a suitable one (on demand), which will write and expect UTF-8 encoded JSON texts (either using *JSON::XS* or *JSON*). The written texts are guaranteed not to contain any newline character.

For security reasons, this encoder will likely *not* handle numbers and strings, only arrays and objects/hashes. The reason is that originally JSON was self-delimited, but Dougles Crockford thought it was a splendid idea to redefine JSON incompatibly, so this is no longer true.

For protocols that used back-to-back JSON texts, this might lead to run-ins, where two or more JSON texts will be interpreted as one JSON text.

For this reason, if the default encoder uses *JSON::XS*, it will default to not allowing anything but arrays and objects/hashes, at least for the forseeable future (it will change at some point). This might or might not be true for the *JSON* module, so this might cause a security issue.

If you depend on either behaviour, you should create your own json object and pass it in explicitly.

– cbor => CBOR::XS object

This is the cbor coder object used by the `cbor` read and write types.

If you don't supply it, then AnyEvent::Handle will create and use a suitable one (on demand), which will write CBOR without using extensions, if possible.

Note that you are responsible to depend on the CBOR::XS module if you want to use this functionality, as AnyEvent does not have a dependency on it itself.

- $fh = $handle->fh

  This method returns the file handle used to create the *AnyEvent::Handle* object.

- $handle->on_error ($cb)

  Replace the current `on_error` callback (see the `on_error` constructor argument).

- $handle->on_eof ($cb)

  Replace the current `on_eof` callback (see the `on_eof` constructor argument).

- $handle->on_timeout ($cb)

- $handle->on_rtimeout ($cb)

- $handle->on_wtimeout ($cb)

  Replace the current `on_timeout`, `on_rtimeout` or `on_wtimeout` callback, or disables the callback (but not the timeout) if `$cb` = `undef`. See the `timeout` constructor argument and method.

- $handle->autocork ($boolean)

Enables or disables the current autocork behaviour (see `autocork` constructor argument). Changes will only take effect on the next write.

- $handle->no_delay ($boolean)

  Enables or disables the `no_delay` setting (see constructor argument of the same name for details).

- $handle->keepalive ($boolean)

  Enables or disables the `keepalive` setting (see constructor argument of the same name for details).

- $handle->oobinline ($boolean)

  Enables or disables the `oobinline` setting (see constructor argument of the same name for details).

- $handle->on_starttls ($cb)

  Replace the current `on_starttls` callback (see the `on_starttls` constructor argument).

- $handle->on_stoptls ($cb)

  Replace the current `on_stoptls` callback (see the `on_stoptls` constructor argument).

- $handle->rbuf_max ($max_octets)

  Configures the `rbuf_max` setting (`undef` disables it).

- $handle->wbuf_max ($max_octets)

  Configures the `wbuf_max` setting (`undef` disables it).

- $handle->timeout ($seconds)
- $handle->rtimeout ($seconds)
- $handle->wtimeout ($seconds)

  Configures (or disables) the inactivity timeout.

  The timeout will be checked instantly, so this method might destroy the handle before it returns.

- $handle->timeout_reset
- $handle->rtimeout_reset
- $handle->wtimeout_reset

  Reset the activity timeout, as if data was received or sent.

  These methods are cheap to call.

WRITE QUEUE

AnyEvent::Handle manages two queues per handle, one for writing and one for reading.

The write queue is very simple: you can add data to its end, and AnyEvent::Handle will automatically try to get rid of it for you.

When data could be written and the write buffer is shorter then the low water mark, the `on_drain` callback will be invoked once.

- $handle->on_drain ($cb)

  Sets the `on_drain` callback or clears it (see the description of `on_drain` in the constructor).

  This method may invoke callbacks (and therefore the handle might be destroyed after it returns).

- $handle->push_write ($data)

  Queues the given scalar to be written. You can push as much data as you want (only limited by the available memory and `wbuf_max`), as `AnyEvent::Handle` buffers it independently of the kernel.

  This method may invoke callbacks (and therefore the handle might be destroyed after it returns).

- $handle->push_write (type => @args)

  Instead of formatting your data yourself, you can also let this module do the job by specifying a type and type-specific arguments. You can also specify the (fully qualified) name of a package, in which case AnyEvent tries to load the package and then expects to find the `anyevent_write_type` function inside (see "custom write types", below).

  Predefined types are (if you have ideas for additional types, feel free to drop by and tell us):

  – netstring => $string

    Formats the given value as netstring (http://cr.yp.to/proto/netstrings.txt, this is not a recommendation to use them).

  – packstring => $format, $data

    An octet string prefixed with an encoded length. The encoding `$format` uses the same format as a Perl `pack` format, but must specify a single integer only (only one of `cCsSlLqQiInNvVjJw` is allowed, plus an optional `!`, < or > modifier).

  – json => $array_or_hashref

    Encodes the given hash or array reference into a JSON object. Unless you provide your own JSON object, this means it will be encoded to JSON text in UTF-8.

    The default encoder might or might not handle every type of JSON value - it might be limited to arrays and objects for security reasons. See the `json` constructor attribute for more details.

    JSON objects (and arrays) are self-delimiting, so if you only use arrays and hashes, you can write JSON at one end of a handle and read them at the other end without using any additional framing.

    The JSON text generated by the default encoder is guaranteed not to contain any newlines: While this module doesn't need delimiters after or between JSON texts to be able to read them, many other languages depend on them.

A simple RPC protocol that interoperates easily with other languages is to send JSON arrays (or objects, although arrays are usually the better choice as they mimic how function argument passing works) and a newline after each JSON text:

```
$handle->push_write (json => ["method", "arg1", "arg2"]); #␣
↪whatever
$handle->push_write ("\012");
```

An AnyEvent::Handle receiver would simply use the `json` read type and rely on the fact that the newline will be skipped as leading whitespace:

```
$handle->push_read (json => sub { my $array = $_[1]; ... });
```

Other languages could read single lines terminated by a newline and pass this line into their JSON decoder of choice.

– cbor => $perl_scalar

Encodes the given scalar into a CBOR value. Unless you provide your own CBOR::XS object, this means it will be encoded to a CBOR string not using any extensions, if possible.

CBOR values are self-delimiting, so you can write CBOR at one end of a handle and read them at the other end without using any additional framing.

A simple nd very very fast RPC protocol that interoperates with other languages is to send CBOR and receive CBOR values (arrays are recommended):

```
$handle->push_write (cbor => ["method", "arg1", "arg2"]); #␣
↪whatever
```

An AnyEvent::Handle receiver would simply use the `cbor` read type:

```
$handle->push_read (cbor => sub { my $array = $_[1]; ... });
```

– storable => $reference

Freezes the given reference using *Storable* and writes it to the handle. Uses the `nfreeze` format.

- $handle->push_shutdown

Sometimes you know you want to close the socket after writing your data before it was actually written. One way to do that is to replace your `on_drain` handler by a callback that shuts down the socket (and set `low_water_mark` to `0`). This method is a shorthand for just that, and replaces the `on_drain` callback with:

```
sub { shutdown $_[0]{fh}, 1 }
```

This simply shuts down the write side and signals an EOF condition to the the peer.

You can rely on the normal read queue and `on_eof` handling afterwards. This is the cleanest way to close a connection.

This method may invoke callbacks (and therefore the handle might be destroyed after it returns).

- custom write types - Package::anyevent_write_type $handle, @args

  Instead of one of the predefined types, you can also specify the name of a package. AnyEvent will try to load the package and then expects to find a function named `anyevent_write_type` inside. If it isn't found, it progressively tries to load the parent package until it either finds the function (good) or runs out of packages (bad).

  Whenever the given `type` is used, `push_write` will the function with the handle object and the remaining arguments.

  The function is supposed to return a single octet string that will be appended to the write buffer, so you can mentally treat this function as a "arguments to on-the-wire-format" converter.

  Example: implement a custom write type `join` that joins the remaining arguments using the first one.

```
$handle->push_write (My::Type => " ", 1,2,3);

# uses the following package, which can be defined in the
 ↪"My::Type" or in
# the "My" modules to be auto-loaded, or just about anywhere␣
 ↪when the
# My::Type::anyevent_write_type is defined before invoking it.

package My::Type;

sub anyevent_write_type {
   my ($handle, $delim, @args) = @_;

   join $delim, @args
}
```

READ QUEUE

AnyEvent::Handle manages two queues per handle, one for writing and one for reading.

The read queue is more complex than the write queue. It can be used in two ways, the "simple" way, using only `on_read` and the "complex" way, using a queue.

In the simple case, you just install an `on_read` callback and whenever new data arrives, it will be called. You can then remove some data (if enough is there) from the read buffer (`$handle->rbuf`). Or you can leave the data there if you want to accumulate more (e.g. when only a partial message has been received so far), or change the read queue with e.g. `push_read`.

In the more complex case, you want to queue multiple callbacks. In this case, AnyEvent::Handle will call the first queued callback each time new data arrives (also the first time it is queued) and remove it when it has done its job (see `push_read`, below).

This way you can, for example, push three line-reads, followed by reading a chunk of data, and AnyEvent::Handle will execute them in order.

Example 1: EPP protocol parser. EPP sends 4 byte length info, followed by the specified number of bytes which give an XML datagram.

```
# in the default state, expect some header bytes
$handle->on_read (sub {
   # some data is here, now queue the length-header-read (4 octets)
   shift->unshift_read (chunk => 4, sub {
      # header arrived, decode
      my $len = unpack "N", $_[1];

      # now read the payload
      shift->unshift_read (chunk => $len, sub {
         my $xml = $_[1];
         # handle xml
      });
   });
});
```

Example 2: Implement a client for a protocol that replies either with “OK” and another line or “ERROR” for the first request that is sent, and 64 bytes for the second request. Due to the availability of a queue, we can just pipeline sending both requests and manipulate the queue as necessary in the callbacks.

When the first callback is called and sees an “OK” response, it will `unshift` another line-read. This line-read will be queued *before* the 64-byte chunk callback.

```
# request one, returns either "OK + extra line" or "ERROR"
$handle->push_write ("request 1\015\012");

# we expect "ERROR" or "OK" as response, so push a line read
$handle->push_read (line => sub {
   # if we got an "OK", we have to _prepend_ another line,
   # so it will be read before the second request reads its 64 bytes
   # which are already in the queue when this callback is called
   # we don't do this in case we got an error
   if ($_[1] eq "OK") {
      $_[0]->unshift_read (line => sub {
         my $response = $_[1];
         ...
      });
   }
});

# request two, simply returns 64 octets
$handle->push_write ("request 2\015\012");

# simply read 64 bytes, always
$handle->push_read (chunk => 64, sub {
   my $response = $_[1];
   ...
});
```

- $handle->on_read ($cb)

  This replaces the currently set `on_read` callback, or clears it (when the new callback is `undef`). See the description of `on_read` in the constructor.

  This method may invoke callbacks (and therefore the handle might be destroyed after it returns).

- $handle->rbuf

  Returns the read buffer (as a modifiable lvalue). You can also access the read buffer directly as the `->{rbuf}` member, if you want (this is much faster, and no less clean).

  The only operation allowed on the read buffer (apart from looking at it) is removing data from its beginning. Otherwise modifying or appending to it is not allowed and will lead to hard-to-track-down bugs.

  NOTE: The read buffer should only be used or modified in the `on_read` callback or when `push_read` or `unshift_read` are used with a single callback (i.e. untyped). Typed `push_read` and `unshift_read` methods will manage the read buffer on their own.

- $handle->push_read ($cb)

- $handle->unshift_read ($cb)

  Append the given callback to the end of the queue (`push_read`) or prepend it (`unshift_read`).

  The callback is called each time some additional read data arrives.

  It must check whether enough data is in the read buffer already.

  If not enough data is available, it must return the empty list or a false value, in which case it will be called repeatedly until enough data is available (or an error condition is detected).

  If enough data was available, then the callback must remove all data it is interested in (which can be none at all) and return a true value. After returning true, it will be removed from the queue.

  These methods may invoke callbacks (and therefore the handle might be destroyed after it returns).

- $handle->push_read (type => @args, $cb)

- $handle->unshift_read (type => @args, $cb)

  Instead of providing a callback that parses the data itself you can chose between a number of predefined parsing formats, for chunks of data, lines etc. You can also specify the (fully qualified) name of a package, in which case AnyEvent tries to load the package and then expects to find the `anyevent_read_type` function inside (see "custom read types", below).

  Predefined types are (if you have ideas for additional types, feel free to drop by and tell us):

  – chunk => $octets, $cb->($handle, $data)

Invoke the callback only once `$octets` bytes have been read. Pass the data read to the callback. The callback will never be called with less data.

Example: read 2 bytes.

```
$handle->push_read (chunk => 2, sub {
   say "yay " . unpack "H*", $_[1];
});
```

– line => [$eol,]$cb->($handle, $line, $eol)

The callback will be called only once a full line (including the end of line marker, `$eol`) has been read. This line (excluding the end of line marker) will be passed to the callback as second argument (`$line`), and the end of line marker as the third argument (`$eol`).

The end of line marker, `$eol`, can be either a string, in which case it will be interpreted as a fixed record end marker, or it can be a regex object (e.g. created by `qr`), in which case it is interpreted as a regular expression.

The end of line marker argument `$eol` is optional, if it is missing (NOT undef), then `qr|\015?\012|` is used (which is good for most internet protocols).

Partial lines at the end of the stream will never be returned, as they are not marked by the end of line marker.

– regex => $accept[, $reject[, $skip], $cb->($handle, $data)

Makes a regex match against the regex object `$accept` and returns everything up to and including the match. All the usual regex variables ($1, %+ etc.) from the regex match are available in the callback.

Example: read a single line terminated by '\n'.

```
$handle->push_read (regex => qr<\n>, sub { ... });
```

If `$reject` is given and not undef, then it determines when the data is to be rejected: it is matched against the data when the `$accept` regex does not match and generates an `EBADMSG` error when it matches. This is useful to quickly reject wrong data (to avoid waiting for a timeout or a receive buffer overflow).

Example: expect a single decimal number followed by whitespace, reject anything else (not the use of an anchor).

```
$handle->push_read (regex => qr<^[0-9]+\s>, qr<[^0-9]>, sub
↪{ ... });
```

If `$skip` is given and not `undef`, then it will be matched against the receive buffer when neither `$accept` nor `$reject` match, and everything preceding and including the match will be accepted unconditionally. This is useful to skip large amounts of data that you know cannot be matched, so that the `$accept` or `$reject` regex do not have to start matching from the beginning. This is purely an optimisation and is usually worth it only when you expect more than a few kilobytes.

Example: expect a http header, which ends at `\015\012\015\012`. Since we expect the header to be very large (it isn't in practice, but...), we use a skip

regex to skip initial portions. The skip regex is tricky in that it only accepts something not ending in either \015 or \012, as these are required for the accept regex.

```
$handle->push_read (regex =>
   qr<\015\012\015\012>,
   undef, # no reject
   qr<^.*[^\015\012]>,
   sub { ... });
```

– netstring => $cb->($handle, $string)

A netstring (http://cr.yp.to/proto/netstrings.txt, this is not an endorsement).

Throws an error with `$!` set to EBADMSG on format violations.

– packstring => $format, $cb->($handle, $string)

An octet string prefixed with an encoded length. The encoding `$format` uses the same format as a Perl `pack` format, but must specify a single integer only (only one of `cCsSlLqQiInNvVjJw` is allowed, plus an optional `!`, < or > modifier).

For example, DNS over TCP uses a prefix of `n` (2 octet network order), EPP uses a prefix of `N` (4 octtes).

Example: read a block of data prefixed by its length in BER-encoded format (very efficient).

```
$handle->push_read (packstring => "w", sub {
   my ($handle, $data) = @_;
});
```

– json => $cb->($handle, $hash_or_arrayref)

Reads a JSON object or array, decodes it and passes it to the callback. When a parse error occurs, an `EBADMSG` error will be raised.

If a `json` object was passed to the constructor, then that will be used for the final decode, otherwise it will create a *JSON::XS* or *JSON::PP* coder object expecting UTF-8.

This read type uses the incremental parser available with JSON version 2.09 (and JSON::XS version 2.2) and above.

Since JSON texts are fully self-delimiting, the `json` read and write types are an ideal simple RPC protocol: just exchange JSON datagrams. See the `json` write type description, above, for an actual example.

– cbor => $cb->($handle, $scalar)

Reads a CBOR value, decodes it and passes it to the callback. When a parse error occurs, an `EBADMSG` error will be raised.

If a CBOR::XS object was passed to the constructor, then that will be used for the final decode, otherwise it will create a CBOR coder without enabling any options.

You have to provide a dependency to CBOR::XS on your own: this module will load the CBOR::XS module, but AnyEvent does not depend on it itself.

Since CBOR values are fully self-delimiting, the `cbor` read and write types are an ideal simple RPC protocol: just exchange CBOR datagrams. See the `cbor` write type description, above, for an actual example.

– storable => $cb->($handle, $ref)

Deserialises a *Storable* frozen representation as written by the `storable` write type (BER-encoded length prefix followed by nfreeze'd data).

Raises `EBADMSG` error if the data could not be decoded.

– tls_detect => $cb->($handle, $detect, $major, $minor)

Checks the input stream for a valid SSL or TLS handshake TLSPaintext record without consuming anything. Only SSL version 3 or higher is handled, up to the fictituous protocol 4.x (but both SSL3+ and SSL2-compatible framing is supported).

If it detects that the input data is likely TLS, it calls the callback with a true value for `$detect` and the (on-wire) TLS version as second and third argument (`$major` is 3, and `$minor` is 0..4 for SSL 3.0, TLS 1.0, 1.1, 1.2 and 1.3, respectively). If it detects the input to be definitely not TLS, it calls the callback with a false value for `$detect`.

The callback could use this information to decide whether or not to start TLS negotiation.

In all cases the data read so far is passed to the following read handlers.

Usually you want to use the `tls_autostart` read type instead.

If you want to design a protocol that works in the presence of TLS dtection, make sure that any non-TLS data doesn't start with the octet 22 (ASCII SYN, 16 hex) or 128-255 (i.e. highest bit set). The checks this read type does are a bit more strict, but might losen in the future to accomodate protocol changes.

This read type does not rely on *AnyEvent::TLS* (and thus, not on *Net::SSLeay*).

– tls_autostart => [$tls_ctx,]$tls

Tries to detect a valid SSL or TLS handshake. If one is detected, it tries to start tls by calling `starttls` with the given arguments.

In practise, `$tls` must be `accept`, or a Net::SSLeay context that has been configured to accept, as servers do not normally send a handshake on their own and ths cannot be detected in this way.

See `tls_detect` above for more details.

Example: give the client a chance to start TLS before accepting a text line.

```
$hdl->push_read (tls_autostart => "accept");
$hdl->push_read (line => sub {
   print "received ", ($_[0]{tls} ? "encrypted" : "cleartext
↪"), " <$_[1]>\n";
});
```

- custom read types - Package::anyevent_read_type $handle, $cb, @args

  Instead of one of the predefined types, you can also specify the name of a package. AnyEvent will try to load the package and then expects to find a function named `anyevent_read_type` inside. If it isn't found, it progressively tries to load the parent package until it either finds the function (good) or runs out of packages (bad).

  Whenever this type is used, `push_read` will invoke the function with the handle object, the original callback and the remaining arguments.

  The function is supposed to return a callback (usually a closure) that works as a plain read callback (see `->push_read ($cb)`), so you can mentally treat the function as a "configurable read type to read callback" converter.

  It should invoke the original callback when it is done reading (remember to pass `$handle` as first argument as all other callbacks do that, although there is no strict requirement on this).

  For examples, see the source of this module (`perldoc -m AnyEvent::Handle`, search for `register_read_type`)).

- $handle->stop_read

- $handle->start_read

  In rare cases you actually do not want to read anything from the socket. In this case you can call `stop_read`. Neither `on_read` nor any queued callbacks will be executed then. To start reading again, call `start_read`.

  Note that AnyEvent::Handle will automatically `start_read` for you when you change the `on_read` callback or push/unshift a read callback, and it will automatically `stop_read` for you when neither `on_read` is set nor there are any read requests in the queue.

  In older versions of this module (<= 5.3), these methods had no effect, as TLS does not support half-duplex connections. In current versions they work as expected, as this behaviour is required to avoid certain resource attacks, where the program would be forced to read (and buffer) arbitrary amounts of data before being able to send some data. The drawback is that some readings of the the SSL/TLS specifications basically require this attack to be working, as SSL/TLS implementations might stall sending data during a rehandshake.

  As a guideline, during the initial handshake, you should not stop reading, and as a client, it might cause problems, depending on your application.

- $handle->starttls ($tls[, $tls_ctx])

  Instead of starting TLS negotiation immediately when the AnyEvent::Handle object is created, you can also do that at a later time by calling `starttls`. See the `tls` constructor argument for general info.

  Starting TLS is currently an asynchronous operation - when you push some write data and then call `->starttls` then TLS negotiation will start immediately, after which the queued write data is then sent. This might change in future versions, so best make sure you have no outstanding write data when calling this method.

  The first argument is the same as the `tls` constructor argument (either `"connect"`, `"accept"` or an existing Net::SSLeay object).

The second argument is the optional `AnyEvent::TLS` object that is used when AnyEvent::Handle has to create its own TLS connection object, or a hash reference with `key => value` pairs that will be used to construct a new context.

The TLS connection object will end up in `$handle->{tls}`, the TLS context in `$handle->{tls_ctx}` after this call and can be used or changed to your liking. Note that the handshake might have already started when this function returns.

Due to bugs in OpenSSL, it might or might not be possible to do multiple handshakes on the same stream. It is best to not attempt to use the stream after stopping TLS.

This method may invoke callbacks (and therefore the handle might be destroyed after it returns).

- $handle->stoptls

  Shuts down the SSL connection - this makes a proper EOF handshake by sending a close notify to the other side, but since OpenSSL doesn't support non-blocking shut downs, it is not guaranteed that you can re-use the stream afterwards.

  This method may invoke callbacks (and therefore the handle might be destroyed after it returns).

- $handle->resettls

  This rarely-used method simply resets and TLS state on the handle, usually causing data loss.

  One case where it may be useful is when you want to skip over the data in the stream but you are not interested in interpreting it, so data loss is no concern.

- $handle->destroy

  Shuts down the handle object as much as possible - this call ensures that no further callbacks will be invoked and as many resources as possible will be freed. Any method you will call on the handle object after destroying it in this way will be silently ignored (and it will return the empty list).

  Normally, you can just "forget" any references to an AnyEvent::Handle object and it will simply shut down. This works in fatal error and EOF callbacks, as well as code outside. It does *NOT* work in a read or write callback, so when you want to destroy the AnyEvent::Handle object from within such an callback. You *MUST* call `->destroy` explicitly in that case.

  Destroying the handle object in this way has the advantage that callbacks will be removed as well, so if those are the only reference holders (as is common), then one doesn't need to do anything special to break any reference cycles.

  The handle might still linger in the background and write out remaining data, as specified by the `linger` option, however.

- $handle->destroyed

  Returns false as long as the handle hasn't been destroyed by a call to `->destroy`, true otherwise.

  Can be useful to decide whether the handle is still valid after some callback possibly destroyed the handle. For example, `->push_write`, `->starttls` and other methods can call user callbacks, which in turn can destroy the handle, so work can be avoided by checking sometimes:

```
$hdl->starttls ("accept");
return if $hdl->destroyed;
$hdl->push_write (...
```

Note that the call to `push_write` will silently be ignored if the handle has been destroyed, so often you can just ignore the possibility of the handle being destroyed.

- AnyEvent::Handle::TLS_CTX

  This function creates and returns the AnyEvent::TLS object used by default for TLS mode.

  The context is created by calling *AnyEvent::TLS* without any arguments.

NONFREQUENTLY ASKED QUESTIONS

- I `undef` the AnyEvent::Handle reference inside my callback and still get further invocations!

  That's because AnyEvent::Handle keeps a reference to itself when handling read or write callbacks.

  It is only safe to "forget" the reference inside EOF or error callbacks, from within all other callbacks, you need to explicitly call the `->destroy` method.

- Why is my `on_eof` callback never called?

  Probably because your `on_error` callback is being called instead: When you have outstanding requests in your read queue, then an EOF is considered an error as you clearly expected some data.

  To avoid this, make sure you have an empty read queue whenever your handle is supposed to be "idle" (i.e. connection closes are O.K.). You can set an `on_read` handler that simply pushes the first read requests in the queue.

  See also the next question, which explains this in a bit more detail.

- How can I serve requests in a loop?

  Most protocols consist of some setup phase (authentication for example) followed by a request handling phase, where the server waits for requests and handles them, in a loop.

  There are two important variants: The first (traditional, better) variant handles requests until the server gets some QUIT command, causing it to close the connection first (highly desirable for a busy TCP server). A client dropping the connection is an error, which means this variant can detect an unexpected detection close.

  To handle this case, always make sure you have a non-empty read queue, by pushing the "read request start" handler on it:

```
# we assume a request starts with a single line
my @start_request; @start_request = (line => sub {
   my ($hdl, $line) = @_;

   ... handle request
```

(continues on next page)

(continued from previous page)

```
   # push next request read, possibly from a nested callback
   $hdl->push_read (@start_request);
});

# auth done, now go into request handling loop
# now push the first @start_request
$hdl->push_read (@start_request);
```

By always having an outstanding `push_read`, the handle always expects some data and raises the `EPIPE` error when the connction is dropped unexpectedly.

The second variant is a protocol where the client can drop the connection at any time. For TCP, this means that the server machine may run out of sockets easier, and in general, it means you cannot distinguish a protocl failure/client crash from a normal connection close. Nevertheless, these kinds of protocols are common (and sometimes even the best solution to the problem).

Having an outstanding read request at all times is possible if you ignore `EPIPE` errors, but this doesn't help with when the client drops the connection during a request, which would still be an error.

A better solution is to push the initial request read in an `on_read` callback. This avoids an error, as when the server doesn't expect data (i.e. is idly waiting for the next request, an EOF will not raise an error, but simply result in an `on_eof` callback. It is also a bit slower and simpler:

```
# auth done, now go into request handling loop
$hdl->on_read (sub {
   my ($hdl) = @_;

   # called each time we receive data but the read queue is␣
↪empty
   # simply start read the request

   $hdl->push_read (line => sub {
      my ($hdl, $line) = @_;

      ... handle request

      # do nothing special when the request has been handled,␣
↪just
      # let the request queue go empty.
   });
});
```

- I get different callback invocations in TLS mode/Why can't I pause reading?

  Unlike, say, TCP, TLS connections do not consist of two independent communication channels, one for each direction. Or put differently, the read and write directions are not independent of each other: you cannot write data unless you are also prepared to read, and vice versa.

This means that, in TLS mode, you might get `on_error` or `on_eof` callback invocations when you are not expecting any read data - the reason is that AnyEvent::Handle always reads in TLS mode.

During the connection, you have to make sure that you always have a non-empty read-queue, or an `on_read` watcher. At the end of the connection (or when you no longer want to use it) you can call the `destroy` method.

- How do I read data until the other side closes the connection?

  If you just want to read your data into a perl scalar, the easiest way to achieve this is by setting an `on_read` callback that does nothing, clearing the `on_eof` callback and in the `on_error` callback, the data will be in `$_[0]{rbuf}`:

```
$handle->on_read (sub { });
$handle->on_eof (undef);
$handle->on_error (sub {
   my $data = delete $_[0]{rbuf};
});
```

  Note that this example removes the `rbuf` member from the handle object, which is not normally allowed by the API. It is expressly permitted in this case only, as the handle object needs to be destroyed afterwards.

  The reason to use `on_error` is that TCP connections, due to latencies and packets loss, might get closed quite violently with an error, when in fact all data has been received.

  It is usually better to use acknowledgements when transferring data, to make sure the other side hasn't just died and you got the data intact. This is also one reason why so many internet protocols have an explicit QUIT command.

- I don't want to destroy the handle too early - how do I wait until all data has been written?

  After writing your last bits of data, set the `on_drain` callback and destroy the handle in there - with the default setting of `low_water_mark` this will be called precisely when all data has been written to the socket:

```
$handle->push_write (...);
$handle->on_drain (sub {
   AE::log debug => "All data submitted to the kernel.";
   undef $handle;
});
```

  If you just want to queue some data and then signal EOF to the other side, consider using `->push_shutdown` instead.

- I want to contact a TLS/SSL server, I don't care about security.

  If your TLS server is a pure TLS server (e.g. HTTPS) that only speaks TLS, connect to it and then create the AnyEvent::Handle with the `tls` parameter:

```
tcp_connect $host, $port, sub {
   my ($fh) = @_;
```

(continues on next page)

(continued from previous page)

```
   my $handle = new AnyEvent::Handle
      fh  => $fh,
      tls => "connect",
      on_error => sub { ... };

   $handle->push_write (...);
};
```

- I want to contact a TLS/SSL server, I do care about security.

  Then you should additionally enable certificate verification, including peername verification, if the protocol you use supports it (see *AnyEvent::TLS*, `verify_peername`).

  E.g. for HTTPS:

```
tcp_connect $host, $port, sub {
   my ($fh) = @_;

    my $handle = new AnyEvent::Handle
       fh       => $fh,
       peername => $host,
       tls      => "connect",
       tls_ctx  => { verify => 1, verify_peername => "https" },
       ...
```

  Note that you must specify the hostname you connected to (or whatever "peername" the protocol needs) as the `peername` argument, otherwise no peername verification will be done.

  The above will use the system-dependent default set of trusted CA certificates. If you want to check against a specific CA, add the `ca_file` (or `ca_cert`) arguments to `tls_ctx`:

```
tls_ctx  => {
   verify          => 1,
   verify_peername => "https",
   ca_file         => "my-ca-cert.pem",
},
```

- I want to create a TLS/SSL server, how do I do that?

  Well, you first need to get a server certificate and key. You have three options: a) ask a CA (buy one, use cacert.org etc.) b) create a self-signed certificate (cheap. check the search engine of your choice, there are many tutorials on the net) or c) make your own CA (tinyca2 is a nice program for that purpose).

  Then create a file with your private key (in PEM format, see *AnyEvent::TLS*), followed by the certificate (also in PEM format). The file should then look like this:

```
-----BEGIN RSA PRIVATE KEY-----
...header data
```

(continues on next page)

(continued from previous page)

```
... lots of base64'y-stuff
-----END RSA PRIVATE KEY-----

-----BEGIN CERTIFICATE-----
... lots of base64'y-stuff
-----END CERTIFICATE-----
```

The important bits are the “PRIVATE KEY” and “CERTIFICATE” parts. Then specify this file as `cert_file`:

```
tcp_server undef, $port, sub {
   my ($fh) = @_;

   my $handle = new AnyEvent::Handle
      fh       => $fh,
      tls      => "accept",
      tls_ctx  => { cert_file => "my-server-keycert.pem" },
      ...
```

When you have intermediate CA certificates that your clients might not know about, just append them to the `cert_file`.

SUBCLASSING AnyEvent::Handle

In many cases, you might want to subclass AnyEvent::Handle.

To make this easier, a given version of AnyEvent::Handle uses these conventions:

- all constructor arguments become object members.

  At least initially, when you pass a `tls`-argument to the constructor it will end up in `$handle->{tls}`. Those members might be changed or mutated later on (for example `tls` will hold the TLS connection object).

- other object member names are prefixed with an _.

  All object members not explicitly documented (internal use) are prefixed with an underscore character, so the remaining non-_-namespace is free for use for subclasses.

- all members not documented here and not prefixed with an underscore are free to use in subclasses.

  Of course, new versions of AnyEvent::Handle may introduce more “public” member variables, but that’s just life. At least it is documented.

AnyEvent::IO

the DBI of asynchronous I/O implementations

SYNOPSIS

```
use AnyEvent::IO;

# load /etc/passwd, call callback with the file data when done.
aio_load "/etc/passwd", sub {
   my ($data) = @_
      or return AE::log error => "/etc/passwd: $!";

   warn "/etc/passwd contains ", ($data =~ y/:/:/) , " colons.\n";
};

# the rest of the SYNOPSIS does the same, but with individual I/O
↪calls

# also import O_XXX flags
use AnyEvent::IO qw(:DEFAULT :flags);

my $filedata = AE::cv;

# first open the file
aio_open "/etc/passwd", O_RDONLY, 0, sub {
   my ($fh) = @_
      or return AE::log error => "/etc/passwd: $!";

   # now stat the file to get the size
   aio_stat $fh, sub {
      @_
         or return AE::log error => "/etc/passwd: $!";

      my $size = -s _;

      # now read all the file data
      aio_read $fh, $size, sub {
         my ($data) = @_
            or return AE::log error => "/etc/passwd: $!";

         $size == length $data
            or return AE::log error => "/etc/passwd: short read,
↪file changed?";

         # mostly the same as aio_load, above - $data contains
         # the file contents now.
         $filedata->($data);
      };
   };
```

(continues on next page)

(continued from previous page)

```
};

my $passwd = $filedata->recv;
warn length $passwd, " octets.\n";
```

DESCRIPTION

This module provides functions that do I/O in an asynchronous fashion. It is to I/O the same as *AnyEvent* is to event libraries - it only *interfaces* to other implementations or to a portable pure-perl implementation (which does not, however, do asynchronous I/O).

The only other implementation that is supported (or even known to the author) is IO::AIO, which is used automatically when it can be loaded (via AnyEvent::AIO, which also needs to be installed). If it is not available, then *AnyEvent::IO* falls back to its synchronous pure-perl implementation.

Unlike *AnyEvent*, which model to use is currently decided at module load time, not at first use. Future releases might change this.

RATIONALE

While disk I/O often seems "instant" compared to, say, socket I/O, there are many situations where your program can block for extended time periods when doing disk I/O. For example, you access a disk on an NFS server and it is gone - can take ages to respond again, if ever. Or your system is extremely busy because it creates or restores a backup - reading data from disk can then take seconds. Or you use Linux, which for so many years has a close-to-broken VM/IO subsystem that can often induce minutes or more of delay for disk I/O, even under what I would consider light I/O loads.

Whatever the situation, some programs just can't afford to block for long times (say, half a second or more), because they need to respond as fast as possible.

For those cases, you need asynchronous I/O.

The problem is, AnyEvent itself sometimes reads disk files (for example, when looking at `/etc/hosts`), and under the above situations, this can bring your program to a complete halt even if your program otherwise takes care to only use asynchronous I/O for everything (e.g. by using IO::AIO).

On the other hand, requiring IO::AIO for AnyEvent is clearly impossible, as AnyEvent promises to stay pure-perl, and the overhead of IO::AIO for small programs would be immense, especially when asynchronous I/O isn't even needed.

Clearly, this calls for an abstraction layer, and that is what you are looking at right now :-)

ASYNCHRONOUS VS. NON-BLOCKING

Many people are continuously confused on what the difference is between asynchronous I/O and non-blocking I/O. In fact, those two terms are not well defined, which often makes it hard to even talk about the difference. Here is a short guideline that should leave you less confused. It only talks about read operations, but the reasoning works with other I/O operations as well.

Non-blocking I/O means that data is delivered by some external means, automatically - that is, something *pushes* data towards your file handle, without you having to do anything. Non-blocking means that if your operating system currently has no data (or EOF, or some error) available for you, it will not wait ("block") as it would normally do, but immediately return with an error (e.g. `EWOULDBLOCK` - "I would have blocked, but you forbid it").

Your program can then wait for data to arrive by other means, for example, an I/O watcher which tells you when to re-attempt the read, after which it can try to read again, and so on.

Often, you would expect this to work for disk files as well - if the data isn't already in memory, one might want to wait for it and then re-attempt the read for example. While this is sound reasoning, the POSIX API does not support this, because disk drives and file systems do not send data "on their own", and more so, the OS already knows that data is there, it doesn't need to "wait" until it arrives from some external entity, it only needs to transfer the data from disk to your memory buffer.

So basically, while the concept is sound, the existing OS APIs do not support this. Therefore, it makes no sense to switch a disk file handle into non-blocking mode - it will behave exactly the same as in blocking mode, namely it will block until the data has been read from the disk.

The alternative to non-blocking I/O that actually works with disk files is usually called *asynchronous I/O*. Asynchronous, because the actual I/O is done while your program does something else: there is no need to call the read function to see if data is there, you only order the read once, and it will notify you when the read has finished and the data is your buffer - all the work is done in the background.

This works with disk files, and even with sockets and other sources. It is, however, not very efficient when used with sources that could be driven in a non-blocking way, because it usually has higher overhead in the OS than non-blocking I/O, because it ties memory buffers for a potentially unlimited time and often only a limited number of operations can be done in parallel.

That's why asynchronous I/O makes most sense when confronted with disk files, and non-blocking I/O only makes sense with sockets, pipes and similar streaming sources.

IMPORT TAGS

By default, this module exports all `aio_xxx` functions. In addition, the following import tags can be used:

```
:aio       all aio_* functions, same as :DEFAULT
:flags     the fcntl open flags (O_CREAT, O_RDONLY, ...)
```

API NOTES

The functions in this module are not meant to be the most versatile or the highest-performers (they are not very slow either, of course). They are primarily meant to give users of your code the option to do the I/O asynchronously (by installing IO::AIO and AnyEvent::AIO), without adding a dependency on those modules.

NAMING

All the functions in this module implement an I/O operation, usually with the same or similar name as the Perl built-in that they mimic, but with an `aio_` prefix. If you like you can think of the `aio_xxx` functions as "AnyEvent I/O" or "Asynchronous I/O" variants of Perl built-ins.

CALLING CONVENTIONS AND ERROR REPORTING

Each function expects a callback as their last argument. The callback is usually called with the result data or result code. An error is usually signalled by passing no arguments to the callback, which is then free to look at `$!` for the error code.

This makes all of the following forms of error checking valid:

```
aio_open ...., sub {
   my $fh = shift   # scalar assignment - will assign undef on error
      or return AE::log error => "...";

   my ($fh) = @_    # list assignment - will be 0 elements on error
      or return AE::log error => "...";

   @_               # check the number of elements directly
      or return AE::log error => "...";
```

CAVEAT: RELATIVE PATHS

When a path is specified, this path *must be an absolute* path, unless you make certain that nothing in your process calls `chdir` or an equivalent function while the request executes.

CAVEAT: OTHER SHARED STATE

Changing the `umask` while any requests execute that create files (or otherwise rely on the current umask) results in undefined behaviour - likewise changing anything else that would change the outcome, such as your effective user or group ID.

CALLBACKS MIGHT BE CALLED BEFORE FUNCTION RETURNS TO CALLER

Unlike other functions in the AnyEvent module family, these functions *may* call your callback instantly, before returning. This should not be a real problem, as these functions never return anything useful.

BEHAVIOUR AT PROGRAM EXIT

Both *AnyEvent::IO::Perl* and *AnyEvent::IO::IOAIO* implementations make sure that operations that have started will be finished on a clean programs exit. That makes programs work that start some I/O operations and then exit. For example this complete program:

```
use AnyEvent::IO;

aio_stat "path1", sub {
   aio_stat "path2", sub {
      warn "both stats done\n";
   };
};
```

Starts a `stat` operation and then exits by "falling off the end" of the program. Nevertheless, *both* `stat` operations will be executed, as AnyEvent::IO waits for all outstanding requests to finish and you can start new requests from request callbacks.

In fact, since *AnyEvent::IO::Perl* is currently synchronous, the program will do both stats before falling off the end, but with *AnyEvent::IO::IOAIO*, the program first falls of the end, then the stats are executed.

While not guaranteed, this behaviour will be present in future versions, if reasonably possible (which is extreemly likely :).

GLOBAL VARIABLES AND FUNCTIONS

- $AnyEvent::IO::MODEL

  Contains the package name of the backend I/O model in use - at the moment, this is usually `AnyEvent::IO::Perl` or `AnyEvent::IO::IOAIO`.

- aio_load $path, $cb->($data)

  Tries to open `$path` and read its contents into memory (obviously, should only be used on files that are "small enough"), then passes them to the callback as a string.

  Example: load `/etc/hosts`.

  ```
  aio_load "/etc/hosts", sub {
     my ($hosts) = @_
        or return AE::log error => "/etc/hosts: $!";

     AE::log info => "/etc/hosts contains ", ($hosts =~ y/\n/), "␣
  ↪lines\n";
  };
  ```

- aio_open $path, $flags, $mode, $cb->($fh)

  Tries to open the file specified by `$path` with the O_XXX-flags `$flags` (from the Fcntl module, or see below) and the mode `$mode` (a good value is 0666 for `O_CREAT`, and `0` otherwise).

  The (normal, standard, perl) file handle associated with the opened file is then passed to the callback.

  This works very much like Perl's `sysopen` function.

  Changing the `umask` while this request executes results in undefined behaviour - likewise changing anything else that would change the outcome, such as your effective user or group ID.

To avoid having to load *Fcntl*, this module provides constants for `O_RDONLY`, `O_WRONLY`, `O_RDWR`, `O_CREAT`, `O_EXCL`, `O_TRUNC` and `O_APPEND` - you can either access them directly (`AnyEvent::IO::O_RDONLY`) or import them by specifying the `:flags` import tag (see SYNOPSIS).

Example: securely open a file in `/var/tmp`, fail if it exists or is a symlink.

```
use AnyEvent::IO qw(:flags);

aio_open "/var/tmp/mytmp$$", O_CREAT | O_EXCL | O_RDWR, 0600,␣
↪sub {
   my ($fh) = @_
      or return AE::log error => "$! - denial of service attack?
↪";

   # now we have $fh
};
```

- aio_close $fh, $cb->($success)

  Closes the file handle (yes, close can block your process indefinitely) and passes a true value to the callback on success.

  Due to idiosyncrasies in perl, instead of calling `close`, the file handle might get closed by dup2'ing another file descriptor over it, that is, the `$fh` might still be open, but can be closed safely afterwards and must not be used for anything.

  Example: close a file handle, and dirty as we are, do not even bother to check for errors.

```
aio_close $fh, sub { };
```

- aio_read $fh, $length, $cb->($data)

  Tries to read `$length` octets from the current position from `$fh` and passes these bytes to `$cb`. Otherwise the semantics are very much like those of Perl's `sysread`.

  If less than `$length` octets have been read, `$data` will contain only those bytes actually read. At EOF, `$data` will be a zero-length string. If an error occurs, then nothing is passed to the callback.

  Obviously, multiple `aio_read`'s or `aio_write`'s at the same time on file handles sharing the underlying open file description results in undefined behaviour, due to sharing of the current file offset (and less obviously so, because OS X is not thread safe and corrupts data when you try).

  Example: read 128 octets from a file.

```
aio_read $fh, 128, sub {
   my ($data) = @_
      or return AE::log error "read from fh: $!";

   if (length $data) {
      print "read ", length $data, " octets.\n";
   } else {
```

(continues on next page)

(continued from previous page)

```
      print "EOF\n";
   }
};
```

- aio_seek $fh, $offset, $whence, $callback->($offs)

  Seeks the filehandle to the new `$offset`, similarly to Perl's `sysseek`. The `$whence` are the traditional values (`0` to count from start, 1 to count from the current position and 2 to count from the end).

  The resulting absolute offset will be passed to the callback on success.

  Example: measure the size of the file in the old-fashioned way using seek.

```
aio_seek $fh, 0, 2, sub {
   my ($size) = @_
      or return AE::log error => "seek to end failed: $!";

   # maybe we need to seek to the beginning again?
   aio_seek $fh, 0, 0, sub {
      # now we are hopefully at the beginning
   };
};
```

- aio_write $fh, $data, $cb->($length)

  Tries to write the octets in `$data` to the current position of `$fh` and passes the actual number of bytes written to the `$cb`. Otherwise the semantics are very much like those of Perl's `syswrite`.

  If less than `length $data` octets have been written, `$length` will reflect that. If an error occurs, then nothing is passed to the callback.

  Obviously, multiple `aio_read`'s or `aio_write`'s at the same time on file handles sharing the underlying open file description results in undefined behaviour, due to sharing of the current file offset (and less obviously so, because OS X is not thread safe and corrupts data when you try).

- aio_truncate $fh_or_path, $new_length, $cb->($success)

  Calls `truncate` on the path or perl file handle and passes a true value to the callback on success.

  Example: truncate `/etc/passwd` to zero length - this only works on systems that support `truncate`, should not be tried out for obvious reasons and debian will probably open yte another security bug about this example.

```
aio_truncate "/etc/passwd", sub {
   @_
      or return AE::log error => "/etc/passwd: $! - are you␣
↪root enough?";
};
```

- aio_utime $fh_or_path, $atime, $mtime, $cb->($success)

Calls `utime` on the path or perl file handle and passes a true value to the callback on success.

The special case of both `$atime` and `$mtime` being `undef` sets the times to the current time, on systems that support this.

Example: try to touch `file`.

```
aio_utime "file", undef, undef, sub { };
```

- aio_chown $fh_or_path, $uid, $gid, $cb->($success)

  Calls `chown` on the path or perl file handle and passes a true value to the callback on success.

  If `$uid` or `$gid` can be specified as `undef`, in which case the uid or gid of the file is not changed. This differs from Perl's `chown` built-in, which wants `-1` for this.

  Example: update the group of `file` to 0 (root), but leave the owner alone.

```
aio_chown "file", undef, 0, sub {
   @_
      or return AE::log error => "chown 'file': $!";
};
```

- aio_chmod $fh_or_path, $perms, $cb->($success)

  Calls `chmod` on the path or perl file handle and passes a true value to the callback on success.

  Example: change `file` to be user/group/world-readable, but leave the other flags alone.

```
aio_stat "file", sub {
   @_
      or return AE::log error => "file: $!";

   aio_chmod "file", (stat _)[2] & 07777 | 00444, sub { };
};
```

- aio_stat $fh_or_path, $cb->($success)
- aio_lstat $path, $cb->($success)

  Calls `stat` or `lstat` on the path or perl file handle and passes a true value to the callback on success.

  The stat data will be available by `stat`'ing the _ file handle (e.g. `-x _`, `stat _` and so on).

  Example: see if we can find the number of subdirectories of `/etc`.

```
aio_stat "/etc", sub {
   @_
      or return AE::log error => "/etc: $!";

   (stat _)[3] >= 2
```

(continues on next page)

(continued from previous page)

```
      or return AE::log warn => "/etc has low link count - non-
↪POSIX filesystem?";

   print "/etc has ", (stat _)[3] - 2, " subdirectories.\n";
};
```

- aio_link $oldpath, $newpath, $cb->($success)

  Calls `link` on the paths and passes a true value to the callback on success.

  Example: link "`file` to `file.bak`, then rename `file.new` over `file`, to atomically replace it.

```
aio_link "file", "file.bak", sub {
   @_
      or return AE::log error => "file: $!";

   aio_rename "file.new", "file", sub {
      @_
         or return AE::log error => "file.new: $!";

      print "file atomically replaced by file.new, backup file.
↪bak\n";
   };
};
```

- aio_symlink $oldpath, $newpath, $cb->($success)

  Calls `symlink` on the paths and passes a true value to the callback on success.

  Example: create a symlink "`slink` containing "random data".

```
aio_symlink "random data", "slink", sub {
   @_
      or return AE::log error => "slink: $!";
};
```

- aio_readlink $path, $cb->($target)

  Calls `readlink` on the paths and passes the link target string to the callback.

  Example: read the symlink called Fyslink> and verify that it contains "random data".

```
aio_readlink "slink", sub {
   my ($target) = @_
      or return AE::log error => "slink: $!";

   $target eq "random data"
      or AE::log critical => "omg, the world will end!";
};
```

- aio_rename $oldpath, $newpath, $cb->($success)

Calls `rename` on the paths and passes a true value to the callback on success.

See `aio_link` for an example.

- aio_unlink $path, $cb->($success)

  Tries to unlink the object at `$path` and passes a true value to the callback on success.

  Example: try to delete the file `tmpfile.dat~`.

```
aio_unlink "tmpfile.dat~", sub { };
```

- aio_mkdir $path, $perms, $cb->($success)

  Calls `mkdir` on the path with the given permissions `$perms` (when in doubt, `0777` is a good value) and passes a true value to the callback on success.

  Example: try to create the directory `subdir` and leave it to whoeveer comes after us to check whether it worked.

```
aio_mkdir "subdir", 0777, sub { };
```

- aio_rmdir $path, $cb->($success)

  Tries to remove the directory at `$path` and passes a true value to the callback on success.

  Example: try to remove the directory `subdir` and don't give a damn if that fails.

```
aio_rmdir "subdir", sub { };
```

- aio_readdir $path, $cb->(\@names)

  Reads all filenames from the directory specified by `$path` and passes them to the callback, as an array reference with the names (without a path prefix). The `.` and `..` names will be filtered out first.

  The ordering of the file names is undefined - backends that are capable of it (e.g. IO::AIO) will return the ordering that most likely is fastest to `stat` through, and furthermore put entries that likely are directories first in the array.

  If you need best performance in recursive directory traversal or when looking at really big directories, you are advised to use IO::AIO directly, specifically the `aio_readdirx` and `aio_scandir` functions, which have more options to tune performance.

  Example: recursively scan a directory hierarchy, silently skip diretcories we couldn't read and print all others.

```
sub scan($); # visibility-in-next statement is not so useful␣
↪these days
sub scan($) {
   my ($path) = @_;

   aio_readdir $path, sub {
      my ($names) = @_
```

(continues on next page)

(continued from previous page)

```
         or return;

      print "$path\n";

      for my $name (@$names) {
         aio_lstat "$path/$name", sub {
            scan "$path/$name"
               if -d _;
         };
      }
   };
}

scan "/etc";
```

ENVIRONMENT VARIABLES

See the description of `PERL_ANYEVENT_IO_MODEL` in the *AnyEvent* manpage.

```

Modules

- `AnyEvent::IO::IOAIO` - AnyEvent::IO backend based on IO::AIO
- `AnyEvent::IO::Perl` - pure perl backend for AnyEvent::IO

AnyEvent::IO::IOAIO

AnyEvent::IO backend based on IO::AIO

SYNOPSIS

```
use AnyEvent::IO;
```

DESCRIPTION

This is the IO::AIO-based backend of *AnyEvent::IO* (via AnyEvent::AIO). All I/O operations it implements are done asynchronously.

FUNCTIONS

SEE ALSO

AnyEvent::IO, *AnyEvent*.

AUTHOR

```
Marc Lehmann <schmorp@schmorp.de>
http://anyevent.schmorp.de
```

AnyEvent::IO::Perl

pure perl backend for AnyEvent::IO

SYNOPSIS

```
use AnyEvent::IO;
```

DESCRIPTION

This is the pure-perl backend of *AnyEvent::IO* - it is always available, but does not actually implement any I/O operation asynchronously - everything is synchronous.

For simple programs that can wait for I/O, this is likely the most efficient implementation.

SEE ALSO

AnyEvent::IO, *AnyEvent*.

AUTHOR

```

AnyEvent::Impl

Namespace containing the following modules:

- `AnyEvent::Impl::Cocoa` - AnyEvent adaptor for Cocoa::EventLoop
- `AnyEvent::Impl::EV` - AnyEvent adaptor for EV
- `AnyEvent::Impl::Event` - AnyEvent adaptor for Event
- `AnyEvent::Impl::EventLib` - AnyEvent adaptor for Event::Lib
- `AnyEvent::Impl::FLTK` - AnyEvent adaptor for FLTK (Fast Light Toolkit version two)
- `AnyEvent::Impl::Glib` - AnyEvent adaptor for Glib

- `AnyEvent::Impl::IOAsync` - AnyEvent adaptor for IO::Async
- `AnyEvent::Impl::Irssi` - AnyEvent adaptor for Irssi
- `AnyEvent::Impl::POE` - AnyEvent adaptor for POE
- `AnyEvent::Impl::Perl` - AnyEvent adaptor for AnyEvent's pure perl AnyEvent::Loop
- `AnyEvent::Impl::Qt` - AnyEvent adaptor for Qt
- `AnyEvent::Impl::Tk` - AnyEvent adaptor for Tk
- `AnyEvent::Impl::UV` - AnyEvent adaptor for UV

AnyEvent::Impl::Cocoa

AnyEvent adaptor for Cocoa::EventLoop

SYNOPSIS

```
use AnyEvent;
use Cocoa::EventLoop;

# do something
```

DESCRIPTION

This module provides NSRunLoop support to AnyEvent.

NSRunLoop is an event loop for Cocoa applications, wrapped by Cocoa::EventLoop. By using this module, you can use Cocoa based API in your AnyEvent application, or AnyEvent within Cocoa applications.

It does not support blocking waits.

BUGS

Right now, Cocoa::EventLoop (and this module) are in an early development phase and has some shortcomings and likely bugs.

For example, there seems to be no way to just handle a single event with Cocoa (is there nothing they can implement properly?), so this module currently wakes up at least ten times a second when waiting for events. Also, events caused by timers might get delayed by up to 0.1 seconds.

AnyEvent::Impl::EV

AnyEvent adaptor for EV

SYNOPSIS

```
use AnyEvent;
use EV;

# this module gets loaded automatically as required
```

DESCRIPTION

This module provides transparent support for AnyEvent. You don't have to do anything to make EV work with AnyEvent except by loading EV before creating the first AnyEvent watcher.

EV is the fastest event library for perl, and best supported by AnyEvent. Most functions from the *AE* API are implemented as direct aliases to EV functions, so using EV via AE is as fast as using EV directly.

SEE ALSO

AnyEvent, *EV*.

```

AnyEvent::Impl::Event

AnyEvent adaptor for Event

SYNOPSIS

```
use AnyEvent;
use Event;

# this module gets loaded automatically as required
```

DESCRIPTION

This module provides transparent support for AnyEvent. You don't have to do anything to make Event work with AnyEvent except by loading Event before creating the first AnyEvent watcher.

The event module is reasonably efficient and generally works correctly even with many watchers, except that its signal handling is inherently racy and requires the wake-up-frequently workaround.

SEE ALSO

AnyEvent, *Event*.

AnyEvent::Impl::EventLib

AnyEvent adaptor for Event::Lib

SYNOPSIS

```
use AnyEvent;
use Event::Lib;

# this module gets loaded automatically as required
```

DESCRIPTION

This module provides transparent support for AnyEvent. You don't have to do anything to make Event work with AnyEvent except by loading Event::Lib before creating the first AnyEvent watcher.

Note: the AnyEvent author has not found recent releases of Event::Lib to be even remotely working (not even the examples from the manpage or the testsuite work), so this event backend should be avoided (or somebody should step up and maintain it, hint, hint).

The Event::Lib module suffers from the same limitations and bugs as libevent, most notably it kills already-installed watchers on a file descriptor and it is unable to support fork. These are not fatal issues, and are worked-around by this module, but the Event::Lib perl module itself has many additional bugs such as taking references to file handles and callbacks instead of making a copy or freeing still-allocated scalars, causing memory corruption and random crashes. Only Tk rivals it in its brokenness.

This adaptor module employs the same workaround around the watcher problems as Tk and should therefore be avoided. (This was done for simplicity, one could in theory work around the problems with lower overhead by managing our own watchers).

Event::Lib also leaks file handles and memory and tends to just exit on problems.

It also doesn't work around the Windows bug of not signalling TCP connection failures.

It also doesn't work with many special devices on Linux (`/dev/random` works, `/dev/urandom` fails, `/dev/tty` works, `/dev/null` fails and so on).

Event::Lib does not support idle watchers. They could be emulated using low-priority timers but as the priority range (and availability) is not queryable nor guaranteed, and the default priority is likely the lowest one, this module cannot use them.

Avoid Event::Lib if you can.

SEE ALSO

AnyEvent, Event::Lib.

```

AnyEvent::Impl::FLTK

AnyEvent adaptor for FLTK (Fast Light Toolkit version two)

SYNOPSIS

```
use AnyEvent;
use FLTK;

# this module gets loaded automatically as required
```

DESCRIPTION

This module provides transparent support for AnyEvent. You don't have to do anything to make FLTK work with AnyEvent except by loading FLTK before creating the first AnyEvent watcher.

This implementation is not to be confused with AnyEvent::Impl::FLTK by Sanko Robinson. That implementation is completely broken, and the author is apparently unreachable.

In any case, FLTK suffers from typical GUI-ToolKit diseases, such as O(n) or worse for every operation (adding a timer, destroying a timer etc.), the typical Not-Well-Tested Perl Interface disases such as non-random memory corruption and the typical Event-Loop-as-an-Afterthrough issues, such as multiple watchers on the same fd silently overwriting the others.

It doesn't have native idle, signal or child watchers, so all of these are emulated.

SEE ALSO

AnyEvent, FLTK.

AnyEvent::Impl::Glib

AnyEvent adaptor for Glib

SYNOPSIS

```
use AnyEvent;
use Glib;

# this module gets loaded automatically as required
```

DESCRIPTION

This module provides transparent support for AnyEvent. You don't have to do anything to make Glib work with AnyEvent except by loading Glib before creating the first AnyEvent watcher.

Glib is probably the most inefficient event loop that has ever seen the light of the world: Glib not only scans all its watchers (really, ALL of them, whether I/O-related, timer-related or what not) during each loop iteration, it also does so multiple times and rebuilds the poll list for the kernel each time again, dynamically even. Newer versions of libglib fortunately do not call malloc/free on every single watcher invocation, though.

Glib also enforces certain undocumented behaviours, for example, you cannot always remove active child watchers, and the conditions on when it is valid to do so are not documented. Of course, if you get it wrong, you get "GLib-CRITICAL" messages. This makes it extremely hard to write "correct" glib programs, as you have to study the source code to get it right, and hope future versions don't change any internals.

AnyEvent implements the necessary workarounds, at a small performance cost.

On the positive side, and most importantly, when it works, Glib generally works correctly, no quarrels there.

If you create many watchers (as in: more than two), you might consider one of the Glib::EV, EV::Glib or Glib::Event modules that map Glib to other, more efficient, event loops.

This module uses the default Glib main context for all its watchers.

```

AnyEvent::Impl::IOAsync

AnyEvent adaptor for IO::Async

SYNOPSIS

```
use AnyEvent;
use IO::Async::Loop;

# optionally set another event loop
use AnyEvent::Impl::IOAsync;
my $loop = new IO::Async::Loop;
AnyEvent::Impl::IOAsync::set_loop $loop;
```

DESCRIPTION

This module provides support for IO::Async as AnyEvent backend. It supports I/O, timers, signals and child process watchers. Idle watchers are emulated. I/O watchers need to dup their fh because IO::Async only supports IO handles, not plain file descriptors.

FUNCTIONS AND VARIABLES

The only user-servicible part in this module is the `set_loop` function and `$LOOP` variable:

- AnyEvent::Impl::IOAsync::set_loop $new_loop

  Unfortunately, IO::Async has no concept of a default loop. Modules using IO::Async must be told by their caller which loop to use, which makes it impossible to transparently use IO::Async from a module.

  This module is no exception. It creates a new IO::Async::Loop object when it is loaded. This might not be the right loop object, though, and thus you can replace it by a call to this function with the loop object of your choice.

  Note that switching loops while watchers are already initialised can have unexpected effects, and is not supported unless you can live witht he consequences.

- $AnyEvent::Impl::IOAsync::LOOP

  This variable always contains the IO::Async::Loop object used by this AnyEvent backend. See above for more info.

Storing the "default" loop makes this module a possible arbiter for other modules that want to use IO::Async transparently. It's advised to directly refer to this variable each time you want to use it, without making a local copy.

PROBLEMS WITH IO::Async

This section had a long list of problems and shortcomings that made it almost impossible to support IO::Async. With version 0.33 of IO::Async, however, most of these have been fixed, so IO::Async can now be used as easily as many other loops.

There are a few remaining problems that require emulation or workarounds:

- No support for multiple watchers per event

  In most (all? documentation?) cases you cannot have multiple watchers for the same event (what's the point of having all these fancy notifier classes when you cannot have multiple notifiers for the same event? That's like only allowing one timer per second or so...).

  For I/O watchers, AnyEvent has to dup() every file handle, as IO::Async fails to support the same or different file handles pointing to the same fd (the good thing is that it is documented, but why not fix it instead?).

Apart from these fatal flaws, there are a number of unpleasent properties that just need some mentioning:

- Confusing and misleading names

  Another rather negative point about this module family is its name, which is deeply confusing: Despite the "async" in the name, IO::Async only does *synchronous* I/O, there is nothing "asynchronous" about it whatsoever (when I first heard about it, I thought, "wow, a second async I/O module, what does it do compared to IO::AIO", and was somehow set back when I learned that the only "async" aspect of it is the name).

- Inconsistent, incomplete and convoluted API

  Implementing AnyEvent's rather simple timers on top of IO::Async's timers was a nightmare (try implementing a timer with configurable interval and delay value...).

  The method naming is chaotic: `watch_child` creates a child watcher, but `watch_io` is an internal method; `detach_signal` removes a signal watcher, but `detach_child` forks a subprocess and so on).

- Unpleasant surprises on GNU/Linux

  When you develop your program on FreeBSD and run it on GNU/Linux, you might have unpleasant surprises, as IO::Async::Loop will by default use IO::Async::Loop::Epoll, which is incompatible with `fork`, so your network server will run into spurious and very hard to debug problems under heavy load, as IO::Async forks a lot of processes, e.g. for DNS resolution. It would be better if IO::Async would only load "safe" backends by default (or fix the epoll backend to work in the presence of fork, which admittedly is hard - EV does it for you, and also does not use unsafe backends by default).

On the positive side, performance with IO::Async is quite good even in my very demanding eyes.

AnyEvent::Impl::Irssi

AnyEvent adaptor for Irssi

SYNOPSIS

```
use AnyEvent;

# this module gets loaded automatically when running under irssi
```

DESCRIPTION

This module provides transparent support for AnyEvent. You don't have to do anything to make Irssi scripts work with AnyEvent.

Limitations of this backend and implementation details:

- This backend does not support blocking waits.

  That means you must set a callback on any condvars, or otherwise make sure to never call `recv` on a condvar that hasn't been signalled yet.

- Child exits will be handled by AnyEvent.

  AnyEvent will take over child handling, as Irssi only polls for children once/second and cannot handle unspecific child watchers.

  This *should* have no negative effect, as AnyEvent will emit a pidwait signal just like irssi itself would.

- Artificial timer delays.

  Irssi artificially enforces timers to have at least a 10ms delay (by croaking, even).

  This means that some applications will be limited to a rate of 100Hz (for example, *Coro::AnyEvent* thread scheduling).

- Irssi leaks memory like hell.

  Yeah.

Apart from that, documentation is notoriously wrong (e.g. file handles are not supported by `input_add`, contrary to documentation), hooking into irssi has to be done in... weird... ways, but otherwise, Irssi is surprisingly full-featured (for basically being a hack).

AnyEvent::Impl::POE

AnyEvent adaptor for POE

SYNOPSIS

```
use AnyEvent;
use POE;

# this module gets loaded automatically as required
```

DESCRIPTION

This module provides transparent support for AnyEvent. You don't have to do anything to make POE work with AnyEvent except by loading POE before creating the first AnyEvent watcher. There are some cases where POE will issue spurious (and non-suppressible) warnings. These can be avoided by loading AnyEvent::Impl::POE before loading any other modules using POE and AnyEvent, i.e. in your main program.

AnyEvent::Impl::POE will output some spurious message how to work around POE's spurious messages when it detects these cases.

Unfortunately, POE isn't generic enough to implement a fully working AnyEvent backend: POE is too badly designed, too badly documented and too badly implemented.

Here are the details, and what it means to you if you want to be interoperable with POE:

- Weird messages

  If you only use `run_one_timeslice` (as AnyEvent has to for its condition variables), POE will print an ugly, unsuppressible, message at program exit:

  ```
  Sessions were started, but POE::Kernel's run() method was never.
  ↪..
  ```

  The message is correct, the question is why POE prints it in the first place in a correct program (this is not a singular case though).

AnyEvent consequently patches the POE kernel so it thinks it already ran. Other workarounds, even the one cited in the POE documentation itself, have serious side effects, such as throwing away events.

The author of POE verified that this is indeed true, and has no plans to change this.

POE has other weird messages, and sometimes weird behaviour, for example, it doesn't support overloaded code references as callbacks for no apparent reason.

- One POE session per Event

  AnyEvent has to create one POE::Session per event watcher, which is immensely slow and makes watchers very large. The reason for this is lacking lifetime management (mostly undocumented, too). Without one session/watcher it is not possible to easily keep the kernel from running endlessly.

  This is not just a problem with the way AnyEvent has to interact with POE, but is a principal issue with POEs lifetime management (namely that stopping the kernel stops sessions, but AnyEvent has no control over who and when the kernel starts or stops w.r.t. AnyEvent watcher creation/destruction).

  From benchmark data it is not clear that session creation is that costly, though - the real inefficiencies with POE seem to come from other sources, such as event handling.

- One watcher per fd/event combo

  POE, of course, suffers from the same bug as Tk and some other badly designed event models in that it doesn't support multiple watchers per fd/poll combo. The workaround is the same as with Tk: AnyEvent::Impl::POE creates a separate file descriptor to hand to POE, which isn't fast and certainly not nice to your resources.

  Of course, without the workaround, POE also prints ugly messages again that say the program *might* be buggy.

  While this is not good to performance, at least regarding speed, with a modern Linux kernel, the overhead is actually quite small.

- Timing deficiencies

  POE manages to not have a function that returns the current time. This is extremely problematic, as POE can use different time functions, which can differ by more than a second - and user code is left guessing which one is used.

  In addition, most timer functions in POE want an absolute timestamp, which is hard to create if all you have is a relative time and no function to return the "current time".

  And of course POE doesn't handle time jumps at all (not even when using an event loop that happens to do that, such as *EV*, as it does its own unoptimised timer management).

  AnyEvent works around the unavailability of the current time using relative timers exclusively, in the hope that POE gets it right at least internally.

- Lack of defined event ordering

  POE cannot guarantee the order of callback invocation for timers, and usually gets it wrong. That is, if you have two timers, one timing out after another (all else being equal), the callbacks might be called in reverse order.

How one manages to even implement stuff that way escapes me.

- Child watchers

  POE offers child watchers - which is a laudable thing, as few event loops do. Unfortunately, they cannot even implement AnyEvent's simple child watchers: they are not generic enough (the POE implementation isn't even generic enough to let properly designed back-end use their native child watcher instead - it insist on doing it itself the broken way).

  Unfortunately, POE's child handling is inherently racy: if the child exits before the handler is created (because e.g. it crashes or simply is quick about it), then current versions of POE (1.352) will *never* invoke the child watcher, and there is nothing that can be done about it. Older versions of POE only delayed in this case. The reason is that POE first checks if the child has already exited, and *then* installs the signal handler - aa classical race.

  Your only hope is for the fork'ed process to not exit too quickly, in which case everything happens to work.

  Of course, whenever POE reaps an unrelated child it will also output a message for it that you cannot suppress (which shouldn't be too surprising at this point). Very professional.

  As a workaround, AnyEvent::Impl::POE will take advantage of undocumented behaviour in POE::Kernel to catch the status of all child processes, but it cannot guarantee delivery.

  How one manages to have such a glaring bug in an event loop after ten years of development escapes me.

  (There are more annoying bugs, for example, POE runs `waitpid` unconditionally at finaliser time, so your program will hang until all child processes have exited.)

- Documentation quality

  At the time of this writing, POE was in its tenth year. Still, its documentation is extremely lacking, making it impossible to implement stuff as trivial as AnyEvent watchers without having to resort to undocumented behaviour or features.

  For example, the POE::Kernel manpage has nine occurrences of the word TODO with an explanation of whats missing. In general, the POE man pages are littered with comments like "section not yet written".

  Some other gems:

```
This allows many object methods to also be package methods.
```

  This is nice, but since it doesn't document *which* methods these are, this is utterly useless information.

```
Terminal signals will kill sessions if they are not handled by a
"sig_handled"() call. The OS signals that usually kill or dump a
process are considered terminal in POE, but they never trigger a
coredump. These are: HUP, INT, QUIT and TERM.
```

  Although AnyEvent calls `sig_handled`, removing it has no apparent effects on POE handling SIGINT.

```
refcount_increment SESSION_ID, COUNTER_NAME
```

Nowhere is explained which COUNTER_NAMEs are valid and which aren't - not all scalars (or even strings) are valid counter names. Take your guess, failure is of course completely silent. I found this out the hard way, as the first name I came up with was silently ignored.

```
get_next_event_time() returns the time the next event is due,␣
↪in a form
compatible with the UNIX time() function.
```

And surely, one would hope that POE supports sub-second accuracy as documented elsewhere, unlike the explanation above implies. Yet:

```
POE::Kernel timers support subsecond accuracy, but don't expect␣
↪too
much here. Perl is not the right language for realtime␣
↪programming.
```

... of course, Perl is not the right language to expect sub-second accuracy - the manpage author must hate Perl to spread so much FUD in so little space. The Deliantra game server logs with 100µs-accuracy because Perl is fast enough to require this, and is still able to deliver map updates with little jitter at exactly the right time. It does not, however, use POE.

```
Furthermore, since the Kernel keeps track of everything␣
↪sessions do, it
knows when a session has run out of tasks to perform.
```

This is impossible - how does the kernel know that a session is no longer watching for some (external) event (e.g. by some other session)? It cannot, and therefore this is wrong - but you would be hard pressed to find out how to work around this and tell the kernel manually about such events.

It gets worse, though - the notion of "task" or "resource", although used throughout the documentation, is not defined in a usable way. For example, waiting for a timeout is considered to be a task, waiting for a signal is not (a session that only waits for a signal is considered finished and gets removed). The user is left guessing when waiting for an event counts as task and when not (in fact, the issue with signals is mentioned in passing in a section about child watchers and directly contradicts earlier parts in that document).

One could go on endlessly - ten years, no usable documentation.

It is likely that differences between documentation, or the one or two things I had to guess, cause unanticipated problems with this adaptor.

- Fragile and inconsistent API

  The POE API is extremely inconsistent - sometimes you have to pass a session argument, sometimes it gets ignored, sometimes a session-specific method must not use a session argument.

  Error handling is sub-standard as well: even for programming mistakes, POE does

not `croak` but, in most cases, just sets `$!` or simply does nothing at all, leading to fragile programs.

Sometimes registering a handler uses the "eventname, parameter" ordering (timeouts), sometimes it is "parameter, eventname" (signals). There is little consistency overall.

- Lack of knowledge

```
The IO::Poll event loop provides an alternative that␣
↪theoretically
scales better than select().
```

The IO::Poll "event loop" (who in his right mind would call that an event loop) of course scales about identically (sometimes it is a bit faster, sometimes a bit slower) to select in theory, and also in practise, of course, as both are O(n) in the number of file descriptors, which is rather bad.

This is just one place where it gets obvious how little the author of the POE manpage understands.

- No idle events

The POE-recommended workaround to this is apparently to use `fork`. Consequently, idle watchers will have to be emulated by AnyEvent.

- Questionable maintainer behaviour

The author of POE is known to fabricate statements and post these to public mailinglists - apparently, spreading FUD about competing (in his eyes) projects or their maintainers is acceptable to him.

This has (I believe) zero effects on the quality or usefulness of his code, but it does completely undermine his trustworthyness - so don't blindly believe anything he says, he might have just made it up to suit his needs (benchmark results, the names of my ten wifes, the length of my penis, etc. etc.). When in doubt, double-check - not just him, anybody actually.

Example: http://www.nntp.perl.org/group/perl.perl5.porters/2012/01/msg182141.html. I challenged him in that thread to provide evidence for his statement by giving at least two examples, but of course since he just made it up, he couldn't provide any evidence.

On the good side, AnyEvent allows you to write your modules in a 100% POE-compatible way (bug-for-bug compatible even), without forcing your module to use POE - it is still open to better event models, of which there are plenty.

Oh, and one other positive thing:

```
RUNNING_IN_HELL
```

POE knows about the nature of the beast!

AnyEvent::Impl::Perl

AnyEvent adaptor for AnyEvent's pure perl AnyEvent::Loop

SYNOPSIS

```
use AnyEvent;
use AnyEvent::Loop;
# this module gets loaded automatically as required
```

DESCRIPTION

This module provides transparent support for AnyEvent in case no other event loop could be found or loaded.

If you want to use this module instead of autoloading another event loop you can simply load *AnyEvent::Loop* before creating the first watcher.

Naturally, it supports all features of AnyEvent.

See *AnyEvent::Loop* for more details on performance characteristics.

```

AnyEvent::Impl::Qt

AnyEvent adaptor for Qt

SYNOPSIS

```
use AnyEvent;
use Qt;

my $app = Qt::Application \@ARGV; # REQUIRED!

# this module gets loaded automatically as required
```

DESCRIPTION

This module provides transparent support for AnyEvent. You don't have to do anything to make Qt work with AnyEvent except by loading Qt before creating the first AnyEvent watcher *and instantiating the Qt::Application object*. Failure to do so will result in segfaults, which is why this model doesn't work as a default model and will not be autoprobed (but it will be autodetected when the main program uses Qt).

Qt suffers from the same limitations as Event::Lib and Tk, the workaround is also the same (duplicating file descriptors).

Qt doesn't support idle events, so they are being emulated.

Avoid Qt if you can.

```

AnyEvent::Impl::Tk

AnyEvent adaptor for Tk

SYNOPSIS

```
use AnyEvent;
use Tk;

# this module gets loaded automatically as required
```

DESCRIPTION

This module provides transparent support for AnyEvent. You don't have to do anything to make Tk work with AnyEvent except by loading Tk before creating the first AnyEvent watcher.

Tk is buggy. Tk is extremely buggy. Tk is so unbelievably buggy that for each bug reported and fixed, you get one new bug followed by reintroduction of the old bug in a

later revision. It is also basically unmaintained: the maintainers are not even interested in improving the situation - reporting bugs is considered rude, and fixing bugs is considered changing holy code, so it's apparently better to leave it broken.

I regularly run out of words to describe how bad it really is.

To work around some of the many, many bugs in Tk that don't get fixed, this adaptor dup()'s all filehandles that get passed into its I/O watchers, so if you register a read and a write watcher for one fh, AnyEvent will create two additional file descriptors (and handles).

This creates a high overhead and is slow, but seems to work around most known bugs in Tk::fileevent on 32 bit architectures (Tk seems to be terminally broken on 64 bit, do not expect more than 10 or so watchers to work on 64 bit machines).

Do not expect these workarounds to avoid segfaults and crashes inside Tk.

Note also that Tk event ids wrap around after 2**32 or so events, which on my machine can happen within less than 12 hours, after which Tk will stomp on random other events and kill them. So don't run Tk programs for more than an hour or so.

To be able to access the Tk event loop, this module creates a main window and withdraws it immediately. This might cause flickering on some platforms, but Tk perversely requires a window to be able to wait for file handle readyness notifications. This window is always created (in this version of AnyEvent) and can be accessed as `$AnyEvent::Impl::Tk::mw`.

AnyEvent::Log

simple logging "framework"

SYNOPSIS

Simple uses:

```
use AnyEvent;

AE::log fatal => "No config found, cannot continue!"; # never␣
 ↪returns
AE::log alert => "The battery died!";
AE::log crit  => "The battery is too hot!";
AE::log error => "Division by zero attempted.";
AE::log warn  => "Couldn't delete the file.";
AE::log note  => "Attempted to create config, but config already␣
 ↪exists.";
AE::log info  => "File soandso successfully deleted.";
AE::log debug => "the function returned 3";
AE::log trace => "going to call function abc";
```

Log level overview:

```
LVL  NAME      SYSLOG   PERL  NOTE
 1   fatal     emerg    exit  system unusable, aborts program!
 2   alert                    failure in primary system
 3   critical  crit             failure in backup system
 4   error     err      die   non-urgent program errors, a bug
 5   warn      warning          possible problem, not necessarily error
 6   note      notice           unusual conditions
 7   info                       normal messages, no action required
 8   debug                      debugging messages for development
 9   trace                      copious tracing output
```

"Complex" uses (for speed sensitive code, e.g. trace/debug messages):

```
use AnyEvent::Log;

my $tracer = AnyEvent::Log::logger trace => \my $trace;

$tracer->("i am here") if $trace;
$tracer->(sub { "lots of data: " . Dumper $self }) if $trace;
```

Configuration (also look at the EXAMPLES section):

```
# set default logging level to suppress anything below "notice"
# i.e. enable logging at "notice" or above - the default is to
# to not log anything at all.
$AnyEvent::Log::FILTER->level ("notice");

# set logging for the current package to errors and higher only
AnyEvent::Log::ctx->level ("error");

# enable logging for the current package, regardless of global␣
 ↪logging level
AnyEvent::Log::ctx->attach ($AnyEvent::Log::LOG);

# enable debug logging for module some::mod and enable logging by␣
 ↪default
(AnyEvent::Log::ctx "some::mod")->level ("debug");
(AnyEvent::Log::ctx "some::mod")->attach ($AnyEvent::Log::LOG);

# send all critical and higher priority messages to syslog,
# regardless of (most) other settings
$AnyEvent::Log::COLLECT->attach (new AnyEvent::Log::Ctx
   level         => "critical",
   log_to_syslog => "user",
);
```

DESCRIPTION

This module implements a relatively simple “logging framework”. It doesn’t attempt to be “the” logging solution or even “a” logging solution for AnyEvent - AnyEvent simply creates logging messages internally, and this module more or less exposes the mechanism, with some extra spiff to allow using it from other modules as well.

Remember that the default verbosity level is 4 (`error`), so only errors and more important messages will be logged, unless you set `PERL_ANYEVENT_VERBOSE` to a higher number before starting your program (`AE_VERBOSE=5` is recommended during development), or change the logging level at runtime with something like:

```
use AnyEvent::Log;
$AnyEvent::Log::FILTER->level ("info");
```

The design goal behind this module was to keep it simple (and small), but make it powerful enough to be potentially useful for any module, and extensive enough for the most common tasks, such as logging to multiple targets, or being able to log into a database.

The module is also usable before AnyEvent itself is initialised, in which case some of the functionality might be reduced.

The amount of documentation might indicate otherwise, but the runtime part of the module is still just below 300 lines of code.

LOGGING LEVELS

Logging levels in this module range from 1 (highest priority) to 9 (lowest priority). Note that the lowest numerical value is the highest priority, so when this document says "higher priority" it means "lower numerical value".

Instead of specifying levels by name you can also specify them by aliases:

```
LVL NAME      SYSLOG   PERL  NOTE
 1  fatal     emerg    exit  system unusable, aborts program!
 2  alert                    failure in primary system
 3  critical  crit             failure in backup system
 4  error     err      die   non-urgent program errors, a bug
 5  warn      warning          possible problem, not necessarily error
 6  note      notice           unusual conditions
 7  info                       normal messages, no action required
 8  debug                      debugging messages for development
 9  trace                      copious tracing output
```

As you can see, some logging levels have multiple aliases - the first one is the "official" name, the second one the "syslog" name (if it differs) and the third one the "perl" name, suggesting (only!) that you log `die` messages at `error` priority. The NOTE column tries to provide some rationale on how to chose a logging level.

As a rough guideline, levels 1..3 are primarily meant for users of the program (admins, staff), and are the only ones logged to STDERR by default. Levels 4..6 are meant for users and developers alike, while levels 7..9 are usually meant for developers.

You can normally only log a message once at highest priority level (`1`, `fatal`), because logging a fatal message will also quit the program - so use it sparingly :)

For example, a program that finds an unknown switch on the commandline might well use a fatal logging level to tell users about it - the "system" in this case would be the program, or module.

Some methods also offer some extra levels, such as `0`, `off`, none or `all` - these are only valid for the methods that documented them.

LOGGING FUNCTIONS

The following functions allow you to log messages. They always use the caller's package as a "logging context". Also, the main logging function, `log`, is aliased to `AnyEvent::log` and `AE::log` when the `AnyEvent` module is loaded.

- AnyEvent::Log::log $level, $msg[, @args]

  Requests logging of the given `$msg` with the given log level, and returns true if the message was logged *somewhere*.

  For loglevel `fatal`, the program will abort.

If only a `$msg` is given, it is logged as-is. With extra `@args`, the `$msg` is interpreted as an sprintf format string.

The `$msg` should not end with `\n`, but may if that is convenient for you. Also, multiline messages are handled properly.

Last not least, `$msg` might be a code reference, in which case it is supposed to return the message. It will be called only then the message actually gets logged, which is useful if it is costly to create the message in the first place.

This function takes care of saving and restoring `$!` and `$@`, so you don't have to.

Whether the given message will be logged depends on the maximum log level and the caller's package. The return value can be used to ensure that messages or not "lost" - for example, when *AnyEvent::Debug* detects a runtime error it tries to log it at `die` level, but if that message is lost it simply uses warn.

Note that you can (and should) call this function as `AnyEvent::log` or `AE::log`, without `use`-ing this module if possible (i.e. you don't need any additional functionality), as those functions will load the logging module on demand only. They are also much shorter to write.

Also, if you optionally generate a lot of debug messages (such as when tracing some code), you should look into using a logger callback and a boolean enabler (see `logger`, below).

Example: log something at error level.

```
AE::log error => "something";
```

Example: use printf-formatting.

```
AE::log info => "%5d %-10.10s %s", $index, $category, $msg;
```

Example: only generate a costly dump when the message is actually being logged.

