    A time_t value when the certificate starts to be valid. Defaults to current time.

  - not_after

    A time_t value when the certificate ends to be valid. Defaults to current time plus one 365 days.

  - serial

    The serial number. If not given a cryptographically random 32-bit value is generated using `Net::SSLeay::RAND_bytes`.

  - version

    The version of the certificate, default 2 (x509v3).

  - CA true|false

    If true declare certificate as CA, defaults to false.

– purpose string|array|hash

Set the purpose of the certificate. The different purposes can be given as a string separated by non-word character, as array or hash. With string or array each purpose can be prefixed with '+' (enable) or '-' (disable) and same can be done with the value when given as a hash. By default enabling the purpose is assumed.

If the CA option is given and true the defaults "ca,sslca,emailca,objca" are assumed, but can be overridden with explicit purpose. If the CA option is given and false the defaults "server,client" are assumed. If no CA option and no purpose is given it defaults to "server,client".

Purpose affects basicConstraints, keyUsage, extKeyUsage and netscapeCertType. The following purposes are defined (case is not important):

```
client
server
email
objsign

CA
sslCA
emailCA
objCA

emailProtection
codeSigning
timeStamping

digitalSignature
nonRepudiation
keyEncipherment
dataEncipherment
keyAgreement
keyCertSign
cRLSign
encipherOnly
decipherOnly
```

Examples:

```
# root-CA for SSL certificates
purpose => 'sslCA'   # or CA => 1

# server certificate and CA (typically self-signed)
purpose => 'sslCA,server'

# client certificate
purpose => 'client',
```

– ext [{ sn => .., data => ... }, ...]

List of extensions. The type of the extension can be specified as name with sn

or as NID with `nid` and the data with `data`. These data must be in the same syntax as expected within openssl.cnf, e.g. something like `OCSP;URI=http://...`. Additionally the critical flag can be set with `critical = 1`>.

– key key

use given key as key for certificate, otherwise a new one will be generated and returned

– issuer_cert cert

set issuer for new certificate

– issuer_key key

sign new certificate with given key

– issuer [cert, key]

Instead of giving issuer_key and issuer_cert as separate arguments they can be given both together.

– digest algorithm

specify the algorithm used to sign the certificate, default SHA-256.

– ignore_invalid_args

ignore any unknown arguments which might be in the argument list (which might be in the arguments for example as result from CERT_asHash)

IO::Socket::UNIX

Object interface for AF_UNIX domain sockets

SYNOPSIS

```
use IO::Socket::UNIX;

my $SOCK_PATH = "$ENV{HOME}/unix-domain-socket-test.sock";

# Server:
my $server = IO::Socket::UNIX->new(
    Type => SOCK_STREAM(),
    Local => $SOCK_PATH,
    Listen => 1,
);

my $count = 1;
while (my $conn = $server->accept()) {
    $conn->print("Hello " . ($count++) . "\n");
}
```

(continues on next page)

(continued from previous page)

```
# Client:
my $client = IO::Socket::UNIX->new(
    Type => SOCK_STREAM(),
    Peer => $SOCK_PATH,
);

# Now read and write from $client
```

DESCRIPTION

`IO::Socket::UNIX` provides an object interface to creating and using sockets in the AF_UNIX domain. It is built upon the *IO::Socket* interface and inherits all the methods defined by *IO::Socket*.

CONSTRUCTOR

- new ([ARGS])

  Creates an `IO::Socket::UNIX` object, which is a reference to a newly created symbol (see the *Symbol* package). new optionally takes arguments, these arguments are in key-value pairs.

  In addition to the key-value pairs accepted by *IO::Socket*, `IO::Socket::UNIX` provides.

  ```
  Type        Type of socket (eg SOCK_STREAM or SOCK_DGRAM)
  Local       Path to local fifo
  Peer        Path to peer fifo
  Listen      Queue size for listen
  ```

  If the constructor is only passed a single argument, it is assumed to be a `Peer` specification.

  If the `Listen` argument is given, but false, the queue size will be set to 5.

  If the constructor fails it will return `undef` and set the `$IO::Socket::errstr` package variable to contain an error message.

  ```
  $sock = IO::Socket::UNIX->new(...)
      or die "Cannot create socket - $IO::Socket::errstr\n";
  ```

  For legacy reasons the error message is also set into the global `$@` variable, and you may still find older code which looks here instead.

  ```
  $sock = IO::Socket::UNIX->new(...)
      or die "Cannot create socket - $@\n";
  ```

METHODS

- hostpath()

  Returns the pathname to the fifo at the local end

- peerpath()

  Returns the pathanme to the fifo at the peer end

SEE ALSO

Socket, *IO::Socket*

IO::Tty

Pseudo-terminals and the terminal constants: the compiled part under `IO::Pty` (a pty master and its slave as handles) and `IO::Tty`.

Synopsis

```
use IO::Pty;
my $pty = IO::Pty->new;                 # IO::Pty::pty_allocate
my $slave = $pty->slave;                # IO::Tty::_open_tty
print $pty->ttyname, "\n";              # e.g. /dev/pts/3

use IO::Tty qw(TIOCSWINSZ);             # IO::Tty::Constant
my $ws = IO::Tty::pack_winsize(24, 80);
```

How it works

`IO::Pty::pty_allocate` returns a pty's master and slave descriptors and the slave's name, or an empty list. It tries `posix_openpt`, then `getpt`, `openpty` and `/dev/ptmx`, then the BSD-style `/dev/pty??` names; for each master it grants and unlocks the slave, names it with `ptsname_r` or `ptsname`, opens it, and moves both descriptors above 2. With `$IO::Tty::DEBUG` true it says on stderr what it tries; with `use warnings` (category `io`) each method that fails warns. `IO::Tty::_open_tty` opens a terminal by name, `ttyname` names a handle's terminal, and `pack_winsize`/`unpack_winsize` convert a `struct winsize`. Loading defines the constants of `IO::Tty::Constant`, undef for the ones this system lacks, and `$IO::Tty::CONFIG`.

This is a native implementation of `Tty.xs` of IO-Tty 1.31 as its Makefile.PL configures it on Linux, with the `xssubs.c` it writes; `IO/Tty.pm`, `IO/Pty.pm` and the `IO/Tty/Constant.pm` it writes are used unchanged.

Differences from upstream

One, where perl 5.44 with Tty.xs crashes or reports memory it never wrote (t/81-xs-native/IO-Tty/150-or-better.t):

- `unpack_winsize` of a value with no string - undef, a number, a reference - dies "Bad arg length - got 0, expected 8". perl5 reads the length of a string that is not there: undef segfaults, and the others report a number from memory ("got 94515720394056").

Modules

- `IO::Tty::Constant` - Terminal Constants (autogenerated)

Functions

Pseudo-terminals

`ttyname`

The name of the terminal a handle is open on, or undef.

`pack_winsize`

A `struct winsize` as a string, for the TIOCSWINSZ `ioctl`.

`unpack_winsize`

The four numbers of a `struct winsize` string.

Synopsis

```
my ($rows, $cols, $xpixel, $ypixel) = IO::Tty::unpack_winsize($ws);
```

What you get back

Four numbers; a string that is not eight bytes long dies "IO::Tty::unpack_winsize(): Bad arg length - got N, expected 8".

IO::Tty::Constant

Terminal Constants (autogenerated)

SYNOPSIS

```
use IO::Tty::Constant qw(TIOCNOTTY);
...
```

DESCRIPTION

This package defines constants usually found in <termio.h> or <termios.h> (and their #include hierarchy). Find below an autogenerated alphabetic list of all known constants and whether they are defined on your system (prefixed with '+') and have compilation problems ('o'). Undefined or problematic constants are set to 'undef'.

FOR MORE INFO SEE

IO::Tty

ttyname

The name of the terminal a handle is open on, or undef.

Synopsis

```
my $name = IO::Tty::ttyname(\*STDIN);    # e.g. /dev/pts/3
```

What you get back

The name, or undef with `$!` set when the handle is not open on a terminal (or not open at all, EINVAL). Something that is not a handle dies “Bad filehandle”.

pack_winsize

A `struct winsize` as a string, for the TIOCSWINSZ `ioctl`.

Synopsis

```
my $ws = IO::Tty::pack_winsize($rows, $cols, $xpixel, $ypixel);
ioctl($tty, IO::Tty::Constant::TIOCSWINSZ(), $ws);
```

What you get back

Eight bytes, four unsigned shorts in native order; each number is taken modulo 65536, and the pixel sizes default to 0.

IO::Uncompress

Namespace containing the following modules:

- `IO::Uncompress::AnyInflate` - Uncompress zlib-based (zip, gzip) file/buffer
- `IO::Uncompress::AnyUncompress` - Uncompress gzip, zip, bzip2, zstd, xz, lzma, lzip, lzf or lzop file/buffer
- `IO::Uncompress::Base` - Base Class for IO::Uncompress modules
- `IO::Uncompress::Bunzip2` - Read bzip2 files/buffers
- `IO::Uncompress::Gunzip` - Read RFC 1952 files/buffers
- `IO::Uncompress::Inflate` - Read RFC 1950 files/buffers
- `IO::Uncompress::RawInflate` - Read RFC 1951 files/buffers
- `IO::Uncompress::Unzip` - Read zip files/buffers

IO::Uncompress::AnyInflate

Uncompress zlib-based (zip, gzip) file/buffer

SYNOPSIS

```
use IO::Uncompress::AnyInflate qw(anyinflate $AnyInflateError) ;

my $status = anyinflate $input => $output [,OPTS]
    or die "anyinflate failed: $AnyInflateError\n";

my $z = IO::Uncompress::AnyInflate->new( $input [OPTS] )
    or die "anyinflate failed: $AnyInflateError\n";

$status = $z->read($buffer)
$status = $z->read($buffer, $length)
$status = $z->read($buffer, $length, $offset)
$line = $z->getline()
$char = $z->getc()
$char = $z->ungetc()
$char = $z->opened()

$status = $z->inflateSync()

$data = $z->trailingData()
$status = $z->nextStream()
$data = $z->getHeaderInfo()
$z->tell()
$z->seek($position, $whence)
$z->binmode()
$z->fileno()
$z->eof()
$z->close()

$AnyInflateError ;

# IO::File mode

<$z>
read($z, $buffer);
read($z, $buffer, $length);
read($z, $buffer, $length, $offset);
tell($z)
seek($z, $position, $whence)
binmode($z)
fileno($z)
eof($z)
close($z)
```

DESCRIPTION

This module provides a Perl interface that allows the reading of files/buffers that have been compressed in a number of formats that use the zlib compression library.

The formats supported are

- RFC 1950
- RFC 1951 (optionally)
- gzip (RFC 1952)
- zip

The module will auto-detect which, if any, of the supported compression formats is being used.

Functional Interface

A top-level function, `anyinflate`, is provided to carry out "one-shot" uncompression between buffers and/or files. For finer control over the uncompression process, see the "OO Interface" section.

```
use IO::Uncompress::AnyInflate qw(anyinflate $AnyInflateError) ;

anyinflate $input_filename_or_reference => $output_filename_or_
 ↪reference [,OPTS]
    or die "anyinflate failed: $AnyInflateError\n";
```

The functional interface needs Perl5.005 or better.

anyinflate $input_filename_or_reference => $output_filename_or_reference [, OPTS]

`anyinflate` expects at least two parameters, `$input_filename_or_reference` and `$output_filename_or_reference` and zero or more optional parameters (see "Optional Parameters")

The `$input_filename_or_reference` parameter

The parameter, `$input_filename_or_reference`, is used to define the source of the compressed data.

It can take one of the following forms:

- A filename

  If the `$input_filename_or_reference` parameter is a simple scalar, it is assumed to be a filename. This file will be opened for reading and the input data will be read from it.

- A filehandle

  If the `$input_filename_or_reference` parameter is a filehandle, the input data will be read from it. The string '-' can be used as an alias for standard input.

- A scalar reference

  If `$input_filename_or_reference` is a scalar reference, the input data will be read from `$$input_filename_or_reference`.

- An array reference

  If `$input_filename_or_reference` is an array reference, each element in the array must be a filename.

  The input data will be read from each file in turn.

  The complete array will be walked to ensure that it only contains valid filenames before any data is uncompressed.

- An Input FileGlob string

  If `$input_filename_or_reference` is a string that is delimited by the characters "<" and ">" `anyinflate` will assume that it is an *input fileglob string*. The input is the list of files that match the fileglob.

  See *File::GlobMapper* for more details.

If the `$input_filename_or_reference` parameter is any other type, `undef` will be returned.

The `$output_filename_or_reference` parameter

The parameter `$output_filename_or_reference` is used to control the destination of the uncompressed data. This parameter can take one of these forms.

- A filename

  If the `$output_filename_or_reference` parameter is a simple scalar, it is assumed to be a filename. This file will be opened for writing and the uncompressed data will be written to it.

- A filehandle

  If the `$output_filename_or_reference` parameter is a filehandle, the uncompressed data will be written to it. The string '-' can be used as an alias for standard output.

- A scalar reference

  If `$output_filename_or_reference` is a scalar reference, the uncompressed data will be stored in `$$output_filename_or_reference`.

- An Array Reference

  If `$output_filename_or_reference` is an array reference, the uncompressed data will be pushed onto the array.

- An Output FileGlob

  If `$output_filename_or_reference` is a string that is delimited by the characters "<" and ">" `anyinflate` will assume that it is an *output fileglob string*. The output is the list of files that match the fileglob.

  When `$output_filename_or_reference` is an fileglob string, `$input_filename_or_reference` must also be a fileglob string. Anything else is an error.

See *File::GlobMapper* for more details.

If the `$output_filename_or_reference` parameter is any other type, `undef` will be returned.

Notes

When `$input_filename_or_reference` maps to multiple compressed files/buffers and `$output_filename_or_reference` is a single file/buffer, after uncompression `$output_filename_or_reference` will contain a concatenation of all the uncompressed data from each of the input files/buffers.

Optional Parameters

The optional parameters for the one-shot function `anyinflate` are (for the most part) identical to those used with the OO interface defined in the "Constructor Options" section. The exceptions are listed below

- `AutoClose => 0|1`

  This option applies to any input or output data streams to `anyinflate` that are filehandles.

  If `AutoClose` is specified, and the value is true, it will result in all input and/or output filehandles being closed once `anyinflate` has completed.

  This parameter defaults to 0.

- `BinModeOut => 0|1`

  This option is now a no-op. All files will be written in binmode.

- `Append => 0|1`

  The behaviour of this option is dependent on the type of output data stream.

  - A Buffer

    If Append is enabled, all uncompressed data will be append to the end of the output buffer. Otherwise the output buffer will be cleared before any uncompressed data is written to it.

  - A Filename

    If Append is enabled, the file will be opened in append mode. Otherwise the contents of the file, if any, will be truncated before any uncompressed data is written to it.

  - A Filehandle

    If Append is enabled, the filehandle will be positioned to the end of the file via a call to `seek` before any uncompressed data is written to it. Otherwise the file pointer will not be moved.

  When Append is specified, and set to true, it will *append* all uncompressed data to the output data stream.

  So when the output is a filehandle it will carry out a seek to the eof before writing any uncompressed data. If the output is a filename, it will be opened for appending.

If the output is a buffer, all uncompressed data will be appended to the existing buffer.

Conversely when Append is not specified, or it is present and is set to false, it will operate as follows.

When the output is a filename, it will truncate the contents of the file before writing any uncompressed data. If the output is a filehandle its position will not be changed. If the output is a buffer, it will be wiped before any uncompressed data is output.

Defaults to 0.

- `MultiStream => 0|1`

  If the input file/buffer contains multiple compressed data streams, this option will uncompress the whole lot as a single data stream.

  Defaults to 0.

- `TrailingData => $scalar`

  Returns the data, if any, that is present immediately after the compressed data stream once uncompression is complete.

  This option can be used when there is useful information immediately following the compressed data stream, and you don't know the length of the compressed data stream.

  If the input is a buffer, `trailingData` will return everything from the end of the compressed data stream to the end of the buffer.

  If the input is a filehandle, `trailingData` will return the data that is left in the filehandle input buffer once the end of the compressed data stream has been reached. You can then use the filehandle to read the rest of the input file.

  Don't bother using `trailingData` if the input is a filename.

  If you know the length of the compressed data stream before you start uncompressing, you can avoid having to use `trailingData` by setting the `InputLength` option.

OneShot Examples

To read the contents of the file `file1.txt.Compressed` and write the uncompressed data to the file `file1.txt`.

```
use strict ;
use warnings ;
use IO::Uncompress::AnyInflate qw(anyinflate $AnyInflateError) ;

my $input = "file1.txt.Compressed";
my $output = "file1.txt";
anyinflate $input => $output
    or die "anyinflate failed: $AnyInflateError\n";
```

To read from an existing Perl filehandle, `$input`, and write the uncompressed data to a buffer, `$buffer`.

```
use strict ;
use warnings ;
use IO::Uncompress::AnyInflate qw(anyinflate $AnyInflateError) ;
use IO::File ;

my $input = IO::File->new( "<file1.txt.Compressed" )
    or die "Cannot open 'file1.txt.Compressed': $!\n" ;
my $buffer ;
anyinflate $input => \$buffer
    or die "anyinflate failed: $AnyInflateError\n";
```

To uncompress all files in the directory "/my/home" that match "*.txt.Compressed" and store the compressed data in the same directory

```
use strict ;
use warnings ;
use IO::Uncompress::AnyInflate qw(anyinflate $AnyInflateError) ;

anyinflate '</my/home/*.txt.Compressed>' => '</my/home/#1.txt>'
    or die "anyinflate failed: $AnyInflateError\n";
```

and if you want to compress each file one at a time, this will do the trick

```
use strict ;
use warnings ;
use IO::Uncompress::AnyInflate qw(anyinflate $AnyInflateError) ;

for my $input ( glob "/my/home/*.txt.Compressed" )
{
    my $output = $input;
    $output =~ s/.Compressed// ;
    anyinflate $input => $output
        or die "Error compressing '$input': $AnyInflateError\n";
}
```

OO Interface

Constructor

The format of the constructor for IO::Uncompress::AnyInflate is shown below

```
my $z = IO::Uncompress::AnyInflate->new( $input [OPTS] )
    or die "IO::Uncompress::AnyInflate failed: $AnyInflateError\n";
```

The constructor takes one mandatory parameter, `$input`, defined below, and zero or more `OPTS`, defined in "Constructor Options".

Returns an `IO::Uncompress::AnyInflate` object on success and undef on failure. The variable `$AnyInflateError` will contain an error message on failure.

If you are running Perl 5.005 or better the object, `$z`, returned from IO::Uncompress::AnyInflate can be used exactly like an *IO::File* filehandle. This means that all

normal input file operations can be carried out with `$z`. For example, to read a line from a compressed file/buffer you can use either of these forms

```
$line = $z->getline();
$line = <$z>;
```

Below is a simple exaple of using the OO interface to read the compressed file `myfile.Compressed` and write its contents to stdout.

```
my $filename = "myfile.Compressed";
my $z = IO::Uncompress::AnyInflate->new($filename)
    or die "IO::Uncompress::AnyInflate failed: $AnyInflateError\n";

while (<$z>) {
    print $_;
}
$z->close();
```

See “EXAMPLES” for further examples

The mandatory parameter `$input` is used to determine the source of the compressed data. This parameter can take one of three forms.

- A filename

  If the `$input` parameter is a scalar, it is assumed to be a filename. This file will be opened for reading and the compressed data will be read from it.

- A filehandle

  If the `$input` parameter is a filehandle, the compressed data will be read from it. The string ‘-’ can be used as an alias for standard input.

- A scalar reference

  If `$input` is a scalar reference, the compressed data will be read from `$$input`.

Constructor Options

The option names defined below are case insensitive and can be optionally prefixed by a ‘-’. So all of the following are valid

```
-AutoClose
-autoclose
AUTOCLOSE
autoclose
```

OPTS is a combination of the following options:

- `AutoClose => 0|1`

  This option is only valid when the `$input` parameter is a filehandle. If specified, and the value is true, it will result in the file being closed once either the `close` method is called or the IO::Uncompress::AnyInflate object is destroyed.

  This parameter defaults to 0.

- `MultiStream => 0|1`

  Allows multiple concatenated compressed streams to be treated as a single compressed stream. Decompression will stop once either the end of the file/buffer is reached, an error is encountered (premature eof, corrupt compressed data) or the end of a stream is not immediately followed by the start of another stream.

  This parameter defaults to 0.

- `Prime => $string`

  This option will uncompress the contents of `$string` before processing the input file/buffer.

  This option can be useful when the compressed data is embedded in another file/data structure and it is not possible to work out where the compressed data begins without having to read the first few bytes. If this is the case, the uncompression can be *primed* with these bytes using this option.

- `Transparent => 0|1`

  If this option is set and the input file/buffer is not compressed data, the module will allow reading of it anyway.

  In addition, if the input file/buffer does contain compressed data and there is non-compressed data immediately following it, setting this option will make this module treat the whole file/buffer as a single data stream.

  This option defaults to 1.

- `BlockSize => $num`

  When reading the compressed input data, IO::Uncompress::AnyInflate will read it in blocks of `$num` bytes.

  This option defaults to 4096.

- `InputLength => $size`

  When present this option will limit the number of compressed bytes read from the input file/buffer to `$size`. This option can be used in the situation where there is useful data directly after the compressed data stream and you know beforehand the exact length of the compressed data stream.

  This option is mostly used when reading from a filehandle, in which case the file pointer will be left pointing to the first byte directly after the compressed data stream.

  This option defaults to off.

- `Append => 0|1`

  This option controls what the `read` method does with uncompressed data.

  If set to 1, all uncompressed data will be appended to the output parameter of the `read` method.

  If set to 0, the contents of the output parameter of the `read` method will be overwritten by the uncompressed data.

  Defaults to 0.

- `Strict => 0|1`

  This option controls whether the extra checks defined below are used when carrying out the decompression. When Strict is on, the extra tests are carried out, when Strict is off they are not.

  The default for this option is off.

  If the input is an RFC 1950 data stream, the following will be checked:

  1. The ADLER32 checksum field must be present.
  2. The value of the ADLER32 field read must match the adler32 value of the uncompressed data actually contained in the file.

  If the input is a gzip (RFC 1952) data stream, the following will be checked:

  1. If the FHCRC bit is set in the gzip FLG header byte, the CRC16 bytes in the header must match the crc16 value of the gzip header actually read.
  2. If the gzip header contains a name field (FNAME) it consists solely of ISO 8859-1 characters.
  3. If the gzip header contains a comment field (FCOMMENT) it consists solely of ISO 8859-1 characters plus line-feed.
  4. If the gzip FEXTRA header field is present it must conform to the sub-field structure as defined in RFC 1952.
  5. The CRC32 and ISIZE trailer fields must be present.
  6. The value of the CRC32 field read must match the crc32 value of the uncompressed data actually contained in the gzip file.
  7. The value of the ISIZE fields read must match the length of the uncompressed data actually read from the file.

- `RawInflate => 0|1`

  When auto-detecting the compressed format, try to test for raw-deflate (RFC 1951) content using the `IO::Uncompress::RawInflate` module.

  The reason this is not default behaviour is because RFC 1951 content can only be detected by attempting to uncompress it. This process is error prone and can result is false positives.

  Defaults to 0.

- `ParseExtra => 0|1` If the gzip FEXTRA header field is present and this option is set, it will force the module to check that it conforms to the sub-field structure as defined in RFC 1952.

  If the `Strict` is on it will automatically enable this option.

  Defaults to 0.

Methods

read

Usage is

```
$status = $z->read($buffer)
```

Reads a block of compressed data (the size of the compressed block is determined by the `Buffer` option in the constructor), uncompresses it and writes any uncompressed data into `$buffer`. If the `Append` parameter is set in the constructor, the uncompressed data will be appended to the `$buffer` parameter. Otherwise `$buffer` will be overwritten.

Returns the number of uncompressed bytes written to `$buffer`, zero if eof or a negative number on error.

read

Usage is

```
$status = $z->read($buffer, $length)
$status = $z->read($buffer, $length, $offset)

$status = read($z, $buffer, $length)
$status = read($z, $buffer, $length, $offset)
```

Attempt to read `$length` bytes of uncompressed data into `$buffer`.

The main difference between this form of the `read` method and the previous one, is that this one will attempt to return *exactly* `$length` bytes. The only circumstances that this function will not is if end-of-file or an IO error is encountered.

Returns the number of uncompressed bytes written to `$buffer`, zero if eof or a negative number on error.

getline

Usage is

```
$line = $z->getline()
$line = <$z>
```

Reads a single line.

This method fully supports the use of the variable `$/` (or `$INPUT_RECORD_SEPARATOR` or `$RS` when `English` is in use) to determine what constitutes an end of line. Paragraph mode, record mode and file slurp mode are all supported.

getc

Usage is

```
$char = $z->getc()
```

Read a single character.

ungetc

Usage is

```
$char = $z->ungetc($string)
```

inflateSync

Usage is

```
$status = $z->inflateSync()
```

TODO

getHeaderInfo

Usage is

```
$hdr  = $z->getHeaderInfo();
@hdrs = $z->getHeaderInfo();
```

This method returns either a hash reference (in scalar context) or a list or hash references (in array context) that contains information about each of the header fields in the compressed data stream(s).

tell

Usage is

```
$z->tell()
tell $z
```

Returns the uncompressed file offset.

eof

Usage is

```
$z->eof();
eof($z);
```

Returns true if the end of the compressed input stream has been reached.

seek

```
$z->seek($position, $whence);
seek($z, $position, $whence);
```

Provides a sub-set of the `seek` functionality, with the restriction that it is only legal to seek forward in the input file/buffer. It is a fatal error to attempt to seek backward.

Note that the implementation of `seek` in this module does not provide true random access to a compressed file/buffer. It works by uncompressing data from the current offset in the file/buffer until it reaches the uncompressed offset specified in the parameters to `seek`. For very small files this may be acceptable behaviour. For large files it may cause an unacceptable delay.

The `$whence` parameter takes one the usual values, namely SEEK_SET, SEEK_CUR or SEEK_END.

Returns 1 on success, 0 on failure.

binmode

Usage is

```
$z->binmode
binmode $z ;
```

This is a noop provided for completeness.

opened

```
$z->opened()
```

Returns true if the object currently refers to a opened file/buffer.

autoflush

```
my $prev = $z->autoflush()
my $prev = $z->autoflush(EXPR)
```

If the `$z` object is associated with a file or a filehandle, this method returns the current autoflush setting for the underlying filehandle. If `EXPR` is present, and is non-zero, it will enable flushing after every write/print operation.

If `$z` is associated with a buffer, this method has no effect and always returns `undef`.

Note that the special variable `$|` **cannot** be used to set or retrieve the autoflush setting.

input_line_number

```
$z->input_line_number()
$z->input_line_number(EXPR)
```

Returns the current uncompressed line number. If `EXPR` is present it has the effect of setting the line number. Note that setting the line number does not change the current position within the file/buffer being read.

The contents of `$/` are used to determine what constitutes a line terminator.

fileno

```
$z->fileno()
fileno($z)
```

If the `$z` object is associated with a file or a filehandle, `fileno` will return the underlying file descriptor. Once the `close` method is called `fileno` will return `undef`.

If the `$z` object is associated with a buffer, this method will return `undef`.

close

```
$z->close() ;
close $z ;
```

Closes the output file/buffer.

For most versions of Perl this method will be automatically invoked if the IO::Uncompress::AnyInflate object is destroyed (either explicitly or by the variable with the reference to the object going out of scope). The exceptions are Perl versions 5.005 through 5.00504 and 5.8.0. In these cases, the `close` method will be called automatically, but not until global destruction of all live objects when the program is terminating.

Therefore, if you want your scripts to be able to run on all versions of Perl, you should call `close` explicitly and not rely on automatic closing.

Returns true on success, otherwise 0.

If the `AutoClose` option has been enabled when the IO::Uncompress::AnyInflate object was created, and the object is associated with a file, the underlying file will also be closed.

nextStream

Usage is

```
my $status = $z->nextStream();
```

Skips to the next compressed data stream in the input file/buffer. If a new compressed data stream is found, the eof marker will be cleared and `$.` will be reset to 0.

Returns 1 if a new stream was found, 0 if none was found, and -1 if an error was encountered.

trailingData

Usage is

```
my $data = $z->trailingData();
```

Returns the data, if any, that is present immediately after the compressed data stream once uncompression is complete. It only makes sense to call this method once the end of the compressed data stream has been encountered.

This option can be used when there is useful information immediately following the compressed data stream, and you don't know the length of the compressed data stream.

If the input is a buffer, `trailingData` will return everything from the end of the compressed data stream to the end of the buffer.

If the input is a filehandle, `trailingData` will return the data that is left in the filehandle input buffer once the end of the compressed data stream has been reached. You can then use the filehandle to read the rest of the input file.

Don't bother using `trailingData` if the input is a filename.

If you know the length of the compressed data stream before you start uncompressing, you can avoid having to use `trailingData` by setting the `InputLength` option in the constructor.

Importing

No symbolic constants are required by IO::Uncompress::AnyInflate at present.

- :all

  Imports `anyinflate` and `$AnyInflateError`. Same as doing this

```
use IO::Uncompress::AnyInflate qw(anyinflate $AnyInflateError) ;
```

EXAMPLES

Working with Net::FTP

See IO::Compress::FAQ

SUPPORT

General feedback/questions/bug reports should be sent to https://github.com/pmqs/IO-Compress/issues (preferred) or https://rt.cpan.org/Public/Dist/Display.html?Name=IO-Compress.