```
AE::log debug => sub { require Data::Dump; Data::Dump::dump \
 ↪%cache };
```

- $logger = AnyEvent::Log::logger $level[, \$enabled]

  Creates a code reference that, when called, acts as if the `AnyEvent::Log::log` function was called at this point with the given level. `$logger` is passed a `$msg` and optional `@args`, just as with the `AnyEvent::Log::log` function:

  ```
  my $debug_log = AnyEvent::Log::logger "debug";

  $debug_log->("debug here");
  $debug_log->("%06d emails processed", 12345);
  $debug_log->(sub { $obj->as_string });
  ```

  The idea behind this function is to decide whether to log before actually logging - when the `logger` function is called once, but the returned logger callback often, then this can be a tremendous speed win.

  Despite this speed advantage, changes in logging configuration will still be reflected by the logger callback, even if configuration changes *after* it was created.

To further speed up logging, you can bind a scalar variable to the logger, which contains true if the logger should be called or not - if it is false, calling the logger can be safely skipped. This variable will be updated as long as `$logger` is alive.

Full example:

```
# near the init section
use AnyEvent::Log;

my $debug_log = AnyEvent::Log::logger debug => \my $debug;

# and later in your program
$debug_log->("yo, stuff here") if $debug;

$debug and $debug_log->("123");
```

- AnyEvent::Log::exact_time $on

  By default, `AnyEvent::Log` will use `AE::now`, i.e. the cached eventloop time, for the log timestamps. After calling this function with a true value it will instead resort to `AE::time`, i.e. fetch the current time on each log message. This only makes a difference for event loops that actually cache the time (such as *EV* or *AnyEvent::Loop*).

  This setting can be changed at any time by calling this function.

  Since `AnyEvent::Log` has to work even before the *AnyEvent* has been initialised, this switch will also decide whether to use `CORE::time` or `Time::HiRes::time` when logging a message before *AnyEvent* becomes available.

- AnyEvent::Log::format_time $timestamp

  Formats a timestamp as returned by `AnyEvent->now` or `AnyEvent->time` or many other functions in the same way as `AnyEvent::Log` does.

  In your main program (as opposed to in your module) you can override the default timestamp display format by loading this module and then redefining this function.

  Most commonly, this function can be used in formatting callbacks.

- AnyEvent::Log::default_format $time, $ctx, $level, $msg

  Format a log message using the given timestamp, logging context, log level and log message.

  This is the formatting function used to format messages when no custom function is provided.

  In your main program (as opposed to in your module) you can override the default message format by loading this module and then redefining this function.

- AnyEvent::Log::fatal_exit()

  This is the function that is called after logging a `fatal` log message. It must not return.

  The default implementation simply calls `exit 1`.

  In your main program (as opposed to in your module) you can override the fatal exit function by loading this module and then redefining this function. Make sure

you don't return.

LOGGING CONTEXTS

This module associates every log message with a so-called *logging context*, based on the package of the caller. Every perl package has its own logging context.

A logging context has three major responsibilities: filtering, logging and propagating the message.

For the first purpose, filtering, each context has a set of logging levels, called the log level mask. Messages not in the set will be ignored by this context (masked).

For logging, the context stores a formatting callback (which takes the timestamp, context, level and string message and formats it in the way it should be logged) and a logging callback (which is responsible for actually logging the formatted message and telling `AnyEvent::Log` whether it has consumed the message, or whether it should be propagated).

For propagation, a context can have any number of attached *slave contexts*. Any message that is neither masked by the logging mask nor masked by the logging callback returning true will be passed to all slave contexts.

Each call to a logging function will log the message at most once per context, so it does not matter (much) if there are cycles or if the message can arrive at the same context via multiple paths.

DEFAULTS

By default, all logging contexts have an full set of log levels ("all"), a disabled logging callback and the default formatting callback.

Package contexts have the package name as logging title by default.

They have exactly one slave - the context of the "parent" package. The parent package is simply defined to be the package name without the last component, i.e. `AnyEvent::Debug::Wrapped` becomes `AnyEvent::Debug`, and `AnyEvent` becomes ... `$AnyEvent::Log::COLLECT` which is the exception of the rule - just like the "parent" of any single-component package name in Perl is `main`, the default slave of any top-level package context is `$AnyEvent::Log::COLLECT`.

Since perl packages form only an approximate hierarchy, this slave context can of course be removed.

All other (anonymous) contexts have no slaves and an empty title by default.

When the module is loaded it creates the `$AnyEvent::Log::LOG` logging context that simply logs everything via `warn`, without propagating anything anywhere by default. The purpose of this context is to provide a convenient place to override the global logging target or to attach additional log targets. It's not meant for filtering.

It then creates the `$AnyEvent::Log::FILTER` context whose purpose is to suppress all messages with priority higher than `$ENV{PERL_ANYEVENT_VERBOSE}`. It then attached the `$AnyEvent::Log::LOG` context to it. The purpose of the filter context is to simply provide filtering according to some global log level.

Finally it creates the top-level package context `$AnyEvent::Log::COLLECT` and attaches the `$AnyEvent::Log::FILTER` context to it, but otherwise leaves it at default config. Its purpose is simply to collect all log messages system-wide.

The hierarchy is then:

```
any package, eventually -> $COLLECT -> $FILTER -> $LOG
```

The effect of all this is that log messages, by default, wander up to the `$AnyEvent::Log::COLLECT` context where all messages normally end up, from there to `$AnyEvent::Log::FILTER` where log messages with lower priority then `$ENV{PERL_ANYEVENT_VERBOSE}` will be filtered out and then to the `$AnyEvent::Log::LOG` context to be passed to `warn`.

This makes it easy to set a global logging level (by modifying $FILTER), but still allow other contexts to send, for example, their debug and trace messages to the $LOG target despite the global logging level, or to attach additional log targets that log messages, regardless of the global logging level.

It also makes it easy to modify the default warn-logger ($LOG) to something that logs to a file, or to attach additional logging targets (such as loggign to a file) by attaching it to $FILTER.

CREATING/FINDING/DESTROYING CONTEXTS

- $ctx = AnyEvent::Log::ctx [$pkg]

  This function creates or returns a logging context (which is an object).

  If a package name is given, then the context for that package is returned. If it is called without any arguments, then the context for the callers package is returned (i.e. the same context as a `AE::log` call would use).

  If `undef` is given, then it creates a new anonymous context that is not tied to any package and is destroyed when no longer referenced.

- AnyEvent::Log::reset

  Resets all package contexts and recreates the default hierarchy if necessary, i.e. resets the logging subsystem to defaults, as much as possible. This process keeps references to contexts held by other parts of the program intact.

  This can be used to implement config-file (re-)loading: before loading a configuration, reset all contexts.

- $ctx = new AnyEvent::Log::Ctx methodname => param...

  This is a convenience constructor that makes it simpler to construct anonymous logging contexts.

  Each key-value pair results in an invocation of the method of the same name as the key with the value as parameter, unless the value is an arrayref, in which case it calls the method with the contents of the array. The methods are called in the same order as specified.

  Example: create a new logging context and set both the default logging level, some slave contexts and a logging callback.

```
$ctx = new AnyEvent::Log::Ctx
   title    => "dubious messages",
   level    => "error",
   log_cb   => sub { print STDOUT shift; 0 },
   slaves   => [$ctx1, $ctx, $ctx2],
;
```

CONFIGURING A LOG CONTEXT

The following methods can be used to configure the logging context.

- $ctx->title ([$new_title])

  Returns the title of the logging context - this is the package name, for package contexts, and a user defined string for all others.

  If `$new_title` is given, then it replaces the package name or title.

LOGGING LEVELS

The following methods deal with the logging level set associated with the log context.

The most common method to use is probably `$ctx->level ($level)`, which configures the specified and any higher priority levels.

All functions which accept a list of levels also accept the special string `all` which expands to all logging levels.

- $ctx->levels ($level[, $level...)

  Enables logging for the given levels and disables it for all others.

- $ctx->level ($level)

  Enables logging for the given level and all lower level (higher priority) ones. In addition to normal logging levels, specifying a level of `0` or `off` disables all logging for this level.

  Example: log warnings, errors and higher priority messages.

  ```
  $ctx->level ("warn");
  $ctx->level (5); # same thing, just numeric
  ```

- $ctx->enable ($level[, $level...])

  Enables logging for the given levels, leaving all others unchanged.

- $ctx->disable ($level[, $level...])

  Disables logging for the given levels, leaving all others unchanged.

- $ctx->cap ($level)

  Caps the maximum priority to the given level, for all messages logged to, or passing through, this context. That is, while this doesn't affect whether a message is logged or passed on, the maximum priority of messages will be limited to the specified level - messages with a higher priority will be set to the specified priority.

Another way to view this is that `->level` filters out messages with a too low priority, while `->cap` modifies messages with a too high priority.

This is useful when different log targets have different interpretations of priority. For example, for a specific command line program, a wrong command line switch might well result in a `fatal` log message, while the same message, logged to syslog, is likely *not* fatal to the system or syslog facility as a whole, but more likely a mere `error`.

This can be modeled by having a stderr logger that logs messages "as-is" and a syslog logger that logs messages with a level cap of, say, `error`, or, for truly system-critical components, actually `critical`.

SLAVE CONTEXTS

The following methods attach and detach another logging context to a logging context.

Log messages are propagated to all slave contexts, unless the logging callback consumes the message.

- $ctx->attach ($ctx2[, $ctx3...])

  Attaches the given contexts as slaves to this context. It is not an error to add a context twice (the second add will be ignored).

  A context can be specified either as package name or as a context object.

- $ctx->detach ($ctx2[, $ctx3...])

  Removes the given slaves from this context - it's not an error to attempt to remove a context that hasn't been added.

  A context can be specified either as package name or as a context object.

- $ctx->slaves ($ctx2[, $ctx3...])

  Replaces all slaves attached to this context by the ones given.

LOG TARGETS

The following methods configure how the logging context actually does the logging (which consists of formatting the message and printing it or whatever it wants to do with it).

- $ctx->log_cb ($cb->($str))

  Replaces the logging callback on the context (`undef` disables the logging callback).

  The logging callback is responsible for handling formatted log messages (see `fmt_cb` below) - normally simple text strings that end with a newline (and are possibly multiline themselves).

  It also has to return true iff it has consumed the log message, and false if it hasn't. Consuming a message means that it will not be sent to any slave context. When in doubt, return `0` from your logging callback.

  Example: a very simple logging callback, simply dump the message to STDOUT and do not consume it.

```
$ctx->log_cb (sub { print STDERR shift; 0 });
```

You can filter messages by having a log callback that simply returns 1 and does not do anything with the message, but this counts as "message being logged" and might not be very efficient.

Example: propagate all messages except for log levels "debug" and "trace". The messages will still be generated, though, which can slow down your program.

```
$ctx->levels ("debug", "trace");
$ctx->log_cb (sub { 1 }); # do not log, but eat debug and trace
 ↪messages
```

- $ctx->fmt_cb ($fmt_cb->($timestamp, $orig_ctx, $level, $message))

  Replaces the formatting callback on the context (`undef` restores the default formatter).

  The callback is passed the (possibly fractional) timestamp, the original logging context (object, not title), the (numeric) logging level and the raw message string and needs to return a formatted log message. In most cases this will be a string, but it could just as well be an array reference that just stores the values.

  If, for some reason, you want to use `caller` to find out more about the logger then you should walk up the call stack until you are no longer inside the `AnyEvent::Log` package.

  To implement your own logging callback, you might find the `AnyEvent::Log::format_time` and `AnyEvent::Log::default_format` functions useful.

  Example: format the message just as AnyEvent::Log would, by letting AnyEvent::Log do the work. This is a good basis to design a formatting callback that only changes minor aspects of the formatting.

```
$ctx->fmt_cb (sub {
   my ($time, $ctx, $lvl, $msg) = @_;

   AnyEvent::Log::default_format $time, $ctx, $lvl, $msg
});
```

  Example: format just the raw message, with numeric log level in angle brackets.

```
$ctx->fmt_cb (sub {
   my ($time, $ctx, $lvl, $msg) = @_;

   "<$lvl>$msg\n"
});
```

  Example: return an array reference with just the log values, and use `PApp::SQL::sql_exec` to store the message in a database.

```
$ctx->fmt_cb (sub { \@_ });
$ctx->log_cb (sub {
```

(continues on next page)

(continued from previous page)

```
   my ($msg) = @_;

   sql_exec "insert into log (when, subsys, prio, msg) values (?
↪, ?, ?, ?)",
            $msg->[0] + 0,
            "$msg->[1]",
            $msg->[2] + 0,
            "$msg->[3]";

   0
});
```

- $ctx->log_to_warn

  Sets the `log_cb` to simply use `CORE::warn` to report any messages (usually this logs to STDERR).

- $ctx->log_to_file ($path)

  Sets the `log_cb` to log to a file (by appending), unbuffered. The function might return before the log file has been opened or created.

- $ctx->log_to_path ($path)

  Same as `->log_to_file`, but opens the file for each message. This is much slower, but allows you to change/move/rename/delete the file at basically any time.

  Needless(?) to say, if you do not want to be bitten by some evil person calling `chdir`, the path should be absolute. Doesn't help with `chroot`, but hey...

- $ctx->log_to_syslog ([$facility])

  Logs all messages via *Sys::Syslog*, mapping `trace` to debug and all the others in the obvious way. If specified, then the `$facility` is used as the facility (`user`, `auth`, `local0` and so on). The default facility is `user`.

  Note that this function also sets a `fmt_cb` - the logging part requires an array reference with [$level, $str] as input.

MESSAGE LOGGING

These methods allow you to log messages directly to a context, without going via your package context.

- $ctx->log ($level, $msg[, @params])

  Same as `AnyEvent::Log::log`, but uses the given context as log context.

  Example: log a message in the context of another package.

```
(AnyEvent::Log::ctx "Other::Package")->log (warn => "heely bo");
```

- $logger = $ctx->logger ($level[, \$enabled])

  Same as `AnyEvent::Log::logger`, but uses the given context as log context.

CONFIGURATION VIA $ENV{PERL_ANYEVENT_LOG}

Logging can also be configured by setting the environment variable `PERL_ANYEVENT_LOG` (or `AE_LOG`).

The value consists of one or more logging context specifications separated by : or whitespace. Each logging specification in turn starts with a context name, followed by =, followed by zero or more comma-separated configuration directives, here are some examples:

```
# set default logging level
filter=warn

# log to file instead of to stderr
log=file=/tmp/mylog

# log to file in addition to stderr
log=+%file:%file=file=/tmp/mylog

# enable debug log messages, log warnings and above to syslog
filter=debug:log=+%warnings:%warnings=warn,syslog=LOG_LOCAL0

# log trace messages (only) from AnyEvent::Debug to file
AnyEvent::Debug=+%trace:%trace=only,trace,file=/tmp/tracelog
```

A context name in the log specification can be any of the following:

- `collect`, `filter`, `log`

  Correspond to the three predefined `$AnyEvent::Log::COLLECT`, `AnyEvent::Log::FILTER` and `$AnyEvent::Log::LOG` contexts.

- `%name`

  Context names starting with a % are anonymous contexts created when the name is first mentioned. The difference to package contexts is that by default they have no attached slaves.

  This makes it possible to create new log contexts that can be refered to multiple times by name within the same log specification.

- a perl package name

  Any other string references the logging context associated with the given Perl `package`. In the unlikely case where you want to specify a package context that matches on of the other context name forms, you can add a `::` to the package name to force interpretation as a package.

The configuration specifications can be any number of the following:

- `stderr`

  Configures the context to use Perl's `warn` function (which typically logs to `STDERR`). Works like `log_to_warn`.

- `file=`*path*

  Configures the context to log to a file with the given path. Works like `log_to_file`.

- `path=`*path*

  Configures the context to log to a file with the given path. Works like `log_to_path`.

- `syslog` or `syslog=`*expr*

  Configures the context to log to syslog. If *expr* is given, then it is evaluated in the *Sys::Syslog* package, so you could use:

```
log=syslog=LOG_LOCAL0
```

- `nolog`

  Configures the context to not log anything by itself, which is the default. Same as `$ctx->log_cb (undef)`.

- `cap=`*level*

  Caps logging messages entering this context at the given level, i.e. reduces the priority of messages with higher priority than this level. The default is `0` (or `off`), meaning the priority will not be touched.

- `0` or `off`

  Sets the logging level of the context to `0`, i.e. all messages will be filtered out.

- `all`

  Enables all logging levels, i.e. filtering will effectively be switched off (the default).

- `only`

  Disables all logging levels, and changes the interpretation of following level specifications to enable the specified level only.

  Example: only enable debug messages for a context.

```
context=only,debug
```

- `except`

  Enables all logging levels, and changes the interpretation of following level specifications to disable that level. Rarely used.

  Example: enable all logging levels except fatal and trace (this is rather nonsensical).

```
filter=exept,fatal,trace
```

- `level`

  Enables all logging levels, and changes the interpretation of following level specifications to be “that level or any higher priority message”. This is the default.

  Example: log anything at or above warn level.

```
filter=warn

# or, more verbose
filter=only,level,warn
```

- 1..9 or a logging level name (`error`, debug etc.)

  A numeric loglevel or the name of a loglevel will be interpreted according to the most recent `only`, `except` or `level` directive. By default, specifying a logging level enables that and any higher priority messages.

- *+context*

  Attaches the named context as slave to the context.

- +

  A lone + detaches all contexts, i.e. clears the slave list from the context. Anonymous (`%name`) contexts have no attached slaves by default, but package contexts have the parent context as slave by default.

  Example: log messages from My::Module to a file, do not send them to the default log collector.

  ```
  My::Module=+,file=/tmp/mymodulelog
  ```

Any character can be escaped by prefixing it with a `\` (backslash), as usual, so to log to a file containing a comma, colon, backslash and some spaces in the filename, you would do this:

```
PERL_ANYEVENT_LOG='log=file=/some\ \:file\ with\,\ \\-escapes'
```

Since whitespace (which includes newlines) is allowed, it is fine to specify multiple lines in `PERL_ANYEVENT_LOG`, e.g.:

```
PERL_ANYEVENT_LOG="
   filter=warn
   AnyEvent::Debug=+%trace
   %trace=only,trace,+log
" myprog
```

Also, in the unlikely case when you want to concatenate specifications, use whitespace as separator, as `::` will be interpreted as part of a module name, an empty spec with two separators:

```
PERL_ANYEVENT_LOG="$PERL_ANYEVENT_LOG MyMod=debug"
```

EXAMPLES

This section shows some common configurations, both as code, and as `PERL_ANYEVENT_LOG` string.

- Setting the global logging level.

  Either put `PERL_ANYEVENT_VERBOSE=<number>` into your environment before running your program, use `PERL_ANYEVENT_LOG` or modify the log level of the root context at runtime:

  ```
  PERL_ANYEVENT_VERBOSE=5 ./myprog
  ```

(continues on next page)

(continued from previous page)

```
PERL_ANYEVENT_LOG=log=warn

$AnyEvent::Log::FILTER->level ("warn");
```

- Append all messages to a file instead of sending them to STDERR.

  This is affected by the global logging level.

```
$AnyEvent::Log::LOG->log_to_file ($path);

PERL_ANYEVENT_LOG=log=file=/some/path
```

- Write all messages with priority `error` and higher to a file.

  This writes them only when the global logging level allows it, because it is attached to the default context which is invoked *after* global filtering.

```
$AnyEvent::Log::FILTER->attach (
   new AnyEvent::Log::Ctx log_to_file => $path);

PERL_ANYEVENT_LOG=filter=+%filelogger:%filelogger=file=/some/
 ↪path
```

  This writes them regardless of the global logging level, because it is attached to the toplevel context, which receives all messages *before* the global filtering.

```
$AnyEvent::Log::COLLECT->attach (
   new AnyEvent::Log::Ctx log_to_file => $path);

PERL_ANYEVENT_LOG=%filelogger=file=/some/path:collect=+
 ↪%filelogger
```

  In both cases, messages are still written to STDERR.

- Additionally log all messages with `warn` and higher priority to `syslog`, but cap at `error`.

  This logs all messages to the default log target, but also logs messages with priority `warn` or higher (and not filtered otherwise) to syslog facility `user`. Messages with priority higher than `error` will be logged with level `error`.

```
$AnyEvent::Log::LOG->attach (
   new AnyEvent::Log::Ctx
      level  => "warn",
      cap    => "error",
      syslog => "user",
);

PERL_ANYEVENT_LOG=log=+%syslog:%syslog=warn,cap=error,syslog
```

- Write trace messages (only) from *AnyEvent::Debug* to the default logging target(s).

  Attach the `$AnyEvent::Log::LOG` context to the `AnyEvent::Debug` context - this simply circumvents the global filtering for trace messages.

```
my $debug = AnyEvent::Debug->AnyEvent::Log::ctx;
$debug->attach ($AnyEvent::Log::LOG);

PERL_ANYEVENT_LOG=AnyEvent::Debug=+log
```

This of course works for any package, not just *AnyEvent::Debug*, but assumes the log level for AnyEvent::Debug hasn't been changed from the default.

ASYNCHRONOUS DISK I/O

This module uses *AnyEvent::IO* to actually write log messages (in `log_to_file` and `log_to_path`), so it doesn't block your program when the disk is busy and a non-blocking *AnyEvent::IO* backend is available.

AnyEvent::Loop

AnyEvent's Pure-Perl event loop

SYNOPSIS

```
use AnyEvent;
# use AnyEvent::Loop;

# this module gets loaded automatically when no other loop can be
 ↪found

# Explicit use:
use AnyEvent::Loop;
use AnyEvent;

...

AnyEvent::Loop::run; # run the event loop
```

DESCRIPTION

This module provides an event loop for AnyEvent in case no other event loop could be found or loaded. You don't have to do anything to make it work with AnyEvent except by possibly loading it before creating the first AnyEvent watcher.

This module is *not* some loop abstracion used by AnyEvent, but just another event loop like EV or Glib, just written in pure perl and delivered with AnyEvent, so AnyEvent always works, even in the absence of any other backend.

If you want to use this module instead of autoloading a potentially better event loop you can simply load it (and no other event loops) before creating the first watcher.

As for performance, this module is on par with (and usually faster than) most select/poll-based C event modules such as Event or Glib (it does not even come close to EV, though), with respect to I/O watchers. Timers are handled less optimally, but for many common tasks, it is still on par with event loops written in C.

This event loop has been optimised for the following use cases:

- monotonic clock is available

  This module will use the POSIX monotonic clock option (if it can be detected at runtime) or the POSIX `times` function (if the resolution is at least 100Hz), in which case it will not suffer adversely from time jumps.

  If no monotonic clock is available, this module will not attempt to correct for time jumps in any way.

  The clock chosen will be reported if the environment variable `$PERL_ANYEVENT_VERBOSE` is set to 8 or higher.

- any number of watchers on one fd

  Supporting a large number of watchers per fd is purely a dirty benchmark optimisation not relevant in practise. The more common case of having one watcher per fd/poll combo is special-cased, however, and therefore fast, too.

- relatively few active fds per `select` call

  This module expects that only a tiny amount of fds is active at any one time. This is relatively typical of larger servers (but not the case where `select` traditionally is fast), at the expense of the “dense activity case” where most of the fds are active (which suits `select`).

  The optimal implementation of the “dense” case is not much faster, though, so the module should behave very well in most cases, subject to the bad scalability of `select` in the presence of a large number of inactive file descriptors.

- lots of timer changes/iteration, or none at all

  This module sorts the timer list using perl’s `sort`, even though a total ordering is not required for timers internally.

  This sorting is expensive, but means sorting can be avoided unless the timer list has changed in a way that requires a new sort.

  This means that adding lots of timers is very efficient, as well as not changing the timers. Advancing timers (e.g. recreating a timeout watcher on activity) is also relatively efficient, for example, if you have a large number of timeout watchers that time out after 10 seconds, then the timer list will be sorted only once every 10 seconds.

  This should not have much of an impact unless you have hundreds or thousands of timers, though, or your timers have very small timeouts.

FUNCTIONS

The only user-visible functions provided by this module loop related - watchers are created via the normal AnyEvent mechanisms.

- AnyEvent::Loop::run

  Run the event loop, usually the last thing done in the main program when you want to use the pure-perl backend.

- AnyEvent::Loop::one_event

  Blocks until at least one new event has been received by the operating system, whether or not it was AnyEvent-related.

AnyEvent::Socket

useful IPv4 and IPv6 stuff. also unix domain sockets. and stuff.

SYNOPSIS

```
use AnyEvent::Socket;

tcp_connect "gameserver.deliantra.net", 13327, sub {
   my ($fh) = @_
      or die "gameserver.deliantra.net connect failed: $!";

   # enjoy your filehandle
};

# a simple tcp server
tcp_server undef, 8888, sub {
   my ($fh, $host, $port) = @_;

   syswrite $fh, "The internet is full, $host:$port. Go away!\015\
 ↪012";
};
```

DESCRIPTION

This module implements various utility functions for handling internet protocol addresses and sockets, in an as transparent and simple way as possible.

All functions documented without `AnyEvent::Socket::` prefix are exported by default.

- $ipn = parse_ipv4 $dotted_quad

  Tries to parse the given dotted quad IPv4 address and return it in octet form (or undef when it isn't in a parsable format). Supports all forms specified by POSIX (e.g. `10.0.0.1`, `10.1`, `10.0x020304`, `0x12345678` or `0377.0377.0377.0377`).

- $ipn = parse_ipv6 $textual_ipv6_address

  Tries to parse the given IPv6 address and return it in octet form (or undef when it isn't in a parsable format).

  Should support all forms specified by RFC 2373 (and additionally all IPv4 forms supported by parse_ipv4). Note that scope-id's are not supported (and will not parse).

  This function works similarly to `inet_pton AF_INET6, ...`.

  Example:

```
print unpack "H*", parse_ipv6 "2002:5345::10.0.0.1";
# => 2002534500000000000000000a000001

print unpack "H*", parse_ipv6 "192.89.98.1";
# => 00000000000000000000ffffc0596201
```

- $token = parse_unix $hostname

  This function exists mainly for symmetry to the other `parse_protocol` functions - it takes a hostname and, if it is `unix/`, it returns a special address token, otherwise `undef`.

  The only use for this function is probably to detect whether a hostname matches whatever AnyEvent uses for unix domain sockets.

- $ipn = parse_address $ip

  Combines `parse_ipv4`, `parse_ipv6` and `parse_unix` in one function. The address here refers to the host address (not socket address) in network form (binary).

  If the `$text` is `unix/`, then this function returns a special token recognised by the other functions in this module to mean "UNIX domain socket".

  If the `$text` to parse is a plain IPv4 or mapped IPv4 in IPv6 address (:ffff::<ipv4>), then it will be treated as an IPv4 address and four octets will be returned. If you don't want that, you have to call `parse_ipv4` and/or `parse_ipv6` manually (the latter always returning a 16 octet IPv6 address for mapped IPv4 addresses).

  Example:

```
print unpack "H*", parse_address "10.1.2.3";
# => 0a010203
```

- $ipn = AnyEvent::Socket::aton $ip

  Same as `parse_address`, but not exported (think `Socket::inet_aton` but *without* name resolution).

- ($name, $aliases, $proto) = getprotobyname $name

  Works like the builtin function of the same name, except it tries hard to work even on broken platforms (well, that's windows), where getprotobyname is traditionally very unreliable.

  Example: get the protocol number for TCP (usually 6)

```
my $proto = getprotobyname "tcp";
```

- ($host, $service) = parse_hostport $string[, $default_service]

  Splitting a string of the form `hostname:port` is a common problem. Unfortunately, just splitting on the colon makes it hard to specify IPv6 addresses and doesn't support the less common but well standardised `[ip literal]` syntax.

  This function tries to do this job in a better way, it supports (at least) the following formats, where `port` can be a numerical port number of a service name, or a `name=port` string, and the `port` and `:port` parts are optional. Also, everywhere where an IP address is supported a hostname or unix domain socket address is also supported (see `parse_unix`), and strings starting with `/` will also be interpreted as unix domain sockets.

```
hostname:port    e.g. "www.linux.org", "www.x.de:443", "www.x.
↪de:https=443",
ipv4:port        e.g. "198.182.196.56", "127.1:22"
ipv6             e.g. "::1", "affe::1"
[ipv4or6]:port   e.g. "[::1]", "[10.0.1]:80"
[ipv4or6] port   e.g. "[127.0.0.1]", "[www.x.org] 17"
ipv4or6 port     e.g. "::1 443", "10.0.0.1 smtp"
unix/:path       e.g. "unix/:/path/to/socket"
/path            e.g. "/path/to/socket"
```

  It also supports defaulting the service name in a simple way by using `$default_service` if no service was detected. If neither a service was detected nor a default was specified, then this function returns the empty list. The same happens when a parse error was detected, such as a hostname with a colon in it (the function is rather forgiving, though).

  Example:

```
print join ",", parse_hostport "localhost:443";
# => "localhost,443"

print join ",", parse_hostport "localhost", "https";
# => "localhost,https"

print join ",", parse_hostport "[::1]";
# => "," (empty list)
```

(continues on next page)

(continued from previous page)

```
print join ",", parse_hostport "/tmp/debug.sock";
# => "unix/", "/tmp/debug.sock"
```

- $string = format_hostport $host, $port

  Takes a host (in textual form) and a port and formats in unambigiously in a way that `parse_hostport` can parse it again. `$port` can be `undef`.

- $sa_family = address_family $ipn

  Returns the address family/protocol-family (AF_xxx/PF_xxx, in one value :) of the given host address in network format.

- $text = format_ipv4 $ipn

  Expects a four octet string representing a binary IPv4 address and returns its textual format. Rarely used, see `format_address` for a nicer interface.

- $text = format_ipv6 $ipn

  Expects a sixteen octet string representing a binary IPv6 address and returns its textual format. Rarely used, see `format_address` for a nicer interface.

- $text = format_address $ipn

  Covnvert a host address in network format (e.g. 4 octets for IPv4 or 16 octets for IPv6) and convert it into textual form.

  Returns `unix/` for UNIX domain sockets.

  This function works similarly to `inet_ntop AF_INET || AF_INET6, ...`, except it automatically detects the address type.

  Returns `undef` if it cannot detect the type.

  If the `$ipn` is a mapped IPv4 in IPv6 address (:ffff::<ipv4>), then just the contained IPv4 address will be returned. If you do not want that, you have to call `format_ipv6` manually.

  Example:

```
print format_address "\x01\x02\x03\x05";
=> 1.2.3.5
```

- $text = AnyEvent::Socket::ntoa $ipn

  Same as format_address, but not exported (think `inet_ntoa`).

- inet_aton $name_or_address, $cb->(@addresses)

  Works similarly to its Socket counterpart, except that it uses a callback. Use the length to distinguish between ipv4 and ipv6 (4 octets for IPv4, 16 for IPv6), or use `format_address` to convert it to a more readable format.

  Note that `resolve_sockaddr`, while initially a more complex interface, resolves host addresses, IDNs, service names and SRV records and gives you an ordered list of socket addresses to try and should be preferred over `inet_aton`.

  Example.

```
inet_aton "www.google.com", my $cv = AE::cv;
say unpack "H*", $_
   for $cv->recv;
# => d155e363
# => d155e367 etc.

inet_aton "ipv6.google.com", my $cv = AE::cv;
say unpack "H*", $_
   for $cv->recv;
# => 20014860a003000000000000000000068
```

- $sa = AnyEvent::Socket::pack_sockaddr $service, $host

  Pack the given port/host combination into a binary sockaddr structure. Handles both IPv4 and IPv6 host addresses, as well as UNIX domain sockets ($host == unix/ and $service == absolute pathname).

  Example:

```
my $bind = AnyEvent::Socket::pack_sockaddr 43, v195.234.53.120;
bind $socket, $bind
   or die "bind: $!";
```

- ($service, $host) = AnyEvent::Socket::unpack_sockaddr $sa

  Unpack the given binary sockaddr structure (as used by bind, getpeername etc.) into a $service, $host combination.

  For IPv4 and IPv6, $service is the port number and $host the host address in network format (binary).

  For UNIX domain sockets, $service is the absolute pathname and $host is a special token that is understood by the other functions in this module (format_address converts it to unix/).

- AnyEvent::Socket::resolve_sockaddr $node, $service, $proto, $family, $type, $cb->([$family, $type, $proto, $sockaddr], ...)

  Tries to resolve the given nodename and service name into protocol families and sockaddr structures usable to connect to this node and service in a protocol-independent way. It works remotely similar to the getaddrinfo posix function.

  For internet addresses, $node is either an IPv4 or IPv6 address, an internet hostname (DNS domain name or IDN), and $service is either a service name (port name from /etc/services) or a numerical port number. If both $node and $service are names, then SRV records will be consulted to find the real service, otherwise they will be used as-is. If you know that the service name is not in your services database, then you can specify the service in the format name=port (e.g. http=80).

  If a host cannot be found via DNS, then it will be looked up in /etc/hosts (or the file specified via $ENV{PERL_ANYEVENT_HOSTS}). If they are found, the addresses there will be used. The effect is as if entries from /etc/hosts would yield A and AAAA records for the host name unless DNS already had records for them.

For UNIX domain sockets, $node must be the string unix/ and $service must be the absolute pathname of the socket. In this case, $proto will be ignored.

$proto must be a protocol name, currently tcp, udp or sctp. The default is currently tcp, but in the future, this function might try to use other protocols such as sctp, depending on the socket type and any SRV records it might find.

$family must be either 0 (meaning any protocol is OK), 4 (use only IPv4) or 6 (use only IPv6). The default is influenced by $ENV{PERL_ANYEVENT_PROTOCOLS}.

$type must be SOCK_STREAM, SOCK_DGRAM or SOCK_SEQPACKET (or undef in which case it gets automatically chosen to be SOCK_STREAM unless $proto is udp).

The callback will receive zero or more array references that contain $family, $type, $proto for use in socket and a binary $sockaddr for use in connect (or bind).

The application should try these in the order given.

Example:

```
resolve_sockaddr "google.com", "http", 0, undef, undef, sub { ..
 ↪. };
```

- $guard = tcp_connect $host, $service, $connect_cb[, $prepare_cb]

  This is a convenience function that creates a TCP socket and makes a 100% non-blocking connect to the given $host (which can be a DNS/IDN hostname or a textual IP address, or the string unix/ for UNIX domain sockets) and $service (which can be a numeric port number or a service name, or a servicename=portnumber string, or the pathname to a UNIX domain socket).

  If both $host and $port are names, then this function will use SRV records to locate the real target(s).

  In either case, it will create a list of target hosts (e.g. for multihomed hosts or hosts with both IPv4 and IPv6 addresses) and try to connect to each in turn.

  After the connection is established, then the $connect_cb will be invoked with the socket file handle (in non-blocking mode) as first, and the peer host (as a textual IP address) and peer port as second and third arguments, respectively. The fourth argument is a code reference that you can call if, for some reason, you don't like this connection, which will cause tcp_connect to try the next one (or call your callback without any arguments if there are no more connections). In most cases, you can simply ignore this argument.

  ```
  $cb->($filehandle, $host, $port, $retry)
  ```

  If the connect is unsuccessful, then the $connect_cb will be invoked without any arguments and $! will be set appropriately (with ENXIO indicating a DNS resolution failure).

  The callback will *never* be invoked before tcp_connect returns, even if tcp_connect was able to connect immediately (e.g. on unix domain sockets).

  The file handle is perfect for being plugged into *AnyEvent::Handle*, but can be used as a normal perl file handle as well.

Unless called in void context, `tcp_connect` returns a guard object that will automatically cancel the connection attempt when it gets destroyed - in which case the callback will not be invoked. Destroying it does not do anything to the socket after the connect was successful - you cannot "uncall" a callback that has been invoked already.

Sometimes you need to "prepare" the socket before connecting, for example, to `bind` it to some port, or you want a specific connect timeout that is lower than your kernel's default timeout. In this case you can specify a second callback, `$prepare_cb`. It will be called with the file handle in not-yet-connected state as only argument and must return the connection timeout value (or `0`, `undef` or the empty list to indicate the default timeout is to be used).

Note to the poor Microsoft Windows users: Windows (of course) doesn't correctly signal connection errors, so unless your event library works around this, failed connections will simply hang. The only event libraries that handle this condition correctly are *EV* and Glib. Additionally, AnyEvent works around this bug with *Event* and in its pure-perl backend. All other libraries cannot correctly handle this condition. To lessen the impact of this windows bug, a default timeout of 30 seconds will be imposed on windows. Cygwin is not affected.

Simple Example: connect to localhost on port 22.

```
tcp_connect localhost => 22, sub {
   my $fh = shift
      or die "unable to connect: $!";
   # do something
};
```

Complex Example: connect to www.google.com on port 80 and make a simple GET request without much error handling. Also limit the connection timeout to 15 seconds.

```
tcp_connect "www.google.com", "http",
   sub {
      my ($fh) = @_
         or die "unable to connect: $!";

      my $handle; # avoid direct assignment so on_eof has it in
↪scope.
      $handle = new AnyEvent::Handle
         fh     => $fh,
         on_error => sub {
            AE::log error => $_[2];
            $_[0]->destroy;
         },
         on_eof => sub {
            $handle->destroy; # destroy handle
            AE::log info => "Done.";
         };

      $handle->push_write ("GET / HTTP/1.0\015\012\015\012");
```

(continues on next page)

(continued from previous page)

```
      $handle->push_read (line => "\015\012\015\012", sub {
         my ($handle, $line) = @_;

         # print response header
         print "HEADER\n$line\n\nBODY\n";

         $handle->on_read (sub {
            # print response body
            print $_[0]->rbuf;
            $_[0]->rbuf = "";
         });
      });
   }, sub {
      my ($fh) = @_;
      # could call $fh->bind etc. here

      15
   };
```

Example: connect to a UNIX domain socket.

```
tcp_connect "unix/", "/tmp/.X11-unix/X0", sub {
   ...
}
```

- $guard = tcp_server $host, $service, $accept_cb[, $prepare_cb]

  Create and bind a stream socket to the given host address and port, set the SO_REUSEADDR flag (if applicable) and call `listen`. Unlike the name implies, this function can also bind on UNIX domain sockets.

  For internet sockets, `$host` must be an IPv4 or IPv6 address (or `undef`, in which case it binds either to `0` or to `::`, depending on whether IPv4 or IPv6 is the preferred protocol, and maybe to both in future versions, as applicable).

  To bind to the IPv4 wildcard address, use `0`, to bind to the IPv6 wildcard address, use `::`.

  The port is specified by `$service`, which must be either a service name or a numeric port number (or `0` or `undef`, in which case an ephemeral port will be used).

  For UNIX domain sockets, `$host` must be `unix/` and `$service` must be the absolute pathname of the socket. This function will try to `unlink` the socket before it tries to bind to it, and will try to unlink it after it stops using it. See SECURITY CONSIDERATIONS, below.

  For each new connection that could be `accepted`, call the `$accept_cb->($fh, $host, $port)` with the file handle (in non-blocking mode) as first, and the peer host and port as second and third arguments (see `tcp_connect` for details).

  Croaks on any errors it can detect before the listen.

  In non-void context, this function returns a guard object whose lifetime it tied to

the TCP server: If the object gets destroyed, the server will be stopped and the listening socket will be cleaned up/unlinked (already accepted connections will not be affected).

When called in void-context, AnyEvent will keep the listening socket alive internally. In this case, there is no guarantee that the listening socket will be cleaned up or unlinked.

In all cases, when the function returns to the caller, the socket is bound and in listening state.

If you need more control over the listening socket, you can provide a `$prepare_cb->($fh, $host, $port)`, which is called just before the `listen ()` call, with the listen file handle as first argument, and IP address and port number of the local socket endpoint as second and third arguments.

It should return the length of the listen queue (or `0` for the default).

Note to IPv6 users: RFC-compliant behaviour for IPv6 sockets listening on `::` is to bind to both IPv6 and IPv4 addresses by default on dual-stack hosts. Unfortunately, only GNU/Linux seems to implement this properly, so if you want both IPv4 and IPv6 listening sockets you should create the IPv6 socket first and then attempt to bind on the IPv4 socket, but ignore any `EADDRINUSE` errors.

Example: bind on some TCP port on the local machine and tell each client to go away.

```
tcp_server undef, undef, sub {
   my ($fh, $host, $port) = @_;

   syswrite $fh, "The internet is full, $host:$port. Go away!\
↪015\012";
}, sub {
   my ($fh, $thishost, $thisport) = @_;
   AE::log info => "Bound to $thishost, port $thisport.";
};
```

Example: bind a server on a unix domain socket.

```
tcp_server "unix/", "/tmp/mydir/mysocket", sub {
   my ($fh) = @_;
};
```

- $guard = AnyEvent::Socket::tcp_bind $host, $service, $done_cb[, $prepare_cb]

  Same as `tcp_server`, except it doesn't call `accept` in a loop for you but simply passes the listen socket to the `$done_cb`. This is useful when you want to have a convenient set up for your listen socket, but want to do the `accept`'ing yourself, for example, in another process.

  In case of an error, `tcp_bind` either croaks, or passes `undef` to the `$done_cb`.

  In non-void context, a guard will be returned. It will clean up/unlink the listening socket when destroyed. In void context, no automatic clean up might be performed.

- tcp_nodelay $fh, $enable

Enables (or disables) the TCP_NODELAY socket option (also known as Nagle's algorithm). Returns false on error, true otherwise.

- tcp_congestion $fh, $algorithm

  Sets the tcp congestion avoidance algorithm (via the TCP_CONGESTION socket option). The default is OS-specific, but is usually reno. Typical other available choices include cubic, lp, bic, highspeed, htcp, hybla, illinois, scalable, vegas, veno, westwood and yeah.

SECURITY CONSIDERATIONS

This module is quite powerful, with with power comes the ability to abuse as well: If you accept "hostnames" and ports from untrusted sources, then note that this can be abused to delete files (host=unix/). This is not really a problem with this module, however, as blindly accepting any address and protocol and trying to bind a server or connect to it is harmful in general.

AnyEvent::Strict

force strict mode on for the whole process

SYNOPSIS

```
use AnyEvent::Strict;
# strict mode now switched on
```

DESCRIPTION

This module implements AnyEvent's strict mode.

Loading it makes AnyEvent check all arguments to AnyEvent-methods, at the expense of being slower (often the argument checking takes longer than the actual function). It also wraps all callbacks to check for modifications of $_, which indicates a programming bug inside the watcher callback.

Normally, you don't load this module yourself but instead use it indirectly via the PERL_ANYEVENT_STRICT environment variable (see *AnyEvent*). However, this module can be loaded manually at any time.

AnyEvent::TLS

SSLv2/SSLv3/TLSv1 contexts for use in AnyEvent::Handle

SYNOPSIS

```
# via AnyEvent::Handle

use AnyEvent;
use AnyEvent::Handle;
use AnyEvent::Socket;

# simple https-client
my $handle = new AnyEvent::Handle
   connect  => [$host, $port],
   tls      => "connect",
   tls_ctx  => { verify => 1, verify_peername => "https" },
   ...

# simple ssl-server
tcp_server undef, $port, sub {
   my ($fh) = @_;

   my $handle = new AnyEvent::Handle
      fh       => $fh,
      tls      => "accept",
      tls_ctx  => { cert_file => "my-server-keycert.pem" },
      ...

# directly

my $tls = new AnyEvent::TLS
   verify => 1,
   verify_peername => "ldaps",
   ca_file => "/etc/cacertificates.pem";
```

DESCRIPTION

This module is a helper module that implements TLS/SSL (Transport Layer Security/Secure Sockets Layer) contexts. A TLS context is a common set of configuration values for use in establishing TLS connections.

For some quick facts about SSL/TLS, see the section of the same name near the end of the document.

A single TLS context can be used for any number of TLS connections that wish to use the same certificates, policies etc.

Note that this module is inherently tied to *Net::SSLeay*, as this library is used to implement it. Since that perl module is rather ugly, and OpenSSL has a rather ugly license, AnyEvent might switch TLS providers at some future point, at which this API

will change dramatically, at least in the Net::SSLeay-specific parts (most constructor arguments should still work, though).

Although this module does not require a specific version of Net::SSLeay, many features will gradually stop working, or bugs will be introduced with old versions (verification might succeed when it shouldn't - this is a real security issue). Version 1.35 is recommended, 1.33 should work, 1.32 might, and older versions are yours to keep.

USAGE EXAMPLES

See the *AnyEvent::Handle* manpage, NONFREQUENTLY ASKED QUESTIONS, for some actual usage examples.

PUBLIC METHODS AND FUNCTIONS

- $tls = new AnyEvent::TLS key => value...

  The constructor supports these arguments (all as key => value pairs).

  – method => "SSLv2" | "SSLv3" | "TLSv1" | "TLSv1_1" | "TLSv1_2" | "any"

    The protocol parser to use. `SSLv2`, `SSLv3`, `TLSv1`, `TLSv1_1` and `TLSv1_2` will use a parser for those protocols only (so will *not* accept or create connections with/to other protocol versions), while `any` (the default) uses a parser capable of all three protocols.

    The default is to use `"any"` but disable SSLv2. This has the effect of sending a SSLv2 hello, indicating the support for SSLv3 and TLSv1, but not actually negotiating an (insecure) SSLv2 connection.

    Specifying a specific version is almost always wrong to use for a server speaking to a wide variety of clients (e.g. web browsers), and often wrong for a client. If you only want to allow a specific protocol version, use the `sslv2`, `sslv3`, `tlsv1`, `tlsv1_1` or `tlsv1_2` arguments instead.

    For new services it is usually a good idea to enforce a `TLSv1` method from the beginning.

    `TLSv1_1` and `TLSv1_2` require *Net::SSLeay* >= 1.55 and OpenSSL >= 1.0.1. Check the *Net::SSLeay* and OpenSSL documentations for more details.

  – sslv2 => $enabled

    Enable or disable SSLv2 (normally *disabled*).

  – sslv3 => $enabled

    Enable or disable SSLv3 (normally *enabled*).

  – tlsv1 => $enabled

    Enable or disable TLSv1 (normally *enabled*).

  – tlsv1_1 => $enabled

    Enable or disable TLSv1_1 (normally *enabled*).

    This requires *Net::SSLeay* >= 1.55 and OpenSSL >= 1.0.1. Check the *Net::SSLeay* and OpenSSL documentations for more details.

– tlsv1_2 => $enabled

  Enable or disable TLSv1_2 (normally *enabled*).

  This requires *Net::SSLeay* >= 1.55 and OpenSSL >= 1.0.1. Check the *Net::SSLeay* and OpenSSL documentations for more details.

– verify => $enable

  Enable or disable peer certificate checking (default is *disabled*, which is *not recommended*).

  This is the "master switch" for all verify-related parameters and functions.

  If it is disabled, then no peer certificate verification will be done - the connection will be encrypted, but the peer certificate won't be verified against any known CAs, or whether it is still valid or not. No peername verification or custom verification will be done either.

  If enabled, then the peer certificate (required in client mode, optional in server mode, see `verify_require_client_cert`) will be checked against its CA certificate chain - that means there must be a signing chain from the peer certificate to any of the CA certificates you trust locally, as specified by the `ca_file` and/or `ca_path` and/or `ca_cert` parameters (or the system default CA repository, if all of those parameters are missing - see also the *AnyEvent* manpage for the description of PERL_ANYEVENT_CA_FILE).

  Other basic checks, such as checking the validity period, will also be done, as well as optional peername/hostname/common name verification `verify_peername`.

  An optional `verify_cb` callback can also be set, which will be invoked with the verification results, and which can override the decision.

– verify_require_client_cert => $enable

  Enable or disable mandatory client certificates (default is *disabled*). When this mode is enabled, then a client certificate will be required in server mode (a server certificate is mandatory, so in client mode, this switch has no effect).

– verify_peername => $scheme | $callback->($tls, $cert, $peername)

  TLS only protects the data that is sent - it cannot automatically verify that you are really talking to the right peer. The reason is that certificates contain a "common name" (and a set of possible alternative "names") that need to be checked against the peername (usually, but not always, the DNS name of the server) in a protocol-dependent way.

  This can be implemented by specifying a callback that has to verify that the actual `$peername` matches the given certificate in `$cert`.

  Since this can be rather hard to implement, AnyEvent::TLS offers a variety of predefined "schemes" (lifted from *IO::Socket::SSL*) that are named like the protocols that use them:

  * ldap (rfc4513), pop3,imap,acap (rfc2995), nntp (rfc4642)

    Simple wildcards in subjectAltNames are possible, e.g. *.example.org matches www.example.org but not lala.www.example.org. If nothing

from subjectAltNames matches, it checks against the common name, but there are no wildcards allowed.

* http (rfc2818)

  Extended wildcards in subjectAltNames are possible, e.g. *.example.org or even www*.example.org. Wildcards in the common name are not allowed. The common name will be only checked if no host names are given in subjectAltNames.

* smtp (rfc3207)

  This RFC isn't very useful in determining how to do verification so it just assumes that subjectAltNames are possible, but no wildcards are possible anywhere.

* [$wildcards_in_alt, $wildcards_in_cn, $check_cn]

  You can also specify a scheme yourself by using an array reference with three integers.

  `$wildcards_in_alt` and `$wildcards_in_cn` specify whether and where wildcards (`*`) are allowed in subjectAltNames and the common name, respectively. `0` means no wildcards are allowed, `1` means they are allowed only as the first component (`*.example.org`), and `2` means they can be used anywhere (`www*.example.org`), except that very dangerous matches will not be allowed (`*.org` or `*`).

  `$check_cn` specifies if and how the common name field is checked: `0` means it will be completely ignored, `1` means it will only be used if no host names have been found in the subjectAltNames, and `2` means the common name will always be checked against the peername.

You can specify either the name of the parent protocol (recommended, e.g. `http`, `ldap`), the protocol name as usually used in URIs (e.g. `https`, `ldaps`) or the RFC (not recommended, e.g. `rfc2995`, `rfc3920`).

This verification will only be done when verification is enabled (`verify => 1`).

– verify_cb => $callback->($tls, $ref, $cn, $depth, $preverify_ok, $x509_store_ctx, $cert)

Provide a custom peer verification callback used by TLS sessions, which is called with the result of any other verification (`verify`, `verify_peername`).

This callback will only be called when verification is enabled (`verify = > 1`).

`$tls` is the `AnyEvent::TLS` object associated with the session, while `$ref` is whatever the user associated with the session (usually an *AnyEvent::Handle* object when used by AnyEvent::Handle).

`$depth` is the current verification depth - `$depth = 0` means the certificate to verify is the peer certificate, higher levels are its CA certificate and so on. In most cases, you can just return `$preverify_ok` if the `$depth` is non-zero:

```
verify_cb => sub {
   my ($tls, $ref, $cn, $depth, $preverify_ok, $x509_store_
↪ctx, $cert) = @_;

   return $preverify_ok
      if $depth;

   # more verification
},
```

`$preverify_ok` is true iff the basic verification of the certificates was successful (a valid CA chain must exist, the certificate has passed basic validity checks, peername verification succeeded).

`$x509_store_ctx` is the Net::SSLeay::X509_CTX> object.

`$cert` is the `Net::SSLeay::X509` object representing the peer certificate, or zero if there was an error. You can call `AnyEvent::TLS::certname $cert` to get a nice user-readable string to identify the certificate.

The callback must return either `0` to indicate failure, or `1` to indicate success.

– verify_client_once => $enable

Enable or disable skipping the client certificate verification on renegotiations (default is *disabled*, the certificate will always be checked). Only makes sense in server mode.

– ca_file => $path

If this parameter is specified and non-empty, it will be the path to a file with (server) CA certificates in PEM format that will be loaded. Each certificate will look like:

```
-----BEGIN CERTIFICATE-----
... (CA certificate in base64 encoding) ...
-----END CERTIFICATE-----
```

You have to enable verify mode (`verify => 1`) for this parameter to have any effect.

– ca_path => $path

If this parameter is specified and non-empty, it will be the path to a directory with hashed CA certificate files in PEM format. When the ca certificate is being verified, the certificate will be hashed and looked up in that directory (see http://www.openssl.org/docs/ssl/SSL_CTX_load_verify_locations.html for details)

The certificates specified via `ca_file` take precedence over the ones found in `ca_path`.

You have to enable verify mode (`verify => 1`) for this parameter to have any effect.

– ca_cert => $string

In addition or instead of using `ca_file` and/or `ca_path`, you can also use `ca_cert` to directly specify the CA certificates (there can be multiple) in PEM format, in a string.

– check_crl => $enable

Enable or disable certificate revocation list checking. If enabled, then peer certificates will be checked against a list of revoked certificates issued by the CA. The revocation lists will be expected in the `ca_path` directory.

certificate verification will fail if this is enabled but no revocation list was found.

This requires OpenSSL >= 0.9.7b. Check the OpenSSL documentation for more details.

– key_file => $path

Path to the local private key file in PEM format (might be a combined certificate/private key file).

The local certificate is used to authenticate against the peer - servers mandatorily need a certificate and key, clients can use a certificate and key optionally to authenticate, e.g. for log-in purposes.

The key in the file should look similar this:

```
-----BEGIN RSA PRIVATE KEY-----
...header data
... (key data in base64 encoding) ...
-----END RSA PRIVATE KEY-----
```

– key => $string

The private key string in PEM format (see `key_file`, only one of `key_file` or `key` can be specified).

The idea behind being able to specify a string is to avoid blocking in I/O. Unfortunately, Net::SSLeay fails to implement any interface to the needed OpenSSL functionality, this is currently implemented by writing to a temporary file.

– cert_file => $path

The path to the local certificate file in PEM format (might be a combined certificate/private key file, including chained certificates).

The local certificate (and key) are used to authenticate against the peer - servers mandatorily need a certificate and key, clients can use certificate and key optionally to authenticate, e.g. for log-in purposes.

The certificate in the file should look like this:

```
-----BEGIN CERTIFICATE-----
... (certificate in base64 encoding) ...
-----END CERTIFICATE-----
```

If the certificate file or string contain both the certificate and private key, then there is no need to specify a separate `key_file` or `key`.

Additional signing certifiates to send to the peer (in SSLv3 and newer) can be specified by appending them to the certificate proper: the order must be from issuer certificate over any intermediate CA certificates to the root CA.

So the recommended ordering for a combined key/cert/chain file, specified via `cert_file` or `cert` looks like this:

```
certificate private key
client/server certificate
ca 1, signing client/server certficate
ca 2, signing ca 1
...
```

– cert => $string

The local certificate in PEM format (might be a combined certificate/private key file). See `cert_file`.

The idea behind being able to specify a string is to avoid blocking in I/O. Unfortunately, Net::SSLeay fails to implement any interface to the needed OpenSSL functionality, this is currently implemented by writing to a temporary file.

– cert_password => $string | $callback->($tls)

The certificate password - if the certificate is password-protected, then you can specify its password here.

Instead of providing a password directly (which is not so recommended), you can also provide a password-query callback. The callback will be called whenever a password is required to decode a local certificate, and is supposed to return the password.

– dh_file => $path

Path to a file containing Diffie-Hellman parameters in PEM format, for use in servers. See also dh on how to specify them directly, or use a pre-generated set.

Diffie-Hellman key exchange generates temporary encryption keys that are not transferred over the connection, which means that even if the certificate key(s) are made public at a later time and a full dump of the connection exists, the key still cannot be deduced.

These ciphers are only available with SSLv3 and later (which is the default with AnyEvent::TLS), and are only used in server/accept mode. Anonymous DH protocols are usually disabled by default, and usually not even compiled into the underlying library, as they provide no direct protection against man-in-the-middle attacks. The same is true for the common practise of self-signed certificates that you have to accept first, of course.

– dh => $string

Specify the Diffie-Hellman parameters in PEM format directly as a string (see `dh_file`), the default is `ffdhe3072` unless `dh_file` was specified.

AnyEvent::TLS supports supports a number of precomputed DH parameters, since computing them is expensive. They are:

```
# from RFC 7919 - recommended
ffdhe2048, ffdhe3072, ffdhe4096, ffdhe6144, ffdhe8192

# from "Assigned Number for SKIP Protocols"
skip512, skip1024, skip2048, skip4096

# from schmorp
schmorp1024, schmorp1539, schmorp2048, schmorp4096,␣
↪schmorp8192
```

It is said that 2048 bit DH parameters are safe till 2030, and DH parameters shorter than 900 bits are totally insecure.

To disable DH protocols completely, specify `undef` as dh parameter.

– dh_single_use => $enable

Enables or disables “use only once” mode when using Diffie-Hellman key exchange. When enabled (default), each time a new key is exchanged a new Diffie-Hellman key is generated, which improves security as each key is only used once. When disabled, the key will be created as soon as the AnyEvent::TLS object is created and will be reused.

All the DH parameters supplied with AnyEvent::TLS should be safe with `dh_single_use` switched off, but YMMV.

– cipher_list => $string

The list of ciphers to use, as a string (example: `AES:ALL:!aNULL:!eNULL:+RC4:@STRENGTH`). The format of this string and its default value is documented at http://www.openssl.org/docs/apps/ciphers.html#CIPHER_STRINGS.

– session_ticket => $enable

Enables or disables RC5077 support (Session Resumption without Server-Side State). The default is disabled for clients, as many (buggy) TLS/SSL servers choke on it, but enabled for servers.

When enabled and supported by the server, a session ticket will be provided to the client, which allows fast resuming of connections.

– prepare => $coderef->($tls)

If this argument is present, then it will be called with the new AnyEvent::TLS object after any other initialisation has bee done, in case you wish to fine-tune something...

- $tls = new_from_ssleay AnyEvent::TLS $ctx

  This constructor takes an existing *Net::SSLeay* SSL_CTX object (which is just an integer) and converts it into an `AnyEvent::TLS` object. This only works because AnyEvent::TLS is currently implemented using Net::SSLeay. As this is such a horrible perl module and OpenSSL has such an annoying license, this might change in the future, in which case this method might vanish.

- $ctx = $tls->ctx

Returns the actual Net::SSLeay::CTX object (just an integer).

- AnyEvent::TLS::init

  AnyEvent::TLS does on-demand initialisation, and normally there is no need to call an initialise function.

  As initialisation might take some time (to read e.g. `/dev/urandom`), this could be annoying in some highly interactive programs. In that case, you can call `AnyEvent::TLS::init` to make sure there will be no costly initialisation later. It is harmless to call `AnyEvent::TLS::init` multiple times.

- $certname = AnyEvent::TLS::certname $x509

  Utility function that returns a user-readable string identifying the X509 certificate object.

SSL/TLS QUICK FACTS

Here are some quick facts about TLS/SSL that might help you:

- A certificate is the public key part, a key is the private key part.

  While not strictly true, certificates are the things you can hand around publicly as a kind of identity, while keys should really be kept private, as proving that you have the private key is usually interpreted as being the entity behind the certificate.

- A certificate is signed by a CA (Certificate Authority).

  By signing, the CA basically claims that the certificate it signs really belongs to the identity named in it, verified according to the CA policies. For e.g. HTTPS, the CA usually makes some checks that the hostname mentioned in the certificate really belongs to the company/person that requested the signing and owns the domain.

- CAs can be certified by other CAs.

  Or by themselves - a certificate that is signed by a CA that is itself is called a self-signed certificate, a trust chain of length zero. When you find a certificate signed by another CA, which is in turn signed by another CA you trust, you have a trust chain of depth two.

- “Trusting” a CA means trusting all certificates it has signed.

  If you “trust” a CA certificate, then all certificates signed by it are automatically considered trusted as well.

- A successfully verified certificate means that you can be reasonably sure that whoever you are talking with really is who he claims he is.

  By verifying certificates against a number of CAs that you trust (meaning it is signed directly or indirectly by such a CA), you can find out that the other side really is whoever he claims, according to the CA policies, and your belief in the integrity of the CA.

- Verifying the certificate signature is not everything.

  Even when the certificate is correct, it might belong to somebody else: if www.attacker.com can make your computer believe that it is really called www.mybank.com (by making your DNS server believe this for example), then it could send you the certificate for www.attacker.com that your software trusts because

it is signed by a CA you trust, and intercept all your traffic that you think goes to www.mybank.com. This works because your software sees that the certificate is correctly signed (for www.attacker.com) and you think you are talking to your bank.

To thwart this attack vector, peername verification should be used, which basically checks that the certificate (for www.attacker.com) really belongs to the host you are trying to talk to (www.mybank.com), which in this example is not the case, as www.attacker.com (from the certificate) doesn't match www.mybank.com (the hostname used to create the connection).

So peername verification is almost as important as checking the CA signing. Unfortunately, every protocol implements this differently, if at all...

- Switching off verification is sometimes reasonable.

  You can switch off verification. You still get an encrypted connection that is protected against eavesdropping and injection - you just lose protection against man in the middle attacks, i.e. somebody else with enough abilities to intercept all traffic can masquerade herself as the other side.

  For many applications, switching off verification is entirely reasonable. Downloading random stuff from websites using HTTPS for no reason is such an application. Talking to your bank and entering TANs is not such an application.

- A SSL/TLS server always needs a certificate/key pair to operate, for clients this is optional.

  Apart from (usually disabled) anonymous cipher suites, a server always needs a certificate/key pair to operate.

  Clients almost never use certificates, but if they do, they can be used to authenticate the client, just as server certificates can be used to authenticate the server.

- SSL version 2 is very insecure.

  SSL version 2 is old and not only has it some security issues, SSLv2-only implementations are usually buggy, too, due to their age.

- Sometimes, even losing your "private" key might not expose all your data.

  With Diffie-Hellman ephemeral key exchange, you can lose the DH parameters (the "keys"), but all your connections are still protected. Diffie-Hellman needs special set-up (done by default by AnyEvent::TLS).

SECURITY CONSIDERATIONS

When you use any of the options that pass in keys or certificates as strings (e.g. `ca_cert`), then, due to serious shortcomings in *Net::SSLeay*, this module creates a temporary file to store the string - see *File::Temp* and possibly its `safe_level` setting for more details on what to watch out for.

BUGS

Due to the abysmal code quality of Net::SSLeay, this module will leak small amounts of memory per TLS connection (currently at least one perl scalar).

AUTHORS

Marc Lehmann schmorp@schmorp.de.

Some of the API, documentation and implementation (verify_hostname), and a lot of ideas/workarounds/knowledge have been taken from the *IO::Socket::SSL* module. Care has been taken to keep the API similar to that and other modules, to the extent possible while providing a sensible API for AnyEvent.

AnyEvent::Util

various utility functions.

SYNOPSIS

```
use AnyEvent::Util;
```

DESCRIPTION

This module implements various utility functions, mostly replacing well-known functions by event-ised counterparts.

All functions documented without `AnyEvent::Util::` prefix are exported by default.

- ($r, $w) = portable_pipe

  Calling `pipe` in Perl is portable - except it doesn't really work on sucky windows platforms (at least not with most perls - cygwin's perl notably works fine): On windows, you actually get two file handles you cannot use select on.

  This function gives you a pipe that actually works even on the broken windows platform (by creating a pair of TCP sockets on windows, so do not expect any speed from that) and using `pipe` everywhere else.

  See `portable_socketpair`, below, for a bidirectional "pipe".

  Returns the empty list on any errors.

- ($fh1, $fh2) = portable_socketpair

  Just like `portable_pipe`, above, but returns a bidirectional pipe (usually by calling `socketpair` to create a local loopback socket pair, except on windows, where it again returns two interconnected TCP sockets).

  Returns the empty list on any errors.

- fork_call { CODE } @args, $cb->(@res)

  Executes the given code block asynchronously, by forking. Everything the block returns will be transferred to the calling process (by serialising and deserialising via *Storable*).

If there are any errors, then the `$cb` will be called without any arguments. In that case, either `$@` contains the exception (and `$!` is irrelevant), or `$!` contains an error number. In all other cases, `$@` will be undefined.

The code block must not ever call an event-polling function or use event-based programming that might cause any callbacks registered in the parent to run.

Win32 spoilers: Due to the endlessly sucky and broken native windows perls (there is no way to cleanly exit a child process on that platform that doesn't also kill the parent), you have to make sure that your main program doesn't exit as long as any `fork_calls` are still in progress, otherwise the program won't exit. Also, on most windows platforms some memory will leak for every invocation.

Note that forking can be expensive in large programs (RSS 200MB+). On windows, it is abysmally slow, do not expect more than 5..20 forks/s on that sucky platform (note this uses perl's pseudo-threads, so avoid those like the plague).

Example: poor man's async disk I/O (better use *AnyEvent::IO* together with IO::AIO).

```
fork_call {
   open my $fh, "</etc/passwd"
      or die "passwd: $!";
   local $/;
   <$fh>
} sub {
   my ($passwd) = @_;
   ...
};
```

- $AnyEvent::Util::MAX_FORKS [default: 10]

  The maximum number of child processes that `fork_call` will fork in parallel. Any additional requests will be queued until a slot becomes free again.

  The environment variable `PERL_ANYEVENT_MAX_FORKS` is used to initialise this value.

- fh_nonblocking $fh, $nonblocking

  Sets the blocking state of the given filehandle (true == nonblocking, false == blocking). Uses fcntl on anything sensible and ioctl FIONBIO on broken (i.e. windows) platforms.

  Instead of using this function, you could use `AnyEvent::fh_block` or `AnyEvent::fh_unblock`.

- $guard = guard { CODE }

  This function creates a special object that, when destroyed, will execute the code block.

  This is often handy in continuation-passing style code to clean up some resource regardless of where you break out of a process.

  The *Guard* module will be used to implement this function, if it is available. Otherwise a pure-perl implementation is used.

While the code is allowed to throw exceptions in unusual conditions, it is not defined whether this exception will be reported (at the moment, the Guard module and AnyEvent's pure-perl implementation both try to report the error and continue).

You can call one method on the returned object:

- $guard->cancel

  This simply causes the code block not to be invoked: it "cancels" the guard.

- AnyEvent::Util::close_all_fds_except @fds

  This rarely-used function simply closes all file descriptors (or tries to) of the current process except the ones given as arguments.

  When you want to start a long-running background server, then it is often beneficial to do this, as too many C-libraries are too stupid to mark their internal fd's as close-on-exec.

  The function expects to be called shortly before an `exec` call.

  Example: close all fds except 0, 1, 2.

```
close_all_fds_except 0, 2, 1;
```

- $cv = run_cmd $cmd, key => value...

  Run a given external command, potentially redirecting file descriptors and return a condition variable that gets sent the exit status (like `$?`) when the program exits *and* all redirected file descriptors have been exhausted.

  The `$cmd` is either a single string, which is then passed to a shell, or an arrayref, which is passed to the `execvp` function (the first array element is used both for the executable name and argv[0]).

  The key-value pairs can be:

  – ">" => $filename

    Redirects program standard output into the specified filename, similar to `>filename` in the shell.

  – ">" => \$data

    Appends program standard output to the referenced scalar. The condvar will not be signalled before EOF or an error is signalled.

    Specifying the same scalar in multiple ">" pairs is allowed, e.g. to redirect both stdout and stderr into the same scalar:

```
">"  => \$output,
"2>" => \$output,
```

  – ">" => $filehandle

    Redirects program standard output to the given filehandle (or actually its underlying file descriptor).

  – ">" => $callback->($data)

Calls the given callback each time standard output receives some data, passing it the data received. On EOF or error, the callback will be invoked once without any arguments.

The condvar will not be signalled before EOF or an error is signalled.

– "fd>" => $see_above

Like ">", but redirects the specified fd number instead.

– "<" => $see_above

The same, but redirects the program's standard input instead. The same forms as for ">" are allowed.

In the callback form, the callback is supposed to return data to be written, or the empty list or `undef` or a zero-length scalar to signal EOF.

Similarly, either the write data must be exhausted or an error is to be signalled before the condvar is signalled, for both string-reference and callback forms.

– "fd<" => $see_above

Like "<", but redirects the specified file descriptor instead.

– on_prepare => $cb

Specify a callback that is executed just before the command is `exec`'ed, in the child process. Be careful not to use any event handling or other services not available in the child.

This can be useful to set up the environment in special ways, such as changing the priority of the command or manipulating signal handlers (e.g. setting `SIGINT` to `IGNORE`).

– close_all => $boolean

When `close_all` is enabled (default is disabled), then all extra file descriptors will be closed, except the ones that were redirected and `0`, `1` and `2`.

See `close_all_fds_except` for more details.

– '$$' => \$pid

A reference to a scalar which will receive the PID of the newly-created subprocess after `run_cmd` returns.

Note the the PID might already have been recycled and used by an unrelated process at the time `run_cmd` returns, so it's not useful to send signals, use as a unique key in data structures and so on.

Example: run `rm -rf /`, redirecting standard input, output and error to `/dev/null`.

```
my $cv = run_cmd [qw(rm -rf /)],
   "<", "/dev/null",
   ">", "/dev/null",
   "2>", "/dev/null";
$cv->recv and die "d'oh! something survived!"
```

Example: run `openssl` and create a self-signed certificate and key, storing them in `$cert` and `$key`. When finished, check the exit status in the callback and print key and certificate.

```
my $cv = run_cmd [qw(openssl req
                     -new -nodes -x509 -days 3650
                     -newkey rsa:2048 -keyout /dev/fd/3
                     -batch -subj /CN=AnyEvent
                    )],
   "<", "/dev/null",
   ">" , \my $cert,
   "3>", \my $key,
   "2>", "/dev/null";

$cv->cb (sub {
   shift->recv and die "openssl failed";

   print "$key\n$cert\n";
});
```

- AnyEvent::Util::punycode_encode $string

  Punycode-encodes the given `$string` and returns its punycode form. Note that uppercase letters are *not* casefolded - you have to do that yourself.

  Croaks when it cannot encode the string.

- AnyEvent::Util::punycode_decode $string

  Tries to punycode-decode the given `$string` and return its unicode form. Again, uppercase letters are not casefoled, you have to do that yourself.

  Croaks when it cannot decode the string.

- AnyEvent::Util::idn_nameprep $idn[, $display]

  Implements the IDNA nameprep normalisation algorithm. Or actually the UTS#46 algorithm. Or maybe something similar - reality is complicated between IDNA2003, UTS#46 and IDNA2008. If `$display` is true then the name is prepared for display, otherwise it is prepared for lookup (default).

  If you have no clue what this means, look at `idn_to_ascii` instead.

  This function is designed to avoid using a lot of resources - it uses about 1MB of RAM (most of this due to Unicode::Normalize). Also, names that are already "simple" will only be checked for basic validity, without the overhead of full nameprep processing.

- $domainname = AnyEvent::Util::idn_to_ascii $idn

  Converts the given unicode string (`$idn`, international domain name, e.g. 日本語。ＪＰ) to a pure-ASCII domain name (this is usually called the "IDN ToAscii" transform). This transformation is idempotent, which means you can call it just in case and it will do the right thing.

  Unlike some other "ToAscii" implementations, this one works on full domain names and should never fail - if it cannot convert the name, then it will return

it unchanged.

This function is an amalgam of IDNA2003, UTS#46 and IDNA2008 - it tries to be reasonably compatible to other implementations, reasonably secure, as much as IDNs can be secure, and reasonably efficient when confronted with IDNs that are already valid DNS names.

- $idn = AnyEvent::Util::idn_to_unicode $idn

  Converts the given unicode string ($idn, international domain name, e.g. 日本語。ＪＰ, www.deliantra.net, www.xn–l-0ga.de) to unicode form (this is usually called the "IDN ToUnicode" transform). This transformation is idempotent, which means you can call it just in case and it will do the right thing.

  Unlike some other "ToUnicode" implementations, this one works on full domain names and should never fail - if it cannot convert the name, then it will return it unchanged.

  This function is an amalgam of IDNA2003, UTS#46 and IDNA2008 - it tries to be reasonably compatible to other implementations, reasonably secure, as much as IDNs can be secure, and reasonably efficient when confronted with IDNs that are already valid DNS names.

  At the moment, this function simply calls `idn_nameprep $idn, 1`, returning its argument when that function fails.

5.2.4 App

Namespace containing the following modules:

- `App::Cpan` - easily interact with CPAN from the command line
- `App::Prove` - Implements the `prove` command.

App::Cpan

easily interact with CPAN from the command line

SYNOPSIS

```
# with arguments and no switches, installs specified modules
cpan module_name [ module_name ... ]

# with switches, installs modules with extra behavior
cpan [-cfFimtTw] module_name [ module_name ... ]

# use local::lib
cpan -I module_name [ module_name ... ]
```

(continues on next page)

(continued from previous page)

```
# one time mirror override for faster mirrors
cpan -p ...

# with just the dot, install from the distribution in the
# current directory
cpan .

# without arguments, starts CPAN.pm shell
cpan

# without arguments, but some switches
cpan [-ahpruvACDLOPX]
```

DESCRIPTION

This script provides a command interface (not a shell) to CPAN. At the moment it uses CPAN.pm to do the work, but it is not a one-shot command runner for CPAN.pm.

Options

- -a

  Creates a CPAN.pm autobundle with CPAN::Shell->autobundle.

- -A module [module ...]

  Shows the primary maintainers for the specified modules.

- -c module

  Runs a `make clean` in the specified module's directories.

- -C module [module ...]

  Show the `Changes` files for the specified modules

- -D module [module ...]

  Show the module details. This prints one line for each out-of-date module (meaning, modules locally installed but have newer versions on CPAN). Each line has three columns: module name, local version, and CPAN version.

- -f

  Force the specified action, when it normally would have failed. Use this to install a module even if its tests fail. When you use this option, -i is not optional for installing a module when you need to force it:

  ```
  % cpan -f -i Module::Foo
  ```

- -F

  Turn off CPAN.pm's attempts to lock anything. You should be careful with this since you might end up with multiple scripts trying to muck in the same directory. This

isn't so much of a concern if you're loading a special config with `-j`, and that config sets up its own work directories.

- -g module [module ...]

  Downloads to the current directory the latest distribution of the module.

- -G module [module ...]

  UNIMPLEMENTED

  Download to the current directory the latest distribution of the modules, unpack each distribution, and create a git repository for each distribution.

  If you want this feature, check out Yanick Champoux's `Git::CPAN::Patch` distribution.

- -h

  Print a help message and exit. When you specify `-h`, it ignores all of the other options and arguments.

- -i module [module ...]

  Install the specified modules. With no other switches, this switch is implied.

- -I

  Load `local::lib` (think like `-I` for loading lib paths). Too bad `-l` was already taken.

- -j Config.pm

  Load the file that has the CPAN configuration data. This should have the same format as the standard `CPAN/Config.pm` file, which defines `$CPAN::Config` as an anonymous hash.

  If the file does not exist, `cpan` dies.

- -J

  Dump the configuration in the same format that CPAN.pm uses. This is useful for checking the configuration as well as using the dump as a starting point for a new, custom configuration.

- -l

  List all installed modules with their versions

- -L author [author ...]

  List the modules by the specified authors.

- -m

  Make the specified modules.

- -M mirror1,mirror2,...

  A comma-separated list of mirrors to use for just this run. The `-P` option can find them for you automatically.

- -n

  Do a dry run, but don't actually install anything. (unimplemented)

- -O

  Show the out-of-date modules.

- -p

  Ping the configured mirrors and print a report

- -P

  Find the best mirrors you could be using and use them for the current session.

- -r

  Recompiles dynamically loaded modules with CPAN::Shell->recompile.

- -s

  Drop in the CPAN.pm shell. This command does this automatically if you don't specify any arguments.

- -t module [module ...]

  Run a `make test` on the specified modules.

- -T

  Do not test modules. Simply install them.

- -u

  Upgrade all installed modules. Blindly doing this can really break things, so keep a backup.

- -v

  Print the script version and CPAN.pm version then exit.

- -V

  Print detailed information about the cpan client.

- -w

  UNIMPLEMENTED

  Turn on cpan warnings. This checks various things, like directory permissions, and tells you about problems you might have.

- -x module [module ...]

  Find close matches to the named modules that you think you might have mistyped. This requires the optional installation of Text::Levenshtein or Text::Levenshtein::Damerau.

- -X

  Dump all the namespaces to standard output.

Examples

```
# print a help message
cpan -h

# print the version numbers
cpan -v

# create an autobundle
cpan -a

# recompile modules
cpan -r

# upgrade all installed modules
cpan -u

# install modules ( sole -i is optional )
cpan -i Netscape::Booksmarks Business::ISBN

# force install modules ( must use -i )
cpan -fi CGI::Minimal URI

# install modules but without testing them
cpan -Ti CGI::Minimal URI
```

Environment variables

There are several components in CPAN.pm that use environment variables. The build tools, *ExtUtils::MakeMaker* and Module::Build use some, while others matter to the levels above them. Some of these are specified by the Perl Toolchain Gang:

Lancaster Consensus: https://github.com/Perl-Toolchain-Gang/toolchain-site/blob/master/lancaster-consensus.md

Oslo Consensus: https://github.com/Perl-Toolchain-Gang/toolchain-site/blob/master/oslo-consensus.md

- NONINTERACTIVE_TESTING

  Assume no one is paying attention and skips prompts for distributions that do that correctly. `cpan(1)` sets this to 1 unless it already has a value (even if that value is false).

- PERL_MM_USE_DEFAULT

  Use the default answer for a prompted questions. `cpan(1)` sets this to 1 unless it already has a value (even if that value is false).

- CPAN_OPTS

  As with PERL5OPT, a string of additional `cpan(1)` options to add to those you specify on the command line.

- CPANSCRIPT_LOGLEVEL

The log level to use, with either the embedded, minimal logger or Log::Log4perl if it is installed. Possible values are the same as the `Log::Log4perl` levels: `TRACE`, `DEBUG`, `INFO`, `WARN`, `ERROR`, and `FATAL`. The default is `INFO`.

- GIT_COMMAND

  The path to the `git` binary to use for the Git features. The default is `/usr/local/bin/git`.

Methods

- run(ARGS)

  Just do it.

  The `run` method returns 0 on success and a positive number on failure. See the section on EXIT CODES for details on the values.

  CPAN.pm sends all the good stuff either to STDOUT, or to a temp file if $CPAN::Be_Silent is set. I have to intercept that output so I can find out what happened.

  Stolen from File::Path::Expand

EXIT VALUES

The script exits with zero if it thinks that everything worked, or a positive number if it thinks that something failed. Note, however, that in some cases it has to divine a failure by the output of things it does not control. For now, the exit codes are vague:

```
1       An unknown error

2       The was an external problem

4       There was an internal problem with the script

8       A module failed to install
```

TO DO

* There is initial support for Log4perl if it is available, but I haven't gone through everything to make the NullLogger work out correctly if Log4perl is not installed.

* When I capture CPAN.pm output, I need to check for errors and report them to the user.

* Warnings switch

* Check then exit

BUGS

* none noted

App::Prove

Implements the `prove` command.

VERSION

Version 3.52

DESCRIPTION

Test::Harness provides a command, `prove`, which runs a TAP based test suite and prints a report. The `prove` command is a minimal wrapper around an instance of this module.

SYNOPSIS

```
use App::Prove;

my $app = App::Prove->new;
$app->process_args(@ARGV);
$app->run;
```

METHODS

Class Methods

new

Create a new `App::Prove`. Optionally a hash ref of attribute initializers may be passed.

state_class

Getter/setter for the name of the class used for maintaining state. This class should either subclass from `App::Prove::State` or provide an identical interface.

state_manager

Getter/setter for the instance of the `state_class`.

add_rc_file

```
$prove->add_rc_file('myproj/.proverc');
```

Called before `process_args` to prepend the contents of an rc file to the options.

process_args

```
$prove->process_args(@args);
```

Processes the command-line arguments. Attributes will be set appropriately. Any filenames may be found in the `argv` attribute.

Dies on invalid arguments.

run

Perform whatever actions the command line args specified. The `prove` command line tool consists of the following code:

```
use App::Prove;

my $app = App::Prove->new;
$app->process_args(@ARGV);
exit( $app->run ? 0 : 1 );  # if you need the exit code
```

require_harness

Load a harness replacement class.

```
$prove->require_harness($for => $class_name);
```

print_version

Display the version numbers of the loaded *TAP::Harness* and the current Perl.

Attributes

After command line parsing the following attributes reflect the values of the corresponding command line switches. They may be altered before calling `run`.

- `archive`
- `argv`
- `backwards`
- `blib`
- `color`
- `directives`
- `dry`
- `exec`
- `extensions`
- `failures`
- `comments`
- `formatter`
- `harness`
- `ignore_exit`
- `includes`
- `jobs`
- `lib`

- merge
- modules
- parse
- plugins
- quiet
- really_quiet
- recurse
- rules
- show_count
- show_help
- show_man
- show_version
- shuffle
- state
- state_class
- taint_fail
- taint_warn
- test_args
- timer
- verbose
- warnings_fail
- warnings_warn
- tapversion
- trap

PLUGINS

App::Prove provides support for 3rd-party plugins. These are currently loaded at run-time, *after* arguments have been parsed (so you can not change the way arguments are processed, sorry), typically with the -P_plugin_ switch, eg:

```
prove -PMyPlugin
```

This will search for a module named App::Prove::Plugin::MyPlugin, or failing that, MyPlugin. If the plugin can't be found, prove will complain & exit.

You can pass an argument to your plugin by appending an = after the plugin name, eg -PMyPlugin=foo. You can pass multiple arguments using commas:

```
prove -PMyPlugin=foo,bar,baz
```

These are passed in to your plugin's `load()` class method (if it has one), along with a reference to the `App::Prove` object that is invoking your plugin:

```
sub load {
    my ($class, $p) = @_;

    my @args = @{ $p->{args} };
    # @args will contain ( 'foo', 'bar', 'baz' )
    $p->{app_prove}->do_something;
    ...
}
```

Sample Plugin

Here's a sample plugin, for your reference:

```
package App::Prove::Plugin::Foo;

# Sample plugin, try running with:
# prove -PFoo=bar -r -j3
# prove -PFoo -Q
# prove -PFoo=bar,My::Formatter

use strict;
use warnings;

sub load {
    my ($class, $p) = @_;
    my @args = @{ $p->{args} };
    my $app  = $p->{app_prove};

    print "loading plugin: $class, args: ", join(', ', @args ), "\n
 ↪";

    # turn on verbosity
    $app->verbose( 1 );

    # set the formatter?
    $app->formatter( $args[1] ) if @args > 1;

    # print some of App::Prove's state:
    for my $attr (qw( jobs quiet really_quiet recurse verbose )) {
        my $val = $app->$attr;
        $val    = 'undef' unless defined( $val );
        print "$attr: $val\n";
    }

    return 1;
```

(continues on next page)

(continued from previous page)

```
}

1;
```

SEE ALSO

prove, *TAP::Harness*

Modules

- `App::Prove::State` - State storage for the `prove` command.

App::Prove::State

State storage for the `prove` command.

VERSION

Version 3.52

DESCRIPTION

The `prove` command supports a `--state` option that instructs it to store persistent state across runs. This module implements that state and the operations that may be performed on it.

SYNOPSIS

```
# Re-run failed tests
$ prove --state=failed,save -rbv
```

METHODS

Class Methods

new

Accepts a hashref with the following key/value pairs:

- `store`

  The filename of the data store holding the data that App::Prove::State reads.

- `extensions` (optional)

  The test name extensions. Defaults to `.t`.

- `result_class` (optional)

  The name of the `result_class`. Defaults to `App::Prove::State::Result`.

result_class

Getter/setter for the name of the class used for tracking test results. This class should either subclass from `App::Prove::State::Result` or provide an identical interface.

extensions

Get or set the list of extensions that files must have in order to be considered tests. Defaults to ['.t'].

results

Get the results of the last test run. Returns a `result_class()` instance.

commit

Save the test results. Should be called after all tests have run.

Instance Methods

apply_switch

```
$self->apply_switch('failed,save');
```

Apply a list of switch options to the state, updating the internal object state as a result. Nothing is returned.

Diagnostics: - "Illegal state option: %s"

- `last`

  Run in the same order as last time

- `failed`

  Run only the failed tests from last time

- `passed`

  Run only the passed tests from last time

- `all`

  Run all tests in normal order

- `hot`

  Run the tests that most recently failed first

- `todo`

  Run the tests ordered by number of todos.

- `slow`

  Run the tests in slowest to fastest order.

- `fast`

  Run test tests in fastest to slowest order.

- `new`

  Run the tests in newest to oldest order.

- `old`

  Run the tests in oldest to newest order.

- `save`

  Save the state on exit.

`get_tests`

Given a list of args get the names of tests that should run

`observe_test`

Store the results of a test.

`save`

Write the state to a file.

`load`

Load the state from a file

Modules

- `App::Prove::State::Result` - Individual test suite results.

App::Prove::State::Result

Individual test suite results.

VERSION

Version 3.52

DESCRIPTION

The `prove` command supports a `--state` option that instructs it to store persistent state across runs. This module encapsulates the results for a single test suite run.

SYNOPSIS

```
# Re-run failed tests
$ prove --state=failed,save -rbv
```

METHODS

Class Methods

new

```
my $result = App::Prove::State::Result->new({
    generation => $generation,
    tests      => \%tests,
});
```

Returns a new `App::Prove::State::Result` instance.

state_version

Returns the current version of state storage.

test_class

Returns the name of the class used for tracking individual tests. This class should either subclass from `App::Prove::State::Result::Test` or provide an identical interface.

generation

Getter/setter for the "generation" of the test suite run. The first generation is 1 (one) and subsequent generations are 2, 3, etc.

last_run_time

Getter/setter for the time of the test suite run.

tests

Returns the tests for a given generation. This is a hashref or a hash, depending on context called. The keys to the hash are the individual test names and the value is a hashref with various interesting values. Each k/v pair might resemble something like this:

```
't/foo.t' => {
   elapsed        => '0.0428488254547119',
   gen            => '7',
   last_pass_time => '1219328376.07815',
   last_result    => '0',
   last_run_time  => '1219328376.07815',
   last_todo      => '0',
```

(continues on next page)

(continued from previous page)

```
    mtime           => '1191708862',
    seq             => '192',
    total_passes    => '6',
 }
```

test

```
my $test = $result->test('t/customer/create.t');
```

Returns an individual `App::Prove::State::Result::Test` instance for the given test name (usually the filename). Will return a new `App::Prove::State::Result::Test` instance if the name is not found.

test_names

Returns an list of test names, sorted by run order.

remove

```
$result->remove($test_name);            # remove the test
my $test = $result->test($test_name);   # fatal error
```

Removes a given test from results. This is a no-op if the test name is not found.

num_tests

Returns the number of tests for a given test suite result.

raw

Returns a hashref of raw results, suitable for serialization by YAML.

Modules

- `App::Prove::State::Result::Test` - Individual test results.

App::Prove::State::Result::Test

Individual test results.

VERSION

Version 3.52

DESCRIPTION

The `prove` command supports a `--state` option that instructs it to store persistent state across runs. This module encapsulates the results for a single test.

SYNOPSIS

```
# Re-run failed tests
$ prove --state=failed,save -rbv
```

METHODS

Class Methods

new

Instance Methods

name

The name of the test. Usually a filename.

elapsed

The total elapsed times the test took to run, in seconds from the epoch..

generation

The number for the “generation” of the test run. The first generation is 1 (one) and subsequent generations are 2, 3, etc.

last_pass_time

The last time the test program passed, in seconds from the epoch.

Returns `undef` if the program has never passed.

last_fail_time

The last time the test suite failed, in seconds from the epoch.

Returns `undef` if the program has never failed.

mtime

Returns the mtime of the test, in seconds from the epoch.

raw

Returns a hashref of raw test data, suitable for serialization by YAML.

result

Currently, whether or not the test suite passed with no 'problems' (such as TODO passed).

run_time

The total time it took for the test to run, in seconds. If `Time::HiRes` is available, it will have finer granularity.

num_todo

The number of tests with TODO directives.

sequence

The order in which this test was run for the given test suite result.

total_passes

The number of times the test has passed.

total_failures

The number of times the test has failed.

parser

The underlying parser object. This is useful if you need the full information for the test program.

5.2.5 Archive

Namespace containing the following modules:

- `Archive::Tar` - module for manipulations of tar archives

Archive::Tar

module for manipulations of tar archives

SYNOPSIS

```
use Archive::Tar;
my $tar = Archive::Tar->new;
```

(continues on next page)

(continued from previous page)

```
$tar->read('origin.tgz');
$tar->extract();

$tar->add_files('file/foo.pl', 'docs/README');
$tar->add_data('file/baz.txt', 'This is the contents now');

$tar->rename('oldname', 'new/file/name');
$tar->chown('/', 'root');
$tar->chown('/', 'root:root');
$tar->chmod('/tmp', '1777');

$tar->write('files.tar');                   # plain tar
$tar->write('files.tgz', COMPRESS_GZIP);    # gzip compressed
$tar->write('files.tbz', COMPRESS_BZIP);    # bzip2 compressed
$tar->write('files.txz', COMPRESS_XZ);      # xz compressed
```

DESCRIPTION

Archive::Tar provides an object oriented mechanism for handling tar files. It provides class methods for quick and easy files handling while also allowing for the creation of tar file objects for custom manipulation. If you have the IO::Zlib module installed, Archive::Tar will also support compressed or gzipped tar files.

An object of class Archive::Tar represents a .tar(.gz) archive full of files and things.

Object Methods

Archive::Tar->new([$file, $compressed])

Returns a new Tar object. If given any arguments, `new()` calls the `read()` method automatically, passing on the arguments provided to the `read()` method.

If `new()` is invoked with arguments and the `read()` method fails for any reason, `new()` returns undef.

$tar->read ($filename|$handle, [$compressed, {opt => 'val'}])

Read the given tar file into memory. The first argument can either be the name of a file or a reference to an already open filehandle (or an IO::Zlib object if it's compressed)

The `read` will *replace* any previous content in `$tar`!

The second argument may be considered optional, but remains for backwards compatibility. Archive::Tar now looks at the file magic to determine what class should be used to open the file and will transparently Do The Right Thing.

Archive::Tar will warn if you try to pass a bzip2 / xz compressed file and the IO::Uncompress::Bunzip2 / IO::Uncompress::UnXz are not available and simply return.

Note that you can currently **not** pass a `gzip` compressed filehandle, which is not opened with `IO::Zlib`, a `bzip2` compressed filehandle, which is not opened with `IO::Uncompress::Bunzip2`, a `xz` compressed filehandle, which is not opened with `IO::Uncom-`

`press::UnXz`, nor a string containing the full archive information (either compressed or uncompressed). These are worth while features, but not currently implemented. See the `TODO` section.

The third argument can be a hash reference with options. Note that all options are case-sensitive.

- limit

  Do not read more than `limit` files. This is useful if you have very big archives, and are only interested in the first few files.

- filter

  Can be set to a regular expression. Only files with names that match the expression will be read.

- md5

  Set to 1 and the md5sum of files will be returned (instead of file data) my $iter = Archive::Tar->iter($file, 1, {md5 => 1}); while(my $f = $iter->()) { print $f->data . "\t" . $f->full_path . $/; }

- extract

  If set to true, immediately extract entries when reading them. This gives you the same memory break as the `extract_archive` function. Note however that entries will not be read into memory, but written straight to disk. This means no `Archive::Tar::File` objects are created for you to inspect.

All files are stored internally as `Archive::Tar::File` objects. Please consult the *Archive::Tar::File* documentation for details.

Returns the number of files read in scalar context, and a list of `Archive::Tar::File` objects in list context.

$tar->contains_file($filename)

Check if the archive contains a certain file. It will return true if the file is in the archive, false otherwise.

Note however, that this function does an exact match using `eq` on the full path. So it cannot compensate for case-insensitive file- systems or compare 2 paths to see if they would point to the same underlying file.

$tar->extract([@filenames])

Write files whose names are equivalent to any of the names in `@filenames` to disk, creating subdirectories as necessary. This might not work too well under VMS. Under MacPerl, the file's modification time will be converted to the MacOS zero of time, and appropriate conversions will be done to the path. However, the length of each element of the path is not inspected to see whether it's longer than MacOS currently allows (32 characters).

If `extract` is called without a list of file names, the entire contents of the archive are extracted.

Returns a list of filenames extracted.

$tar->extract_file($file, [$extract_path])

Write an entry, whose name is equivalent to the file name provided to disk. Optionally takes a second parameter, which is the full native path (including filename) the entry will be written to.

For example:

```
$tar->extract_file( 'name/in/archive', 'name/i/want/to/give/it' );

$tar->extract_file( $at_file_object,   'name/i/want/to/give/it' );
```

Returns true on success, false on failure.

$tar->list_files([\@properties])

Returns a list of the names of all the files in the archive.

If `list_files()` is passed an array reference as its first argument it returns a list of hash references containing the requested properties of each file. The following list of properties is supported: name, size, mtime (last modified date), mode, uid, gid, linkname, uname, gname, devmajor, devminor, prefix.

Passing an array reference containing only one element, 'name', is special cased to return a list of names rather than a list of hash references, making it equivalent to calling `list_files` without arguments.

$tar->get_files([@filenames])

Returns the `Archive::Tar::File` objects matching the filenames provided. If no filename list was passed, all `Archive::Tar::File` objects in the current Tar object are returned.

Please refer to the `Archive::Tar::File` documentation on how to handle these objects.

$tar->get_content($file)

Return the content of the named file.

$tar->replace_content($file, $content)

Make the string $content be the content for the file named $file.

$tar->rename($file, $new_name)

Rename the file of the in-memory archive to $new_name.

Note that you must specify a Unix path for $new_name, since per tar standard, all files in the archive must be Unix paths.

Returns true on success and false on failure.

$tar->chmod($file, $mode)

Change mode of $file to $mode.

Returns true on success and false on failure.

$tar->chown($file, $uname [, $gname])

Change owner $file to $uname and $gname.

Returns true on success and false on failure.

$tar->remove (@filenamelist)

Removes any entries with names matching any of the given filenames from the in-memory archive. Returns a list of `Archive::Tar::File` objects that remain.

$tar->clear

`clear` clears the current in-memory archive. This effectively gives you a 'blank' object, ready to be filled again. Note that `clear` only has effect on the object, not the underlying tarfile.

$tar->write ([$file, $compressed, $prefix])

Write the in-memory archive to disk. The first argument can either be the name of a file or a reference to an already open filehandle (a GLOB reference).

The second argument is used to indicate compression. You can compress using `gzip`, `bzip2` or `xz`. If you pass a digit, it's assumed to be the `gzip` compression level (between 1 and 9), but the use of constants is preferred:

```
# write a gzip compressed file
$tar->write( 'out.tgz', COMPRESS_GZIP );

# write a bzip compressed file
$tar->write( 'out.tbz', COMPRESS_BZIP );

# write a xz compressed file
$tar->write( 'out.txz', COMPRESS_XZ );
```

Note that when you pass in a filehandle, the compression argument is ignored, as all files are printed verbatim to your filehandle. If you wish to enable compression with filehandles, use an `IO::Zlib`, `IO::Compress::Bzip2` or `IO::Compress::Xz` filehandle instead.

The third argument is an optional prefix. All files will be tucked away in the directory you specify as prefix. So if you have files 'a' and 'b' in your archive, and you specify 'foo' as prefix, they will be written to the archive as 'foo/a' and 'foo/b'.

If no arguments are given, `write` returns the entire formatted archive as a string, which could be useful if you'd like to stuff the archive into a socket or a pipe to gzip or something.

$tar->add_files(@filenamelist)

Takes a list of filenames and adds them to the in-memory archive.

The path to the file is automatically converted to a Unix like equivalent for use in the archive, and, if on MacOS, the file's modification time is converted from the MacOS epoch to the Unix epoch. So tar archives created on MacOS with **Archive::Tar** can be read both with *tar* on Unix and applications like *suntar* or *Stuffit Expander* on MacOS.

Be aware that the file's type/creator and resource fork will be lost, which is usually what you want in cross-platform archives.

Instead of a filename, you can also pass it an existing `Archive::Tar::File` object from, for example, another archive. The object will be clone, and effectively be a copy of the original, not an alias.

Returns a list of `Archive::Tar::File` objects that were just added.

$tar->add_data ($filename, $data, [$opthashref])

Takes a filename, a scalar full of data and optionally a reference to a hash with specific options.

Will add a file to the in-memory archive, with name `$filename` and content `$data`. Specific properties can be set using `$opthashref`. The following list of properties is supported: name, size, mtime (last modified date), mode, uid, gid, linkname, uname, gname, devmajor, devminor, prefix, type. (On MacOS, the file's path and modification times are converted to Unix equivalents.)

Valid values for the file type are the following constants defined by Archive::Tar::Constant:

- FILE

  Regular file.

- HARDLINK

- SYMLINK

  Hard and symbolic ("soft") links; linkname should specify target.

- CHARDEV

- BLOCKDEV

  Character and block devices. devmajor and devminor should specify the major and minor device numbers.

- DIR

  Directory.

- FIFO

  FIFO (named pipe).

- SOCKET

  Socket.

Returns the `Archive::Tar::File` object that was just added, or `undef` on failure.

$tar->error([$BOOL])

Returns the current error string (usually, the last error reported). If a true value was specified, it will give the `Carp::longmess` equivalent of the error, in effect giving you a stacktrace.

For backwards compatibility, this error is also available as `$Archive::Tar::error` although it is much recommended you use the method call instead.

$tar->setcwd($cwd);

`Archive::Tar` needs to know the current directory, and it will run `Cwd::cwd()` *every* time it extracts a *relative* entry from the tarfile and saves it in the file system. (As of version 1.30, however, `Archive::Tar` will use the speed optimization described below automatically, so it's only relevant if you're using `extract_file()`).

Since `Archive::Tar` doesn't change the current directory internally while it is extracting the items in a tarball, all calls to `Cwd::cwd()` can be avoided if we can guarantee that the current directory doesn't get changed externally.

To use this performance boost, set the current directory via

```
use Cwd;
$tar->setcwd( cwd() );
```

once before calling a function like `extract_file` and `Archive::Tar` will use the current directory setting from then on and won't call `Cwd::cwd()` internally.

To switch back to the default behaviour, use

```
$tar->setcwd( undef );
```

and `Archive::Tar` will call `Cwd::cwd()` internally again.

If you're using `Archive::Tar`'s `extract()` method, `setcwd()` will be called for you.

Class Methods

Archive::Tar->create_archive($file, $compressed, @filelist)

Creates a tar file from the list of files provided. The first argument can either be the name of the tar file to create or a reference to an open file handle (e.g. a GLOB reference).

The second argument is used to indicate compression. You can compress using `gzip`, `bzip2` or `xz`. If you pass a digit, it's assumed to be the `gzip` compression level (between 1 and 9), but the use of constants is preferred:

```
# write a gzip compressed file
Archive::Tar->create_archive( 'out.tgz', COMPRESS_GZIP, @filelist );

# write a bzip compressed file
Archive::Tar->create_archive( 'out.tbz', COMPRESS_BZIP, @filelist );

# write a xz compressed file
Archive::Tar->create_archive( 'out.txz', COMPRESS_XZ, @filelist );
```

Note that when you pass in a filehandle, the compression argument is ignored, as all files are printed verbatim to your filehandle. If you wish to enable compression with filehandles, use an `IO::Zlib`, `IO::Compress::Bzip2` or `IO::Compress::Xz` filehandle instead.

The remaining arguments list the files to be included in the tar file. These files must all exist. Any files which don't exist or can't be read are silently ignored.

If the archive creation fails for any reason, `create_archive` will return false. Please use the `error` method to find the cause of the failure.

Note that this method does not write on `the fly` as it were; it still reads all the files into memory before writing out the archive. Consult the FAQ below if this is a problem.

Archive::Tar->iter($filename, [$compressed, {opt => $val}])

Returns an iterator function that reads the tar file without loading it all in memory. Each time the function is called it will return the next file in the tarball. The files are returned as `Archive::Tar::File` objects. The iterator function returns the empty list once it has exhausted the files contained.

The second argument can be a hash reference with options, which are identical to the arguments passed to `read()`.

Example usage:

```
my $next = Archive::Tar->iter( "example.tar.gz", 1, {filter => qr/\.
 ↪pm$/} );

while( my $f = $next->() ) {
    print $f->name, "\n";

    $f->extract or warn "Extraction failed";

    # ....
}
```

Archive::Tar->list_archive($file, $compressed, [\@properties])

Returns a list of the names of all the files in the archive. The first argument can either be the name of the tar file to list or a reference to an open file handle (e.g. a GLOB reference).

If `list_archive()` is passed an array reference as its third argument it returns a list of hash references containing the requested properties of each file. The following list of properties is supported: full_path, name, size, mtime (last modified date), mode, uid, gid, linkname, uname, gname, devmajor, devminor, prefix, type.

See `Archive::Tar::File` for details about supported properties.

Passing an array reference containing only one element, 'name', is special cased to return a list of names rather than a list of hash references.

Archive::Tar->extract_archive($file, $compressed)

Extracts the contents of the tar file. The first argument can either be the name of the tar file to create or a reference to an open file handle (e.g. a GLOB reference). All relative paths in the tar file will be created underneath the current working directory.

`extract_archive` will return a list of files it extracted. If the archive extraction fails for any reason, `extract_archive` will return false. Please use the `error` method to find the cause of the failure.

$bool = Archive::Tar->has_io_string

Returns true if we currently have `IO::String` support loaded.

Either `IO::String` or `perlio` support is needed to support writing stringified archives. Currently, `perlio` is the preferred method, if available.

See the `GLOBAL VARIABLES` section to see how to change this preference.

$bool = Archive::Tar->has_perlio

Returns true if we currently have `perlio` support loaded.

This requires `perl-5.8` or higher, compiled with `perlio`

Either `IO::String` or `perlio` support is needed to support writing stringified archives. Currently, `perlio` is the preferred method, if available.

See the `GLOBAL VARIABLES` section to see how to change this preference.

$bool = Archive::Tar->has_zlib_support

Returns true if `Archive::Tar` can extract `zlib` compressed archives

$bool = Archive::Tar->has_bzip2_support

Returns true if `Archive::Tar` can extract `bzip2` compressed archives

$bool = Archive::Tar->has_xz_support

Returns true if `Archive::Tar` can extract `xz` compressed archives

Archive::Tar->can_handle_compressed_files

A simple checking routine, which will return true if `Archive::Tar` is able to uncompress compressed archives on the fly with `IO::Zlib`, `IO::Compress::Bzip2` and `IO::Compress::Xz` or false if not both are installed.

You can use this as a shortcut to determine whether `Archive::Tar` will do what you think before passing compressed archives to its `read` method.

GLOBAL VARIABLES

$Archive::Tar::FOLLOW_SYMLINK

Set this variable to `1` to make `Archive::Tar` effectively make a copy of the file when extracting. Default is `0`, which means the symlink stays intact. Of course, you will have to pack the file linked to as well.

This option is checked when you write out the tarfile using `write` or `create_archive`.

This works just like `/bin/tar`'s `-h` option.

$Archive::Tar::CHOWN

By default, `Archive::Tar` will try to `chown` your files if it is able to. In some cases, this may not be desired. In that case, set this variable to `0` to disable `chown`-ing, even if it were possible.

The default is 1.

$Archive::Tar::CHMOD

By default, `Archive::Tar` will try to `chmod` your files to whatever mode was specified for the particular file in the archive. In some cases, this may not be desired. In that case, set this variable to `0` to disable `chmod`-ing.

The default is 1.

$Archive::Tar::SAME_PERMISSIONS

When, `$Archive::Tar::CHMOD` is enabled, this setting controls whether the permissions on files from the archive are used without modification of if they are filtered by removing any setid bits and applying the current umask.

The default is 1 for the root user and `0` for normal users.

$Archive::Tar::DO_NOT_USE_PREFIX

By default, `Archive::Tar` will try to put paths that are over 100 characters in the `prefix` field of your tar header, as defined per POSIX-standard. However, some (older) tar programs do not implement this spec. To retain compatibility with these older or non-POSIX compliant versions, you can set the `$DO_NOT_USE_PREFIX` variable to a true value, and `Archive::Tar` will use an alternate way of dealing with paths over 100 characters by using the `GNU Extended Header` feature.

Note that clients who do not support the `GNU Extended Header` feature will not be able to read these archives. Such clients include tars on `Solaris`, `Irix` and `AIX`.

The default is `0`.

$Archive::Tar::DEBUG

Set this variable to 1 to always get the `Carp::longmess` output of the warnings, instead of the regular `carp`. This is the same message you would get by doing:

```
$tar->error(1);
```

Defaults to `0`.

$Archive::Tar::WARN

Set this variable to `0` if you do not want any warnings printed. Personally I recommend against doing this, but people asked for the option. Also, be advised that this is of course not threadsafe.

Defaults to 1.

$Archive::Tar::error

Holds the last reported error. Kept for historical reasons, but its use is very much discouraged. Use the `error()` method instead:

```
warn $tar->error unless $tar->extract;
```

Note that in older versions of this module, the `error()` method would return an effectively global value even when called an instance method as above. This has since been fixed, and multiple instances of `Archive::Tar` now have separate error strings.

$Archive::Tar::INSECURE_EXTRACT_MODE

This variable indicates whether `Archive::Tar` should allow files to be extracted outside their current working directory.

Allowing this could have security implications, as a malicious tar archive could alter or replace any file the extracting user has permissions to. Therefor, the default is to not allow insecure extractions.

If you trust the archive, or have other reasons to allow the archive to write files outside your current working directory, set this variable to `true`.

Note that this is a backwards incompatible change from version `1.36` and before.

$Archive::Tar::EXTRACT_HARDLINK

Prior to version `3.06` Archive::Tar would honour hardlinks in archives. Version `3.06` and onwards will skip hardlinks unless this flag is set. Exercise caution when enabling this.

$Archive::Tar::HAS_PERLIO

This variable holds a boolean indicating if we currently have `perlio` support loaded. This will be enabled for any perl greater than `5.8` compiled with `perlio`.

If you feel strongly about disabling it, set this variable to `false`. Note that you will then need `IO::String` installed to support writing stringified archives.

Don't change this variable unless you **really** know what you're doing.

$Archive::Tar::HAS_IO_STRING

This variable holds a boolean indicating if we currently have `IO::String` support loaded. This will be enabled for any perl that has a loadable `IO::String` module.

If you feel strongly about disabling it, set this variable to `false`. Note that you will then need `perlio` support from your perl to be able to write stringified archives.

Don't change this variable unless you **really** know what you're doing.

$Archive::Tar::ZERO_PAD_NUMBERS

This variable holds a boolean indicating if we will create zero padded numbers for `size`, `mtime` and `checksum`. The default is `0`, indicating that we will create space padded numbers. Added for compatibility with `busybox` implementations.

Tuning the way RESOLVE_SYMLINK will works

You can tune the behaviour by setting the $Archive::Tar::RESOLVE_SYMLINK variable, or $ENV{PERL5_AT_RESOLVE_SYMLINK} before loading the module Archive::Tar.

Values can be one of the following:

- none

  Disable this mechanism and failed as it was in previous version (<1.88)

- speed (default)

  If you prefer speed this will read again the whole archive using read() so all entries will be available

- memory

  If you prefer memory

Limitation: It won't work for terminal, pipe or sockets or every non seekable source.

$Archive::Tar::EXTRACT_BLOCK_SIZE

This variable holds an integer with the block size that should be used when writing files during extraction. It defaults to 1 GiB. Please note that this cannot be arbitrarily large since some operating systems limit the number of bytes that can be written in one call to `write(2)`, so if this is too large, extraction may fail with an error.

$Archive::Tar::MAX_FILE_SIZE

This variable holds an upper bound on the per-entry declared size that `Archive::Tar` will accept when reading an archive. Entries whose header claims a larger size are refused with an error before any read allocation. Defaults to 1 GiB. Set to 0 to disable the cap.

FAQ

- What's the minimum perl version required to run Archive::Tar?

  You will need perl version 5.005_03 or newer.

- Isn't Archive::Tar slow?

  Yes it is. It's pure perl, so it's a lot slower then your `/bin/tar` However, it's very portable. If speed is an issue, consider using `/bin/tar` instead.

- Isn't Archive::Tar heavier on memory than /bin/tar?

  Yes it is, see previous answer. Since `Compress::Zlib` and therefore `IO::Zlib` doesn't support `seek` on their filehandles, there is little choice but to read the archive into memory. This is ok if you want to do in-memory manipulation of the archive.

  If you just want to extract, use the `extract_archive` class method instead. It will optimize and write to disk immediately.

  Another option is to use the `iter` class method to iterate over the files in the tarball without reading them all in memory at once.

- Can you lazy-load data instead?

  In some cases, yes. You can use the `iter` class method to iterate over the files in the tarball without reading them all in memory at once.

- How much memory will an X kb tar file need?

  Probably more than X kb, since it will all be read into memory. If this is a problem, and you don't need to do in memory manipulation of the archive, consider using the `iter` class method, or `/bin/tar` instead.

- What do you do with unsupported filetypes in an archive?

  `Unix` has a few filetypes that aren't supported on other platforms, like `Win32`. If we encounter a `hardlink` or `symlink` we'll just try to make a copy of the original file, rather than throwing an error.

  This does require you to read the entire archive in to memory first, since otherwise we wouldn't know what data to fill the copy with. (This means that you cannot use the class methods, including `iter` on archives that have incompatible filetypes and still expect things to work).

  For other filetypes, like `chardevs` and `blockdevs` we'll warn that the extraction of this particular item didn't work.

- I'm using WinZip, or some other non-POSIX client, and files are not being extracted properly!

  By default, `Archive::Tar` is in a completely POSIX-compatible mode, which uses the POSIX-specification of `tar` to store files. For paths greater than 100 characters, this is done using the `POSIX header prefix`. Non-POSIX-compatible clients may not support this part of the specification, and may only support the `GNU Extended Header` functionality. To facilitate those clients, you can set the `$Archive::Tar::DO_NOT_USE_PREFIX` variable to `true`. See the `GLOBAL VARIABLES` section for details on this variable.

Note that GNU tar earlier than version 1.14 does not cope well with the POSIX header prefix. If you use such a version, consider setting the `$Archive::Tar::DO_NOT_USE_PREFIX` variable to `true`.

- How do I extract only files that have property X from an archive?

  Sometimes, you might not wish to extract a complete archive, just the files that are relevant to you, based on some criteria.

  You can do this by filtering a list of `Archive::Tar::File` objects based on your criteria. For example, to extract only files that have the string `foo` in their title, you would use:

```
$tar->extract(
    grep { $_->full_path =~ /foo/ } $tar->get_files
);
```

  This way, you can filter on any attribute of the files in the archive. Consult the `Archive::Tar::File` documentation on how to use these objects.

- How do I access .tar.Z files?

  The `Archive::Tar` module can optionally use `Compress::Zlib` (via the `IO::Zlib` module) to access tar files that have been compressed with `gzip`. Unfortunately tar files compressed with the Unix `compress` utility cannot be read by `Compress::Zlib` and so cannot be directly accesses by `Archive::Tar`.

  If the `uncompress` or `gunzip` programs are available, you can use one of these workarounds to read `.tar.Z` files from `Archive::Tar`

  Firstly with `uncompress`

```
use Archive::Tar;

open F, "uncompress -c $filename |";
my $tar = Archive::Tar->new(*F);
...
```

  and this with `gunzip`

```
use Archive::Tar;

open F, "gunzip -c $filename |";
my $tar = Archive::Tar->new(*F);
...
```

  Similarly, if the `compress` program is available, you can use this to write a `.tar.Z` file

```
use Archive::Tar;
use IO::File;

my $fh = IO::File->new( "| compress -c >$filename" );
my $tar = Archive::Tar->new();
...
```

(continues on next page)

(continued from previous page)

```
$tar->write($fh);
$fh->close ;
```

- How do I handle Unicode strings?

  `Archive::Tar` uses byte semantics for any files it reads from or writes to disk. This is not a problem if you only deal with files and never look at their content or work solely with byte strings. But if you use Unicode strings with character semantics, some additional steps need to be taken.

  For example, if you add a Unicode string like

```
# Problem
$tar->add_data('file.txt', "Euro: \x{20AC}");
```

  then there will be a problem later when the tarfile gets written out to disk via `$tar->write()`:

```
Wide character in print at .../Archive/Tar.pm line 1014.
```

  The data was added as a Unicode string and when writing it out to disk, the `:utf8` line discipline wasn't set by `Archive::Tar`, so Perl tried to convert the string to ISO-8859 and failed. The written file now contains garbage.

  For this reason, Unicode strings need to be converted to UTF-8-encoded bytestrings before they are handed off to `add_data()`:

```
use Encode;
my $data = "Accented character: \x{20AC}";
$data = encode('utf8', $data);

$tar->add_data('file.txt', $data);
```

  A opposite problem occurs if you extract a UTF8-encoded file from a tarball. Using `get_content()` on the `Archive::Tar::File` object will return its content as a bytestring, not as a Unicode string.

  If you want it to be a Unicode string (because you want character semantics with operations like regular expression matching), you need to decode the UTF8-encoded content and have Perl convert it into a Unicode string:

```
use Encode;
my $data = $tar->get_content();

# Make it a Unicode string
$data = decode('utf8', $data);
```

  There is no easy way to provide this functionality in `Archive::Tar`, because a tarball can contain many files, and each of which could be encoded in a different way.

CAVEATS

The AIX tar does not fill all unused space in the tar archive with 0x00. This sometimes leads to warning messages from `Archive::Tar`.

```
Invalid header block at offset nnn
```

A fix for that problem is scheduled to be released in the following levels of AIX, all of which should be coming out in the 4th quarter of 2009:

```
AIX 5.3 TL7 SP10
AIX 5.3 TL8 SP8
AIX 5.3 TL9 SP5
AIX 5.3 TL10 SP2

AIX 6.1 TL0 SP11
AIX 6.1 TL1 SP7
AIX 6.1 TL2 SP6
AIX 6.1 TL3 SP3
```

The IBM APAR number for this problem is IZ50240 (Reported component ID: 5765G0300 / AIX 5.3). It is possible to get an ifix for that problem. If you need an ifix please contact your local IBM AIX support.

TODO

- Check if passed in handles are open for read/write

  Currently I don't know of any portable pure perl way to do this. Suggestions welcome.

- Allow archives to be passed in as string

  Currently, we only allow opened filehandles or filenames, but not strings. The internals would need some reworking to facilitate stringified archives.

- Facilitate processing an opened filehandle of a compressed archive

  Currently, we only support this if the filehandle is an IO::Zlib object. Environments, like apache, will present you with an opened filehandle to an uploaded file, which might be a compressed archive.

Modules

- `Archive::Tar::File` - a subclass for in-memory extracted file from Archive::Tar

Archive::Tar::File

a subclass for in-memory extracted file from Archive::Tar

SYNOPSIS

```
my @items = $tar->get_files;

print $_->name, ' ', $_->size, "\n" for @items;

print $object->get_content;
$object->replace_content('new content');

$object->rename( 'new/full/path/to/file.c' );
```

DESCRIPTION

Archive::Tar::File provides a neat little object layer for in-memory extracted files. It's mostly used internally in Archive::Tar to tidy up the code, but there's no reason users shouldn't use this API as well.

Accessors

A lot of the methods in this package are accessors to the various fields in the tar header:

- name

  The file's name

- mode

  The file's mode

- uid

  The user id owning the file

- gid

  The group id owning the file

- size

  File size in bytes

- mtime

  Modification time. Adjusted to mac-time on MacOS if required

- chksum

  Checksum field for the tar header

- type

  File type – numeric, but comparable to exported constants – see Archive::Tar's documentation

- linkname

  If the file is a symlink, the file it's pointing to

- magic

  Tar magic string – not useful for most users

- version

  Tar version string – not useful for most users

- uname

  The user name that owns the file

- gname

  The group name that owns the file

- devmajor

  Device major number in case of a special file

- devminor

  Device minor number in case of a special file

- prefix

  Any directory to prefix to the extraction path, if any

- raw

  Raw tar header – not useful for most users

Methods

Archive::Tar::File->new(file => $path)

Returns a new Archive::Tar::File object from an existing file.

Returns undef on failure.

Archive::Tar::File->new(data => $path, $data, $opt)

Returns a new Archive::Tar::File object from data.

`$path` defines the file name (which need not exist), `$data` the file contents, and `$opt` is a reference to a hash of attributes which may be used to override the default attributes (fields in the tar header), which are described above in the Accessors section.

Returns undef on failure.

Archive::Tar::File->new(chunk => $chunk)

Returns a new Archive::Tar::File object from a raw 512-byte tar archive chunk.

Returns undef on failure.

$bool = $file->extract([$alternative_name])

Extract this object, optionally to an alternative name.

See `Archive::Tar->extract_file` for details.

Returns true on success and false on failure.

$path = $file->full_path

Returns the full path from the tar header; this is basically a concatenation of the `prefix` and `name` fields.

$bool = $file->validate

Done by Archive::Tar internally when reading the tar file: validate the header against the checksum to ensure integer tar file.

Returns true on success, false on failure

$bool = $file->has_content

Returns a boolean to indicate whether the current object has content. Some special files like directories and so on never will have any content. This method is mainly to make sure you don't get warnings for using uninitialized values when looking at an object's content.

$content = $file->get_content

Returns the current content for the in-memory file

$cref = $file->get_content_by_ref

Returns the current content for the in-memory file as a scalar reference. Normal users won't need this, but it will save memory if you are dealing with very large data files in your tar archive, since it will pass the contents by reference, rather than make a copy of it first.

$bool = $file->replace_content($content)

Replace the current content of the file with the new content. This only affects the in-memory archive, not the on-disk version until you write it.

Returns true on success, false on failure.

$bool = $file->rename($new_name)

Rename the current file to $new_name.

Note that you must specify a Unix path for $new_name, since per tar standard, all files in the archive must be Unix paths.

Returns true on success and false on failure.

$bool = $file->chmod($mode)

Change mode of $file to $mode. The mode can be a string or a number which is interpreted as octal whether or not a leading 0 is given.

Returns true on success and false on failure.

$bool = $file->chown($user [, $group])

Change owner of $file to $user. If a $group is given that is changed as well. You can also pass a single parameter with a colon separating the use and group as in 'root:wheel'.

Returns true on success and false on failure.

Convenience methods

To quickly check the type of a `Archive::Tar::File` object, you can use the following methods:

- $file->is_file

  Returns true if the file is of type `file`

- $file->is_dir

  Returns true if the file is of type `dir`

- $file->is_hardlink

  Returns true if the file is of type `hardlink`

- $file->is_symlink

  Returns true if the file is of type `symlink`

- $file->is_chardev

  Returns true if the file is of type `chardev`

- $file->is_blockdev

  Returns true if the file is of type `blockdev`

- $file->is_fifo

  Returns true if the file is of type `fifo`

- $file->is_socket

  Returns true if the file is of type `socket`

- $file->is_longlink

  Returns true if the file is of type `LongLink`. Should not happen after a successful `read`.

- $file->is_label

  Returns true if the file is of type `Label`. Should not happen after a successful `read`.

- $file->is_unknown

  Returns true if the file type is unknown

5.2.6 Attribute

Namespace containing the following modules:

- `Attribute::Handlers` - Simpler definition of attribute handlers

Attribute::Handlers

Simpler definition of attribute handlers

VERSION

This document describes version 1.03 of Attribute::Handlers.

SYNOPSIS

```
package MyClass;
require 5.006;
use Attribute::Handlers;
no warnings 'redefine';
```

(continues on next page)

(continued from previous page)

```
sub Good : ATTR(SCALAR) {
    my ($package, $symbol, $referent, $attr, $data) = @_;

    # Invoked for any scalar variable with a :Good attribute,
    # provided the variable was declared in MyClass (or
    # a derived class) or typed to MyClass.

    # Do whatever to $referent here (executed in CHECK phase).
    ...
}

sub Bad : ATTR(SCALAR) {
    # Invoked for any scalar variable with a :Bad attribute,
    # provided the variable was declared in MyClass (or
    # a derived class) or typed to MyClass.
    ...
}

sub Good : ATTR(ARRAY) {
    # Invoked for any array variable with a :Good attribute,
    # provided the variable was declared in MyClass (or
    # a derived class) or typed to MyClass.
    ...
}

sub Good : ATTR(HASH) {
    # Invoked for any hash variable with a :Good attribute,
    # provided the variable was declared in MyClass (or
    # a derived class) or typed to MyClass.
    ...
}

sub Ugly : ATTR(CODE) {
    # Invoked for any subroutine declared in MyClass (or a
    # derived class) with an :Ugly attribute.
    ...
}

sub Omni : ATTR {
    # Invoked for any scalar, array, hash, or subroutine
    # with an :Omni attribute, provided the variable or
    # subroutine was declared in MyClass (or a derived class)
    # or the variable was typed to MyClass.
    # Use ref($_[2]) to determine what kind of referent it was.
    ...
}

use Attribute::Handlers autotie => { Cycle => Tie::Cycle };
```

(continues on next page)

(continued from previous page)

```
my $next : Cycle(['A'..'Z']);
```

DESCRIPTION

This module, when inherited by a package, allows that package's class to define attribute handler subroutines for specific attributes. Variables and subroutines subsequently defined in that package, or in packages derived from that package may be given attributes with the same names as the attribute handler subroutines, which will then be called in one of the compilation phases (i.e. in a `BEGIN`, `CHECK`, `INIT`, or `END` block). (`UNITCHECK` blocks don't correspond to a global compilation phase, so they can't be specified here.)

To create a handler, define it as a subroutine with the same name as the desired attribute, and declare the subroutine itself with the
attribute `:ATTR`. For example:

```
package LoudDecl;
use Attribute::Handlers;

sub Loud :ATTR {
    my ($package, $symbol, $referent, $attr, $data, $phase,
        $filename, $linenum) = @_;
    print STDERR
        ref($referent), " ",
        *{$symbol}{NAME}, " ",
        "($referent) ", "was just declared ",
        "and ascribed the ${attr} attribute ",
        "with data ($data)\n",
        "in phase $phase\n",
        "in file $filename at line $linenum\n";
}
```

This creates a handler for the attribute `:Loud` in the class LoudDecl. Thereafter, any subroutine declared with a `:Loud` attribute in the class LoudDecl:

```
package LoudDecl;

sub foo: Loud {...}
```

causes the above handler to be invoked, and passed:

- [0]

  the name of the package into which it was declared;

- [1]

  a reference to the symbol table entry (typeglob) containing the subroutine;

- [2]

  a reference to the subroutine;

- [3]

the name of the attribute;

- [4]

  any data associated with that attribute;

- [5]

  the name of the phase in which the handler is being invoked;

- [6]

  the filename in which the handler is being invoked;

- [7]

  the line number in this file.

Likewise, declaring any variables with the `:Loud` attribute within the package:

```
package LoudDecl;

my $foo :Loud;
my @foo :Loud;
my %foo :Loud;
```

will cause the handler to be called with a similar argument list (except, of course, that `$_[2]` will be a reference to the variable).

The package name argument will typically be the name of the class into which the subroutine was declared, but it may also be the name of a derived class (since handlers are inherited).

If a lexical variable is given an attribute, there is no symbol table to which it belongs, so the symbol table argument (`$_[1]`) is set to the string `'LEXICAL'` in that case. Likewise, ascribing an attribute to an anonymous subroutine results in a symbol table argument of `'ANON'`.

The data argument passes in the value (if any) associated with the attribute. For example, if `&foo` had been declared:

```
sub foo :Loud("turn it up to 11, man!") {...}
```

then a reference to an array containing the string `"turn it up to 11, man!"` would be passed as the last argument.

Attribute::Handlers makes strenuous efforts to convert the data argument (`$_[4]`) to a usable form before passing it to the handler (but see "Non-interpretive attribute handlers"). If those efforts succeed, the interpreted data is passed in an array reference; if they fail, the raw data is passed as a string. For example, all of these:

```
sub foo :Loud(till=>ears=>are=>bleeding) {...}
sub foo :Loud(qw/till ears are bleeding/) {...}
sub foo :Loud(qw/till, ears, are, bleeding/) {...}
sub foo :Loud(till,ears,are,bleeding) {...}
```

causes it to pass `['till','ears','are','bleeding']` as the handler's data argument. While:

```
sub foo :Loud(['till','ears','are','bleeding']) {...}
```

causes it to pass `[ ['till','ears','are','bleeding'] ]`; the array reference specified in the data being passed inside the standard array reference indicating successful interpretation.

However, if the data can't be parsed as valid Perl, then it is passed as an uninterpreted string. For example:

```
sub foo :Loud(my,ears,are,bleeding) {...}
sub foo :Loud(qw/my ears are bleeding) {...}
```

cause the strings `'my,ears,are,bleeding'` and `'qw/my ears are bleeding'` respectively to be passed as the data argument.

If no value is associated with the attribute, `undef` is passed.

Typed lexicals

Regardless of the package in which it is declared, if a lexical variable is ascribed an attribute, the handler that is invoked is the one belonging to the package to which it is typed. For example, the following declarations:

```
package OtherClass;

my LoudDecl $loudobj : Loud;
my LoudDecl @loudobjs : Loud;
my LoudDecl %loudobjex : Loud;
```

causes the LoudDecl::Loud handler to be invoked (even if OtherClass also defines a handler for `:Loud` attributes).

Type-specific attribute handlers

If an attribute handler is declared and the `:ATTR` specifier is given the name of a built-in type (`SCALAR`, `ARRAY`, `HASH`, or `CODE`), the handler is only applied to declarations of that type. For example, the following definition:

```
package LoudDecl;

sub RealLoud :ATTR(SCALAR) { print "Yeeeeow!" }
```

creates an attribute handler that applies only to scalars:

```
package Painful;
use base LoudDecl;

my $metal : RealLoud;           # invokes &LoudDecl::RealLoud
my @metal : RealLoud;           # error: unknown attribute
my %metal : RealLoud;           # error: unknown attribute
sub metal : RealLoud {...}      # error: unknown attribute
```

You can, of course, declare separate handlers for these types as well (but you'll need to specify `no warnings 'redefine'` to do it quietly):

```
package LoudDecl;
use Attribute::Handlers;
no warnings 'redefine';

sub RealLoud :ATTR(SCALAR) { print "Yeeeeow!" }
sub RealLoud :ATTR(ARRAY) { print "Urrrrrrrrrr!" }
sub RealLoud :ATTR(HASH) { print "Arrrrrgggghhhhhh!" }
sub RealLoud :ATTR(CODE) { croak "Real loud sub torpedoed" }
```

You can also explicitly indicate that a single handler is meant to be used for all types of referents like so:

```
package LoudDecl;
use Attribute::Handlers;

sub SeriousLoud :ATTR(ANY) { warn "Hearing loss imminent" }
```

(I.e. `ATTR(ANY)` is a synonym for `:ATTR`).

Non-interpretive attribute handlers

Occasionally the strenuous efforts Attribute::Handlers makes to convert the data argument (`$_[4]`) to a usable form before passing it to the handler get in the way.

You can turn off that eagerness-to-help by declaring an attribute handler with the keyword `RAWDATA`. For example:

```
sub Raw          : ATTR(RAWDATA) {...}
sub Nekkid       : ATTR(SCALAR,RAWDATA) {...}
sub Au::Naturale : ATTR(RAWDATA,ANY) {...}
```

Then the handler makes absolutely no attempt to interpret the data it receives and simply passes it as a string:

```
my $power : Raw(1..100);        # handlers receives "1..100"
```

Phase-specific attribute handlers

By default, attribute handlers are called at the end of the compilation phase (in a `CHECK` block). This seems to be optimal in most cases because most things that can be defined are defined by that point but nothing has been executed.

However, it is possible to set up attribute handlers that are called at other points in the program's compilation or execution, by explicitly stating the phase (or phases) in which you wish the attribute handler to be called. For example:

```
sub Early    :ATTR(SCALAR,BEGIN) {...}
sub Normal   :ATTR(SCALAR,CHECK) {...}
sub Late     :ATTR(SCALAR,INIT) {...}
```

(continues on next page)

(continued from previous page)

```
sub Final    :ATTR(SCALAR,END) {...}
sub Bookends :ATTR(SCALAR,BEGIN,END) {...}
```

As the last example indicates, a handler may be set up to be (re)called in two or more phases. The phase name is passed as the handler's final argument.

Note that attribute handlers that are scheduled for the `BEGIN` phase are handled as soon as the attribute is detected (i.e. before any subsequently defined `BEGIN` blocks are executed).

Attributes as `tie` interfaces

Attributes make an excellent and intuitive interface through which to tie variables. For example:

```
use Attribute::Handlers;
use Tie::Cycle;

sub UNIVERSAL::Cycle : ATTR(SCALAR) {
    my ($package, $symbol, $referent, $attr, $data, $phase) = @_;
    $data = [ $data ] unless ref $data eq 'ARRAY';
    tie $$referent, 'Tie::Cycle', $data;
}

# and thereafter...

package main;

my $next : Cycle('A'..'Z');     # $next is now a tied variable

while (<>) {
    print $next;
}
```

Note that, because the `Cycle` attribute receives its arguments in the `$data` variable, if the attribute is given a list of arguments, `$data` will consist of a single array reference; otherwise, it will consist of the single argument directly. Since Tie::Cycle requires its cycling values to be passed as an array reference, this means that we need to wrap non-array-reference arguments in an array constructor:

```
$data = [ $data ] unless ref $data eq 'ARRAY';
```

Typically, however, things are the other way around: the tieable class expects its arguments as a flattened list, so the attribute looks like:

```
sub UNIVERSAL::Cycle : ATTR(SCALAR) {
    my ($package, $symbol, $referent, $attr, $data, $phase) = @_;
    my @data = ref $data eq 'ARRAY' ? @$data : $data;
    tie $$referent, 'Tie::Whatever', @data;
}
```

This software pattern is so widely applicable that Attribute::Handlers provides a way to automate it: specifying `'autotie'` in the `use Attribute::Handlers` statement. So, the cycling example, could also be written:

```
use Attribute::Handlers autotie => { Cycle => 'Tie::Cycle' };

# and thereafter...

package main;

my $next : Cycle(['A'..'Z']);     # $next is now a tied variable

while (<>) {
    print $next;
}
```

Note that we now have to pass the cycling values as an array reference, since the `autotie` mechanism passes `tie` a list of arguments as a list (as in the Tie::Whatever example), *not* as an array reference (as in the original Tie::Cycle example at the start of this section).

The argument after `'autotie'` is a reference to a hash in which each key is the name of an attribute to be created, and each value is the class to which variables ascribed that attribute should be tied.

Note that there is no longer any need to import the Tie::Cycle module – Attribute::Handlers takes care of that automagically. You can even pass arguments to the module's `import` subroutine, by appending them to the class name. For example:

```
use Attribute::Handlers
     autotie => { Dir => 'Tie::Dir qw(DIR_UNLINK)' };
```

If the attribute name is unqualified, the attribute is installed in the current package. Otherwise it is installed in the qualifier's package:

```
package Here;

use Attribute::Handlers autotie => {
     Other::Good => Tie::SecureHash, # tie attr installed in Other::
             Bad => Tie::Taxes,      # tie attr installed in Here::
 UNIVERSAL::Ugly => Software::Patent # tie attr installed everywhere
};
```

Autoties are most commonly used in the module to which they actually tie, and need to export their attributes to any module that calls them. To facilitate this, Attribute::Handlers recognizes a special "pseudo-class" – `__CALLER__`, which may be specified as the qualifier of an attribute:

```
package Tie::Me::Kangaroo::Down::Sport;

use Attribute::Handlers autotie =>
     { '__CALLER__::Roo' => __PACKAGE__ };
```

This causes Attribute::Handlers to define the Roo attribute in the package that imports the Tie::Me::Kangaroo::Down::Sport module.

Note that it is important to quote the __CALLER__::Roo identifier because a bug in perl 5.8 will refuse to parse it and cause an unknown error.

Passing the tied object to `tie`

Occasionally it is important to pass a reference to the object being tied to the TIESCALAR, TIEHASH, etc. that ties it.

The `autotie` mechanism supports this too. The following code:

```
use Attribute::Handlers autotieref => { Selfish => Tie::Selfish };
my $var : Selfish(@args);
```

has the same effect as:

```
tie my $var, 'Tie::Selfish', @args;
```

But when `"autotieref"` is used instead of `"autotie"`:

```
use Attribute::Handlers autotieref => { Selfish => Tie::Selfish };
my $var : Selfish(@args);
```

the effect is to pass the `tie` call an extra reference to the variable being tied:

```
tie my $var, 'Tie::Selfish', \$var, @args;
```

EXAMPLES

If the class shown in “SYNOPSIS” were placed in the MyClass.pm module, then the following code:

```
package main;
use MyClass;

my MyClass $slr :Good :Bad(1**1-1) :Omni(-vorous);

package SomeOtherClass;
use base MyClass;

sub tent { 'acle' }

sub fn :Ugly(sister) :Omni('po',tent()) {...}
my @arr :Good :Omni(s/cie/nt/);
my %hsh :Good(q/bye/) :Omni(q/bus/);
```

would cause the following handlers to be invoked:

```
# my MyClass $slr :Good :Bad(1**1-1) :Omni(-vorous);
```

(continues on next page)

(continued from previous page)

```
MyClass::Good:ATTR(SCALAR)( 'MyClass',          # class
                            'LEXICAL',          # no typeglob
                            \$slr,              # referent
                            'Good',             # attr name
                            undef               # no attr data
                            'CHECK',            # compiler phase
                          );

MyClass::Bad:ATTR(SCALAR)( 'MyClass',           # class
                           'LEXICAL',           # no typeglob
                           \$slr,               # referent
                           'Bad',               # attr name
                           0                    # eval'd attr data
                           'CHECK',             # compiler phase
                         );

MyClass::Omni:ATTR(SCALAR)( 'MyClass',          # class
                            'LEXICAL',          # no typeglob
                            \$slr,              # referent
                            'Omni',             # attr name
                            '-vorous'           # eval'd attr data
                            'CHECK',            # compiler phase
                          );

# sub fn :Ugly(sister) :Omni('po',tent()) {...}

MyClass::UGLY:ATTR(CODE)( 'SomeOtherClass',     # class
                          \*SomeOtherClass::fn, # typeglob
                          \&SomeOtherClass::fn, # referent
                          'Ugly',               # attr name
                          'sister'              # eval'd attr data
                          'CHECK',              # compiler phase
                        );

MyClass::Omni:ATTR(CODE)( 'SomeOtherClass',     # class
                          \*SomeOtherClass::fn, # typeglob
                          \&SomeOtherClass::fn, # referent
                          'Omni',               # attr name
                          ['po','acle']         # eval'd attr data
                          'CHECK',              # compiler phase
                        );

# my @arr :Good :Omni(s/cie/nt/);

MyClass::Good:ATTR(ARRAY)( 'SomeOtherClass',    # class
                           'LEXICAL',           # no typeglob
                           \@arr,               # referent
```

(continues on next page)

(continued from previous page)

```
                              'Good',              # attr name
                              undef                # no attr data
                              'CHECK',             # compiler phase
                            );

MyClass::Omni:ATTR(ARRAY)( 'SomeOtherClass',     # class
                              'LEXICAL',           # no typeglob
                              \@arr,               # referent
                              'Omni',              # attr name
                              ""                   # eval'd attr data
                              'CHECK',             # compiler phase
                            );

# my %hsh :Good(q/bye) :Omni(q/bus/);

MyClass::Good:ATTR(HASH)( 'SomeOtherClass',      # class
                              'LEXICAL',           # no typeglob
                              \%hsh,               # referent
                              'Good',              # attr name
                              'q/bye'              # raw attr data
                              'CHECK',             # compiler phase
                            );

MyClass::Omni:ATTR(HASH)( 'SomeOtherClass',      # class
                              'LEXICAL',           # no typeglob
                              \%hsh,               # referent
                              'Omni',              # attr name
                              'bus'                # eval'd attr data
                              'CHECK',             # compiler phase
                            );
```

Installing handlers into UNIVERSAL, makes them...err..universal. For example:

```
package Descriptions;
use Attribute::Handlers;

my %name;
sub name { return $name{$_[2]}||*{$_[1]}{NAME} }

sub UNIVERSAL::Name :ATTR {
    $name{$_[2]} = $_[4];
}

sub UNIVERSAL::Purpose :ATTR {
    print STDERR "Purpose of ", &name, " is $_[4]\n";
}

sub UNIVERSAL::Unit :ATTR {
```

(continues on next page)

(continued from previous page)

```
    print STDERR &name, " measured in $_[4]\n";
}
```

Let's you write:

```
use Descriptions;

my $capacity : Name(capacity)
             : Purpose(to store max storage capacity for files)
             : Unit(Gb);

package Other;

sub foo : Purpose(to foo all data before barring it) { }

# etc.
```

UTILITY FUNCTIONS

This module offers a single utility function, `findsym()`.

- findsym

  ```
  my $symbol = Attribute::Handlers::findsym($package, $referent);
  ```

  The function looks in the symbol table of `$package` for the typeglob for `$referent`, which is a reference to a variable or subroutine (SCALAR, ARRAY, HASH, or CODE). If it finds the typeglob, it returns it. Otherwise, it returns undef. Note that `findsym` memoizes the typeglobs it has previously successfully found, so subsequent calls with the same arguments should be much faster.

DIAGNOSTICS

- `Bad attribute type: ATTR(%s)`

  An attribute handler was specified with an `:ATTR(_ref_type_)`, but the type of referent it was defined to handle wasn't one of the five permitted: `SCALAR`, `ARRAY`, `HASH`, `CODE`, or `ANY`.

- `Attribute handler %s doesn't handle %s attributes`

  A handler for attributes of the specified name *was* defined, but not for the specified type of declaration. Typically encountered when trying to apply a `VAR` attribute handler to a subroutine, or a `SCALAR` attribute handler to some other type of variable.

- `Declaration of %s attribute in package %s may clash with future reserved word`

  A handler for an attributes with an all-lowercase name was declared. An attribute with an all-lowercase name might have a meaning to Perl itself some day, even though most don't yet. Use a mixed-case attribute name, instead.

- `Can't have two ATTR specifiers on one subroutine`

  You just can't, okay? Instead, put all the specifications together with commas between them in a single `ATTR(_specification_)`.

- `Can't autotie a %s`

  You can only declare autoties for types `"SCALAR"`, `"ARRAY"`, and `"HASH"`. They're the only things (apart from typeglobs – which are not declarable) that Perl can tie.

- `Internal error: %s symbol went missing`

  Something is rotten in the state of the program. An attributed subroutine ceased to exist between the point it was declared and the point at which its attribute handler(s) would have been called.

- `Won't be able to apply END handler`

  You have defined an END handler for an attribute that is being applied to a lexical variable. Since the variable may not be available during END this won't happen.

AUTHOR

5.2.7 AutoLoader

load subroutines only on demand

SYNOPSIS

```
package Foo;
use AutoLoader 'AUTOLOAD';   # import the default AUTOLOAD␣
↪subroutine

package Bar;
use AutoLoader;              # don't import AUTOLOAD, define our own
sub AUTOLOAD {
```

(continues on next page)

(continued from previous page)

```
    ...
    $AutoLoader::AUTOLOAD = "...";
    goto &AutoLoader::AUTOLOAD;
}
```

DESCRIPTION

The **AutoLoader** module works with the **AutoSplit** module and the `__END__` token to defer the loading of some subroutines until they are used rather than loading them all at once.

To use **AutoLoader**, the author of a module has to place the definitions of subroutines to be autoloaded after an `__END__` token. (See *perldata*.) The **AutoSplit** module can then be run manually to extract the definitions into individual files `auto/funcname.al`.

AutoLoader implements an AUTOLOAD subroutine. When an undefined subroutine in is called in a client module of **AutoLoader**, **AutoLoader**'s AUTOLOAD subroutine attempts to locate the subroutine in a file with a name related to the location of the file from which the client module was read. As an example, if `POSIX.pm` is located in `/usr/local/lib/perl5/POSIX.pm`, **AutoLoader** will look for perl subroutines **POSIX** in `/usr/local/lib/perl5/auto/POSIX/*.al`, where the `.al` file has the same name as the subroutine, sans package. If such a file exists, AUTOLOAD will read and evaluate it, thus (presumably) defining the needed subroutine. AUTOLOAD will then `goto` the newly defined subroutine.

Once this process completes for a given function, it is defined, so future calls to the subroutine will bypass the AUTOLOAD mechanism.

Subroutine Stubs

In order for object method lookup and/or prototype checking to operate correctly even when methods have not yet been defined it is necessary to "forward declare" each subroutine (as in `sub NAME;`). See *"SYNOPSIS" in perlsub*. Such forward declaration creates "subroutine stubs", which are place holders with no code.

The AutoSplit and **AutoLoader** modules automate the creation of forward declarations. The AutoSplit module creates an 'index' file containing forward declarations of all the AutoSplit subroutines. When the AutoLoader module is 'use'd it loads these declarations into its callers package.

Because of this mechanism it is important that **AutoLoader** is always `used` and not `required`.

Using AutoLoader's AUTOLOAD Subroutine

In order to use **AutoLoader**'s AUTOLOAD subroutine you *must* explicitly import it:

```
use AutoLoader 'AUTOLOAD';
```

Overriding AutoLoader's AUTOLOAD Subroutine

Some modules, mainly extensions, provide their own AUTOLOAD subroutines. They typically need to check for some special cases (such as constants) and then fallback to **AutoLoader**'s AUTOLOAD for the rest.

Such modules should *not* import **AutoLoader**'s AUTOLOAD subroutine. Instead, they should define their own AUTOLOAD subroutines along these lines:

```
use AutoLoader;
use Carp;

sub AUTOLOAD {
    my $sub = $AUTOLOAD;
    (my $constname = $sub) =~ s/.*::///;
    my $val = constant($constname, @_ ? $_[0] : 0);
    if ($! != 0) {
        if ($! =~ /Invalid/ || $!{EINVAL}) {
            $AutoLoader::AUTOLOAD = $sub;
            goto &AutoLoader::AUTOLOAD;
        }
        else {
            croak "Your vendor has not defined constant $constname";
        }
    }
    *$sub = sub { $val }; # same as: eval "sub $sub { $val }";
    goto &$sub;
}
```

If any module's own AUTOLOAD subroutine has no need to fallback to the AutoLoader's AUTOLOAD subroutine (because it doesn't have any AutoSplit subroutines), then that module should not use **AutoLoader** at all.

Package Lexicals

Package lexicals declared with `my` in the main block of a package using **AutoLoader** will not be visible to auto-loaded subroutines, due to the fact that the given scope ends at the `__END__` marker. A module using such variables as package globals will not work properly under the **AutoLoader**.

The `vars` pragma (see "vars" in perlmod) may be used in such situations as an alternative to explicitly qualifying all globals with the package namespace. Variables pre-declared with this pragma will be visible to any autoloaded routines (but will not be invisible outside the package, unfortunately).

Not Using AutoLoader

You can stop using AutoLoader by simply

```
no AutoLoader;
```

AutoLoader vs. SelfLoader

The **AutoLoader** is similar in purpose to **SelfLoader**: both delay the loading of subroutines.

SelfLoader uses the `__DATA__` marker rather than `__END__`. While this avoids the use of a hierarchy of disk files and the associated open/close for each routine loaded, **SelfLoader** suffers a startup speed disadvantage in the one-time parsing of the lines after `__DATA__`, after which routines are cached. **SelfLoader** can also handle multiple packages in a file.

AutoLoader only reads code as it is requested, and in many cases should be faster, but requires a mechanism like **AutoSplit** be used to create the individual files. *ExtUtils::MakeMaker* will invoke **AutoSplit** automatically if **AutoLoader** is used in a module source file.

Forcing AutoLoader to Load a Function

Sometimes, it can be necessary or useful to make sure that a certain function is fully loaded by AutoLoader. This is the case, for example, when you need to wrap a function to inject debugging code. It is also helpful to force early loading of code before forking to make use of copy-on-write as much as possible.

Starting with AutoLoader 5.73, you can call the `AutoLoader::autoload_sub` function with the fully-qualified name of the function to load from its `.al` file. The behaviour is exactly the same as if you called the function, triggering the regular `AUTOLOAD` mechanism, but it does not actually execute the autoloaded function.

CAVEATS

AutoLoaders prior to Perl 5.002 had a slightly different interface. Any old modules which use **AutoLoader** should be changed to the new calling style. Typically this just means changing a require to a use, adding the explicit `'AUTOLOAD'` import if needed, and removing **AutoLoader** from `@ISA`.

On systems with restrictions on file name length, the file corresponding to a subroutine may have a shorter name that the routine itself. This can lead to conflicting file names. The *AutoSplit* package warns of these potential conflicts when used to split a module.

AutoLoader may fail to find the autosplit files (or even find the wrong ones) in cases where `@INC` contains relative paths, **and** the program does `chdir`.

SEE ALSO

SelfLoader - an autoloader that doesn't use external files.

For those of you that choose to use the GNU General Public License,
my interpretation of the GNU General Public License is that no Perl
script falls under the terms of the GPL unless you explicitly put
said script under the terms of the GPL yourself.  Furthermore, any
object code linked with perl does not automatically fall under the
terms of the GPL, provided such object code only adds definitions
of subroutines and variables, and does not otherwise impair the
resulting interpreter from executing any standard Perl script.  I
consider linking in C subroutines in this manner to be the moral
equivalent of defining subroutines in the Perl language itself.  You

 ↪that.
```

5.2.8 AutoSplit

split a package for autoloading

SYNOPSIS

```
autosplit($file, $dir, $keep, $check, $modtime);

autosplit_lib_modules(@modules);
```

DESCRIPTION

This function will split up your program into files that the AutoLoader module can handle. It is used by both the standard perl libraries and by the MakeMaker utility, to automatically configure libraries for autoloading.

The `autosplit` interface splits the specified file into a hierarchy rooted at the directory `$dir`. It creates directories as needed to reflect class hierarchy, and creates the file `autosplit.ix`. This file acts as both forward declaration of all package routines, and as timestamp for the last update of the hierarchy.

The remaining three arguments to `autosplit` govern other options to the autosplitter.

- $keep

  If the third argument, *$keep*, is false, then any pre-existing `*.al` files in the autoload directory are removed if they are no longer part of the module (obsoleted functions). $keep defaults to 0.

- $check

The fourth argument, *$check*, instructs `autosplit` to check the module currently being split to ensure that it includes a `use` specification for the AutoLoader module, and skips the module if AutoLoader is not detected. $check defaults to 1.

- $modtime

  Lastly, the *$modtime* argument specifies that `autosplit` is to check the modification time of the module against that of the `autosplit.ix` file, and only split the module if it is newer. $modtime defaults to 1.

Typical use of AutoSplit in the perl MakeMaker utility is via the command-line with:

```
perl -e 'use AutoSplit; autosplit($ARGV[0], $ARGV[1], 0, 1, 1)'
```

Defined as a Make macro, it is invoked with file and directory arguments; `autosplit` will split the specified file into the specified directory and delete obsolete `.al` files, after checking first that the module does use the AutoLoader, and ensuring that the module is not already currently split in its current form (the modtime test).

The `autosplit_lib_modules` form is used in the building of perl. It takes as input a list of files (modules) that are assumed to reside in a directory **lib** relative to the current directory. Each file is sent to the autosplitter one at a time, to be split into the directory **lib/auto**.

In both usages of the autosplitter, only subroutines defined following the perl *__END__* token are split out into separate files. Some routines may be placed prior to this marker to force their immediate loading and parsing.

Multiple packages

As of version 1.01 of the AutoSplit module it is possible to have multiple packages within a single file. Both of the following cases are supported:

```
package NAME;
__END__
sub AAA { ... }
package NAME::option1;
sub BBB { ... }
package NAME::option2;
sub BBB { ... }

package NAME;
__END__
sub AAA { ... }
sub NAME::option1::BBB { ... }
sub NAME::option2::BBB { ... }
```

DIAGNOSTICS

`AutoSplit` will inform the user if it is necessary to create the top-level directory specified in the invocation. It is preferred that the script or installation process that invokes `AutoSplit` have created the full directory path ahead of time. This warning may indicate that the module is being split into an incorrect path.

`AutoSplit` will warn the user of all subroutines whose name causes potential file naming conflicts on machines with drastically limited (8 characters or less) file name length. Since the subroutine name is used as the file name, these warnings can aid in portability to such systems.

Warnings are issued and the file skipped if `AutoSplit` cannot locate either the *__END__* marker or a "package Name;"-style specification.

`AutoSplit` will also emit general diagnostics for inability to create directories or files.

AUTHOR

`AutoSplit` is maintained by the perl5-porters. Please direct any questions to the canonical mailing list. Anything that is applicable to the CPAN release can be sent to its maintainer, though.

For those of you that choose to use the GNU General Public License,
my interpretation of the GNU General Public License is that no Perl
script falls under the terms of the GPL unless you explicitly put
said script under the terms of the GPL yourself.  Furthermore, any
object code linked with perl does not automatically fall under the
terms of the GPL, provided such object code only adds definitions
of subroutines and variables, and does not otherwise impair the
resulting interpreter from executing any standard Perl script.  I
consider linking in C subroutines in this manner to be the moral
equivalent of defining subroutines in the Perl language itself.  You
may sell such an object file as proprietary provided that you␣
 ↪provide
or offer to provide the Perl source, as specified by the GNU General
Public License.  (This is merely an alternate way of specifying␣
 ↪input
to the program.)  You may also sell a binary produced by the dumping␣
 ↪of
a running Perl script that belongs to you, provided that you provide␣
 ↪or
offer to provide the Perl source as specified by the GPL.  (The
fact that a Perl interpreter and your code are in the same binary␣
 ↪file
is, in this case, a form of mere aggregation.)  This is my␣
 ↪interpretation
of the GPL.  If you still have concerns or difficulties␣
 ↪understanding
my intent, feel free to contact me.  Of course, the Artistic License
spells all this out for your protection, so you may prefer to use␣
 ↪that.
```

5.2.9 B

Inspect a running Perl program's own optree, symbol table, and compiled subs.

`B` is the compiler back-end interface. It hands a script introspective access to the data structures the interpreter already holds: the root of the main optree, every compiled sub's CV, the symbol table (stash) graph, and the SV/AV/HV/GV objects those structures point at. Subclasses such as `B::OP`, `B::CV`, `B::GV`, `B::SV` (and its type-specific children) wrap those pointers as blessed Perl objects with accessor methods.

Common callers are back-end modules like `B::Deparse`, `B::Concise`, and `B::Xref`; debugging tooling that walks the optree; and scripts that introspect the symbol table to

generate code or diagnostics.

```
use B qw(svref_2object class);

sub add { my ($x, $y) = @_; return $x + $y }

my $cv = svref_2object(\&add);                  # a B::CV
printf "%s defined in %s at line %d\n", $cv->GV->NAME, $cv->FILE =~␣
 ↪s{.*/}{}r,
    $cv->START->line;                           # add defined in add.
 ↪pl at line 3

# Walk the sub's ops in execution order.
my @ops;
for (my $op = $cv->START; $$op; $op = $op->next) {
    push @ops, $op->name;
}
print "@ops\n";
# nextstate padrange aassign nextstate padsv padsv add leavesub

my $sv = svref_2object(\"text");
printf "%s, PV %s, length %d\n", class($sv), $sv->PV, $sv->CUR;   #␣
 ↪PV, PV text, length 4
print "main program: ", class(B::main_cv()), ", root ", B::main_
 ↪root()->name, "\n";
# main program: CV, root leave
```

The ops are pperl's own, the ones perl 5.44 builds for the same source: the names, flags, order and tree shape that `B::Concise` and `B::Deparse` read are perl5's.

This is a native implementation of the XS half of B 1.92; its `B.pm` and the `B::*` modules built on it are used unchanged. B exports nothing by default; on request, its functions (`svref_2object`, `class`, `main_root`, `main_start`, `main_cv`, `walkoptree`, `walksymtable`, ppname, opnumber, `begin_av` ...) and its constants - the `SVf_*`, `OPf_*`, `OPp*`, `CVf_*`, `GVf_*`, `PMf_*` flags and the rest.

Differences from upstream

One, where perl 5.44 with B.xs crashes: a `B::OP` method called on a `B::NULL` - the object for a missing op, such as the ROOT of an XSUB - as `B::OP::name($null)` answers as for the null op (name is "null", an op or SV field is a `B::NULL`, a number is 0). B.xs follows the NULL pointer and crashes (t/81-xs-native/B/470-or-better.t).

Modules

- `B::AV`
- `B::BINOP`
- `B::BM`
- `B::COP`

- B::COW - Ask whether a string shares its buffer copy-on-write, and how many scalars share it.
- B::CV
- B::Concise - Walk Perl syntax tree, printing concise info about ops
- B::Deparse - Perl compiler backend to produce perl code
- B::FM
- B::GV
- B::HE
- B::HV
- B::IO
- B::IV
- B::LISTOP
- B::LOGOP
- B::LOOP
- B::MAGIC
- B::METHOP
- B::NV
- B::OP
- B::Op_private - OP op_private flag definitions
- B::PADLIST
- B::PADNAME
- B::PADNAMELIST
- B::PADOP
- B::PMOP
- B::PV
- B::PVLV
- B::PVMG
- B::RHE
- B::SV
- B::SVOP
- B::Showlex - Show lexical variables used in functions or files
- B::Terse - Walk Perl syntax tree, printing terse info about ops
- B::UNOP
- B::UNOP_AUX
- B::Xref - Generates cross reference reports for Perl programs

Functions

Entry points

svref_2object

Wrap a reference's referent as a `B::*` object.

opnumber

Return the numeric op-type for an op name, or `-1` if unknown.

ppname

Return the pp_-prefixed name for a numeric op-type.

Synopsis

```
my $name = B::ppname($op->type);   # e.g. "pp_print"
```

Inverse of `B::opnumber`. Returns `undef` if the number is out of range.

sv_undef

Return a `B::SPECIAL` wrapping perl's shared `PL_sv_undef`.

sv_yes

Return a `B::SPECIAL` wrapping perl's shared `PL_sv_yes`.

sv_no

Return a `B::SPECIAL` wrapping perl's shared `PL_sv_no`.

main_root

Return a `B::OP` for the root of the program's main optree.

main_start

Return a `B::OP` for the first op executed in the main program.

Synopsis

```
my $start = B::main_start;
```

Where `B::main_root` gives the syntactic root, `B::main_start` gives the head of the linked list perl follows at run time via `op_next`.

cast_I32

Truncate `$i` to a signed 32-bit integer.

Synopsis

```
B::cast_I32(0x1_0000_0001);   # 1 (low 32 bits, sign-extended)
```

Exists so Perl back-ends can reproduce perl's own I32 truncation when they need to emit exact values for an op field typed I32 in C.

amagic_generation

Return the overload-magic generation counter (always `0` in modern perl).

comppadlist

Return the padlist of the currently-compiling unit as a `B::PADLIST`.

formfeed

Return `$^L`, the form-feed string, as a `B::SV`.

address

Return the memory address of an SV as an integer.

Synopsis

```
my $addr = B::address(\$x);
```

Mostly useful as an identity key: two `B::*` objects wrapping the same underlying SV will report the same address.

threadsv_names

Return the list of thread-local special-variable names (empty).

minus_c

Request that compilation stop after the compile phase (`-c`).

save_BEGINs

Request that `BEGIN` blocks be saved rather than freed (`save_BEGINs`).

Walking the optree

walkoptree

Recursively walk an optree, calling `$method` on each op.

walkoptree_debug

Get or set the walkoptree debug flag.

String and hash helpers

cstring

Return $sv's contents as a double-quoted C-style string literal.

perlstring

Return $sv's contents as a double-quoted Perl string literal.

Synopsis

```
B::perlstring('say $x@y');    # "say \$x\@y"
```

Like B::cstring, but also escapes $ and @ so the result can be pasted back into Perl source without interpolation surprises.

cchar

Return the first character of $sv as a single-quoted C character literal.

hash

Return perl's hash of a string, formatted as 0xNNNNNNNN.

safename

Return a string with a leading control character rendered as ^X.

B::GV methods

B::GV::SAFENAME

Return the GV's name with a leading control character rendered as ^X.

Interpreter globals

sub_generation

B::sub_generation(): perl's global method-cache generation (PL_sub_generation). It goes up when every method cache is invalidated at once - a change to UNIVERSAL or one of its parents, among a few others; ordinary sub definitions and @ISA changes only invalidate their own classes and leave it alone. B::dowarn() is perl's warning switch word (PL_dowarn): 0 normally, 1 under -w, 3 under -W, 4 under -X.

Also available as B::dowarn.

main_cv

Return a `B::CV` for the implicit CV of the main program.

inc_gv

Return a `B::GV` for `*INC`, the module-loading search list.

defstash

Return a `B::HV` for `%main::`, the default stash.

curstash

Return a `B::HV` for the currently active compile-time stash.

warnhook

Return a `B::SV` for the current `$SIG{__WARN__}` handler.

diehook

Return a `B::SV` for the current `$SIG{__DIE__}` handler.

init_av

Return a `B::AV` of the `INIT` blocks queued for execution.

check_av

Return a `B::AV` of `CHECK` blocks queued for execution.

unitcheck_av

Return a `B::AV` of `UNITCHECK` blocks queued for execution.

begin_av

Return a `B::AV` of `BEGIN` blocks already executed.

end_av

Return a `B::AV` of `END` blocks queued to run at interpreter exit.

B::AV

Functions

Other Functions

FILL

Return the logical last index of the array (AvFILL, i.e. $#a).

MAX

Return the allocated capacity of the array (AvMAX).

ARRAY

Return the array's elements as a list of B:: objects (AvARRAY).

ARRAYelt

Return the Nth element as a B:: object (AvARRAYelt).

B::BINOP

Functions

B::OP methods

last

Return the last child of a BINOP/LISTOP (op_last).

B::BM

Functions

Other Functions

TABLE

Return the Boyer-Moore skip table of a studied string.

PREVIOUS

Always 0.

RARE

Always 0.

USEFUL

Return how many times the Boyer-Moore study has paid for itself.

B::COP

Functions

B::OP methods

cop_seq

Return a COP's compile sequence number (`cop_seq`).

line

Return a COP's source line number (`cop_line`).

hints

Return a COP's hint bits (`cop_hints`).

file

Return a COP's source filename (`CopFILE`).

stash

Return a COP's package stash as a B::HV (`cop_stash`).

stashpv

Return a COP's package name (`CopSTASHPV`).

label

Return a COP's statement label, or undef (`CopLABEL`).

stashoff

Croaks: a COP's stash pad offset only exists on a threaded perl.

B::COW

Ask whether a string shares its buffer copy-on-write, and how many scalars share it.

perl copies a string by sharing its buffer and copying only when one of the copies is modified. These helpers expose that state, mostly to test code that wants to know a copy was avoided.

Synopsis

```
use B::COW qw(can_cow is_cow cowrefcnt cowrefcnt_max);

my $a = "x" x 100;
my $b = $a;                          # shares $a's buffer
print is_cow($b) ? "shared\n" : "own\n";
print cowrefcnt($a), "\n";           # how many share it, as perl
 ↪counts
print cowrefcnt_max(), "\n";         # 255
```

Functions

`can_cow()` is true: this perl copies on write. `is_cow($sv)` is true for a string whose buffer is shared copy-on-write. `cowrefcnt($sv)` is the share count perl keeps in the buffer (0 for a shared hash key string, which has no such count), or `undef` for a value that is not copy-on-write. `cowrefcnt_max()` is the largest count, after which perl copies instead of sharing. Nothing is exported by default.

This is a native implementation of B::COW 0.007's `COW.xs`; its `B/COW.pm` is used unchanged.

Differences from upstream

None.

Functions

Copy on write

`can_cow`

Whether this perl copies strings on write.

Synopsis

```
use B::COW qw(can_cow);
print can_cow() ? "copy on write\n" : "plain copies\n";
```

What you get back

True: pperl, like perl 5.44, shares string buffers copy-on-write.

`is_cow`

Whether a string shares its buffer copy-on-write.

`cowrefcnt`

How many scalars share a copy-on-write buffer, as perl counts.

cowrefcnt_max

The largest copy-on-write share count.

is_cow

Whether a string shares its buffer copy-on-write.

Synopsis

```
use B::COW qw(is_cow);
my $copy = $string;
print is_cow($copy) ? "shared\n" : "own buffer\n";
```

What you get back

True for a string value whose buffer is shared copy-on-write with other scalars or with a hash key, false otherwise - including for a value that is not a string.

cowrefcnt

How many scalars share a copy-on-write buffer, as perl counts.

Synopsis

```
use B::COW qw(cowrefcnt);
my $n = cowrefcnt($string);
```

What you get back

The share count perl keeps in the last byte of the buffer, 0 for a string that shares a hash key's buffer (those have no count), or `undef` when the value is not copy-on-write.

cowrefcnt_max

The largest copy-on-write share count.

Synopsis

```
use B::COW qw(cowrefcnt_max);
print cowrefcnt_max(), "\n";   # 255
```

What you get back

255: the count is one byte, and a string already shared that often is copied instead of shared again.

B::CV

Functions

B::CV methods

GV

Return the `B::GV` that a named CV belongs to.

STASH

Return the `B::HV` for the package the CV was compiled in.

FILE

Return the source filename the CV was compiled from.

Synopsis

```
print $cv->FILE;    # e.g. "MyModule.pm"
```

Returns an empty string for XSUBs that do not carry a file record.

ROOT

Return the root op of the CV's optree, or `B::NULL` for an XSUB.

Synopsis

```
my $root = $cv->ROOT;
```

XSUBs carry compiled C code and have no optree, so `ROOT` returns a `B::NULL`. Test with `$cv->CvFLAGS & B::CVf_ISXSUB` first if it matters.

XSUB

Return the CV's C function pointer as an integer, or `0` for a Perl sub.

Synopsis

```
my $addr = $cv->XSUB;   # non-zero iff the sub is an XSUB
```

XSUBANY

Return `CvXSUBANY` - per-XSUB private data.

Synopsis

```
my $any = $cv->XSUBANY;          # any_iv; 0 for Perl subs
my $sv  = $const_cv->XSUBANY;    # B object of the constant for␣
 ↪CvCONST subs
```

START

Return the first op executed in the CV's body, or `B::NULL` for an XSUB.

DEPTH

Return the current recursion depth of the sub.

CvFLAGS

Return the raw `CvFLAGS` word of the CV.

NAME_HEK

Return the CV's name when it was stored as a HEK rather than via a GV.

OUTSIDE

Return the lexically enclosing CV (`CvOUTSIDE`).

PADLIST

Return the CV's padlist as a `B::PADLIST`, or `B::NULL` for an XSUB.

OUTSIDE_SEQ

Return the COP sequence number at which the CV was closed over.

CONST

Return `CVf_CONST` if the CV is a constant (inlinable) sub, else 0.

HSCXT

Return the XS handshake context pointer as an integer, or `0` for a Perl sub.

const_sv

Return the SV a constant sub yields, as a B:: object (`const_sv`).

GV

Return the `B::GV` that a named CV belongs to.

Synopsis

```
my $cv = B::svref_2object(\&main::foo);
my $gv = $cv->GV;       # B::GV for *main::foo
print $gv->NAME;        # "foo"
```

Anonymous and lexical subs may return a `B::SPECIAL` or a sentinel rather than a real `B::GV`; check with `isa` before calling `NAME`.

NAME_HEK

Return the CV's name when it was stored as a HEK rather than via a GV.

Synopsis

```
my $name = $cv->NAME_HEK;    # undef unless CVf_NAMED is set
```

Modern perl stores some sub names directly in a hash-key slot on the CV (cheaper than a full GV). If the CV does not use that slot, returns `undef`; callers generally fall back to `$cv->GV->NAME`.

B::Concise

Walk Perl syntax tree, printing concise info about ops

SYNOPSIS

```
perl -MO=Concise[,OPTIONS] foo.pl

use B::Concise qw(set_style add_callback);
```

DESCRIPTION

This compiler backend prints the internal OPs of a Perl program's syntax tree in one of several space-efficient text formats suitable for debugging the inner workings of perl or other compiler backends. It can print OPs in the order they appear in the OP tree, in the order they will execute, or in a text approximation to their tree structure, and the format of the information displayed is customizable. Its function is similar to that of perl's **-Dx** debugging flag or the **B::Terse** module, but it is more sophisticated and flexible.

EXAMPLE

Here's two outputs (or 'renderings'), using the -exec and -basic (i.e. default) formatting conventions on the same code snippet.