IO::Uncompress::AnyUncompress

Uncompress gzip, zip, bzip2, zstd, xz, lzma, lzip, lzf or lzop file/buffer

SYNOPSIS

```
use IO::Uncompress::AnyUncompress qw(anyuncompress
 ↪$AnyUncompressError) ;

my $status = anyuncompress $input => $output [,OPTS]
    or die "anyuncompress failed: $AnyUncompressError\n";

my $z = IO::Uncompress::AnyUncompress->new( $input [OPTS] )
    or die "anyuncompress failed: $AnyUncompressError\n";

$status = $z->read($buffer)
$status = $z->read($buffer, $length)
$status = $z->read($buffer, $length, $offset)
$line = $z->getline()
$char = $z->getc()
$char = $z->ungetc()
$char = $z->opened()

$data = $z->trailingData()
$status = $z->nextStream()
$data = $z->getHeaderInfo()
$z->tell()
$z->seek($position, $whence)
$z->binmode()
$z->fileno()
```

(continues on next page)

(continued from previous page)

```
$z->eof()
$z->close()

$AnyUncompressError ;

# IO::File mode

<$z>
read($z, $buffer);
read($z, $buffer, $length);
read($z, $buffer, $length, $offset);
tell($z)
seek($z, $position, $whence)
binmode($z)
fileno($z)
eof($z)
close($z)
```

DESCRIPTION

This module provides a Perl interface that allows the reading of files/buffers that have been compressed with a variety of compression libraries.

The formats supported are:

- RFC 1950
- RFC 1951 (optionally)
- gzip (RFC 1952)
- zip
- zstd (Zstandard)
- bzip2
- lzop
- lzf
- lzma
- lzip
- xz

The module will auto-detect which, if any, of the supported compression formats is being used.

Functional Interface

A top-level function, `anyuncompress`, is provided to carry out "one-shot" uncompression between buffers and/or files. For finer control over the uncompression process, see the "OO Interface" section.

```
use IO::Uncompress::AnyUncompress qw(anyuncompress
 ↪$AnyUncompressError) ;

anyuncompress $input_filename_or_reference => $output_filename_or_
 ↪reference [,OPTS]
    or die "anyuncompress failed: $AnyUncompressError\n";
```

The functional interface needs Perl5.005 or better.

anyuncompress $input_filename_or_reference => $output_filename_or_reference [, OPTS]

anyuncompress expects at least two parameters, `$input_filename_or_reference` and `$output_filename_or_reference` and zero or more optional parameters (see "Optional Parameters")

The `$input_filename_or_reference` parameter

The parameter, `$input_filename_or_reference`, is used to define the source of the compressed data.

It can take one of the following forms:

- A filename

  If the `$input_filename_or_reference` parameter is a simple scalar, it is assumed to be a filename. This file will be opened for reading and the input data will be read from it.

- A filehandle

  If the `$input_filename_or_reference` parameter is a filehandle, the input data will be read from it. The string '-' can be used as an alias for standard input.

- A scalar reference

  If `$input_filename_or_reference` is a scalar reference, the input data will be read from `$$input_filename_or_reference`.

- An array reference

  If `$input_filename_or_reference` is an array reference, each element in the array must be a filename.

  The input data will be read from each file in turn.

  The complete array will be walked to ensure that it only contains valid filenames before any data is uncompressed.

- An Input FileGlob string

  If `$input_filename_or_reference` is a string that is delimited by the characters "<" and ">" anyuncompress will assume that it is an *input fileglob string*. The input is the list of files that match the fileglob.

  See *File::GlobMapper* for more details.

If the `$input_filename_or_reference` parameter is any other type, `undef` will be returned.

The `$output_filename_or_reference` parameter

The parameter `$output_filename_or_reference` is used to control the destination of the uncompressed data. This parameter can take one of these forms.

- A filename

  If the `$output_filename_or_reference` parameter is a simple scalar, it is assumed to be a filename. This file will be opened for writing and the uncompressed data will be written to it.

- A filehandle

  If the `$output_filename_or_reference` parameter is a filehandle, the uncompressed data will be written to it. The string '-' can be used as an alias for standard output.

- A scalar reference

  If `$output_filename_or_reference` is a scalar reference, the uncompressed data will be stored in `$$output_filename_or_reference`.

- An Array Reference

  If `$output_filename_or_reference` is an array reference, the uncompressed data will be pushed onto the array.

- An Output FileGlob

  If `$output_filename_or_reference` is a string that is delimited by the characters "<" and ">" `anyuncompress` will assume that it is an *output fileglob string*. The output is the list of files that match the fileglob.

  When `$output_filename_or_reference` is an fileglob string, `$input_filename_or_reference` must also be a fileglob string. Anything else is an error.

  See *File::GlobMapper* for more details.

If the `$output_filename_or_reference` parameter is any other type, `undef` will be returned.

Notes

When `$input_filename_or_reference` maps to multiple compressed files/buffers and `$output_filename_or_reference` is a single file/buffer, after uncompression `$output_filename_or_reference` will contain a concatenation of all the uncompressed data from each of the input files/buffers.

Optional Parameters

The optional parameters for the one-shot function `anyuncompress` are (for the most part) identical to those used with the OO interface defined in the "Constructor Options" section. The exceptions are listed below

- `AutoClose => 0|1`

  This option applies to any input or output data streams to anyuncompress that are filehandles.

  If `AutoClose` is specified, and the value is true, it will result in all input and/or output filehandles being closed once anyuncompress has completed.

  This parameter defaults to 0.

- `BinModeOut => 0|1`

  This option is now a no-op. All files will be written in binmode.

- `Append => 0|1`

  The behaviour of this option is dependent on the type of output data stream.

  - A Buffer

    If Append is enabled, all uncompressed data will be append to the end of the output buffer. Otherwise the output buffer will be cleared before any uncompressed data is written to it.

  - A Filename

    If Append is enabled, the file will be opened in append mode. Otherwise the contents of the file, if any, will be truncated before any uncompressed data is written to it.

  - A Filehandle

    If Append is enabled, the filehandle will be positioned to the end of the file via a call to `seek` before any uncompressed data is written to it. Otherwise the file pointer will not be moved.

  When Append is specified, and set to true, it will *append* all uncompressed data to the output data stream.

  So when the output is a filehandle it will carry out a seek to the eof before writing any uncompressed data. If the output is a filename, it will be opened for appending. If the output is a buffer, all uncompressed data will be appended to the existing buffer.

  Conversely when Append is not specified, or it is present and is set to false, it will operate as follows.

  When the output is a filename, it will truncate the contents of the file before writing any uncompressed data. If the output is a filehandle its position will not be changed. If the output is a buffer, it will be wiped before any uncompressed data is output.

  Defaults to 0.

- `MultiStream => 0|1`

  If the input file/buffer contains multiple compressed data streams, this option will uncompress the whole lot as a single data stream.

  Defaults to 0.

- `TrailingData => $scalar`

  Returns the data, if any, that is present immediately after the compressed data stream once uncompression is complete.

  This option can be used when there is useful information immediately following the compressed data stream, and you don't know the length of the compressed data stream.

  If the input is a buffer, `trailingData` will return everything from the end of the compressed data stream to the end of the buffer.

  If the input is a filehandle, `trailingData` will return the data that is left in the filehandle input buffer once the end of the compressed data stream has been reached. You can then use the filehandle to read the rest of the input file.

  Don't bother using `trailingData` if the input is a filename.

  If you know the length of the compressed data stream before you start uncompressing, you can avoid having to use `trailingData` by setting the `InputLength` option.

OneShot Examples

To read the contents of the file `file1.txt.Compressed` and write the uncompressed data to the file `file1.txt`.

```
use strict ;
use warnings ;
use IO::Uncompress::AnyUncompress qw(anyuncompress
 ↪$AnyUncompressError) ;

my $input = "file1.txt.Compressed";
my $output = "file1.txt";
anyuncompress $input => $output
    or die "anyuncompress failed: $AnyUncompressError\n";
```

To read from an existing Perl filehandle, `$input`, and write the uncompressed data to a buffer, `$buffer`.

```
use strict ;
use warnings ;
use IO::Uncompress::AnyUncompress qw(anyuncompress
 ↪$AnyUncompressError) ;
use IO::File ;

my $input = IO::File->new( "<file1.txt.Compressed" )
    or die "Cannot open 'file1.txt.Compressed': $!\n" ;
my $buffer ;
anyuncompress $input => \$buffer
    or die "anyuncompress failed: $AnyUncompressError\n";
```

To uncompress all files in the directory "/my/home" that match "*.txt.Compressed" and store the compressed data in the same directory

```
use strict ;
use warnings ;
use IO::Uncompress::AnyUncompress qw(anyuncompress
 ↪$AnyUncompressError) ;

anyuncompress '</my/home/*.txt.Compressed>' => '</my/home/#1.txt>'
    or die "anyuncompress failed: $AnyUncompressError\n";
```

and if you want to compress each file one at a time, this will do the trick

```
use strict ;
use warnings ;
use IO::Uncompress::AnyUncompress qw(anyuncompress
 ↪$AnyUncompressError) ;

for my $input ( glob "/my/home/*.txt.Compressed" )
{
    my $output = $input;
    $output =~ s/.Compressed// ;
    anyuncompress $input => $output
        or die "Error compressing '$input': $AnyUncompressError\n";
}
```

OO Interface

Constructor

The format of the constructor for IO::Uncompress::AnyUncompress is shown below

```
my $z = IO::Uncompress::AnyUncompress->new( $input [OPTS] )
    or die "IO::Uncompress::AnyUncompress failed:
 ↪$AnyUncompressError\n";
```

The constructor takes one mandatory parameter, `$input`, defined below, and zero or more `OPTS`, defined in “Constructor Options”.

Returns an `IO::Uncompress::AnyUncompress` object on success and undef on failure. The variable `$AnyUncompressError` will contain an error message on failure.

If you are running Perl 5.005 or better the object, `$z`, returned from IO::Uncompress::AnyUncompress can be used exactly like an *IO::File* filehandle. This means that all normal input file operations can be carried out with `$z`. For example, to read a line from a compressed file/buffer you can use either of these forms

```
$line = $z->getline();
$line = <$z>;
```

Below is a simple exaple of using the OO interface to read the compressed file `myfile.Compressed` and write its contents to stdout.

```
my $filename = "myfile.Compressed";
my $z = IO::Uncompress::AnyUncompress->new($filename)
    or die "IO::Uncompress::AnyUncompress failed:
 ↪$AnyUncompressError\n";

while (<$z>) {
    print $_;
}
$z->close();
```

See “EXAMPLES” for further examples

The mandatory parameter `$input` is used to determine the source of the compressed data. This parameter can take one of three forms.

- A filename

  If the `$input` parameter is a scalar, it is assumed to be a filename. This file will be opened for reading and the compressed data will be read from it.

- A filehandle

  If the `$input` parameter is a filehandle, the compressed data will be read from it. The string ‘-’ can be used as an alias for standard input.

- A scalar reference

  If `$input` is a scalar reference, the compressed data will be read from `$$input`.

Constructor Options

The option names defined below are case insensitive and can be optionally prefixed by a ‘-’. So all of the following are valid

```
-AutoClose
-autoclose
AUTOCLOSE
autoclose
```

OPTS is a combination of the following options:

- `AutoClose => 0|1`

  This option is only valid when the `$input` parameter is a filehandle. If specified, and the value is true, it will result in the file being closed once either the `close` method is called or the IO::Uncompress::AnyUncompress object is destroyed.

  This parameter defaults to 0.

- `MultiStream => 0|1`

  Allows multiple concatenated compressed streams to be treated as a single compressed stream. Decompression will stop once either the end of the file/buffer is reached, an error is encountered (premature eof, corrupt compressed data) or the end of a stream is not immediately followed by the start of another stream.

  This parameter defaults to 0.

- `Prime => $string`

  This option will uncompress the contents of `$string` before processing the input file/buffer.

  This option can be useful when the compressed data is embedded in another file/data structure and it is not possible to work out where the compressed data begins without having to read the first few bytes. If this is the case, the uncompression can be *primed* with these bytes using this option.

- `Transparent => 0|1`

  If this option is set and the input file/buffer is not compressed data, the module will allow reading of it anyway.

  In addition, if the input file/buffer does contain compressed data and there is non-compressed data immediately following it, setting this option will make this module treat the whole file/buffer as a single data stream.

  This option defaults to 1.

- `BlockSize => $num`

  When reading the compressed input data, IO::Uncompress::AnyUncompress will read it in blocks of `$num` bytes.

  This option defaults to 4096.

- `InputLength => $size`

  When present this option will limit the number of compressed bytes read from the input file/buffer to `$size`. This option can be used in the situation where there is useful data directly after the compressed data stream and you know beforehand the exact length of the compressed data stream.

  This option is mostly used when reading from a filehandle, in which case the file pointer will be left pointing to the first byte directly after the compressed data stream.

  This option defaults to off.

- `Append => 0|1`

  This option controls what the `read` method does with uncompressed data.

  If set to 1, all uncompressed data will be appended to the output parameter of the `read` method.

  If set to 0, the contents of the output parameter of the `read` method will be overwritten by the uncompressed data.

  Defaults to 0.

- `Strict => 0|1`

  This option controls whether the extra checks defined below are used when carrying out the decompression. When Strict is on, the extra tests are carried out, when Strict is off they are not.

  The default for this option is off.

- `RawInflate => 0|1`

  When auto-detecting the compressed format, try to test for raw-deflate (RFC 1951) content using the `IO::Uncompress::RawInflate` module.

  The reason this is not default behaviour is because RFC 1951 content can only be detected by attempting to uncompress it. This process is error prone and can result is false positives.

  Defaults to 0.

- `UnLzma => 0|1`

  When auto-detecting the compressed format, try to test for lzma_alone content using the `IO::Uncompress::UnLzma` module.

  The reason this is not default behaviour is because lzma_alone content can only be detected by attempting to uncompress it. This process is error prone and can result is false positives.

  Defaults to 0.

Methods

read

Usage is

```
$status = $z->read($buffer)
```

Reads a block of compressed data (the size of the compressed block is determined by the `Buffer` option in the constructor), uncompresses it and writes any uncompressed data into `$buffer`. If the Append parameter is set in the constructor, the uncompressed data will be appended to the `$buffer` parameter. Otherwise `$buffer` will be overwritten.

Returns the number of uncompressed bytes written to `$buffer`, zero if eof or a negative number on error.

read

Usage is

```
$status = $z->read($buffer, $length)
$status = $z->read($buffer, $length, $offset)

$status = read($z, $buffer, $length)
$status = read($z, $buffer, $length, $offset)
```

Attempt to read `$length` bytes of uncompressed data into `$buffer`.

The main difference between this form of the `read` method and the previous one, is that this one will attempt to return *exactly* `$length` bytes. The only circumstances that this function will not is if end-of-file or an IO error is encountered.

Returns the number of uncompressed bytes written to `$buffer`, zero if eof or a negative number on error.

getline

Usage is

```
$line = $z->getline()
$line = <$z>
```

Reads a single line.

This method fully supports the use of the variable `$/` (or `$INPUT_RECORD_SEPARATOR` or `$RS` when `English` is in use) to determine what constitutes an end of line. Paragraph mode, record mode and file slurp mode are all supported.

getc

Usage is

```
$char = $z->getc()
```

Read a single character.

ungetc

Usage is

```
$char = $z->ungetc($string)
```

getHeaderInfo

Usage is

```
$hdr  = $z->getHeaderInfo();
@hdrs = $z->getHeaderInfo();
```

This method returns either a hash reference (in scalar context) or a list or hash references (in array context) that contains information about each of the header fields in the compressed data stream(s).

tell

Usage is

```
$z->tell()
tell $z
```

Returns the uncompressed file offset.

eof

Usage is

```
$z->eof();
eof($z);
```

Returns true if the end of the compressed input stream has been reached.

seek

```
$z->seek($position, $whence);
seek($z, $position, $whence);
```

Provides a sub-set of the `seek` functionality, with the restriction that it is only legal to seek forward in the input file/buffer. It is a fatal error to attempt to seek backward.

Note that the implementation of `seek` in this module does not provide true random access to a compressed file/buffer. It works by uncompressing data from the current offset in the file/buffer until it reaches the uncompressed offset specified in the parameters to `seek`. For very small files this may be acceptable behaviour. For large files it may cause an unacceptable delay.

The `$whence` parameter takes one the usual values, namely SEEK_SET, SEEK_CUR or SEEK_END.

Returns 1 on success, 0 on failure.

binmode

Usage is

```
$z->binmode
binmode $z ;
```

This is a noop provided for completeness.

opened

```
$z->opened()
```

Returns true if the object currently refers to a opened file/buffer.

autoflush

```
my $prev = $z->autoflush()
my $prev = $z->autoflush(EXPR)
```

If the `$z` object is associated with a file or a filehandle, this method returns the current autoflush setting for the underlying filehandle. If `EXPR` is present, and is non-zero, it will enable flushing after every write/print operation.

If `$z` is associated with a buffer, this method has no effect and always returns `undef`.

Note that the special variable `$|` **cannot** be used to set or retrieve the autoflush setting.

input_line_number

```
$z->input_line_number()
$z->input_line_number(EXPR)
```

Returns the current uncompressed line number. If `EXPR` is present it has the effect of setting the line number. Note that setting the line number does not change the current position within the file/buffer being read.

The contents of `$/` are used to determine what constitutes a line terminator.

fileno

```
$z->fileno()
fileno($z)
```

If the `$z` object is associated with a file or a filehandle, `fileno` will return the underlying file descriptor. Once the `close` method is called `fileno` will return `undef`.

If the `$z` object is associated with a buffer, this method will return `undef`.

close

```
$z->close() ;
close $z ;
```

Closes the output file/buffer.

For most versions of Perl this method will be automatically invoked if the IO::Uncompress::AnyUncompress object is destroyed (either explicitly or by the variable with the reference to the object going out of scope). The exceptions are Perl versions 5.005 through 5.00504 and 5.8.0. In these cases, the `close` method will be called automatically, but not until global destruction of all live objects when the program is terminating.

Therefore, if you want your scripts to be able to run on all versions of Perl, you should call `close` explicitly and not rely on automatic closing.

Returns true on success, otherwise 0.

If the `AutoClose` option has been enabled when the IO::Uncompress::AnyUncompress object was created, and the object is associated with a file, the underlying file will also be closed.

nextStream

Usage is

```
my $status = $z->nextStream();
```

Skips to the next compressed data stream in the input file/buffer. If a new compressed data stream is found, the eof marker will be cleared and `$.` will be reset to 0.

Returns 1 if a new stream was found, 0 if none was found, and -1 if an error was encountered.

trailingData

Usage is

```
my $data = $z->trailingData();
```

Returns the data, if any, that is present immediately after the compressed data stream once uncompression is complete. It only makes sense to call this method once the end of the compressed data stream has been encountered.

This option can be used when there is useful information immediately following the compressed data stream, and you don't know the length of the compressed data stream.

If the input is a buffer, `trailingData` will return everything from the end of the compressed data stream to the end of the buffer.

If the input is a filehandle, `trailingData` will return the data that is left in the filehandle input buffer once the end of the compressed data stream has been reached. You can then use the filehandle to read the rest of the input file.

Don't bother using `trailingData` if the input is a filename.

If you know the length of the compressed data stream before you start uncompressing, you can avoid having to use `trailingData` by setting the `InputLength` option in the constructor.

Importing

No symbolic constants are required by IO::Uncompress::AnyUncompress at present.

- :all

  Imports `anyuncompress` and `$AnyUncompressError`. Same as doing this

  ```
  use IO::Uncompress::AnyUncompress qw(anyuncompress
  ↪$AnyUncompressError) ;
  ```

IO::Uncompress::Bunzip2

Read bzip2 files/buffers

SYNOPSIS

```
use IO::Uncompress::Bunzip2 qw(bunzip2 $Bunzip2Error) ;

my $status = bunzip2 $input => $output [,OPTS]
    or die "bunzip2 failed: $Bunzip2Error\n";

my $z = IO::Uncompress::Bunzip2->new( $input [OPTS] )
    or die "bunzip2 failed: $Bunzip2Error\n";

$status = $z->read($buffer)
$status = $z->read($buffer, $length)
$status = $z->read($buffer, $length, $offset)
$line = $z->getline()
$char = $z->getc()
$char = $z->ungetc()
$char = $z->opened()
```

(continues on next page)

(continued from previous page)

```
$data = $z->trailingData()
$status = $z->nextStream()
$data = $z->getHeaderInfo()
$z->tell()
$z->seek($position, $whence)
$z->binmode()
$z->fileno()
$z->eof()
$z->close()

$Bunzip2Error ;

# IO::File mode

<$z>
read($z, $buffer);
read($z, $buffer, $length);
read($z, $buffer, $length, $offset);
tell($z)
seek($z, $position, $whence)
binmode($z)
fileno($z)
eof($z)
close($z)
```

DESCRIPTION

This module provides a Perl interface that allows the reading of bzip2 files/buffers.

For writing bzip2 files/buffers, see the companion module IO::Compress::Bzip2.

Functional Interface

A top-level function, bunzip2, is provided to carry out "one-shot" uncompression between buffers and/or files. For finer control over the uncompression process, see the "OO Interface" section.

```
use IO::Uncompress::Bunzip2 qw(bunzip2 $Bunzip2Error) ;

bunzip2 $input_filename_or_reference => $output_filename_or_
 ↪reference [,OPTS]
    or die "bunzip2 failed: $Bunzip2Error\n";
```

The functional interface needs Perl5.005 or better.

bunzip2 $input_filename_or_reference => $output_filename_or_reference [, OPTS]

bunzip2 expects at least two parameters, `$input_filename_or_reference` and `$output_filename_or_reference` and zero or more optional parameters (see "Optional Parameters")

The `$input_filename_or_reference` parameter

The parameter, `$input_filename_or_reference`, is used to define the source of the compressed data.

It can take one of the following forms:

- A filename

  If the `$input_filename_or_reference` parameter is a simple scalar, it is assumed to be a filename. This file will be opened for reading and the input data will be read from it.

- A filehandle

  If the `$input_filename_or_reference` parameter is a filehandle, the input data will be read from it. The string '-' can be used as an alias for standard input.

- A scalar reference

  If `$input_filename_or_reference` is a scalar reference, the input data will be read from `$$input_filename_or_reference`.

- An array reference

  If `$input_filename_or_reference` is an array reference, each element in the array must be a filename.

  The input data will be read from each file in turn.

  The complete array will be walked to ensure that it only contains valid filenames before any data is uncompressed.

- An Input FileGlob string

  If `$input_filename_or_reference` is a string that is delimited by the characters "<" and ">" bunzip2 will assume that it is an *input fileglob string*. The input is the list of files that match the fileglob.

  See *File::GlobMapper* for more details.

If the `$input_filename_or_reference` parameter is any other type, `undef` will be returned.

The `$output_filename_or_reference` parameter

The parameter `$output_filename_or_reference` is used to control the destination of the uncompressed data. This parameter can take one of these forms.

- A filename

  If the `$output_filename_or_reference` parameter is a simple scalar, it is assumed to be a filename. This file will be opened for writing and the uncompressed data will be written to it.

- A filehandle

  If the `$output_filename_or_reference` parameter is a filehandle, the uncompressed data will be written to it. The string '-' can be used as an alias for standard output.

- A scalar reference

  If `$output_filename_or_reference` is a scalar reference, the uncompressed data will be stored in `$$output_filename_or_reference`.

- An Array Reference

  If `$output_filename_or_reference` is an array reference, the uncompressed data will be pushed onto the array.

- An Output FileGlob

  If `$output_filename_or_reference` is a string that is delimited by the characters "<" and ">" `bunzip2` will assume that it is an *output fileglob string*. The output is the list of files that match the fileglob.

  When `$output_filename_or_reference` is an fileglob string, `$input_filename_or_reference` must also be a fileglob string. Anything else is an error.

  See *File::GlobMapper* for more details.

If the `$output_filename_or_reference` parameter is any other type, `undef` will be returned.

Notes

When `$input_filename_or_reference` maps to multiple compressed files/buffers and `$output_filename_or_reference` is a single file/buffer, after uncompression `$output_filename_or_reference` will contain a concatenation of all the uncompressed data from each of the input files/buffers.

Optional Parameters

The optional parameters for the one-shot function `bunzip2` are (for the most part) identical to those used with the OO interface defined in the "Constructor Options" section. The exceptions are listed below

- `AutoClose => 0|1`

  This option applies to any input or output data streams to `bunzip2` that are filehandles.

  If `AutoClose` is specified, and the value is true, it will result in all input and/or output filehandles being closed once `bunzip2` has completed.

  This parameter defaults to 0.

- `BinModeOut => 0|1`

  This option is now a no-op. All files will be written in binmode.

- `Append => 0|1`

  The behaviour of this option is dependent on the type of output data stream.

- A Buffer

  If Append is enabled, all uncompressed data will be append to the end of the output buffer. Otherwise the output buffer will be cleared before any uncompressed data is written to it.

- A Filename

  If Append is enabled, the file will be opened in append mode. Otherwise the contents of the file, if any, will be truncated before any uncompressed data is written to it.

- A Filehandle

  If Append is enabled, the filehandle will be positioned to the end of the file via a call to `seek` before any uncompressed data is written to it. Otherwise the file pointer will not be moved.

When Append is specified, and set to true, it will *append* all uncompressed data to the output data stream.

So when the output is a filehandle it will carry out a seek to the eof before writing any uncompressed data. If the output is a filename, it will be opened for appending. If the output is a buffer, all uncompressed data will be appended to the existing buffer.

Conversely when Append is not specified, or it is present and is set to false, it will operate as follows.

When the output is a filename, it will truncate the contents of the file before writing any uncompressed data. If the output is a filehandle its position will not be changed. If the output is a buffer, it will be wiped before any uncompressed data is output.

Defaults to 0.

- `MultiStream => 0|1`

  If the input file/buffer contains multiple compressed data streams, this option will uncompress the whole lot as a single data stream.

  Defaults to 0.

- `TrailingData => $scalar`

  Returns the data, if any, that is present immediately after the compressed data stream once uncompression is complete.

  This option can be used when there is useful information immediately following the compressed data stream, and you don't know the length of the compressed data stream.

  If the input is a buffer, `trailingData` will return everything from the end of the compressed data stream to the end of the buffer.

  If the input is a filehandle, `trailingData` will return the data that is left in the filehandle input buffer once the end of the compressed data stream has been reached. You can then use the filehandle to read the rest of the input file.

  Don't bother using `trailingData` if the input is a filename.

If you know the length of the compressed data stream before you start uncompressing, you can avoid having to use `trailingData` by setting the `InputLength` option.

OneShot Examples

To read the contents of the file `file1.txt.bz2` and write the uncompressed data to the file `file1.txt`.

```
use strict ;
use warnings ;
use IO::Uncompress::Bunzip2 qw(bunzip2 $Bunzip2Error) ;

my $input = "file1.txt.bz2";
my $output = "file1.txt";
bunzip2 $input => $output
    or die "bunzip2 failed: $Bunzip2Error\n";
```

To read from an existing Perl filehandle, `$input`, and write the uncompressed data to a buffer, `$buffer`.

```
use strict ;
use warnings ;
use IO::Uncompress::Bunzip2 qw(bunzip2 $Bunzip2Error) ;
use IO::File ;

my $input = IO::File->new( "<file1.txt.bz2" )
    or die "Cannot open 'file1.txt.bz2': $!\n" ;
my $buffer ;
bunzip2 $input => \$buffer
    or die "bunzip2 failed: $Bunzip2Error\n";
```

To uncompress all files in the directory "/my/home" that match "*.txt.bz2" and store the compressed data in the same directory

```
use strict ;
use warnings ;
use IO::Uncompress::Bunzip2 qw(bunzip2 $Bunzip2Error) ;

bunzip2 '</my/home/*.txt.bz2>' => '</my/home/#1.txt>'
    or die "bunzip2 failed: $Bunzip2Error\n";
```

and if you want to compress each file one at a time, this will do the trick

```
use strict ;
use warnings ;
use IO::Uncompress::Bunzip2 qw(bunzip2 $Bunzip2Error) ;

for my $input ( glob "/my/home/*.txt.bz2" )
{
    my $output = $input;
```

(continues on next page)

(continued from previous page)

```
    $output =~ s/.bz2// ;
    bunzip2 $input => $output
        or die "Error compressing '$input': $Bunzip2Error\n";
}
```

OO Interface

Constructor

The format of the constructor for IO::Uncompress::Bunzip2 is shown below

```
my $z = IO::Uncompress::Bunzip2->new( $input [OPTS] )
    or die "IO::Uncompress::Bunzip2 failed: $Bunzip2Error\n";
```

The constructor takes one mandatory parameter, `$input`, defined below, and zero or more `OPTS`, defined in "Constructor Options".

Returns an `IO::Uncompress::Bunzip2` object on success and undef on failure. The variable `$Bunzip2Error` will contain an error message on failure.

If you are running Perl 5.005 or better the object, `$z`, returned from IO::Uncompress::Bunzip2 can be used exactly like an *IO::File* filehandle. This means that all normal input file operations can be carried out with `$z`. For example, to read a line from a compressed file/buffer you can use either of these forms

```
$line = $z->getline();
$line = <$z>;
```

Below is a simple exaple of using the OO interface to read the compressed file `myfile.bz2` and write its contents to stdout.

```
my $filename = "myfile.bz2";
my $z = IO::Uncompress::Bunzip2->new($filename)
    or die "IO::Uncompress::Bunzip2 failed: $Bunzip2Error\n";

while (<$z>) {
    print $_;
}
$z->close();
```

See "EXAMPLES" for further examples

The mandatory parameter `$input` is used to determine the source of the compressed data. This parameter can take one of three forms.