```
    % perl -MO=Concise,-exec -e '$a = $b + 42'
    1  <0> enter
    2  <;> nextstate(main 1 -e:1) v
    3  <#> gvsv[*b] s
    4  <$> const[IV 42] s
*   5  <2> add[t3] sK/2
    6  <#> gvsv[*a] s
    7  <2> sassign vKS/2
    8  <@> leave[1 ref] vKP/REFC
```

In this -exec rendering, each opcode is executed in the order shown. The add opcode, marked with '*', is discussed in more detail.

The 1st column is the op's sequence number, starting at 1, and is displayed in base 36 by default. Here they're purely linear; the sequences are very helpful when looking at code with loops and branches.

The symbol between angle brackets indicates the op's type, for example; <2> is a BINOP, <@> a LISTOP, and <#> is a PADOP, which is used in threaded perls. (see "OP class abbreviations").

The opname, as in **'add[t1]'**, may be followed by op-specific information in parentheses or brackets (ex **'[t1]'**).

The op-flags (ex **'sK/2'**) are described in ("OP flags abbreviations").

```
   % perl -MO=Concise -e '$a = $b + 42'
   8  <@> leave[1 ref] vKP/REFC ->(end)
   1     <0> enter ->2
   2     <;> nextstate(main 1 -e:1) v ->3
   7     <2> sassign vKS/2 ->8
*  5        <2> add[t1] sK/2 ->6
   -           <1> ex-rv2sv sK/1 ->4
   3              <$> gvsv(*b) s ->4
   4           <$> const(IV 42) s ->5
   -        <1> ex-rv2sv sKRM*/1 ->7
   6           <$> gvsv(*a) s ->7
```

The default rendering is top-down, so they're not in execution order. This form reflects the way the stack is used to parse and evaluate expressions; the add operates on the two terms below it in the tree.

Nullops appear as `ex-opname`, where *opname* is an op that has been optimized away by perl. They're displayed with a sequence-number of '-', because they are not executed (they don't appear in previous example), they're printed here because they reflect the parse.

The arrow points to the sequence number of the next op; they're not displayed in -exec mode, for obvious reasons.

Note that because this rendering was done on a non-threaded perl, the PADOPs in the previous examples are now SVOPs, and some (but not all) of the square brackets have been replaced by round ones. This is a subtle feature to provide some visual distinction between renderings on threaded and un-threaded perls.

OPTIONS

Arguments that don't start with a hyphen are taken to be the names of subroutines or formats to render; if no such functions are specified, the main body of the program (outside any subroutines, and not including use'd or require'd files) is rendered. Passing `BEGIN`, `UNITCHECK`, `CHECK`, `INIT`, or `END` will cause all of the corresponding special blocks to be printed. Arguments must follow options.

Options affect how things are rendered (ie printed). They're presented here by their visual effect, 1st being strongest. They're grouped according to how they interrelate;

within each group the options are mutually exclusive (unless otherwise stated).

Options for Opcode Ordering

These options control the 'vertical display' of opcodes. The display 'order' is also called 'mode' elsewhere in this document.

- **-basic**

  Print OPs in the order they appear in the OP tree (a preorder traversal, starting at the root). The indentation of each OP shows its level in the tree, and the '->' at the end of the line indicates the next opcode in execution order. This mode is the default, so the flag is included simply for completeness.

- **-exec**

  Print OPs in the order they would normally execute (for the majority of constructs this is a postorder traversal of the tree, ending at the root). In most cases the OP that usually follows a given OP will appear directly below it; alternate paths are shown by indentation. In cases like loops when control jumps out of a linear path, a 'goto' line is generated.

- **-tree**

  Print OPs in a text approximation of a tree, with the root of the tree at the left and 'left-to-right' order of children transformed into 'top-to-bottom'. Because this mode grows both to the right and down, it isn't suitable for large programs (unless you have a very wide terminal).

Options for Line-Style

These options select the line-style (or just style) used to render each opcode, and dictates what info is actually printed into each line.

- **-concise**

  Use the author's favorite set of formatting conventions. This is the default, of course.

- **-terse**

  Use formatting conventions that emulate the output of **B::Terse**. The basic mode is almost indistinguishable from the real **B::Terse**, and the exec mode looks very similar, but is in a more logical order and lacks curly brackets. **B::Terse** doesn't have a tree mode, so the tree mode is only vaguely reminiscent of **B::Terse**.

- **-linenoise**

  Use formatting conventions in which the name of each OP, rather than being written out in full, is represented by a one- or two-character abbreviation. This is mainly a joke.

- **-debug**

  Use formatting conventions reminiscent of CPAN module **B::Debug**; these aren't very concise at all.

- **-env**

  Use formatting conventions read from the environment variables `B_CONCISE_FORMAT`, `B_CONCISE_GOTO_FORMAT`, and `B_CONCISE_TREE_FORMAT`.

Options for tree-specific formatting

- **-compact**

  Use a tree format in which the minimum amount of space is used for the lines connecting nodes (one character in most cases). This squeezes out a few precious columns of screen real estate.

- **-loose**

  Use a tree format that uses longer edges to separate OP nodes. This format tends to look better than the compact one, especially in ASCII, and is the default.

- **-vt**

  Use tree connecting characters drawn from the VT100 line-drawing set. This looks better if your terminal supports it.

- **-ascii**

  Draw the tree with standard ASCII characters like + and `|`. These don't look as clean as the VT100 characters, but they'll work with almost any terminal (or the horizontal scrolling mode of less(1)) and are suitable for text documentation or email. This is the default.

These are pairwise exclusive, i.e. compact or loose, vt or ascii.

Options controlling sequence numbering

- **-base***n*

  Print OP sequence numbers in base *n*. If *n* is greater than 10, the digit for 11 will be 'a', and so on. If *n* is greater than 36, the digit for 37 will be 'A', and so on until 62. Values greater than 62 are not currently supported. The default is 36.

- **-bigendian**

  Print sequence numbers with the most significant digit first. This is the usual convention for Arabic numerals, and the default.

- **-littleendian**

  Print sequence numbers with the least significant digit first. This is obviously mutually exclusive with bigendian.

Other options

- **-src**

  With this option, the rendering of each statement (starting with the nextstate OP) will be preceded by the 1st line of source code that generates it. For example:

```
1  <0> enter
# 1: my $i;
2  <;> nextstate(main 1 junk.pl:1) v:{
3  <0> padsv[$i:1,10] vM/LVINTRO
# 3: for $i (0..9) {
4  <;> nextstate(main 3 junk.pl:3) v:{
5  <0> pushmark s
6  <$> const[IV 0] s
7  <$> const[IV 9] s
8  <{> enteriter(next->j last->m redo->9)[$i:1,10] lKS
k  <0> iter s
l  <|> and(other->9) vK/1
# 4:     print "line ";
9      <;> nextstate(main 2 junk.pl:4) v
a      <0> pushmark s
b      <$> const[PV "line "] s
c      <@> print vK
# 5:     print "$i\n";
...
```

- **-stash=”somepackage”**

  With this, “somepackage” will be required, then the stash is inspected, and each function is rendered.

The following options are pairwise exclusive.

- **-main**

  Include the main program in the output, even if subroutines were also specified. This rendering is normally suppressed when a subroutine name or reference is given.

- **-nomain**

  This restores the default behavior after you’ve changed it with ‘-main’ (it’s not normally needed). If no subroutine name/ref is given, main is rendered, regardless of this flag.

- **-nobanner**

  Renderings usually include a banner line identifying the function name or stringified subref. This suppresses the printing of the banner.

  TBC: Remove the stringified coderef; while it provides a ‘cookie’ for each function rendered, the cookies used should be 1,2,3.. not a random hex-address. It also complicates string comparison of two different trees.

- **-banner**

  restores default banner behavior.

- **-banneris** => subref

  TBC: a hookpoint (and an option to set it) for a user-supplied function to produce a banner appropriate for users needs. It’s not ideal, because the rendering-state

variables, which are a natural candidate for use in concise.t, are unavailable to the user.

Option Stickiness

If you invoke Concise more than once in a program, you should know that the options are 'sticky'. This means that the options you provide in the first call will be remembered for the 2nd call, unless you re-specify or change them.

ABBREVIATIONS

The concise style uses symbols to convey maximum info with minimal clutter (like hex addresses). With just a little practice, you can start to see the flowers, not just the branches, in the trees.

OP class abbreviations

These symbols appear before the op-name, and indicate the B:: namespace that represents the ops in your Perl code.

```
0      OP (aka BASEOP)  An OP with no children
1      UNOP             An OP with one child
+      UNOP_AUX         A UNOP with auxillary fields
2      BINOP            An OP with two children
|      LOGOP            A control branch OP
@      LISTOP           An OP that could have lots of children
/      PMOP             An OP with a regular expression
$      SVOP             An OP with an SV
"      PVOP             An OP with a string
{      LOOP             An OP that holds pointers for a loop
;      COP              An OP that marks the start of a statement
#      PADOP            An OP with a GV on the pad
.      METHOP           An OP with method call info
```

OP flags abbreviations

OP flags are either public or private. The public flags alter the behavior of each opcode in consistent ways, and are represented by 0 or more single characters.

```
v      OPf_WANT_VOID    Want nothing (void context)
s      OPf_WANT_SCALAR  Want single value (scalar context)
l      OPf_WANT_LIST    Want list of any length (list context)
                        Want is unknown
K      OPf_KIDS         There is a firstborn child.
P      OPf_PARENS       This operator was parenthesized.
                         (Or block needs explicit scope entry.)
R      OPf_REF          Certified reference.
                         (Return container, not containee).
M      OPf_MOD          Will modify (lvalue).
```

(continues on next page)

(continued from previous page)

```
S       OPf_STACKED     Some arg is arriving on the stack.
*       OPf_SPECIAL     Do something weird for this op (see op.h)
```

Private flags, if any are set for an opcode, are displayed after a '/'

```
8  <@> leave[1 ref] vKP/REFC ->(end)
7     <2> sassign vKS/2 ->8
```

They're opcode specific, and occur less often than the public ones, so they're represented by short mnemonics instead of single-chars; see B::Op_private and `regen/op_private` for more details.

Note that a number after a '/' often indicates the number of arguments. In the *sassign* example above, the OP takes 2 arguments. These values are sometimes used at runtime: in particular, the MAXARG macro makes use of them.

FORMATTING SPECIFICATIONS

For each line-style ('concise', 'terse', 'linenoise', etc.) there are 3 format-specs which control how OPs are rendered.

The first is the 'default' format, which is used in both basic and exec modes to print all opcodes. The 2nd, goto-format, is used in exec mode when branches are encountered. They're not real opcodes, and are inserted to look like a closing curly brace. The tree-format is tree specific.

When a line is rendered, the correct format-spec is copied and scanned for the following items; data is substituted in, and other manipulations like basic indenting are done, for each opcode rendered.

There are 3 kinds of items that may be populated; special patterns, #vars, and literal text, which is copied verbatim. (Yes, it's a set of s///g steps.)

Special Patterns

These items are the primitives used to perform indenting, and to select text from amongst alternatives.

- **(x(***exec_text***;***basic_text***)x)**

  Generates *exec_text* in exec mode, or *basic_text* in basic mode.

- **(*(***text***)*)**

  Generates one copy of *text* for each indentation level.

- **(*(***text1***;***text2***)*)**

  Generates one fewer copies of *text1* than the indentation level, followed by one copy of *text2* if the indentation level is more than 0.

- **(?(***text1#var__Text2***)?)**

  If the value of *var* is true (not empty or zero), generates the value of *var* surrounded by *text1* and *Text2*, otherwise nothing.

- ~

  Any number of tildes and surrounding whitespace will be collapsed to a single space.

Variables

These #vars represent opcode properties that you may want as part of your rendering. The '#' is intended as a private sigil; a #var's value is interpolated into the style-line, much like "read $this".

These vars take 3 forms:

- *#var*

  A property named 'var' is assumed to exist for the opcodes, and is interpolated into the rendering.

- *#var__N*

  Generates the value of *var*, left justified to fill *N* spaces. Note that this means while you can have properties 'foo' and 'foo2', you cannot render 'foo2', but you could with 'foo2a'. You would be wise not to rely on this behavior going forward ;-)

- *#Var*

  This ucfirst form of #var generates a tag-value form of itself for display; it converts '#Var' into a 'Var => #var' style, which is then handled as described above. (Imp-note: #Vars cannot be used for conditional-fills, because the => #var transform is done after the check for #Var's value).

The following variables are 'defined' by B::Concise; when they are used in a style, their respective values are plugged into the rendering of each opcode.

Only some of these are used by the standard styles, the others are provided for you to delve into optree mechanics, should you wish to add a new style (see "add_style" below) that uses them. You can also add new ones using "add_callback".

- **#addr**

  The address of the OP, in hexadecimal.

- **#arg**

  The OP-specific information of the OP (such as the SV for an SVOP, the non-local exit pointers for a LOOP, etc.) enclosed in parentheses.

- **#class**

  The B-determined class of the OP, in all caps.

- **#classsym**

  A single symbol abbreviating the class of the OP.

- **#coplabel**

  The label of the statement or block the OP is the start of, if any.

- **#exname**

  The name of the OP, or 'ex-foo' if the OP is a null that used to be a foo.

- **#extarg**

  The target of the OP, or nothing for a nulled OP.

- **#firstaddr**

  The address of the OP's first child, in hexadecimal.

- **#flags**

  The OP's flags, abbreviated as a series of symbols.

- **#flagval**

  The numeric value of the OP's flags.

- **#hints**

  The COP's hint flags, rendered with abbreviated names if possible. An empty string if this is not a COP. Here are the symbols used:

```
 $ strict refs
 & strict subs
 * strict vars
x$ explicit use/no strict refs
x& explicit use/no strict subs
x* explicit use/no strict vars
 i integers
 l locale
 b bytes
 { block scope
 % localise %^H
 < open in
 > open out
 I overload int
 F overload float
 B overload binary
 S overload string
 R overload re
 T taint
 E eval
 X filetest access
 U utf-8

 us      use feature 'unicode_strings'
 fea=NNN feature bundle number
```

- **#hintsval**

  The numeric value of the COP's hint flags, or an empty string if this is not a COP.

- **#hyphseq**

  The sequence number of the OP, or a hyphen if it doesn't have one.

- **#label**

'NEXT', 'LAST', or 'REDO' if the OP is a target of one of those in exec mode, or empty otherwise.

- **#lastaddr**

  The address of the OP's last child, in hexadecimal.

- **#name**

  The OP's name.

- **#NAME**

  The OP's name, in all caps.

- **#next**

  The sequence number of the OP's next OP.

- **#nextaddr**

  The address of the OP's next OP, in hexadecimal.

- **#noise**

  A one- or two-character abbreviation for the OP's name.

- **#private**

  The OP's private flags, rendered with abbreviated names if possible.

- **#privval**

  The numeric value of the OP's private flags.

- **#seq**

  The sequence number of the OP. Note that this is a sequence number generated by B::Concise.

- **#opt**

  Whether or not the op has been optimized by the peephole optimizer.

- **#sibaddr**

  The address of the OP's next youngest sibling, in hexadecimal.

- **#svaddr**

  The address of the OP's SV, if it has an SV, in hexadecimal.

- **#svclass**

  The class of the OP's SV, if it has one, in all caps (e.g., 'IV').

- **#svval**

  The value of the OP's SV, if it has one, in a short human-readable format.

- **#targ**

  The numeric value of the OP's targ.

- **#targarg**

  The name of the variable the OP's targ refers to, if any, otherwise the letter t followed by the OP's targ in decimal.

- **#targarglife**

  Same as **#targarg**, but followed by the COP sequence numbers that delimit the variable's lifetime (or 'end' for a variable in an open scope) for a variable.

- **#typenum**

  The numeric value of the OP's type, in decimal.

One-Liner Command tips

- perl -MO=Concise,bar foo.pl

  Renders only bar() from foo.pl. To see main, drop the ',bar'. To see both, add ',-main'

- perl -MDigest::MD5=md5 -MO=Concise,md5 -e1

  The export is needed so that BC can find it in main.

- perl -MPOSIX -MO=Concise,_POSIX_ARG_MAX -e1

  Identifies _POSIX_ARG_MAX as a constant sub, optimized to an IV. Although POSIX isn't entirely consistent across platforms, this is likely to be present in virtually all of them.

- perl -MPOSIX -MO=Concise -e 'print _POSIX_SAVED_IDS'

  This renders a print statement, which includes a call to the function. It's identical to rendering a file with a use call and that single statement, except for the filename which appears in the nextstate ops.

- perl -MPOSIX -MO=Concise,a -e 'sub a{print _POSIX_SAVED_IDS}'

  This is **very** similar to previous, only the first two ops differ. This subroutine rendering is more representative, insofar as a single main program will have many subs.

- perl -MB::Concise -e 'B::Concise::compile("-exec","-src", \%B::Concise::)->()'

  This renders all functions in the B::Concise package with the source lines. It eschews the O framework so that the stashref can be passed directly to B::Concise::compile(). See -stash option for a more convenient way to render a package.

Using B::Concise outside of the O framework

The common (and original) usage of B::Concise was for command-line renderings of simple code, as given in EXAMPLE. But you can also use **B::Concise** from your code, and call compile() directly, and repeatedly. By doing so, you can avoid the compile-time only operation of O.pm, and even use the debugger to step through B::Concise::compile() itself.

Once you're doing this, you may alter Concise output by adding new rendering styles, and by optionally adding callback routines which populate new variables, if such were referenced from those (just added) styles.

Example: Altering Concise Renderings

```
use B::Concise qw(set_style add_callback);
add_style($yourStyleName => $defaultfmt, $gotofmt, $treefmt);
add_callback
  ( sub {
        my ($h, $op, $format, $level, $stylename) = @_;
        $h->{variable} = some_func($op);
    });
$walker = B::Concise::compile(@options,@subnames,@subrefs);
$walker->();
```

set_style()

set_style accepts 3 arguments, and updates the three format-specs comprising a line-style (basic-exec, goto, tree). It has one minor drawback though; it doesn't register the style under a new name. This can become an issue if you render more than once and switch styles. Thus you may prefer to use add_style() and/or set_style_standard() instead.

set_style_standard($name)

This restores one of the standard line-styles: `terse`, `concise`, `linenoise`, debug, env, into effect. It also accepts style names previously defined with add_style().

add_style ()

This subroutine accepts a new style name and three style arguments as above, and creates, registers, and selects the newly named style. It is an error to re-add a style; call set_style_standard() to switch between several styles.

add_callback ()

If your newly minted styles refer to any new #variables, you'll need to define a callback subroutine that will populate (or modify) those variables. They are then available for use in the style you've chosen.

The callbacks are called for each opcode visited by Concise, in the same order as they are added. Each subroutine is passed five parameters.

```
1. A hashref, containing the variable names and values which are
   populated into the report-line for the op
2. the op, as a B<B::OP> object
3. a reference to the format string
4. the formatting (indent) level
5. the selected stylename
```

To define your own variables, simply add them to the hash, or change existing values if you need to. The level and format are passed in as references to scalars, but it is unlikely that they will need to be changed or even used.

Running B::Concise::compile()

compile accepts options as described above in "OPTIONS", and arguments, which are either coderefs, or subroutine names.

It constructs and returns a $treewalker coderef, which when invoked, traverses, or walks, and renders the optrees of the given arguments to STDOUT. You can reuse this, and can change the rendering style used each time; thereafter the coderef renders in the new style.

walk_output lets you change the print destination from STDOUT to another open filehandle, or into a string passed as a ref (unless you've built perl with -Uuseperlio).

```
my $walker = B::Concise::compile('-terse','aFuncName', \&aSubRef); #
↪1
walk_output(\my $buf);
$walker->();                          # 1 renders -terse
set_style_standard('concise');        # 2
$walker->();                          # 2 renders -concise
$walker->(@new);                      # 3 renders whatever
print "3 different renderings: terse, concise, and @new: $buf\n";
```

When $walker is called, it traverses the subroutines supplied when it was created, and renders them using the current style. You can change the style afterwards in several different ways:

```
1. call C<compile>, altering style or mode/order
2. call C<set_style_standard>
3. call $walker, passing @new options
```

Passing new options to the $walker is the easiest way to change amongst any pre-defined styles (the ones you add are automatically recognized as options), and is the only way to alter rendering order without calling compile again. Note however that rendering state is still shared amongst multiple $walker objects, so they must still be used in a coordinated manner.

B::Concise::reset_sequence()

This function (not exported) lets you reset the sequence numbers (note that they're numbered arbitrarily, their goal being to be human readable). Its purpose is mostly to support testing, i.e. to compare the concise output from two identical anonymous subroutines (but different instances). Without the reset, B::Concise, seeing that they're separate optrees, generates different sequence numbers in the output.

Errors

Errors in rendering (non-existent function-name, non-existent coderef) are written to the STDOUT, or wherever you've set it via walk_output().

Errors using the various *style* calls, and bad args to walk_output(), result in die(). Use an eval if you wish to catch these errors and continue processing.

Stephen McCamant, <smcc@CSUA.Berkeley.EDU>.

B::Deparse

Perl compiler backend to produce perl code

SYNOPSIS

perl -MO=Deparse[,-d][,-f*FILE*][,-p][,-q][,-l] [,-s*LETTERS*][,-x*LEVEL*] *prog.pl*

DESCRIPTION

`B::Deparse` is a backend module for the Perl compiler that generates perl source code, based on the internal compiled structure that perl itself creates after parsing a program. The output of `B::Deparse` won't be exactly the same as the original source, since perl doesn't keep track of comments or whitespace, and there isn't a one-to-one correspondence between perl's syntactical constructions and their compiled form, but it will often be close. When you use the **-p** option, the output also includes parentheses even when they are not required by precedence, which can make it easy to see if perl is parsing your expressions the way you intended.

While `B::Deparse` goes to some lengths to try to figure out what your original program was doing, some parts of the language can still trip it up; it still fails even on some parts of Perl's own test suite. If you encounter a failure other than the most common ones described in the BUGS section below, you can help contribute to `B::Deparse`'s ongoing development by submitting a bug report with a small example.

OPTIONS

As with all compiler backend options, these must follow directly after the `-MO=Deparse`, separated by a comma but not any white space.

- **-d**

  Output data values (when they appear as constants) using *Data::Dumper*. Without this option, `B::Deparse` will use some simple routines of its own for the same purpose. Currently, *Data::Dumper* is better for some kinds of data (such as complex structures with sharing and self-reference) while the built-in routines are better for others (such as odd floating-point values).

- **-f***FILE*

  Normally, `B::Deparse` deparses the main code of a program, and all the subs defined in the same file. To include subs defined in other files, pass the **-f** option with the filename. You can pass the **-f** option several times, to include more than one secondary file. (Most of the time you don't want to use it at all.) You can also use this option to include subs which are defined in the scope of a **#line** directive with two parameters.

- **-l**

Add `#line` declarations to the output based on the line and file locations of the original code.

- **-p**

  Print extra parentheses. Without this option, `B::Deparse` includes parentheses in its output only when they are needed, based on the structure of your program. With **-p**, it uses parentheses (almost) whenever they would be legal. This can be useful if you are used to LISP, or if you want to see how perl parses your input. If you say

```
if ($var & 0x7f == 65) {print "Gimme an A!"}
print ($which ? $a : $b), "\n";
$name = $ENV{USER} or "Bob";
```

  `B::Deparse,-p` will print

```
if (($var & 0)) {
    print('Gimme an A!')
};
(print(($which ? $a : $b)), '???');
(($name = $ENV{'USER'}) or '???')
```

  which probably isn't what you intended (the `'???'` is a sign that perl optimized away a constant value).

- **-P**

  Disable prototype checking. With this option, all function calls are deparsed as if no prototype was defined for them. In other words,

```
perl -MO=Deparse,-P -e 'sub foo (\@) { 1 } foo @x'
```

  will print

```
sub foo (\@) {
    1;
}
&foo(\@x);
```

  making clear how the parameters are actually passed to `foo`.

- **-q**

  Expand double-quoted strings into the corresponding combinations of concatenation, `uc`, `ucfirst`, `lc`, `lcfirst`, `quotemeta`, and `join`. For instance, print

```
print "Hello, $world, @ladies, \u$gentlemen\E, \u\L$me!";
```

  as

```
print 'Hello, ' . $world . ', ' . join($", @ladies) . ', '
      . ucfirst($gentlemen) . ', ' . ucfirst(lc $me . '!');
```

  Note that the expanded form represents the way perl handles such constructions internally – this option actually turns off the reverse translation that `B::Deparse`

usually does. On the other hand, note that `$x = "$y"` is not the same as `$x = $y`: the former makes the value of `$y` into a string before doing the assignment.

- **-s***LETTERS*

  Tweak the style of `B::Deparse`'s output. The letters should follow directly after the 's', with no space or punctuation. The following options are available:

  - **C**

    Cuddle `elsif`, `else`, and `continue` blocks. For example, print

    ```
    if (...) {
        ...
    } else {
        ...
    }
    ```

    instead of

    ```
    if (...) {
        ...
    }
    else {
        ...
    }
    ```

    The default is not to cuddle.

  - **i***NUMBER*

    Indent lines by multiples of *NUMBER* columns. The default is 4 columns.

  - **T**

    Use tabs for each 8 columns of indent. The default is to use only spaces. For instance, if the style options are **-si4T**, a line that's indented 3 times will be preceded by one tab and four spaces; if the options were **-si8T**, the same line would be preceded by three tabs.

  - **v***STRING***.**

    Print *STRING* for the value of a constant that can't be determined because it was optimized away (mnemonic: this happens when a constant is used in **v**oid context). The end of the string is marked by a period. The string should be a valid perl expression, generally a constant. Note that unless it's a number, it probably needs to be quoted, and on a command line quotes need to be protected from the shell. Some conventional values include 0, 1, 42, '', 'foo', and 'Useless use of constant omitted' (which may need to be **-sv"'Useless use of constant omitted'."** or something similar depending on your shell). The default is '???'. If you're using `B::Deparse` on a module or other file that's `require`'d, you shouldn't use a value that evaluates to false, since the customary true constant at the end of a module will be in void context when the file is compiled as a main program.

- **-x***LEVEL*

Expand conventional syntax constructions into equivalent ones that expose their internal operation. *LEVEL* should be a digit, with higher values meaning more expansion. As with **-q**, this actually involves turning off special cases in `B::Deparse`'s normal operations.

If *LEVEL* is at least 3, `for` loops will be translated into equivalent while loops with continue blocks; for instance

```
for ($i = 0; $i < 10; ++$i) {
    print $i;
}
```

turns into

```
$i = 0;
while ($i < 10) {
    print $i;
} continue {
    ++$i
}
```

Note that in a few cases this translation can't be perfectly carried back into the source code – if the loop's initializer declares a my variable, for instance, it won't have the correct scope outside of the loop.

If *LEVEL* is at least 5, `use` declarations will be translated into `BEGIN` blocks containing calls to `require` and `import`; for instance,

```
use strict 'refs';
```

turns into

```
sub BEGIN {
    require strict;
    do {
        'strict'->import('refs')
    };
}
```

If *LEVEL* is at least 7, `if` statements will be translated into equivalent expressions using &&, `?:` and do `{}`; for instance

```
print 'hi' if $nice;
if ($nice) {
    print 'hi';
}
if ($nice) {
    print 'hi';
} else {
    print 'bye';
}
```

turns into

```
$nice and print 'hi';
$nice and do { print 'hi' };
$nice ? do { print 'hi' } : do { print 'bye' };
```

Long sequences of elsifs will turn into nested ternary operators, which `B::Deparse` doesn't know how to indent nicely.

USING B::Deparse AS A MODULE

Synopsis

```
use B::Deparse;
$deparse = B::Deparse->new("-p", "-sC");
$body = $deparse->coderef2text(\&func);
eval "sub func $body"; # the inverse operation
```

Description

`B::Deparse` can also be used on a sub-by-sub basis from other perl programs.

new

```
$deparse = B::Deparse->new(OPTIONS)
```

Create an object to store the state of a deparsing operation and any options. The options are the same as those that can be given on the command line (see "OPTIONS"); options that are separated by commas after **-MO=Deparse** should be given as separate strings.

ambient_pragmas

```
$deparse->ambient_pragmas(strict => 'all', '$' => $[);
```

The compilation of a subroutine can be affected by a few compiler directives, **pragmas**. These are:

- use strict;
- use warnings;
- Assigning to the special variable $[
- use integer;
- use bytes;
- use utf8;
- use re;

Ordinarily, if you use `B::Deparse` on a subroutine which has been compiled in the presence of one or more of these pragmas, the output will include statements to turn on the appropriate directives. So if you then compile the code returned by ["coderef2text", it will behave the same way as the subroutine which you deparsed.

However, you may know that you intend to use the results in a particular context, where some pragmas are already in scope. In this case, you use the "ambient_pragmas" method to describe the assumptions you wish to make.

Not all of the options currently have any useful effect. See "BUGS" for more details.

The parameters it accepts are:

- strict

  Takes a string, possibly containing several values separated by whitespace. The special values "all" and "none" mean what you'd expect.

```
$deparse->ambient_pragmas(strict => 'subs refs');
```

- $[

  Takes a number, the value of the array base `$[`. Obsolete: cannot be non-zero.

- bytes
- utf8
- integer

  If the value is true, then the appropriate pragma is assumed to be in the ambient scope, otherwise not.

- re

  Takes a string, possibly containing a whitespace-separated list of values. The values "all" and "none" are special. It's also permissible to pass an array reference here.

```
$deparser->ambient_pragmas(re => 'eval');
```

- warnings

  Takes a string, possibly containing a whitespace-separated list of values. The values "all" and "none" are special, again. It's also permissible to pass an array reference here.

```
$deparser->ambient_pragmas(warnings => [qw[void io]]);
```

  If one of the values is the string "FATAL", then all the warnings in that list will be considered fatal, just as with the **warnings** pragma itself. Should you need to specify that some warnings are fatal, and others are merely enabled, you can pass the **warnings** parameter twice:

```
$deparser->ambient_pragmas(
    warnings => 'all',
    warnings => [FATAL => qw/void io/],
);
```

  See *warnings* for more information about lexical warnings.

- hint_bits
- warning_bits

These two parameters are used to specify the ambient pragmas in the format used by the special variables `$^H` and `${^WARNING_BITS}`.

They exist principally so that you can write code like:

```
{ my ($hint_bits, $warning_bits);
BEGIN {($hint_bits, $warning_bits) = ($^H, ${^WARNING_BITS})}
$deparser->ambient_pragmas (
    hint_bits    => $hint_bits,
    warning_bits => $warning_bits,
    '$'          => 0 + $[
); }
```

which specifies that the ambient pragmas are exactly those which are in scope at the point of calling. However, see also [“ambient_pragmas_from_caller”.

- This parameter is used to specify the ambient pragmas which are stored in the special hash %^H.

ambient_pragmas_from_caller

```
$deparse->ambient_pragmas_from_caller()
```

A convenient shortcut for setting the hints and warnings ambient pragmas to those of the immediately calling code. This uses the *caller* function to determine the hints and warnings bits in effect at the callsite to this method, and sets those as the ambient settings for the deparser.

coderef2text

```
$body = $deparse->coderef2text(\&func)
$body = $deparse->coderef2text(sub ($$) { ... })
```

Return source code for the body of a subroutine (a block, optionally preceded by a prototype in parens), given a reference to the sub. Because a subroutine can have no names, or more than one name, this method doesn’t return a complete subroutine definition – if you want to eval the result, you should prepend “sub subname “, or “sub “ for an anonymous function constructor. Unless the sub was defined in the main:: package, the code will include a package declaration.

Normally, `B::Deparse` will emit code that includes the *feature* pragma if required to enable features that are used in the fragment that follows. However, as “coderef2text” emits only the body of a subroutine and expects the caller to prepend the `sub` and optional name onto the beginning of it, it will not have the opportunity to emit a `use feature 'signatures'` if the subroutine uses a signature, and the signatures feature is not enabled in the ambient pragmas.

In the particular situation of a subroutine that uses the `signatures` feature to parse its arguments being passed to “coderef2text” when the feature is **not** enabled in “ambient_pragmas”, `B::Deparse` will attempt to emit pure-perl code that emulates the behaviour of the signature as closely as possible. This is performed on a **best-effort** basis. It is not guaranteed to perfectly capture the semantics of the signature’s behaviour, only

to offer a human-readable suggestion as to what it might do. Furthermore, it is not guaranteed to be able to reproduce every possible behaviour of signatures in future versions of Perl. It may be that a future version introduces a behaviour that does not have a tidy way to express it in this pure-perl emulation code without using the `signatures` feature.

If this is of importance to you, make sure to use the "ambient_pragmas" or "ambient_pragmas_from_caller" method to enable the `signatures` feature, ensuring that `B::Deparse` will use it to deparse subroutines that use signatures.

BUGS

- The only pragmas to be completely supported are: `use warnings`, `use strict`, `use bytes`, `use integer` and `use feature`.

  Excepting those listed above, we're currently unable to guarantee that `B::Deparse` will produce a pragma at the correct point in the program. (Specifically, pragmas at the beginning of a block often appear right before the start of the block instead.) Since the effects of pragmas are often lexically scoped, this can mean that the pragma holds sway over a different portion of the program than in the input file.

- In fact, the above is a specific instance of a more general problem: we can't guarantee to produce `BEGIN` blocks or `use` declarations in exactly the right place. So if you use a module which affects compilation (such as by over-riding keywords, overloading constants or whatever) then the output code might not work as intended.

- Some constants don't print correctly either with or without **-d**. For instance, neither `B::Deparse` nor *Data::Dumper* know how to print dual-valued scalars correctly, as in:

```
use constant E2BIG => ($!=7); $y = E2BIG; print $y, 0+$y;

use constant H => { "#" => 1 }; H->{"#"};
```

- An input file that uses source filtering probably won't be deparsed into runnable code, because it will still include the **use** declaration for the source filtering module, even though the code that is produced is already ordinary Perl which shouldn't be filtered again.

- Optimized-away statements are rendered as '???'. This includes statements that have a compile-time side-effect, such as the obscure

```
my $x if 0;
```

  which is not, consequently, deparsed correctly.

```
  foreach my $i (@_) { 0 }
=>
  foreach my $i (@_) { '???' }
```

- Lexical (my) variables declared in scopes external to a subroutine appear in "coderef2text" output text as package variables. This is a tricky problem, as perl

has no native facility for referring to a lexical variable defined within a different scope, although *PadWalker* is a good start.

See also Data::Dump::Streamer, which combines B::Deparse and *PadWalker* to serialize closures properly.

- There are probably many more bugs on non-ASCII platforms (EBCDIC).

AUTHOR

Stephen McCamant <smcc@CSUA.Berkeley.EDU>, based on an earlier version by Malcolm Beattie mbeattie@sable.ox.ac.uk, with contributions from Gisle Aas, James Duncan, Albert Dvornik, Robin Houston, Dave Mitchell, Hugo van der Sanden, Gurusamy Sarathy, Nick Ing-Simmons, and Rafael Garcia-Suarez.

B::FM

Functions

Other Functions

LINES

Always `0`.

B::GV

Functions

B::GV methods

NAME

Return the GV's unqualified name.

FILE

Return the source file that first introduced the GV.

Synopsis

```
print $gv->FILE;    # e.g. "MyModule.pm"
```

The filename perl recorded when the glob was created or first accessed as an lvalue. An empty string for globs with no recorded origin.

STASH

Return the `B::HV` for the stash that owns the GV.

SV

Return the scalar slot of the GV as a `B::SV`.

FORM

Return the format slot of the GV as a `B::CV` (stash walking via `O=Deparse` visits every GP slot).

IO

Return the IO slot of the GV as a `B::IO`.

CVGEN

Return the GV's method-cache generation number.

AV

Return the array slot of the GV as a `B::AV`.

HV

Return the hash slot of the GV as a `B::HV`.

CV

Return the code slot of the GV as a `B::CV`.

EGV

Return the "effective" GV (`GvEGV`) - for aliased globs, the canonical one.

GvREFCNT

Return the refcount of the GV's GP (slot-bundle) record.

LINE

Return the source line where the GV was first introduced.

isGV_with_GP

Return true if the SV is a GV that has a GP slot-bundle attached.

is_empty

Return true if the GV has no slot-bundle (GP) at all.

GvFLAGS

Return the GV-specific flag bits.

GP

Return the address of the glob's GP as an integer.

GPFLAGS

Return the GP-level flag bits (GVf_INTRO, GVf_ASSUMECV, ...).

FILEGV

Return the *main::_<FILE glob for the file this GV was declared in.

NAME

Return the GV's unqualified name.

Synopsis

```
my $gv = B::svref_2object(\*main::foo);
print $gv->NAME;     # "foo"
```

The name alone, without the stash prefix. For *main::foo this is "foo"; combine with B::GV::STASH->NAME to recover the full name.

SV

Return the scalar slot of the GV as a B::SV.

Synopsis

```
our $x = 42;
my $gv = B::svref_2object(\*main::x);
print $gv->SV->IV;       # 42
```

Equivalent to *foo{SCALAR} in Perl, but wrapped as a B::SV.

B::HE

Functions

Other Functions

VAL

Return the hash entry's value as a B:: object.

SVKEY_force

Return the hash entry's key as a B:: object, whatever its storage.

HASH

Return the entry's cached hash value.

B::HV

Functions

B::HV methods

NAME

Return the package name of a stash HV.

KEYS

Return the number of keys in the hash (`HvKEYS`).

ARRAY

Return the hash's contents as a key/B-object list (stash walking: B::Deparse's stash_subs via `O=Deparse` is the main consumer).

MAX

Return the hash's bucket-array size (`HvMAX`).

FILL

Return the number of used buckets (`HvFILL`).

RITER

Return the hash's iterator position (`HvRITER`).

NAME

Return the package name of a stash HV.

Synopsis

```
my $stash = B::svref_2object(\%main::);
print $stash->NAME;     # "main"
```

Meaningful only on stash hashes (those accessible as %Pkg::). A plain user hash returns an empty string.

B::IO

Functions

Other Functions

LINES

$. - the input line number for this handle.

PAGE

$% - the current format page number.

PAGE_LEN

$= - lines per format page.

LINES_LEFT

$- - lines left on the current format page.

TOP_NAME

$^ - the name of the top-of-page format, or undef.

TOP_GV

The B::GV holding the top-of-page format.

FMT_NAME

$~ - the name of the body format, or undef.

FMT_GV

The B::GV holding the body format.

BOTTOM_NAME

The name of the bottom-of-page format, or undef.

BOTTOM_GV

The `B::GV` holding the bottom-of-page format.

IoTYPE

The handle's kind as a one-character string: `<` read, `>` write, `+` read-write, `|` pipe, `-` `-` (STDIN via ARGV), `s` socket.

IoFLAGS

The handle's flag bits (`IOf_ARGV`, `IOf_START`, `IOf_FLUSH`, `IOf_DIDTOP`, `IOf_UNTAINT`, `IOf_NOLINE`, `IOf_FAKE_DIRP`).

IsSTD

True if this IO is one of the three standard handles.

IsSTD

True if this IO is one of the three standard handles.

Synopsis

```
$io->IsSTD('stdout') and print "that's STDOUT\n";
```

Compares the actual `PerlIO *`, so it stays right after a reopen that leaves the glob's name unchanged. Croaks on any name other than `stdin`, `stdout` or `stderr`.

B::IV

Functions

B::IV methods

IVX

Return the IV slot of the wrapped SV without coercion.

UVX

Return the UV slot of the wrapped SV without coercion.

packiv

Return the IV as 8 network-order bytes.

needs64bits

True when the IV does not survive a round trip through 32 bits.

IV

Return the SV's IV slot without coercion (`B::IV::IV`).

packiv

Return the IV as 8 network-order bytes.

Synopsis

```
my $packed = B::svref_2object(\$n)->packiv;
```

A fixed-width, endian-independent encoding, so a compiler backend can emit an integer constant once and have it read back the same on any machine. Ask `needs64bits` first if you only want to spend 4 bytes.

B::LISTOP

Functions

B::OP methods

children

Return the number of children in a LISTOP.

B::LOGOP

Functions

B::OP methods

other

Return a LOGOP's alternate branch target (`op_other`).

B::LOOP

Functions

B::OP methods

redoop

Return a LOOP's redo target (op_redoop).

nextop

Return a LOOP's next target (op_nextop).

lastop

Return a LOOP's last target (op_lastop).

B::MAGIC

Functions

Other Functions

MOREMAGIC

The next magic in the chain, or undef (B::MAGIC::MOREMAGIC).

PRIVATE

mg_private (B::MAGIC::PRIVATE).

TYPE

The magic type as a one-character string (B::MAGIC::TYPE).

FLAGS

mg_flags (B::MAGIC::FLAGS).

LENGTH

mg_len (B::MAGIC::LENGTH).

OBJ

The magic's object slot as a B::* object (B::MAGIC::OBJ).

PTR

The magic's pointer slot (B::MAGIC::PTR).

REGEX

The compiled regexp behind r-magic, as an IV (`B::MAGIC::REGEX`).

precomp

The original pattern text of r-magic (`B::MAGIC::precomp`).

B::METHOP

Functions

B::OP methods

first

Return a METHOP's first child for dynamic method calls.

meth_sv

Return a METHOP's method-name SV (`meth_sv`).

rclass

Return a METHOP's redirect class SV (`rclass`).

B::NV

Functions

B::NV methods

NV

Return the floating-point value of the wrapped SV, coercing if needed.

NVX

Return the NV slot of the wrapped SV without coercion.

B::OP

Functions

B::OP methods

next

Return the next op in execution order (`op_next`).

`sibling`

Return the next syntactic sibling.

`targ`

Return the op's pad target index (`op_targ`).

`flags`

Return the op's shared flag byte (`op_flags`).

`private`

Return the op's private flag byte (`op_private`).

`name`

Return the short op name (e.g. "print").

`desc`

Return the human-readable op description.

`ppaddr`

Return a C-source reference to the op's pp function.

`type`

Return the numeric op-type code (`op_type`).

`opt`

Return the `op_opt` bit (peephole-optimised flag).

`moresib`

Return the `op_moresib` bit.

`parent`

Return the syntactic parent of the op.

`oplist`

Return every op reachable from this one in execution order.

oplist

Return every op reachable from this one in execution order.

Synopsis

```
my @ops = B::main_root->oplist;
```

Follows op_next and also descends the side chains it does not thread through - a LOGOP's other, a LOOP's redoop/nextop/lastop, a substitution's replacement, and a sort block's comparator.

This clears op_opt on every op it visits, which is how it avoids walking a shared branch twice. Run it after the peephole optimiser, and expect B::OP::opt to read 0 afterwards.

B::Op_private

OP op_private flag definitions

SYNOPSIS

```
use B::Op_private;

# flag details for bit 7 of OP_AELEM's op_private:
my $name  = $B::Op_private::bits{aelem}{7}; # OPpLVAL_INTRO
my $value = $B::Op_private::defines{$name}; # 128
my $label = $B::Op_private::labels{$name};  # LVINTRO

# the bit field at bits 5..6 of OP_AELEM's op_private:
my $bf  = $B::Op_private::bits{aelem}{6};
my $mask = $bf->{bitmask}; # etc
```

DESCRIPTION

This module provides four global hashes:

```
%B::Op_private::bits
%B::Op_private::defines
%B::Op_private::labels
%B::Op_private::ops_using
```

which contain information about the per-op meanings of the bits in the op_private field.

%bits

This is indexed by op name and then bit number (0..7). For single bit flags, it returns the name of the define (if any) for that bit:

```
$B::Op_private::bits{aelem}{7} eq 'OPpLVAL_INTRO';
```

For bit fields, it returns a hash ref containing details about the field. The same reference will be returned for all bit positions that make up the bit field; so for example these both return the same hash ref:

```
$bitfield = $B::Op_private::bits{aelem}{5};
$bitfield = $B::Op_private::bits{aelem}{6};
```

The general format of this hash ref is

```
{
    # The bit range and mask; these are always present.
    bitmin        => 5,
    bitmax        => 6,
    bitmask       => 0x60,

    # (The remaining keys are optional)

    # The names of any defines that were requested:
    mask_def      => 'OPpFOO_MASK',
    baseshift_def => 'OPpFOO_SHIFT',
    bitcount_def  => 'OPpFOO_BITS',

    # If present, Concise etc will display the value with a 'FOO='
    # prefix. If it equals '-', then Concise will treat the bit
    # field as raw bits and not try to interpret it.
    label         => 'FOO',

    # If present, specifies the names of some defines and the
    # display labels that are used to assign meaning to particu-
    # lar integer values within the bit field; e.g. 3 is dis-
    # played as 'C'.
    enum          => [ qw(
                          1   OPpFOO_A  A
                          2   OPpFOO_B  B
                          3   OPpFOO_C  C
                      )],

};
```

%defines

This gives the value of every OPp define, e.g.

```
$B::Op_private::defines{OPpLVAL_INTRO} == 128;
```

%labels

This gives the short display label for each define, as used by `B::Concise` and `perl -Dx`, e.g.

```
$B::Op_private::labels{OPpLVAL_INTRO} eq 'LVINTRO';
```

If the label equals '-', then Concise will treat the bit as a raw bit and not try to display it symbolically.

%ops_using

For each define, this gives a reference to an array of op names that use the flag.

```
@ops_using_lvintro = @{ $B::Op_private::ops_using{OPp_LVAL_INTRO} };
```

B::PADLIST

Functions

Other Functions

MAX

Return the highest index in the padlist (`PadlistMAX`).

NAMES

Return the padlist's PADNAMELIST (`PadlistNAMES`).

ARRAY

Return (NAMES, pad, pad, ...) as a list (`PadlistARRAY`).

ARRAYelt

Return the Nth padlist element (`PadlistARRAYelt`).

B::PADNAME

Functions

Other Functions

PV

Return the pad name PV with its sigil (e.g. "$x", "@arr") (`PadnamePV`).

LEN

Return the pad name length in bytes (`PadnameLEN`).

FLAGS

Return the pad name flags (`PadnameFLAGS`), with SVf_FAKE OR'd for OUTER.

TYPE

Return the padname's type stash as a B:: object (`PadnameTYPE`).

OURSTASH

Return the 'our' stash for the padname (`PadnameOURSTASH`).

B::PADNAMELIST

Functions

Other Functions

MAX

Return the highest index in the padname list (`PadnamelistMAX`).

ARRAY

Return the padnames as a list of B::PADNAME objects (`PadnamelistARRAY`).

ARRAYelt

Return the Nth padname as a B::PADNAME (`PadnamelistARRAYelt`).

B::PADOP

Functions

B::OP methods

padix

Return a PADOP's pad index (`op_padix`).

B::PMOP

Functions

B::OP methods

pmflags

Return a PMOP's compiled-pattern flags (`op_pmflags`).

pmreplroot

Return a PMOP's replacement-optree root (`pmreplroot`).

precomp

Return a PMOP's precompiled pattern source (`RX_PRECOMP`).

pmregexp

Return a PMOP's compiled regexp as a B::REGEXP.

pmoffset

Croaks: a PMOP's pattern index only exists on a threaded perl.

pmstashpv

Croaks: use `pmstash` instead - `pmstashpv` is the threaded spelling.

B::PV

Functions

B::PV methods

PV

Return the string contents of a PV SV, preserving `SVf_UTF8`.

PVX

Return the PV buffer contents as a C-style NUL-terminated string.

CUR

Return the current length in bytes of the PV buffer (`SvCUR`).

LEN

Return the allocated buffer size in bytes (`SvLEN`).

PVBM

Return the whole `SvPVX` buffer, table and all, as raw bytes.

RV

Return the referent of a reference SV as a B:: object (`B::PV::RV`).

PV

Return the string contents of a PV SV, preserving `SVf_UTF8`.

Synopsis

```
my $pv = B::svref_2object(\"hello");
print $pv->PV;
```

Returns the full `SvCUR` bytes, so embedded `\0` are kept. An SV with no PV slot returns an empty string.

B::PVLV

Functions

Other Functions

TARGOFF

Return where this lvalue's window starts inside its target.

TARGLEN

Return the length of this lvalue's window into its target.

TARG

Return the SV this lvalue is a view onto.

TYPE

Return the one-character lvalue kind: `x` substr, `.` vec, `y` defelem, `/` the `$/`-style tied slot, `t` a `local`ised element.

B::PVMG

Functions

B::SV methods

SvSTASH

B.xs `B::PVMG::SvSTASH` (an ALIAS of the PVMG accessor group, PVMG_stash_ix). B::HV and friends inherit it - sv_stash.t reaches it as `B::HV->SvSTASH`, RT#126410.

Other Functions

MAGIC

Every magic in the SV's chain, as `B::MAGIC` objects (`B::PVMG::MAGIC`).

B::RHE

Functions

Other Functions

HASH

Return the hints hash wrapped by a `B::RHE` object as a plain hash reference (`B::RHE::HASH`).

B::SV

Functions

B::SV methods

REFCNT

Return the reference count of the wrapped SV.

FLAGS

Return the raw `SvFLAGS` word of the wrapped SV.

SvTYPE

Return the SV type as a numeric `SVt_*` code.

object_2svref

Return a Perl reference back to the SV wrapped by a `B::*` object.

IsBOOL

B.xs `B::SV::SvIsBOOL` / `SvTRUE` / `SvTRUE_nomg`, PREFIX = Sv. Three separate XSUBs upstream, each `bool f(B::SV sv)`.

REFCNT

Return the reference count of the wrapped SV.

Synopsis

```
my $sv = B::svref_2object(\$x);
print $sv->REFCNT;
```

Calling `REFCNT` does not itself alter the count the `B::*` wrapper reports (the wrapper holds a weak handle, not a strong reference).

SvTYPE

Return the SV type as a numeric `SVt_*` code.

Synopsis

```
if ($sv->SvTYPE == B::SVt_PVCV) { ... }
```

Compare against `B::SVt_NULL`, `B::SVt_IV`, `B::SVt_PVCV`, etc. The blessed class of the wrapper already encodes the type at a coarser granularity; `SvTYPE` is the precise value.

object_2svref

Return a Perl reference back to the SV wrapped by a `B::*` object.

Synopsis

```
my $b   = B::svref_2object(\$x);
my $ref = $b->object_2svref;   # same as \$x
```

Inverse of `B::svref_2object`. Useful when a back-end has descended into a sub-structure via `B::*` methods and needs a plain Perl reference to the SV it's now looking at.

B::SVOP

Functions

B::OP methods

sv

Return an SVOP's SV payload (`op_sv`).

gv

Return an SVOP's GV payload (`op_sv`, GV-typed).

B::Showlex

Show lexical variables used in functions or files

SYNOPSIS

```
perl -MO=Showlex[,-OPTIONS][,SUBROUTINE] foo.pl
```

DESCRIPTION

When a comma-separated list of subroutine names is given as options, Showlex prints the lexical variables used in those subroutines. Otherwise, it prints the file-scope lexicals in the file.

EXAMPLES

Traditional form:

```
$ perl -MO=Showlex -e 'my ($i,$j,$k)=(1,"foo")'
Pad of lexical names for comppadlist has 4 entries
0: (0x8caea4) undef
1: (0x9db0fb0) $i
2: (0x9db0f38) $j
3: (0x9db0f50) $k
Pad of lexical values for comppadlist has 5 entries
0: SPECIAL #1 &PL_sv_undef
1: NULL (0x9da4234)
2: NULL (0x9db0f2c)
3: NULL (0x9db0f44)
4: NULL (0x9da4264)
-e syntax OK
```

New-style form:

```
$ perl -MO=Showlex,-newlex -e 'my ($i,$j,$k)=(1,"foo")'
main Pad has 4 entries
0: (0x8caea4) undef
1: (0xa0c4fb8) "$i" = NULL (0xa0b8234)
2: (0xa0c4f40) "$j" = NULL (0xa0c4f34)
3: (0xa0c4f58) "$k" = NULL (0xa0c4f4c)
-e syntax OK
```

New form, no specials, outside O framework:

```
$ perl -MB::Showlex -e \
   'my ($i,$j,$k)=(1,"foo"); B::Showlex::compile(-newlex,-nosp)->()'
main Pad has 4 entries
1: (0x998ffb0) "$i" = IV (0x9983234) 1
2: (0x998ff68) "$j" = PV (0x998ff5c) "foo"
3: (0x998ff80) "$k" = NULL (0x998ff74)
```

Note that this example shows the values of the lexicals, whereas the other examples did not (as they're compile-time only).

OPTIONS

The `-newlex` option produces a more readable `name => value` format, and is shown in the second example above.

The `-nosp` option eliminates reporting of SPECIALs, such as `0: SPECIAL \#1 &PL_sv_undef` above. Reporting of SPECIALs can sometimes overwhelm your declared lexicals.

SEE ALSO

B::Showlex can also be used outside of the O framework, as in the third example. See *B::Concise* for a fuller explanation of reasons.

TODO

Some of the reported info, such as hex addresses, is not particularly valuable. Other information would be more useful for the typical programmer, such as line-numbers, pad-slot reuses, etc.. Given this, -newlex is not a particularly good flag-name.

AUTHOR

Malcolm Beattie, `mbeattie@sable.ox.ac.uk`

B::Terse

Walk Perl syntax tree, printing terse info about ops

SYNOPSIS

```
perl -MO=Terse[,OPTIONS] foo.pl
```

DESCRIPTION

This module prints the contents of the parse tree, but without as much information as CPAN module B::Debug. For comparison, `print "Hello, world."` produced 96 lines of output from B::Debug, but only 6 from B::Terse.

This module is useful for people who are writing their own back end, or who are learning about the Perl internals. It's not useful to the average programmer.

This version of B::Terse is really just a wrapper that calls *B::Concise* with the **-terse** option. It is provided for compatibility with old scripts (and habits) but using B::Concise directly is now recommended instead.

For compatibility with the old B::Terse, this module also adds a method named `terse` to B::OP and B::SV objects. The B::SV method is largely compatible with the old one, though authors of new software might be advised to choose a more user-friendly output format.

The B::OP `terse` method, however, doesn't work well. Since B::Terse was first written, much more information in OPs has migrated to the scratchpad datastructure, but the `terse` interface doesn't have any way of getting to the correct pad. As a kludge, the new version will always use the pad for the main program, but for OPs in subroutines this will give the wrong answer or crash.

AUTHOR

The original version of B::Terse was written by Malcolm Beattie, mbeattie@sable.ox.ac.uk. This wrapper was written by Stephen McCamant, <smcc@MIT.EDU>.

B::UNOP

Functions

B::OP methods

`first`

Return the first child of a UNOP (`op_first`).

B::UNOP_AUX

Functions

Other Functions

`string`

Return a string representation of `op_aux` where possible.

`aux_list`

Return the contents of the `op_aux` array as a list of IV/GV/etc.

B::Xref

Generates cross reference reports for Perl programs

SYNOPSIS

perl -MO=Xref[,OPTIONS] foo.pl

DESCRIPTION

The B::Xref module is used to generate a cross reference listing of all definitions and uses of variables, subroutines and formats in a Perl program. It is implemented as a backend for the Perl compiler.

The report generated is in the following format:

```
File filename1
  Subroutine subname1
    Package package1
      object1        line numbers
      object2        line numbers
      ...
    Package package2
    ...
```

Each **File** section reports on a single file. Each **Subroutine** section reports on a single subroutine apart from the special cases "(definitions)" and "(main)". These report, respectively, on subroutine definitions found by the initial symbol table walk and on the main part of the program or module external to all subroutines.

The report is then grouped by the **Package** of each variable, subroutine or format with the special case "(lexicals)" meaning lexical variables. Each **object** name (implicitly qualified by its containing **Package**) includes its type character(s) at the beginning where possible. Lexical variables are easier to track and even included dereferencing information where possible.

The `line numbers` are a comma separated list of line numbers (some preceded by code letters) where that object is used in some way. Simple uses aren't preceded by a code letter. Introductions (such as where a lexical is first defined with `my`) are indicated with the letter "i". Subroutine and method calls are indicated by the character "&". Subroutine definitions are indicated by "s" and format definitions by "f".

For instance, here's part of the report from the *pod2man* program that comes with Perl:

```
Subroutine clear_noremap
  Package (lexical)
    $ready_to_print   i1069, 1079
  Package main
    $&                1086
    $.                1086
    $0                1086
    $1                1087
    $2                1085, 1085
    $3                1085, 1085
    $ARGV             1086
    %HTML_Escapes     1085, 1085
```

This shows the variables used in the subroutine `clear_noremap`. The variable `$ready_to_print` is a my() (lexical) variable, **i**ntroduced (first declared with my()) on line 1069, and used on line 1079. The variable `$&` from the main package is used on 1086, and so on.

A line number may be prefixed by a single letter:

- i

  Lexical variable introduced (declared with my()) for the first time.

- &

  Subroutine or method call.

- s

  Subroutine defined.

- r

  Format defined.

The most useful option the cross referencer has is to save the report to a separate file. For instance, to save the report on *myperlprogram* to the file *report*:

```
$ perl -MO=Xref,-oreport myperlprogram
```

OPTIONS

Option words are separated by commas (not whitespace) and follow the usual conventions of compiler backend options.

- `-oFILENAME`

  Directs output to `FILENAME` instead of standard output.

- `-r`

  Raw output. Instead of producing a human-readable report, outputs a line in machine-readable form for each definition/use of a variable/sub/format.

- `-d`

  Don't output the "(definitions)" sections.

- `-D[tO]`

  (Internal) debug options, probably only useful if `-r` included. The `t` option prints the object on the top of the stack as it's being tracked. The `O` option prints each operator as it's being processed in the execution order of the program.

BUGS

Non-lexical variables are quite difficult to track through a program. Sometimes the type of a non-lexical variable's use is impossible to determine. Introductions of non-lexical non-scalars don't seem to be reported properly.

AUTHOR

Malcolm Beattie, mbeattie@sable.ox.ac.uk.

svref_2object

Wrap a reference's referent as a `B::*` object.

Synopsis

```
my $obj = B::svref_2object(\&some_sub);
my $cv  = B::svref_2object(\&main::foo);   # returns B::CV
my $av  = B::svref_2object(\@ARGV);        # returns B::AV
```

Given a Perl reference, return a blessed `B::*` object that wraps the underlying SV, AV, HV, CV, GV, etc. Croaks with `argument is not a reference` if the input is not a reference. This is the usual entry point into `B`: most introspection starts from a reference the caller already has.

opnumber

Return the numeric op-type for an op name, or `-1` if unknown.

Synopsis

```
my $n = B::opnumber("print");      # numeric type
my $n = B::opnumber("pp_print");   # leading "pp_" is tolerated
```

Accepts either the bare name or the pp_-prefixed form. The returned integer is an index into perl's global op-name / op-desc tables and is the value `B::OP::type` produces.

main_root

Return a `B::OP` for the root of the program's main optree.

Synopsis

```
my $root = B::main_root;
$root->name;     # typically "leave"
```

The root op is the top of the tree that `B::Deparse` and friends walk. Paired with `B::main_start`, which gives the entry point in execution order.

walkoptree

Recursively walk an optree, calling `$method` on each op.

Synopsis

```
B::walkoptree(B::main_root, "visit");
```

Each op is blessed into its `B::*OP` class and then `$method` is dispatched on it. Children are visited after the parent. Back-end classes such as `B::Concise` define a visit method on their own package and call `walkoptree` to drive tree-traversal without writing the walk themselves.

walkoptree_debug

Get or set the `walkoptree` debug flag.

Synopsis

```
my $prev = B::walkoptree_debug(1);    # enable
B::walkoptree_debug($prev);           # restore
```

When enabled, `B::walkoptree` also calls a `walkoptree_debug` method on each node before the regular visit method, which lets a back-end print diagnostics as it walks. Returns the previous flag value.

cstring

Return `$sv`'s contents as a double-quoted C-style string literal.

Synopsis

```
B::cstring("hi\tthere");   # "hi\tthere"
B::cstring(undef);         # 0
```

Unprintable bytes become `\n`, `\t`, `\r`, `\a`, `\b`, `\f`, `\v`, or octal escapes. An undef SV renders as the literal `0` (no quotes), which is the convention `B::Deparse` depends on. Used by back-ends that emit C-level source.

cchar

Return the first character of `$sv` as a single-quoted C character literal.

Synopsis

```
B::cchar("A");    # 'A'
B::cchar("\n");   # '\n'
```

Non-printable bytes are escaped the same way as in `B::cstring`. Only the first byte is inspected.

hash

Return perl's hash of a string, formatted as `0xNNNNNNNN`.

Synopsis

```
my $h = B::hash("foo");    # e.g. "0x2ad53e4d"
```

Uses the same hash function the interpreter uses for hash keys, so the value is useful for reasoning about bucket placement and hash collisions in a live hash, not as a general-purpose checksum.

comppadlist

Return the padlist of the currently-compiling unit as a `B::PADLIST`.

Synopsis

```
my $pad = B::comppadlist;
my ($names, $vals) = $pad->ARRAY;
```

At run time this is `PL_main_cv`'s padlist - the file-scope lexicals of the main program. Inside a `CHECK`/`INIT` block during compilation it is `PL_compcv`'s. `B::Xref` starts every cross-reference here.

B::GV::SAFENAME

Return the GV's name with a leading control character rendered as `^X`.

Synopsis

```
B::svref_2object(\*{"main::\cA"})->SAFENAME;   # "^A"
```

The single-character control names (`*^A`, `*^D`, `*^?`) appear in the stash with raw control bytes in their name; `SAFENAME` renders them in the caret form normally used in Perl source. Only the first character is converted, so `*^WARNING_BITS` gives `^WARNING_BITS`; the conversion itself is `B::safename`.

safename

Return a string with a leading control character rendered as `^X`.

Synopsis

```
use B qw(safename);
safename("\cGx");     # "^Gx"
safename("\x7f");     # "^?"
safename("a\cG");     # "a\cG" - only the first character is
 ↪converted
```

A first character in `\cA` to `\cZ`, `\c[`, `\c\`, `\c]`, `\c^` or `\c_` becomes `^` followed by the matching printable character, and `\c?` (DEL) becomes `^?`; everything else is returned unchanged. This is the conversion `B::GV::SAFENAME` applies to a glob's name, and the form Perl source uses for variables such as `${^WARNING_BITS}`.

Exported on request.

5.2.10 Benchmark

Benchmark running times of Perl code

SYNOPSIS

```
use Benchmark qw(:all);

timethis($count, "code");

# Use Perl code in strings...
timethese($count, {
    'Name1' => '...code1...',
    'Name2' => '...code2...',
});

# ... or use subroutine references.
timethese($count, {
    'Name1' => sub { ...code1... },
    'Name2' => sub { ...code2... },
});

# cmpthese can be used both ways as well
cmpthese($count, {
    'Name1' => '...code1...',
    'Name2' => '...code2...',
});

cmpthese($count, {
    'Name1' => sub { ...code1... },
    'Name2' => sub { ...code2... },
});

# ...or in two stages
$results = timethese($count,
    {
        'Name1' => sub { ...code1... },
        'Name2' => sub { ...code2... },
    },
    'none'
);
cmpthese( $results );

my $t1 = timeit($count, '...other code...');
print "$count loops of other code took:", timestr($t1),"\n";

my $t2 = countit($time, '...other code...');
$count = $t2->iters;
print "$count loops of other code took:", timestr($t2),"\n";

# Enable hires wallclock timing if possible
use Benchmark ':hireswallclock';
```

DESCRIPTION

The `Benchmark` module encapsulates a number of routines to help you figure out how long it takes to execute some code.

`timethis` - Run a chunk of code several times

`timethese` - Run several chunks of code several times

`cmpthese` - Print results of `timethese` as a comparison chart

`timeit` - Run a chunk of code and see how long it goes

`countit` - See how many times a chunk of code runs in a given time

Methods

- new

  Returns the current time. Example:

```
use Benchmark;
my $t0 = Benchmark->new;
# ... your code here ...
my $t1 = Benchmark->new;
my $td = timediff($t1, $t0);
print "the code took:",timestr($td),"\n";
```

- debug

  Enables or disable debugging by setting the `$Benchmark::Debug` flag:

```
Benchmark->debug(1);
my $t = timeit(10, ' 5 ** $Global ');
Benchmark->debug(0);
```

- iters

  Returns the number of iterations.

Standard Exports

The following routines will be exported into your namespace if you use the Benchmark module:

- timeit(COUNT, CODE)

  Arguments: COUNT is the number of times to run the loop, and CODE is the code to run. CODE may be either a code reference or a string to be eval'd; either way it will be run in the caller's package.

  Returns: a Benchmark object.

- timethis (COUNT, CODE, [TITLE, [STYLE]])

  Time COUNT iterations of CODE. CODE may be a string to eval or a code reference; either way the CODE will run in the caller's package. Results will be printed to STDOUT as TITLE followed by the times. TITLE defaults to "timethis COUNT" if

none is provided. STYLE determines the format of the output, as described for timestr() below.

The COUNT can be zero or negative: this means the *minimum number of CPU seconds* to run. A zero signifies the default of 3 seconds. For example to run at least for 10 seconds:

```
timethis(-10, $code);
```

or to run two pieces of code tests for at least 3 seconds:

```
timethese(0, { test1 => '...', test2 => '...'});
```

CPU seconds is, in UNIX terms, the user time plus the system time of the process itself, as opposed to the real (wallclock) time and the time spent by the child processes. Less than 0.1 seconds is not accepted (-0.01 as the count, for example, will cause a fatal runtime exception).

Note that the CPU seconds is the **minimum** time: CPU scheduling and other operating system factors may complicate the attempt so that a little bit more time is spent. The benchmark output will, however, also tell the number of `$code` runs/second, which should be a more interesting number than the actually spent seconds.

Returns a Benchmark object.

- timethese (COUNT, CODEHASHREF, [STYLE])

  The CODEHASHREF is a reference to a hash containing names as keys and either a string to eval or a code reference for each value. For each (KEY, VALUE) pair in the CODEHASHREF, this routine will call

  ```
  timethis(COUNT, VALUE, KEY, STYLE);
  ```

  The routines are called in string comparison order of KEY.

  The COUNT can be zero or negative, see timethis().

  Returns a hash reference of Benchmark objects, keyed by name.

- timediff (T1, T2)

  Returns the difference between two Benchmark times as a Benchmark object suitable for passing to timestr().

- timestr (TIMEDIFF, [STYLE, [FORMAT]])

  Returns a string that formats the times in the TIMEDIFF object in the requested STYLE. TIMEDIFF is expected to be a Benchmark object similar to that returned by timediff().

  STYLE can be any of 'all', 'none', 'noc', 'nop' or 'auto'. 'all' shows each of the 5 times available ('wallclock' time, user time, system time, user time of children, and system time of children). 'noc' shows all except the two children times. 'nop' shows only wallclock and the two children times. 'auto' (the default) will act as 'all' unless the children times are both zero, in which case it acts as 'noc'. 'none' prevents output.

  FORMAT is the printf(3)-style format specifier (without the leading '%') to use to print the times. It defaults to '5.2f'.

Optional Exports

The following routines will be exported into your namespace if you specifically ask that they be imported:

- clearcache (COUNT)

  Clear the cached time for COUNT rounds of the null loop.

- clearallcache ( )

  Clear all cached times.

- cmpthese (COUNT, CODEHASHREF, [STYLE])

- cmpthese (RESULTSHASHREF, [STYLE])

  Optionally calls timethese(), then outputs comparison chart. This:

```
cmpthese( -1, { a => "++\$i", b => "\$i *= 2" } );
```

  outputs a chart like:

```
       Rate    b    a
b 2831802/s   -- -61%
a 7208959/s 155%   --
```

  This chart is sorted from slowest to fastest, and shows the percent speed difference between each pair of tests.

  `cmpthese` can also be passed the data structure that timethese() returns:

```
my $results = timethese( -1,
    { a => "++\$i", b => "\$i *= 2" } );
cmpthese( $results );
```

  in case you want to see both sets of results. If the first argument is an unblessed hash reference, that is RESULTSHASHREF; otherwise that is COUNT.

  Returns a reference to an ARRAY of rows, each row is an ARRAY of cells from the above chart, including labels. This:

```
my $rows = cmpthese( -1,
    { a => '++$i', b => '$i *= 2' }, "none" );
```

  returns a data structure like:

```
[
    [ '',       'Rate',   'b',    'a' ],
    [ 'b', '2885232/s',  '--', '-59%' ],
    [ 'a', '7099126/s', '146%',  '--' ],
]
```

  NOTE: This result value differs from previous versions, which returned the `timethese()` result structure. If you want that, just use the two statement `timethese...cmpthese` idiom shown above.

Incidentally, note the variance in the result values between the two examples; this is typical of benchmarking. If this were a real benchmark, you would probably want to run a lot more iterations.

- countit(TIME, CODE)

  Arguments: TIME is the minimum length of time to run CODE for, and CODE is the code to run. CODE may be either a code reference or a string to be eval'd; either way it will be run in the caller's package.

  TIME is *not* negative. countit() will run the loop many times to calculate the speed of CODE before running it for TIME. The actual time run for will usually be greater than TIME due to system clock resolution, so it's best to look at the number of iterations divided by the times that you are concerned with, not just the iterations.

  Returns: a Benchmark object.

- disablecache ( )

  Disable caching of timings for the null loop. This will force Benchmark to recalculate these timings for each new piece of code timed.

- enablecache ( )

  Enable caching of timings for the null loop. The time taken for COUNT rounds of the null loop will be calculated only once for each different COUNT used.

- timesum (T1, T2)

  Returns the sum of two Benchmark times as a Benchmark object suitable for passing to timestr().

:hireswallclock

If the Time::HiRes module has been installed, you can specify the special tag `:hireswallclock` for Benchmark (if Time::HiRes is not available, the tag will be silently ignored). This tag will cause the wallclock time to be measured in microseconds, instead of integer seconds. Note though that the speed computations are still conducted in CPU time, not wallclock time.

Benchmark Object

Many of the functions in this module return a Benchmark object, or in the case of `timethese()`, a reference to a hash, the values of which are Benchmark objects. This is useful if you want to store or further process results from Benchmark functions.

Internally the Benchmark object holds timing values, described in "NOTES" below. The following methods can be used to access them:

- cpu_p

  Total CPU (User + System) of the main (parent) process.

- cpu_c

  Total CPU (User + System) of any children processes.

- cpu_a

  Total CPU of parent and any children processes.

- real

  Real elapsed time “wallclock seconds”.

- iters

  Number of iterations run.

The following illustrates use of the Benchmark object:

```
my $result = timethis(100000, sub { ... });
print "total CPU = ", $result->cpu_a, "\n";
```

NOTES

The data is stored as a list of values from the time and times functions:

```
($real, $user, $system, $children_user, $children_system, $iters)
```

in seconds for the whole loop (not divided by the number of rounds).

The timing is done using time(3) and times(3).

Code is executed in the caller’s package.

The time of the null loop (a loop with the same number of rounds but empty loop body) is subtracted from the time of the real loop.

The null loop times can be cached, the key being the number of rounds. The caching can be controlled using calls like these:

```
clearcache($key);
clearallcache();

disablecache();
enablecache();
```

Caching is off by default, as it can (usually slightly) decrease accuracy and does not usually noticeably affect runtimes.

EXAMPLES

For example,

```
use Benchmark qw( cmpthese ) ;
my $x = 3;
cmpthese( -5, {
    a => sub{$x*$x},
    b => sub{$x**2},
} );
```

outputs something like this:

```
Benchmark: running a, b, each for at least 5 CPU seconds...
       Rate    b    a
```

(continues on next page)

(continued from previous page)

```
b 1559428/s   -- -62%
a 4152037/s 166%   --
```

while

```
use Benchmark qw( timethese cmpthese ) ;
my $x = 3;
my $r = timethese( -5, {
    a => sub{$x*$x},
    b => sub{$x**2},
} );
cmpthese $r;
```

outputs something like this:

```
Benchmark: running a, b, each for at least 5 CPU seconds...
         a: 10 wallclock secs ( 5.14 usr +  0.13 sys =  5.27 CPU) @␣
↪3835055.60/s (n=20210743)
         b:  5 wallclock secs ( 5.41 usr +  0.00 sys =  5.41 CPU) @␣
↪1574944.92/s (n=8520452)
       Rate    b    a
b 1574945/s   -- -59%
a 3835056/s 144%   --
```

INHERITANCE

Benchmark inherits from no other class, except of course from Exporter.

CAVEATS

Comparing eval'd strings with code references will give you inaccurate results: a code reference will show a slightly slower execution time than the equivalent eval'd string.

The real time timing is done using time(2) and the granularity is therefore only one second.

Short tests may produce negative figures because perl can appear to take longer to execute the empty loop than a short test; try:

```
timethis(100,'1');
```

The system time of the null loop might be slightly more than the system time of the loop with the actual code and therefore the difference might end up being < 0.

Devel::NYTProf - a Perl code profiler

AUTHORS

Jarkko Hietaniemi <jhi@iki.fi>, Tim Bunce <Tim.Bunce@ig.co.uk>

MODIFICATION HISTORY

September 8th, 1994; by Tim Bunce.

March 28th, 1997; by Hugo van der Sanden: added support for code references and the already documented 'debug' method; revamped documentation.

April 04-07th, 1997: by Jarkko Hietaniemi, added the run-for-some-time functionality.

September, 1999; by Barrie Slaymaker: math fixes and accuracy and efficiency tweaks. Added cmpthese(). A result is now returned from timethese(). Exposed countit() (was runfor()).

December, 2001; by Nicholas Clark: make timestr() recognise the style 'none' and return an empty string. If cmpthese is calling timethese, make it pass the style in. (so that 'none' will suppress output). Make sub new dump its debugging output to STDERR, to be consistent with everything else. All bugs found while writing a regression test.

September, 2002; by Jarkko Hietaniemi: add ':hireswallclock' special tag.

February, 2004; by Chia-liang Kao: make cmpthese and timestr use time statistics for children instead of parent when the style is 'nop'.

November, 2007; by Christophe Grosjean: make cmpthese and timestr compute time consistently with style argument, default is 'all' not 'noc' any more.

5.2.11 CPAN

query, download and build perl modules from CPAN sites

SYNOPSIS

Interactive mode:

```
perl -MCPAN -e shell
```

–or–

```
cpan
```

Basic commands:

```
# Modules:

cpan> install Acme::Meta                        # in the shell

CPAN::Shell->install("Acme::Meta");              # in perl

# Distributions:

cpan> install NWCLARK/Acme-Meta-0.02.tar.gz     # in the shell
```

(continues on next page)

(continued from previous page)

```
CPAN::Shell->
  install("NWCLARK/Acme-Meta-0.02.tar.gz");    # in perl

# module objects:

$mo = CPAN::Shell->expandany($mod);
$mo = CPAN::Shell->expand("Module",$mod);      # same thing

# distribution objects:

$do = CPAN::Shell->expand("Module",$mod)->distribution;
$do = CPAN::Shell->expandany($distro);         # same thing
$do = CPAN::Shell->expand("Distribution",
                          $distro);            # same thing
```

DESCRIPTION

The CPAN module automates or at least simplifies the make and install of perl modules and extensions. It includes some primitive searching capabilities and knows how to use LWP, HTTP::Tiny, Net::FTP and certain external download clients to fetch distributions from the net.

These are fetched from one or more mirrored CPAN (Comprehensive Perl Archive Network) sites and unpacked in a dedicated directory.

The CPAN module also supports named and versioned *bundles* of modules. Bundles simplify handling of sets of related modules. See Bundles below.

The package contains a session manager and a cache manager. The session manager keeps track of what has been fetched, built, and installed in the current session. The cache manager keeps track of the disk space occupied by the make processes and deletes excess space using a simple FIFO mechanism.

All methods provided are accessible in a programmer style and in an interactive shell style.

CPAN::shell([$prompt, $command]) Starting Interactive Mode

Enter interactive mode by running

```
perl -MCPAN -e shell
```

or

```
cpan
```

which puts you into a readline interface. If `Term::ReadKey` and either of `Term::ReadLine::Perl` or `Term::ReadLine::Gnu` are installed, history and command completion are supported.

Once at the command line, type h for one-page help screen; the rest should be self-explanatory.

The function call `shell` takes two optional arguments: one the prompt, the second the default initial command line (the latter only works if a real ReadLine interface module is installed).

The most common uses of the interactive modes are

- Searching for authors, bundles, distribution files and modules

  There are corresponding one-letter commands `a`, `b`, `d`, and `m` for each of the four categories and another, `i` for any of the mentioned four. Each of the four entities is implemented as a class with slightly differing methods for displaying an object.

  Arguments to these commands are either strings exactly matching the identification string of an object, or regular expressions matched case-insensitively against various attributes of the objects. The parser only recognizes a regular expression when you enclose it with slashes.

  The principle is that the number of objects found influences how an item is displayed. If the search finds one item, the result is displayed with the rather verbose method `as_string`, but if more than one is found, each object is displayed with the terse method `as_glimpse`.

  Examples:

```
cpan> m Acme::MetaSyntactic
Module id = Acme::MetaSyntactic
    CPAN_USERID  BOOK (Philippe Bruhat (BooK) <[...]>)

Module    Filter::NumberLines    (BEATNIK/Filter-NumberLines-0.
↪02.tar.gz)
Author          [...]
```

The examples illustrate several aspects: the first three queries target modules, authors, or distros directly and yield exactly one result. The last two use regular expressions and yield several results. The last one targets all of bundles, modules, authors, and distros simultaneously. When more than one result is available, they are printed in one-line format.

- `get`, `make`, `test`, `install`, `clean` modules or distributions

  These commands take any number of arguments and investigate what is necessary to perform the action. Argument processing is as follows:

```
known module name in format Foo/Bar.pm   module
other embedded slash                     distribution
  - with trailing slash dot              directory
enclosing slashes                        regexp
known module name in format Foo::Bar     module
```

  If the argument is a distribution file name (recognized by embedded slashes), it is processed. If it is a module, CPAN determines the distribution file in which this module is included and processes that, following any dependencies named in the module's META.yml or Makefile.PL (this behavior is controlled by the configuration parameter `prerequisites_policy`). If an argument is enclosed in slashes it is treated as a regular expression: it is expanded and if the result is a single object (distribution, bundle or module), this object is processed.

  Example:

```
install Dummy::Perl                    # installs the module
install AUXXX/Dummy-Perl-3.14.tar.gz   # installs that␣
↪distribution
install /Dummy-Perl-3.14/              # same if the regexp is␣
↪unambiguous
```

  `get` downloads a distribution file and untars or unzips it, `make` builds it, `test` runs the test suite, and `install` installs it.

  Any `make` or `test` is run unconditionally. An

```
install <distribution_file>
```

  is also run unconditionally. But for

```
install <module>
```

CPAN checks whether an install is needed and prints *module up to date* if the distribution file containing the module doesn't need updating.

CPAN also keeps track of what it has done within the current session and doesn't try to build a package a second time regardless of whether it succeeded or not. It does not repeat a test run if the test has been run successfully before. Same for install runs.

The `force` pragma may precede another command (currently: `get`, `make`, `test`, or `install`) to execute the command from scratch and attempt to continue past certain errors. See the section below on the `force` and the `fforce` pragma.

The `notest` pragma skips the test part in the build process.

Example:

```
cpan> notest install Tk
```

A `clean` command results in a

```
make clean
```

being executed within the distribution file's working directory.

- `readme`, `perldoc`, `look` module or distribution

  `readme` displays the README file of the associated distribution. `Look` gets and untars (if not yet done) the distribution file, changes to the appropriate directory and opens a subshell process in that directory. `perldoc` displays the module's pod documentation in html or plain text format.

- `ls` author
- `ls` globbing_expression

  The first form lists all distribution files in and below an author's CPAN directory as stored in the CHECKSUMS files distributed on CPAN. The listing recurses into subdirectories.

  The second form limits or expands the output with shell globbing as in the following examples:

```
ls JV/make*
ls GSAR/*make*
ls */*make*
```

  The last example is very slow and outputs extra progress indicators that break the alignment of the result.

  Note that globbing only lists directories explicitly asked for, for example FOO/* will not list FOO/bar/Acme-Sthg-n.nn.tar.gz. This may be regarded as a bug that may be changed in some future version.

- `failed`

The `failed` command reports all distributions that failed on one of `make`, `test` or `install` for some reason in the currently running shell session.

- Persistence between sessions

  If the `YAML` or the `YAML::Syck` module is installed a record of the internal state of all modules is written to disk after each step. The files contain a signature of the currently running perl version for later perusal.

  If the configurations variable `build_dir_reuse` is set to a true value, then CPAN.pm reads the collected YAML files. If the stored signature matches the currently running perl, the stored state is loaded into memory such that persistence between sessions is effectively established.

- The `force` and the `fforce` pragma

  To speed things up in complex installation scenarios, CPAN.pm keeps track of what it has already done and refuses to do some things a second time. A `get`, a `make`, and an `install` are not repeated. A `test` is repeated only if the previous test was unsuccessful. The diagnostic message when CPAN.pm refuses to do something a second time is one of _Has already been `_unwrapped|made|tested successfully` or something similar. Another situation where CPAN refuses to act is an `install` if the corresponding `test` was not successful.

  In all these cases, the user can override this stubborn behaviour by prepending the command with the word force, for example:

```
cpan> force get Foo
cpan> force make AUTHOR/Bar-3.14.tar.gz
cpan> force test Baz
cpan> force install Acme::Meta
```

  Each *forced* command is executed with the corresponding part of its memory erased.

  The `fforce` pragma is a variant that emulates a `force get` which erases the entire memory followed by the action specified, effectively restarting the whole get/make/test/install procedure from scratch.

- Lockfile

  Interactive sessions maintain a lockfile, by default `~/.cpan/.lock`. Batch jobs can run without a lockfile and not disturb each other.

  The shell offers to run in *downgraded mode* when another process is holding the lockfile. This is an experimental feature that is not yet tested very well. This second shell then does not write the history file, does not use the metadata file, and has a different prompt.

- Signals

  CPAN.pm installs signal handlers for SIGINT and SIGTERM. While you are in the cpan-shell, it is intended that you can press `^C` anytime and return to the cpan-shell prompt. A SIGTERM will cause the cpan-shell to clean up and leave the shell loop. You can emulate the effect of a SIGTERM by sending two consecutive SIGINTs, which usually means by pressing `^C` twice.

CPAN.pm ignores SIGPIPE. If the user sets `inactivity_timeout`, a SIGALRM is used during the run of the `perl Makefile.PL` or `perl Build.PL` subprocess. A SIGALRM is also used during module version parsing, and is controlled by `version_timeout`.

CPAN::Shell

The commands available in the shell interface are methods in the package CPAN::Shell. If you enter the shell command, your input is split by the Text::ParseWords::shellwords() routine, which acts like most shells do. The first word is interpreted as the method to be invoked, and the rest of the words are treated as the method's arguments. Continuation lines are supported by ending a line with a literal backslash.

autobundle

`autobundle` writes a bundle file into the `$CPAN::Config->{cpan_home}/Bundle` directory. The file contains a list of all modules that are both available from CPAN and currently installed within @INC. Duplicates of each distribution are suppressed. The name of the bundle file is based on the current date and a counter, e.g. `Bundle/Snapshot_2012_05_21_00.pm`. This is installed again by running `cpan Bundle::Snapshot_2012_05_21_00`, or installing `Bundle::Snapshot_2012_05_21_00` from the CPAN shell.

Return value: path to the written file.

hosts

Note: this feature is still in alpha state and may change in future versions of CPAN.pm

This commands provides a statistical overview over recent download activities. The data for this is collected in the YAML file `FTPstats.yml` in your `cpan_home` directory. If no YAML module is configured or YAML not installed, or if `ftpstats_size` is set to a value `<=0`, no stats are provided.

install_tested

Install all distributions that have been tested successfully but have not yet been installed. See also `is_tested`.

is_tested

List all build directories of distributions that have been tested successfully but have not yet been installed. See also `install_tested`.

mkmyconfig

mkmyconfig() writes your own CPAN::MyConfig file into your `~/.cpan/` directory so that you can save your own preferences instead of the system-wide ones.

r [Module|/Regexp/]...

scans current perl installation for modules that have a newer version available on CPAN and provides a list of them. If called without argument, all potential upgrades are listed; if called with arguments the list is filtered to the modules and regexps given as arguments.

The listing looks something like this:

```
Package namespace         installed    latest  in CPAN file
CPAN                        1.94_64    1.9600  ANDK/CPAN-1.9600.tar.
 ↪gz
CPAN::Reporter               1.1801    1.1902  DAGOLDEN/CPAN-
 ↪Reporter-1.1902.tar.gz
YAML                           0.70      0.73  INGY/YAML-0.73.tar.gz
YAML::Syck                     1.14      1.17  AVAR/YAML-Syck-1.17.
 ↪tar.gz
YAML::Tiny                     1.44      1.50  ADAMK/YAML-Tiny-1.50.
 ↪tar.gz
CGI                            3.43      3.55  MARKSTOS/CGI.pm-3.55.
 ↪tar.gz
Module::Build::YAML            1.40      1.41  DAGOLDEN/Module-
 ↪Build-0.3800.tar.gz
TAP::Parser::Result::YAML      3.22      3.23  ANDYA/Test-Harness-3.
 ↪23.tar.gz
YAML::XS                       0.34      0.35  INGY/YAML-LibYAML-0.
 ↪35.tar.gz
```

It suppresses duplicates in the column `in CPAN file` such that distributions with many upgradeable modules are listed only once.

Note that the list is not sorted.

recent ***EXPERIMENTAL COMMAND***

The `recent` command downloads a list of recent uploads to CPAN and displays them *slowly*. While the command is running, a $SIG{INT} exits the loop after displaying the current item.

Note: This command requires XML::LibXML installed.

Note: This whole command currently is just a hack and will probably change in future versions of CPAN.pm, but the general approach will likely remain.

Note: See also smoke

recompile

The primary purpose of this command is to finish a network installation. Imagine you have a common source tree for two different architectures. You decide to do a completely independent fresh installation. You start on one architecture with the help of a Bundle file produced earlier. CPAN installs the whole Bundle for you, but when you try to repeat the job on the second architecture, CPAN responds with a `"Foo up to date"`

message for all modules. So you invoke CPAN's recompile on the second architecture and you're done.

Another popular use for `recompile` is to act as a rescue in case your perl breaks binary compatibility. If one of the modules that CPAN uses is in turn depending on binary compatibility (so you cannot run CPAN commands), then you should try the CPAN::Nox module for recovery.

report Bundle|Distribution|Module

The `report` command temporarily turns on the `test_report` config variable, then runs the `force test` command with the given arguments. The `force` pragma reruns the tests and repeats every step that might have failed before.

smoke ***EXPERIMENTAL COMMAND***

***** WARNING: this command downloads and executes software from CPAN to your computer of completely unknown status. You should never do this with your normal account and better have a dedicated well separated and secured machine to do this. *****

The `smoke` command takes the list of recent uploads to CPAN as provided by the `recent` command and tests them all. While the command is running $SIG{INT} is defined to mean that the current item shall be skipped.

Note: This whole command currently is just a hack and will probably change in future versions of CPAN.pm, but the general approach will likely remain.

Note: See also recent

upgrade [Module|/Regexp/]...

The `upgrade` command first runs an `r` command with the given arguments and then installs the newest versions of all modules that were listed by that.

The four CPAN::* Classes: Author, Bundle, Module, Distribution

Although it may be considered internal, the class hierarchy does matter for both users and programmer. CPAN.pm deals with the four classes mentioned above, and those classes all share a set of methods. Classical single polymorphism is in effect. A metaclass object registers all objects of all kinds and indexes them with a string. The strings referencing objects have a separated namespace (well, not completely separated):

```
      Namespace                         Class

words containing a "/" (slash)      Distribution
 words starting with Bundle::          Bundle
       everything else             Module or Author
```

Modules know their associated Distribution objects. They always refer to the most recent official release. Developers may mark their releases as unstable development versions (by inserting an underscore into the module version number which will also be reflected in the distribution name when you run 'make dist'), so the really hottest and

newest distribution is not always the default. If a module Foo circulates on CPAN in both version 1.23 and 1.23_90, CPAN.pm offers a convenient way to install version 1.23 by saying

```
install Foo
```

This would install the complete distribution file (say BAR/Foo-1.23.tar.gz) with all accompanying material. But if you would like to install version 1.23_90, you need to know where the distribution file resides on CPAN relative to the authors/id/ directory. If the author is BAR, this might be BAR/Foo-1.23_90.tar.gz; so you would have to say

```
install BAR/Foo-1.23_90.tar.gz
```

The first example will be driven by an object of the class CPAN::Module, the second by an object of class CPAN::Distribution.

Integrating local directories

Note: this feature is still in alpha state and may change in future versions of CPAN.pm

Distribution objects are normally distributions from the CPAN, but there is a slightly degenerate case for Distribution objects, too, of projects held on the local disk. These distribution objects have the same name as the local directory and end with a dot. A dot by itself is also allowed for the current directory at the time CPAN.pm was used. All actions such as `make`, `test`, and `install` are applied directly to that directory. This gives the command `cpan .` an interesting touch: while the normal mantra of installing a CPAN module without CPAN.pm is one of

```
perl Makefile.PL                  perl Build.PL
       ( go and get prerequisites )
make                              ./Build
make test                         ./Build test
make install                      ./Build install
```

the command `cpan .` does all of this at once. It figures out which of the two mantras is appropriate, fetches and installs all prerequisites, takes care of them recursively, and finally finishes the installation of the module in the current directory, be it a CPAN module or not.

The typical usage case is for private modules or working copies of projects from remote repositories on the local disk.

Redirection

The usual shell redirection symbols | and > are recognized by the cpan shell **only when surrounded by whitespace**. So piping to pager or redirecting output into a file works somewhat as in a normal shell, with the stipulation that you must type extra spaces.

Plugin support ***EXPERIMENTAL***

Plugins are objects that implement any of currently eight methods:

```
pre_get
post_get
pre_make
post_make
pre_test
post_test
pre_install
post_install
```

The `plugin_list` configuration parameter holds a list of strings of the form

```
Modulename=arg0,arg1,arg2,arg3,...
```

eg:

```
CPAN::Plugin::Flurb=dir,/opt/pkgs/flurb/raw,verbose,1
```

At run time, each listed plugin is instantiated as a singleton object by running the equivalent of this pseudo code:

```
my $plugin = <string representation from config>;
<generate Modulename and arguments from $plugin>;
my $p = $instance{$plugin} ||= Modulename->new($arg0,$arg1,...);
```

The generated singletons are kept around from instantiation until the end of the shell session. <plugin_list> can be reconfigured at any time at run time. While the cpan shell is running, it checks all activated plugins at each of the 8 reference points listed above and runs the respective method if it is implemented for that object. The method is called with the active CPAN::Distribution object passed in as an argument.

CONFIGURATION

When the CPAN module is used for the first time, a configuration dialogue tries to determine a couple of site specific options. The result of the dialog is stored in a hash reference `$CPAN::Config` in a file CPAN/Config.pm.

Default values defined in the CPAN/Config.pm file can be overridden in a user specific file: CPAN/MyConfig.pm. Such a file is best placed in `$HOME/.cpan/CPAN/MyConfig.pm`, because `$HOME/.cpan` is added to the search path of the CPAN module before the use() or require() statements. The mkmyconfig command writes this file for you.

If you want to keep your own CPAN/MyConfig.pm somewhere else, you should load it before loading CPAN.pm, e.g.:

```
 perl -I/tmp/somewhere -MCPAN::MyConfig -MCPAN -eshell

 --or--

perl -I/tmp/somewhere -MCPAN::MyConfig -S cpan
```

Once you are in the shell you can change your configuration as follows.

The `o conf` command has various bells and whistles:

- completion support

  If you have a ReadLine module installed, you can hit TAB at any point of the commandline and `o conf` will offer you completion for the built-in subcommands and/or config variable names.

- displaying some help: o conf help

  Displays a short help

- displaying current values: o conf [KEY]

  Displays the current value(s) for this config variable. Without KEY, displays all subcommands and config variables.

  Example:

```
o conf shell
```

  If KEY starts and ends with a slash, the string in between is treated as a regular expression and only keys matching this regexp are displayed

  Example:

```
o conf /color/
```

- changing of scalar values: o conf KEY VALUE

  Sets the config variable KEY to VALUE. The empty string can be specified as usual in shells, with `''` or `""`

  Example:

```
o conf wget /usr/bin/wget
```

- changing of list values: o conf KEY SHIFT|UNSHIFT|PUSH|POP|SPLICE|LIST

  If a config variable name ends with `list`, it is a list. `o conf KEY shift` removes the first element of the list, `o conf KEY pop` removes the last element of the list. `o conf KEYS unshift LIST` prepends a list of values to the list, `o conf KEYS push LIST` appends a list of valued to the list.

  Likewise, `o conf KEY splice LIST` passes the LIST to the corresponding splice command.

  Finally, any other list of arguments is taken as a new list value for the KEY variable discarding the previous value.

  Examples:

```
o conf urllist unshift http://cpan.dev.local/CPAN
o conf urllist splice 3 1
o conf urllist http://cpan1.local http://cpan2.local ftp://ftp.
 ↪perl.org
```

- reverting to saved: o conf defaults

  Reverts all config variables to the state in the saved config file.

- saving the config: o conf commit

  Saves all config variables to the current config file (CPAN/Config.pm or CPAN/MyConfig.pm that was loaded at start).

The configuration dialog can be started any time later again by issuing the command o `conf init` in the CPAN shell. A subset of the configuration dialog can be run by issuing `o conf init WORD` where WORD is any valid config variable or a regular expression.

Config Variables

The following keys in the hash reference $CPAN::Config are currently defined:

```
allow_installing_module_downgrades
                    allow or disallow installing module downgrades
allow_installing_outdated_dists
                    allow or disallow installing modules that are
                    indexed in the cpan index pointing to a distro
                    with a higher distro-version number
applypatch          path to external prg
auto_commit         commit all changes to config variables to disk
build_cache         size of cache for directories to build modules
build_dir           locally accessible directory to build modules
build_dir_reuse     boolean if distros in build_dir are persistent
build_requires_install_policy
                    to install or not to install when a module is
                    only needed for building. yes|no|ask/yes|ask/no
bzip2               path to external prg
cache_metadata      use serializer to cache metadata
check_sigs          if signatures should be verified
cleanup_after_install
                    remove build directory immediately after a
                    successful install and remember that for the
                    duration of the session
colorize_debug      Term::ANSIColor attributes for debugging output
colorize_output     boolean if Term::ANSIColor should colorize output
colorize_print      Term::ANSIColor attributes for normal output
colorize_warn       Term::ANSIColor attributes for warnings
commandnumber_in_prompt
                    boolean if you want to see current command number
commands_quote      preferred character to use for quoting external
                    commands when running them. Defaults to double
                    quote on Windows, single tick everywhere else;
                    can be set to space to disable quoting
connect_to_internet_ok
                    whether to ask if opening a connection is ok␣
↪before
                    urllist is specified
```

```

You can set and query each of these options interactively in the cpan shell with the `o conf` or the `o conf init` command as specified below.

- `o conf <scalar option>`

  prints the current value of the *scalar option*

- `o conf <scalar option> <value>`

  Sets the value of the *scalar option* to *value*

- `o conf <list option>`

  prints the current value of the *list option* in MakeMaker's neatvalue format.

- `o conf <list option> [shift|pop]`

  shifts or pops the array in the *list option* variable

- `o conf <list option> [unshift|push|splice] <list>`

  works like the corresponding perl commands.

- interactive editing: o conf init [MATCH|LIST]

  Runs an interactive configuration dialog for matching variables. Without argument runs the dialog over all supported config variables. To specify a MATCH the

argument must be enclosed by slashes.

Examples:

```
o conf init ftp_passive ftp_proxy
o conf init /color/
```

Note: this method of setting config variables often provides more explanation about the functioning of a variable than the manpage.

CPAN::anycwd($path): Note on config variable getcwd

CPAN.pm changes the current working directory often and needs to determine its own current working directory. By default it uses Cwd::cwd, but if for some reason this doesn't work on your system, configure alternatives according to the following table:

- cwd

  Calls Cwd::cwd

- getcwd

  Calls Cwd::getcwd

- fastcwd

  Calls Cwd::fastcwd

- getdcwd

  Calls Cwd::getdcwd

- backtickcwd

  Calls the external command cwd.

Note on the format of the urllist parameter

urllist parameters are URLs according to RFC 1738. We do a little guessing if your URL is not compliant, but if you have problems with `file` URLs, please try the correct format. Either:

```
file://localhost/whatever/ftp/pub/CPAN/
```

or

```
file:///home/ftp/pub/CPAN/
```

The urllist parameter has CD-ROM support

The `urllist` parameter of the configuration table contains a list of URLs used for downloading. If the list contains any `file` URLs, CPAN always tries there first. This feature is disabled for index files. So the recommendation for the owner of a CD-ROM with CPAN contents is: include your local, possibly outdated CD-ROM as a `file` URL at the end of urllist, e.g.

```
o conf urllist push file://localhost/CDROM/CPAN
```

CPAN.pm will then fetch the index files from one of the CPAN sites that come at the beginning of urllist. It will later check for each module to see whether there is a local copy of the most recent version.

Another peculiarity of urllist is that the site that we could successfully fetch the last file from automatically gets a preference token and is tried as the first site for the next request. So if you add a new site at runtime it may happen that the previously preferred site will be tried another time. This means that if you want to disallow a site for the next transfer, it must be explicitly removed from urllist.

Maintaining the urllist parameter

If you have YAML.pm (or some other YAML module configured in `yaml_module`) installed, CPAN.pm collects a few statistical data about recent downloads. You can view the statistics with the `hosts` command or inspect them directly by looking into the `FTPstats.yml` file in your `cpan_home` directory.

To get some interesting statistics, it is recommended that `randomize_urllist` be set; this introduces some amount of randomness into the URL selection.

The `requires` and `build_requires` dependency declarations

Since CPAN.pm version 1.88_51 modules declared as `build_requires` by a distribution are treated differently depending on the config variable `build_requires_install_policy`. By setting `build_requires_install_policy` to `no`, such a module is not installed. It is only built and tested, and then kept in the list of tested but uninstalled modules. As such, it is available during the build of the dependent module by integrating the path to the `blib/arch` and `blib/lib` directories in the environment variable PERL5LIB. If `build_requires_install_policy` is set to `yes`, then both modules declared as `requires` and those declared as `build_requires` are treated alike. By setting to `ask/yes` or `ask/no`, CPAN.pm asks the user and sets the default accordingly.

Configuration of the allow_installing_* parameters

The `allow_installing_*` parameters are evaluated during the `make` phase. If set to `yes`, they allow the testing and the installation of the current distro and otherwise have no effect. If set to `no`, they may abort the build (preventing testing and installing), depending on the contents of the `blib/` directory. The `blib/` directory is the directory that holds all the files that would usually be installed in the `install` phase.

`allow_installing_outdated_dists` compares the `blib/` directory with the CPAN index. If it finds something there that belongs, according to the index, to a different dist, it aborts the current build.

`allow_installing_module_downgrades` compares the `blib/` directory with already installed modules, actually their version numbers, as determined by ExtUtils::MakeMaker or equivalent. If a to-be-installed module would downgrade an already installed module, the current build is aborted.

An interesting twist occurs when a distroprefs document demands the installation of an outdated dist via goto while `allow_installing_outdated_dists` forbids it. With-

out additional provisions, this would let the `allow_installing_outdated_dists` win and the distroprefs lose. So the proper arrangement in such a case is to write a second distroprefs document for the distro that `goto` points to and overrule the `cpanconfig` there. E.g.:

```
---
match:
  distribution: "^MAUKE/Keyword-Simple-0.04.tar.gz"
goto: "MAUKE/Keyword-Simple-0.03.tar.gz"
---
match:
  distribution: "^MAUKE/Keyword-Simple-0.03.tar.gz"
cpanconfig:
  allow_installing_outdated_dists: yes
```

Configuration for individual distributions (*Distroprefs*)

(**Note:** This feature has been introduced in CPAN.pm 1.8854)

Distributions on CPAN usually behave according to what we call the CPAN mantra. Or since the advent of Module::Build we should talk about two mantras:

```
perl Makefile.PL     perl Build.PL
make                 ./Build
make test            ./Build test
make install         ./Build install
```

But some modules cannot be built with this mantra. They try to get some extra data from the user via the environment, extra arguments, or interactively–thus disturbing the installation of large bundles like Phalanx100 or modules with many dependencies like Plagger.

The distroprefs system of `CPAN.pm` addresses this problem by allowing the user to specify extra informations and recipes in YAML files to either

- pass additional arguments to one of the four commands,
- set environment variables
- instantiate an Expect object that reads from the console, waits for some regular expressions and enters some answers
- temporarily override assorted `CPAN.pm` configuration variables
- specify dependencies the original maintainer forgot
- disable the installation of an object altogether

See the YAML and Data::Dumper files that come with the `CPAN.pm` distribution in the `distroprefs/` directory for examples.

Filenames

The YAML files themselves must have the `.yml` extension; all other files are ignored (for two exceptions see *Fallback Data::Dumper and Storable* below). The containing directory can be specified in `CPAN.pm` in the `prefs_dir` config variable. Try `o conf init prefs_dir` in the CPAN shell to set and activate the distroprefs system.

Every YAML file may contain arbitrary documents according to the YAML specification, and every document is treated as an entity that can specify the treatment of a single distribution.

Filenames can be picked arbitrarily; `CPAN.pm` always reads all files (in alphabetical order) and takes the key `match` (see below in *Language Specs*) as a hashref containing match criteria that determine if the current distribution matches the YAML document or not.

Fallback Data::Dumper and Storable

If neither your configured `yaml_module` nor YAML.pm is installed, CPAN.pm falls back to using Data::Dumper and Storable and looks for files with the extensions `.dd` or `.st` in the `prefs_dir` directory. These files are expected to contain one or more hashrefs. For Data::Dumper generated files, this is expected to be done with by defining `$VAR1`, `$VAR2`, etc. The YAML shell would produce these with the command

```
ysh < somefile.yml > somefile.dd
```

For Storable files the rule is that they must be constructed such that `Storable::retrieve(file)` returns an array reference and the array elements represent one distropref object each. The conversion from YAML would look like so:

```
perl -MYAML=LoadFile -MStorable=nstore -e '
    @y=LoadFile(shift);
    nstore(\@y, shift)' somefile.yml somefile.st
```

In bootstrapping situations it is usually sufficient to translate only a few YAML files to Data::Dumper for crucial modules like `YAML::Syck`, `YAML.pm` and `Expect.pm`. If you prefer Storable over Data::Dumper, remember to pull out a Storable version that writes an older format than all the other Storable versions that will need to read them.

Blueprint

The following example contains all supported keywords and structures with the exception of `eexpect` which can be used instead of `expect`.

```
---
comment: "Demo"
match:
  module: "Dancing::Queen"
  distribution: "^CHACHACHA/Dancing-"
  not_distribution: "\.zip$"
  perl: "/usr/local/cariba-perl/bin/perl"
  perlconfig:

    Spiffy: 0.30
```

Language Specs

Every YAML document represents a single hash reference. The valid keys in this hash are as follows:

- comment [scalar]

  A comment

- cpanconfig [hash]

  Temporarily override assorted `CPAN.pm` configuration variables.

  Supported are: `build_requires_install_policy`, `check_sigs`, `make`, `make_install_make_command`, `prefer_installer`, `test_report`. Please report as a bug when you need another one supported.

- depends [hash] *** EXPERIMENTAL FEATURE ***

  All three types, namely `configure_requires`, `build_requires`, and `requires` are supported in the way specified in the META.yml specification. The current implementation *merges* the specified dependencies with those declared by the package maintainer. In a future implementation this may be changed to override the original declaration.

- disabled [boolean]

  Specifies that this distribution shall not be processed at all.

- features [array] *** EXPERIMENTAL FEATURE ***

  Experimental implementation to deal with optional_features from META.yml. Still needs coordination with installer software and currently works only for META.yml declaring `dynamic_config=0`. Use with caution.

- goto [string]

  The canonical name of a delegate distribution to install instead. Useful when a new version, although it tests OK itself, breaks something else or a developer release or a fork is already uploaded that is better than the last released version.

- install [hash]

  Processing instructions for the `make install` or `./Build install` phase of the CPAN mantra. See below under *Processing Instructions*.

- make [hash]

  Processing instructions for the `make` or `./Build` phase of the CPAN mantra. See below under *Processing Instructions*.

- match [hash]

  A hashref with one or more of the keys `distribution`, `module`, `perl`, `perlconfig`, and `env` that specify whether a document is targeted at a specific CPAN distribution or installation. Keys prefixed with `not_` negates the corresponding match.

  The corresponding values are interpreted as regular expressions. The `distribution` related one will be matched against the canonical distribution name, e.g. "AUTHOR/Foo-Bar-3.14.tar.gz".

  The `module` related one will be matched against *all* modules contained in the distribution until one module matches.

  The `perl` related one will be matched against `$^X` (but with the absolute path).

  The value associated with `perlconfig` is itself a hashref that is matched against corresponding values in the `%Config::Config` hash living in the `Config.pm` module. Keys prefixed with `not_` negates the corresponding match.

  The value associated with `env` is itself a hashref that is matched against corresponding values in the `%ENV` hash. Keys prefixed with `not_` negates the corresponding match.

  If more than one restriction of `module`, `distribution`, etc. is specified, the results of the separately computed match values must all match. If so, the hashref represented by the YAML document is returned as the preference structure for the current distribution.

- patches [array]

  An array of patches on CPAN or on the local disk to be applied in order via an external patch program. If the value for the `-p` parameter is `0` or `1` is determined by reading the patch beforehand. The path to each patch is either an absolute path on the local filesystem or relative to a patch directory specified in the `patches_dir` configuration variable or in the format of a canonical distro name. For examples please consult the distroprefs/ directory in the CPAN.pm distribution (these examples are not installed by default).

  Note: if the `applypatch` program is installed and `CPAN::Config` knows about it **and** a patch is written by the `makepatch` program, then `CPAN.pm` lets `applypatch` apply the patch. Both `makepatch` and `applypatch` are available from CPAN in the `JV/makepatch-*` distribution.

- pl [hash]

  Processing instructions for the `perl Makefile.PL` or `perl Build.PL` phase of the CPAN mantra. See below under *Processing Instructions*.

- test [hash]

  Processing instructions for the `make test` or `./Build test` phase of the CPAN mantra. See below under *Processing Instructions*.

Processing Instructions

- args [array]

  Arguments to be added to the command line

- commandline

  A full commandline to run via `system()`. During execution, the environment variable PERL is set to $^X (but with an absolute path). If `commandline` is specified, `args` is not used.

- eexpect [hash]

  Extended `expect`. This is a hash reference with four allowed keys, `mode`, `timeout`, `reuse`, and `talk`.

  You must install the `Expect` module to use `eexpect`. CPAN.pm does not install it for you.

  `mode` may have the values `deterministic` for the case where all questions come in the order written down and `anyorder` for the case where the questions may come in any order. The default mode is `deterministic`.

  `timeout` denotes a timeout in seconds. Floating-point timeouts are OK. With `mode=deterministic`, the timeout denotes the timeout per question; with `mode=anyorder` it denotes the timeout per byte received from the stream or questions.

  `talk` is a reference to an array that contains alternating questions and answers. Questions are regular expressions and answers are literal strings. The Expect module watches the stream from the execution of the external program (`perl Makefile.PL`, `perl Build.PL`, `make`, etc.).

  For `mode=deterministic`, the CPAN.pm injects the corresponding answer as soon as the stream matches the regular expression.

  For `mode=anyorder` CPAN.pm answers a question as soon as the timeout is reached for the next byte in the input stream. In this mode you can use the `reuse` parameter to decide what will happen with a question-answer pair after it has been used. In the default case (reuse=0) it is removed from the array, avoiding being used again accidentally. If you want to answer the question `Do you really want to do that` several times, then it must be included in the array at least as often as you want this answer to be given. Setting the parameter `reuse` to 1 makes this repetition unnecessary.

- env [hash]

  Environment variables to be set during the command

- expect [array]

  You must install the `Expect` module to use `expect`. CPAN.pm does not install it for you.

  `expect: <array>` is a short notation for this `eexpect`:

```
eexpect:
        mode: deterministic
```

(continues on next page)

(continued from previous page)

```
        timeout: 15
        talk: <array>
```

Schema verification with Kwalify

If you have the Kwalify module installed (which is part of the Bundle::CPANxxl), then all your distroprefs files are checked for syntactic correctness.

Example Distroprefs Files

CPAN.pm comes with a collection of example YAML files. Note that these are really just examples and should not be used without care because they cannot fit everybody's purpose. After all, the authors of the packages that ask questions had a need to ask, so you should watch their questions and adjust the examples to your environment and your needs. You have been warned:-)

PROGRAMMER'S INTERFACE

If you do not enter the shell, shell commands are available both as methods (`CPAN::Shell->install(...)`) and as functions in the calling package (`install(...)`). Before calling low-level commands, it makes sense to initialize components of CPAN you need, e.g.:

```
CPAN::HandleConfig->load;
CPAN::Shell::setup_output;
CPAN::Index->reload;
```

High-level commands do such initializations automatically.

There's currently only one class that has a stable interface - CPAN::Shell. All commands that are available in the CPAN shell are methods of the class CPAN::Shell. The arguments on the commandline are passed as arguments to the method.

So if you take for example the shell command

```
notest install A B C
```

the actually executed command is

```
CPAN::Shell->notest("install","A","B","C");
```

Each of the commands that produce listings of modules (`r`, `autobundle`, `u`) also return a list of the IDs of all modules within the list.

- expand($type,@things)

  The IDs of all objects available within a program are strings that can be expanded to the corresponding real objects with the `CPAN::Shell->expand("Module", @things)` method. Expand returns a list of CPAN::Module objects according to the `@things` arguments given. In scalar context, it returns only the first element of the list.

- expandany(@things)

  Like expand, but returns objects of the appropriate type, i.e. CPAN::Bundle objects for bundles, CPAN::Module objects for modules, and CPAN::Distribution objects for distributions. Note: it does not expand to CPAN::Author objects.

- Programming Examples

  This enables the programmer to do operations that combine functionalities that are available in the shell.

```
# install everything that is outdated on my disk:
perl -MCPAN -e 'CPAN::Shell->install(CPAN::Shell->r)'

# install my favorite programs if necessary:
for $mod (qw(Net::FTP Digest::SHA Data::Dumper)) {
    CPAN::Shell->install($mod);
}

# list all modules on my disk that have no VERSION number
for $mod (CPAN::Shell->expand("Module","/./")) {
    next unless $mod->inst_file;
    # MakeMaker convention for undefined $VERSION:
    next unless $mod->inst_version eq "undef";
    print "No VERSION in ", $mod->id, "\n";
}

# find out which distribution on CPAN contains a module:
print CPAN::Shell->expand("Module","Apache::Constants")->cpan_
 ↪file
```

  Or if you want to schedule a *cron* job to watch CPAN, you could list all modules that need updating. First a quick and dirty way:

```
perl -e 'use CPAN; CPAN::Shell->r;'
```

  If you don't want any output should all modules be up to date, parse the output of above command for the regular expression `/modules are up to date/` and decide to mail the output only if it doesn't match.

  If you prefer to do it more in a programmerish style in one single process, something like this may better suit you:

```
# list all modules on my disk that have newer versions on CPAN
for $mod (CPAN::Shell->expand("Module","/./")) {
  next unless $mod->inst_file;
  next if $mod->uptodate;
  printf "Module %s is installed as %s, could be updated to %s␣
 ↪from CPAN\n",
      $mod->id, $mod->inst_version, $mod->cpan_version;
}
```

  If that gives too much output every day, you may want to watch only for three modules. You can write

```
for $mod (CPAN::Shell->expand("Module","/Apache|LWP|CGI/")) {
```

as the first line instead. Or you can combine some of the above tricks:

```
# watch only for a new mod_perl module
$mod = CPAN::Shell->expand("Module","mod_perl");
exit if $mod->uptodate;
# new mod_perl arrived, let me know all update recommendations
CPAN::Shell->r;
```

Methods in the other Classes

- CPAN::Author::as_glimpse()

  Returns a one-line description of the author

- CPAN::Author::as_string()

  Returns a multi-line description of the author

- CPAN::Author::email()

  Returns the author's email address

- CPAN::Author::fullname()

  Returns the author's name

- CPAN::Author::name()

  An alias for fullname

- CPAN::Bundle::as_glimpse()

  Returns a one-line description of the bundle

- CPAN::Bundle::as_string()

  Returns a multi-line description of the bundle

- CPAN::Bundle::clean()

  Recursively runs the `clean` method on all items contained in the bundle.

- CPAN::Bundle::contains()

  Returns a list of objects' IDs contained in a bundle. The associated objects may be bundles, modules or distributions.

- CPAN::Bundle::force($method,@args)

  Forces CPAN to perform a task that it normally would have refused to do. Force takes as arguments a method name to be called and any number of additional arguments that should be passed to the called method. The internals of the object get the needed changes so that CPAN.pm does not refuse to take the action. The `force` is passed recursively to all contained objects. See also the section above on the `force` and the `fforce` pragma.

- CPAN::Bundle::get()

  Recursively runs the `get` method on all items contained in the bundle

- CPAN::Bundle::inst_file()

  Returns the highest installed version of the bundle in either @INC or `$CPAN::Config->{cpan_home}`. Note that this is different from CPAN::Module::inst_file.

- CPAN::Bundle::inst_version()

  Like CPAN::Bundle::inst_file, but returns the $VERSION

- CPAN::Bundle::uptodate()

  Returns 1 if the bundle itself and all its members are up-to-date.

- CPAN::Bundle::install()

  Recursively runs the `install` method on all items contained in the bundle

- CPAN::Bundle::make()

  Recursively runs the `make` method on all items contained in the bundle

- CPAN::Bundle::readme()

  Recursively runs the `readme` method on all items contained in the bundle

- CPAN::Bundle::test()

  Recursively runs the `test` method on all items contained in the bundle

- CPAN::Distribution::as_glimpse()

  Returns a one-line description of the distribution

- CPAN::Distribution::as_string()

  Returns a multi-line description of the distribution

- CPAN::Distribution::author

  Returns the CPAN::Author object of the maintainer who uploaded this distribution

- CPAN::Distribution::pretty_id()

  Returns a string of the form “AUTHORID/TARBALL”, where AUTHORID is the author’s PAUSE ID and TARBALL is the distribution filename.

- CPAN::Distribution::base_id()

  Returns the distribution filename without any archive suffix. E.g “Foo-Bar-0.01”

- CPAN::Distribution::clean()

  Changes to the directory where the distribution has been unpacked and runs `make clean` there.

- CPAN::Distribution::containsmods()

  Returns a list of IDs of modules contained in a distribution file. Works only for distributions listed in the 02packages.details.txt.gz file. This typically means that just most recent version of a distribution is covered.

- CPAN::Distribution::cvs_import()

  Changes to the directory where the distribution has been unpacked and runs something like

```
cvs -d $cvs_root import -m $cvs_log $cvs_dir $userid v$version
```

there.

- CPAN::Distribution::dir()

  Returns the directory into which this distribution has been unpacked.

- CPAN::Distribution::force($method,@args)

  Forces CPAN to perform a task that it normally would have refused to do. Force takes as arguments a method name to be called and any number of additional arguments that should be passed to the called method. The internals of the object get the needed changes so that CPAN.pm does not refuse to take the action. See also the section above on the `force` and the `fforce` pragma.

- CPAN::Distribution::get()

  Downloads the distribution from CPAN and unpacks it. Does nothing if the distribution has already been downloaded and unpacked within the current session.

- CPAN::Distribution::install()

  Changes to the directory where the distribution has been unpacked and runs the external command `make install` there. If `make` has not yet been run, it will be run first. A `make test` is issued in any case and if this fails, the install is cancelled. The cancellation can be avoided by letting `force` run the `install` for you.

  This install method only has the power to install the distribution if there are no dependencies in the way. To install an object along with all its dependencies, use CPAN::Shell->install.

  Note that install() gives no meaningful return value. See uptodate().

- CPAN::Distribution::isa_perl()

  Returns 1 if this distribution file seems to be a perl distribution. Normally this is derived from the file name only, but the index from CPAN can contain a hint to achieve a return value of true for other filenames too.

- CPAN::Distribution::look()

  Changes to the directory where the distribution has been unpacked and opens a subshell there. Exiting the subshell returns.

- CPAN::Distribution::make()

  First runs the `get` method to make sure the distribution is downloaded and unpacked. Changes to the directory where the distribution has been unpacked and runs the external commands `perl Makefile.PL` or `perl Build.PL` and `make` there.

- CPAN::Distribution::perldoc()

  Downloads the pod documentation of the file associated with a distribution (in HTML format) and runs it through the external command *lynx* specified in `$CPAN::Config->{lynx}`. If *lynx* isn't available, it converts it to plain text with the external command *html2text* and runs it through the pager specified in `$CPAN::Config->{pager}`.

- CPAN::Distribution::prefs()

  Returns the hash reference from the first matching YAML file that the user has deposited in the `prefs_dir/` directory. The first succeeding match wins. The files in the `prefs_dir/` are processed alphabetically, and the canonical distro name (e.g. AUTHOR/Foo-Bar-3.14.tar.gz) is matched against the regular expressions stored in the $root->{match}{distribution} attribute value. Additionally all module names contained in a distribution are matched against the regular expressions in the $root->{match}{module} attribute value. The two match values are ANDed together. Each of the two attributes are optional.

- CPAN::Distribution::prereq_pm()

  Returns the hash reference that has been announced by a distribution as the `requires` and `build_requires` elements. These can be declared either by the `META.yml` (if authoritative) or can be deposited after the run of `Build.PL` in the file `./_build/prereqs` or after the run of `Makefile.PL` written as the `PREREQ_PM` hash in a comment in the produced `Makefile`. *Note*: this method only works after an attempt has been made to `make` the distribution. Returns undef otherwise.

- CPAN::Distribution::readme()

  Downloads the README file associated with a distribution and runs it through the pager specified in `$CPAN::Config->{pager}`.

- CPAN::Distribution::reports()

  Downloads report data for this distribution from www.cpantesters.org and displays a subset of them.

- CPAN::Distribution::read_yaml()

  Returns the content of the META.yml of this distro as a hashref. Note: works only after an attempt has been made to `make` the distribution. Returns undef otherwise. Also returns undef if the content of META.yml is not authoritative. (The rules about what exactly makes the content authoritative are still in flux.)

- CPAN::Distribution::test()

  Changes to the directory where the distribution has been unpacked and runs `make test` there.

- CPAN::Distribution::uptodate()

  Returns 1 if all the modules contained in the distribution are up-to-date. Relies on containsmods.

- CPAN::Index::force_reload()

  Forces a reload of all indices.

- CPAN::Index::reload()

  Reloads all indices if they have not been read for more than `$CPAN::Config->{index_expire}` days.

- CPAN::InfoObj::dump()

  CPAN::Author, CPAN::Bundle, CPAN::Module, and CPAN::Distribution inherit this method. It prints the data structure associated with an object. Useful for debug-

ging. Note: the data structure is considered internal and thus subject to change without notice.

- CPAN::Module::as_glimpse()

  Returns a one-line description of the module in four columns: The first column contains the word `Module`, the second column consists of one character: an equals sign if this module is already installed and up-to-date, a less-than sign if this module is installed but can be upgraded, and a space if the module is not installed. The third column is the name of the module and the fourth column gives maintainer or distribution information.

- CPAN::Module::as_string()

  Returns a multi-line description of the module

- CPAN::Module::clean()

  Runs a clean on the distribution associated with this module.

- CPAN::Module::cpan_file()

  Returns the filename on CPAN that is associated with the module.

- CPAN::Module::cpan_version()

  Returns the latest version of this module available on CPAN.

- CPAN::Module::cvs_import()

  Runs a cvs_import on the distribution associated with this module.

- CPAN::Module::description()

  Returns a 44 character description of this module. Only available for modules listed in The Module List (CPAN/modules/00modlist.long.html or 00modlist.long.txt.gz)

- CPAN::Module::distribution()

  Returns the CPAN::Distribution object that contains the current version of this module.

- CPAN::Module::dslip_status()

  Returns a hash reference. The keys of the hash are the letters `D`, `S`, `L`, `I`, and , for development status, support level, language, interface and public licence respectively. The data for the DSLIP status are collected by pause.perl.org when authors register their namespaces. The values of the 5 hash elements are one-character words whose meaning is described in the table below. There are also 5 hash elements `DV`, `SV`, `LV`, `IV`, and that carry a more verbose value of the 5 status variables.

  Where the 'DSLIP' characters have the following meanings:

```
D - Development Stage  (Note: *NO IMPLIED TIMESCALES*):
  i   - Idea, listed to gain consensus or as a placeholder
  c   - under construction but pre-alpha (not yet released)
  a/b - Alpha/Beta testing
  R   - Released
  M   - Mature (no rigorous definition)
  S   - Standard, supplied with Perl 5
```

(continues on next page)

(continued from previous page)

```
S - Support Level:
  m    - Mailing-list
  d    - Developer
  u    - Usenet newsgroup comp.lang.perl.modules
  n    - None known, try comp.lang.perl.modules
  a    - abandoned; volunteers welcome to take over maintenance

L - Language Used:
  p    - Perl-only, no compiler needed, should be platform␣
↪independent
  c    - C and perl, a C compiler will be needed
  h    - Hybrid, written in perl with optional C code, no␣
↪compiler needed
  +    - C++ and perl, a C++ compiler will be needed
  o    - perl and another language other than C or C++

I - Interface Style
  f    - plain Functions, no references used
  h    - hybrid, object and function interfaces available
  n    - no interface at all (huh?)
  r    - some use of unblessed References or ties
  O    - Object oriented using blessed references and/or␣
↪inheritance

P - Public License
  p    - Standard-Perl: user may choose between GPL and Artistic
  g    - GPL: GNU General Public License
  l    - LGPL: "GNU Lesser General Public License" (previously␣

  b    - BSD: The BSD License
  a    - Artistic license alone
  2    - Artistic license 2.0 or later
  o    - open source: approved by www.opensource.org
  d    - allows distribution without restrictions
  r    - restricted distribution
  n    - no license at all
```

- CPAN::Module::force($method,@args)

  Forces CPAN to perform a task it would normally refuse to do. Force takes as arguments a method name to be invoked and any number of additional arguments to pass that method. The internals of the object get the needed changes so that CPAN.pm does not refuse to take the action. See also the section above on the `force` and the `fforce` pragma.

- CPAN::Module::get()

  Runs a get on the distribution associated with this module.

- CPAN::Module::inst_file()

Returns the filename of the module found in @INC. The first file found is reported, just as perl itself stops searching @INC once it finds a module.

- CPAN::Module::available_file()

  Returns the filename of the module found in PERL5LIB or @INC. The first file found is reported. The advantage of this method over `inst_file` is that modules that have been tested but not yet installed are included because PERL5LIB keeps track of tested modules.

- CPAN::Module::inst_version()

  Returns the version number of the installed module in readable format.

- CPAN::Module::available_version()

  Returns the version number of the available module in readable format.

- CPAN::Module::install()

  Runs an `install` on the distribution associated with this module.

- CPAN::Module::look()

  Changes to the directory where the distribution associated with this module has been unpacked and opens a subshell there. Exiting the subshell returns.

- CPAN::Module::make()

  Runs a `make` on the distribution associated with this module.

- CPAN::Module::manpage_headline()

  If module is installed, peeks into the module's manpage, reads the headline, and returns it. Moreover, if the module has been downloaded within this session, does the equivalent on the downloaded module even if it hasn't been installed yet.

- CPAN::Module::perldoc()

  Runs a `perldoc` on this module.

- CPAN::Module::readme()

  Runs a `readme` on the distribution associated with this module.

- CPAN::Module::reports()

  Calls the reports() method on the associated distribution object.

- CPAN::Module::test()

  Runs a `test` on the distribution associated with this module.

- CPAN::Module::uptodate()

  Returns 1 if the module is installed and up-to-date.

- CPAN::Module::userid()

  Returns the author's ID of the module.

Cache Manager

Currently the cache manager only keeps track of the build directory ($CPAN::Config->{build_dir}). It is a simple FIFO mechanism that deletes complete directories below `build_dir` as soon as the size of all directories there gets bigger than $CPAN::Config->{build_cache} (in MB). The contents of this cache may be used for later re-installations that you intend to do manually, but will never be trusted by CPAN itself. This is due to the fact that the user might use these directories for building modules on different architectures.

There is another directory ($CPAN::Config->{keep_source_where}) where the original distribution files are kept. This directory is not covered by the cache manager and must be controlled by the user. If you choose to have the same directory as build_dir and as keep_source_where directory, then your sources will be deleted with the same fifo mechanism.

Bundles

A bundle is just a perl module in the namespace Bundle:: that does not define any functions or methods. It usually only contains documentation.

It starts like a perl module with a package declaration and a $VERSION variable. After that the pod section looks like any other pod with the only difference being that *one special pod section* exists starting with (verbatim):

```
=head1 CONTENTS
```

In this pod section each line obeys the format

```
Module_Name [Version_String] [- optional text]
```

The only required part is the first field, the name of a module (e.g. Foo::Bar, i.e. *not* the name of the distribution file). The rest of the line is optional. The comment part is delimited by a dash just as in the man page header.

The distribution of a bundle should follow the same convention as other distributions.

Bundles are treated specially in the CPAN package. If you say 'install Bundle::Tkkit' (assuming such a bundle exists), CPAN will install all the modules in the CONTENTS section of the pod. You can install your own Bundles locally by placing a conformant Bundle file somewhere into your @INC path. The autobundle() command which is available in the shell interface does that for you by including all currently installed modules in a snapshot bundle file.

PREREQUISITES

The CPAN program is trying to depend on as little as possible so the user can use it in hostile environment. It works better the more goodies the environment provides. For example if you try in the CPAN shell

```
install Bundle::CPAN
```

or

```
install Bundle::CPANxxl
```

you will find the shell more convenient than the bare shell before.

If you have a local mirror of CPAN and can access all files with "file:" URLs, then you only need a perl later than perl5.003 to run this module. Otherwise Net::FTP is strongly recommended. LWP may be required for non-UNIX systems, or if your nearest CPAN site is associated with a URL that is not `ftp:`.

If you have neither Net::FTP nor LWP, there is a fallback mechanism implemented for an external ftp command or for an external lynx command.

UTILITIES

Finding packages and VERSION

This module presumes that all packages on CPAN

- declare their $VERSION variable in an easy to parse manner. This prerequisite can hardly be relaxed because it consumes far too much memory to load all packages into the running program just to determine the $VERSION variable. Currently all programs that are dealing with version use something like this

  ```
  perl -MExtUtils::MakeMaker -le \
      'print MM->parse_version(shift)' filename
  ```

  If you are author of a package and wonder if your $VERSION can be parsed, please try the above method.

- come as compressed or gzipped tarfiles or as zip files and contain a `Makefile.PL` or `Build.PL` (well, we try to handle a bit more, but with little enthusiasm).

Debugging

Debugging this module is more than a bit complex due to interference from the software producing the indices on CPAN, the mirroring process on CPAN, packaging, configuration, synchronicity, and even (gasp!) due to bugs within the CPAN.pm module itself.

For debugging the code of CPAN.pm itself in interactive mode, some debugging aid can be turned on for most packages within CPAN.pm with one of

- o debug package...

  sets debug mode for packages.

- o debug -package...

  unsets debug mode for packages.

- o debug all

  turns debugging on for all packages.

- o debug number

which sets the debugging packages directly. Note that `o debug 0` turns debugging off.

What seems a successful strategy is the combination of `reload cpan` and the debugging switches. Add a new debug statement while running in the shell and then issue a `reload cpan` and see the new debugging messages immediately without losing the current context.

`o debug` without an argument lists the valid package names and the current set of packages in debugging mode. `o debug` has built-in completion support.

For debugging of CPAN data there is the `dump` command which takes the same arguments as make/test/install and outputs each object's Data::Dumper dump. If an argument looks like a perl variable and contains one of `$`, `@` or `%`, it is eval()ed and fed to Data::Dumper directly.

Floppy, Zip, Offline Mode

CPAN.pm works nicely without network access, too. If you maintain machines that are not networked at all, you should consider working with `file:` URLs. You'll have to collect your modules somewhere first. So you might use CPAN.pm to put together all you need on a networked machine. Then copy the $CPAN::Config->{keep_source_where} (but not $CPAN::Config->{build_dir}) directory on a floppy. This floppy is kind of a personal CPAN. CPAN.pm on the non-networked machines works nicely with this floppy. See also below the paragraph about CD-ROM support.

Basic Utilities for Programmers

- has_inst($module)

  Returns true if the module is installed. Used to load all modules into the running CPAN.pm that are considered optional. The config variable `dontload_list` intercepts the `has_inst()` call such that an optional module is not loaded despite being available. For example, the following command will prevent `YAML.pm` from being loaded:

  ```
  cpan> o conf dontload_list push YAML
  ```

  See the source for details.

- use_inst($module)

  Similary to has_inst() tries to load optional library but also dies if library is not available

- has_usable($module)

  Returns true if the module is installed and in a usable state. Only useful for a handful of modules that are used internally. See the source for details.

- instance($module)

  The constructor for all the singletons used to represent modules, distributions, authors, and bundles. If the object already exists, this method returns the object; otherwise, it calls the constructor.

- frontend()

- frontend($new_frontend)

Getter/setter for frontend object. Method just allows to subclass CPAN.pm.

SECURITY

There's no strong security layer in CPAN.pm. CPAN.pm helps you to install foreign, unmasked, unsigned code on your machine. We compare to a checksum that comes from the net just as the distribution file itself. But we try to make it easy to add security on demand:

Cryptographically signed modules

Since release 1.77, CPAN.pm has been able to verify cryptographically signed module distributions using Module::Signature. The CPAN modules can be signed by their authors, thus giving more security. The simple unsigned MD5 checksums that were used before by CPAN protect mainly against accidental file corruption.

You will need to have Module::Signature installed, which in turn requires that you have at least one of Crypt::OpenPGP module or the command-line gpg tool installed.

You will also need to be able to connect over the Internet to the public key servers, like pgp.mit.edu, and their port 11731 (the HKP protocol).

The configuration parameter check_sigs is there to turn signature checking on or off.

EXPORT

Most functions in package CPAN are exported by default. The reason for this is that the primary use is intended for the cpan shell or for one-liners.

ENVIRONMENT

When the CPAN shell enters a subshell via the look command, it sets the environment CPAN_SHELL_LEVEL to 1, or increments that variable if it is already set.

When CPAN runs, it sets the environment variable PERL5_CPAN_IS_RUNNING to the ID of the running process. It also sets PERL5_CPANPLUS_IS_RUNNING to prevent runaway processes which could happen with older versions of Module::Install.

When running `perl Makefile.PL`, the environment variable `PERL5_CPAN_IS_EXECUTING` is set to the full path of the `Makefile.PL` that is being executed. This prevents runaway processes with newer versions of Module::Install.

When the config variable ftp_passive is set, all downloads will be run with the environment variable FTP_PASSIVE set to this value. This is in general a good idea as it influences both Net::FTP and LWP based connections. The same effect can be achieved by starting the cpan shell with this environment variable set. For Net::FTP alone, one can also always set passive mode by running libnetcfg.

POPULATE AN INSTALLATION WITH LOTS OF MODULES

Populating a freshly installed perl with one's favorite modules is pretty easy if you maintain a private bundle definition file. To get a useful blueprint of a bundle definition file, the command autobundle can be used on the CPAN shell command line. This command writes a bundle definition file for all modules installed for the current perl interpreter.

It's recommended to run this command once only, and from then on maintain the file manually under a private name, say Bundle/my_bundle.pm. With a clever bundle file you can then simply say

```
cpan> install Bundle::my_bundle
```

then answer a few questions and go out for coffee (possibly even in a different city).

Maintaining a bundle definition file means keeping track of two things: dependencies and interactivity. CPAN.pm sometimes fails on calculating dependencies because not all modules define all MakeMaker attributes correctly, so a bundle definition file should specify prerequisites as early as possible. On the other hand, it's annoying that so many distributions need some interactive configuring. So what you can try to accomplish in your private bundle file is to have the packages that need to be configured early in the file and the gentle ones later, so you can go out for coffee after a few minutes and leave CPAN.pm to churn away unattended.

WORKING WITH CPAN.pm BEHIND FIREWALLS

Thanks to Graham Barr for contributing the following paragraphs about the interaction between perl, and various firewall configurations. For further information on firewalls, it is recommended to consult the documentation that comes with the *ncftp* program. If you are unable to go through the firewall with a simple Perl setup, it is likely that you can configure *ncftp* so that it works through your firewall.

Three basic types of firewalls

Firewalls can be categorized into three basic types.

- http firewall

  This is when the firewall machine runs a web server, and to access the outside world, you must do so via that web server. If you set environment variables like http_proxy or ftp_proxy to values beginning with http://, or in your web browser you've proxy information set, then you know you are running behind an http firewall.

  To access servers outside these types of firewalls with perl (even for ftp), you need LWP or HTTP::Tiny.

- ftp firewall

  This where the firewall machine runs an ftp server. This kind of firewall will only let you access ftp servers outside the firewall. This is usually done by connecting to the firewall with ftp, then entering a username like "user@outside.host.com".

  To access servers outside these type of firewalls with perl, you need Net::FTP.

- One-way visibility

  One-way visibility means these firewalls try to make themselves invisible to users inside the firewall. An FTP data connection is normally created by sending your IP address to the remote server and then listening for the return connection. But the remote server will not be able to connect to you because of the firewall. For these types of firewall, FTP connections need to be done in a passive mode.

There are two that I can think off.

– SOCKS

If you are using a SOCKS firewall, you will need to compile perl and link it with the SOCKS library. This is what is normally called a 'socksified' perl. With this executable you will be able to connect to servers outside the firewall as if it were not there.

– IP Masquerade

This is when the firewall implemented in the kernel (via NAT, or networking address translation), it allows you to hide a complete network behind one IP address. With this firewall no special compiling is needed as you can access hosts directly.

For accessing ftp servers behind such firewalls you usually need to set the environment variable `FTP_PASSIVE` or the config variable ftp_passive to a true value.

Configuring lynx or ncftp for going through a firewall

If you can go through your firewall with e.g. lynx, presumably with a command such as

```
/usr/local/bin/lynx -pscott:tiger
```

then you would configure CPAN.pm with the command

```
o conf lynx "/usr/local/bin/lynx -pscott:tiger"
```

That's all. Similarly for ncftp or ftp, you would configure something like

```
o conf ncftp "/usr/bin/ncftp -f /home/scott/ncftplogin.cfg"
```

Your mileage may vary...

FAQ

- 1)

  I installed a new version of module X but CPAN keeps saying, I have the old version installed

  Probably you **do** have the old version installed. This can happen if a module installs itself into a different directory in the @INC path than it was previously installed. This is not really a CPAN.pm problem, you would have the same problem when installing the module manually. The easiest way to prevent this behaviour is to add the argument `UNINST=1` to the `make install` call, and that is why many people add this argument permanently by configuring

  ```
  o conf make_install_arg UNINST=1
  ```

- 2)

  So why is UNINST=1 not the default?

Because there are people who have their precise expectations about who may install where in the @INC path and who uses which @INC array. In fine tuned environments `UNINST=1` can cause damage.

- 3)

  I want to clean up my mess, and install a new perl along with all modules I have. How do I go about it?

  Run the autobundle command for your old perl and optionally rename the resulting bundle file (e.g. Bundle/mybundle.pm), install the new perl with the Configure option prefix, e.g.

```
./Configure -Dprefix=/usr/local/perl-5.6.78.9
```

  Install the bundle file you produced in the first step with something like

```
cpan> install Bundle::mybundle
```

  and you're done.

- 4)

  When I install bundles or multiple modules with one command there is too much output to keep track of.

  You may want to configure something like

```
o conf make_arg "| tee -ai /root/.cpan/logs/make.out"
o conf make_install_arg "| tee -ai /root/.cpan/logs/make_
↪install.out"
```

  so that STDOUT is captured in a file for later inspection.

- 5)

  I am not root, how can I install a module in a personal directory?

  As of CPAN 1.9463, if you do not have permission to write the default perl library directories, CPAN's configuration process will ask you whether you want to bootstrap <local::lib>, which makes keeping a personal perl library directory easy.

  Another thing you should bear in mind is that the UNINST parameter can be dangerous when you are installing into a private area because you might accidentally remove modules that other people depend on that are not using the private area.

- 6)

  How to get a package, unwrap it, and make a change before building it?

  Have a look at the `look` (!) command.

- 7)

  I installed a Bundle and had a couple of fails. When I retried, everything resolved nicely. Can this be fixed to work on first try?

  The reason for this is that CPAN does not know the dependencies of all modules when it starts out. To decide about the additional items to install, it just uses data found in the META.yml file or the generated Makefile. An undetected missing piece

breaks the process. But it may well be that your Bundle installs some prerequisite later than some depending item and thus your second try is able to resolve everything. Please note, CPAN.pm does not know the dependency tree in advance and cannot sort the queue of things to install in a topologically correct order. It resolves perfectly well **if** all modules declare the prerequisites correctly with the PREREQ_PM attribute to MakeMaker or the `requires` stanza of Module::Build. For bundles which fail and you need to install often, it is recommended to sort the Bundle definition file manually.

- 8)

  In our intranet, we have many modules for internal use. How can I integrate these modules with CPAN.pm but without uploading the modules to CPAN?

  Have a look at the CPAN::Site module.

- 9)

  When I run CPAN's shell, I get an error message about things in my `/etc/inputrc` (or `~/.inputrc`) file.

  These are readline issues and can only be fixed by studying readline configuration on your architecture and adjusting the referenced file accordingly. Please make a backup of the `/etc/inputrc` or `~/.inputrc` and edit them. Quite often harmless changes like uppercasing or lowercasing some arguments solves the problem.

- 10)

  Some authors have strange characters in their names.

  Internally CPAN.pm uses the UTF-8 charset. If your terminal is expecting ISO-8859-1 charset, a converter can be activated by setting term_is_latin to a true value in your config file. One way of doing so would be

  ```
  cpan> o conf term_is_latin 1
  ```

  If other charset support is needed, please file a bug report against CPAN.pm at rt.cpan.org and describe your needs. Maybe we can extend the support or maybe UTF-8 terminals become widely available.

  Note: this config variable is deprecated and will be removed in a future version of CPAN.pm. It will be replaced with the conventions around the family of $LANG and $LC_* environment variables.

- 11)

  When an install fails for some reason and then I correct the error condition and retry, CPAN.pm refuses to install the module, saying `Already tried without success`.

  You could use the force pragma like so

  ```
  force install Foo::Bar
  ```

  Or, to avoid a force install (which would install even if the tests fail), you can force only the test and then install:

```
force test Foo::Bar
install Foo::Bar
```

Or you can use

```
look Foo::Bar
```

and then `make install` directly in the subshell.

- 12)

  How do I install a "DEVELOPER RELEASE" of a module?

  By default, CPAN will install the latest non-developer release of a module. If you want to install a dev release, you have to specify the partial path starting with the author id to the tarball you wish to install, like so:

```
cpan> install KWILLIAMS/Module-Build-0.27_07.tar.gz
```

  Note that you can use the `ls` command to get this path listed.

- 13)

  How do I install a module and all its dependencies from the commandline, without being prompted for anything, despite my CPAN configuration (or lack thereof)?

  CPAN uses ExtUtils::MakeMaker's prompt() function to ask its questions, so if you set the PERL_MM_USE_DEFAULT environment variable, you shouldn't be asked any questions at all (assuming the modules you are installing are nice about obeying that variable as well):

```
% PERL_MM_USE_DEFAULT=1 perl -MCPAN -e 'install My::Module'
```

- 14)

  How do I create a Module::Build based Build.PL derived from an ExtUtils::MakeMaker focused Makefile.PL?

  http://search.cpan.org/dist/Module-Build-Convert/

- 15)

  I'm frequently irritated with the CPAN shell's inability to help me select a good mirror.

  CPAN can now help you select a "good" mirror, based on which ones have the lowest 'ping' round-trip times. From the shell, use the command 'o conf init urllist' and allow CPAN to automatically select mirrors for you.

  Beyond that help, the urllist config parameter is yours. You can add and remove sites at will. You should find out which sites have the best up-to-dateness, bandwidth, reliability, etc. and are topologically close to you. Some people prefer fast downloads, others up-to-dateness, others reliability. You decide which to try in which order.

  Henk P. Penning maintains a site that collects data about CPAN sites:

```
http://mirrors.cpan.org/
```

Also, feel free to play with experimental features. Run

```
o conf init randomize_urllist ftpstats_period ftpstats_size
```

and choose your favorite parameters. After a few downloads running the `hosts` command will probably assist you in choosing the best mirror sites.

- 16)

  Why do I get asked the same questions every time I start the shell?

  You can make your configuration changes permanent by calling the command `o conf commit`. Alternatively set the `auto_commit` variable to true by running `o conf init auto_commit` and answering the following question with yes.

- 17)

  Older versions of CPAN.pm had the original root directory of all tarballs in the build directory. Now there are always random characters appended to these directory names. Why was this done?

  The random characters are provided by File::Temp and ensure that each module's individual build directory is unique. This makes running CPAN.pm in concurrent processes simultaneously safe.

- 18)

  Speaking of the build directory. Do I have to clean it up myself?

  You have the choice to set the config variable `scan_cache` to `never`. Then you must clean it up yourself. The other possible values, `atstart` and `atexit` clean up the build directory when you start (or more precisely, after the first extraction into the build directory) or exit the CPAN shell, respectively. If you never start up the CPAN shell, you probably also have to clean up the build directory yourself.

- 19)

  How can I switch to sudo instead of local::lib?

  The following 5 environment veriables need to be reset to the previous values: PATH, PERL5LIB, PERL_LOCAL_LIB_ROOT, PERL_MB_OPT, PERL_MM_OPT; and these two CPAN.pm config variables must be reconfigured: make_install_make_command and mbuild_install_build_command. The five env variables have probably been overwritten in your $HOME/.bashrc or some equivalent. You either find them there and delete their traces and logout/login or you override them temporarily, depending on your exact desire. The two cpanpm config variables can be set with:

  ```
  o conf init /install_.*_command/
  ```

  probably followed by

  ```
  o conf commit
  ```

- 20)

How do recommends_policy and suggests_policy work, exactly?

The terms `recommends` and `suggests` have been standardized in https://metacpan.org/pod/CPAN::Meta::Spec

In CPAN.pm, if you set `recommands_policy` to a true value, that means: if you then install a distribution `Foo` that *recommends* a module `Bar`, both `Foo` and `Bar` will be tested and potentially installed.

Similarly, if you set `suggests_policy` to a true value, it means: if you install a distribution `Foo` that *suggests* a module `Bar`, both `Foo` and `Bar` will be tested and potentially installed.

In either case, when `Foo` passes its tests and `Bar` does not pass its tests, `Foo` will be installed nontheless. But if `Foo` does not pass its tests, neither will be installed.

This also works recursively for all recommends and suggests of the module `Bar`.

This has also been illustrated by a cpan tester, who wrote:

I just tested Starlink-AST-3.03 which recommends Tk::Zinc; Tk-Zinc-3.306 fails with http://www.cpantesters.org/cpan/report/a2de7c38-810d-11ee-9ad4-e2167316189a ; nonetheless Starlink-AST-3.03 succeeds with http://www.cpantesters.org/cpan/report/9352e754-810d-11ee-90e9-46117316189a

COMPATIBILITY

OLD PERL VERSIONS

CPAN.pm is regularly tested to run under 5.005 and assorted newer versions. It is getting more and more difficult to get the minimal prerequisites working on older perls. It is close to impossible to get the whole Bundle::CPAN working there. If you're in the position to have only these old versions, be advised that CPAN is designed to work fine without the Bundle::CPAN installed.

To get things going, note that GBARR/Scalar-List-Utils-1.18.tar.gz is compatible with ancient perls and that File::Temp is listed as a prerequisite but CPAN has reasonable workarounds if it is missing.

CPANPLUS

This module and its competitor, the CPANPLUS module, are both much cooler than the other. CPAN.pm is older. CPANPLUS was designed to be more modular, but it was never intended to be compatible with CPAN.pm.

CPANMINUS

In the year 2010 App::cpanminus was launched as a new approach to a cpan shell with a considerably smaller footprint. Very cool stuff.

SECURITY ADVICE

This software enables you to upgrade software on your computer and so is inherently dangerous because the newly installed software may contain bugs and may alter the way your computer works or even make it unusable. Please consider backing up your data before every upgrade.

BUGS

Please report bugs via http://rt.cpan.org/

Before submitting a bug, please make sure that the traditional method of building a Perl module package from a shell by following the installation instructions of that package still works in your environment.

TRANSLATIONS

Kawai,Takanori provides a Japanese translation of a very old version of this manpage at http://homepage3.nifty.com/hippo2000/perltips/CPAN.htm

SEE ALSO

Many people enter the CPAN shell by running the cpan utility program which is installed in the same directory as perl itself. So if you have this directory in your PATH variable (or some equivalent in your operating system) then typing `cpan` in a console window will work for you as well. Above that the utility provides several commandline shortcuts.

melezhik (Alexey) sent me a link where he published a chef recipe to work with CPAN.pm: http://community.opscode.com/cookbooks/cpan.

Modules

- `CPAN::Debug` - internal debugging for CPAN.pm
- `CPAN::Distroprefs` - read and match distroprefs
- `CPAN::FirstTime` - Utility for CPAN::Config file Initialization
- `CPAN::HandleConfig` - internal configuration handling for CPAN.pm
- `CPAN::Kwalify` - Interface between CPAN.pm and Kwalify.pm
- `CPAN::Meta` - the distribution metadata for a CPAN dist
- `CPAN::Mirrors` - Get CPAN mirror information and select a fast one

- `CPAN::Nox` - Interactive mode:
- `CPAN::Plugin` - Base class for CPAN shell extensions
- `CPAN::Queue` - internal queue support for CPAN.pm
- `CPAN::Tarzip` - internal handling of tar archives for CPAN.pm
- `CPAN::Version` - utility functions to compare CPAN versions

CPAN::Debug

internal debugging for CPAN.pm

CPAN::Distroprefs

read and match distroprefs

SYNOPSIS

```
use CPAN::Distroprefs;

my %info = (... distribution/environment info ...);

my $finder = CPAN::Distroprefs->find($prefs_dir, \%ext_map);

while (my $result = $finder->next) {

    die $result->as_string if $result->is_fatal;

    warn($result->as_string), next if $result->is_warning;

    for my $pref (@{ $result->prefs }) {
        if ($pref->matches(\%info)) {
            return $pref;
        }
    }
}
```

DESCRIPTION

This module encapsulates reading *Distroprefs* and matching them against CPAN distributions.

INTERFACE

```
my $finder = CPAN::Distroprefs->find($dir, \%ext_map);

while (my $result = $finder->next) { ... }
```

Build an iterator which finds distroprefs files in the tree below the given directory. Within the tree directories matching `m/^[._]/` are pruned.

`%ext_map` is a hashref whose keys are file extensions and whose values are modules used to load matching files:

```
{
    'yml' => 'YAML::Syck',
    'dd'  => 'Data::Dumper',
    ...
}
```

Each time `$finder->next` is called, the iterator returns one of two possible values:

- a CPAN::Distroprefs::Result object
- `undef`, indicating that no prefs files remain to be found

RESULTS

`find()` returns CPAN::Distroprefs::Result objects to indicate success or failure when reading a prefs file.

Common

All results share some common attributes:

type

`success`, `warning`, or `fatal`

file

the file from which these prefs were read, or to which this error refers (relative filename)

ext

the file's extension, which determines how to load it

dir

the directory the file was read from

abs

the absolute path to the file

Errors

Error results (warning and fatal) contain:

msg

the error message (usually either `$!` or a YAML error)

Successes

Success results contain:

prefs

an arrayref of CPAN::Distroprefs::Pref objects

PREFS

CPAN::Distroprefs::Pref objects represent individual distroprefs documents. They are constructed automatically as part of `success` results from `find()`.

data

the pref information as a hashref, suitable for e.g. passing to Kwalify

match_attributes

returns a list of the valid match attributes (see the Distroprefs section in *CPAN*)

currently: `env perl perlconfig distribution module`

has_any_match

true if this pref has a 'match' attribute at all

has_valid_subkeys

true if this pref has a 'match' attribute and at least one valid match attribute

matches

```
if ($pref->matches(\%arg)) { ... }
```

true if this pref matches the passed-in hashref, which must have a value for each of the `match_attributes` (above)

LICENSE

CPAN::FirstTime

Utility for CPAN::Config file Initialization

SYNOPSIS

CPAN::FirstTime::init()

DESCRIPTION

The init routine asks a few questions and writes a CPAN/Config.pm or CPAN/MyConfig.pm file (depending on what it is currently using).

In the following all questions and explanations regarding config variables are collected.

- allow_installing_module_downgrades

  The CPAN shell can watch the `blib/` directories that are built up before running `make test` to determine whether the current distribution will end up with modules being overwritten with decreasing module version numbers. It can then let the build of this distro fail when it discovers a downgrade.

  Do you want to allow installing distros with decreasing module versions compared to what you have installed (yes, no, ask/yes, ask/no)?

- allow_installing_outdated_dists

  The CPAN shell can watch the `blib/` directories that are built up before running `make test` to determine whether the current distribution contains modules that are indexed with a distro with a higher distro-version number than the current one. It can then let the build of this distro fail when it would not represent the most up-to-date version of the distro.

  Note: choosing anything but 'yes' for this option will need CPAN::DistnameInfo being installed for taking effect.

  Do you want to allow installing distros that are not indexed as the highest distro-version for all contained modules (yes, no, ask/yes, ask/no)?

- auto_commit

  Normally CPAN.pm keeps config variables in memory and changes need to be saved in a separate 'o conf commit' command to make them permanent between sessions. If you set the 'auto_commit' option to true, changes to a config variable are always automatically committed to disk.

  Always commit changes to config variables to disk?

- build_cache

  CPAN.pm can limit the size of the disk area for keeping the build directories with all the intermediate files.

Cache size for build directory (in MB)?

- build_dir

  Directory where the build process takes place?

- build_dir_reuse

  Until version 1.88 CPAN.pm never trusted the contents of the build_dir directory between sessions. Since 1.88_58 CPAN.pm has a YAML-based mechanism that makes it possible to share the contents of the build_dir/ directory between different sessions with the same version of perl. People who prefer to test things several days before installing will like this feature because it saves a lot of time.

  If you say yes to the following question, CPAN will try to store enough information about the build process so that it can pick up in future sessions at the same state of affairs as it left a previous session.

  Store and re-use state information about distributions between CPAN.pm sessions?

- build_requires_install_policy

  When a module declares another one as a 'build_requires' prerequisite this means that the other module is only needed for building or testing the module but need not be installed permanently. In this case you may wish to install that other module nonetheless or just keep it in the 'build_dir' directory to have it available only temporarily. Installing saves time on future installations but makes the perl installation bigger.

  You can choose if you want to always install (yes), never install (no) or be always asked. In the latter case you can set the default answer for the question to yes (ask/yes) or no (ask/no).

  Policy on installing 'build_requires' modules (yes, no, ask/yes, ask/no)?

- cache_metadata

  To considerably speed up the initial CPAN shell startup, it is possible to use Storable to create a cache of metadata. If Storable is not available, the normal index mechanism will be used.

  Note: this mechanism is not used when use_sqlite is on and SQLite is running.

  Cache metadata (yes/no)?

- check_sigs

  CPAN packages can be digitally signed by authors and thus verified with the security provided by strong cryptography. The exact mechanism is defined in the Module::Signature module. While this is generally considered a good thing, it is not always convenient to the end user to install modules that are signed incorrectly or where the key of the author is not available or where some prerequisite for Module::Signature has a bug and so on.

  With the check_sigs parameter you can turn signature checking on and off. The default is off for now because the whole tool chain for the functionality is not yet considered mature by some. The author of CPAN.pm would recommend setting it to true most of the time and turning it off only if it turns out to be annoying.

Note that if you do not have Module::Signature installed, no signature checks will be performed at all.

Always try to check and verify signatures if a SIGNATURE file is in the package and Module::Signature is installed (yes/no)?

- cleanup_after_install

  Users who install modules and do not intend to look back, can free occupied disk space quickly by letting CPAN.pm cleanup each build directory immediately after a successful install.

  Remove build directory after a successful install? (yes/no)?

- colorize_output

  When you have Term::ANSIColor installed, you can turn on colorized output to have some visual differences between normal CPAN.pm output, warnings, debugging output, and the output of the modules being installed. Set your favorite colors after some experimenting with the Term::ANSIColor module.

  Please note that on Windows platforms colorized output also requires the Win32::Console::ANSI module.

  Do you want to turn on colored output?

- colorize_print

  Color for normal output?

- colorize_warn

  Color for warnings?

- colorize_debug

  Color for debugging messages?

- commandnumber_in_prompt

  The prompt of the cpan shell can contain the current command number for easier tracking of the session or be a plain string.

  Do you want the command number in the prompt (yes/no)?

- connect_to_internet_ok

  If you have never defined your own `urllist` in your configuration then `CPAN.pm` will be hesitant to use the built in default sites for downloading. It will ask you once per session if a connection to the internet is OK and only if you say yes, it will try to connect. But to avoid this question, you can choose your favorite download sites once and get away with it. Or, if you have no favorite download sites answer yes to the following question.

  If no urllist has been chosen yet, would you prefer CPAN.pm to connect to the built-in default sites without asking? (yes/no)?

- ftp_passive

  Shall we always set the FTP_PASSIVE environment variable when dealing with ftp download (yes/no)?

- ftpstats_period

  Statistics about downloads are truncated by size and period simultaneously.

  How many days shall we keep statistics about downloads?

- ftpstats_size

  Statistics about downloads are truncated by size and period simultaneously. Setting this to zero or negative disables download statistics.

  How many items shall we keep in the statistics about downloads?

- getcwd

  CPAN.pm changes the current working directory often and needs to determine its own current working directory. Per default it uses Cwd::cwd but if this doesn't work on your system for some reason, alternatives can be configured according to the following table:

```
cwd          Cwd::cwd
getcwd       Cwd::getcwd
fastcwd      Cwd::fastcwd
getdcwd      Cwd::getdcwd
backtickcwd external command cwd
```

  Preferred method for determining the current working directory?

- halt_on_failure

  Normally, CPAN.pm continues processing the full list of targets and dependencies, even if one of them fails. However, you can specify that CPAN should halt after the first failure. (Note that optional recommended or suggested modules that fail will not cause a halt.)

  Do you want to halt on failure (yes/no)?

- histfile

  If you have one of the readline packages (Term::ReadLine::Perl, Term::ReadLine::Gnu, possibly others) installed, the interactive CPAN shell will have history support. The next two questions deal with the filename of the history file and with its size. If you do not want to set this variable, please hit SPACE ENTER to the following question.

  File to save your history?

- histsize

  Number of lines to save?

- inactivity_timeout

  Sometimes you may wish to leave the processes run by CPAN alone without caring about them. Because the Makefile.PL or the Build.PL sometimes contains question you're expected to answer, you can set a timer that will kill a 'perl Makefile.PL' process after the specified time in seconds.

  If you set this value to 0, these processes will wait forever. This is the default and recommended setting.

Timeout for inactivity during {Makefile,Build}.PL?

- index_expire

  The CPAN indexes are usually rebuilt once or twice per hour, but the typical CPAN mirror mirrors only once or twice per day. Depending on the quality of your mirror and your desire to be on the bleeding edge, you may want to set the following value to more or less than one day (which is the default). It determines after how many days CPAN.pm downloads new indexes.

  Let the index expire after how many days?

- inhibit_startup_message

  When the CPAN shell is started it normally displays a greeting message that contains the running version and the status of readline support.

  Do you want to turn this message off?

- keep_source_where

  Unless you are accessing the CPAN on your filesystem via a file: URL, CPAN.pm needs to keep the source files it downloads somewhere. Please supply a directory where the downloaded files are to be kept.

  Download target directory?

- load_module_verbosity

  When CPAN.pm loads a module it needs for some optional feature, it usually reports about module name and version. Choose 'v' to get this message, 'none' to suppress it.

  Verbosity level for loading modules (none or v)?

- makepl_arg

  Every Makefile.PL is run by perl in a separate process. Likewise we run 'make' and 'make install' in separate processes. If you have any parameters (e.g. PREFIX, UNINST or the like) you want to pass to the calls, please specify them here.

  If you don't understand this question, just press ENTER.

  Typical frequently used settings:

```
PREFIX=~/perl    # non-root users (please see manual for more␣
↪hints)
```

  Parameters for the 'perl Makefile.PL' command?

- make_arg

  Parameters for the 'make' command? Typical frequently used setting:

```
-j3              # dual processor system (on GNU make)
```

  Your choice:

- make_install_arg

  Parameters for the 'make install' command? Typical frequently used setting:

```
UNINST=1          # to always uninstall potentially conflicting␣
↪files
                  # (but do NOT use with local::lib or INSTALL_
↪BASE)
```

Your choice:

- make_install_make_command

  Do you want to use a different make command for 'make install'? Cautious people will probably prefer:

```
   su root -c make
or
   sudo make
or
   /path1/to/sudo -u admin_account /path2/to/make
```

  or some such. Your choice:

- mbuildpl_arg

  A Build.PL is run by perl in a separate process. Likewise we run './Build' and './Build install' in separate processes. If you have any parameters you want to pass to the calls, please specify them here.

  Typical frequently used settings:

```
--install_base /home/xxx             # different installation␣
↪directory
```

  Parameters for the 'perl Build.PL' command?

- mbuild_arg

  Parameters for the './Build' command? Setting might be:

```
--extra_linker_flags -L/usr/foo/lib  # non-standard library␣
↪location
```

  Your choice:

- mbuild_install_arg

  Parameters for the './Build install' command? Typical frequently used setting:

```
--uninst 1        # uninstall conflicting files
                  # (but do NOT use with local::lib or INSTALL_
↪BASE)
```

  Your choice:

- mbuild_install_build_command

  Do you want to use a different command for './Build install'? Sudo users will probably prefer:

```
   su root -c ./Build
or
   sudo ./Build
or
   /path1/to/sudo -u admin_account ./Build
```

or some such. Your choice:

- pager

  What is your favorite pager program?

- prefer_installer

  When you have Module::Build installed and a module comes with both a Makefile.PL and a Build.PL, which shall have precedence?

  The main two standard installer modules are the old and well established ExtUtils::MakeMaker (for short: EUMM) which uses the Makefile.PL. And the next generation installer Module::Build (MB) which works with the Build.PL (and often comes with a Makefile.PL too). If a module comes only with one of the two we will use that one but if both are supplied then a decision must be made between EUMM and MB. See also http://rt.cpan.org/Ticket/Display.html?id=29235 for a discussion about the right default.

  Or, as a third option you can choose RAND which will make a random decision (something regular CPAN testers will enjoy).

  In case you can choose between running a Makefile.PL or a Build.PL, which installer would you prefer (EUMM or MB or RAND)?

- prefs_dir

  CPAN.pm can store customized build environments based on regular expressions for distribution names. These are YAML files where the default options for CPAN.pm and the environment can be overridden and dialog sequences can be stored that can later be executed by an Expect.pm object. The CPAN.pm distribution comes with some prefab YAML files that cover sample distributions that can be used as blueprints to store your own prefs. Please check out the distroprefs/ directory of the CPAN.pm distribution to get a quick start into the prefs system.

  Directory where to store default options/environment/dialogs for building modules that need some customization?

- prerequisites_policy

  The CPAN module can detect when a module which you are trying to build depends on prerequisites. If this happens, it can build the prerequisites for you automatically ('follow'), ask you for confirmation ('ask'), or just ignore them ('ignore'). Choosing 'follow' also sets PERL_AUTOINSTALL and PERL_EXTUTILS_AUTOINSTALL for "–defaultdeps" if not already set.

  Please set your policy to one of the three values.

  Policy on building prerequisites (follow, ask or ignore)?

- pushy_https

Boolean. Defaults to true. If this option is true, the cpan shell will use https://cpan.org/ to download stuff from the CPAN. It will fall back to http://cpan.org/ if it can't handle https for some reason (missing modules, missing programs). Whenever it falls back to the http protocol, it will issue a warning.

If this option is true, the option `urllist` will be ignored. Consequently, if you want to work with local mirrors via your own configured list of URLs, you will have to choose no below.

Do you want to turn the pushy_https behaviour on?

- randomize_urllist

  CPAN.pm can introduce some randomness when using hosts for download that are configured in the urllist parameter. Enter a numeric value between 0 and 1 to indicate how often you want to let CPAN.pm try a random host from the urllist. A value of one specifies to always use a random host as the first try. A value of zero means no randomness at all. Anything in between specifies how often, on average, a random host should be tried first.