- A filename

  If the `$input` parameter is a scalar, it is assumed to be a filename. This file will be opened for reading and the compressed data will be read from it.

- A filehandle

  If the `$input` parameter is a filehandle, the compressed data will be read from it. The string '-' can be used as an alias for standard input.

- A scalar reference

  If `$input` is a scalar reference, the compressed data will be read from `$$input`.

Constructor Options

The option names defined below are case insensitive and can be optionally prefixed by a '-'. So all of the following are valid

```
-AutoClose
-autoclose
AUTOCLOSE
autoclose
```

OPTS is a combination of the following options:

- `AutoClose => 0|1`

  This option is only valid when the `$input` parameter is a filehandle. If specified, and the value is true, it will result in the file being closed once either the `close` method is called or the IO::Uncompress::Bunzip2 object is destroyed.

  This parameter defaults to 0.

- `MultiStream => 0|1`

  Allows multiple concatenated compressed streams to be treated as a single compressed stream. Decompression will stop once either the end of the file/buffer is reached, an error is encountered (premature eof, corrupt compressed data) or the end of a stream is not immediately followed by the start of another stream.

  This parameter defaults to 0.

- `Prime => $string`

  This option will uncompress the contents of `$string` before processing the input file/buffer.

  This option can be useful when the compressed data is embedded in another file/data structure and it is not possible to work out where the compressed data begins without having to read the first few bytes. If this is the case, the uncompression can be *primed* with these bytes using this option.

- `Transparent => 0|1`

  If this option is set and the input file/buffer is not compressed data, the module will allow reading of it anyway.

  In addition, if the input file/buffer does contain compressed data and there is non-compressed data immediately following it, setting this option will make this module treat the whole file/buffer as a single data stream.

  This option defaults to 1.

- `BlockSize => $num`

  When reading the compressed input data, IO::Uncompress::Bunzip2 will read it in blocks of `$num` bytes.

  This option defaults to 4096.

- `InputLength => $size`

  When present this option will limit the number of compressed bytes read from the input file/buffer to `$size`. This option can be used in the situation where there is useful data directly after the compressed data stream and you know beforehand the exact length of the compressed data stream.

  This option is mostly used when reading from a filehandle, in which case the file pointer will be left pointing to the first byte directly after the compressed data stream.

  This option defaults to off.

- `Append => 0|1`

  This option controls what the `read` method does with uncompressed data.

  If set to 1, all uncompressed data will be appended to the output parameter of the `read` method.

  If set to 0, the contents of the output parameter of the `read` method will be overwritten by the uncompressed data.

  Defaults to 0.

- `Strict => 0|1`

  This option is a no-op.

- `Small => 0|1`

  When non-zero this options will make bzip2 use a decompression algorithm that uses less memory at the expense of increasing the amount of time taken for decompression.

  Default is 0.

Methods

read

Usage is

```
$status = $z->read($buffer)
```

Reads a block of compressed data (the size of the compressed block is determined by the `Buffer` option in the constructor), uncompresses it and writes any uncompressed data into `$buffer`. If the Append parameter is set in the constructor, the uncompressed data will be appended to the `$buffer` parameter. Otherwise `$buffer` will be overwritten.

Returns the number of uncompressed bytes written to `$buffer`, zero if eof or a negative number on error.

read

Usage is

```
$status = $z->read($buffer, $length)
$status = $z->read($buffer, $length, $offset)

$status = read($z, $buffer, $length)
$status = read($z, $buffer, $length, $offset)
```

Attempt to read `$length` bytes of uncompressed data into `$buffer`.

The main difference between this form of the `read` method and the previous one, is that this one will attempt to return *exactly* `$length` bytes. The only circumstances that this function will not is if end-of-file or an IO error is encountered.

Returns the number of uncompressed bytes written to `$buffer`, zero if eof or a negative number on error.

getline

Usage is

```
$line = $z->getline()
$line = <$z>
```

Reads a single line.

This method fully supports the use of the variable `$/` (or `$INPUT_RECORD_SEPARATOR` or `$RS` when `English` is in use) to determine what constitutes an end of line. Paragraph mode, record mode and file slurp mode are all supported.

getc

Usage is

```
$char = $z->getc()
```

Read a single character.

ungetc

Usage is

```
$char = $z->ungetc($string)
```

getHeaderInfo

Usage is

```
$hdr  = $z->getHeaderInfo();
@hdrs = $z->getHeaderInfo();
```

This method returns either a hash reference (in scalar context) or a list or hash references (in array context) that contains information about each of the header fields in the compressed data stream(s).

tell

Usage is

```
$z->tell()
tell $z
```

Returns the uncompressed file offset.

eof

Usage is

```
$z->eof();
eof($z);
```

Returns true if the end of the compressed input stream has been reached.

seek

```
$z->seek($position, $whence);
seek($z, $position, $whence);
```

Provides a sub-set of the `seek` functionality, with the restriction that it is only legal to seek forward in the input file/buffer. It is a fatal error to attempt to seek backward.

Note that the implementation of `seek` in this module does not provide true random access to a compressed file/buffer. It works by uncompressing data from the current offset in the file/buffer until it reaches the uncompressed offset specified in the parameters to `seek`. For very small files this may be acceptable behaviour. For large files it may cause an unacceptable delay.

The `$whence` parameter takes one the usual values, namely SEEK_SET, SEEK_CUR or SEEK_END.

Returns 1 on success, 0 on failure.

binmode

Usage is

```
$z->binmode
binmode $z ;
```

This is a noop provided for completeness.

opened

```
$z->opened()
```

Returns true if the object currently refers to a opened file/buffer.

autoflush

```
my $prev = $z->autoflush()
my $prev = $z->autoflush(EXPR)
```

If the `$z` object is associated with a file or a filehandle, this method returns the current autoflush setting for the underlying filehandle. If `EXPR` is present, and is non-zero, it will enable flushing after every write/print operation.

If `$z` is associated with a buffer, this method has no effect and always returns `undef`.

Note that the special variable `$|` **cannot** be used to set or retrieve the autoflush setting.

input_line_number

```
$z->input_line_number()
$z->input_line_number(EXPR)
```

Returns the current uncompressed line number. If `EXPR` is present it has the effect of setting the line number. Note that setting the line number does not change the current position within the file/buffer being read.

The contents of `$/` are used to determine what constitutes a line terminator.

fileno

```
$z->fileno()
fileno($z)
```

If the `$z` object is associated with a file or a filehandle, `fileno` will return the underlying file descriptor. Once the `close` method is called `fileno` will return `undef`.

If the `$z` object is associated with a buffer, this method will return `undef`.

close

```
$z->close() ;
close $z ;
```

Closes the output file/buffer.

For most versions of Perl this method will be automatically invoked if the IO::Uncompress::Bunzip2 object is destroyed (either explicitly or by the variable with the reference to the object going out of scope). The exceptions are Perl versions 5.005 through 5.00504 and 5.8.0. In these cases, the `close` method will be called automatically, but not until global destruction of all live objects when the program is terminating.

Therefore, if you want your scripts to be able to run on all versions of Perl, you should call `close` explicitly and not rely on automatic closing.

Returns true on success, otherwise 0.

If the `AutoClose` option has been enabled when the IO::Uncompress::Bunzip2 object was created, and the object is associated with a file, the underlying file will also be closed.

nextStream

Usage is

```
my $status = $z->nextStream();
```

Skips to the next compressed data stream in the input file/buffer. If a new compressed data stream is found, the eof marker will be cleared and `$.` will be reset to 0.

Returns 1 if a new stream was found, 0 if none was found, and -1 if an error was encountered.

trailingData

Usage is

```
my $data = $z->trailingData();
```

Returns the data, if any, that is present immediately after the compressed data stream once uncompression is complete. It only makes sense to call this method once the end of the compressed data stream has been encountered.

This option can be used when there is useful information immediately following the compressed data stream, and you don't know the length of the compressed data stream.

If the input is a buffer, `trailingData` will return everything from the end of the compressed data stream to the end of the buffer.

If the input is a filehandle, `trailingData` will return the data that is left in the filehandle input buffer once the end of the compressed data stream has been reached. You can then use the filehandle to read the rest of the input file.

Don't bother using `trailingData` if the input is a filename.

If you know the length of the compressed data stream before you start uncompressing, you can avoid having to use `trailingData` by setting the `InputLength` option in the constructor.

Importing

No symbolic constants are required by IO::Uncompress::Bunzip2 at present.

- :all

  Imports `bunzip2` and `$Bunzip2Error`. Same as doing this

  ```
  use IO::Uncompress::Bunzip2 qw(bunzip2 $Bunzip2Error) ;
  ```

EXAMPLES

Working with Net::FTP

IO::Uncompress::Gunzip

Read RFC 1952 files/buffers

SYNOPSIS

```
use IO::Uncompress::Gunzip qw(gunzip $GunzipError) ;

my $status = gunzip $input => $output [,OPTS]
    or die "gunzip failed: $GunzipError\n";

my $z = IO::Uncompress::Gunzip->new( $input [OPTS] )
    or die "gunzip failed: $GunzipError\n";
```

(continues on next page)

(continued from previous page)

```
$status = $z->read($buffer)
$status = $z->read($buffer, $length)
$status = $z->read($buffer, $length, $offset)
$line = $z->getline()
$char = $z->getc()
$char = $z->ungetc()
$char = $z->opened()

$status = $z->inflateSync()

$data = $z->trailingData()
$status = $z->nextStream()
$data = $z->getHeaderInfo()
$z->tell()
$z->seek($position, $whence)
$z->binmode()
$z->fileno()
$z->eof()
$z->close()

$GunzipError ;

# IO::File mode

<$z>
read($z, $buffer);
read($z, $buffer, $length);
read($z, $buffer, $length, $offset);
tell($z)
seek($z, $position, $whence)
binmode($z)
fileno($z)
eof($z)
close($z)
```

DESCRIPTION

This module provides a Perl interface that allows the reading of files/buffers that conform to RFC 1952.

For writing RFC 1952 files/buffers, see the companion module IO::Compress::Gzip.

Functional Interface

A top-level function, gunzip, is provided to carry out “one-shot” uncompression between buffers and/or files. For finer control over the uncompression process, see the “OO Interface” section.

```
use IO::Uncompress::Gunzip qw(gunzip $GunzipError) ;

gunzip $input_filename_or_reference => $output_filename_or_reference␣
↪[,OPTS]
    or die "gunzip failed: $GunzipError\n";
```

The functional interface needs Perl5.005 or better.

gunzip $input_filename_or_reference => $output_filename_or_reference [, OPTS]

gunzip expects at least two parameters, `$input_filename_or_reference` and `$output_filename_or_reference` and zero or more optional parameters (see "Optional Parameters")

The $input_filename_or_reference parameter

The parameter, `$input_filename_or_reference`, is used to define the source of the compressed data.

It can take one of the following forms:

- A filename

  If the `$input_filename_or_reference` parameter is a simple scalar, it is assumed to be a filename. This file will be opened for reading and the input data will be read from it.

- A filehandle

  If the `$input_filename_or_reference` parameter is a filehandle, the input data will be read from it. The string '-' can be used as an alias for standard input.

- A scalar reference

  If `$input_filename_or_reference` is a scalar reference, the input data will be read from `$$input_filename_or_reference`.

- An array reference

  If `$input_filename_or_reference` is an array reference, each element in the array must be a filename.

  The input data will be read from each file in turn.

  The complete array will be walked to ensure that it only contains valid filenames before any data is uncompressed.

- An Input FileGlob string

  If `$input_filename_or_reference` is a string that is delimited by the characters "<" and ">" gunzip will assume that it is an *input fileglob string*. The input is the list of files that match the fileglob.

  See *File::GlobMapper* for more details.

If the `$input_filename_or_reference` parameter is any other type, `undef` will be returned.

The $output_filename_or_reference parameter

The parameter $output_filename_or_reference is used to control the destination of the uncompressed data. This parameter can take one of these forms.

- A filename

  If the $output_filename_or_reference parameter is a simple scalar, it is assumed to be a filename. This file will be opened for writing and the uncompressed data will be written to it.

- A filehandle

  If the $output_filename_or_reference parameter is a filehandle, the uncompressed data will be written to it. The string '-' can be used as an alias for standard output.

- A scalar reference

  If $output_filename_or_reference is a scalar reference, the uncompressed data will be stored in $$output_filename_or_reference.

- An Array Reference

  If $output_filename_or_reference is an array reference, the uncompressed data will be pushed onto the array.

- An Output FileGlob

  If $output_filename_or_reference is a string that is delimited by the characters "<" and ">" gunzip will assume that it is an *output fileglob string*. The output is the list of files that match the fileglob.

  When $output_filename_or_reference is an fileglob string, $input_filename_or_reference must also be a fileglob string. Anything else is an error.

  See *File::GlobMapper* for more details.

If the $output_filename_or_reference parameter is any other type, undef will be returned.

Notes

When $input_filename_or_reference maps to multiple compressed files/buffers and $output_filename_or_reference is a single file/buffer, after uncompression $output_filename_or_reference will contain a concatenation of all the uncompressed data from each of the input files/buffers.

Optional Parameters

The optional parameters for the one-shot function gunzip are (for the most part) identical to those used with the OO interface defined in the "Constructor Options" section. The exceptions are listed below

- AutoClose => 0|1

  This option applies to any input or output data streams to gunzip that are filehandles.

If `AutoClose` is specified, and the value is true, it will result in all input and/or output filehandles being closed once `gunzip` has completed.

This parameter defaults to 0.

- `BinModeOut => 0|1`

  This option is now a no-op. All files will be written in binmode.

- `Append => 0|1`

  The behaviour of this option is dependent on the type of output data stream.

  - A Buffer

    If Append is enabled, all uncompressed data will be append to the end of the output buffer. Otherwise the output buffer will be cleared before any uncompressed data is written to it.

  - A Filename

    If Append is enabled, the file will be opened in append mode. Otherwise the contents of the file, if any, will be truncated before any uncompressed data is written to it.

  - A Filehandle

    If Append is enabled, the filehandle will be positioned to the end of the file via a call to `seek` before any uncompressed data is written to it. Otherwise the file pointer will not be moved.

  When Append is specified, and set to true, it will *append* all uncompressed data to the output data stream.

  So when the output is a filehandle it will carry out a seek to the eof before writing any uncompressed data. If the output is a filename, it will be opened for appending. If the output is a buffer, all uncompressed data will be appended to the existing buffer.

  Conversely when Append is not specified, or it is present and is set to false, it will operate as follows.

  When the output is a filename, it will truncate the contents of the file before writing any uncompressed data. If the output is a filehandle its position will not be changed. If the output is a buffer, it will be wiped before any uncompressed data is output.

  Defaults to 0.

- `MultiStream => 0|1`

  If the input file/buffer contains multiple compressed data streams, this option will uncompress the whole lot as a single data stream.

  Defaults to 0.

- `TrailingData => $scalar`

  Returns the data, if any, that is present immediately after the compressed data stream once uncompression is complete.

This option can be used when there is useful information immediately following the compressed data stream, and you don't know the length of the compressed data stream.

If the input is a buffer, `trailingData` will return everything from the end of the compressed data stream to the end of the buffer.

If the input is a filehandle, `trailingData` will return the data that is left in the filehandle input buffer once the end of the compressed data stream has been reached. You can then use the filehandle to read the rest of the input file.

Don't bother using `trailingData` if the input is a filename.

If you know the length of the compressed data stream before you start uncompressing, you can avoid having to use `trailingData` by setting the `InputLength` option.

OneShot Examples

To read the contents of the file `file1.txt.gz` and write the uncompressed data to the file `file1.txt`.

```
use strict ;
use warnings ;
use IO::Uncompress::Gunzip qw(gunzip $GunzipError) ;

my $input = "file1.txt.gz";
my $output = "file1.txt";
gunzip $input => $output
    or die "gunzip failed: $GunzipError\n";
```

To read from an existing Perl filehandle, `$input`, and write the uncompressed data to a buffer, `$buffer`.

```
use strict ;
use warnings ;
use IO::Uncompress::Gunzip qw(gunzip $GunzipError) ;
use IO::File ;

my $input = IO::File->new( "<file1.txt.gz" )
    or die "Cannot open 'file1.txt.gz': $!\n" ;
my $buffer ;
gunzip $input => \$buffer
    or die "gunzip failed: $GunzipError\n";
```

To uncompress all files in the directory "/my/home" that match "*.txt.gz" and store the compressed data in the same directory

```
use strict ;
use warnings ;
use IO::Uncompress::Gunzip qw(gunzip $GunzipError) ;
```

(continues on next page)

(continued from previous page)

```
gunzip '</my/home/*.txt.gz>' => '</my/home/#1.txt>'
    or die "gunzip failed: $GunzipError\n";
```

and if you want to compress each file one at a time, this will do the trick

```
use strict ;
use warnings ;
use IO::Uncompress::Gunzip qw(gunzip $GunzipError) ;

for my $input ( glob "/my/home/*.txt.gz" )
{
    my $output = $input;
    $output =~ s/.gz// ;
    gunzip $input => $output
        or die "Error compressing '$input': $GunzipError\n";
}
```

OO Interface

Constructor

The format of the constructor for IO::Uncompress::Gunzip is shown below

```
my $z = IO::Uncompress::Gunzip->new( $input [OPTS] )
    or die "IO::Uncompress::Gunzip failed: $GunzipError\n";
```

The constructor takes one mandatory parameter, `$input`, defined below, and zero or more `OPTS`, defined in “Constructor Options”.

Returns an `IO::Uncompress::Gunzip` object on success and undef on failure. The variable `$GunzipError` will contain an error message on failure.

If you are running Perl 5.005 or better the object, `$z`, returned from IO::Uncompress::Gunzip can be used exactly like an *IO::File* filehandle. This means that all normal input file operations can be carried out with `$z`. For example, to read a line from a compressed file/buffer you can use either of these forms

```
$line = $z->getline();
$line = <$z>;
```

Below is a simple exaple of using the OO interface to read the compressed file `myfile.gz` and write its contents to stdout.

```
my $filename = "myfile.gz";
my $z = IO::Uncompress::Gunzip->new($filename)
    or die "IO::Uncompress::Gunzip failed: $GunzipError\n";

while (<$z>) {
    print $_;
}
$z->close();
```

See “EXAMPLES” for further examples

The mandatory parameter `$input` is used to determine the source of the compressed data. This parameter can take one of three forms.

- A filename

  If the `$input` parameter is a scalar, it is assumed to be a filename. This file will be opened for reading and the compressed data will be read from it.

- A filehandle

  If the `$input` parameter is a filehandle, the compressed data will be read from it. The string ‘-’ can be used as an alias for standard input.

- A scalar reference

  If `$input` is a scalar reference, the compressed data will be read from `$$input`.

Constructor Options

The option names defined below are case insensitive and can be optionally prefixed by a ‘-’. So all of the following are valid

```
-AutoClose
-autoclose
AUTOCLOSE
autoclose
```

OPTS is a combination of the following options:

- `AutoClose => 0|1`

  This option is only valid when the `$input` parameter is a filehandle. If specified, and the value is true, it will result in the file being closed once either the `close` method is called or the IO::Uncompress::Gunzip object is destroyed.

  This parameter defaults to 0.

- `MultiStream => 0|1`

  Allows multiple concatenated compressed streams to be treated as a single compressed stream. Decompression will stop once either the end of the file/buffer is reached, an error is encountered (premature eof, corrupt compressed data) or the end of a stream is not immediately followed by the start of another stream.

  This parameter defaults to 0.

- `Prime => $string`

  This option will uncompress the contents of `$string` before processing the input file/buffer.

  This option can be useful when the compressed data is embedded in another file/data structure and it is not possible to work out where the compressed data begins without having to read the first few bytes. If this is the case, the uncompression can be *primed* with these bytes using this option.

- `Transparent => 0|1`

If this option is set and the input file/buffer is not compressed data, the module will allow reading of it anyway.

In addition, if the input file/buffer does contain compressed data and there is non-compressed data immediately following it, setting this option will make this module treat the whole file/buffer as a single data stream.

This option defaults to 1.

- `BlockSize => $num`

  When reading the compressed input data, IO::Uncompress::Gunzip will read it in blocks of `$num` bytes.

  This option defaults to 4096.

- `InputLength => $size`

  When present this option will limit the number of compressed bytes read from the input file/buffer to `$size`. This option can be used in the situation where there is useful data directly after the compressed data stream and you know beforehand the exact length of the compressed data stream.

  This option is mostly used when reading from a filehandle, in which case the file pointer will be left pointing to the first byte directly after the compressed data stream.

  This option defaults to off.

- `Append => 0|1`

  This option controls what the `read` method does with uncompressed data.

  If set to 1, all uncompressed data will be appended to the output parameter of the `read` method.

  If set to 0, the contents of the output parameter of the `read` method will be overwritten by the uncompressed data.

  Defaults to 0.

- `Strict => 0|1`

  This option controls whether the extra checks defined below are used when carrying out the decompression. When Strict is on, the extra tests are carried out, when Strict is off they are not.

  The default for this option is off.

  1. If the FHCRC bit is set in the gzip FLG header byte, the CRC16 bytes in the header must match the crc16 value of the gzip header actually read.
  2. If the gzip header contains a name field (FNAME) it consists solely of ISO 8859-1 characters.
  3. If the gzip header contains a comment field (FCOMMENT) it consists solely of ISO 8859-1 characters plus line-feed.
  4. If the gzip FEXTRA header field is present it must conform to the sub-field structure as defined in RFC 1952.
  5. The CRC32 and ISIZE trailer fields must be present.

6. The value of the CRC32 field read must match the crc32 value of the uncompressed data actually contained in the gzip file.
7. The value of the ISIZE fields read must match the length of the uncompressed data actually read from the file.

- `ParseExtra => 0|1` If the gzip FEXTRA header field is present and this option is set, it will force the module to check that it conforms to the sub-field structure as defined in RFC 1952.

  If the `Strict` is on it will automatically enable this option.

  Defaults to 0.

Methods

read

Usage is

```
$status = $z->read($buffer)
```

Reads a block of compressed data (the size of the compressed block is determined by the `Buffer` option in the constructor), uncompresses it and writes any uncompressed data into `$buffer`. If the `Append` parameter is set in the constructor, the uncompressed data will be appended to the `$buffer` parameter. Otherwise `$buffer` will be overwritten.

Returns the number of uncompressed bytes written to `$buffer`, zero if eof or a negative number on error.

read

Usage is

```
$status = $z->read($buffer, $length)
$status = $z->read($buffer, $length, $offset)

$status = read($z, $buffer, $length)
$status = read($z, $buffer, $length, $offset)
```

Attempt to read `$length` bytes of uncompressed data into `$buffer`.

The main difference between this form of the `read` method and the previous one, is that this one will attempt to return *exactly* `$length` bytes. The only circumstances that this function will not is if end-of-file or an IO error is encountered.

Returns the number of uncompressed bytes written to `$buffer`, zero if eof or a negative number on error.

getline

Usage is

```
$line = $z->getline()
$line = <$z>
```

Reads a single line.

This method fully supports the use of the variable `$/` (or `$INPUT_RECORD_SEPARATOR` or `$RS` when `English` is in use) to determine what constitutes an end of line. Paragraph mode, record mode and file slurp mode are all supported.

getc

Usage is

```
$char = $z->getc()
```

Read a single character.

ungetc

Usage is

```
$char = $z->ungetc($string)
```

inflateSync

Usage is

```
$status = $z->inflateSync()
```

TODO

getHeaderInfo

Usage is

```
$hdr  = $z->getHeaderInfo();
@hdrs = $z->getHeaderInfo();
```

This method returns either a hash reference (in scalar context) or a list or hash references (in array context) that contains information about each of the header fields in the compressed data stream(s).

- Name

  The contents of the Name header field, if present. If no name is present, the value will be undef. Note this is different from a zero length name, which will return an empty string.

- Comment

  The contents of the Comment header field, if present. If no comment is present, the value will be undef. Note this is different from a zero length comment, which will return an empty string.

tell

Usage is

```
$z->tell()
tell $z
```

Returns the uncompressed file offset.

eof

Usage is

```
$z->eof();
eof($z);
```

Returns true if the end of the compressed input stream has been reached.

seek

```
$z->seek($position, $whence);
seek($z, $position, $whence);
```

Provides a sub-set of the `seek` functionality, with the restriction that it is only legal to seek forward in the input file/buffer. It is a fatal error to attempt to seek backward.

Note that the implementation of `seek` in this module does not provide true random access to a compressed file/buffer. It works by uncompressing data from the current offset in the file/buffer until it reaches the uncompressed offset specified in the parameters to `seek`. For very small files this may be acceptable behaviour. For large files it may cause an unacceptable delay.

The `$whence` parameter takes one the usual values, namely SEEK_SET, SEEK_CUR or SEEK_END.

Returns 1 on success, 0 on failure.

binmode

Usage is

```
$z->binmode
binmode $z ;
```

This is a noop provided for completeness.

opened

```
$z->opened()
```

Returns true if the object currently refers to a opened file/buffer.

autoflush

```
my $prev = $z->autoflush()
my $prev = $z->autoflush(EXPR)
```

If the `$z` object is associated with a file or a filehandle, this method returns the current autoflush setting for the underlying filehandle. If `EXPR` is present, and is non-zero, it will enable flushing after every write/print operation.

If `$z` is associated with a buffer, this method has no effect and always returns `undef`.

Note that the special variable `$|` **cannot** be used to set or retrieve the autoflush setting.

input_line_number

```
$z->input_line_number()
$z->input_line_number(EXPR)
```

Returns the current uncompressed line number. If `EXPR` is present it has the effect of setting the line number. Note that setting the line number does not change the current position within the file/buffer being read.

The contents of `$/` are used to determine what constitutes a line terminator.

fileno

```
$z->fileno()
fileno($z)
```

If the `$z` object is associated with a file or a filehandle, `fileno` will return the underlying file descriptor. Once the `close` method is called `fileno` will return `undef`.

If the `$z` object is associated with a buffer, this method will return `undef`.

close

```
$z->close() ;
close $z ;
```

Closes the output file/buffer.

For most versions of Perl this method will be automatically invoked if the IO::Uncompress::Gunzip object is destroyed (either explicitly or by the variable with the reference to the object going out of scope). The exceptions are Perl versions 5.005 through 5.00504 and 5.8.0. In these cases, the `close` method will be called automatically, but not until global destruction of all live objects when the program is terminating.

Therefore, if you want your scripts to be able to run on all versions of Perl, you should call `close` explicitly and not rely on automatic closing.

Returns true on success, otherwise 0.

If the `AutoClose` option has been enabled when the IO::Uncompress::Gunzip object was created, and the object is associated with a file, the underlying file will also be closed.

nextStream

Usage is

```
my $status = $z->nextStream();
```

Skips to the next compressed data stream in the input file/buffer. If a new compressed data stream is found, the eof marker will be cleared and `$.` will be reset to 0.

Returns 1 if a new stream was found, 0 if none was found, and -1 if an error was encountered.

trailingData

Usage is

```
my $data = $z->trailingData();
```

Returns the data, if any, that is present immediately after the compressed data stream once uncompression is complete. It only makes sense to call this method once the end of the compressed data stream has been encountered.

This option can be used when there is useful information immediately following the compressed data stream, and you don't know the length of the compressed data stream.

If the input is a buffer, `trailingData` will return everything from the end of the compressed data stream to the end of the buffer.

If the input is a filehandle, `trailingData` will return the data that is left in the filehandle input buffer once the end of the compressed data stream has been reached. You can then use the filehandle to read the rest of the input file.

Don't bother using `trailingData` if the input is a filename.

If you know the length of the compressed data stream before you start uncompressing, you can avoid having to use `trailingData` by setting the `InputLength` option in the constructor.

Importing

No symbolic constants are required by IO::Uncompress::Gunzip at present.

- :all

  Imports `gunzip` and `$GunzipError`. Same as doing this

  ```
  use IO::Uncompress::Gunzip qw(gunzip $GunzipError) ;
  ```

EXAMPLES

Working with Net::FTP

IO::Uncompress::Inflate

Read RFC 1950 files/buffers

SYNOPSIS

```
use IO::Uncompress::Inflate qw(inflate $InflateError) ;

my $status = inflate $input => $output [,OPTS]
    or die "inflate failed: $InflateError\n";

my $z = IO::Uncompress::Inflate->new( $input [OPTS] )
    or die "inflate failed: $InflateError\n";

$status = $z->read($buffer)
$status = $z->read($buffer, $length)
$status = $z->read($buffer, $length, $offset)
$line = $z->getline()
$char = $z->getc()
$char = $z->ungetc()
$char = $z->opened()

$status = $z->inflateSync()

$data = $z->trailingData()
$status = $z->nextStream()
$data = $z->getHeaderInfo()
$z->tell()
$z->seek($position, $whence)
$z->binmode()
$z->fileno()
$z->eof()
$z->close()

$InflateError ;

# IO::File mode

<$z>
read($z, $buffer);
read($z, $buffer, $length);
read($z, $buffer, $length, $offset);
tell($z)
seek($z, $position, $whence)
binmode($z)
fileno($z)
eof($z)
close($z)
```

DESCRIPTION

This module provides a Perl interface that allows the reading of files/buffers that conform to RFC 1950.

For writing RFC 1950 files/buffers, see the companion module IO::Compress::Deflate.