  Randomize parameter

- recommends_policy

  (Experimental feature!) Some CPAN modules recommend additional, optional dependencies. These should generally be installed except in resource constrained environments. When this policy is true, recommended modules will be included with required modules.

  Include recommended modules?

- scan_cache

  By default, each time the CPAN module is started, cache scanning is performed to keep the cache size in sync ('atstart'). Alternatively, scanning and cleanup can happen when CPAN exits ('atexit'). To prevent any cache cleanup, answer 'never'.

  Perform cache scanning ('atstart', 'atexit' or 'never')?

- shell

  What is your favorite shell?

- show_unparsable_versions

  During the 'r' command CPAN.pm finds modules without version number. When the command finishes, it prints a report about this. If you want this report to be very verbose, say yes to the following variable.

  Show all individual modules that have no $VERSION?

- show_upload_date

  The 'd' and the 'm' command normally only show you information they have in their in-memory database and thus will never connect to the internet. If you set the 'show_upload_date' variable to true, 'm' and 'd' will additionally show you the upload date of the module or distribution. Per default this feature is off because it may require a net connection to get at the upload date.

  Always try to show upload date with 'd' and 'm' command (yes/no)?

- show_zero_versions

  During the 'r' command CPAN.pm finds modules with a version number of zero. When the command finishes, it prints a report about this. If you want this report to be very verbose, say yes to the following variable.

  Show all individual modules that have a $VERSION of zero?

- suggests_policy

  (Experimental feature!) Some CPAN modules suggest additional, optional dependencies. These 'suggest' dependencies provide enhanced operation. When this policy is true, suggested modules will be included with required modules.

  Include suggested modules?

- tar_verbosity

  When CPAN.pm uses the tar command, which switch for the verbosity shall be used? Choose 'none' for quiet operation, 'v' for file name listing, 'vv' for full listing.

  Tar command verbosity level (none or v or vv)?

- term_is_latin

  The next option deals with the charset (a.k.a. character set) your terminal supports. In general, CPAN is English speaking territory, so the charset does not matter much but some CPAN have names that are outside the ASCII range. If your terminal supports UTF-8, you should say no to the next question. If it expects ISO-8859-1 (also known as LATIN1) then you should say yes. If it supports neither, your answer does not matter because you will not be able to read the names of some authors anyway. If you answer no, names will be output in UTF-8.

  Your terminal expects ISO-8859-1 (yes/no)?

- term_ornaments

  When using Term::ReadLine, you can turn ornaments on so that your input stands out against the output from CPAN.pm.

  Do you want to turn ornaments on?

- test_report

  The goal of the CPAN Testers project (http://testers.cpan.org/) is to test as many CPAN packages as possible on as many platforms as possible. This provides valuable feedback to module authors and potential users to identify bugs or platform compatibility issues and improves the overall quality and value of CPAN.

  One way you can contribute is to send test results for each module that you install. If you install the CPAN::Reporter module, you have the option to automatically generate and deliver test reports to CPAN Testers whenever you run tests on a CPAN package.

  See the CPAN::Reporter documentation for additional details and configuration settings. If your firewall blocks outgoing traffic, you may need to configure CPAN::Reporter before sending reports.

  Generate test reports if CPAN::Reporter is installed (yes/no)?

- perl5lib_verbosity

  When CPAN.pm extends @INC via PERL5LIB, it prints a list of directories added (or a summary of how many directories are added). Choose 'v' to get this message, 'none' to suppress it.

  Verbosity level for PERL5LIB changes (none or v)?

- prefer_external_tar

  Per default all untar operations are done with the perl module Archive::Tar; by setting this variable to true the external tar command is used if available; on Unix this is usually preferred because they have a reliable and fast gnutar implementation.

  Use the external tar program instead of Archive::Tar?

- trust_test_report_history

  When a distribution has already been tested by CPAN::Reporter on this machine, CPAN can skip the test phase and just rely on the test report history instead.

  Note that this will not apply to distributions that failed tests because of missing dependencies. Also, tests can be run regardless of the history using "force".

  Do you want to rely on the test report history (yes/no)?

- urllist_ping_external

  When automatic selection of the nearest cpan mirrors is performed, turn on the use of the external ping via Net::Ping::External. This is recommended in the case the local network has a transparent proxy.

  Do you want to use the external ping command when autoselecting mirrors?

- urllist_ping_verbose

  When automatic selection of the nearest cpan mirrors is performed, this option can be used to turn on verbosity during the selection process.

  Do you want to see verbosity turned on when autoselecting mirrors?

- use_prompt_default

  When this is true, CPAN will set PERL_MM_USE_DEFAULT to a true value. This causes ExtUtils::MakeMaker (and compatible) prompts to use default values instead of stopping to prompt you to answer questions. It also sets NONINTERACTIVE_TESTING to a true value to signal more generally that distributions should not try to interact with you.

  Do you want to use prompt defaults (yes/no)?

- use_sqlite

  CPAN::SQLite is a layer between the index files that are downloaded from the CPAN and CPAN.pm that speeds up metadata queries and reduces memory consumption of CPAN.pm considerably.

  Use CPAN::SQLite if available? (yes/no)?

- version_timeout

  This timeout prevents CPAN from hanging when trying to parse a pathologically coded $VERSION from a module.

The default is 15 seconds. If you set this value to 0, no timeout will occur, but this is not recommended.

Timeout for parsing module versions?

- yaml_load_code

  Both YAML.pm and YAML::Syck are capable of deserialising code. As this requires a string eval, which might be a security risk, you can use this option to enable or disable the deserialisation of code via CPAN::DeferredCode. (Note: This does not work under perl 5.6)

  Do you want to enable code deserialisation (yes/no)?

- yaml_module

  At the time of this writing (2009-03) there are three YAML implementations working: YAML, YAML::Syck, and YAML::XS. The latter two are faster but need a C compiler installed on your system. There may be more alternative YAML conforming modules. When I tried two other players, YAML::Tiny and YAML::Perl, they seemed not powerful enough to work with CPAN.pm. This may have changed in the meantime.

  Which YAML implementation would you prefer?

CPAN::HandleConfig

internal configuration handling for CPAN.pm

CLASS->safe_quote ITEM

Quotes an item to become safe against spaces in shell interpolation. An item is enclosed in double quotes if:

```
- the item contains spaces in the middle
- the item does not start with a quote
```

This happens to avoid shell interpolation problems when whitespace is present in directory names.

This method uses `commands_quote` to determine the correct quote. If `commands_quote` is a space, no quoting will take place.

if it starts and ends with the same quote character: leave it as it is

if it contains no whitespace: leave it as it is

if it contains whitespace, then

if it contains quotes: better leave it as it is

else: quote it with the correct quote type for the box we're on

CPAN::Kwalify

Interface between CPAN.pm and Kwalify.pm

SYNOPSIS

```
use CPAN::Kwalify;
validate($schema_name, $data, $file, $doc);
```

DESCRIPTION

- _validate($schema_name, $data, $file, $doc)

  $schema_name is the name of a supported schema. Currently only `distroprefs` is supported. $data is the data to be validated. $file is the absolute path to the file the data are coming from. $doc is the index of the document within $doc that is to be validated. The last two arguments are only there for better error reporting.

  Relies on being called from within CPAN.pm.

  Dies if something fails. Does not return anything useful.

- yaml($schema_name)

  Returns the YAML text of that schema. Dies if something fails.

CPAN::Meta

the distribution metadata for a CPAN dist

VERSION

version 2.150013

SYNOPSIS

```
use v5.10;
use strict;
use warnings;
use CPAN::Meta;
use Module::Load;

my $meta = CPAN::Meta->load_file('META.json');

printf "testing requirements for %s version %s\n",
$meta->name,
$meta->version;

my $prereqs = $meta->effective_prereqs;

for my $phase ( qw/configure runtime build test/ ) {
    say "Requirements for $phase:";
    my $reqs = $prereqs->requirements_for($phase, "requires");
    for my $module ( sort $reqs->required_modules ) {
        my $status;
        if ( eval { load $module unless $module eq 'perl'; 1 } ) {
            my $version = $module eq 'perl' ? $] : $module->VERSION;
            $status = $reqs->accepts_module($module, $version)
                    ? "$version ok" : "$version not ok";
        } else {
            $status = "missing"
        };
        say "  $module ($status)";
    }
}
```

DESCRIPTION

Software distributions released to the CPAN include a `META.json` or, for older distributions, `META.yml`, which describes the distribution, its contents, and the requirements for building and installing the distribution. The data structure stored in the `META.json` file is described in *CPAN::Meta::Spec*.

CPAN::Meta provides a simple class to represent this distribution metadata (or *distmeta*), along with some helpful methods for interrogating that data.

The documentation below is only for the methods of the CPAN::Meta object. For information on the meaning of individual fields, consult the spec.

METHODS

new

```
my $meta = CPAN::Meta->new($distmeta_struct, \%options);
```

Returns a valid CPAN::Meta object or dies if the supplied metadata hash reference fails to validate. Older-format metadata will be up-converted to version 2 if they validate against the original stated specification.

It takes an optional hashref of options. Valid options include:

- lazy_validation – if true, new will attempt to convert the given metadata to version 2 before attempting to validate it. This means than any fixable errors will be handled by CPAN::Meta::Converter before validation. (Note that this might result in invalid optional data being silently dropped.) The default is false.

create

```
my $meta = CPAN::Meta->create($distmeta_struct, \%options);
```

This is same as `new()`, except that `generated_by` and `meta-spec` fields will be generated if not provided. This means the metadata structure is assumed to otherwise follow the latest *CPAN::Meta::Spec*.

load_file

```
my $meta = CPAN::Meta->load_file($distmeta_file, \%options);
```

Given a pathname to a file containing metadata, this deserializes the file according to its file suffix and constructs a new `CPAN::Meta` object, just like `new()`. It will die if the deserialized version fails to validate against its stated specification version.

It takes the same options as `new()` but `lazy_validation` defaults to true.

load_yaml_string

```
my $meta = CPAN::Meta->load_yaml_string($yaml, \%options);
```

This method returns a new CPAN::Meta object using the first document in the given YAML string. In other respects it is identical to `load_file()`.

load_json_string

```
my $meta = CPAN::Meta->load_json_string($json, \%options);
```

This method returns a new CPAN::Meta object using the structure represented by the given JSON string. In other respects it is identical to `load_file()`.

load_string

```
my $meta = CPAN::Meta->load_string($string, \%options);
```

If you don't know if a string contains YAML or JSON, this method will use *Parse::CPAN::Meta* to guess. In other respects it is identical to `load_file()`.

save

```
$meta->save($distmeta_file, \%options);
```

Serializes the object as JSON and writes it to the given file. The only valid option is `version`, which defaults to '2'. On Perl 5.8.1 or later, the file is saved with UTF-8 encoding.

For `version` 2 (or higher), the filename should end in '.json'. *JSON::PP* is the default JSON backend. Using another JSON backend requires *JSON* 2.5 or later and you must set the `$ENV{PERL_JSON_BACKEND}` to a supported alternate backend like *JSON::XS*.

For `version` less than 2, the filename should end in '.yml'. *CPAN::Meta::Converter* is used to generate an older metadata structure, which is serialized to YAML. CPAN::Meta::YAML is the default YAML backend. You may set the `$ENV{PERL_YAML_BACKEND}` to a supported alternative backend, though this is not recommended due to subtle incompatibilities between YAML parsers on CPAN.

meta_spec_version

This method returns the version part of the `meta_spec` entry in the distmeta structure. It is equivalent to:

```
$meta->meta_spec->{version};
```

effective_prereqs

```
my $prereqs = $meta->effective_prereqs;

my $prereqs = $meta->effective_prereqs( \@feature_identifiers );
```

This method returns a *CPAN::Meta::Prereqs* object describing all the prereqs for the distribution. If an arrayref of feature identifiers is given, the prereqs for the identified features are merged together with the distribution's core prereqs before the CPAN::Meta::Prereqs object is returned.

should_index_file

```
... if $meta->should_index_file( $filename );
```

This method returns true if the given file should be indexed. It decides this by checking the `file` and `directory` keys in the `no_index` property of the distmeta structure. Note that neither the version format nor `release_status` are considered.

`$filename` should be given in unix format.

should_index_package

```
... if $meta->should_index_package( $package );
```

This method returns true if the given package should be indexed. It decides this by checking the `package` and `namespace` keys in the `no_index` property of the distmeta structure. Note that neither the version format nor `release_status` are considered.

features

```
my @feature_objects = $meta->features;
```

This method returns a list of *CPAN::Meta::Feature* objects, one for each optional feature described by the distribution's metadata.

feature

```
my $feature_object = $meta->feature( $identifier );
```

This method returns a *CPAN::Meta::Feature* object for the optional feature with the given identifier. If no feature with that identifier exists, an exception will be raised.

as_struct

```
my $copy = $meta->as_struct( \%options );
```

This method returns a deep copy of the object's metadata as an unblessed hash reference. It takes an optional hashref of options. If the hashref contains a `version` argument, the copied metadata will be converted to the version of the specification and returned. For example:

```
my $old_spec = $meta->as_struct( {version => "1.4"} );
```

as_string

```
my $string = $meta->as_string( \%options );
```

This method returns a serialized copy of the object's metadata as a character string. (The strings are **not** UTF-8 encoded.) It takes an optional hashref of options. If the hashref contains a `version` argument, the copied metadata will be converted to the version of the specification and returned. For example:

```
my $string = $meta->as_string( {version => "1.4"} );
```

For `version` greater than or equal to 2, the string will be serialized as JSON. For `version` less than 2, the string will be serialized as YAML. In both cases, the same rules are followed as in the `save()` method for choosing a serialization backend.

The serialized structure will include a `x_serialization_backend` entry giving the package and version used to serialize. Any existing key in the given `$meta` object will be clobbered.

STRING DATA

The following methods return a single value, which is the value for the corresponding entry in the distmeta structure. Values should be either undef or strings.

- abstract
- description
- dynamic_config
- generated_by
- name
- release_status
- version

LIST DATA

These methods return lists of string values, which might be represented in the distmeta structure as arrayrefs or scalars:

- authors
- keywords
- licenses

The `authors` and `licenses` methods may also be called as `author` and `license`, respectively, to match the field name in the distmeta structure.

MAP DATA

These readers return hashrefs of arbitrary unblessed data structures, each described more fully in the specification:

- meta_spec
- resources
- provides
- no_index
- prereqs
- optional_features

CUSTOM DATA

A list of custom keys are available from the `custom_keys` method and particular keys may be retrieved with the `custom` method.

```
say $meta->custom($_) for $meta->custom_keys;
```

If a custom key refers to a data structure, a deep clone is returned.

BUGS

Please report any bugs or feature using the CPAN Request Tracker. Bugs can be submitted through the web interface at http://rt.cpan.org/Dist/Display.html?Queue=CPAN-Meta

When submitting a bug or request, please include a test-file or a patch to an existing test-file that illustrates the bug or desired feature.

Modules

- `CPAN::Meta::Converter` - Convert CPAN distribution metadata structures
- `CPAN::Meta::Feature` - an optional feature provided by a CPAN distribution
- `CPAN::Meta::History` - history of CPAN Meta Spec changes
- `CPAN::Meta::Merge` - Merging CPAN Meta fragments

- `CPAN::Meta::Prereqs` - a set of distribution prerequisites by phase and type
- `CPAN::Meta::Requirements` - a set of version requirements for a CPAN dist
- `CPAN::Meta::Spec` - specification for CPAN distribution metadata
- `CPAN::Meta::Validator` - validate CPAN distribution metadata structures
- `CPAN::Meta::YAML` - Read and write a subset of YAML for CPAN Meta files

CPAN::Meta::Converter

Convert CPAN distribution metadata structures

VERSION

version 2.150013

SYNOPSIS

```
my $struct = decode_json_file('META.json');

my $cmc = CPAN::Meta::Converter->new( $struct );

my $new_struct = $cmc->convert( version => "2" );
```

DESCRIPTION

This module converts CPAN Meta structures from one form to another. The primary use is to convert older structures to the most modern version of the specification, but other transformations may be implemented in the future as needed. (E.g. stripping all custom fields or stripping all optional fields.)

METHODS

new

```
my $cmc = CPAN::Meta::Converter->new( $struct );
```

The constructor should be passed a valid metadata structure but invalid structures are accepted. If no meta-spec version is provided, version 1.0 will be assumed.

Optionally, you can provide a `default_version` argument after `$struct`:

```
my $cmc = CPAN::Meta::Converter->new( $struct, default_version =>
↪"1.4" );
```

This is only needed when converting a metadata fragment that does not include a `meta-spec` field.

convert

```
my $new_struct = $cmc->convert( version => "2" );
```

Returns a new hash reference with the metadata converted to a different form. `convert` will die if any conversion/standardization still results in an invalid structure.

Valid parameters include:

- `version` – Indicates the desired specification version (e.g. “1.0”, “1.1” ... “1.4”, “2”). Defaults to the latest version of the CPAN Meta Spec.

Conversion proceeds through each version in turn. For example, a version 1.2 structure might be converted to 1.3 then 1.4 then finally to version 2. The conversion process attempts to clean-up simple errors and standardize data. For example, if `author` is given as a scalar, it will converted to an array reference containing the item. (Converting a structure to its own version will also clean-up and standardize.)

When data are cleaned and standardized, missing or invalid fields will be replaced with sensible defaults when possible. This may be lossy or imprecise. For example, some badly structured META.yml files on CPAN have prerequisite modules listed as both keys and values:

```
requires => { 'Foo::Bar' => 'Bam::Baz' }
```

These would be split and each converted to a prerequisite with a minimum version of zero.

When some mandatory fields are missing or invalid, the conversion will attempt to provide a sensible default or will fill them with a value of ‘unknown’. For example a missing or unrecognized `license` field will result in a `license` field of ‘unknown’. Fields that may get an ‘unknown’ include:

- abstract
- author
- license

upgrade_fragment

```
my $new_struct = $cmc->upgrade_fragment;
```

Returns a new hash reference with the metadata converted to the latest version of the CPAN Meta Spec. No validation is done on the result – you must validate after merging fragments into a complete metadata document.

Available since version 2.141170.

BUGS

Please report any bugs or feature using the CPAN Request Tracker. Bugs can be submitted through the web interface at http://rt.cpan.org/Dist/Display.html?Queue=CPAN-Meta

When submitting a bug or request, please include a test-file or a patch to an existing test-file that illustrates the bug or desired feature.

CPAN::Meta::Feature

an optional feature provided by a CPAN distribution

VERSION

version 2.150013

DESCRIPTION

A CPAN::Meta::Feature object describes an optional feature offered by a CPAN distribution and specified in the distribution's `META.json` (or `META.yml`) file.

For the most part, this class will only be used when operating on the result of the `feature` or `features` methods on a *CPAN::Meta* object.

METHODS

new

```
my $feature = CPAN::Meta::Feature->new( $identifier => \%spec );
```

This returns a new Feature object. The `%spec` argument to the constructor should be the same as the value of the `optional_feature` entry in the distmeta. It must contain entries for `description` and `prereqs`.

identifier

This method returns the feature's identifier.

description

This method returns the feature's long description.

prereqs

This method returns the feature's prerequisites as a *CPAN::Meta::Prereqs* object.

BUGS

Please report any bugs or feature using the CPAN Request Tracker. Bugs can be submitted through the web interface at http://rt.cpan.org/Dist/Display.html?Queue=CPAN-Meta

When submitting a bug or request, please include a test-file or a patch to an existing test-file that illustrates the bug or desired feature.

CPAN::Meta::History

history of CPAN Meta Spec changes

VERSION

version 2.150013

DESCRIPTION

The CPAN Meta Spec has gone through several iterations. It was originally written in HTML and later revised into POD (though published in HTML generated from the POD). Fields were added, removed or changed, sometimes by design and sometimes to reflect real-world usage after the fact.

This document reconstructs the history of the CPAN Meta Spec based on change logs, repository commit messages and the published HTML files. In some cases, particularly prior to version 1.2, the exact version when certain fields were introduced or changed is inconsistent between sources. When in doubt, the published HTML files for versions 1.0 to 1.4 as they existed when version 2 was developed are used as the definitive source.

Starting with version 2, the specification document is part of the CPAN-Meta distribution and will be published on CPAN as *CPAN::Meta::Spec*.

Going forward, specification version numbers will be integers and decimal portions will correspond to a release date for the CPAN::Meta library.

HISTORY

Version 2

April 2010

- Revised spec examples as perl data structures rather than YAML
- Switched to JSON serialization from YAML
- Specified allowed version number formats
- Replaced 'requires', 'build_requires', 'configure_requires', 'recommends' and 'conflicts' with new 'prereqs' data structure divided by *phase* (configure, build, test, runtime, etc.) and *relationship* (requires, recommends, suggests, conflicts)
- Added support for 'develop' phase for requirements for maintaining a list of authoring tools
- Changed 'license' to a list and revised the set of valid licenses
- Made 'dynamic_config' mandatory to reduce confusion
- Changed 'resources' subkey 'repository' to a hash that clarifies repository type, url for browsing and url for checkout
- Changed 'resources' subkey 'bugtracker' to a hash for either web or mailto resource
- Changed specification of 'optional_features':
  - Added formal specification and usage guide instead of just example
  - Changed to use new prereqs data structure instead of individual keys
- Clarified intended use of 'author' as generalized contact list
- Added 'release_status' field to indicate stable, testing or unstable status to provide hints to indexers
- Added 'description' field for a longer description of the distribution
- Formalized use of "x_" or "X_" for all custom keys not listed in the official spec

Version 1.4

June 2008

- Noted explicit support for 'perl' in prerequisites
- Added 'configure_requires' prerequisite type
- Changed 'optional_features'
  - Example corrected to show map of maps instead of list of maps (though descriptive text said 'map' even in v1.3)
  - Removed 'requires_packages', 'requires_os' and 'excluded_os' as valid subkeys

Version 1.3

November 2006

- Added 'no_index' subkey 'directory' and removed 'dir' to match actual usage in the wild
- Added a 'repository' subkey to 'resources'

Version 1.2

August 2005

- Re-wrote and restructured spec in POD syntax
- Changed 'name' to be mandatory
- Changed 'generated_by' to be mandatory
- Changed 'license' to be mandatory
- Added version range specifications for prerequisites
- Added required 'abstract' field
- Added required 'author' field
- Added required 'meta-spec' field to define 'version' (and 'url') of the CPAN Meta Spec used for metadata
- Added 'provides' field
- Added 'no_index' field and deprecated 'private' field. 'no_index' subkeys include 'file', 'dir', 'package' and 'namespace'
- Added 'keywords' field
- Added 'resources' field with subkeys 'homepage', 'license', and 'bugtracker'
- Added 'optional_features' field as an alternate under 'recommends'. Includes 'description', 'requires', 'build_requires', 'conflicts', 'requires_packages', 'requires_os' and 'excluded_os' as valid subkeys
- Removed 'license_uri' field

Version 1.1

May 2003

- Changed 'version' to be mandatory
- Added 'private' field
- Added 'license_uri' field

Version 1.0

March 2003

- Original release (in HTML format only)

- Included ‘name’, ‘version’, ‘license’, ‘distribution_type’, ‘requires’, ‘recommends’, ‘build_requires’, ‘conflicts’, ‘dynamic_config’, ‘generated_by’

CPAN::Meta::Merge

Merging CPAN Meta fragments

VERSION

version 2.150013

SYNOPSIS

```
my $merger = CPAN::Meta::Merge->new(default_version => "2");
my $meta = $merger->merge($base, @additional);
```

DESCRIPTION

METHODS

new

This creates a CPAN::Meta::Merge object. It takes one mandatory named argument, `version`, declaring the version of the meta-spec that must be used for the merge. It can optionally take an `extra_mappings` argument that allows one to add additional merging functions for specific elements.

The `extra_mappings` arguments takes a hash ref with the same type of structure as described in *CPAN::Meta::Spec*, except with its values as one of the defined merge strategies or a code ref to a merging function.

```
my $merger = CPAN::Meta::Merge->new(
    default_version => '2',
    extra_mappings => {
        'optional_features' => \&custom_merge_function,
```

(continues on next page)

(continued from previous page)

```
        'x_custom' => 'set_addition',
        'x_meta_meta' => {
            name => 'identical',
            tags => 'set_addition',
        }
    }
);
```

merge(@fragments)

Merge all `@fragments` together. It will accept both CPAN::Meta objects and (possibly incomplete) hashrefs of metadata.

MERGE STRATEGIES

`merge` uses various strategies to combine different elements of the CPAN::Meta objects. The following strategies can be used with the extra_mappings argument of new:

- identical

  The elements must be identical

- set_addition

  The union of two array refs

  ```
  [ a, b ] U [ a, c]  = [ a, b, c ]
  ```

- uniq_map

  Key value pairs from the right hash are merged to the left hash. Key collisions are only allowed if their values are the same. This merge function will recurse into nested hash refs following the same merge rules.

- improvise

  This merge strategy will try to pick the appropriate predefined strategy based on what element type. Array refs will try to use the `set_addition` strategy, Hash refs will try to use the `uniq_map` strategy, and everything else will try the `identical` strategy.

CPAN::Meta::Prereqs

a set of distribution prerequisites by phase and type

VERSION

version 2.150013

DESCRIPTION

A CPAN::Meta::Prereqs object represents the prerequisites for a CPAN distribution or one of its optional features. Each set of prereqs is organized by phase and type, as described in *CPAN::Meta::Prereqs*.

METHODS

new

```
my $prereq = CPAN::Meta::Prereqs->new( \%prereq_spec );
```

This method returns a new set of Prereqs. The input should look like the contents of the `prereqs` field described in *CPAN::Meta::Spec*, meaning something more or less like this:

```
my $prereq = CPAN::Meta::Prereqs->new({
  runtime => {
    requires => {
      'Some::Module' => '1.234',
      ...,
    },
    ...,
  },
  ...,
});
```

You can also construct an empty set of prereqs with:

```
my $prereqs = CPAN::Meta::Prereqs->new;
```

This empty set of prereqs is useful for accumulating new prereqs before finally dumping the whole set into a structure or string.

requirements_for

```
my $requirements = $prereqs->requirements_for( $phase, $type );
```

This method returns a *CPAN::Meta::Requirements* object for the given phase/type combination. If no prerequisites are registered for that combination, a new CPAN::Meta::Requirements object will be returned, and it may be added to as needed.

If `$phase` or `$type` are undefined or otherwise invalid, an exception will be raised.

phases

```
my @phases = $prereqs->phases;
```

This method returns the list of all phases currently populated in the prereqs object, suitable for iterating.

types_in

```
my @runtime_types = $prereqs->types_in('runtime');
```

This method returns the list of all types currently populated in the prereqs object for the provided phase, suitable for iterating.

with_merged_prereqs

```
my $new_prereqs = $prereqs->with_merged_prereqs( $other_prereqs );

my $new_prereqs = $prereqs->with_merged_prereqs( \@other_prereqs );
```

This method returns a new CPAN::Meta::Prereqs objects in which all the other prerequisites given are merged into the current set. This is primarily provided for combining a distribution's core prereqs with the prereqs of one of its optional features.

The new prereqs object has no ties to the originals, and altering it further will not alter them.

merged_requirements

```
my $new_reqs = $prereqs->merged_requirements( \@phases, \@types );
my $new_reqs = $prereqs->merged_requirements( \@phases );
my $new_reqs = $prereqs->merged_requirements();
```

This method joins together all requirements across a number of phases and types into a new *CPAN::Meta::Requirements* object. If arguments are omitted, it defaults to "runtime", "build" and "test" for phases and "requires" and "recommends" for types.

as_string_hash

This method returns a hashref containing structures suitable for dumping into a distmeta data structure. It is made up of hashes and strings, only; there will be no Prereqs, CPAN::Meta::Requirements, or `version` objects inside it.

is_finalized

This method returns true if the set of prereqs has been marked "finalized," and cannot be altered.

finalize

Calling `finalize` on a Prereqs object will close it for further modification. Attempting to make any changes that would actually alter the prereqs will result in an exception being thrown.

clone

```
my $cloned_prereqs = $prereqs->clone;
```

This method returns a Prereqs object that is identical to the original object, but can be altered without affecting the original object. Finalization does not survive cloning, meaning that you may clone a finalized set of prereqs and then modify the clone.

BUGS

Please report any bugs or feature using the CPAN Request Tracker. Bugs can be submitted through the web interface at http://rt.cpan.org/Dist/Display.html?Queue=CPAN-Meta

When submitting a bug or request, please include a test-file or a patch to an existing test-file that illustrates the bug or desired feature.

CPAN::Meta::Requirements

a set of version requirements for a CPAN dist

VERSION

version 2.145

SYNOPSIS

```
use CPAN::Meta::Requirements;

my $build_requires = CPAN::Meta::Requirements->new;

$build_requires->add_minimum('Library::Foo' => 1.208);

$build_requires->add_minimum('Library::Foo' => 2.602);

$build_requires->add_minimum('Module::Bar'  => 'v1.2.3');

$METAyml->{build_requires} = $build_requires->as_string_hash;
```

DESCRIPTION

A CPAN::Meta::Requirements object models a set of version constraints like those specified in the `META.yml` or `META.json` files in CPAN distributions, and as defined by *CPAN::Meta::Spec*. It can be built up by adding more and more constraints, and it will reduce them to the simplest representation.

Logically impossible constraints will be identified immediately by thrown exceptions.

METHODS

new

```
my $req = CPAN::Meta::Requirements->new;
```

This returns a new CPAN::Meta::Requirements object. It takes an optional hash reference argument. Currently, only one key is supported:

- `bad_version_hook` – if provided, when a version cannot be parsed into a version object, this code reference will be called with the invalid version string as first argument, and the module name as second argument. It must return a valid version object.

All other keys are ignored.

add_minimum

```
$req->add_minimum( $module => $version );
```

This adds a new minimum version requirement. If the new requirement is redundant to the existing specification, this has no effect.

Minimum requirements are inclusive. `$version` is required, along with any greater version number.

This method returns the requirements object.

add_maximum

```
$req->add_maximum( $module => $version );
```

This adds a new maximum version requirement. If the new requirement is redundant to the existing specification, this has no effect.

Maximum requirements are inclusive. No version strictly greater than the given version is allowed.

This method returns the requirements object.

add_exclusion

```
$req->add_exclusion( $module => $version );
```

This adds a new excluded version. For example, you might use these three method calls:

```
$req->add_minimum( $module => '1.00' );
$req->add_maximum( $module => '1.82' );

$req->add_exclusion( $module => '1.75' );
```

Any version between 1.00 and 1.82 inclusive would be acceptable, except for 1.75.

This method returns the requirements object.

exact_version

```
$req->exact_version( $module => $version );
```

This sets the version required for the given module to *exactly* the given version. No other version would be considered acceptable.

This method returns the requirements object.

version_range_for_module

```
$req->version_range_for_module( $another_req_object );
```

add_requirements

```
$req->add_requirements( $another_req_object );
```

This method adds all the requirements in the given CPAN::Meta::Requirements object to the requirements object on which it was called. If there are any conflicts, an exception is thrown.

This method returns the requirements object.

accepts_module

```
my $bool = $req->accepts_module($module => $version);
```

Given an module and version, this method returns true if the version specification for the module accepts the provided version. In other words, given:

```
Module => '>= 1.00, < 2.00'
```

We will accept 1.00 and 1.75 but not 0.50 or 2.00.

For modules that do not appear in the requirements, this method will return true.

clear_requirement

```
$req->clear_requirement( $module );
```

This removes the requirement for a given module from the object.

This method returns the requirements object.

requirements_for_module

```
$req->requirements_for_module( $module );
```

This returns a string containing the version requirements for a given module in the format described in *CPAN::Meta::Spec* or undef if the given module has no requirements. This should only be used for informational purposes such as error messages and should not be interpreted or used for comparison (see “accepts_module” instead).

structured_requirements_for_module

```
$req->structured_requirements_for_module( $module );
```

This returns a data structure containing the version requirements for a given module or undef if the given module has no requirements. This should not be used for version checks (see “accepts_module” instead).

Added in version 2.134.

required_modules

This method returns a list of all the modules for which requirements have been specified.

clone

```
$req->clone;
```

This method returns a clone of the invocant. The clone and the original object can then be changed independent of one another.

is_simple

This method returns true if and only if all requirements are inclusive minimums – that is, if their string expression is just the version number.

is_finalized

This method returns true if the requirements have been finalized by having the `finalize` method called on them.

finalize

This method marks the requirements finalized. Subsequent attempts to change the requirements will be fatal, *if* they would result in a change. If they would not alter the requirements, they have no effect.

If a finalized set of requirements is cloned, the cloned requirements are not also finalized.

as_string_hash

This returns a reference to a hash describing the requirements using the strings in the *CPAN::Meta::Spec* specification.

For example after the following program:

```
my $req = CPAN::Meta::Requirements->new;

$req->add_minimum('CPAN::Meta::Requirements' => 0.102);

$req->add_minimum('Library::Foo' => 1.208);

$req->add_maximum('Library::Foo' => 2.602);

$req->add_minimum('Module::Bar'  => 'v1.2.3');

$req->add_exclusion('Module::Bar'  => 'v1.2.8');
```

(continues on next page)

(continued from previous page)

```
$req->exact_version('Xyzzy'  => '6.01');

my $hashref = $req->as_string_hash;
```

$hashref would contain:

```
{
  'CPAN::Meta::Requirements' => '0.102',
  'Library::Foo' => '>= 1.208, <= 2.206',
  'Module::Bar'  => '>= v1.2.3, != v1.2.8',
  'Xyzzy'        => '== 6.01',
}
```

add_string_requirement

```
$req->add_string_requirement('Library::Foo' => '>= 1.208, <= 2.206
↪');
$req->add_string_requirement('Library::Foo' => v1.208);
```

This method parses the passed in string and adds the appropriate requirement for the given module. A version can be a Perl "v-string". It understands version ranges as described in the *"Version Ranges" in CPAN::Meta::Spec*. For example:

- 1.3
- = 1.3
- <= 1.3
- == 1.3
- != 1.3
- 1.3
- < 1.3
- = 1.3, != 1.5, <= 2.0

  A version number without an operator is equivalent to specifying a minimum (>=). Extra whitespace is allowed.

from_string_hash

```
my $req = CPAN::Meta::Requirements->from_string_hash( \%hash );
my $req = CPAN::Meta::Requirements->from_string_hash( \%hash, \%opts␣
↪);
```

This is an alternate constructor for a CPAN::Meta::Requirements object. It takes a hash of module names and version requirement strings and returns a new CPAN::Meta::Requirements object. As with add_string_requirement, a version can be a Perl "v-string". Optionally, you can supply a hash-reference of options, exactly as with the "new" method.

SUPPORT

Bugs / Feature Requests

Please report any bugs or feature requests through the issue tracker at https://github.com/Perl-Toolchain-Gang/CPAN-Meta-Requirements/issues. You will be notified automatically of any progress on your issue.

Modules

- `CPAN::Meta::Requirements::Range` - a set of version requirements for a CPAN dist

CPAN::Meta::Requirements::Range

a set of version requirements for a CPAN dist

VERSION

version 2.145

SYNOPSIS

```
use CPAN::Meta::Requirements::Range;

my $range = CPAN::Meta::Requirements::Range->with_minimum(1);

$range = $range->with_maximum('v2.2');

my $stringified = $range->as_string;
```

DESCRIPTION

A CPAN::Meta::Requirements::Range object models a set of version constraints like those specified in the `META.yml` or `META.json` files in CPAN distributions, and as defined by *CPAN::Meta::Spec*; It can be built up by adding more and more constraints, and it will reduce them to the simplest representation.

Logically impossible constraints will be identified immediately by thrown exceptions.

METHODS

with_string_requirement

```
$req->with_string_requirement('>= 1.208, <= 2.206');
$req->with_string_requirement(v1.208);
```

This method parses the passed in string and adds the appropriate requirement. A version can be a Perl "v-string". It understands version ranges as described in the *"Version Ranges" in CPAN::Meta::Spec*. For example:

- 1.3
- = 1.3
- <= 1.3
- == 1.3
- != 1.3

- 1.3
- < 1.3
- = 1.3, != 1.5, <= 2.0

  A version number without an operator is equivalent to specifying a minimum (>=). Extra whitespace is allowed.

with_range

```
$range->with_range($other_range)
```

This creates a new range object that is a merge two others.

with_exact_version

```
$range->with_exact_version( $version );
```

This sets the version required to *exactly* the given version. No other version would be considered acceptable.

This method returns the version range object.

with_minimum

```
$range->with_minimum( $version );
```

This adds a new minimum version requirement. If the new requirement is redundant to the existing specification, this has no effect.

Minimum requirements are inclusive. `$version` is required, along with any greater version number.

This method returns the version range object.

with_maximum

```
$range->with_maximum( $version );
```

This adds a new maximum version requirement. If the new requirement is redundant to the existing specification, this has no effect.

Maximum requirements are inclusive. No version strictly greater than the given version is allowed.

This method returns the version range object.

with_exclusion

```
$range->with_exclusion( $version );
```

This adds a new excluded version. For example, you might use these three method calls:

```
$range->with_minimum( '1.00' );
$range->with_maximum( '1.82' );

$range->with_exclusion( '1.75' );
```

Any version between 1.00 and 1.82 inclusive would be acceptable, except for 1.75.

This method returns the requirements object.

as_struct

```
$range->as_struct( $module );
```

This returns a data structure containing the version requirements. This should not be used for version checks (see "accepts_module" instead).

as_string

```
$range->as_string;
```

This returns a string containing the version requirements in the format described in *CPAN::Meta::Spec*. This should only be used for informational purposes such as error messages and should not be interpreted or used for comparison (see "accepts" instead).

accepts

```
my $bool = $range->accepts($version);
```

Given a version, this method returns true if the version specification accepts the provided version. In other words, given:

```
'>= 1.00, < 2.00'
```

We will accept 1.00 and 1.75 but not 0.50 or 2.00.

is_simple

This method returns true if and only if the range is an inclusive minimum – that is, if their string expression is just the version number.

};
```

DESCRIPTION

This document describes version 2 of the CPAN distribution metadata specification, also known as the "CPAN Meta Spec".

Revisions of this specification for typo corrections and prose clarifications may be issued as CPAN::Meta::Spec 2.*x*. These revisions will never change semantics or add or remove specified behavior.

Distribution metadata describe important properties of Perl distributions. Distribution building tools like Module::Build, Module::Install, ExtUtils::MakeMaker or Dist::Zilla should create a metadata file in accordance with this specification and include it with the distribution for use by automated tools that index, examine, package or install Perl distributions.

TERMINOLOGY

- distribution

  This is the primary object described by the metadata. In the context of this document it usually refers to a collection of modules, scripts, and/or documents that are distributed together for other developers to use. Examples of distributions are `Class-Container`, `libwww-perl`, or `DBI`.

- module

This refers to a reusable library of code contained in a single file. Modules usually contain one or more packages and are often referred to by the name of a primary package that can be mapped to the file name. For example, one might refer to `File::Spec` instead of `File/Spec.pm`

- package

  This refers to a namespace declared with the Perl `package` statement. In Perl, packages often have a version number property given by the `$VERSION` variable in the namespace.

- consumer

  This refers to code that reads a metadata file, deserializes it into a data structure in memory, or interprets a data structure of metadata elements.

- producer

  This refers to code that constructs a metadata data structure, serializes into a bytestream and/or writes it to disk.

- must, should, may, etc.

  These terms are interpreted as described in IETF RFC 2119.

DATA TYPES

Fields in the "STRUCTURE" section describe data elements, each of which has an associated data type as described herein. There are four primitive types: Boolean, String, List and Map. Other types are subtypes of primitives and define compound data structures or define constraints on the values of a data element.

Boolean

A *Boolean* is used to provide a true or false value. It **must** be represented as a defined value that is either "1" or "0" or stringifies to those values.

String

A *String* is data element containing a non-zero length sequence of Unicode characters, such as an ordinary Perl scalar that is not a reference.

List

A *List* is an ordered collection of zero or more data elements. Elements of a List may be of mixed types.

Producers **must** represent List elements using a data structure which unambiguously indicates that multiple values are possible, such as a reference to a Perl array (an "arrayref").

Consumers expecting a List **must** consider a String as equivalent to a List of length 1.

Map

A *Map* is an unordered collection of zero or more data elements ("values"), indexed by associated String elements ("keys"). The Map's value elements may be of mixed types.

License String

A *License String* is a subtype of String with a restricted set of values. Valid values are described in detail in the description of the "license" field.

URL

URL is a subtype of String containing a Uniform Resource Locator or Identifier. [This type is called URL and not URI for historical reasons.]

Version

A *Version* is a subtype of String containing a value that describes the version number of packages or distributions. Restrictions on format are described in detail in the "Version Formats" section.

Version Range

The *Version Range* type is a subtype of String. It describes a range of Versions that may be present or installed to fulfill prerequisites. It is specified in detail in the "Version Ranges" section.

STRUCTURE

The metadata structure is a data element of type Map. This section describes valid keys within the Map.

Any keys not described in this specification document (whether top-level or within compound data structures described herein) are considered *custom keys* and **must** begin with an "x" or "X" and be followed by an underscore; i.e. they must match the pattern: `qr{\Ax_}i`. If a custom key refers to a compound data structure, subkeys within it do not need an "x_" or "X_" prefix.

Consumers of metadata may ignore any or all custom keys. All other keys not described herein are invalid and should be ignored by consumers. Producers must not generate or output invalid keys.

For each key, an example is provided followed by a description. The description begins with the version of spec in which the key was added or in which the definition was modified, whether the key is *required* or *optional* and the data type of the corresponding data element. These items are in parentheses, brackets and braces, respectively.

If a data type is a Map or Map subtype, valid subkeys will be described as well.

Some fields are marked *Deprecated*. These are shown for historical context and must not be produced in or consumed from any metadata structure of version 2 or higher.

REQUIRED FIELDS

abstract

Example:

```
abstract => 'Build and install Perl modules'
```

(Spec 1.2) [required] {String}

This is a short description of the purpose of the distribution.

author

Example:

```
author => [ 'Ken Williams <kwilliams@cpan.org>' ]
```

(Spec 1.2) [required] {List of one or more Strings}

This List indicates the person(s) to contact concerning the distribution. The preferred form of the contact string is:

```
contact-name <email-address>
```

This field provides a general contact list independent of other structured fields provided within the "resources" field, such as `bugtracker`. The addressee(s) can be contacted for any purpose including but not limited to (security) problems with the distribution, questions about the distribution or bugs in the distribution.

A distribution's original author is usually the contact listed within this field. Co-maintainers, successor maintainers or mailing lists devoted to the distribution may also be listed in addition to or instead of the original author.

dynamic_config

Example:

```
dynamic_config => 1
```

(Spec 2) [required] {Boolean}

A boolean flag indicating whether a `Build.PL` or `Makefile.PL` (or similar) must be executed to determine prerequisites.

This field should be set to a true value if the distribution performs some dynamic configuration (asking questions, sensing the environment, etc.) as part of its configuration. This field should be set to a false value to indicate that prerequisites included in metadata may be considered final and valid for static analysis.

Note: when this field is true, post-configuration prerequisites are not guaranteed to bear any relation whatsoever to those stated in the metadata, and relying on them doing so is an error. See also "Prerequisites for dynamically configured distributions" in the implementors' notes.

This field explicitly **does not** indicate whether installation may be safely performed without using a Makefile or Build file, as there may be special files to install or custom installation targets (e.g. for dual-life modules that exist on CPAN as well as in the Perl core). This field only defines whether or not prerequisites are exactly as given in the metadata.

generated_by

Example:

```
generated_by => 'Module::Build version 0.36'
```

(Spec 1.0) [required] {String}

This field indicates the tool that was used to create this metadata. There are no defined semantics for this field, but it is traditional to use a string in the form "Generating::Package version 1.23" or the author's name, if the file was generated by hand.

license

Example:

```
license => [ 'perl_5' ]

license => [ 'apache_2_0', 'mozilla_1_0' ]
```

(Spec 2) [required] {List of one or more License Strings}

One or more licenses that apply to some or all of the files in the distribution. If multiple licenses are listed, the distribution documentation should be consulted to clarify the interpretation of multiple licenses.

The following list of license strings are valid:

```
string          description
-------------   ---------------------------------------------
agpl_3          GNU Affero General Public License, Version 3
apache_1_1      Apache Software License, Version 1.1
apache_2_0      Apache License, Version 2.0
artistic_1      Artistic License, (Version 1)
artistic_2      Artistic License, Version 2.0
bsd             BSD License (three-clause)
freebsd         FreeBSD License (two-clause)
gfdl_1_2        GNU Free Documentation License, Version 1.2
gfdl_1_3        GNU Free Documentation License, Version 1.3
gpl_1           GNU General Public License, Version 1
gpl_2           GNU General Public License, Version 2
gpl_3           GNU General Public License, Version 3
lgpl_2_1        GNU Lesser General Public License, Version 2.1
lgpl_3_0        GNU Lesser General Public License, Version 3.0
mit             MIT (aka X11) License
mozilla_1_0     Mozilla Public License, Version 1.0
```

(continues on next page)

(continued from previous page)

```
mozilla_1_1     Mozilla Public License, Version 1.1
openssl         OpenSSL License
perl_5          The Perl 5 License (Artistic 1 & GPL 1 or later)
qpl_1_0         Q Public License, Version 1.0
ssleay          Original SSLeay License
sun             Sun Internet Standards Source License (SISSL)
zlib            zlib License
```

The following license strings are also valid and indicate other licensing not described above:

```
string          description
-------------   ------------------------------------------------
open_source     Other Open Source Initiative (OSI) approved license
restricted      Requires special permission from copyright holder
unrestricted    Not an OSI approved license, but not restricted
unknown         License not provided in metadata
```

All other strings are invalid in the license field.

meta-spec

Example:

```
'meta-spec' => {
  version => '2',
  url     => 'http://search.cpan.org/perldoc?CPAN::Meta::Spec',
}
```

(Spec 1.2) [required] {Map}

This field indicates the version of the CPAN Meta Spec that should be used to interpret the metadata. Consumers must check this key as soon as possible and abort further metadata processing if the meta-spec version is not supported by the consumer.

The following keys are valid, but only `version` is required.

- version

  This subkey gives the integer *Version* of the CPAN Meta Spec against which the document was generated.

- url

  This is a *URL* of the metadata specification document corresponding to the given version. This is strictly for human-consumption and should not impact the interpretation of the document.

  For the version 2 spec, either of these are recommended:

  – `https://metacpan.org/pod/CPAN::Meta::Spec`

  – `http://search.cpan.org/perldoc?CPAN::Meta::Spec`

name

Example:

```
name => 'Module-Build'
```

(Spec 1.0) [required] {String}

This field is the name of the distribution. This is often created by taking the "main package" in the distribution and changing `::` to `-`, but the name may be completely unrelated to the packages within the distribution. For example, LWP::UserAgent is distributed as part of the distribution name "libwww-perl".

release_status

Example:

```
release_status => 'stable'
```

(Spec 2) [required] {String}

This field provides the release status of this distribution. If the `version` field contains an underscore character, then `release_status` **must not** be "stable."

The `release_status` field **must** have one of the following values:

- stable

  This indicates an ordinary, "final" release that should be indexed by PAUSE or other indexers.

- testing

  This indicates a "beta" release that is substantially complete, but has an elevated risk of bugs and requires additional testing. The distribution should not be installed over a stable release without an explicit request or other confirmation from a user. This release status may also be used for "release candidate" versions of a distribution.

- unstable

  This indicates an "alpha" release that is under active development, but has been released for early feedback or testing and may be missing features or may have serious bugs. The distribution should not be installed over a stable release without an explicit request or other confirmation from a user.

Consumers **may** use this field to determine how to index the distribution for CPAN or other repositories in addition to or in replacement of heuristics based on version number or file name.

version

Example:

```
version => '0.36'
```

(Spec 1.0) [required] {Version}

This field gives the version of the distribution to which the metadata structure refers.

OPTIONAL FIELDS

description

Example:

```
description =>  "Module::Build is a system for "
  . "building, testing, and installing Perl modules. "
  . "It is meant to ... blah blah blah ...",
```

(Spec 2) [optional] {String}

A longer, more complete description of the purpose or intended use of the distribution than the one provided by the `abstract` key.

keywords

Example:

```
keywords => [ qw/ toolchain cpan dual-life / ]
```

(Spec 1.1) [optional] {List of zero or more Strings}

A List of keywords that describe this distribution. Keywords **must not** include whitespace.

no_index

Example:

```
no_index => {
  file      => [ 'My/Module.pm' ],
  directory => [ 'My/Private' ],
  package   => [ 'My::Module::Secret' ],
  namespace => [ 'My::Module::Sample' ],
}
```

(Spec 1.2) [optional] {Map}

This Map describes any files, directories, packages, and namespaces that are private to the packaging or implementation of the distribution and should be ignored by indexing or search tools. Note that this is a list of exclusions, and the spec does not define what to *include* - see “Indexing distributions a la PAUSE” in the implementors notes for more information.

Valid subkeys are as follows:

- file

  A *List* of relative paths to files. Paths **must be** specified with unix conventions.

- directory

  A *List* of relative paths to directories. Paths **must be** specified with unix conventions.

  [Note: previous editions of the spec had `dir` instead of `directory`]

- package

  A *List* of package names.

- namespace

  A *List* of package namespaces, where anything below the namespace must be ignored, but *not* the namespace itself.

  In the example above for `no_index`, `My::Module::Sample::Foo` would be ignored, but `My::Module::Sample` would not.

optional_features

Example:

```
optional_features => {
  sqlite => {
    description => 'Provides SQLite support',
    prereqs => {
      runtime => {
        requires => {
          'DBD::SQLite' => '1.25'
        }
      }
    }
  }
}
```

(Spec 2) [optional] {Map}

This Map describes optional features with incremental prerequisites. Each key of the `optional_features` Map is a String used to identify the feature and each value is a Map with additional information about the feature. Valid subkeys include:

- description

  This is a String describing the feature. Every optional feature should provide a description

- prereqs

  This entry is required and has the same structure as that of the `"prereqs"` key. It provides a list of package requirements that must be satisfied for the feature to be supported or enabled.

  There is one crucial restriction: the prereqs of an optional feature **must not** include `configure` phase prereqs.

Consumers **must not** include optional features as prerequisites without explicit instruction from users (whether via interactive prompting, a function parameter or a configuration value, etc.).

If an optional feature is used by a consumer to add additional prerequisites, the consumer should merge the optional feature prerequisites into those given by the `prereqs` key using the same semantics. See “Merging and Resolving Prerequisites” for details on merging prerequisites.

Suggestion for disuse: Because there is currently no way for a distribution to specify a dependency on an optional feature of another dependency, the use of `optional_feature` is discouraged. Instead, create a separate, installable distribution that ensures the desired feature is available. For example, if `Foo::Bar` has a `Baz` feature, release a separate `Foo-Bar-Baz` distribution that satisfies requirements for the feature.

prereqs

Example:

```
prereqs => {
  runtime => {
    requires => {
      'perl'           => '5.006',
      'File::Spec'     => '0.86',
      'JSON'           => '2.16',
    },
    recommends => {
      'JSON::XS'       => '2.26',
    },
    suggests => {
      'Archive::Tar'   => '0',
    },
  },
  build => {
    requires => {
      'Alien::SDL'     => '1.00',
    },
  },
  test => {
    recommends => {
      'Test::Deep'     => '0.10',
    },
  }
}
```

(Spec 2) [optional] {Map}

This is a Map that describes all the prerequisites of the distribution. The keys are phases of activity, such as `configure`, `build`, `test` or `runtime`. Values are Maps in which the keys name the type of prerequisite relationship such as `requires`, `recommends`, or `suggests` and the value provides a set of prerequisite relations. The set of relations **must** be specified as a Map of package names to version ranges.

The full definition for this field is given in the "Prereq Spec" section.

provides

Example:

```
provides => {
  'Foo::Bar' => {
    file    => 'lib/Foo/Bar.pm',
    version => '0.27_02',
  },
  'Foo::Bar::Blah' => {
    file    => 'lib/Foo/Bar/Blah.pm',
  },
  'Foo::Bar::Baz' => {
    file    => 'lib/Foo/Bar/Baz.pm',
    version => '0.3',
  },
}
```

(Spec 1.2) [optional] {Map}

This describes all packages provided by this distribution. This information is used by distribution and automation mechanisms like PAUSE, CPAN, metacpan.org and search.cpan.org to build indexes saying in which distribution various packages can be found.

The keys of `provides` are package names that can be found within the distribution. If a package name key is provided, it must have a Map with the following valid subkeys:

- file

  This field is required. It must contain a Unix-style relative file path from the root of the distribution directory to a file that contains or generates the package. It may be given as `META.yml` or `META.json` to claim a package for indexing without needing a `*.pm`.

- version

  If it exists, this field must contains a *Version* String for the package. If the package does not have a `$VERSION`, this field must be omitted.

resources

Example:

```
resources => {
  license     => [ 'http://dev.perl.org/licenses/' ],
  homepage    => 'http://sourceforge.net/projects/module-build',
  bugtracker  => {
    web     => 'http://rt.cpan.org/Public/Dist/Display.html?
↪Name=CPAN-Meta',
    mailto => 'meta-bugs@example.com',
  },
```

(continues on next page)

(continued from previous page)

```
  repository  => {
    url  => 'git://github.com/dagolden/cpan-meta.git',
    web  => 'http://github.com/dagolden/cpan-meta',
    type => 'git',
  },
  x_twitter   => 'http://twitter.com/cpan_linked/',
}
```

(Spec 2) [optional] {Map}

This field describes resources related to this distribution.

Valid subkeys include:

- homepage

  The official home of this project on the web.

- license

  A List of *URL*'s that relate to this distribution's license. As with the top-level `license` field, distribution documentation should be consulted to clarify the interpretation of multiple licenses provided here.

- bugtracker

  This entry describes the bug tracking system for this distribution. It is a Map with the following valid keys:

  ```
  web    - a URL pointing to a web front-end for the bug tracker
  mailto - an email address to which bugs can be sent
  ```

- repository

  This entry describes the source control repository for this distribution. It is a Map with the following valid keys:

  ```
  url  - a URL pointing to the repository itself
  web  - a URL pointing to a web front-end for the repository
  type - a lowercase string indicating the VCS used
  ```

  Because a url like `http://myrepo.example.com/` is ambiguous as to type, producers should provide a `type` whenever a `url` key is given. The `type` field should be the name of the most common program used to work with the repository, e.g. `git`, `svn`, `cvs`, `darcs`, `bzr` or `hg`.

DEPRECATED FIELDS

build_requires

(Deprecated in Spec 2) [optional] {String}

Replaced by `prereqs`

configure_requires

(Deprecated in Spec 2) [optional] {String}

Replaced by `prereqs`

conflicts

(Deprecated in Spec 2) [optional] {String}

Replaced by `prereqs`

distribution_type

(Deprecated in Spec 2) [optional] {String}

This field indicated 'module' or 'script' but was considered meaningless, since many distributions are hybrids of several kinds of things.

license_uri

(Deprecated in Spec 1.2) [optional] {URL}

Replaced by `license` in `resources`

private

(Deprecated in Spec 1.2) [optional] {Map}

This field has been renamed to "no_index".

recommends

(Deprecated in Spec 2) [optional] {String}

Replaced by `prereqs`

requires

(Deprecated in Spec 2) [optional] {String}

Replaced by `prereqs`

VERSION NUMBERS

Version Formats

This section defines the Version type, used by several fields in the CPAN Meta Spec.

Version numbers must be treated as strings, not numbers. For example, `1.200` **must not** be serialized as `1.2`. Version comparison should be delegated to the Perl *version* module, version 0.80 or newer.

Unless otherwise specified, version numbers **must** appear in one of two formats:

- Decimal versions

  Decimal versions are regular "decimal numbers", with some limitations. They **must** be non-negative and **must** begin and end with a digit. A single underscore **may** be included, but **must** be between two digits. They **must not** use exponential notation ("1.23e-2").

```
version => '1.234'       # OK
version => '1.23_04'     # OK

version => '1.23_04_05'  # Illegal
version => '1.'          # Illegal
version => '.1'          # Illegal
```

- Dotted-integer versions

  Dotted-integer (also known as dotted-decimal) versions consist of positive integers separated by full stop characters (i.e. "dots", "periods" or "decimal points"). This are equivalent in format to Perl "v-strings", with some additional restrictions on form. They must be given in "normal" form, which has a leading "v" character and at least three integer components. To retain a one-to-one mapping with decimal versions, all components after the first **should** be restricted to the range 0 to 999. The final component **may** be separated by an underscore character instead of a period.

```
version => 'v1.2.3'      # OK
version => 'v1.2_3'      # OK
version => 'v1.2.3.4'    # OK
version => 'v1.2.3_4'    # OK
version => 'v2009.10.31' # OK

version => 'v1.2'          # Illegal
version => '1.2.3'         # Illegal
version => 'v1.2_3_4'      # Illegal
version => 'v1.2009.10.31' # Not recommended
```

Version Ranges

Some fields (prereq, optional_features) indicate the particular version(s) of some other module that may be required as a prerequisite. This section details the Version Range type used to provide this information.

The simplest format for a Version Range is just the version number itself, e.g. `2.4`. This means that **at least** version 2.4 must be present. To indicate that **any** version of a prerequisite is okay, even if the prerequisite doesn't define a version at all, use the version `0`.

Alternatively, a version range **may** use the operators < (less than), <= (less than or equal), > (greater than), >= (greater than or equal), == (equal), and != (not equal). For example, the specification `< 2.0` means that any version of the prerequisite less than 2.0 is suitable.

For more complicated situations, version specifications **may** be AND-ed together using commas. The specification `>= 1.2, != 1.5, < 2.0` indicates a version that must be

at least 1.2, **less than** 2.0, and **not equal to** 1.5.

PREREQUISITES

Prereq Spec

The `prereqs` key in the top-level metadata and within `optional_features` define the relationship between a distribution and other packages. The prereq spec structure is a hierarchical data structure which divides prerequisites into *Phases* of activity in the installation process and *Relationships* that indicate how prerequisites should be resolved.

For example, to specify that `Data::Dumper` is `required` during the `test` phase, this entry would appear in the distribution metadata:

```
prereqs => {
  test => {
    requires => {
      'Data::Dumper' => '2.00'
    }
  }
}
```

Phases

Requirements for regular use must be listed in the `runtime` phase. Other requirements should be listed in the earliest stage in which they are required and consumers must accumulate and satisfy requirements across phases before executing the activity. For example, `build` requirements must also be available during the `test` phase.

```
before action       requirements that must be met
----------------    ------------------------------
perl Build.PL       configure
perl Makefile.PL

make                configure, runtime, build
Build

make test           configure, runtime, build, test
Build test
```

Consumers that install the distribution must ensure that *runtime* requirements are also installed and may install dependencies from other phases.

```
after action        requirements that must be met
----------------    ------------------------------
make install        runtime
Build install
```

- configure

  The configure phase occurs before any dynamic configuration has been attempted. Libraries required by the configure phase **must** be available for use before the distribution building tool has been executed.

- build

  The build phase is when the distribution's source code is compiled (if necessary) and otherwise made ready for installation.

- test

  The test phase is when the distribution's automated test suite is run. Any library that is needed only for testing and not for subsequent use should be listed here.

- runtime

  The runtime phase refers not only to when the distribution's contents are installed, but also to its continued use. Any library that is a prerequisite for regular use of this distribution should be indicated here.

- develop

  The develop phase's prereqs are libraries needed to work on the distribution's source code as its author does. These tools might be needed to build a release tarball, to run author-only tests, or to perform other tasks related to developing new versions of the distribution.

Relationships

- requires

  These dependencies **must** be installed for proper completion of the phase.

- recommends

  Recommended dependencies are *strongly* encouraged and should be satisfied except in resource constrained environments.

- suggests

  These dependencies are optional, but are suggested for enhanced operation of the described distribution.

- conflicts

  These libraries cannot be installed when the phase is in operation. This is a very rare situation, and the `conflicts` relationship should be used with great caution, or not at all.

Merging and Resolving Prerequisites

Whenever metadata consumers merge prerequisites, either from different phases or from `optional_features`, they should merged in a way which preserves the intended semantics of the prerequisite structure. Generally, this means concatenating the version specifications using commas, as described in the "Version Ranges" section.

Another subtle error that can occur in resolving prerequisites comes from the way that modules in prerequisites are indexed to distribution files on CPAN. When a module is deleted from a distribution, prerequisites calling for that module could indicate an older distribution should be installed, potentially overwriting files from a newer distribution.

For example, as of Oct 31, 2009, the CPAN index file contained these module-distribution mappings:

```
Class::MOP                      0.94  D/DR/DROLSKY/Class-MOP-0.94.tar.
 ↪gz
Class::MOP::Class               0.94  D/DR/DROLSKY/Class-MOP-0.94.tar.
 ↪gz
Class::MOP::Class::Immutable 0.04  S/ST/STEVAN/Class-MOP-0.36.tar.gz
```

Consider the case where "Class::MOP" 0.94 is installed. If a distribution specified "Class::MOP::Class::Immutable" as a prerequisite, it could result in Class-MOP-0.36.tar.gz being installed, overwriting any files from Class-MOP-0.94.tar.gz.

Consumers of metadata **should** test whether prerequisites would result in installed module files being "downgraded" to an older version and **may** warn users or ignore the prerequisite that would cause such a result.

SERIALIZATION

Distribution metadata should be serialized (as a hashref) as JSON-encoded data and packaged with distributions as the file `META.json`.

In the past, the distribution metadata structure had been packed with distributions as `META.yml`, a file in the YAML Tiny format (for which, see YAML::Tiny). Tools that consume distribution metadata from disk should be capable of loading `META.yml`, but should prefer `META.json` if both are found.

NOTES FOR IMPLEMENTORS

Extracting Version Numbers from Perl Modules

To get the version number from a Perl module, consumers should use the `MM->parse_version($file)` method provided by *ExtUtils::MakeMaker* or *Module::Metadata*. For example, for the module given by `$mod`, the version may be retrieved in one of the following ways:

```
# via ExtUtils::MakeMaker
my $file = MM->_installed_file_for_module($mod);
my $version = MM->parse_version($file)
```

The private `_installed_file_for_module` method may be replaced with other methods for locating a module in `@INC`.

```
# via Module::Metadata
my $info = Module::Metadata->new_from_module($mod);
my $version = $info->version;
```

If only a filename is available, the following approach may be used:

```
# via Module::Metadata
my $info = Module::Metadata->new_from_file($file);
my $version = $info->version;
```

Comparing Version Numbers

The *version* module provides the most reliable way to compare version numbers in all the various ways they might be provided or might exist within modules. Given two strings containing version numbers, `$v1` and `$v2`, they should be converted to `version` objects before using ordinary comparison operators. For example:

```
use version;
if ( version->new($v1) <=> version->new($v2) ) {
  print "Versions are not equal\n";
}
```

If the only comparison needed is whether an installed module is of a sufficiently high version, a direct test may be done using the `VERSION` method. For example, for module `$mod` and version prerequisite `$prereq`:

```
use Module::Load 'load';
if ( $mod =~ m/\A[\w:']+\z/a and eval { load $mod; $mod->VERSION(
↪$prereq); 1 } ) {
  print "Module $mod version is OK.\n";
}
```

The regexp checks that `$mod` only includes characters legal for module names before passing it to *"load" in Module::Load*, which also accepts file paths that may escape `@INC`. Alternatively, if Module::Runtime is installed, the `use_module` function can load the module and perform the version check at the same time, and does not accept file paths:

```
use Module::Runtime 'use_module';
if ( eval { use_module $mod, $prereq; 1 } ) {
  print "Module $mod version is OK.\n";
}
```

Prerequisites for dynamically configured distributions

When `dynamic_config` is true, it is an error to presume that the prerequisites given in distribution metadata will have any relationship whatsoever to the actual prerequisites of the distribution.

In practice, however, one can generally expect such prerequisites to be one of two things:

- The minimum prerequisites for the distribution, to which dynamic configuration will only add items
- Whatever the distribution configured with on the releaser's machine at release time

The second case often turns out to have identical results to the first case, albeit only by accident.

As such, consumers may use this data for informational analysis, but presenting it to the user as canonical or relying on it as such is invariably the height of folly.

Indexing distributions a la PAUSE

While no_index tells you what must be ignored when indexing, this spec holds no opinion on how you should get your initial candidate list of things to possibly index. For "normal" distributions you might consider simply indexing the contents of lib/, but there are many fascinating oddities on CPAN and many dists from the days when it was normal to put the main .pm file in the root of the distribution archive - so PAUSE currently indexes all .pm and .PL files that are not either (a) specifically excluded by no_index (b) in `inc`, `xt`, or `t` directories, or common 'mistake' directories such as `perl5`.

Or: If you're trying to be PAUSE-like, make sure you skip `inc`, `xt` and `t` as well as anything marked as no_index.

Also remember: If the META file contains a provides field, you shouldn't be indexing anything in the first place - just use that.

HISTORY

Ken Williams wrote the original CPAN Meta Spec (also known as the "META.yml spec") in 2003 and maintained it through several revisions with input from various members of the community. In 2005, Randy Sims redrafted it from HTML to POD for the version 1.2 release. Ken continued to maintain the spec through version 1.4.

In late 2009, David Golden organized the version 2 proposal review process. David and Ricardo Signes drafted the final version 2 spec in April 2010 based on the version 1.4 spec and patches contributed during the proposal process.

CPAN::Meta::Validator

validate CPAN distribution metadata structures

VERSION

version 2.150013

SYNOPSIS

```
my $struct = decode_json_file('META.json');

my $cmv = CPAN::Meta::Validator->new( $struct );

unless ( $cmv->is_valid ) {
  my $msg = "Invalid META structure.  Errors found:\n";
  $msg .= join( "\n", $cmv->errors );
  die $msg;
}
```

DESCRIPTION

This module validates a CPAN Meta structure against the version of the the specification claimed in the `meta-spec` field of the structure.

METHODS

new

```
my $cmv = CPAN::Meta::Validator->new( $struct )
```

The constructor must be passed a metadata structure.

is_valid

```
if ( $cmv->is_valid ) {
  ...
}
```

Returns a boolean value indicating whether the metadata provided is valid.

errors

```
warn( join "\n", $cmv->errors );
```

Returns a list of errors seen during validation.

BUGS

Please report any bugs or feature using the CPAN Request Tracker. Bugs can be submitted through the web interface at http://rt.cpan.org/Dist/Display.html?Queue=CPAN-Meta

When submitting a bug or request, please include a test-file or a patch to an existing test-file that illustrates the bug or desired feature.

CPAN::Meta::YAML

Read and write a subset of YAML for CPAN Meta files

VERSION

version 0.020

SYNOPSIS

```
use CPAN::Meta::YAML;

# reading a META file
open $fh, "<:utf8", "META.yml";
$yaml_text = do { local $/; <$fh> };
$yaml = CPAN::Meta::YAML->read_string($yaml_text)
  or die CPAN::Meta::YAML->errstr;

# finding the metadata
$meta = $yaml->[0];
```

(continues on next page)

(continued from previous page)

```
# writing a META file
$yaml_text = $yaml->write_string
  or die CPAN::Meta::YAML->errstr;
open $fh, ">:utf8", "META.yml";
print $fh $yaml_text;
```

DESCRIPTION

This module implements a subset of the YAML specification for use in reading and writing CPAN metadata files like `META.yml` and `MYMETA.yml`. It should not be used for any other general YAML parsing or generation task.

NOTE: `META.yml` (and `MYMETA.yml`) files should be UTF-8 encoded. Users are responsible for proper encoding and decoding. In particular, the `read` and `write` methods do **not** support UTF-8 and should not be used.

SUPPORT

This module is currently derived from YAML::Tiny by Adam Kennedy. If there are bugs in how it parses a particular META.yml file, please file a bug report in the YAML::Tiny bugtracker: https://github.com/Perl-Toolchain-Gang/YAML-Tiny/issues

CPAN::Mirrors

Get CPAN mirror information and select a fast one

SYNOPSIS

```
use CPAN::Mirrors;

my $mirrors = CPAN::Mirrors->new( $mirrored_by_file );

my $seen = {};

my $best_continent = $mirrors->find_best_continents( { seen => $seen
 ↪} );
my @mirrors        = $mirrors->get_mirrors_by_continents( $best_
 ↪continent );

my $callback = sub {
    my( $m ) = @_;
    printf "%s = %s\n", $m->hostname, $m->rtt
    };
$mirrors->get_mirrors_timings( \@mirrors, $seen, $callback, %args );

@mirrors = sort { $a->rtt <=> $b->rtt } @mirrors;

print "Best mirrors are ", map( { $_->rtt } @mirrors[0..3] ), "\n";
```

DESCRIPTION

- new(LOCAL_FILE_NAME)

  Create a new CPAN::Mirrors object from LOCAL_FILE_NAME. This file should look like that in http://www.cpan.org/MIRRORED.BY .

- continents()

  Return a list of continents based on those defined in `MIRRORED.BY`.

- countries([CONTINENTS])

  Return a list of countries based on those defined in `MIRRORED.BY`. It only returns countries for the continents you specify (as defined in `continents`). If you don't specify any continents, it returns all of the countries listed in `MIRRORED.BY`.

- mirrors([COUNTRIES])

  Return a list of mirrors based on those defined in `MIRRORED.BY`. It only returns mirrors for the countries you specify (as defined in `countries`). If you don't specify any countries, it returns all of the mirrors listed in `MIRRORED.BY`.

- get_mirrors_by_countries([COUNTRIES])

  A more sensible synonym for mirrors.

- get_mirrors_by_continents([CONTINENTS])

  Return a list of mirrors for all of continents you specify. If you don't specify any continents, it returns all of the mirrors.

  You can specify a single continent or an array reference of continents.

- get_countries_by_continents([CONTINENTS])

  A more sensible synonym for countries.

- default_mirror

  Returns the default mirror, http://www.cpan.org/ . This mirror uses dynamic DNS to give a close mirror.

- best_mirrors

  `best_mirrors` checks for the best mirrors based on the list of continents you pass, or, without that, all continents, as defined by `CPAN::Mirrored::By`. It pings each mirror, up to the value of `how_many`. In list context, it returns up to `how_many` mirrors. In scalar context, it returns the single best mirror.

  Arguments

```
how_many      - the number of mirrors to return. Default: 1
callback      - a callback for find_best_continents
verbose       - true or false on all the whining and moaning.␣
↪Default: false
continents    - an array ref of the continents to check
external_ping - if true, use external ping via␣
↪Net::Ping::External. Default: false
```

  If you don't specify the continents, `best_mirrors` calls `find_best_continents` to get the list of continents to check.

  If you don't have *Net::Ping* v2.13 or later, needed for timings, this returns the default mirror.

  `external_ping` should be set and then `Net::Ping::External` needs to be installed, if the local network has a transparent proxy.

- get_n_random_mirrors_by_continents(N, [CONTINENTS])

  Returns up to N random mirrors for the specified continents. Specify the continents as an array reference.

- get_mirrors_timings(MIRROR_LIST, SEEN, CALLBACK, %ARGS);

  Pings the listed mirrors and returns a list of mirrors sorted in ascending ping times.

  `MIRROR_LIST` is an anonymous array of `CPAN::Mirrored::By` objects to ping.

  The optional argument `SEEN` is a hash reference used to track the mirrors you've already pinged.

  The optional argument `CALLBACK` is a subroutine reference to call after each ping. It gets the `CPAN::Mirrored::By` object after each ping.

- find_best_continents(HASH_REF);

  `find_best_continents` goes through each continent and pings `N` random mirrors on that continent. It then orders the continents by ascending median ping time. In list context, it returns the ordered list of continent. In scalar context, it returns the same list as an anonymous array.

  Arguments:

```
n        - the number of hosts to ping for each continent. Default: 3
seen     - a hashref of cached hostname ping times
verbose  - true or false for noisy or quiet. Default: false
callback - a subroutine to run after each ping.
ping_cache_limit - how long, in seconds, to reuse previous ping times.
   Default: 1 day
```

The seen hash has hostnames as keys and anonymous arrays as values. The anonymous array is a triplet of a CPAN::Mirrored::By object, a ping time, and the epoch time for the measurement.

The callback subroutine gets the CPAN::Mirrored::By object, the ping time, and measurement time (the same things in the seen hashref) as arguments. find_best_continents doesn't care what the callback does and ignores the return value.

With a low value for N, a single mirror might skew the results enough to choose a worse continent. If you have that problem, try a larger value.

CPAN::Nox

SYNOPSIS

Interactive mode:

```
perl -MCPAN::Nox -e shell;
```

DESCRIPTION

This package has the same functionality as CPAN.pm, but tries to prevent the usage of compiled extensions during its own execution. Its primary purpose is a rescue in case you upgraded perl and broke binary compatibility somehow.

LICENSE

This program is free software; you can redistribute it and/or modify it under the same terms as Perl itself.

SEE ALSO

CPAN

CPAN::Plugin

Base class for CPAN shell extensions

SYNOPSIS

```
package CPAN::Plugin::Flurb;
use parent 'CPAN::Plugin';

sub post_test {
  my ($self, $distribution_object) = @_;
  $self = $self->new (distribution_object => $distribution_object);
  ...;
}
```

DESCRIPTION

Alpha Status

The plugin system in the CPAN shell was introduced in version 2.07 and is still considered experimental.

How Plugins work?

See *"Plugin support" in CPAN*.

METHODS

plugin_requires

returns list of packages given plugin requires for functionality. This list is evaluated using `CPAN->use_inst` method.

distribution_object

Get current distribution object.

distribution

distribution_info

build_dir

Simple delegatees for misc parameters derived from distribution

Modules

- `CPAN::Plugin::Specfile` - Proof of concept implementation of a trivial CPAN::Plugin

CPAN::Plugin::Specfile

Proof of concept implementation of a trivial CPAN::Plugin

SYNOPSIS

```
# once in the cpan shell
o conf plugin_list push CPAN::Plugin::Specfile

# make permanent
o conf commit

# any time in the cpan shell to write a spec file
test Acme::Meta

# disable
# if it is the last in plugin_list:
o conf plugin_list pop
# otherwise, determine the index to splice:
o conf plugin_list
# and then use splice, e.g. to splice position 3:
o conf plugin_list splice 3 1
```

DESCRIPTION

Implemented as a post-test hook, this plugin writes a specfile after every successful test run. The content is also written to the terminal.

As a side effect, the timestamps of the written specfiles reflect the linear order of all dependencies.

WARNING: This code is just a small demo how to use the plugin system of the CPAN shell, not a full fledged spec file writer. Do not expect new features in this plugin.

OPTIONS

The target directory to store the spec files in can be set using `dir` as in

```
o conf plugin_list push CPAN::Plugin::Specfile=dir,/tmp/specfiles-
↪000042
```

The default directory for this is the `plugins/CPAN::Plugin::Specfile` directory in the *cpan_home* directory.

CPAN::Version

utility functions to compare CPAN versions

SYNOPSIS

```
use CPAN::Version;

CPAN::Version->vgt("1.1","1.1.1");    # 1 bc. 1.1 > 1.001001

CPAN::Version->vlt("1.1","1.1");      # 0 bc. 1.1 not < 1.1

CPAN::Version->vcmp("1.1","1.1.1");   # 1 bc. first is larger

CPAN::Version->vcmp("1.1.1","1.1");   # -1 bc. first is smaller

CPAN::Version->readable(v1.2.3);      # "v1.2.3"
```

(continues on next page)

(continued from previous page)

```
CPAN::Version->vstring("v1.2.3");      # v1.2.3

CPAN::Version->float2vv(1.002003);     # "v1.2.3"
```

DESCRIPTION

This module mediates between some version that perl sees in a package and the version that is published by the CPAN indexer.

It's only written as a helper module for both CPAN.pm and CPANPLUS.pm.

As it stands it predates version.pm but has the same goal: make version strings visible and comparable.

LICENSE

This program is free software; you can redistribute it and/or modify it under the same terms as Perl itself.

5.2.12 Cairo

Perl bindings for cairo, the 2D vector graphics library.

This is the `Cairo` module, version 1.109 of the CPAN API: the same packages, methods, arguments and return values that Perl code written against `Cairo` already expects. Drawing goes to the `libcairo.so.2` installed on the machine, which is located when the module is first used; if that library is absent, the first Cairo call dies with a message naming the distribution package to install.

Objects and their lifetime

A cairo object is an ordinary blessed reference. Nothing has to be freed by hand: the underlying cairo resource is released when the last Perl reference to it goes out of scope. An object obtained from a getter - the pattern from `$cr->get_source`, the surface from `$cr->get_target` - stays valid on its own and may outlive the context it came from.

One class does not follow that shape: `Cairo::Path` is a tied array of hashes rather than an object with methods, so the path returned by `$cr->copy_path` is read with ordinary array and hash syntax.