Functional Interface

A top-level function, `inflate`, is provided to carry out "one-shot" uncompression between buffers and/or files. For finer control over the uncompression process, see the "OO Interface" section.

```
use IO::Uncompress::Inflate qw(inflate $InflateError) ;

inflate $input_filename_or_reference => $output_filename_or_
 ↪reference [,OPTS]
    or die "inflate failed: $InflateError\n";
```

The functional interface needs Perl5.005 or better.

inflate $input_filename_or_reference => $output_filename_or_reference [, OPTS]

`inflate` expects at least two parameters, `$input_filename_or_reference` and `$output_filename_or_reference` and zero or more optional parameters (see "Optional Parameters")

The `$input_filename_or_reference` parameter

The parameter, `$input_filename_or_reference`, is used to define the source of the compressed data.

It can take one of the following forms:

- A filename

  If the `$input_filename_or_reference` parameter is a simple scalar, it is assumed to be a filename. This file will be opened for reading and the input data will be read from it.

- A filehandle

  If the `$input_filename_or_reference` parameter is a filehandle, the input data will be read from it. The string '-' can be used as an alias for standard input.

- A scalar reference

  If `$input_filename_or_reference` is a scalar reference, the input data will be read from `$$input_filename_or_reference`.

- An array reference

  If `$input_filename_or_reference` is an array reference, each element in the array must be a filename.

  The input data will be read from each file in turn.

  The complete array will be walked to ensure that it only contains valid filenames before any data is uncompressed.

- An Input FileGlob string

  If `$input_filename_or_reference` is a string that is delimited by the characters "<" and ">" `inflate` will assume that it is an *input fileglob string*. The input is the list of files that match the fileglob.

See *File::GlobMapper* for more details.

If the `$input_filename_or_reference` parameter is any other type, `undef` will be returned.

The `$output_filename_or_reference` parameter

The parameter `$output_filename_or_reference` is used to control the destination of the uncompressed data. This parameter can take one of these forms.

- A filename

  If the `$output_filename_or_reference` parameter is a simple scalar, it is assumed to be a filename. This file will be opened for writing and the uncompressed data will be written to it.

- A filehandle

  If the `$output_filename_or_reference` parameter is a filehandle, the uncompressed data will be written to it. The string '-' can be used as an alias for standard output.

- A scalar reference

  If `$output_filename_or_reference` is a scalar reference, the uncompressed data will be stored in `$$output_filename_or_reference`.

- An Array Reference

  If `$output_filename_or_reference` is an array reference, the uncompressed data will be pushed onto the array.

- An Output FileGlob

  If `$output_filename_or_reference` is a string that is delimited by the characters "<" and ">" `inflate` will assume that it is an *output fileglob string*. The output is the list of files that match the fileglob.

  When `$output_filename_or_reference` is an fileglob string, `$input_filename_or_reference` must also be a fileglob string. Anything else is an error.

  See *File::GlobMapper* for more details.

If the `$output_filename_or_reference` parameter is any other type, `undef` will be returned.

Notes

When `$input_filename_or_reference` maps to multiple compressed files/buffers and `$output_filename_or_reference` is a single file/buffer, after uncompression `$output_filename_or_reference` will contain a concatenation of all the uncompressed data from each of the input files/buffers.

Optional Parameters

The optional parameters for the one-shot function `inflate` are (for the most part) identical to those used with the OO interface defined in the "Constructor Options" section. The exceptions are listed below

- `AutoClose => 0|1`

  This option applies to any input or output data streams to `inflate` that are filehandles.

  If `AutoClose` is specified, and the value is true, it will result in all input and/or output filehandles being closed once `inflate` has completed.

  This parameter defaults to 0.

- `BinModeOut => 0|1`

  This option is now a no-op. All files will be written in binmode.

- `Append => 0|1`

  The behaviour of this option is dependent on the type of output data stream.

  - A Buffer

    If Append is enabled, all uncompressed data will be append to the end of the output buffer. Otherwise the output buffer will be cleared before any uncompressed data is written to it.

  - A Filename

    If Append is enabled, the file will be opened in append mode. Otherwise the contents of the file, if any, will be truncated before any uncompressed data is written to it.

  - A Filehandle

    If Append is enabled, the filehandle will be positioned to the end of the file via a call to `seek` before any uncompressed data is written to it. Otherwise the file pointer will not be moved.

  When Append is specified, and set to true, it will *append* all uncompressed data to the output data stream.

  So when the output is a filehandle it will carry out a seek to the eof before writing any uncompressed data. If the output is a filename, it will be opened for appending. If the output is a buffer, all uncompressed data will be appended to the existing buffer.

  Conversely when Append is not specified, or it is present and is set to false, it will operate as follows.

  When the output is a filename, it will truncate the contents of the file before writing any uncompressed data. If the output is a filehandle its position will not be changed. If the output is a buffer, it will be wiped before any uncompressed data is output.

  Defaults to 0.

- `MultiStream => 0|1`

If the input file/buffer contains multiple compressed data streams, this option will uncompress the whole lot as a single data stream.

Defaults to 0.

- `TrailingData => $scalar`

  Returns the data, if any, that is present immediately after the compressed data stream once uncompression is complete.

  This option can be used when there is useful information immediately following the compressed data stream, and you don't know the length of the compressed data stream.

  If the input is a buffer, `trailingData` will return everything from the end of the compressed data stream to the end of the buffer.

  If the input is a filehandle, `trailingData` will return the data that is left in the filehandle input buffer once the end of the compressed data stream has been reached. You can then use the filehandle to read the rest of the input file.

  Don't bother using `trailingData` if the input is a filename.

  If you know the length of the compressed data stream before you start uncompressing, you can avoid having to use `trailingData` by setting the `InputLength` option.

OneShot Examples

To read the contents of the file `file1.txt.1950` and write the uncompressed data to the file `file1.txt`.

```
use strict ;
use warnings ;
use IO::Uncompress::Inflate qw(inflate $InflateError) ;

my $input = "file1.txt.1950";
my $output = "file1.txt";
inflate $input => $output
    or die "inflate failed: $InflateError\n";
```

To read from an existing Perl filehandle, `$input`, and write the uncompressed data to a buffer, `$buffer`.

```
use strict ;
use warnings ;
use IO::Uncompress::Inflate qw(inflate $InflateError) ;
use IO::File ;

my $input = IO::File->new( "<file1.txt.1950" )
    or die "Cannot open 'file1.txt.1950': $!\n" ;
my $buffer ;
inflate $input => \$buffer
    or die "inflate failed: $InflateError\n";
```

To uncompress all files in the directory "/my/home" that match "*.txt.1950" and store the compressed data in the same directory

```
use strict ;
use warnings ;
use IO::Uncompress::Inflate qw(inflate $InflateError) ;

inflate '</my/home/*.txt.1950>' => '</my/home/#1.txt>'
    or die "inflate failed: $InflateError\n";
```

and if you want to compress each file one at a time, this will do the trick

```
use strict ;
use warnings ;
use IO::Uncompress::Inflate qw(inflate $InflateError) ;

for my $input ( glob "/my/home/*.txt.1950" )
{
    my $output = $input;
    $output =~ s/.1950// ;
    inflate $input => $output
        or die "Error compressing '$input': $InflateError\n";
}
```

OO Interface

Constructor

The format of the constructor for IO::Uncompress::Inflate is shown below

```
my $z = IO::Uncompress::Inflate->new( $input [OPTS] )
    or die "IO::Uncompress::Inflate failed: $InflateError\n";
```

The constructor takes one mandatory parameter, `$input`, defined below, and zero or more `OPTS`, defined in "Constructor Options".

Returns an `IO::Uncompress::Inflate` object on success and undef on failure. The variable `$InflateError` will contain an error message on failure.

If you are running Perl 5.005 or better the object, `$z`, returned from IO::Uncompress::Inflate can be used exactly like an *IO::File* filehandle. This means that all normal input file operations can be carried out with `$z`. For example, to read a line from a compressed file/buffer you can use either of these forms

```
$line = $z->getline();
$line = <$z>;
```

Below is a simple exaple of using the OO interface to read the compressed file `myfile.1950` and write its contents to stdout.

```
my $filename = "myfile.1950";
my $z = IO::Uncompress::Inflate->new($filename)
```

(continues on next page)

(continued from previous page)

```
    or die "IO::Uncompress::Inflate failed: $InflateError\n";

while (<$z>) {
    print $_;
}
$z->close();
```

See “EXAMPLES” for further examples

The mandatory parameter `$input` is used to determine the source of the compressed data. This parameter can take one of three forms.

- A filename

  If the `$input` parameter is a scalar, it is assumed to be a filename. This file will be opened for reading and the compressed data will be read from it.

- A filehandle

  If the `$input` parameter is a filehandle, the compressed data will be read from it. The string ‘-’ can be used as an alias for standard input.

- A scalar reference

  If `$input` is a scalar reference, the compressed data will be read from `$$input`.

Constructor Options

The option names defined below are case insensitive and can be optionally prefixed by a ‘-’. So all of the following are valid

```
-AutoClose
-autoclose
AUTOCLOSE
autoclose
```

OPTS is a combination of the following options:

- `AutoClose => 0|1`

  This option is only valid when the `$input` parameter is a filehandle. If specified, and the value is true, it will result in the file being closed once either the `close` method is called or the IO::Uncompress::Inflate object is destroyed.

  This parameter defaults to 0.

- `MultiStream => 0|1`

  Allows multiple concatenated compressed streams to be treated as a single compressed stream. Decompression will stop once either the end of the file/buffer is reached, an error is encountered (premature eof, corrupt compressed data) or the end of a stream is not immediately followed by the start of another stream.

  This parameter defaults to 0.

- `Prime => $string`

This option will uncompress the contents of `$string` before processing the input file/buffer.

This option can be useful when the compressed data is embedded in another file/data structure and it is not possible to work out where the compressed data begins without having to read the first few bytes. If this is the case, the uncompression can be *primed* with these bytes using this option.

- `Transparent => 0|1`

  If this option is set and the input file/buffer is not compressed data, the module will allow reading of it anyway.

  In addition, if the input file/buffer does contain compressed data and there is non-compressed data immediately following it, setting this option will make this module treat the whole file/buffer as a single data stream.

  This option defaults to 1.

- `BlockSize => $num`

  When reading the compressed input data, IO::Uncompress::Inflate will read it in blocks of `$num` bytes.

  This option defaults to 4096.

- `InputLength => $size`

  When present this option will limit the number of compressed bytes read from the input file/buffer to `$size`. This option can be used in the situation where there is useful data directly after the compressed data stream and you know beforehand the exact length of the compressed data stream.

  This option is mostly used when reading from a filehandle, in which case the file pointer will be left pointing to the first byte directly after the compressed data stream.

  This option defaults to off.

- `Append => 0|1`

  This option controls what the `read` method does with uncompressed data.

  If set to 1, all uncompressed data will be appended to the output parameter of the `read` method.

  If set to 0, the contents of the output parameter of the `read` method will be overwritten by the uncompressed data.

  Defaults to 0.

- `Strict => 0|1`

  This option controls whether the extra checks defined below are used when carrying out the decompression. When Strict is on, the extra tests are carried out, when Strict is off they are not.

  The default for this option is off.

  1. The ADLER32 checksum field must be present.

2. The value of the ADLER32 field read must match the adler32 value of the uncompressed data actually contained in the file.

Methods

read

Usage is

```
$status = $z->read($buffer)
```

Reads a block of compressed data (the size of the compressed block is determined by the `Buffer` option in the constructor), uncompresses it and writes any uncompressed data into `$buffer`. If the `Append` parameter is set in the constructor, the uncompressed data will be appended to the `$buffer` parameter. Otherwise `$buffer` will be overwritten.

Returns the number of uncompressed bytes written to `$buffer`, zero if eof or a negative number on error.

read

Usage is

```
$status = $z->read($buffer, $length)
$status = $z->read($buffer, $length, $offset)

$status = read($z, $buffer, $length)
$status = read($z, $buffer, $length, $offset)
```

Attempt to read `$length` bytes of uncompressed data into `$buffer`.

The main difference between this form of the `read` method and the previous one, is that this one will attempt to return *exactly* `$length` bytes. The only circumstances that this function will not is if end-of-file or an IO error is encountered.

Returns the number of uncompressed bytes written to `$buffer`, zero if eof or a negative number on error.

getline

Usage is

```
$line = $z->getline()
$line = <$z>
```

Reads a single line.

This method fully supports the use of the variable `$/` (or `$INPUT_RECORD_SEPARATOR` or `$RS` when `English` is in use) to determine what constitutes an end of line. Paragraph mode, record mode and file slurp mode are all supported.

getc

Usage is

```
$char = $z->getc()
```

Read a single character.

ungetc

Usage is

```
$char = $z->ungetc($string)
```

inflateSync

Usage is

```
$status = $z->inflateSync()
```

TODO

getHeaderInfo

Usage is

```
$hdr  = $z->getHeaderInfo();
@hdrs = $z->getHeaderInfo();
```

This method returns either a hash reference (in scalar context) or a list or hash references (in array context) that contains information about each of the header fields in the compressed data stream(s).

tell

Usage is

```
$z->tell()
tell $z
```

Returns the uncompressed file offset.

eof

Usage is

```
$z->eof();
eof($z);
```

Returns true if the end of the compressed input stream has been reached.

seek

```
$z->seek($position, $whence);
seek($z, $position, $whence);
```

Provides a sub-set of the `seek` functionality, with the restriction that it is only legal to seek forward in the input file/buffer. It is a fatal error to attempt to seek backward.

Note that the implementation of `seek` in this module does not provide true random access to a compressed file/buffer. It works by uncompressing data from the current offset in the file/buffer until it reaches the uncompressed offset specified in the parameters to `seek`. For very small files this may be acceptable behaviour. For large files it may cause an unacceptable delay.

The `$whence` parameter takes one the usual values, namely SEEK_SET, SEEK_CUR or SEEK_END.

Returns 1 on success, 0 on failure.

binmode

Usage is

```
$z->binmode
binmode $z ;
```

This is a noop provided for completeness.

opened

```
$z->opened()
```

Returns true if the object currently refers to a opened file/buffer.

autoflush

```
my $prev = $z->autoflush()
my $prev = $z->autoflush(EXPR)
```

If the `$z` object is associated with a file or a filehandle, this method returns the current autoflush setting for the underlying filehandle. If `EXPR` is present, and is non-zero, it will enable flushing after every write/print operation.

If `$z` is associated with a buffer, this method has no effect and always returns `undef`.

Note that the special variable `$|` **cannot** be used to set or retrieve the autoflush setting.

input_line_number

```
$z->input_line_number()
$z->input_line_number(EXPR)
```

Returns the current uncompressed line number. If EXPR is present it has the effect of setting the line number. Note that setting the line number does not change the current position within the file/buffer being read.

The contents of `$/` are used to determine what constitutes a line terminator.

fileno

```
$z->fileno()
fileno($z)
```

If the `$z` object is associated with a file or a filehandle, `fileno` will return the underlying file descriptor. Once the `close` method is called `fileno` will return `undef`.