```
use Cairo;

my $surface = Cairo::ImageSurface->create('argb32', 100, 50);
my $cr = Cairo::Context->create($surface);
$cr->set_source_rgb(0.2, 0.4, 0.8);
$cr->rectangle(10, 10, 80, 30);
$cr->fill;
$cr->set_source_rgb(1, 1, 1);
$cr->move_to(20, 32);
```

(continues on next page)

(continued from previous page)

```
$cr->show_text("cairo");
printf "%dx%d %s, status %s\n", $surface->get_width, $surface->get_
↪height,
    $surface->get_format, $cr->status;          # 100x50 argb32,␣
↪status success
$surface->write_to_png('out.png');
```

Enumerations are their nicknames as strings (`'argb32'`, `'success'`), as in the CPAN module. The classes are documented on the pages below: `Cairo::Context`, the surfaces, patterns, fonts, matrices, paths and regions.

Differences from upstream

None.

Modules

- `Cairo::Context` - the drawing context, cairo's central object
- `Cairo::Font` - The `Cairo::Font` family: font faces, scaled fonts and font options.
- `Cairo::FontFace`
- `Cairo::FontOptions`
- `Cairo::Format`
- `Cairo::FtFontFace`
- `Cairo::Gradient`
- `Cairo::ImageSurface`
- `Cairo::LinearGradient`
- `Cairo::Matrix` - the affine transform every drawing operation goes
- `Cairo::Pattern` - `Cairo::Pattern` and its subclasses - the sources a context paints with.
- `Cairo::PdfSurface`
- `Cairo::PsSurface`
- `Cairo::RadialGradient`
- `Cairo::RecordingSurface`
- `Cairo::Region` - a set of integer-aligned rectangles
- `Cairo::ScaledFont`
- `Cairo::SolidPattern`
- `Cairo::Surface` - `Cairo::Surface` and its subclasses - the things cairo draws onto.
- `Cairo::SurfacePattern`
- `Cairo::SvgSurface`

- `Cairo::ToyFontFace`

Functions

Library information

`version`

Returns the version of the cairo library in use, as a single integer encoded `major * 10000 + minor * 100 + micro`.

Also available as `Cairo::lib_version`.

`version_string`

Returns the version of the cairo library in use as a printable string, for example "1.18.4".

Also available as `Cairo::lib_version_string`.

`VERSION_ENCODE`

Encodes a cairo version triple into the single integer that `Cairo::LIB_VERSION` returns: `major * 10000 + minor * 100 + micro`.

Also available as `Cairo::LIB_VERSION_ENCODE`.

`HAS_PNG_FUNCTIONS`

Returns true if the cairo library in use can read and write PNG files, that is, if `Cairo::ImageSurface->create_from_png` and `$surface->write_to_png` will work.

`HAS_PS_SURFACE`

Returns true if the cairo library in use can write PostScript, that is, if `Cairo::PsSurface->create` will work.

`HAS_PDF_SURFACE`

Returns true if the cairo library in use can write PDF, that is, if `Cairo::PdfSurface->create` will work.

`HAS_SVG_SURFACE`

Returns true if the cairo library in use can write SVG, that is, if `Cairo::SvgSurface->create` will work.

`HAS_RECORDING_SURFACE`

Returns true if the cairo library in use has recording surfaces (`Cairo::RecordingSurface->create`).

HAS_FT_FONT

Returns true if the cairo library in use can take its fonts from FreeType (`Cairo::FtFontFace->create`).

Cairo::Context

`Cairo::Context` - the drawing context, cairo's central object.

A context is made for a surface with `Cairo::Context->create($surface)` and holds the whole drawing state: the current source, line width, dash pattern, font, transformation matrix, clip region and current path. The drawing operations - `fill`, `stroke`, `paint`, `show_text` - apply that state to the context's target surface. `save` and `restore` bracket temporary changes to it.

The getters that hand back another object - `get_source`, `get_target`, `get_group_target`, `get_font_face`, `get_scaled_font` - return the context's own object rather than a copy, so changing it changes what the context will draw with. Each keeps itself alive, so it is still usable after the context has gone. `get_matrix`, `get_font_matrix` and `get_font_options` are the exception: those three return a fresh copy that is yours to modify.

Functions

Other Functions

create

Creates a drawing context for `$surface` and returns it as a `Cairo::Context`.

status

Returns the context's error state as a status name such as `'success'` or `'invalid-restore'`.

pop_group

Ends the group started by `push_group` and returns everything drawn inside it as a pattern.

get_source

Returns the context's current source as a `Cairo::Pattern` subclass matching the kind of source it is.

set_dash

Sets the dash pattern used by `stroke`.

get_dash

Returns the current dash pattern as a flat list, the offset first and the dash lengths after it.

get_matrix

Returns the context's current transformation matrix as a `Cairo::Matrix`.

has_current_point

Returns true if the current path has a current point, that is, if a relative operation such as `rel_line_to` has something to start from.

get_current_point

Returns the current point of the path as the two-element list `($x, $y)`, in user-space coordinates.

in_clip

Returns true if the user-space point `($x, $y)` is inside the area that the current clip would let drawing through.

select_font_face

Selects a font by family name for subsequent `show_text` and `text_extents` calls.

get_font_matrix

Returns the context's current font matrix as a `Cairo::Matrix`.

get_font_options

Returns the context's current font options as a fresh `Cairo::FontOptions`.

get_scaled_font

Returns the context's current scaled font - the font face together with the size and transformation in force - as a `Cairo::ScaledFont`.

show_text

Draws `$text` at the current point using the current font and source, then advances the current point past what was drawn.

text_path

Adds the outlines of `$text` to the current path instead of drawing it, so the text can then be filled, stroked or clipped with.

get_font_face

Returns the context's current font face as a `Cairo::FontFace` subclass matching the kind of face it is.

font_extents

Returns the metrics of the current font as a hash reference with the keys `ascent`, `descent`, `height`, `max_x_advance` and `max_y_advance`.

text_extents

Measures `$text` in the current font and returns a hash reference with the keys `x_bearing`, `y_bearing`, `width`, `height`, `x_advance` and `y_advance`.

get_target

Returns the surface the context draws onto, as the concrete `Cairo::Surface` subclass it really is.

get_group_target

Returns the surface drawing currently goes to: the innermost group's surface while a `push_group` is open, and otherwise the same surface `get_target` returns.

tag_begin

Opens a tagged region, used to attach structure such as links and document outlines to PDF output.

tag_end

Closes the tagged region opened by `tag_begin` with the same `$tag_name`.

show_glyphs

Draws a list of already-positioned glyphs with the current font and source.

glyph_path

Adds the outlines of a list of positioned glyphs to the current path instead of drawing them, so they can be filled, stroked or clipped with.

glyph_extents

Measures a list of positioned glyphs and returns a hash reference with the same keys as `text_extents`: `x_bearing`, `y_bearing`, `width`, `height`, `x_advance` and `y_advance`.

show_text_glyphs

Draws positioned glyphs while also recording which characters of `$text` they came from, so that backends such as PDF and SVG can make the result selectable and searchable.

copy_path

Returns a copy of the current path as a `Cairo::Path`.

copy_path_flat

Returns a copy of the current path as a `Cairo::Path`, with every curve replaced by a chain of line segments.

append_path

Appends a path to the context's current path.

copy_clip_rectangle_list

Returns the current clip region as a plain list of hash references, each with the keys `x`, `y`, `width` and `height` in user space.

select_font_face

Selects a font by family name for subsequent `show_text` and `text_extents` calls.

$cr->select_font_face('Sans', 'normal', 'bold');

`$family` is a font family such as `'Sans'` or `'Serif'`, `$slant` is one of `'normal'`, `'italic'` or `'oblique'`, and `$weight` is `'normal'` or `'bold'`. The family is interpreted as text, so accented and non-Latin names work. This is the simple font-selection interface; `set_font_face` takes a font object instead. Wraps `cairo_select_font_face`.

show_text

Draws `$text` at the current point using the current font and source, then advances the current point past what was drawn.

$cr->move_to(10, 40); $cr->show_text('Hello');

The string is taken as text, so non-ASCII characters are drawn correctly. This is the convenience interface meant for simple labels; use `show_glyphs` or a text-shaping library for real typography. Wraps `cairo_show_text`.

tag_begin

Opens a tagged region, used to attach structure such as links and document outlines to PDF output.

$cr->tag_begin('Link', "uri='https://example.org'"); $cr->show_text('example'); $cr->tag_end('Link');

`$attributes` is a single string of `name=value` pairs. Backends other than PDF ignore tags. Needs cairo 1.16 or newer; on an older library the call dies saying so. Wraps `cairo_tag_begin`.

show_glyphs

Draws a list of already-positioned glyphs with the current font and source.

$cr->show_glyphs({ index => 43, x => 10, y => 40 }, ...);

Each glyph is a hash reference with the keys `index` (the glyph number within the font, not a character), `x` and `y` (its position in user space). Missing keys count as 0. Unlike `show_text` this does not advance the current point, since every glyph carries its own position. Returns nothing. Wraps `cairo_show_glyphs`.

show_text_glyphs

Draws positioned glyphs while also recording which characters of `$text` they came from, so that backends such as PDF and SVG can make the result selectable and searchable.

$cr->show_text_glyphs($text, @glyphs, @clusters, ['backward']);

`\@glyphs` holds `{ index, x, y }` hash references as for `show_glyphs`. `\@clusters` holds `{ num_bytes, num_glyphs }` hash references, each mapping that many bytes of `$text` onto that many glyphs; the clusters must together account for the whole string and the whole glyph list. `$cluster_flags` is an array reference of flag names (only `'backward'` is defined), a single flag name, or `undef` for none. Note that unlike the glyph and cluster lists, which are passed by reference, `show_glyphs` takes its glyphs as a flat list. Returns nothing. Needs cairo 1.8 or newer; on an older library the call dies saying so. Wraps `cairo_show_text_glyphs`.

copy_path

Returns a copy of the current path as a `Cairo::Path`.

A `Cairo::Path` is a tied array of hashes, so it is read with ordinary Perl syntax rather than through methods:

```
my $path = $cr->copy_path;
for my $elem (@$path) {
    print "$elem->{type}\n";      # 'move-to', 'line-to', ...
}
```

The path is a snapshot: later drawing on the context does not change it, and it may be handed back to append_path on this or any other context. Wraps `cairo_copy_path`.

append_path

Appends a path to the context's current path.

$cr->append_path($path);

`$path` may be a `Cairo::Path` obtained from `copy_path` or `copy_path_flat`, or a plain array reference of `{ type => ..., points => [...] }` hashes built by hand. Either way the path is copied into the context, so the argument stays usable afterwards. Returns nothing. Wraps `cairo_append_path`.

copy_clip_rectangle_list

Returns the current clip region as a plain list of hash references, each with the keys `x`, `y`, `width` and `height` in user space.

for my $rect ($cr->copy_clip_rectangle_list) { printf "%g %g %g %g\n", @$rect{qw(x y width height)}; }

A clip that cannot be expressed as a list of rectangles makes the call die with `$@` set to a status name such as `'clip-not-representable'`, so wrap it in `eval` when the clip may come from arbitrary paths. Needs cairo 1.4 or newer; on an older library the call dies saying so. Wraps `cairo_copy_clip_rectangle_list`.

Cairo::Font

The `Cairo::Font` family: font faces, scaled fonts and font options.

This is the font half of the Cairo API. `Cairo::ToyFontFace` picks a font by family name, slant and weight; `Cairo::ScaledFont` is that face fixed at a particular size and transform, and is what answers questions about measurements - font extents, text extents, glyph extents, and turning a string into glyphs. `Cairo::FontOptions` carries the rendering settings (antialiasing, subpixel order, hinting, and on cairo 1.18 the color-font controls) that a context or a scaled font uses. `Cairo::FontFace` is the base class the face classes share, and `Cairo::FtFontFace` is the FreeType face - see its `create` for why it cannot be built here.

Font faces come back as subclasses

Anything returning a font face - `ScaledFont::get_font_face`, `Context::get_font_face` - blesses it into the class matching the font backend cairo reports: a toy face into `Cairo::ToyFontFace`, a FreeType face into `Cairo::FtFontFace`, anything else into the base `Cairo::FontFace`. All of them answer `status`, `get_type` and `DESTROY`, which the subclasses inherit.

Object lifetime

Font faces, scaled fonts and font options are reference-counted by cairo. An object you create owns its reference, and a getter that hands back an object its parent also holds - `ScaledFont::get_font_face` - takes a reference of its own, so what you get stays valid for as long as you hold it. Every object releases its reference when Perl destroys it; nothing has to be freed by hand.

Methods report their cairo version at call time

Each method looks up its cairo entry point in the installed libcairo the first time it is used. A method that libcairo does not provide croaks then and there, naming the version it needs (for instance `Cairo: text_extents requires libcairo >= 1.2`), rather than failing when the module is loaded.

Cairo::FontFace

Functions

Other Functions

`status`

Returns the font face's error status as a nickname string, `success` when the face is usable.

`get_type`

Returns the backend behind this font face as a nickname string: `toy`, `ft`, `win32`, `quartz`, `user` or `dwrite`. Needs libcairo 1.2 or newer.

Cairo::FontOptions

Functions

Other Functions

`create`

Creates a font options object with everything at its default (cairo_font_options_create): `Cairo::FontOptions->create`. Takes no arguments.

`status`

Returns the font options' error status as a nickname string, `success` when they are usable.

`merge`

Merges `$other` into `$opts` in place: every option that `$other` sets to something other than its default replaces the one in `$opts`. The argument is required. Returns nothing.

`equal`

Returns true if `$opts` and `$other` hold the same settings. The argument is required.

hash

Returns a hash value for the options, computed from the settings they hold, for use as a key when caching option objects.

set_color_mode

Sets whether color glyphs are used when the font has them: `default`, `no-color` or `color`. Needs libcairo 1.18 or newer, and croaks with `Cairo: set_color_mode requires cairo >= 1.18` on anything older.

get_color_mode

Returns the color-glyph mode as a nickname string. Needs libcairo 1.18 or newer, and croaks with `Cairo: get_color_mode requires cairo >= 1.18` on anything older.

set_color_palette

Chooses which color palette a color font uses, by index; 0 is the font's default palette. Needs libcairo 1.18 or newer, and croaks with `Cairo: set_color_palette requires cairo >= 1.18` on anything older.

get_color_palette

Returns the index of the color palette in use. Needs libcairo 1.18 or newer, and croaks with `Cairo: get_color_palette requires cairo >= 1.18` on anything older.

set_custom_palette_color

Overrides one entry of the color palette: `$opts->set_custom_palette_color($index, $r, $g, $b, $a)`. All five arguments are required. Needs libcairo 1.18 or newer, and croaks with `Cairo: set_custom_palette_color requires cairo >= 1.18` on anything older.

get_custom_palette_color

Reads back one overridden palette entry, returning the list `($status, $r, $g, $b, $a)`. The status nickname comes first and is `success` only when that entry has been overridden - an index with no override yields `invalid-index`, and the four components are then meaningless. Needs libcairo 1.18 or newer, and croaks with `Cairo: get_custom_palette_color requires cairo >= 1.18` on anything older.

Cairo::Format

Functions

Other Functions

stride_for_width

Returns the number of bytes one row of pixels occupies for a given format and width - the `$stride` that `create_for_data` wants.

stride_for_width

Returns the number of bytes one row of pixels occupies for a given format and width - the `$stride` that `create_for_data` wants.

my $stride = Cairo::Format::stride_for_width('argb32', $width);

Called as a plain FUNCTION, not as a method: write `Cairo::Format::stride_for_width(...)`, not `Cairo::Format->stride_for_width(...)`. The result is usually more than width times bytes-per-pixel, because rows are padded for alignment. Returns a negative number for a format or width cairo cannot handle. Wraps `cairo_format_stride_for_width`.

Cairo::FtFontFace

Functions

Other Functions

create

Not available: calling it always croaks.

create

Not available: calling it always croaks.

A FreeType font face can only be built from a `Font::FreeType::Face` object, and pperl does not provide `Font::FreeType`, so nothing can produce the argument this method needs. It will work once `Font::FreeType` is available as a native libfreetype binding. Until then only the class itself exists: `Cairo::FtFontFace` still inherits from `Cairo::FontFace`, so `isa` and `can` answer correctly, and a face cairo reports as a FreeType one is still blessed into this class.

Cairo::Gradient

Functions

Other Functions

add_color_stop_rgb

Adds an opaque color stop to the gradient at `$offset`, a position from 0 to 1 along the gradient's control vector: `$gradient->add_color_stop_rgb($offset, $r, $g, $b)`. Returns nothing.

add_color_stop_rgba

Adds a translucent color stop to the gradient at `$offset`: `$gradient->add_color_stop_rgba($offset, $r, $g, $b, $a)`. Returns nothing.

get_color_stops

Returns every color stop of the gradient, one five-element arrayref `[$offset, $r, $g, $b, $a]` per stop, in the order cairo holds them. On a pattern that is not a gradient it croaks with `pattern-type-mismatch`. Needs libcairo 1.4 or newer.

Cairo::ImageSurface

Functions

Other Functions

create

Creates an in-memory image surface of `$width` by `$height` pixels and returns it as a `Cairo::ImageSurface`.

create_for_data

Creates an image surface that draws directly into a scalar you already hold, rather than into memory of its own.

get_data

Returns the surface's pixels as a string of `height * stride` bytes, or `undef` if the surface has no accessible pixel data.

get_format

Returns the surface's pixel format as a name such as `'argb32'` or `'rgb24'`.

create_from_png

Reads a PNG file and returns its contents as a `Cairo::ImageSurface`.

create_from_png_stream

Reads a PNG by asking a callback of yours for successive chunks of it, and returns the result as a `Cairo::ImageSurface`.

create_for_data

Creates an image surface that draws directly into a scalar you already hold, rather than into memory of its own.

my $surface = Cairo::ImageSurface->create_for_data($data, 'argb32', $width, $height, $stride);

`$stride` is the number of bytes between the start of one row of pixels and the start of the next; `Cairo::Format::stride_for_width` computes the right value. `$data` must already be at least `$height * $stride` bytes long.

The scalar is NOT copied: the surface writes into its bytes in place. That makes the scalar the pixels, but it also means the scalar has to stay alive and unmodified for as long as the surface exists. Letting it go out of scope first, or assigning to it, leaves the surface drawing into memory that is no longer there. Wraps `cairo_image_surface_create_for_data`.

create_from_png

Reads a PNG file and returns its contents as a `Cairo::ImageSurface`.

my $surface = Cairo::ImageSurface->create_from_png('logo.png');

A file that cannot be read or is not a PNG still yields a surface, but one whose `status` reports the error rather than `'success'`, so check it before drawing. Dies if the cairo installed on this machine was built without PNG support; `Cairo::HAS_PNG_FUNCTIONS` tells you in advance. Wraps `cairo_image_surface_create_from_png`.

create_from_png_stream

Reads a PNG by asking a callback of yours for successive chunks of it, and returns the result as a `Cairo::ImageSurface`.

my $surface = Cairo::ImageSurface->create_from_png_stream(sub { my ($data, $length) = @_; read($fh, my $buf, $length); return $buf; });

The callback is called with two arguments - the optional `$data` value you passed after it, and the number of bytes wanted - and must RETURN the bytes it read. To report a failure, die with a cairo status name such as `'read-error'`; the surface then comes back with that status rather than the call dying. The callback is only used during construction and is not retained afterwards. Dies if the cairo installed on this machine was built without PNG support. Wraps `cairo_image_surface_create_from_png_stream`.

Cairo::LinearGradient

Functions

Other Functions

`create`

Creates a linear gradient running from `($x0, $y0)` to `($x1, $y1)`: `Cairo::LinearGradient->create($x0, $y0, $x1, $y1)`. The gradient has no color until you add stops with `add_color_stop_rgb/_rgba`.

get_points

Returns the linear gradient's two endpoints as the four-element list `($x0, $y0, $x1, $y1)`. On a pattern that is not a linear gradient it croaks with `pattern-type-mismatch`. Needs libcairo 1.4 or newer.

Cairo::Matrix

`Cairo::Matrix` - the affine transform every drawing operation goes through.

A matrix holds the six numbers `(xx, yx, xy, yy, x0, y0)` of a 2D affine transform. The `Cairo::Matrix->init*` constructors build one, `translate`/`scale`/`rotate` modify it in place, `multiply` combines two, `invert` inverts it in place, and `transform_point` / `transform_distance` apply it to a coordinate pair.

Unlike the other cairo objects a matrix is a plain value, not a shared reference-counted handle. Every method that hands one back - `Context::get_matrix`, `Pattern::get_matrix`, `ScaledFont::get_font_matrix` - returns a fresh copy, so changing the matrix you got back never changes the object it came from. The copy is released when Perl destroys it; nothing has to be freed by hand.

The matrix API is stable since cairo 1.0, so no method here depends on a particular libcairo version.

Functions

Other Functions

init

Builds a new matrix from the six affine components, in cairo's order: `Cairo::Matrix->init($xx, $yx, $xy, $yy, $x0, $y0)`. All six are required; a shorter argument list croaks with a usage message.

init_identity

Builds a new matrix set to the identity transform: `Cairo::Matrix->init_identity`.

init_translate

Builds a new matrix that translates by `($tx, $ty)`: `Cairo::Matrix->init_translate($tx, $ty)`.

init_scale

Builds a new matrix that scales by `$sx` in x and `$sy` in y: `Cairo::Matrix->init_scale($sx, $sy)`.

init_rotate

Builds a new matrix that rotates by `$radians`: `Cairo::Matrix->init_rotate($radians)`.

translate

Applies a translation of `($tx, $ty)` to `$matrix` in place (cairo_matrix_translate). Returns nothing.

scale

Applies a scale of `($sx, $sy)` to `$matrix` in place (cairo_matrix_scale). Returns nothing.

rotate

Applies a rotation of `$radians` to `$matrix` in place (cairo_matrix_rotate). Returns nothing.

invert

Inverts `$matrix` in place (cairo_matrix_invert) and returns the outcome as a status nickname: `success`, or `invalid-matrix` if the matrix is not invertible.

multiply

Returns a **new** `Cairo::Matrix` holding the product of `$a` and `$b`.

transform_distance

Transforms the distance vector `($dx, $dy)` by `$matrix` and returns the transformed pair as a two-element list. Only the matrix's linear part is applied - the translation is ignored, which is what makes this a distance rather than a point.

transform_point

Transforms the point `($x, $y)` by `$matrix` and returns the transformed pair as a two-element list. The full affine transform is applied, translation included.

Cairo::Pattern

`Cairo::Pattern` and its subclasses - the sources a context paints with.

A pattern is what `Cairo::Context` draws with: a flat color (`Cairo::SolidPattern`), another surface used as an image or a tile (`Cairo::SurfacePattern`), or a color ramp - `Cairo::LinearGradient` and `Cairo::RadialGradient`, which take their color-stop methods from the abstract `Cairo::Gradient`. Settings shared by all of them (the pattern matrix, the extend mode, the filter) live on the base `Cairo::Pattern`.

Constructors return the concrete subclass

A constructor blesses its result into the class matching what cairo actually built, not into the class you called it on: `Cairo::SolidPattern->create_rgb` hands back a `Cairo::SolidPattern`, `Cairo::LinearGradient->create` a `Cairo::LinearGradient`, and anything cairo reports as some other kind comes back as the base `Cairo::Pattern`. `get_surface` behaves the same way, returning the surface blessed into its own class (`Cairo::ImageSurface`, `Cairo::PdfSurface` and so on).

Object lifetime

Patterns are reference-counted by cairo. A pattern you create owns its reference, and the surface `get_surface` returns takes one of its own, so it stays alive for as long as you hold it. Every object drops its reference when Perl destroys it; nothing has to be freed by hand.

Gradient dithering (cairo 1.18)

`set_dither` and `get_dither` control the dithering cairo applies to a gradient to hide banding. They need libcairo 1.18 or newer; on anything older they croak with `requires cairo >= 1.18`.

Functions

Other Functions

`set_matrix`

Sets the pattern's transformation matrix (cairo_pattern_set_matrix). `$matrix` is a `Cairo::Matrix`, and it maps user space to pattern space. Returns nothing.

`get_matrix`

Returns the pattern's transformation matrix as a fresh `Cairo::Matrix`. It is a copy: changing it does not change the pattern, which needs a `set_matrix` call.

`status`

Returns the pattern's error status as a nickname string, `success` when the pattern is usable.

`set_dither`

Sets how a gradient is dithered, to hide banding: `none`, `default`, `fast`, `good` or `best`. Needs libcairo 1.18 or newer, and croaks with `Cairo: set_dither requires cairo >= 1.18` on anything older.

get_dither

Returns the pattern's dither setting as a nickname string. Needs libcairo 1.18 or newer, and croaks with `Cairo: get_dither requires cairo >= 1.18` on anything older.

Cairo::PdfSurface

Functions

Other Functions

restrict_to_version

Restricts the surface to features present in the given PDF version, named as `'1-4'`, `'1-5'`, `'1-6'` or `'1-7'`.

set_metadata

Sets one document metadata field of the PDF.

set_page_label

Sets the label a PDF viewer shows for the current page, instead of its sheet number.

set_thumbnail_size

Asks for a thumbnail image of the current page, at most `$width` by `$height` pixels, to be embedded in the PDF.

add_outline

Adds an entry to the PDF's document outline (its bookmark tree) and returns the entry's id, for use as the parent of further entries.

set_metadata

Sets one document metadata field of the PDF.

$pdf->set_metadata('title', 'Quarterly report');

`$metadata` names the field: `'title'`, `'author'`, `'subject'`, `'keywords'`, `'creator'`, `'create-date'` or `'mod-date'`. The two date fields take an ISO 8601 string. Needs cairo 1.16 or newer; on an older library the call dies saying so. Wraps `cairo_pdf_surface_set_metadata`.

add_outline

Adds an entry to the PDF's document outline (its bookmark tree) and returns the entry's id, for use as the parent of further entries.

my $id = $pdf->add_outline(Cairo::PdfSurface::OUTLINE_ROOT, 'Chapter 1', "page=1", 0); $pdf->add_outline($id, 'Section 1.1', "page=2", 0);

`$parent_id` is `Cairo::PdfSurface::OUTLINE_ROOT` for a top-level entry, `$link_attribs` a string of `name=value` pairs saying where the entry points, and `$flags` a plain INTEGER bitmask - unlike the other enumerated arguments in this module, it is not a name. Needs cairo 1.16 or newer; on an older library the call dies saying so. Wraps `cairo_pdf_surface_add_outline`.

Cairo::PsSurface

Functions

Other Functions

dsc_comment

Emits a raw DSC comment into the PostScript output.

restrict_to_level

Restricts the surface to features present in the given PostScript language level, named as `'2'` or `'3'`.

set_eps

Switches the surface between plain PostScript and Encapsulated PostScript output.

get_eps

Returns 1 if the surface is producing Encapsulated PostScript, and 0 if it is producing plain PostScript.

Cairo::RadialGradient

Functions

Other Functions

create

Creates a radial gradient between two circles, the first centered on `($cx0, $cy0)` with radius `$r0` and the second on `($cx1, $cy1)` with radius `$r1`: `Cairo::RadialGradient->create($cx0, $cy0, $r0, $cx1, $cy1, $r1)`. The gradient has no color until you add stops.

get_circles

Returns the radial gradient's two circles as the six-element list `($x0, $y0, $r0, $x1, $y1, $r1)`. On a pattern that is not a radial gradient it croaks with `pattern-type-mismatch`. Needs libcairo 1.4 or newer.

Cairo::RecordingSurface

Functions

Other Functions

create

Creates a surface that records the drawing operations performed on it instead of rendering them, so they can be replayed later onto any other surface at any resolution.

ink_extents

Returns the area actually covered by ink so far, as the four-element list `($x0, $y0, $width, $height)`.

get_extents

Returns the bounds the surface was created with, as a hash reference with the keys `x`, `y`, `width` and `height`.

create

Creates a surface that records the drawing operations performed on it instead of rendering them, so they can be replayed later onto any other surface at any resolution.

my $rec = Cairo::RecordingSurface->create('color-alpha', { x => 0, y => 0, width => 100, height => 100 }); my $unbounded = Cairo::RecordingSurface->create('color-alpha');

`$content` is `'color'`, `'alpha'` or `'color-alpha'`. The second argument bounds the recording: a plain hash reference with the keys `x`, `y`, `width` and `height`, or `undef`/omitted for an unbounded surface that accepts drawing anywhere. Replay a recording by using it as a source, for instance through `$cr->set_source_surface`. Wraps `cairo_recording_surface_create`.

Cairo::Region

`Cairo::Region` - a set of integer-aligned rectangles.

Regions describe pixel-aligned areas: build one from rectangles, combine it with another using `intersect`, `union`, `subtract` or `xor`, move it with `translate`, and ask whether a point or a rectangle falls inside it. A region owns its cairo object and releases it when Perl destroys the Perl object, so nothing has to be freed by hand.

Requires cairo >= 1.10

The region API arrived in cairo 1.10. If the installed libcairo is older, every method here croaks with `Cairo::Region requires cairo >= 1.10` when it is called.

Rectangles are plain hashrefs

Everywhere a rectangle is passed in or handed back it is an unblessed hashref with exactly the keys `x`, `y`, `width` and `height`, and the values are **integers** - a region is pixel-aligned, so there are no fractional coordinates. In a rectangle you pass in, a missing key or an `undef` value counts as 0; an argument that is not a hash reference croaks with `cairo_rectangle_int_t must be a hash reference`.

Functions

Other Functions

`create`

Creates a region, dispatching on how many rectangles you pass:

`status`

Returns the region's error status as a nickname string, `success` when the region is usable.

`get_extents`

Returns the smallest rectangle containing the whole region, as a hashref `{x, y, width, height}`.

`num_rectangles`

Returns how many rectangles the region is made of.

`get_rectangle`

Returns the `$nth` rectangle of the region (counting from 0) as a hashref `{x, y, width, height}`.

`is_empty`

Returns true if the region covers nothing at all.

`contains_point`

Returns true if the integer point `($x, $y)` lies inside the region.

`contains_rectangle`

Reports how `$rect` sits relative to the region, as a nickname string: `in` when the rectangle is entirely inside, `out` when it is entirely outside, `part` when it is partly in.

equal

Returns true if `$region` and `$other` cover exactly the same area.

translate

Moves the region by the integer offset `($dx, $dy)`, in place. Returns nothing.

create

Creates a region, dispatching on how many rectangles you pass:

```
Cairo::Region->create()          # empty region
Cairo::Region->create($rect)     # one rectangle
Cairo::Region->create(@rects)    # the union of several rectangles
```

Each rectangle is a hashref `{x, y, width, height}` with integer values.

Cairo::ScaledFont

Functions

Other Functions

create

Creates a scaled font - a font face fixed at one size and transform (cairo_scaled_font_create): `Cairo::ScaledFont->create($face, $font_matrix, $ctm, $options)`. `$font_matrix` sizes and shapes the glyphs, `$ctm` is the transform they will be drawn under, both `Cairo::Matrix`, and `$options` is a `Cairo::FontOptions`. All four arguments are required; a shorter list croaks with a usage message.

status

Returns the scaled font's error status as a nickname string, `success` when it is usable.

get_type

Returns the backend behind this scaled font as a nickname string: `toy`, `ft`, `win32`, `quartz`, `user` or `dwrite`. Needs libcairo 1.2 or newer.

extents

Returns the font's own metrics as a hashref with the keys `ascent`, `descent`, `height`, `max_x_advance` and `max_y_advance`. These describe the font at this size, independent of any particular string.

text_extents

Measures a string in this font and returns a hashref with the keys `x_bearing`, `y_bearing`, `width`, `height`, `x_advance` and `y_advance`. The string is taken as UTF-8. It is required; without it the call croaks with a usage message. Needs libcairo 1.2 or newer.

get_font_face

Returns the font face this scaled font was made from, blessed into the class matching its backend (`Cairo::ToyFontFace`, `Cairo::FtFontFace`, or the base `Cairo::FontFace`). The face stays valid for as long as you hold it, even if the scaled font goes away. Needs libcairo 1.2 or newer.

get_font_matrix

Returns the font matrix the scaled font was created with, as a fresh `Cairo::Matrix`. It is a copy: changing it does not change the scaled font. Needs libcairo 1.2 or newer.

get_ctm

Returns the transform matrix the scaled font was created with, as a fresh `Cairo::Matrix`. It is a copy: changing it does not change the scaled font. Needs libcairo 1.2 or newer.

get_scale_matrix

Returns the scale matrix - the font matrix combined with the transform - as a fresh `Cairo::Matrix`. It is a copy: changing it does not change the scaled font. Needs libcairo 1.8 or newer.

get_font_options

Returns the rendering options the scaled font was created with, as a fresh `Cairo::FontOptions`. It is a separate object: changing it does not change the scaled font. Needs libcairo 1.2 or newer.

glyph_extents

Measures a run of glyphs in this font and returns a hashref with the keys `x_bearing`, `y_bearing`, `width`, `height`, `x_advance` and `y_advance`.

text_to_glyphs

Converts a string into the glyphs this font would use to draw it, laid out starting at `($x, $y)`: `$sf->text_to_glyphs($x, $y, $utf8)`.

text_to_glyphs

Converts a string into the glyphs this font would use to draw it, laid out starting at `($x, $y)`: `$sf->text_to_glyphs($x, $y, $utf8)`.

Returns a **list**: `($status, $glyphs, $clusters, $cluster_flags)`. The status nickname is always returned; the other three come back only when it is `success`, so check the status before using them. `$glyphs` is an arrayref of `{index, x, y}` hashrefs, `$clusters` an arrayref of `{num_bytes, num_glyphs}` hashrefs mapping the text to those glyphs, and `$cluster_flags` an arrayref of set flag names (`backward`, or empty).

All three arguments are required; a shorter list croaks with a usage message. Needs libcairo 1.8 or newer.

Cairo::SolidPattern

Functions

Other Functions

create_rgb

Creates an opaque solid-color pattern from the three components (cairo_pattern_create_rgb): `Cairo::SolidPattern->create_rgb($r, $g, $b)`. Each is in the range 0 to 1. All three are required; a shorter argument list croaks with a usage message. The result is blessed `Cairo::SolidPattern`.

create_rgba

Creates a translucent solid-color pattern (cairo_pattern_create_rgba): `Cairo::SolidPattern->create_rgba($r, $g, $b, $a)`. All four components are in the range 0 to 1 and all four are required.

get_rgba

Returns the solid pattern's color as the four-element list `($r, $g, $b, $a)`. On a pattern that is not solid it croaks with `pattern-type-mismatch`. Needs libcairo 1.4 or newer.

Cairo::Surface

`Cairo::Surface` and its subclasses - the things cairo draws onto.

A surface is where drawing ends up, and its class decides in what form: `Cairo::ImageSurface` for pixels in memory, `Cairo::PdfSurface`, `Cairo::PsSurface` and `Cairo::SvgSurface` for the corresponding file formats, and `Cairo::RecordingSurface` for a replayable record of the drawing operations themselves. All of them inherit from `Cairo::Surface`, which carries the methods common to every backend.

Every constructor returns the concrete subclass, never the bare `Cairo::Surface`, so the surface you get back from `create_similar` or from `$cr->get_target` already responds to the methods of whatever kind of surface it turned out to be. Draw on a surface by creating a context for it with `Cairo::Context->create($surface)`.

Methods that name a string constant - `status`, `get_type`, `get_content`, `get_format` - return a short name such as `'success'`, `'image'`, `'color-alpha'` or `'argb32'`, never a number.

When a backend is missing

Which backends exist depends on how the cairo installed on this machine was built. A cairo without PDF, PostScript, SVG or PNG support still loads, but the methods belonging to the missing backend die with a message saying so, for example "libcairo was built without PDF support". `Cairo::HAS_PNG_FUNCTIONS` reports the PNG case up front. The PDF metadata and outline methods additionally need cairo 1.16 or newer.

Constants

The MIME types `set_mime_data` and `supports_mime_type` take are constants of `Cairo::Surface`: `MIME_TYPE_JPEG` (`"image/jpeg"`), `MIME_TYPE_PNG`, `MIME_TYPE_JP2`, `MIME_TYPE_URI`, `MIME_TYPE_UNIQUE_ID`, `MIME_TYPE_JBIG2`, `MIME_TYPE_JBIG2_GLOBAL`, `MIME_TYPE_JBIG2_GLOBAL_ID`, `MIME_TYPE_CCITT_FAX`, `MIME_TYPE_CCITT_FAX_PARAMS`, `MIME_TYPE_EPS` and `MIME_TYPE_EPS_PARAMS`. `Cairo::PdfSurface::OUTLINE_ROOT` (0) is the parent id to give `add_outline` for a top-level bookmark.

Functions

Other Functions

`status`

Returns the surface's error state as a status name such as `'success'`, `'file-not-found'` or `'no-memory'`.

`get_type`

Returns the kind of surface this is, as a name such as `'image'`, `'pdf'`, `'ps'`, `'svg'` or `'recording'`.

`get_content`

Returns what the surface stores, as one of `'color'`, `'alpha'` or `'color-alpha'`.

`write_to_png`

Writes the surface to `$filename` as a PNG and returns a status name.

`create_similar`

Creates a new surface of the same backend as an existing one, sized `$width` by `$height`, and returns it as the concrete subclass.

set_device_offset

Shifts the surface's origin, so that user-space point (0, 0) lands at device point `($x, $y)` instead.

get_device_offset

Returns the surface's device offset as the two-element list `($x_offset, $y_offset)`.

set_fallback_resolution

Sets the resolution, in pixels per inch, at which a vector backend rasterises anything it cannot express directly.

get_fallback_resolution

Returns the surface's fallback resolution as the two-element list `($x_ppi, $y_ppi)`.

get_font_options

Returns the font rendering options this surface prefers, as a fresh `Cairo::FontOptions`.

mark_dirty_rectangle

Tells cairo that the given rectangle of the surface was changed behind its back, so that any cached copy of that area is discarded.

has_show_text_glyphs

Returns 1 if this surface can record the character-to-glyph mapping that `$cr->show_text_glyphs` supplies, and 0 if it cannot.

create_for_rectangle

Creates a surface that is a window onto part of another one.

supports_mime_type

Returns 1 if the surface can embed data of the given MIME type unchanged in its output, and 0 if it cannot.

write_to_png_stream

Writes the surface as a PNG by handing successive chunks of it to a callback of yours, and returns a status name.

set_mime_data

Attaches the original compressed form of an image to the surface, so that a backend able to embed it does so instead of re-encoding the pixels, and returns a status name.

get_mime_data

Returns the data previously attached with `set_mime_data` for the given MIME type, or `undef` if the surface carries none.

create_similar

Creates a new surface of the same backend as an existing one, sized `$width` by `$height`, and returns it as the concrete subclass.

It can be called either way round, as a class method naming the model surface or as a method on the model surface itself:

```
Cairo::Surface->create_similar($other, $content, $width, $height)
$other->create_similar($content, $width, $height)
```

`$content` is `'color'`, `'alpha'` or `'color-alpha'`. The result is a blank surface, not a copy of `$other`; only the backend and its device characteristics are inherited, which is what makes it the efficient choice for an intermediate you will later composite back. Wraps `cairo_surface_create_similar`.

create_for_rectangle

Creates a surface that is a window onto part of another one.

my $part = Cairo::Surface->create_for_rectangle($target, $x, $y, $width, $height);

Drawing on the result goes through to `$target`, clipped to the given rectangle and with its origin moved to the rectangle's corner. The coordinates are in `$target`'s device space and need not be whole pixels. `$target` is kept alive by the returned surface. Wraps `cairo_surface_create_for_rectangle`.

supports_mime_type

Returns 1 if the surface can embed data of the given MIME type unchanged in its output, and 0 if it cannot.

if ($pdf->supports_mime_type(Cairo::Surface::MIME_TYPE_JPEG)) { $image->set_mime_data(Cairo::Surface::MIME_TYPE_JPEG, $jpeg); }

Worth asking before `set_mime_data`, since attaching data a backend cannot use just wastes memory. Wraps `cairo_surface_supports_mime_type`.

write_to_png_stream

Writes the surface as a PNG by handing successive chunks of it to a callback of yours, and returns a status name.

$surface->write_to_png_stream(sub { my ($data, $chunk) = @_; print {$fh} $chunk; });

The callback is called with two arguments: the optional `$data` value you passed after it, and the chunk of PNG bytes to consume. Its return value is ignored; to report a failure, die with a cairo status name such as `'write-error'`, which then becomes this method's result. The callback is only used during the call and is not retained afterwards. Dies if the cairo installed on this machine was built without PNG support. Wraps `cairo_surface_write_to_png_stream`.

set_mime_data

Attaches the original compressed form of an image to the surface, so that a backend able to embed it does so instead of re-encoding the pixels, and returns a status name.

$image->set_mime_data(Cairo::Surface::MIME_TYPE_JPEG, $jpeg_bytes);

`$mime_type` is one of the `Cairo::Surface::MIME_TYPE_*` constants. Ask `supports_mime_type` first, since a backend that cannot use the data simply ignores it.

The scalar itself is retained, NOT copied, so do not modify `$data` after handing it over; the surface holds on to it until the surface goes away or other data replaces it. Needs cairo 1.10 or newer; on an older library the call dies saying so. Wraps `cairo_surface_set_mime_data`.

Cairo::SurfacePattern

Functions

Other Functions

create

Creates a pattern that paints with the contents of `$surface` (cairo_pattern_create_for_surface): `Cairo::SurfacePattern->create($surface)`. The surface argument is required. The result is blessed `Cairo::SurfacePattern`.

get_surface

Returns the surface the pattern paints with, blessed into its own class (`Cairo::ImageSurface`, `Cairo::PdfSurface`, ...). The surface stays valid for as long as you hold the returned object, even if the pattern goes away. On a pattern that is not a surface pattern it croaks with `pattern-type-mismatch`. Needs libcairo 1.4 or newer.

Cairo::SvgSurface

Functions

Other Functions

restrict_to_version

Restricts the surface to features present in the given SVG version, named as `'1-1'` or `'1-2'`.

Cairo::ToyFontFace

Functions

Other Functions

`create`

Creates a font face for a family name selected the simple way (cairo_toy_font_face_create): `Cairo::ToyFontFace->create($family, $slant, $weight)`. `$slant` is one of `normal`, `italic`, `oblique` and `$weight` one of `normal`, `bold`. All three arguments are required; a shorter list croaks with a usage message. Needs libcairo 1.8 or newer.

`get_family`

Returns the family name the face was created with, as a UTF-8 string.

`get_slant`

Returns the face's slant as a nickname string: `normal`, `italic` or `oblique`.

`get_weight`

Returns the face's weight as a nickname string: `normal` or `bold`.

VERSION_ENCODE

Encodes a cairo version triple into the single integer that `Cairo::LIB_VERSION` returns: `major * 10000 + minor * 100 + micro`.

Also available as `Cairo::LIB_VERSION_ENCODE`.

Spelled `Cairo::VERSION_ENCODE` or `Cairo::LIB_VERSION_ENCODE`, and callable both as a plain function, `Cairo::VERSION_ENCODE(1, 2, 0)`, and as a class method, `Cairo->VERSION_ENCODE(1, 2, 0)`. The last three arguments are the ones read, so the class-method form's leading class name is ignored. Called with fewer numbers, the missing minor and micro components count as 0.

5.2.13 Capture

Namespace containing the following modules:

- `Capture::Tiny` - version 0.50

Capture::Tiny

VERSION

version 0.50

SYNOPSIS

```
use Capture::Tiny ':all';

# capture from external command

($stdout, $stderr, $exit) = capture {
  system( $cmd, @args );
};

# capture from arbitrary code (Perl or external)

($stdout, $stderr, @result) = capture {
  # your code here
};

# capture partial or merged output

$stdout = capture_stdout { ... };
$stderr = capture_stderr { ... };
$merged = capture_merged { ... };

# tee output

($stdout, $stderr) = tee {
  # your code here
};

$stdout = tee_stdout { ... };
$stderr = tee_stderr { ... };
$merged = tee_merged { ... };
```

DESCRIPTION

Optionally, output can be teed so that it is captured while being passed through to the original filehandles. Yes, it even works on Windows (usually). Stop guessing which of a dozen capturing modules to use in any particular situation and just use this one.

USAGE

The following functions are available. None are exported by default.

capture

```
($stdout, $stderr, @result) = capture \&code;
$stdout = capture \&code;
```

The `capture` function takes a code reference and returns what is sent to STDOUT and STDERR as well as any return values from the code reference. In scalar context, it returns only STDOUT. If no output was received for a filehandle, it returns an empty string for

that filehandle. Regardless of calling context, all output is captured – nothing is passed to the existing filehandles.

It is prototyped to take a subroutine reference as an argument. Thus, it can be called in block form:

```
($stdout, $stderr) = capture {
  # your code here ...
};
```

Note that the coderef is evaluated in list context. If you wish to force scalar context on the return value, you must use the `scalar` keyword.

```
($stdout, $stderr, $count) = capture {
  my @list = qw/one two three/;
  return scalar @list; # $count will be 3
};
```

Also note that within the coderef, the `@_` variable will be empty. So don't use arguments from a surrounding subroutine without copying them to an array first:

```
sub wont_work {
  my ($stdout, $stderr) = capture { do_stuff( @_ ) };    # WRONG
  ...
}

sub will_work {
  my @args = @_;
  my ($stdout, $stderr) = capture { do_stuff( @args ) }; # RIGHT
  ...
}
```

Captures are normally done to an anonymous temporary filehandle. To capture via a named file (e.g. to externally monitor a long-running capture), provide custom filehandles as a trailing list of option pairs:

```
my $out_fh = IO::File->new("out.txt", "w+");
my $err_fh = IO::File->new("err.txt", "w+");
capture { ... } stdout => $out_fh, stderr => $err_fh;
```

The filehandles must be read/write and seekable. Modifying the files or filehandles during a capture operation will give unpredictable results. Existing IO layers on them may be changed by the capture.

When called in void context, `capture` saves memory and time by not reading back from the capture handles.

capture_stdout

```
($stdout, @result) = capture_stdout \&code;
$stdout = capture_stdout \&code;
```

The `capture_stdout` function works just like `capture` except only STDOUT is captured. STDERR is not captured.

capture_stderr

```
($stderr, @result) = capture_stderr \&code;
$stderr = capture_stderr \&code;
```

The `capture_stderr` function works just like `capture` except only STDERR is captured. STDOUT is not captured.

capture_merged

```
($merged, @result) = capture_merged \&code;
$merged = capture_merged \&code;
```

The `capture_merged` function works just like `capture` except STDOUT and STDERR are merged. (Technically, STDERR is redirected to the same capturing handle as STDOUT before executing the function.)

Caution: STDOUT and STDERR output in the merged result are not guaranteed to be properly ordered due to buffering.

tee

```
($stdout, $stderr, @result) = tee \&code;
$stdout = tee \&code;
```

The `tee` function works just like `capture`, except that output is captured as well as passed on to the original STDOUT and STDERR.

When called in void context, `tee` saves memory and time by not reading back from the capture handles, except when the original STDOUT or STDERR were tied or opened to a scalar handle.

tee_stdout

```
($stdout, @result) = tee_stdout \&code;
$stdout = tee_stdout \&code;
```

The `tee_stdout` function works just like `tee` except only STDOUT is teed. STDERR is not teed (output goes to STDERR as usual).

tee_stderr

```
($stderr, @result) = tee_stderr \&code;
$stderr = tee_stderr \&code;
```

The `tee_stderr` function works just like `tee` except only STDERR is teed. STDOUT is not teed (output goes to STDOUT as usual).

tee_merged

```
($merged, @result) = tee_merged \&code;
$merged = tee_merged \&code;
```

The `tee_merged` function works just like `capture_merged` except that output is captured as well as passed on to STDOUT.

Caution: STDOUT and STDERR output in the merged result are not guaranteed to be properly ordered due to buffering.

LIMITATIONS

Portability

Portability is a goal, not a guarantee. `tee` requires fork, except on Windows where `system(1, @cmd)` is used instead. Not tested on any particularly esoteric platforms yet. See the CPAN Testers Matrix for test result by platform.

PerlIO layers

Capture::Tiny does its best to preserve PerlIO layers such as ':utf8' or ':crlf' when capturing (only for Perl 5.8.1+) . Layers should be applied to STDOUT or STDERR *before* the call to `capture` or `tee`. This may not work for tied filehandles (see below).

Modifying filehandles before capturing

Generally speaking, you should do little or no manipulation of the standard IO filehandles prior to using Capture::Tiny. In particular, closing, reopening, localizing or tying standard filehandles prior to capture may cause a variety of unexpected, undesirable and/or unreliable behaviors, as described below. Capture::Tiny does its best to compensate for these situations, but the results may not be what you desire.

Closed filehandles

Capture::Tiny will work even if STDIN, STDOUT or STDERR have been previously closed. However, since they will be reopened to capture or tee output, any code within the captured block that depends on finding them closed will, of course, not find them to be closed. If they started closed, Capture::Tiny will close them again when the capture block finishes.

Note that this reopening will happen even for STDIN or a filehandle not being captured to ensure that the filehandle used for capture is not opened to file descriptor 0, as this causes problems on various platforms.

Prior to Perl 5.12, closed STDIN combined with PERL_UNICODE=D leaks filehandles and also breaks tee() for undiagnosed reasons. So don't do that.

Localized filehandles

If code localizes any of Perl's standard filehandles before capturing, the capture will affect the localized filehandles and not the original ones. External system calls are not affected by localizing a filehandle in Perl and will continue to send output to the original filehandles (which will thus not be captured).

Scalar filehandles

If STDOUT or STDERR are reopened to scalar filehandles prior to the call to `capture` or `tee`, then Capture::Tiny will override the output filehandle for the duration of the `capture` or `tee` call and then, for `tee`, send captured output to the output filehandle after the capture is complete. (Requires Perl 5.8)

Capture::Tiny attempts to preserve the semantics of STDIN opened to a scalar reference, but note that external processes will not be able to read from such a handle. Capture::Tiny tries to ensure that external processes will read from the null device instead, but this is not guaranteed.

Tied output filehandles

If STDOUT or STDERR are tied prior to the call to `capture` or `tee`, then Capture::Tiny will attempt to override the tie for the duration of the `capture` or `tee` call and then send captured output to the tied filehandle after the capture is complete. (Requires Perl 5.8)

Capture::Tiny may not succeed resending UTF-8 encoded data to a tied STDOUT or STDERR filehandle. Characters may appear as bytes. If the tied filehandle is based on *Tie::StdHandle*, then Capture::Tiny will attempt to determine appropriate layers like `:utf8` from the underlying filehandle and do the right thing.

Tied input filehandle

Capture::Tiny attempts to preserve the semantics of tied STDIN, but this requires Perl 5.8 and is not entirely predictable. External processes will not be able to read from such a handle.

Unless having STDIN tied is crucial, it may be safest to localize STDIN when capturing:

```
my ($out, $err) = do { local *STDIN; capture { ... } };
```

Modifying filehandles during a capture

Attempting to modify STDIN, STDOUT or STDERR *during* `capture` or `tee` is almost certainly going to cause problems. Don't do that.

Forking inside a capture

Forks aren't portable. The behavior of filehandles during a fork is even less so. If Capture::Tiny detects that a fork has occurred within a capture, it will shortcut in the child process and return empty strings for captures. Other problems may occur in the child or parent, as well. Forking in a capture block is not recommended.

Using threads

Filehandles are global. Mixing up I/O and captures in different threads without coordination is going to cause problems. Besides, threads are officially discouraged.

Dropping privileges during a capture

If you drop privileges during a capture, temporary files created to facilitate the capture may not be cleaned up afterwards.

No support for Perl 5.8.0

It's just too buggy when it comes to layers and UTF-8. Perl 5.8.1 or later is recommended.

Limited support for Perl 5.6

Perl 5.6 predates PerlIO. UTF-8 data may not be captured correctly.

ENVIRONMENT

PERL_CAPTURE_TINY_TIMEOUT

Capture::Tiny uses subprocesses internally for `tee`. By default, Capture::Tiny will timeout with an error if such subprocesses are not ready to receive data within 30 seconds (or whatever is the value of `$Capture::Tiny::TIMEOUT`). An alternate timeout may be specified by setting the `PERL_CAPTURE_TINY_TIMEOUT` environment variable. Setting it to zero will disable timeouts. **NOTE**, this does not timeout the code reference being captured – this only prevents Capture::Tiny itself from hanging your process waiting for its child processes to be ready to proceed.

SEE ALSO

This module was inspired by IO::CaptureOutput, which provides similar functionality without the ability to tee output and with more complicated code and API. IO::CaptureOutput does not handle layers or most of the unusual cases described in the "LIMITATIONS" section and I no longer recommend it.

There are many other CPAN modules that provide some sort of output capture, albeit with various limitations that make them appropriate only in particular circumstances. I'm probably missing some. The long list is provided to show why I felt Capture::Tiny was necessary.

- IO::Capture
- IO::Capture::Extended
- IO::CaptureOutput
- IPC::Capture
- *IPC::Cmd*
- *IPC::Open2*
- *IPC::Open3*

- IPC::Open3::Simple
- IPC::Open3::Utils
- IPC::Run
- IPC::Run::SafeHandles
- IPC::Run::Simple
- IPC::Run3
- IPC::System::Simple
- Tee
- IO::Tee
- File::Tee
- Filter::Handle
- Tie::STDERR
- Tie::STDOUT
- Test::Output

5.2.14 Carp

alternative warn and die for modules

SYNOPSIS

```
use Carp;

# warn user (from perspective of caller)
carp "string trimmed to 80 chars";

# die of errors (from perspective of caller)
croak "We're outta here!";

# die of errors with stack backtrace
confess "not implemented";

# cluck, longmess and shortmess not exported by default
use Carp qw(cluck longmess shortmess);
cluck "This is how we got here!"; # warn with stack backtrace
my $long_message   = longmess( "message from cluck() or confess()"
 ↪);
my $short_message  = shortmess( "message from carp() or croak()" );
```

DESCRIPTION

The Carp routines are useful in your own modules because they act like `die()` or `warn()`, but with a message which is more likely to be useful to a user of your module. In the case of `cluck()` and `confess()`, that context is a summary of every call in the call-stack; `longmess()` returns the contents of the error message.

For a shorter message you can use `carp()` or `croak()` which report the error as being from where your module was called. `shortmess()` returns the contents of this error message. There is no guarantee that that is where the error was, but it is a good educated guess.

Carp takes care not to clobber the status variables $! and $^E in the course of assembling its error messages. This means that a $SIG{__DIE__} or $SIG{__WARN__} handler can capture the error information held in those variables, if it is required to augment the error message, and if the code calling Carp left useful values there. Of course, Carp can't guarantee the latter.

You can also alter the way the output and logic of Carp works, by changing some global variables in the Carp namespace. See the section on "GLOBAL VARIABLES" below.

Here is a more complete description of how carp and croak work. What they do is search the call-stack for a function call stack where they have not been told that there shouldn't be an error. If every call is marked safe, they give up and give a full stack backtrace instead. In other words they presume that the first likely looking potential suspect is guilty. Their rules for telling whether a call shouldn't generate errors work as follows:

1. Any call from a package to itself is safe.
2. Packages claim that there won't be errors on calls to or from packages explicitly marked as safe by inclusion in @CARP_NOT, or (if that array is empty) @ISA. The ability to override what @ISA says is new in 5.8.
3. The trust in item 2 is transitive. If A trusts B, and B trusts C, then A trusts C. So if you do not override @ISA with @CARP_NOT, then this trust relationship is identical to, "inherits from".
4. Any call from an internal Perl module is safe. (Nothing keeps user modules from marking themselves as internal to Perl, but this practice is discouraged.)
5. Any call to Perl's warning system (eg Carp itself) is safe. (This rule is what keeps it from reporting the error at the point where you call carp or croak.)
6. $Carp::CarpLevel can be set to skip a fixed number of additional call levels. Using this is not recommended because it is very difficult to get it to behave correctly.

Forcing a Stack Trace

As a debugging aid, you can force Carp to treat a croak as a confess and a carp as a cluck across *all* modules. In other words, force a detailed stack trace to be given. This can be very helpful when trying to understand why, or from where, a warning or error is being generated.

This feature is enabled by 'importing' the non-existent symbol 'verbose'. You would typically enable it by saying

```
perl -MCarp=verbose script.pl
```

or by including the string -MCarp=verbose in the PERL5OPT environment variable.

Alternately, you can set the global variable $Carp::Verbose to true. See the "GLOBAL VARIABLES" section below.

Stack Trace formatting

At each stack level, the subroutine's name is displayed along with its parameters. For simple scalars, this is sufficient. For complex data types, such as objects and other references, this can simply display `'HASH(0x1ab36d8)'`.

Carp gives two ways to control this.

1. For objects, a method, `CARP_TRACE`, will be called, if it exists. If this method doesn't exist, or it recurses into `Carp`, or it otherwise throws an exception, this is skipped, and Carp moves on to the next option, otherwise checking stops and the string returned is used. It is recommended that the object's type is part of the string to make debugging easier.
2. For any type of reference, `$Carp::RefArgFormatter` is checked (see below). This variable is expected to be a code reference, and the current parameter is passed in. If this function doesn't exist (the variable is undef), or it recurses into `Carp`, or it otherwise throws an exception, this is skipped, and Carp moves on to the next option, otherwise checking stops and the string returned is used.
3. Otherwise, if neither `CARP_TRACE` nor `$Carp::RefArgFormatter` is available, stringify the value ignoring any overloading.

GLOBAL VARIABLES

$Carp::MaxEvalLen

This variable determines how many characters of a string-eval are to be shown in the output. Use a value of `0` to show all text.

Defaults to `0`.

$Carp::MaxArgLen

This variable determines how many characters of each argument to a function to print. Use a value of `0` to show the full length of the argument.

Defaults to `64`.

$Carp::MaxArgNums

This variable determines how many arguments to each function to show. Use a false value to show all arguments to a function call. To suppress all arguments, use `-1` or `'0 but true'`.

Defaults to `8`.

$Carp::Verbose

This variable makes `carp()` and `croak()` generate stack backtraces just like `cluck()` and `confess()`. This is how `use Carp 'verbose'` is implemented internally.

Defaults to `0`.

$Carp::RefArgFormatter

This variable sets a general argument formatter to display references. Plain scalars and objects that implement CARP_TRACE will not go through this formatter. Calling Carp from within this function is not supported.

```
local $Carp::RefArgFormatter = sub {
    require Data::Dumper;
    Data::Dumper->Dump($_[0]); # not necessarily safe
};
```

@CARP_NOT

This variable, *in your package*, says which packages are *not* to be considered as the location of an error. The carp() and cluck() functions will skip over callers when reporting where an error occurred.

NB: This variable must be in the package's symbol table, thus:

```
# These work
our @CARP_NOT; # file scope
use vars qw(@CARP_NOT); # package scope
@My::Package::CARP_NOT = ... ; # explicit package variable

# These don't work
sub xyz { ... @CARP_NOT = ... } # w/o declarations above
my @CARP_NOT; # even at top-level
```

Example of use:

```
package My::Carping::Package;
use Carp;
our @CARP_NOT;
sub bar     { .... or _error('Wrong input') }
sub _error  {
    # temporary control of where'ness, __PACKAGE__ is implicit
    local @CARP_NOT = qw(My::Friendly::Caller);
    carp(@_)
}
```

This would make Carp report the error as coming from a caller not in My::Carping::Package, nor from My::Friendly::Caller.

Also read the "DESCRIPTION" section above, about how Carp decides where the error is reported from.

Use @CARP_NOT, instead of $Carp::CarpLevel.

Overrides Carp's use of @ISA.

%Carp::Internal

This says what packages are internal to Perl. `Carp` will never report an error as being from a line in a package that is internal to Perl. For example:

```
$Carp::Internal{ (__PACKAGE__) }++;
# time passes...
sub foo { ... or confess("whatever") };
```

would give a full stack backtrace starting from the first caller outside of __PACKAGE__. (Unless that package was also internal to Perl.)

%Carp::CarpInternal

This says which packages are internal to Perl's warning system. For generating a full stack backtrace this is the same as being internal to Perl, the stack backtrace will not start inside packages that are listed in `%Carp::CarpInternal`. But it is slightly different for the summary message generated by `carp` or `croak`. There errors will not be reported on any lines that are calling packages in `%Carp::CarpInternal`.

For example `Carp` itself is listed in `%Carp::CarpInternal`. Therefore the full stack backtrace from `confess` will not start inside of `Carp`, and the short message from calling `croak` is not placed on the line where `croak` was called.

$Carp::CarpLevel

This variable determines how many additional call frames are to be skipped that would not otherwise be when reporting where an error occurred on a call to one of `Carp`'s functions. It is fairly easy to count these call frames on calls that generate a full stack backtrace. However it is much harder to do this accounting for calls that generate a short message. Usually people skip too many call frames. If they are lucky they skip enough that `Carp` goes all of the way through the call stack, realizes that something is wrong, and then generates a full stack backtrace. If they are unlucky then the error is reported from somewhere misleading very high in the call stack.

Therefore it is best to avoid `$Carp::CarpLevel`. Instead use `@CARP_NOT`, `%Carp::Internal` and `%Carp::CarpInternal`.

Defaults to `0`.

BUGS

The Carp routines don't handle exception objects currently. If called with a first argument that is a reference, they simply call die() or warn(), as appropriate.

SEE ALSO

Carp::Always, Carp::Clan

CONTRIBUTING

Carp is maintained by the perl 5 porters as part of the core perl 5 version control repository. Please see the perlhack perldoc for how to submit patches and contribute to it.

AUTHOR

The Carp module first appeared in Larry Wall's perl 5.000 distribution. Since then it has been modified by several of the perl 5 porters. Andrew Main (Zefram) zefram@fysh.org divested Carp into an independent distribution.

5.2.15 Class

Namespace containing the following modules:

- `Class::Inspector` - Get information about a class and its structure
- `Class::Load`
- `Class::MOP`
- `Class::Struct` - declare struct-like datatypes as Perl classes
- `Class::XSAccessor` - fast accessors, getters, setters, predicates and

Class::Inspector

Get information about a class and its structure

VERSION

version 1.36

SYNOPSIS

```
use Class::Inspector;

# Is a class installed and/or loaded
Class::Inspector->installed( 'Foo::Class' );
Class::Inspector->loaded( 'Foo::Class' );

# Filename related information
```

(continues on next page)

(continued from previous page)

```
Class::Inspector->filename( 'Foo::Class' );
Class::Inspector->resolved_filename( 'Foo::Class' );

# Get subroutine related information
Class::Inspector->functions( 'Foo::Class' );
Class::Inspector->function_refs( 'Foo::Class' );
Class::Inspector->function_exists( 'Foo::Class', 'bar' );
Class::Inspector->methods( 'Foo::Class', 'full', 'public' );

# Find all loaded subclasses or something
Class::Inspector->subclasses( 'Foo::Class' );
```

DESCRIPTION

Class::Inspector allows you to get information about a loaded class. Most or all of this information can be found in other ways, but they aren't always very friendly, and usually involve a relatively high level of Perl wizardry, or strange and unusual looking code. Class::Inspector attempts to provide an easier, more friendly interface to this information.

METHODS

installed

```
my $bool = Class::Inspector->installed($class);
```

The `installed` static method tries to determine if a class is installed on the machine, or at least available to Perl. It does this by wrapping around `resolved_filename`.

Returns true if installed/available, false if the class is not installed, or `undef` if the class name is invalid.

loaded

```
my $bool = Class::Inspector->loaded($class);
```

The `loaded` static method tries to determine if a class is loaded by looking for symbol table entries.

This method it uses to determine this will work even if the class does not have its own file, but is contained inside a single file with multiple classes in it. Even in the case of some sort of run-time loading class being used, these typically leave some trace in the symbol table, so an Autoload or Class::Autouse-based class should correctly appear loaded.

Returns true if the class is loaded, false if not, or `undef` if the class name is invalid.

filename

```
my $filename = Class::Inspector->filename($class);
```

For a given class, returns the base filename for the class. This will NOT be a fully resolved filename, just the part of the filename BELOW the `@INC` entry.

```
print Class->filename( 'Foo::Bar' );
> Foo/Bar.pm
```

This filename will be returned with the right separator for the local platform, and should work on all platforms.

Returns the filename on success or `undef` if the class name is invalid.

resolved_filename

```
my $filename = Class::Inspector->resolved_filename($class);
my $filename = Class::Inspector->resolved_filename($class, @try_
↪first);
```

For a given class, the `resolved_filename` static method returns the fully resolved filename for a class. That is, the file that the class would be loaded from.

This is not necessarily the file that the class WAS loaded from, as the value returned is determined each time it runs, and the `@INC` include path may change.

To get the actual file for a loaded class, see the `loaded_filename` method.

Returns the filename for the class, or `undef` if the class name is invalid.

loaded_filename

```
my $filename = Class::Inspector->loaded_filename($class);
```

For a given loaded class, the `loaded_filename` static method determines (via the `%INC` hash) the name of the file that it was originally loaded from.

Returns a resolved file path, or false if the class did not have it's own file.

functions

```
my $arrayref = Class::Inspector->functions($class);
```

For a loaded class, the `functions` static method returns a list of the names of all the functions in the classes immediate namespace.

Note that this is not the METHODS of the class, just the functions.

Returns a reference to an array of the function names on success, or `undef` if the class name is invalid or the class is not loaded.

function_refs

```
my $arrayref = Class::Inspector->function_refs($class);
```

For a loaded class, the `function_refs` static method returns references to all the functions in the classes immediate namespace.

Note that this is not the METHODS of the class, just the functions.

Returns a reference to an array of `CODE` refs of the functions on success, or `undef` if the class is not loaded.

function_exists

```
my $bool = Class::Inspector->function_exists($class, $functon);
```

Given a class and function name the `function_exists` static method will check to see if the function exists in the class.

Note that this is as a function, not as a method. To see if a method exists for a class, use the `can` method for any class or object.

Returns true if the function exists, false if not, or `undef` if the class or function name are invalid, or the class is not loaded.

methods

```
my $arrayref = Class::Inspector->methods($class, @options);
```

For a given class name, the `methods` static method will returns ALL the methods available to that class. This includes all methods available from every class up the class' `@ISA` tree.

Returns a reference to an array of the names of all the available methods on success, or `undef` if the class name is invalid or the class is not loaded.

A number of options are available to the `methods` method that will alter the results returned. These should be listed after the class name, in any order.

```
# Only get public methods
my $method = Class::Inspector->methods( 'My::Class', 'public' );
```

- public

  The `public` option will return only 'public' methods, as defined by the Perl convention of prepending an underscore to any 'private' methods. The `public` option will effectively remove any methods that start with an underscore.

- private

  The `private` options will return only 'private' methods, as defined by the Perl convention of prepending an underscore to an private methods. The `private` option will effectively remove an method that do not start with an underscore.

  Note: The `public` and `private` options are mutually exclusive

- full

  `methods` normally returns just the method name. Supplying the `full` option will cause the methods to be returned as the full names. That is, instead of returning `[ 'method1', 'method2', 'method3' ]`, you would instead get `[ 'Class::method1', 'AnotherClass::method2', 'Class::method3' ]`.

- expanded

  The `expanded` option will cause a lot more information about method to be returned. Instead of just the method name, you will instead get an array reference containing the method name as a single combined name, a la `full`, the separate class and method, and a CODE ref to the actual function (if available). Please note that the function reference is not guaranteed to be available. `Class::Inspector` is intended at some later time, to work with modules that have some kind of common run-time loader in place (e.g `Autoloader` or `Class::Autouse` for example.

  The response from `methods( 'Class', 'expanded' )` would look something like the following.

```
[
  [ 'Class::method1',   'Class',   'method1', \&Class::method1 ],
  [ 'Another::method2', 'Another', 'method2', \&Another::method2 ],
  [ 'Foo::bar',         'Foo',     'bar',     \&Foo::bar ],
]
```

subclasses

```
my $arrayref = Class::Inspector->subclasses($class);
```

The `subclasses` static method will search then entire namespace (and thus **all** currently loaded classes) to find all classes that are subclasses of the class provided as a the parameter.

The actual test will be done by calling `isa` on the class as a static method. (i.e. `My::Class->isa($class)`.

Returns a reference to a list of the loaded classes that match the class provided, or false is none match, or `undef` if the class name provided is invalid.

Class::Inspector::Functions

Get information about a class and its structure

VERSION

version 1.36

SYNOPSIS

```
use Class::Inspector::Functions;
# Class::Inspector provides a non-polluting,
# method based interface!

# Is a class installed and/or loaded
installed( 'Foo::Class' );
loaded( 'Foo::Class' );

# Filename related information
filename( 'Foo::Class' );
resolved_filename( 'Foo::Class' );

# Get subroutine related information
functions( 'Foo::Class' );
function_refs( 'Foo::Class' );
function_exists( 'Foo::Class', 'bar' );
methods( 'Foo::Class', 'full', 'public' );

# Find all loaded subclasses or something
subclasses( 'Foo::Class' );
```

DESCRIPTION

Class::Inspector::Functions is a function based interface of *Class::Inspector*. For a thorough documentation of the available functions, please check the manual for the main module.

Exports

The following functions are exported by default.

```
installed
loaded
filename
functions
methods
subclasses
```

The following functions are exported only by request.

```
resolved_filename
loaded_filename
function_refs
function_exists
```

All the functions may be imported using the `:ALL` tag.

Class::Load

Namespace containing the following modules:

- `Class::Load::XS` - The compiled `is_class_loaded` of Class::Load: whether a package has been loaded, judged from its symbol table.

Class::Load::XS

The compiled `is_class_loaded` of Class::Load: whether a package has been loaded, judged from its symbol table.

A package counts as loaded when it has a `$VERSION` (a version object, a reference to a defined value, or any defined value), a non-empty `@ISA`, or at least one sub, constant or stub. With `{ -version => $v }` it counts only when `$class->VERSION($v)` does not die. Class::Load calls this in place of its pure-Perl version; it is not normally called directly.

This is a native implementation of Class::Load::XS 0.10's `XS.xs`; its `Class/Load/XS.pm` is used unchanged, and Class::Load itself comes from CPAN.

Synopsis

```
use Class::Load qw(is_class_loaded);   # takes this one when it can

print is_class_loaded('Some::Class') ? "loaded\n" : "not loaded\n";
print is_class_loaded('Some::Class', { -version => '1.2' }) ? "1.2␣
 ↪or later\n" : "older, or not loaded\n";
```

Differences from upstream

None.

Functions

Class::Load

is_class_loaded

Whether a package is loaded: it has a `$VERSION`, a non-empty `@ISA` or a sub; with `{ -version => $v }`, whether `$class->VERSION($v)` succeeds.

is_class_loaded

Whether a package is loaded: it has a `$VERSION`, a non-empty `@ISA` or a sub; with `{ -version => $v }`, whether `$class->VERSION($v)` succeeds.

Synopsis

```
Class::Load::XS::is_class_loaded('Foo');                    # true␣
↪or false
Class::Load::XS::is_class_loaded('Foo', { -version => 2 });  # Foo 2␣
↪or later, loaded
```

Edge cases

- An empty or non-string class name is not loaded.
- A second argument that is not a hash reference dies "Class::Load::XS::is_class_loaded: options is not a HASH reference".

Class::MOP

Modules

- `Class::MOP::Method`

Functions

Moose

`get_code_info`

The package and the name a sub was defined under.

Class::MOP::Method

Functions

Moose

`is_stub`

Whether a method is only declared: `sub foo;`, or a sub that was referred to but never defined.

is_stub

Whether a method is only declared: `sub foo;`, or a sub that was referred to but never defined.

Synopsis

```
my $method = Class::MOP::Class->initialize('Foo')->get_method('bar
↪');
print $method->is_stub ? "declared only\n" : "defined\n";
```

What you get back

True when the method's body has neither Perl code nor compiled code behind it, false otherwise. Dies when the method's body is not a code reference.

get_code_info

The package and the name a sub was defined under.

Synopsis

```
use Class::MOP;
my ($package, $name) = Class::MOP::get_code_info(\&Foo::bar);  # (
↪'Foo', 'bar')
```

What you get back

The name of the package of the glob the sub was defined in, and the sub's own name in it: __ANON__ for an anonymous sub. Nothing for what is not a code reference, or for a sub that is still being compiled.

Class::Struct

declare struct-like datatypes as Perl classes

SYNOPSIS

```
use Class::Struct;
        # declare struct, based on array:
struct( CLASS_NAME => [ ELEMENT_NAME => ELEMENT_TYPE, ... ]);
        # declare struct, based on hash:
struct( CLASS_NAME => { ELEMENT_NAME => ELEMENT_TYPE, ... });

package CLASS_NAME;
use Class::Struct;
        # declare struct, based on array, implicit class name:
struct( ELEMENT_NAME => ELEMENT_TYPE, ... );

# Declare struct at compile time
use Class::Struct CLASS_NAME => [ELEMENT_NAME => ELEMENT_TYPE, ...];
use Class::Struct CLASS_NAME => {ELEMENT_NAME => ELEMENT_TYPE, ...};

# declare struct at compile time, based on array, implicit
# class name:
package CLASS_NAME;
use Class::Struct ELEMENT_NAME => ELEMENT_TYPE, ... ;

package Myobj;
use Class::Struct;
```

(continues on next page)

(continued from previous page)

```
        # declare struct with four types of elements:
struct( s => '$', a => '@', h => '%', c => 'My_Other_Class' );

my $obj = Myobj->new;               # constructor

                                  # scalar type accessor:
my $element_value = $obj->s;            # element value
$obj->s('new value');                   # assign to element

                                  # array type accessor:
my $ary_ref = $obj->a;                  # reference to whole array
my $ary_element_value = $obj->a(2);     # array element value
$obj->a(2, 'new value');              # assign to array element

                                  # hash type accessor:
my $hash_ref = $obj->h;                 # reference to whole hash
my $hash_element_value = $obj->h('x'); # hash element value
$obj->h('x', 'new value');            # assign to hash element

                                  # class type accessor:
my $element_value = $obj->c;            # object reference
$obj->c->method(...);                 # call method of object
$obj->c(new My_Other_Class);          # assign a new object
```

DESCRIPTION

`Class::Struct` exports a single function, `struct`. Given a list of element names and types, and optionally a class name, `struct` creates a Perl 5 class that implements a "struct-like" data structure.

The new class is given a constructor method, `new`, for creating struct objects.

Each element in the struct data has an accessor method, which is used to assign to the element and to fetch its value. The default accessor can be overridden by declaring a `sub` of the same name in the package. (See Example 2.)

Each element's type can be scalar, array, hash, or class.

The `struct()` function

The `struct` function has three forms of parameter-list.

```
struct( CLASS_NAME => [ ELEMENT_LIST ]);
struct( CLASS_NAME => { ELEMENT_LIST });
struct( ELEMENT_LIST );
```

The first and second forms explicitly identify the name of the class being created. The third form assumes the current package name as the class name.

An object of a class created by the first and third forms is based on an array, whereas an object of a class created by the second form is based on a hash. The array-based forms

will be somewhat faster and smaller; the hash-based forms are more flexible.

The class created by `struct` must not be a subclass of another class other than `UNIVERSAL`.

It can, however, be used as a superclass for other classes. To facilitate this, the generated constructor method uses a two-argument blessing. Furthermore, if the class is hash-based, the key of each element is prefixed with the class name (see *Perl Cookbook*, Recipe 13.12).

A function named `new` must not be explicitly defined in a class created by `struct`.

The *ELEMENT_LIST* has the form

```
NAME => TYPE, ...
```

Each name-type pair declares one element of the struct. Each element name will be defined as an accessor method unless a method by that name is explicitly defined; in the latter case, a warning is issued if the warning flag (**-w**) is set.

Class Creation at Compile Time

`Class::Struct` can create your class at compile time. The main reason for doing this is obvious, so your class acts like every other class in Perl. Creating your class at compile time will make the order of events similar to using any other class (or Perl module).

There is no significant speed gain between compile time and run time class creation, there is just a new, more standard order of events.

Element Types and Accessor Methods

The four element types – scalar, array, hash, and class – are represented by strings – `'$'`, `'@'`, `'%'`, and a class name – optionally preceded by a `'*'`.

The accessor method provided by `struct` for an element depends on the declared type of the element.

- Scalar (`'$'` or `'*$'`)

  The element is a scalar, and by default is initialized to `undef` (but see "Initializing with new").

  The accessor's argument, if any, is assigned to the element.

  If the element type is `'$'`, the value of the element (after assignment) is returned. If the element type is `'*$'`, a reference to the element is returned.

- Array (`'@'` or `'*@'`)

  The element is an array, initialized by default to `()`.

  With no argument, the accessor returns a reference to the element's whole array (whether or not the element was specified as `'@'` or `'*@'`).

  With one or two arguments, the first argument is an index specifying one element of the array; the second argument, if present, is assigned to the array element. If the element type is `'@'`, the accessor returns the array element value. If the element type is `'*@'`, a reference to the array element is returned.

As a special case, when the accessor is called with an array reference as the sole argument, this causes an assignment of the whole array element. The object reference is returned.

- Hash (`'%'` or `'*%'`)

  The element is a hash, initialized by default to `()`.

  With no argument, the accessor returns a reference to the element's whole hash (whether or not the element was specified as `'%'` or `'*%'`).

  With one or two arguments, the first argument is a key specifying one element of the hash; the second argument, if present, is assigned to the hash element. If the element type is `'%'`, the accessor returns the hash element value. If the element type is `'*%'`, a reference to the hash element is returned.

  As a special case, when the accessor is called with a hash reference as the sole argument, this causes an assignment of the whole hash element. The object reference is returned.

- Class (`'Class_Name'` or `'*Class_Name'`)

  The element's value must be a reference blessed to the named class or to one of its subclasses. The element is not initialized by default.

  The accessor's argument, if any, is assigned to the element. The accessor will `croak` if this is not an appropriate object reference.

  If the element type does not start with a `'*'`, the accessor returns the element value (after assignment). If the element type starts with a `'*'`, a reference to the element itself is returned.

Initializing with new

`struct` always creates a constructor called `new`. That constructor may take a list of initializers for the various elements of the new struct.

Each initializer is a pair of values: *element name*=>*value*. The initializer value for a scalar element is just a scalar value. The initializer for an array element is an array reference. The initializer for a hash is a hash reference.

The initializer for a class element is an object of the corresponding class, or of one of it's subclasses, or a reference to a hash containing named arguments to be passed to the element's constructor.

See Example 3 below for an example of initialization.

EXAMPLES

- Example 1

  Giving a struct element a class type that is also a struct is how structs are nested. Here, `Timeval` represents a time (seconds and microseconds), and `Rusage` has two elements, each of which is of type `Timeval`.

```
use Class::Struct;

struct( Rusage => {
    ru_utime => 'Timeval',  # user time used
    ru_stime => 'Timeval',  # system time used
});

struct( Timeval => [
    tv_secs  => '$',        # seconds
    tv_usecs => '$',        # microseconds
]);

# create an object:
my $t = Rusage->new(ru_utime=>Timeval->new(),
    ru_stime=>Timeval->new());

# $t->ru_utime and $t->ru_stime are objects of type Timeval.
# set $t->ru_utime to 100.0 sec and $t->ru_stime to 5.0 sec.
$t->ru_utime->tv_secs(100);
$t->ru_utime->tv_usecs(0);
$t->ru_stime->tv_secs(5);
$t->ru_stime->tv_usecs(0);
```

- Example 2

  An accessor function can be redefined in order to provide additional checking of values, etc. Here, we want the `count` element always to be nonnegative, so we redefine the `count` accessor accordingly.

```
package MyObj;
use Class::Struct;

# declare the struct
struct ( 'MyObj', { count => '$', stuff => '%' } );

# override the default accessor method for 'count'
sub count {
    my $self = shift;
    if ( @_ ) {
        die 'count must be nonnegative' if $_[0] < 0;
        $self->{'MyObj::count'} = shift;
        warn "Too many args to count" if @_;
    }
    return $self->{'MyObj::count'};
}

package main;
$x = new MyObj;
print "\$x->count(5) = ", $x->count(5), "\n";
                         # prints '$x->count(5) = 5'
```

(continues on next page)

(continued from previous page)

```
print "\$x->count = ", $x->count, "\n";
                       # prints '$x->count = 5'

print "\$x->count(-5) = ", $x->count(-5), "\n";
                       # dies due to negative argument!
```

- Example 3

  The constructor of a generated class can be passed a list of *element=>value* pairs, with which to initialize the struct. If no initializer is specified for a particular element, its default initialization is performed instead. Initializers for non-existent elements are silently ignored.

  Note that the initializer for a nested class may be specified as an object of that class, or as a reference to a hash of initializers that are passed on to the nested struct's constructor.

```
use Class::Struct;

struct Breed =>
{
    name  => '$',
    cross => '$',
};

struct Cat =>
[
    name     => '$',
    kittens  => '@',
    markings => '%',
    breed    => 'Breed',
];

my $cat = Cat->new( name => 'Socks',
           kittens  => ['Monica', 'Kenneth'],
           markings => { socks=>1, blaze=>"white" },
           breed    => Breed->new(name=>'short-hair', cross=>1),
      or:  breed    => {name=>'short-hair', cross=>1},
                 );

print "Once a cat called ", $cat->name, "\n";
print "(which was a ", $cat->breed->name, ")\n";
print "had 2 kittens: ", join(' and ', @{$cat->kittens}), "\n";
```

Author and Modification History

Modified by Damian Conway, 2001-09-10, v0.62.

```
Modified implicit construction of nested objects.
Now will also take an object ref instead of requiring a hash ref.
Also default initializes nested object attributes to undef, rather
than calling object constructor without args
Original over-helpfulness was fraught with problems:
    * the class's constructor might not be called 'new'
    * the class might not have a hash-like-arguments constructor
    * the class might not have a no-argument constructor
    * "recursive" data structures didn't work well:
            package Person;
            struct { mother => 'Person', father => 'Person'};
```

Modified by Casey West, 2000-11-08, v0.59.

```
Added the ability for compile time class creation.
```

Modified by Damian Conway, 1999-03-05, v0.58.

```
Added handling of hash-like arg list to class ctor.

Changed to two-argument blessing in ctor to support
derivation from created classes.

Added classname prefixes to keys in hash-based classes
(refer to "Perl Cookbook", Recipe 13.12 for rationale).

Corrected behaviour of accessors for '*@' and '*%' struct
elements.  Package now implements documented behaviour when
returning a reference to an entire hash or array element.
Previously these were returned as a reference to a reference
to the element.
```

Renamed to `Class::Struct` and modified by Jim Miner, 1997-04-02.

```
members() function removed.
Documentation corrected and extended.
Use of struct() in a subclass prohibited.
User definition of accessor allowed.
Treatment of '*' in element types corrected.
Treatment of classes as element types corrected.
Class name to struct() made optional.
Diagnostic checks added.
```

Originally `Class::Template` by Dean Roehrich.

```
# Template.pm   --- struct/member template builder
#   12mar95
#   Dean Roehrich
#
# changes/bugs fixed since 28nov94 version:
#  - podified
```

(continues on next page)

(continued from previous page)

```
# changes/bugs fixed since 21nov94 version:
#  - Fixed examples.
# changes/bugs fixed since 02sep94 version:
#  - Moved to Class::Template.
# changes/bugs fixed since 20feb94 version:
#  - Updated to be a more proper module.
#  - Added "use strict".
#  - Bug in build_methods, was using @var when @$var needed.
#  - Now using my() rather than local().
#
# Uses perl5 classes to create nested data types.
# This is offered as one implementation of Tom Christiansen's
# "structs.pl" idea.
```

Class::XSAccessor

`Class::XSAccessor` - fast accessors, getters, setters, predicates and constructors for hash- and array-based objects, without compiling any Perl at runtime.

```
package MyClass;
use Class::XSAccessor
    constructor => 'new',
    accessors   => { name => 'name' },      # $obj->name / $obj->
↪name($v)
    getters     => { get_age => 'age' },
    setters     => { set_age => 'age' },
    predicates  => { has_age => 'age' },    # defined $obj->{age}
    chained     => 1;                       # setters return $self

package MyArrayClass;
use Class::XSAccessor::Array
    constructor => 'new',
    accessors   => { name => 0 };           # $obj->[0]
```

Every generated method is a compiled subroutine that reads or writes one slot of the object directly. Moo and other object systems use it automatically when it is installed, for their plain attribute accessors.

This is a native implementation of the CPAN distribution Class-XSAccessor 1.19; its `Class/XSAccessor.pm`, `Class/XSAccessor/Array.pm` and `Class/XSAccessor/Heavy.pm` are used unchanged. Like the XS original it rewrites a method call site the first time a generated accessor runs there, so later calls from that site skip the general subroutine-call machinery.

Modules

- `Class::XSAccessor::Array` - Generate fast native accessors without runtime compilation
- `Class::XSAccessor::Heavy` - Guts you don't care about

Functions

Other Functions

`getter`

`$obj->name`: the value of the object's key, or undef.

`lvalue_accessor`

`$obj->name = $value`: the slot itself, assignable.

`setter`

`$obj->set_name($value)`: stores a copy, returns the new value.

`chained_setter`

`$obj->set_name($value)` under `chained => 1`: returns the object.

`accessor`

`$obj->name` / `$obj->name($value)`: get, or set and return the new value.

`chained_accessor`

The accessor under `chained => 1`: setting returns the object.

`exists_predicate`

`$obj->has_name` from `exists_predicates`: whether the key exists.

`defined_predicate`

`$obj->has_name` from `predicates` / `defined_predicates`: whether the value is defined.

`constructor`

`MyClass->new(key => value, ...)`: a hash-based object holding copies of the pairs; an odd count dies.

`constant_false`

A method from `false => [...]`: always false.

constant_true

A method from `true => [...]`: always true.

newxs_defined_predicate

`newxs_getter(name, key)` and its ALIASes newxs_lvalue_accessor (1), newxs_predicate (2), newxs_defined_predicate (3), newxs_exists_predicate (4): install one read-side method.

Also available as `Class::XSAccessor::newxs_exists_predicate`, `Class::XSAccessor::newxs_getter`, `Class::XSAccessor::newxs_lvalue_accessor`, `Class::XSAccessor::newxs_predicate`.

newxs_accessor

`newxs_setter(name, key, chained)` and its ALIAS newxs_accessor (1).

Also available as `Class::XSAccessor::newxs_setter`.

newxs_constructor

`newxs_constructor(name)`.

newxs_boolean

`newxs_boolean(name, truth)`.

newxs_test

`newxs_test(name, key)`.

array_setter_init

`array_setter_init`: the compat setter that optimises its call site.

array_setter

`array_setter`: what an optimised compat setter call site calls.

array_accessor_init

`array_accessor_init`: the compat accessor that optimises its call site.

array_accessor

`array_accessor`: what an optimised compat accessor call site calls.

END

`Class::XSAccessor::END`: does nothing. Freeing the key table here is commented out upstream - accessors may still run after END blocks.

Class::XSAccessor::Array

Generate fast native accessors without runtime compilation

SYNOPSIS

```
package MyClassUsingArraysAsInternalStorage;
use Class::XSAccessor::Array
  constructor => 'new',
  getters => {
    get_foo => 0, # 0 is the array index to access
    get_bar => 1,
  },
  setters => {
    set_foo => 0,
    set_bar => 1,
  },
  accessors => { # a mutator
    buz => 2,
  },
  predicates => { # test for definedness
    has_buz => 2,
  },
  lvalue_accessors => { # see below
    baz => 3,
  },
  true => [ 'is_token', 'is_whitespace' ],
  false => [ 'significant' ];

# The imported methods are implemented natively.

# normal class code here.
```

As of version 1.05, some alternative syntax forms are available:

```
package MyClass;

# Options can be passed as a HASH reference if you prefer it,
# which can also help PerlTidy to flow the statement correctly.
use Class::XSAccessor {
  getters => {
    get_foo => 0,
    get_bar => 1,
  },
};
```

DESCRIPTION

The module implements fast native accessors both for getting at and setting an object attribute. Additionally, the module supports mutators and simple predicates (`has_foo()` like tests for definedness of an attributes). The module works only with objects that are implemented as **arrays**. Using it on hash-based objects is bound to make your life miserable. Refer to *Class::XSAccessor* for an implementation that works with hash-based objects.

A simple benchmark showed a significant performance advantage over writing accessors in Perl.

Since version 0.10, the module can also generate simple constructors (implemented natively) for you. Simply supply the `constructor => 'constructor_name'` option or the `constructors => ['new', 'create', 'spawn']` option. These constructors do the equivalent of the following Perl code:

```
sub new {
  my $class = shift;
  return bless [], ref($class)||$class;
}
```

That means they can be called on objects and classes but will not clone objects entirely. Note that any parameters to new() will be discarded! If there is a better idiom for array-based objects, let me know.

While generally more obscure than hash-based objects, objects using blessed arrays as internal representation are a bit faster as its somewhat faster to access arrays than hashes. Accordingly, this module is slightly faster (~10-15%) than *Class::XSAccessor*, which works on hash-based objects.

The method names may be fully qualified. In the example of the synopsis, you could have written `MyClass::get_foo` instead of `get_foo`. This way, you can install methods in classes other than the current class. See also: The `class` option below.

Since version 1.01, you can generate extremely simple methods which just return true or false (and always do so). If that seems like a really superfluous thing to you, then think of a large class hierarchy with interfaces such as PPI. This is implemented as the `true` and `false` options, see synopsis.

OPTIONS

In addition to specifying the types and names of accessors, you can add options which modify behaviour. The options are specified as key/value pairs just as the accessor declaration. Example:

```
use Class::XSAccessor::Array
  getters => {
    get_foo => 0,
  },
  replace => 1;
```

The list of available options is:

replace

Set this to a true value to prevent `Class::XSAccessor::Array` from complaining about replacing existing subroutines.

chained

Set this to a true value to change the return value of setters and mutators (when called with an argument). If `chained` is enabled, the setters and accessors/mutators will return the object. Mutators called without an argument still return the value of the associated attribute.

As with the other options, `chained` affects all methods generated in the same `use Class::XSAccessor::Array ...` statement.

class

By default, the accessors are generated in the calling class. Using the `class` option, you can explicitly specify where the methods are to be generated.

LVALUES

Support for lvalue accessors via the keyword `lvalue_accessors` was added in version 1.08. At this point, **THEY ARE CONSIDERED HIGHLY EXPERIMENTAL**. Furthermore, their performance hasn't been benchmarked yet.

The following example demonstrates an lvalue accessor:

```
package Address;
use Class::XSAccessor
  constructor => 'new',
  lvalue_accessors => { zip_code => 0 };

package main;
my $address = Address->new(2);
print $address->zip_code, "\n"; # prints 2
$address->zip_code = 76135; # <--- This is it!
print $address->zip_code, "\n"; # prints 76135
```

CAVEATS

Probably wouldn't work if your objects are *tied*. But that's a strange thing to do anyway.

Note that compiling C code at run-time a la Inline::C is a no go.

Threading. With version 1.00, a memory leak has been **fixed** that would leak a small amount of memory if you loaded `Class::XSAccessor`-based classes in a subthread that hadn't been loaded in the "main" thread before. If the subthread then terminated, a hash key and an int per associated method used to be lost. Note that this mattered only if classes were **only** loaded in a sort of throw-away thread.

In the new implementation as of 1.00, the memory will not be released again either in the above situation. But it will be recycled when the same class or a similar class is

loaded again in **any** thread.

Functions

Other Functions

`getter`

Array `$obj->name`: element `index`, or undef.

`lvalue_accessor`

Array `$obj->name = $value`.

`setter`

Array `$obj->set_name($value)`: returns the new value.

`chained_setter`

Array setter under `chained => 1`: returns the object.

`accessor`

Array `$obj->name` / `$obj->name($value)`.

`chained_accessor`

Array accessor under `chained => 1`.

predicate

Array `$obj->has_name`: whether element `index` is defined.

constructor

Array `MyClass->new`: an empty array-based object; arguments are ignored.

newxs_getter

Array `newxs_getter(name, index)` and its ALIASes newxs_lvalue_accessor (1), newxs_predicate (2).

Also available as `Class::XSAccessor::Array::newxs_lvalue_accessor`, `Class::XSAccessor::Array::newxs_predicate`.

newxs_accessor

Array `newxs_setter(name, index, chained)` and its ALIAS newxs_accessor (1).

Also available as `Class::XSAccessor::Array::newxs_setter`.

newxs_constructor

Array `newxs_constructor(name)`.

This library is free software; you can redistribute it and/or modify it under the same terms as Perl itself, either Perl version 5.8 or, at your option, any later version of Perl 5 you may have available.

5.2.16 Clone

Make a deep, independent copy of any Perl value - hashes, arrays, scalars, references, blessed objects, tied variables, and weak references.

`clone` walks a data structure recursively and returns a fresh copy. Shared references inside the input become shared references inside the copy (no accidental duplication), circular structures are reproduced without infinite recursion, weak references come out still weak, and tied variables keep their tie. Modifying the clone never touches the original.

For pure-Perl deep copies, `Clone` is typically faster than `Storable::dclone` on shallow to medium-depth structures (roughly three levels or fewer).

Synopsis

```
use Clone qw(clone);

my $copy = clone($original);       # function form

package Foo;
use parent 'Clone';
my $other = $obj->clone;           # method form (inherited)
```

`clone($data, $depth)` copies only `$depth` levels and shares what lies below. This is a native implementation of Clone 0.50; its `Clone.pm` is used unchanged, and nothing is exported by default.

Differences from upstream

None.

Functions

Cloning

clone

Return a deep, independent copy of a Perl value.

clone

Return a deep, independent copy of a Perl value.

Synopsis

```
use Clone qw(clone);

my $copy = clone($thing);          # function form
my $copy = clone($thing, 5);       # limit recursion depth
my $copy = $obj->clone;            # method form (class inherits
 ↪from Clone)
```

What you get back

A value of the same kind as the input. The copy is fully independent: assigning into `$copy` - at any nesting level - never changes `$thing`.

- Shared references inside the input are de-duplicated: if two slots pointed at the same referent, the corresponding two slots in the copy point at *one* fresh clone of that referent, not two separate clones.
- Circular structures are reproduced with their cycles intact.
- Weak references (see `Scalar::Util::weaken`) come out weak in the copy.
- Tied variables keep their tie; the tie's internal object is itself cloned.
- Blessed objects are reblessed into the same package as the original.

Examples

Basic hash clone - the copy is independent:

```
use Clone qw(clone);
my $h = { name => 'Alice', tags => [qw(admin user)] };
my $c = clone($h);
push @{ $c->{tags} }, 'guest';
print "@{ $h->{tags} }\n";         # admin user
print "@{ $c->{tags} }\n";         # admin user guest
```

Shared references stay shared inside the clone:

```
my $shared = { count => 0 };
my $pair   = { a => $shared, b => $shared };
my $copy   = clone($pair);
$copy->{a}{count} = 42;
print $copy->{b}{count};           # 42  (a and b still point at one
 ↪hash)
print $pair->{a}{count};           # 0   (original untouched)
```

Circular structures:

```
my $a = { name => 'A' };
my $b = { name => 'B', peer => $a };
$a->{peer} = $b;                    # cycle
my $copy = clone($a);
print $copy->{peer}{peer}{name};    # A  (cycle reproduced)
```

Edge cases

- `undef` clones to `undef`.
- A non-reference scalar (`42`, `"hi"`) clones by value - you get a fresh scalar with the same contents.
- Code references are shared, not duplicated: the clone points at the same sub.
- Filehandles and `IO` objects are cloned but share the underlying file descriptor and file position.
- The depth argument caps recursion. `clone($thing, 0)` returns `$thing` unchanged (refcount bump, no copy). A negative or omitted depth means "unlimited"; the runtime still guards against stack overflow by falling back to an iterative cloner once rdepth passes 4000.

Differences from upstream

Fully compatible with upstream `Clone` 0.50.

See also

- `Storable::dclone` - serializer-based deep copy; typically faster for structures 4+ levels deep, slower for shallow ones.
- `Scalar::Util::weaken` - create the weak references that `clone` preserves.
- `Clone::PP` - pure-Perl implementation of the same interface.

5.2.17 Compress

Namespace containing the following modules:

- `Compress::Raw`
- `Compress::Zlib` - Interface to zlib compression library

Compress::Raw

Namespace containing the following modules:

- `Compress::Raw::Bunzip2`
- `Compress::Raw::Bzip2` - Low-level interface to the `bzip2` compression library.
- `Compress::Raw::Zlib` - Low-level interface to the `zlib` compression library.

Compress::Raw::Bunzip2

Functions

Other Functions

new

`Compress::Raw::Bunzip2->new([$appendOut, $consume, $small, $verbosity, $limitOutput])`: a decompressor. In list context also the status, `BZ_OK` on success.

DispStream

`$bunz->DispStream([$message])`: prints the stream's state to stdout, for debugging.

bzinflate

`$bunz->bzinflate($input, $output)`: decompresses `$input` into `$output`, consuming the input it used when the object was made with `consume`. Returns `BZ_OK` while more input is needed, `BZ_STREAM_END` at the end of the stream.

inflateCount

`$bunz->inflateCount()`: bytes the last `bzinflate` produced.

status

`$bunz->status()`: the status the last call returned.

total_in_lo32

`$bunz->total_in_lo32()`: compressed bytes taken in so far (low 32 bits).

total_out_lo32

`$bunz->total_out_lo32()`: bytes put out so far (low 32 bits).

compressedBytes

`$bunz->compressedBytes()`: compressed bytes consumed so far.

uncompressedBytes

`$bunz->uncompressedBytes()`: uncompressed bytes produced so far.

Compress::Raw::Bzip2

Low-level interface to the bzip2 compression library.

`Compress::Raw::Bzip2` is the layer underneath `IO::Compress::Bzip2` and `IO::Uncompress::Bunzip2`, and what Archive::Tar uses for `.tbz` archives. It gives direct access to libbz2's streaming compressor (`Compress::Raw::Bzip2`) and decompressor (`Compress::Raw::Bunzip2`) and the `BZ_*` status constants. Most programs are better served by `IO::Compress::Bzip2` and friends; this module is for code that needs the streams themselves.

```
use Compress::Raw::Bzip2;

my $data = "hello, world\n" x 100;

# Compress: one bzdeflate call per chunk, bzclose at the end.
my ($bz, $status) = Compress::Raw::Bzip2->new(1, 9);   # append,␣
 ↪900k blocks
$status == BZ_OK or die "new: $status";
my $packed = '';
$bz->bzdeflate($data, $packed) == BZ_RUN_OK or die;
$bz->bzclose($packed) == BZ_STREAM_END or die;
printf "%d -> %d bytes\n", $bz->uncompressedBytes, $bz->
 ↪compressedBytes;
# 1300 -> 66 bytes

# Uncompress: bzinflate eats its input and says BZ_STREAM_END at the␣
 ↪end.
my $bunz = Compress::Raw::Bunzip2->new;
my $out = '';
$status = $bunz->bzinflate($packed, $out);
print "status: $status, round trip ", ($out eq $data ? "ok" : "BAD
 ↪"), "\n";
# status: End of Stream, round trip ok
```

Every status is a dualvar: numeric `BZ_*` and the message text, so `$status == BZ_STREAM_END` and `"$status"` both work. `bzdeflate`, `bzflush` and `bzclose` append to the output buffer when the object was made with `appendOut`; `bzinflate` consumes its input when made with `consume` and, with `limitOutput`, decompresses at most one buffer's worth per call.

This is a native implementation of the XS half of Compress::Raw::Bzip2 2.218; `Compress/Raw/Bzip2.pm` is upstream's own. libbz2 is the system's `libbz2.so.1`, loaded when the module is first used.

Differences from upstream

None.

Functions

Other Functions

bzlibversion

`Compress::Raw::Bzip2::bzlibversion()`: the version string of the libbz2 this process loaded, such as "1.0.8, 13-Jul-2019".

new

`Compress::Raw::Bzip2->new([$appendOut, $blockSize100k, $workfactor, $verbosity])`: a compressor. In list context also the status, `BZ_OK` on success.

DispStream

`$bz->DispStream([$message])`: prints the stream's state to stdout, for debugging.

bzdeflate

`$bz->bzdeflate($input, $output)`: compresses `$input`, appending to (or replacing, without appendOut) `$output`. Returns `BZ_RUN_OK` on success.

bzclose

`$bz->bzclose($output)`: ends the stream, writing what is pending and the end-of-stream marker into `$output`. Returns `BZ_STREAM_END`.

bzflush

`$bz->bzflush($output)`: writes what is pending into `$output` without ending the stream. Returns `BZ_RUN_OK`.

total_in_lo32

`$bz->total_in_lo32()`: bytes taken in so far (low 32 bits).

total_out_lo32

`$bz->total_out_lo32()`: bytes put out so far (low 32 bits).

compressedBytes

`$bz->compressedBytes()`: compressed bytes produced so far.

uncompressedBytes

`$bz->uncompressedBytes()`: uncompressed bytes taken in so far.

Compress::Raw::Zlib

Low-level interface to the `zlib` compression library.

`Compress::Raw::Zlib` is the layer underneath `Compress::Zlib` and the whole `IO::Compress::*` / `IO::Uncompress::*` family. It gives direct access to zlib's streaming compressor and decompressor, the `crc32` and `adler32` checksums, and the zlib constants. Most programs are better served by `IO::Compress::Gzip` and friends; this module is for code that needs the streams themselves.

```
use Compress::Raw::Zlib;

my $data = "hello, world\n" x 100;

# Compress: one deflate call per chunk, flush at the end.
my ($d, $status) = Compress::Raw::Zlib::Deflate->new(
    -Level => Z_BEST_COMPRESSION, -AppendOutput => 1, -CRC32 => 1);
$status == Z_OK or die "deflateInit: $status";
my $packed = '';
$d->deflate($data, $packed) == Z_OK or die $d->msg;
$d->flush($packed) == Z_OK or die $d->msg;
printf "%d -> %d bytes, crc32 %08x\n", $d->total_in, $d->total_out,
 ↪$d->crc32;
# 1300 -> 32 bytes, crc32 6d00e0f5

# Uncompress: inflate eats its input and says Z_STREAM_END at the␣
 ↪end.
my $i = Compress::Raw::Zlib::Inflate->new(-AppendOutput => 1);
my $out = '';
$status = $i->inflate($packed, $out);
print "status: $status, round trip ", ($out eq $data ? "ok" : "BAD
 ↪"), "\n";
# status: stream end, round trip ok

# The checksums, one-off or running, and merged.
my $crc = crc32("hello, ");
$crc = crc32("world", $crc);
printf "%08x %08x\n", $crc,
    Compress::Raw::Zlib::crc32_combine(crc32("hello, "), crc32(
 ↪"world"), 5);
# ffab723a ffab723a
```

This is a native implementation of `Compress::Raw::Zlib` 2.222; its `Compress/Raw/Zlib.pm` (the option parser, the constructors, `deflateParams`) is used unchanged. `use Compress::Raw::Zlib` exports `crc32`, `adler32` and every constant: the `Z_*` status, flush, level and strategy values, `MAX_WBITS`, `MAX_MEM_LEVEL`, `WANT_GZIP`, `WANT_GZIP_OR_ZLIB`, `OS_CODE`, `ZLIB_VERSION`, `ZLIB_VERNUM` and the `ZLIBNG_*` version parts.

Status values

The constructors and the stream methods that do work (`deflate`, `flush`, `deflateParams`, `inflate`, `inflateSync`, the resets) return a dual value (`deflateTune` returns a plain number): it compares numerically with the `Z_*` constants (`Z_OK`, `Z_STREAM_END`, `Z_BUF_ERROR`, `Z_DATA_ERROR`, ...) and prints as zlib's text for it ("stream end", "data error"). `$stream->status` repeats the last one as a plain number, and `$stream->msg` returns zlib's message for the last error.

Compressing: Compress::Raw::Zlib::Deflate

`my ($d, $status) = Compress::Raw::Zlib::Deflate->new(OPTIONS)` returns the stream and `Z_OK`, or `undef` and the zlib error code. In scalar context it returns the stream only. The options, all optional, are given as `-Name => value` pairs (or one hash reference):

- `-Level`: 0 to 9, or `Z_NO_COMPRESSION`, `Z_BEST_SPEED`, `Z_BEST_COMPRESSION`, `Z_DEFAULT_COMPRESSION` (the default).
- `-Method`: `Z_DEFLATED`, the only method and the default.
- `-WindowBits`: 8 to 15 for a zlib (RFC 1950) stream, `-MAX_WBITS` for raw deflate (RFC 1951), `WANT_GZIP` for gzip (RFC 1952). The default is `MAX_WBITS`.
- `-MemLevel`: zlib's `memLevel`, default `MAX_MEM_LEVEL`.
- `-Strategy`: `Z_DEFAULT_STRATEGY` (the default), `Z_FILTERED`, `Z_RLE`, `Z_FIXED` or `Z_HUFFMAN_ONLY`.
- `-Dictionary`: a preset dictionary; `$d->dict_adler` is its Adler-32.
- `-Bufsize`: the initial output buffer size and its growth step, default 4096.
- `-AppendOutput`: when true, output is appended to the output argument; when false (the default) the argument is overwritten.
- `-CRC32`, `-ADLER32`: keep a running checksum of the uncompressed data, read with `$d->crc32` / `$d->adler32`.

The methods:

- `$d->deflate($input, $output)` compresses all of `$input` (a scalar or a scalar reference) into `$output` and returns `Z_OK`. zlib may hold data back, so an empty `$output` after a successful call is not an error.
- `$d->flush($output [, $flush_type])` writes out what is pending. The default `Z_FINISH` ends the stream; `Z_SYNC_FLUSH`, `Z_FULL_FLUSH`, `Z_PARTIAL_FLUSH` and `Z_NO_FLUSH` keep it open.
- `$d->deflateReset` starts a new stream on the same object, after a finishing flush.
- `$d->deflateParams(-Level => ..., -Strategy => ..., -BufSize => ...)` changes those settings between calls; options not given stay.
- `$d->deflateTune($good_length, $max_lazy, $nice_length, $max_chain)` is zlib's `deflateTune`.
- `$d->get_Level`, `$d->get_Strategy`, `$d->get_Bufsize` return the settings in force.

- `$d->total_in` and `$d->total_out` count the bytes taken and given by zlib for the current stream; `$d->uncompressedBytes` and `$d->compressedBytes` are the same counts kept by the binding.
- `$d->crc32`, `$d->adler32`, `$d->dict_adler` return the checksums described above (0 when the option is off); `$d->status` the status of the last call; `$d->msg` zlib's last error message.

Uncompressing: Compress::Raw::Zlib::Inflate

`my ($i, $status) = Compress::Raw::Zlib::Inflate->new(OPTIONS)` takes `-WindowBits` (as for deflate, plus `WANT_GZIP_OR_ZLIB` to accept either header), `-Bufsize`, `-Dictionary`, `-AppendOutput`, `-CRC32`, `-ADLER32`, and:

- `-ConsumeInput` (default true): `inflate` removes the compressed data it used from its input argument. What is left after `Z_STREAM_END` is whatever followed the stream - the trailer of a container format, for example.
- `-LimitOutput`: `inflate` stops when the output buffer is full instead of uncompressing all of its input, and returns `Z_BUF_ERROR` or `Z_OK` with input left over; call it again until the input is used up. It turns `-ConsumeInput` on.

The methods:

- `$i->inflate($input, $output [, $eof])` uncompresses `$input` into `$output` and returns `Z_OK`, or `Z_STREAM_END` at the end of the compressed data. `$eof` matters only to zlib older than 1.2.0.
- `$i->inflateSync($input)` skips forward to the next full flush point (made by `flush(Z_FULL_FLUSH)`), to resume after corrupt data.
- `$i->inflateReset` starts a new stream on the same object.
- `$i->set_Append($bool)` switches `-AppendOutput` and returns the old setting.
- `$i->total_in`, `$i->total_out`, `$i->compressedBytes`, `$i->uncompressedBytes`, `$i->inflateCount`, `$i->get_Bufsize`, `$i->crc32`, `$i->adler32`, `$i->dict_adler`, `$i->status` and `$i->msg` report as their deflate counterparts do.

`Compress::Raw::Zlib::InflateScan->new` makes an `inflateScanStream`, which `IO::Compress::Zip` uses to append to an existing deflate stream: `scan`, `getEndOffset`, `getLastBlockOffset`, `getLastBufferOffset`, `resetLastBlockByte`, `inflateReset`, `inflateCount`, `createDeflateStream`, and the same counters as above. Upstream does not document it, and neither does this page. Every stream class also has `DispStream`, which prints the stream's internal state for debugging.

The zlib it uses

zlib is part of the binary, as upstream builds its own copy into the module: no library is loaded, and the module works wherever pperl runs. The implementation is zlib-rs, which has the zlib 1.3 API. `ZLIB_VERSION` reads `1.3.0-zlib-rs-` and the zlib-rs version; `ZLIB_VERNUM` is `0x1300`.

Differences from upstream

- **Compressed bytes.** A stream deflated here is a valid stream that any zlib inflates, and any zlib's stream inflates here, but it is not byte-for-byte the stream perl5 writes for the same input (level 0 excepted), and its size differs slightly. Upstream promises no particular bytes either: they change with the zlib it is built on.
- **Version.** `ZLIB_VERSION` and `ZLIB_VERNUM` are as above, where perl 5.44 with its bundled zlib reports `1.3.2` and `0x1320`.
- There is no zlib-ng mode: the four `is_zlib*` functions answer as for plain zlib.

Functions

Checksums

adler32

`adler32($buffer [, $adler])`: the Adler-32 checksum of `$buffer`. Pass the previous result as `$adler` to continue a running checksum; without it, or with `undef`, the checksum starts afresh. `$buffer` may be a scalar reference. Exported by default.

crc32

`crc32($buffer [, $crc [, $offset]])`: the CRC-32 checksum of `$buffer`, as gzip and zip use it. Pass the previous result as `$crc` to continue a running checksum; without it, or with `undef`, it starts afresh. `$offset` skips that many leading bytes; an offset past the end dies "Offset out of range in Compress::Raw::Zlib::crc32". `$buffer` may be a scalar reference. Exported by default.

crc32_combine

`Compress::Raw::Zlib::crc32_combine($crc1, $crc2, $len2)`: the CRC-32 of two pieces joined, from the CRC-32 of each and the length of the second - without the data. Not exported.

adler32_combine

`Compress::Raw::Zlib::adler32_combine($adler1, $adler2, $len2)`: as `crc32_combine`, for Adler-32. Not exported.

Library info

zlib_version

`Compress::Raw::Zlib::zlib_version()`: the version string of the zlib in use: `1.3.0-zlib-rs-` and the zlib-rs version.

zlibng_version

`Compress::Raw::Zlib::zlibng_version()`: the zlib-ng version string when the library is zlib-ng, and an empty string for zlib.

is_zlib_native

`Compress::Raw::Zlib::is_zlib_native()`: true when the library is zlib itself rather than zlib-ng. With `is_zlibng`, `is_zlibng_compat` and `is_zlibng_native` it tells which library the streams run on.

is_zlibng_native

`Compress::Raw::Zlib::is_zlibng_native()`: true when the binding uses zlib-ng's own API. Always false here: the library is reached through the zlib API.

is_zlibng_compat

`Compress::Raw::Zlib::is_zlibng_compat()`: true when the library is a zlib-ng built with the zlib-compatible API. Always false here.

is_zlibng

`Compress::Raw::Zlib::is_zlibng()`: true when the library is zlib-ng, in either mode.

ZLIB_VERNUM

`ZLIB_VERNUM`: zlib's version as a number, one hex digit per part: `0x1320` for 1.3.2. Exported by default.

zlibCompileFlags

`Compress::Raw::Zlib::zlibCompileFlags()`: zlib's `zlibCompileFlags`, the bit set describing how the library was built (type sizes, debug, assembler code); zlib.h documents the bits. 0 for zlib before 1.2.1.

ZLIBNG_VER_STATUS

`ZLIBNG_VER_STATUS`: the release status part of the zlib-ng version as a string; `"0"` when the library is zlib. Exported by default.

adler32

`adler32($buffer [, $adler])`: the Adler-32 checksum of `$buffer`. Pass the previous result as `$adler` to continue a running checksum; without it, or with `undef`, the checksum starts afresh. `$buffer` may be a scalar reference. Exported by default.

```
my $a = adler32("hello, ");
$a = adler32("world", $a);        # same as adler32("hello, world")
```

A string with characters above 255 that cannot be downgraded dies “Wide character in Compress::Raw::Zlib::adler32”.

Compress::Zlib

Interface to zlib compression library

SYNOPSIS

```
use Compress::Zlib ;

($d, $status) = deflateInit( [OPT] ) ;
$status = $d->deflate($input, $output) ;
$status = $d->flush([$flush_type]) ;
$d->deflateParams(OPTS) ;
$d->deflateTune(OPTS) ;
$d->dict_adler() ;
$d->crc32() ;
$d->adler32() ;
$d->total_in() ;
$d->total_out() ;
$d->msg() ;
$d->get_Strategy();
$d->get_Level();
$d->get_BufSize();

($i, $status) = inflateInit( [OPT] ) ;
$status = $i->inflate($input, $output [, $eof]) ;
$status = $i->inflateSync($input) ;
$i->dict_adler() ;
$d->crc32() ;
$d->adler32() ;
$i->total_in() ;
$i->total_out() ;
$i->msg() ;
$d->get_BufSize();

$dest = compress($source) ;
$dest = uncompress($source) ;

$bytesread = $gz->gzread($buffer [,$size]) ;
$bytesread = $gz->gzreadline($line) ;
$byteswritten = $gz->gzwrite($buffer) ;
$status = $gz->gzflush($flush) ;
$offset = $gz->gztell() ;
$status = $gz->gzseek($offset, $whence) ;
$status = $gz->gzclose() ;
$status = $gz->gzeof() ;
$status = $gz->gzsetparams($level, $strategy) ;
```

(continues on next page)

(continued from previous page)

```
$errstring = $gz->gzerror() ;
$gzerrno

$dest = Compress::Zlib::memGzip($buffer) ;
$dest = Compress::Zlib::memGunzip($buffer) ;

$crc = adler32($buffer [,$crc]) ;
$crc = crc32($buffer [,$crc]) ;

$crc = crc32_combine($crc1, $crc2, $len2);
$adler = adler32_combine($adler1, $adler2, $len2);

my $version = Compress::Raw::Zlib::zlib_version();
```

DESCRIPTION

The *Compress::Zlib* module provides a Perl interface to the *zlib* compression library (see "AUTHOR" for details about where to get *zlib*).

The `Compress::Zlib` module can be split into two general areas of functionality, namely a simple read/write interface to *gzip* files and a low-level in-memory compression/decompression interface.

Each of these areas will be discussed in the following sections.

Notes for users of Compress::Zlib version 1

The main change in `Compress::Zlib` version 2.x is that it does not now interface directly to the zlib library. Instead it uses the `IO::Compress::Gzip` and `IO::Uncompress::Gunzip` modules for reading/writing gzip files, and the `Compress::Raw::Zlib` module for some low-level zlib access.

The interface provided by version 2 of this module should be 100% backward compatible with version 1. If you find a difference in the expected behaviour please contact the author (See "AUTHOR"). See "GZIP INTERFACE"

With the creation of the `IO::Compress` and `IO::Uncompress` modules no new features are planned for `Compress::Zlib` - the new modules do everything that `Compress::Zlib` does and then some. Development on `Compress::Zlib` will be limited to bug fixes only.

If you are writing new code, your first port of call should be one of the new `IO::Compress` or `IO::Uncompress` modules.

GZIP INTERFACE

A number of functions are supplied in *zlib* for reading and writing *gzip* files that conform to RFC 1952. This module provides an interface to most of them.

If you have previously used `Compress::Zlib` 1.x, the following enhancements/changes have been made to the `gzopen` interface:

1. If you want to open either STDIN or STDOUT with `gzopen`, you can now optionally use the special filename "`-`" as a synonym for `\*STDIN` and `\*STDOUT`.

2. In `Compress::Zlib` version 1.x, `gzopen` used the zlib library to open the underlying file. This made things especially tricky when a Perl filehandle was passed to `gzopen`. Behind the scenes the numeric C file descriptor had to be extracted from the Perl filehandle and this passed to the zlib library.

   Apart from being non-portable to some operating systems, this made it difficult to use `gzopen` in situations where you wanted to extract/create a gzip data stream that is embedded in a larger file, without having to resort to opening and closing the file multiple times.

   It also made it impossible to pass a perl filehandle that wasn't associated with a real filesystem file, like, say, an `IO::String`.

   In `Compress::Zlib` version 2.x, the `gzopen` interface has been completely rewritten to use the *IO::Compress::Gzip* for writing gzip files and *IO::Uncompress::Gunzip* for reading gzip files. None of the limitations mentioned above apply.

3. Addition of `gzseek` to provide a restricted `seek` interface.

4. Added `gztell`.

A more complete and flexible interface for reading/writing gzip files/buffers is included with the module `IO-Compress-Zlib`. See *IO::Compress::Gzip* and *IO::Uncompress::Gunzip* for more details.

- **$gz = gzopen($filename, $mode)**
- **$gz = gzopen($filehandle, $mode)**

  This function opens either the *gzip* file `$filename` for reading or writing or attaches to the opened filehandle, `$filehandle`. It returns an object on success and `undef` on failure.

  When writing a gzip file this interface will *always* create the smallest possible gzip header (exactly 10 bytes). If you want greater control over what gets stored in the gzip header (like the original filename or a comment) use *IO::Compress::Gzip* instead. Similarly if you want to read the contents of the gzip header use *IO::Uncompress::Gunzip*.

  The second parameter, `$mode`, is used to specify whether the file is opened for reading or writing and to optionally specify a compression level and compression strategy when writing. The format of the `$mode` parameter is similar to the mode parameter to the 'C' function `fopen`, so "rb" is used to open for reading, "wb" for writing and "ab" for appending (writing at the end of the file).

  To specify a compression level when writing, append a digit between 0 and 9 to the mode string – 0 means no compression and 9 means maximum compression. If no compression level is specified Z_DEFAULT_COMPRESSION is used.

  To specify the compression strategy when writing, append 'f' for filtered data, 'h' for Huffman only compression, or 'R' for run-length encoding. If no strategy is specified Z_DEFAULT_STRATEGY is used.

  So, for example, "wb9" means open for writing with the maximum compression using the default strategy and "wb4R" means open for writing with compression level 4 and run-length encoding.

Refer to the *zlib* documentation for the exact format of the `$mode` parameter.

- **$bytesread = $gz->gzread($buffer [, $size]) ;**

  Reads `$size` bytes from the compressed file into `$buffer`. If `$size` is not specified, it will default to 4096. If the scalar `$buffer` is not large enough, it will be extended automatically.

  Returns the number of bytes actually read. On EOF it returns 0 and in the case of an error, -1.

- **$bytesread = $gz->gzreadline($line) ;**

  Reads the next line from the compressed file into `$line`.

  Returns the number of bytes actually read. On EOF it returns 0 and in the case of an error, -1.

  It is legal to intermix calls to `gzread` and `gzreadline`.

  To maintain backward compatibility with version 1.x of this module `gzreadline` ignores the `$/` variable - it *always* uses the string `"\n"` as the line delimiter.

  If you want to read a gzip file a line at a time and have it respect the `$/` variable (or `$INPUT_RECORD_SEPARATOR`, or `$RS` when `English` is in use) see *IO::Uncompress::Gunzip*.

- **$byteswritten = $gz->gzwrite($buffer) ;**

  Writes the contents of `$buffer` to the compressed file. Returns the number of bytes actually written, or 0 on error.

- **$status = $gz->gzflush($flush_type) ;**

  Flushes all pending output into the compressed file.

  This method takes an optional parameter, `$flush_type`, that controls how the flushing will be carried out. By default the `$flush_type` used is `Z_FINISH`. Other valid values for `$flush_type` are `Z_NO_FLUSH`, `Z_SYNC_FLUSH`, `Z_FULL_FLUSH` and `Z_BLOCK`. It is strongly recommended that you only set the `flush_type` parameter if you fully understand the implications of what it does - overuse of `flush` can seriously degrade the level of compression achieved. See the `zlib` documentation for details.

  Returns 0 on success.

- **$offset = $gz->gztell() ;**

  Returns the uncompressed file offset.

- **$status = $gz->gzseek($offset, $whence) ;**

  Provides a sub-set of the `seek` functionality, with the restriction that it is only legal to seek forward in the compressed file. It is a fatal error to attempt to seek backward.

  When opened for writing, empty parts of the file will have NULL (0x00) bytes written to them.

  The `$whence` parameter should be one of SEEK_SET, SEEK_CUR or SEEK_END.

  Returns 1 on success, 0 on failure.

- **$gz->gzclose**

  Closes the compressed file. Any pending data is flushed to the file before it is closed.

  Returns 0 on success.

- **$gz->gzsetparams($level, $strategy**

  Change settings for the deflate stream `$gz`.

  The list of the valid options is shown below. Options not specified will remain unchanged.

  Note: This method is only available if you are running zlib 1.0.6 or better.

  - **$level**

    Defines the compression level. Valid values are 0 through 9, `Z_NO_COMPRESSION`, `Z_BEST_SPEED`, `Z_BEST_COMPRESSION`, and `Z_DEFAULT_COMPRESSION`.

  - **$strategy**

    Defines the strategy used to tune the compression. The valid values are `Z_DEFAULT_STRATEGY`, `Z_FILTERED` and `Z_HUFFMAN_ONLY`.

- **$gz->gzerror**

  Returns the *zlib* error message or number for the last operation associated with `$gz`. The return value will be the *zlib* error number when used in a numeric context and the *zlib* error message when used in a string context. The *zlib* error number constants, shown below, are available for use.

```
Z_OK
Z_STREAM_END
Z_ERRNO
Z_STREAM_ERROR
Z_DATA_ERROR
Z_MEM_ERROR
Z_BUF_ERROR
```

- **$gzerrno**

  The `$gzerrno` scalar holds the error code associated with the most recent *gzip* routine. Note that unlike `gzerror()`, the error is *not* associated with a particular file.

  As with `gzerror()` it returns an error number in numeric context and an error message in string context. Unlike `gzerror()` though, the error message will correspond to the *zlib* message when the error is associated with *zlib* itself, or the UNIX error message when it is not (i.e. *zlib* returned `Z_ERRORNO`).

  As there is an overlap between the error numbers used by *zlib* and UNIX, `$gzerrno` should only be used to check for the presence of *an* error in numeric context. Use `gzerror()` to check for specific *zlib* errors. The *gzcat* example below shows how the variable can be used safely.

Examples

Here is an example script which uses the interface. It implements a *gzcat* function.

```
use strict ;
use warnings ;

use Compress::Zlib ;

# use stdin if no files supplied
@ARGV = '-' unless @ARGV ;

foreach my $file (@ARGV) {
    my $buffer ;

    my $gz = gzopen($file, "rb")
         or die "Cannot open $file: $gzerrno\n" ;

    print $buffer while $gz->gzread($buffer) > 0 ;

    die "Error reading from $file: $gzerrno" . ($gzerrno+0) . "\n"
        if $gzerrno != Z_STREAM_END ;

    $gz->gzclose() ;
}
```

Below is a script which makes use of `gzreadline`. It implements a very simple *grep* like script.

```
use strict ;
use warnings ;

use Compress::Zlib ;

die "Usage: gzgrep pattern [file...]\n"
    unless @ARGV >= 1;

my $pattern = shift ;

# use stdin if no files supplied
@ARGV = '-' unless @ARGV ;

foreach my $file (@ARGV) {
    my $gz = gzopen($file, "rb")
         or die "Cannot open $file: $gzerrno\n" ;

    while ($gz->gzreadline($_) > 0) {
        print if /$pattern/ ;
    }

    die "Error reading from $file: $gzerrno\n"
```

(continues on next page)

(continued from previous page)

```
        if $gzerrno != Z_STREAM_END ;

    $gz->gzclose() ;
}
```

This script, *gzstream*, does the opposite of the *gzcat* script above. It reads from standard input and writes a gzip data stream to standard output.

```
use strict ;
use warnings ;

use Compress::Zlib ;

binmode STDOUT;  # gzopen only sets it on the fd

my $gz = gzopen(\*STDOUT, "wb")
      or die "Cannot open stdout: $gzerrno\n" ;

while (<>) {
    $gz->gzwrite($_)
      or die "error writing: $gzerrno\n" ;
}

$gz->gzclose ;
```

Compress::Zlib::memGzip

This function is used to create an in-memory gzip file with the minimum possible gzip header (exactly 10 bytes).

```
$dest = Compress::Zlib::memGzip($buffer)
    or die "Cannot compress: $gzerrno\n";
```

If successful, it returns the in-memory gzip file. Otherwise it returns `undef` and the `$gzerrno` variable will store the zlib error code.

The `$buffer` parameter can either be a scalar or a scalar reference.

See *IO::Compress::Gzip* for an alternative way to carry out in-memory gzip compression.

Compress::Zlib::memGunzip

This function is used to uncompress an in-memory gzip file.

```
$dest = Compress::Zlib::memGunzip($buffer)
    or die "Cannot uncompress: $gzerrno\n";
```

If successful, it returns the uncompressed gzip file. Otherwise it returns `undef` and the `$gzerrno` variable will store the zlib error code.

The `$buffer` parameter can either be a scalar or a scalar reference. The contents of the `$buffer` parameter are destroyed after calling this function.

If `$buffer` consists of multiple concatenated gzip data streams only the first will be uncompressed. Use `gunzip` with the `MultiStream` option in the `IO::Uncompress::Gunzip` module if you need to deal with concatenated data streams.

See *IO::Uncompress::Gunzip* for an alternative way to carry out in-memory gzip uncompression.

COMPRESS/UNCOMPRESS

Two functions are provided to perform in-memory compression/uncompression of RFC 1950 data streams. They are called `compress` and `uncompress`.

- **$dest = compress($source [, $level]) ;**

  Compresses `$source`. If successful it returns the compressed data. Otherwise it returns *undef*.

  The source buffer, `$source`, can either be a scalar or a scalar reference.

  The `$level` parameter defines the compression level. Valid values are 0 through 9, `Z_NO_COMPRESSION`, `Z_BEST_SPEED`, `Z_BEST_COMPRESSION`, and `Z_DEFAULT_COMPRESSION`. If `$level` is not specified `Z_DEFAULT_COMPRESSION` will be used.

- **$dest = uncompress($source) ;**

  Uncompresses `$source`. If successful it returns the uncompressed data. Otherwise it returns *undef*.

  The source buffer can either be a scalar or a scalar reference.

Please note: the two functions defined above are *not* compatible with the Unix commands of the same name.

See IO::Deflate and IO::Inflate included with this distribution for an alternative interface for reading/writing RFC 1950 files/buffers.

Deflate Interface

This section defines an interface that allows in-memory compression using the *deflate* interface provided by zlib.

Here is a definition of the interface available:

($d, $status) = deflateInit([OPT])

Initialises a deflation stream.

It combines the features of the *zlib* functions `deflateInit`, `deflateInit2` and `deflateSetDictionary`.

If successful, it will return the initialised deflation stream, `$d` and `$status` of `Z_OK` in a list context. In scalar context it returns the deflation stream, `$d`, only.

If not successful, the returned deflation stream (`$d`) will be *undef* and `$status` will hold the exact *zlib* error code.

The function optionally takes a number of named options specified as `-Name=>value` pairs. This allows individual options to be tailored without having to specify them all in the parameter list.

For backward compatibility, it is also possible to pass the parameters as a reference to a hash containing the name=>value pairs.

The function takes one optional parameter, a reference to a hash. The contents of the hash allow the deflation interface to be tailored.

Here is a list of the valid options:

- **-Level**

  Defines the compression level. Valid values are 0 through 9, `Z_NO_COMPRESSION`, `Z_BEST_SPEED`, `Z_BEST_COMPRESSION`, and `Z_DEFAULT_COMPRESSION`.

  The default is Z_DEFAULT_COMPRESSION.

- **-Method**

  Defines the compression method. The only valid value at present (and the default) is Z_DEFLATED.

- **-WindowBits**

  To create an RFC 1950 data stream, set `WindowBits` to a positive number.

  To create an RFC 1951 data stream, set `WindowBits` to `-MAX_WBITS`.

  For a full definition of the meaning and valid values for `WindowBits` refer to the *zlib* documentation for *deflateInit2*.

  Defaults to MAX_WBITS.

- **-MemLevel**

  For a definition of the meaning and valid values for `MemLevel` refer to the *zlib* documentation for *deflateInit2*.

  Defaults to MAX_MEM_LEVEL.

- **-Strategy**

  Defines the strategy used to tune the compression. The valid values are `Z_DEFAULT_STRATEGY`, `Z_FILTERED` and `Z_HUFFMAN_ONLY`.

  The default is Z_DEFAULT_STRATEGY.

- **-Dictionary**

  When a dictionary is specified *Compress::Zlib* will automatically call `deflateSetDictionary` directly after calling `deflateInit`. The Adler32 value for the dictionary can be obtained by calling the method `$d->dict_adler()`.

  The default is no dictionary.

- **-Bufsize**

  Sets the initial size for the deflation buffer. If the buffer has to be reallocated to increase the size, it will grow in increments of `Bufsize`.

  The default is 4096.

Here is an example of using the `deflateInit` optional parameter list to override the default buffer size and compression level. All other options will take their default values.

```
deflateInit( -Bufsize => 300,
             -Level => Z_BEST_SPEED  ) ;
```

($out, $status) = $d->deflate($buffer)

Deflates the contents of `$buffer`. The buffer can either be a scalar or a scalar reference. When finished, `$buffer` will be completely processed (assuming there were no errors). If the deflation was successful it returns the deflated output, `$out`, and a status value, `$status`, of `Z_OK`.

On error, `$out` will be *undef* and `$status` will contain the *zlib* error code.

In a scalar context `deflate` will return `$out` only.

As with the *deflate* function in *zlib*, it is not necessarily the case that any output will be produced by this method. So don't rely on the fact that `$out` is empty for an error test.

($out, $status) = $d->flush()

=head2 **($out, $status)** = **$d->flush($flush_type)**

Typically used to finish the deflation. Any pending output will be returned via `$out`. `$status` will have a value `Z_OK` if successful.

In a scalar context `flush` will return `$out` only.

Note that flushing can seriously degrade the compression ratio, so it should only be used to terminate a decompression (using `Z_FINISH`) or when you want to create a *full flush point* (using `Z_FULL_FLUSH`).

By default the `flush_type` used is `Z_FINISH`. Other valid values for `flush_type` are `Z_NO_FLUSH`, `Z_PARTIAL_FLUSH`, `Z_SYNC_FLUSH` and `Z_FULL_FLUSH`. It is strongly recommended that you only set the `flush_type` parameter if you fully understand the implications of what it does. See the `zlib` documentation for details.

$status = $d->deflateParams([OPT])

Change settings for the deflate stream `$d`.

The list of the valid options is shown below. Options not specified will remain unchanged.

- **-Level**

  Defines the compression level. Valid values are 0 through 9, `Z_NO_COMPRESSION`, `Z_BEST_SPEED`, `Z_BEST_COMPRESSION`, and `Z_DEFAULT_COMPRESSION`.

- **-Strategy**

  Defines the strategy used to tune the compression. The valid values are `Z_DEFAULT_STRATEGY`, `Z_FILTERED` and `Z_HUFFMAN_ONLY`.

$d->dict_adler()

Returns the adler32 value for the dictionary.

$d->msg()

Returns the last error message generated by zlib.

$d->total_in()

Returns the total number of bytes uncompressed bytes input to deflate.

$d->total_out()

Returns the total number of compressed bytes output from deflate.

Example

Here is a trivial example of using `deflate`. It simply reads standard input, deflates it and writes it to standard output.

```
use strict ;
use warnings ;

use Compress::Zlib ;

binmode STDIN;
binmode STDOUT;
my $x = deflateInit()
   or die "Cannot create a deflation stream\n" ;

my ($output, $status) ;
while (<>)
{
    ($output, $status) = $x->deflate($_) ;

    $status == Z_OK
        or die "deflation failed\n" ;

    print $output ;
}

($output, $status) = $x->flush() ;

$status == Z_OK
    or die "deflation failed\n" ;

print $output ;
```

Inflate Interface

This section defines the interface available that allows in-memory uncompression using the *deflate* interface provided by zlib.

Here is a definition of the interface:

($i, $status) = inflateInit()

Initialises an inflation stream.

In a list context it returns the inflation stream, `$i`, and the *zlib* status code in `$status`. In a scalar context it returns the inflation stream only.

If successful, `$i` will hold the inflation stream and `$status` will be `Z_OK`.

If not successful, `$i` will be *undef* and `$status` will hold the *zlib* error code.

The function optionally takes a number of named options specified as `-Name=>value` pairs. This allows individual options to be tailored without having to specify them all in the parameter list.

For backward compatibility, it is also possible to pass the parameters as a reference to a hash containing the name=>value pairs.

The function takes one optional parameter, a reference to a hash. The contents of the hash allow the deflation interface to be tailored.

Here is a list of the valid options:

- **-WindowBits**

  To uncompress an RFC 1950 data stream, set `WindowBits` to a positive number.

  To uncompress an RFC 1951 data stream, set `WindowBits` to `-MAX_WBITS`.

  For a full definition of the meaning and valid values for `WindowBits` refer to the *zlib* documentation for *inflateInit2*.

  Defaults to MAX_WBITS.

- **-Bufsize**

  Sets the initial size for the inflation buffer. If the buffer has to be reallocated to increase the size, it will grow in increments of `Bufsize`.

  Default is 4096.

- **-Dictionary**

  The default is no dictionary.

Here is an example of using the `inflateInit` optional parameter to override the default buffer size.

```
inflateInit( -Bufsize => 300 ) ;
```

($out, $status) = $i->inflate($buffer)

Inflates the complete contents of `$buffer`. The buffer can either be a scalar or a scalar reference.

Returns `Z_OK` if successful and `Z_STREAM_END` if the end of the compressed data has been successfully reached. If not successful, `$out` will be *undef* and `$status` will hold the *zlib* error code.

The `$buffer` parameter is modified by `inflate`. On completion it will contain what remains of the input buffer after inflation. This means that `$buffer` will be an empty string when the return status is `Z_OK`. When the return status is `Z_STREAM_END` the `$buffer` parameter will contains what (if anything) was stored in the input buffer after the deflated data stream.

This feature is useful when processing a file format that encapsulates a compressed data stream (e.g. gzip, zip).

$status = $i->inflateSync($buffer)

Scans `$buffer` until it reaches either a *full flush point* or the end of the buffer.

If a *full flush point* is found, `Z_OK` is returned and `$buffer` will be have all data up to the flush point removed. This can then be passed to the `deflate` method.

Any other return code means that a flush point was not found. If more data is available, `inflateSync` can be called repeatedly with more compressed data until the flush point is found.

$i->dict_adler()

Returns the adler32 value for the dictionary.

$i->msg()

Returns the last error message generated by zlib.

$i->total_in()

Returns the total number of bytes compressed bytes input to inflate.

$i->total_out()

Returns the total number of uncompressed bytes output from inflate.

Example

Here is an example of using `inflate`.

```
use strict ;
use warnings ;
```

(continues on next page)

(continued from previous page)

```
use Compress::Zlib ;

my $x = inflateInit()
   or die "Cannot create a inflation stream\n" ;

my $input = '' ;
binmode STDIN;
binmode STDOUT;

my ($output, $status) ;
while (read(STDIN, $input, 4096))
{
    ($output, $status) = $x->inflate(\$input) ;

    print $output
        if $status == Z_OK or $status == Z_STREAM_END ;

    last if $status != Z_OK ;
}

die "inflation failed\n"
    unless $status == Z_STREAM_END ;
```

CHECKSUM FUNCTIONS

Two functions are provided by *zlib* to calculate checksums. For the Perl interface, the order of the two parameters in both functions has been reversed. This allows both running checksums and one off calculations to be done.

```
$crc = adler32($buffer [,$crc]) ;
$crc = crc32($buffer [,$crc]) ;
```

The buffer parameters can either be a scalar or a scalar reference.

If the $crc parameters is undef, the crc value will be reset.

If you have built this module with zlib 1.2.3 or better, two more CRC-related functions are available.

```
$crc = crc32_combine($crc1, $crc2, $len2);
$adler = adler32_combine($adler1, $adler2, $len2);
```

These functions allow checksums to be merged. Refer to the *zlib* documentation for more details.

Misc

my $version = Compress::Zlib::zlib_version();

Returns the version of the zlib library.

CONSTANTS

All the *zlib* constants are automatically imported when you make use of *Compress::Zlib*.

5.2.18 Config

Look up the build-time configuration of the running Perl interpreter.

`Config` exposes the values recorded when Perl itself was compiled - platform, compiler flags, install paths, feature toggles. Scripts consult it to make portability decisions, locate installed libraries, or report interpreter characteristics.

Two surfaces are provided:

- The tied hash `%Config`, accessed element-wise as `$Config{key}`. Lookup, existence, and iteration go through the tie hooks. The hash is read-only; `STORE`, `DELETE`, and `CLEAR` croak.
- Programmatic queries: `config_re`, `config_sh`, `config_vars`, `myconfig`, `compile_date`, `bincompat_options`, `non_bincompat_options`, `local_patches`, `header_files`, and the `perl -V` backend `_V`.

Under pperl, every value reflects pperl's own build, not any upstream perl's. Callers using `%Config` entries to drive portability decisions (compiler name, archname, install prefix, feature defines) get answers that match the interpreter they are actually running.

```
use Config;

printf "%s, IVs of %d bytes, threads %s\n",
    $Config{archname}, $Config{ivsize}, $Config{useithreads} // 'no
 ↪';
# x86_64-linux, IVs of 8 bytes, threads no
print "can fork\n" if $Config{d_fork};
eval { $Config{cc} = 'gcc' };        # dies: %Config::Config is␣
 ↪read-only
print Config::myconfig();            # the summary perl -V prints
```

`use Config` exports `%Config`; `myconfig`, `config_sh`, `config_vars`, `config_re` and the other functions are imported by name. `$Config::VERSION` is the interpreter's version, as `$]` is.

Differences from upstream

The values describe pperl, as upstream's describe the perl they were built with: `version` is 5.44.99, `cc` is `rustc`, and `myconfig` starts "Summary of pperl X.Y.Z (perl 5.44 compatible) configuration" with pperl's own version. The keys that describe a C toolchain (`cppstdin`, `d_attribute_format`, `libsfound`, ...) are empty or undef: pperl's build has none. The keys, the functions and the read-only tied hash are upstream's. Three functions are pperl's own: `Config::lib_file` says under which path the interpreter sees a library file, the files inside the binary included, `Config::lib_files` lists the files inside the binary, and `Config::jit_counts` says how much the JIT has compiled. Every key perl 5.44's `%Config` has is here; `build.rs` derives the bulk of them at build time (`src/build_configure.rs`).

Modules

- `Config::Extensions` - hash lookup of which core extensions were built.
- `Config::Perl`

Functions

Querying

`myconfig`

Return a human-readable summary of the interpreter's build.

`config_sh`

Return the full configuration as one shell-assignment block.

`config_vars`

Print selected configuration entries to `STDOUT`.

`config_re`

Grep configuration entries whose key matches a pattern.

Introspection

`lib_file`

Say under which path this interpreter sees a library file.

`lib_files`

`jit_counts`

`compile_date`

Return a one-line description of when and with what the interpreter was built.

`local_patches`

Return the list of local patches applied to the interpreter.

`bincompat_options`

Return the compile-time options that affect binary compatibility.

non_bincompat_options

Return compile-time options that do not affect binary compatibility.

header_files

Return the canonical list of Perl C header filenames.

Config::Extensions

hash lookup of which core extensions were built.

SYNOPSIS

```
use Config::Extensions '%Extensions';
if ($Extensions{PerlIO::via}) {
    # This perl has PerlIO::via built
}
```

DESCRIPTION

The Config::Extensions module provides a hash `%Extensions` containing all the core extensions that were enabled for this perl. The hash is keyed by extension name, with each entry having one of 3 possible values:

- dynamic

  The extension is dynamically linked

- nonxs

  The extension is pure perl, so doesn't need linking to the perl executable

- static

  The extension is statically linked to the perl binary

As all values evaluate to true, a simple `if` test is good enough to determine whether an extension is present.

All the data uses to generate the `%Extensions` hash is already present in the `Config` module, but not in such a convenient format to quickly reference.

Config::Perl

Namespace containing the following modules:

- `Config::Perl::V` - Structured data retrieval of perl -V output

Config::Perl::V

Structured data retrieval of perl -V output

SYNOPSIS

```
use Config::Perl::V;

my $local_config = Config::Perl::V::myconfig ();
print $local_config->{config}{osname};
```

DESCRIPTION

$conf = myconfig ()

This function will collect the data described in "The hash structure" below, and return that as a hash reference. It optionally accepts an option to include more entries from %ENV. See "environment" below.

Note that this will not work on uninstalled perls when called with `-I/path/to/uninstalled/perl/lib`, but it works when that path is in `$PERL5LIB` or in `$PERL5OPT`, as paths passed using `-I` are not known when the `-V` information is collected.

$conf = plv2hash ($text [, ...])

Convert a sole 'perl -V' text block, or list of lines, to a complete myconfig hash. All unknown entries are defaulted.

$info = summary ([$conf])

Return an arbitrary selection of the information. If no `$conf` is given, `myconfig ()` is used instead.

$md5 = signature ([$conf])

Return the MD5 of the info returned by `summary ()` without the `config_args` entry.

If `Digest::MD5` is not available, it return a string with only `0`'s.

The hash structure

The returned hash consists of 4 parts:

- build

  This information is extracted from the second block that is emitted by `perl -V`, and usually looks something like

  ```
  Characteristics of this binary (from libperl):
    Compile-time options: DEBUGGING USE_64_BIT_INT USE_LARGE_FILES
    Locally applied patches:
  ```

(continues on next page)

This information is not available anywhere else, including `%Config`, but it is the information that is only known to the perl binary.

The extracted information is stored in 5 entries in the `build` hash:

- osname

  This is most likely the same as `$Config{osname}`, and was the name known when perl was built. It might be different if perl was cross-compiled.

  The default for this field, if it cannot be extracted, is to copy `$Config{osname}`. The two may be differing in casing (OpenBSD vs openbsd).

- stamp

  This is the time string for which the perl binary was compiled. The default value is 0.

- options

  This is a hash with all the known defines as keys. The value is either 0, which means unknown or unset, or 1, which means defined.

- derived

  As some variables are reported by a different name in the output of `perl -V` than their actual name in `%Config`, I decided to leave the `config` entry as close to reality as possible, and put in the entries that might have been guessed by the printed output in a separate block.

- patches

This is a list of optionally locally applied patches. Default is an empty list.

- environment

  By default this hash is only filled with the environment variables out of %ENV that start with PERL, but you can pass the env option to myconfig to get more

```
my $conf = Config::Perl::V::myconfig ({ env => qr/^ORACLE/ });
my $conf = Config::Perl::V::myconfig ([ env => qr/^ORACLE/ ]);
```

- config

  This hash is filled with the variables that `perl -V` fills its report with, and it has the same variables that `Config::myconfig` returns from `%Config`.

- inc

  This is the list of default @INC.

REASONING

This module was written to be able to return the configuration for the currently used perl as deeply as needed for the CPANTESTERS framework. Up until now they used the output of myconfig as a single text blob, and so it was missing the vital binary characteristics of the running perl and the optional applied patches.

BUGS

Please feedback what is wrong

TODO

```
* Implement retrieval functions/methods
* Documentation
* Error checking
* Tests
```

This library is free software; you can redistribute it and/or modify it under the same terms as Perl itself.

myconfig

Return a human-readable summary of the interpreter's build.

Synopsis

```
use Config;
print Config::myconfig();
```

What you get back

A single multi-line string, suitable for printing verbatim. Groups the values under `Platform`, `Compiler`, and `Linker and Libraries` headings, matching the shape expected by tools that scrape `perl -V`-style output.

Examples

```
use Config;
my $summary = Config::myconfig();
print $summary if $summary =~ /osname=linux/;
```

Edge cases

- Returns a fresh scalar on every call; cache it if used repeatedly in a hot path.

Differences from upstream

- Platform, compiler, and library values describe pperl's build (Rust toolchain, pperl version line) rather than a C-compiled perl. The layout and key names match upstream so existing parsers keep working.

config_sh

Return the full configuration as one shell-assignment block.

Synopsis

```
use Config;
my $sh = Config::config_sh();
```

What you get back

A single scalar containing one line per entry in the form `key='value'`, newline-terminated. The output is stable across calls and suitable for feeding into a shell `eval` or a line-based parser.

Examples

```
use Config;
for my $line (split /^/, Config::config_sh()) {
    print $line if $line =~ /^archname=/;
}
```

Edge cases

- Entries whose value is undef render as `key=''`, matching how the tied hash reports them via `EXISTS` (true) and `FETCH` (undef).

Differences from upstream

Fully compatible with upstream.

config_vars

Print selected configuration entries to `STDOUT`.

Synopsis

```
use Config;
Config::config_vars(qw(archname osname ivsize));
```

What you get back

Nothing. Each named key is written to `STDOUT` on its own line as `key='value';`. Unknown keys render as `key='UNKNOWN';`, keys whose recorded value is undef as `key='undef';`. This is the backend of the `-V:key` command-line switch (see perlrun), including its query syntax: a leading `:` suppresses the `key=` tag, a trailing `:` ends the line with a space instead of `;\n`, and a query containing non-word characters is treated as a regex and answered from `config_re`.

Examples

```
use Config;
Config::config_vars('archname');           # archname='x86_64-linux
 ↪';
Config::config_vars('archname', 'osname'); # two lines
Config::config_vars('ivsize|nvsize');      # regex: both entries
Config::config_vars(':archname');          # 'x86_64-linux'; (no␣
 ↪tag)
```

Edge cases

- Unknown keys print `'UNKNOWN'`; undef values print `'undef'`.
- Regex queries with no match print `pattern:  not found`.
- Output goes straight to the OS `STDOUT`; redirecting with `local *STDOUT` in Perl does not affect it.

Differences from upstream

- Regex queries share `config_re`'s pattern approximation (see `config_re` "Differences from upstream").

config_re

Grep configuration entries whose key matches a pattern.

Synopsis

```
use Config;
my @hits = Config::config_re('^cc');
```

What you get back

A list of strings in `key='value'` form, one per matching entry. The pattern is anchored at the start of each `key='value'` line and must be followed by `=`, so in practice it matches the key; values are included verbatim in the returned strings.

Examples

```
use Config;
my @arch = Config::config_re('arch\w*');  # archname, archlibexp, ..
 ↪.
my @d    = Config::config_re('d_\w+');    # every d_* feature flag
```

Edge cases

- An empty pattern returns no results.
- A pattern that does not compile returns no results and leaves its error in `$@`.

Differences from upstream

Fully compatible with upstream.

lib_file

Say under which path this interpreter sees a library file.

Synopsis

```
use Config;
my $path = Config::lib_file("strict.pm");
my $path = Config::lib_file("ExtUtils/typemap");
my $path = Config::lib_file("Foo/Bar.pm", \@dirs);
```

What you get back

The path of the file a `require` of that name would load, or `undef` when there is none. The name is a path below a library directory, with `/` between the parts, as in `%INC`. The path can be opened.

A file that is part of the pperl binary is found first and reported under `$Config{privlibexp}`, the directory that holds the binary's library: nothing elsewhere can take its place. Any other file is looked for in each directory of `@INC` in turn, and the first one that exists and is not a directory is reported.

With a second argument, a reference to an array of directories, those are searched in place of `@INC`. The pperl binary's own files count only when `$Config{privlibexp}` is among them.

A built-in module written in Rust has no Perl source. Opened under the path reported here it reads as three lines: its package, its `$VERSION` and a true value.

Why it exists

Perl's own way of asking is to walk `@INC` with `-e` or `-r` and take the first hit. That walk works on pperl too, but the first file test of the binary's library writes it to disk, and a walk cannot see that a built-in module wins over a copy in an earlier directory. A tool that must know where a module is, or which version would be loaded, asks here, and nothing is written.

Examples

```
use Config;
use ExtUtils::MakeMaker ();
my $file = Config::lib_file("List/Util.pm");
print MM->parse_version($file), "\n" if defined $file;
```

lib_files

List the library files that are built into this pperl.

Synopsis

```
use Config;
my @names = Config::lib_files();
```

What you get back

The names of all built-in library files, sorted, in the form `require` takes: `strict.pm`, `File/Temp.pm`, `ExtUtils/typemap`. Each is a name `Config::lib_file` answers with a path under `$Config{privlibexp}`. Files installed elsewhere are not listed: walk `@INC` for those.

Examples

```
my @modules = map { s{/}{::}gr =~ s/\.pm\z//r } grep { /\.pm\z/ }␣
 ↪Config::lib_files();
print scalar(@modules), " modules are built in\n";
```

Differences from upstream

pperl's own; perl has no such function.

jit_counts

Say how much code the JIT has compiled so far.

Synopsis

```
use Config;
my ($compiled, $seen) = Config::jit_counts();
```

What you get back

Two numbers, both counted since the program started: the loops the JIT has compiled to machine code, and the loops it has seen and counts the trips of. Neither goes down when code is freed again. An empty list when the JIT is off or this pperl was built without it.

Examples

```
my ($before) = Config::jit_counts();
my $sum = 0;
$sum += $_ * $_ for 1 .. 1_000_000;
my ($after) = Config::jit_counts();
print "the loop was compiled\n" if defined $after && $after >
 ↪$before;
```

Differences from upstream

pperl's own; perl has no such function.

compile_date

Return a one-line description of when and with what the interpreter was built.

Synopsis

```
use Config;
print Config::compile_date(), "\n";
```

What you get back

A string such as `Compiled at Oct 8 2026 20:41:20`: when this pperl binary was built, in the layout perl uses, which `Config::Perl::V` and similar tools parse. `pperl -V` prints the same line. The compiler that built it is `$Config{ccversion}` and friends.

local_patches

Return the list of local patches applied to the interpreter.

Synopsis

```
use Config;
my @patches = Config::local_patches();
```

What you get back

A list of strings, one per local patch. The list is empty when the interpreter was built from pristine sources.

Examples

```
use Config;
print "vanilla build\n" unless Config::local_patches();
```

Differences from upstream

- Always returns an empty list under pperl. pperl is not a patched fork of upstream perl, so there is no patch trail to report.

bincompat_options

Return the compile-time options that affect binary compatibility.

Synopsis

```
use Config;
my @opts = Config::bincompat_options();
```

What you get back

A list of option names (`USE_64_BIT_INT`, `USE_PERLIO`, and so on) representing decisions baked into the interpreter that determine its binary interface. Two builds that disagree on any of them are not binary compatible.

Examples

```
use Config;
print "64-bit ints\n"
    if grep { $_ eq 'USE_64_BIT_INT' } Config::bincompat_options();
```

Differences from upstream

- The list reports the options that truthfully apply to pperl's build. Upstream-specific switches that do not exist in pperl are omitted rather than forged.

non_bincompat_options

Return compile-time options that do not affect binary compatibility.

Synopsis

```
use Config;
my @opts = Config::non_bincompat_options();
```

What you get back

A list of option names (`PERL_COPY_ON_WRITE`, `USE_LOCALE`, and so on) describing behavioural switches that do not change the ABI. Useful for feature-probing scripts that want to know whether a particular semantics is enabled without caring about binary compatibility.

Differences from upstream

- Reports only the switches that meaningfully apply to pperl's build.

header_files

Return the canonical list of Perl C header filenames.

Synopsis

```
use Config;
my @hdrs = Config::header_files();
```

What you get back

A fixed list of bare header filenames (`perl.h`, `sv.h`, `op.h`, and so on) - no paths, no extensions other than `.h`. The call exists so tooling that probes for the interpreter's C build prerequisites keeps working.

Edge cases

- The filenames name headers from the upstream perl C sources. pperl does not ship them as separate files; callers that read the headers from disk will fail to find them.

Differences from upstream

- pperl does not have a C-level public header layout, so the list is informational only. It matches upstream's roster so scripts that merely inspect the names (without opening the files) behave identically.

5.2.19 Coro

the only real threads in perl

> **Note**
>
> This is upstream Coro's documentation. Under pperl, Coro's compiled half is native and `Coro.pm` and every `Coro::*` module run unchanged; see *Coro::State* for what that means.

SYNOPSIS

```
use Coro;

async {
   # some asynchronous thread of execution
   print "2\n";
   cede; # yield back to main
   print "4\n";
};
print "1\n";
cede; # yield to coro
```

(continues on next page)

(continued from previous page)

```
print "3\n";
cede; # and again

# use locking
my $lock = new Coro::Semaphore;
my $locked;

$lock->down;
$locked = 1;
$lock->up;
```

DESCRIPTION

For a tutorial-style introduction, please read the Coro::Intro manpage. This manpage mainly contains reference information.

This module collection manages continuations in general, most often in the form of cooperative threads (also called coros, or simply "coro" in the documentation). They are similar to kernel threads but don't (in general) run in parallel at the same time even on SMP machines. The specific flavor of thread offered by this module also guarantees you that it will not switch between threads unless necessary, at easily-identified points in your program, so locking and parallel access are rarely an issue, making thread programming much safer and easier than using other thread models.

Unlike the so-called "Perl threads" (which are not actually real threads but only the windows process emulation (see section of same name for more details) ported to UNIX, and as such act as processes), Coro provides a full shared address space, which makes communication between threads very easy. And coro threads are fast, too: disabling the Windows process emulation code in your perl and using Coro can easily result in a two to four times speed increase for your programs. A parallel matrix multiplication benchmark (very communication-intensive) runs over 300 times faster on a single core than perls pseudo-threads on a quad core using all four cores.

Coro achieves that by supporting multiple running interpreters that share data, which is especially useful to code pseudo-parallel processes and for event-based programming, such as multiple HTTP-GET requests running concurrently. See *Coro::AnyEvent* to learn more on how to integrate Coro into an event-based environment.

In this module, a thread is defined as "callchain + lexical variables + some package variables + C stack), that is, a thread has its own callchain, its own set of lexicals and its own set of perls most important global variables (see *Coro::State* for more configuration and background info).

See also the SEE ALSO section at the end of this document - the Coro module family is quite large.

CORO THREAD LIFE CYCLE

During the long and exciting (or not) life of a coro thread, it goes through a number of states:

1. Creation

The first thing in the life of a coro thread is its creation - obviously. The typical way to create a thread is to call the `async BLOCK` function:

```
async {
   # thread code goes here
};
```

You can also pass arguments, which are put in `@_`:

```
async {
   print $_[1]; # prints 2
} 1, 2, 3;
```

This creates a new coro thread and puts it into the ready queue, meaning it will run as soon as the CPU is free for it.

`async` will return a Coro object - you can store this for future reference or ignore it - a thread that is running, ready to run or waiting for some event is alive on its own.

Another way to create a thread is to call the `new` constructor with a code-reference:

```
new Coro sub {
   # thread code goes here
}, @optional_arguments;
```

This is quite similar to calling `async`, but the important difference is that the new thread is not put into the ready queue, so the thread will not run until somebody puts it there. `async` is, therefore, identical to this sequence:

```
my $coro = new Coro sub {
   # thread code goes here
};
$coro->ready;
return $coro;
```

2. Startup

   When a new coro thread is created, only a copy of the code reference and the arguments are stored, no extra memory for stacks and so on is allocated, keeping the coro thread in a low-memory state.

   Only when it actually starts executing will all the resources be finally allocated.

   The optional arguments specified at coro creation are available in `@_`, similar to function calls.

3. Running / Blocking

   A lot can happen after the coro thread has started running. Quite usually, it will not run to the end in one go (because you could use a function instead), but it will give up the CPU regularly because it waits for external events.

   As long as a coro thread runs, its Coro object is available in the global variable `$Coro::current`.

The low-level way to give up the CPU is to call the scheduler, which selects a new coro thread to run:

```
Coro::schedule;
```

Since running threads are not in the ready queue, calling the scheduler without doing anything else will block the coro thread forever - you need to arrange either for the coro to put woken up (readied) by some other event or some other thread, or you can put it into the ready queue before scheduling:

```
# this is exactly what Coro::cede does
$Coro::current->ready;
Coro::schedule;
```

All the higher-level synchronisation methods (Coro::Semaphore, Coro::rouse_*...) are actually implemented via `->ready` and `Coro::schedule`.

While the coro thread is running it also might get assigned a C-level thread, or the C-level thread might be unassigned from it, as the Coro runtime wishes. A C-level thread needs to be assigned when your perl thread calls into some C-level function and that function in turn calls perl and perl then wants to switch coroutines. This happens most often when you run an event loop and block in the callback, or when perl itself calls some function such as `AUTOLOAD` or methods via the `tie` mechanism.

4. Termination

   Many threads actually terminate after some time. There are a number of ways to terminate a coro thread, the simplest is returning from the top-level code reference:

```
async {
   # after returning from here, the coro thread is terminated
};

async {
   return if 0.5 <  rand; # terminate a little earlier, maybe
   print "got a chance to print this\n";
   # or here
};
```

   Any values returned from the coroutine can be recovered using `->join`:

```
my $coro = async {
   "hello, world\n" # return a string
};

my $hello_world = $coro->join;

print $hello_world;
```

   Another way to terminate is to call `Coro::terminate`, which at any subroutine call nesting level:

```
async {
   Coro::terminate "return value 1", "return value 2";
};
```

Yet another way is to `->cancel` (or `->safe_cancel`) the coro thread from another thread:

```
my $coro = async {
   exit 1;
};

$coro->cancel; # also accepts values for ->join to retrieve
```

Cancellation *can* be dangerous - it's a bit like calling `exit` without actually exiting, and might leave C libraries and native modules in a weird state. Unlike other thread implementations, however, Coro is exceptionally safe with regards to cancellation, as perl will always be in a consistent state, and for those cases where you want to do truly marvellous things with your coro while it is being cancelled - that is, make sure all cleanup code is executed from the thread being cancelled - there is even a `->safe_cancel` method.

So, cancelling a thread that runs in a native event loop might not be the best idea, but any other combination that deals with perl only (cancelling when a thread is in a `tie` method or an `AUTOLOAD` for example) is safe.

Last not least, a coro thread object that isn't referenced is `->cancel`'ed automatically - just like other objects in Perl. This is not such a common case, however - a running thread is referencedy by `$Coro::current`, a thread ready to run is referenced by the ready queue, a thread waiting on a lock or semaphore is referenced by being in some wait list and so on. But a thread that isn't in any of those queues gets cancelled:

```
async {
   schedule; # cede to other coros, don't go into the ready␣
↪queue
};

cede;
# now the async above is destroyed, as it is not referenced by␣
↪anything.
```

A slightly embellished example might make it clearer:

```
async {
   my $guard = Guard::guard { print "destroyed\n" };
   schedule while 1;
};

cede;
```

Superficially one might not expect any output - since the `async` implements an endless loop, the `$guard` will not be cleaned up. However, since the thread object returned by `async` is not stored anywhere, the thread is initially referenced

because it is in the ready queue, when it runs it is referenced by `$Coro::current`, but when it calls `schedule`, it gets `canceled` causing the guard object to be destroyed (see the next section), and printing its message.

If this seems a bit drastic, remember that this only happens when nothing references the thread anymore, which means there is no way to further execute it, ever. The only options at this point are leaking the thread, or cleaning it up, which brings us to...

5. Cleanup

   Threads will allocate various resources. Most but not all will be returned when a thread terminates, during clean-up.

   Cleanup is quite similar to throwing an uncaught exception: perl will work its way up through all subroutine calls and blocks. On its way, it will release all `my` variables, undo all `local`'s and free any other resources truly local to the thread.

   So, a common way to free resources is to keep them referenced only by my variables:

```
async {
   my $big_cache = new Cache ...;
};
```

   If there are no other references, then the `$big_cache` object will be freed when the thread terminates, regardless of how it does so.

   What it does `NOT` do is unlock any Coro::Semaphores or similar resources, but that's where the `guard` methods come in handy:

```
my $sem = new Coro::Semaphore;

async {
   my $lock_guard = $sem->guard;
   # if we return, or die or get cancelled, here,
   # then the semaphore will be "up"ed.
};
```

   The `Guard::guard` function comes in handy for any custom cleanup you might want to do (but you cannot switch to other coroutines from those code blocks):

```
async {
   my $window = new Gtk2::Window "toplevel";
   # The window will not be cleaned up automatically, even when
↪$window
   # gets freed, so use a guard to ensure its destruction
   # in case of an error:
   my $window_guard = Guard::guard { $window->destroy };

   # we are safe here
};
```

   Last not least, `local` can often be handy, too, e.g. when temporarily replacing the coro thread description:

```
sub myfunction {
   local $Coro::current->{desc} = "inside myfunction(@_)";

   # if we return or die here, the description will be restored
}
```

6. Viva La Zombie Muerte

   Even after a thread has terminated and cleaned up its resources, the Coro object still is there and stores the return values of the thread.

   When there are no other references, it will simply be cleaned up and freed.

   If there areany references, the Coro object will stay around, and you can call `->join` as many times as you wish to retrieve the result values:

```
async {
   print "hi\n";
   1
};

# run the async above, and free everything before returning
# from Coro::cede:
Coro::cede;

{
   my $coro = async {
      print "hi\n";
      1
   };

   # run the async above, and clean up, but do not free the coro
   # object:
   Coro::cede;

   # optionally retrieve the result values
   my @results = $coro->join;

   # now $coro goes out of scope, and presumably gets freed
};
```

GLOBAL VARIABLES

- $Coro::main

  This variable stores the Coro object that represents the main program. While you can `ready` it and do most other things you can do to coro, it is mainly useful to compare again `$Coro::current`, to see whether you are running in the main program or not.

- $Coro::current

  The Coro object representing the current coro (the last coro that the Coro scheduler

switched to). The initial value is `$Coro::main` (of course).

This variable is **strictly** *read-only*. You can take copies of the value stored in it and use it as any other Coro object, but you must not otherwise modify the variable itself.

- $Coro::idle

  This variable is mainly useful to integrate Coro into event loops. It is usually better to rely on *Coro::AnyEvent* or *Coro::EV*, as this is pretty low-level functionality.

  This variable stores a Coro object that is put into the ready queue when there are no other ready threads (without invoking any ready hooks).

  The default implementation dies with "FATAL: deadlock detected.", followed by a thread listing, because the program has no other way to continue.

  This hook is overwritten by modules such as `Coro::EV` and `Coro::AnyEvent` to wait on an external event that hopefully wakes up a coro so the scheduler can run it.

  See *Coro::EV* or *Coro::AnyEvent* for examples of using this technique.

SIMPLE CORO CREATION

- async { ... } [@args...]

  Create a new coro and return its Coro object (usually unused). The coro will be put into the ready queue, so it will start running automatically on the next scheduler run.

  The first argument is a codeblock/closure that should be executed in the coro. When it returns argument returns the coro is automatically terminated.

  The remaining arguments are passed as arguments to the closure.

  See the `Coro::State::new` constructor for info about the coro environment in which coro are executed.

  Calling `exit` in a coro will do the same as calling exit outside the coro. Likewise, when the coro dies, the program will exit, just as it would in the main program.

  If you do not want that, you can provide a default `die` handler, or simply avoid dieing (by use of `eval`).

  Example: Create a new coro that just prints its arguments.

```
async {
   print "@_\n";
} 1,2,3,4;
```

- async_pool { ... } [@args...]

  Similar to `async`, but uses a coro pool, so you should not call terminate or join on it (although you are allowed to), and you get a coro that might have executed other code already (which can be good or bad :).

  On the plus side, this function is about twice as fast as creating (and destroying) a completely new coro, so if you need a lot of generic coros in quick successsion, use `async_pool`, not `async`.

The code block is executed in an `eval` context and a warning will be issued in case of an exception instead of terminating the program, as `async` does. As the coro is being reused, stuff like `on_destroy` will not work in the expected way, unless you call terminate or cancel, which somehow defeats the purpose of pooling (but is fine in the exceptional case).

The priority will be reset to `0` after each run, all `swap_sv` calls will be undone, tracing will be disabled, the description will be reset and the default output filehandle gets restored, so you can change all these. Otherwise the coro will be re-used "as-is": most notably if you change other per-coro global stuff such as `$/` you *must needs* revert that change, which is most simply done by using local as in: `local $/`.

The idle pool size is limited to `8` idle coros (this can be adjusted by changing $Coro::POOL_SIZE), but there can be as many non-idle coros as required.

If you are concerned about pooled coros growing a lot because a single `async_pool` used a lot of stackspace you can e.g. `async_pool { terminate }` once per second or so to slowly replenish the pool. In addition to that, when the stacks used by a handler grows larger than 32kb (adjustable via $Coro::POOL_RSS) it will also be destroyed.

STATIC METHODS

Static methods are actually functions that implicitly operate on the current coro.

- schedule

  Calls the scheduler. The scheduler will find the next coro that is to be run from the ready queue and switches to it. The next coro to be run is simply the one with the highest priority that is longest in its ready queue. If there is no coro ready, it will call the `$Coro::idle` hook.

  Please note that the current coro will *not* be put into the ready queue, so calling this function usually means you will never be called again unless something else (e.g. an event handler) calls `->ready`, thus waking you up.

  This makes `schedule` *the* generic method to use to block the current coro and wait for events: first you remember the current coro in a variable, then arrange for some callback of yours to call `->ready` on that once some event happens, and last you call `schedule` to put yourself to sleep. Note that a lot of things can wake your coro up, so you need to check whether the event indeed happened, e.g. by storing the status in a variable.

  See **HOW TO WAIT FOR A CALLBACK**, below, for some ways to wait for callbacks.

- cede

  "Cede" to other coros. This function puts the current coro into the ready queue and calls `schedule`, which has the effect of giving up the current "timeslice" to other coros of the same or higher priority. Once your coro gets its turn again it will automatically be resumed.

  This function is often called `yield` in other languages.

- Coro::cede_notself

Works like cede, but is not exported by default and will cede to *any* coro, regardless of priority. This is useful sometimes to ensure progress is made.

- terminate [arg...]

  Terminates the current coro with the given status values (see cancel). The values will not be copied, but referenced directly.

- Coro::on_enter BLOCK, Coro::on_leave BLOCK

  These function install enter and leave winders in the current scope. The enter block will be executed when on_enter is called and whenever the current coro is re-entered by the scheduler, while the leave block is executed whenever the current coro is blocked by the scheduler, and also when the containing scope is exited (by whatever means, be it exit, die, last etc.).

  Neither invoking the scheduler, nor exceptions, are allowed within those BLOCKs. That means: do not even think about calling `die` without an eval, and do not even think of entering the scheduler in any way.

  Since both BLOCKs are tied to the current scope, they will automatically be removed when the current scope exits.

  These functions implement the same concept as `dynamic-wind` in scheme does, and are useful when you want to localise some resource to a specific coro.