If the `$z` object is associated with a buffer, this method will return `undef`.

close

```
$z->close() ;
close $z ;
```

Closes the output file/buffer.

For most versions of Perl this method will be automatically invoked if the IO::Uncompress::Inflate object is destroyed (either explicitly or by the variable with the reference to the object going out of scope). The exceptions are Perl versions 5.005 through 5.00504 and 5.8.0. In these cases, the `close` method will be called automatically, but not until global destruction of all live objects when the program is terminating.

Therefore, if you want your scripts to be able to run on all versions of Perl, you should call `close` explicitly and not rely on automatic closing.

Returns true on success, otherwise 0.

If the `AutoClose` option has been enabled when the IO::Uncompress::Inflate object was created, and the object is associated with a file, the underlying file will also be closed.

nextStream

Usage is

```
my $status = $z->nextStream();
```

Skips to the next compressed data stream in the input file/buffer. If a new compressed data stream is found, the eof marker will be cleared and `$.` will be reset to 0.

Returns 1 if a new stream was found, 0 if none was found, and -1 if an error was encountered.

trailingData

Usage is

```
my $data = $z->trailingData();
```

Returns the data, if any, that is present immediately after the compressed data stream once uncompression is complete. It only makes sense to call this method once the end of the compressed data stream has been encountered.

This option can be used when there is useful information immediately following the compressed data stream, and you don't know the length of the compressed data stream.

If the input is a buffer, `trailingData` will return everything from the end of the compressed data stream to the end of the buffer.

If the input is a filehandle, `trailingData` will return the data that is left in the filehandle input buffer once the end of the compressed data stream has been reached. You can then use the filehandle to read the rest of the input file.

Don't bother using `trailingData` if the input is a filename.

If you know the length of the compressed data stream before you start uncompressing, you can avoid having to use `trailingData` by setting the `InputLength` option in the constructor.

Importing

No symbolic constants are required by IO::Uncompress::Inflate at present.

- :all

  Imports `inflate` and `$InflateError`. Same as doing this

  ```
  use IO::Uncompress::Inflate qw(inflate $InflateError) ;
  ```

fileno($z)
eof($z)
close($z)
```

DESCRIPTION

This module provides a Perl interface that allows the reading of files/buffers that conform to RFC 1951.

For writing RFC 1951 files/buffers, see the companion module IO::Compress::RawDeflate.

Functional Interface

A top-level function, `rawinflate`, is provided to carry out "one-shot" uncompression between buffers and/or files. For finer control over the uncompression process, see the "OO Interface" section.

```
use IO::Uncompress::RawInflate qw(rawinflate $RawInflateError) ;

rawinflate $input_filename_or_reference => $output_filename_or_
 ↪reference [,OPTS]
```

(continues on next page)

(continued from previous page)

```
    or die "rawinflate failed: $RawInflateError\n";
```

The functional interface needs Perl5.005 or better.

rawinflate $input_filename_or_reference => $output_filename_or_reference [, OPTS]

`rawinflate` expects at least two parameters, `$input_filename_or_reference` and `$output_filename_or_reference` and zero or more optional parameters (see "Optional Parameters")

The `$input_filename_or_reference` parameter

The parameter, `$input_filename_or_reference`, is used to define the source of the compressed data.

It can take one of the following forms:

- A filename

  If the `$input_filename_or_reference` parameter is a simple scalar, it is assumed to be a filename. This file will be opened for reading and the input data will be read from it.

- A filehandle

  If the `$input_filename_or_reference` parameter is a filehandle, the input data will be read from it. The string '-' can be used as an alias for standard input.

- A scalar reference

  If `$input_filename_or_reference` is a scalar reference, the input data will be read from `$$input_filename_or_reference`.

- An array reference

  If `$input_filename_or_reference` is an array reference, each element in the array must be a filename.

  The input data will be read from each file in turn.

  The complete array will be walked to ensure that it only contains valid filenames before any data is uncompressed.

- An Input FileGlob string

  If `$input_filename_or_reference` is a string that is delimited by the characters "<" and ">" `rawinflate` will assume that it is an *input fileglob string*. The input is the list of files that match the fileglob.

  See *File::GlobMapper* for more details.

If the `$input_filename_or_reference` parameter is any other type, `undef` will be returned.

The $output_filename_or_reference parameter

The parameter $output_filename_or_reference is used to control the destination of the uncompressed data. This parameter can take one of these forms.

- A filename

  If the $output_filename_or_reference parameter is a simple scalar, it is assumed to be a filename. This file will be opened for writing and the uncompressed data will be written to it.

- A filehandle

  If the $output_filename_or_reference parameter is a filehandle, the uncompressed data will be written to it. The string '-' can be used as an alias for standard output.

- A scalar reference

  If $output_filename_or_reference is a scalar reference, the uncompressed data will be stored in $$output_filename_or_reference.

- An Array Reference

  If $output_filename_or_reference is an array reference, the uncompressed data will be pushed onto the array.

- An Output FileGlob

  If $output_filename_or_reference is a string that is delimited by the characters "<" and ">" rawinflate will assume that it is an *output fileglob string*. The output is the list of files that match the fileglob.

  When $output_filename_or_reference is an fileglob string, $input_filename_or_reference must also be a fileglob string. Anything else is an error.

  See *File::GlobMapper* for more details.

If the $output_filename_or_reference parameter is any other type, undef will be returned.

Notes

When $input_filename_or_reference maps to multiple compressed files/buffers and $output_filename_or_reference is a single file/buffer, after uncompression $output_filename_or_reference will contain a concatenation of all the uncompressed data from each of the input files/buffers.

Optional Parameters

The optional parameters for the one-shot function rawinflate are (for the most part) identical to those used with the OO interface defined in the "Constructor Options" section. The exceptions are listed below

- AutoClose => 0|1

  This option applies to any input or output data streams to rawinflate that are filehandles.

If `AutoClose` is specified, and the value is true, it will result in all input and/or output filehandles being closed once `rawinflate` has completed.

This parameter defaults to 0.

- `BinModeOut => 0|1`

  This option is now a no-op. All files will be written in binmode.

- `Append => 0|1`

  The behaviour of this option is dependent on the type of output data stream.

  - A Buffer

    If Append is enabled, all uncompressed data will be append to the end of the output buffer. Otherwise the output buffer will be cleared before any uncompressed data is written to it.

  - A Filename

    If Append is enabled, the file will be opened in append mode. Otherwise the contents of the file, if any, will be truncated before any uncompressed data is written to it.

  - A Filehandle

    If Append is enabled, the filehandle will be positioned to the end of the file via a call to `seek` before any uncompressed data is written to it. Otherwise the file pointer will not be moved.

  When Append is specified, and set to true, it will *append* all uncompressed data to the output data stream.

  So when the output is a filehandle it will carry out a seek to the eof before writing any uncompressed data. If the output is a filename, it will be opened for appending. If the output is a buffer, all uncompressed data will be appended to the existing buffer.

  Conversely when Append is not specified, or it is present and is set to false, it will operate as follows.

  When the output is a filename, it will truncate the contents of the file before writing any uncompressed data. If the output is a filehandle its position will not be changed. If the output is a buffer, it will be wiped before any uncompressed data is output.

  Defaults to 0.

- `MultiStream => 0|1`

  This option is a no-op.

- `TrailingData => $scalar`

  Returns the data, if any, that is present immediately after the compressed data stream once uncompression is complete.

  This option can be used when there is useful information immediately following the compressed data stream, and you don't know the length of the compressed data stream.

If the input is a buffer, `trailingData` will return everything from the end of the compressed data stream to the end of the buffer.

If the input is a filehandle, `trailingData` will return the data that is left in the filehandle input buffer once the end of the compressed data stream has been reached. You can then use the filehandle to read the rest of the input file.

Don't bother using `trailingData` if the input is a filename.

If you know the length of the compressed data stream before you start uncompressing, you can avoid having to use `trailingData` by setting the `InputLength` option.

OneShot Examples

To read the contents of the file `file1.txt.1951` and write the uncompressed data to the file `file1.txt`.

```
use strict ;
use warnings ;
use IO::Uncompress::RawInflate qw(rawinflate $RawInflateError) ;

my $input = "file1.txt.1951";
my $output = "file1.txt";
rawinflate $input => $output
    or die "rawinflate failed: $RawInflateError\n";
```

To read from an existing Perl filehandle, `$input`, and write the uncompressed data to a buffer, `$buffer`.

```
use strict ;
use warnings ;
use IO::Uncompress::RawInflate qw(rawinflate $RawInflateError) ;
use IO::File ;

my $input = IO::File->new( "<file1.txt.1951" )
    or die "Cannot open 'file1.txt.1951': $!\n" ;
my $buffer ;
rawinflate $input => \$buffer
    or die "rawinflate failed: $RawInflateError\n";
```

To uncompress all files in the directory "/my/home" that match "*.txt.1951" and store the compressed data in the same directory

```
use strict ;
use warnings ;
use IO::Uncompress::RawInflate qw(rawinflate $RawInflateError) ;

rawinflate '</my/home/*.txt.1951>' => '</my/home/#1.txt>'
    or die "rawinflate failed: $RawInflateError\n";
```

and if you want to compress each file one at a time, this will do the trick

```
use strict ;
use warnings ;
use IO::Uncompress::RawInflate qw(rawinflate $RawInflateError) ;

for my $input ( glob "/my/home/*.txt.1951" )
{
    my $output = $input;
    $output =~ s/.1951// ;
    rawinflate $input => $output
        or die "Error compressing '$input': $RawInflateError\n";
}
```

OO Interface

Constructor

The format of the constructor for IO::Uncompress::RawInflate is shown below

```
my $z = IO::Uncompress::RawInflate->new( $input [OPTS] )
    or die "IO::Uncompress::RawInflate failed: $RawInflateError\n";
```

The constructor takes one mandatory parameter, `$input`, defined below, and zero or more `OPTS`, defined in "Constructor Options".

Returns an `IO::Uncompress::RawInflate` object on success and undef on failure. The variable `$RawInflateError` will contain an error message on failure.

If you are running Perl 5.005 or better the object, `$z`, returned from IO::Uncompress::RawInflate can be used exactly like an *IO::File* filehandle. This means that all normal input file operations can be carried out with `$z`. For example, to read a line from a compressed file/buffer you can use either of these forms

```
$line = $z->getline();
$line = <$z>;
```

Below is a simple exaple of using the OO interface to read the compressed file `myfile.1951` and write its contents to stdout.

```
my $filename = "myfile.1951";
my $z = IO::Uncompress::RawInflate->new($filename)
    or die "IO::Uncompress::RawInflate failed: $RawInflateError\n";

while (<$z>) {
    print $_;
}
$z->close();
```

See "EXAMPLES" for further examples

The mandatory parameter `$input` is used to determine the source of the compressed data. This parameter can take one of three forms.

- A filename

If the `$input` parameter is a scalar, it is assumed to be a filename. This file will be opened for reading and the compressed data will be read from it.

- A filehandle

  If the `$input` parameter is a filehandle, the compressed data will be read from it. The string '-' can be used as an alias for standard input.

- A scalar reference

  If `$input` is a scalar reference, the compressed data will be read from `$$input`.

Constructor Options

The option names defined below are case insensitive and can be optionally prefixed by a '-'. So all of the following are valid

```
-AutoClose
-autoclose
AUTOCLOSE
autoclose
```

OPTS is a combination of the following options:

- `AutoClose => 0|1`

  This option is only valid when the `$input` parameter is a filehandle. If specified, and the value is true, it will result in the file being closed once either the `close` method is called or the IO::Uncompress::RawInflate object is destroyed.

  This parameter defaults to 0.

- `MultiStream => 0|1`

  Allows multiple concatenated compressed streams to be treated as a single compressed stream. Decompression will stop once either the end of the file/buffer is reached, an error is encountered (premature eof, corrupt compressed data) or the end of a stream is not immediately followed by the start of another stream.

  This parameter defaults to 0.

- `Prime => $string`

  This option will uncompress the contents of `$string` before processing the input file/buffer.

  This option can be useful when the compressed data is embedded in another file/data structure and it is not possible to work out where the compressed data begins without having to read the first few bytes. If this is the case, the uncompression can be *primed* with these bytes using this option.

- `Transparent => 0|1`

  If this option is set and the input file/buffer is not compressed data, the module will allow reading of it anyway.

  In addition, if the input file/buffer does contain compressed data and there is non-compressed data immediately following it, setting this option will make this module treat the whole file/buffer as a single data stream.

This option defaults to 1.

- `BlockSize => $num`

  When reading the compressed input data, IO::Uncompress::RawInflate will read it in blocks of `$num` bytes.

  This option defaults to 4096.

- `InputLength => $size`

  When present this option will limit the number of compressed bytes read from the input file/buffer to `$size`. This option can be used in the situation where there is useful data directly after the compressed data stream and you know beforehand the exact length of the compressed data stream.

  This option is mostly used when reading from a filehandle, in which case the file pointer will be left pointing to the first byte directly after the compressed data stream.

  This option defaults to off.

- `Append => 0|1`

  This option controls what the `read` method does with uncompressed data.

  If set to 1, all uncompressed data will be appended to the output parameter of the `read` method.

  If set to 0, the contents of the output parameter of the `read` method will be overwritten by the uncompressed data.

  Defaults to 0.

- `Strict => 0|1`

  This option is a no-op.

Methods

read

Usage is

```
$status = $z->read($buffer)
```

Reads a block of compressed data (the size of the compressed block is determined by the `Buffer` option in the constructor), uncompresses it and writes any uncompressed data into `$buffer`. If the Append parameter is set in the constructor, the uncompressed data will be appended to the `$buffer` parameter. Otherwise `$buffer` will be overwritten.

Returns the number of uncompressed bytes written to `$buffer`, zero if eof or a negative number on error.

read

Usage is

```
$status = $z->read($buffer, $length)
$status = $z->read($buffer, $length, $offset)

$status = read($z, $buffer, $length)
$status = read($z, $buffer, $length, $offset)
```

Attempt to read `$length` bytes of uncompressed data into `$buffer`.

The main difference between this form of the `read` method and the previous one, is that this one will attempt to return *exactly* `$length` bytes. The only circumstances that this function will not is if end-of-file or an IO error is encountered.

Returns the number of uncompressed bytes written to `$buffer`, zero if eof or a negative number on error.

getline

Usage is

```
$line = $z->getline()
$line = <$z>
```

Reads a single line.

This method fully supports the use of the variable `$/` (or `$INPUT_RECORD_SEPARATOR` or `$RS` when `English` is in use) to determine what constitutes an end of line. Paragraph mode, record mode and file slurp mode are all supported.

getc

Usage is

```
$char = $z->getc()
```

Read a single character.

ungetc

Usage is

```
$char = $z->ungetc($string)
```

inflateSync

Usage is

```
$status = $z->inflateSync()
```

TODO

getHeaderInfo

Usage is

```
$hdr  = $z->getHeaderInfo();
@hdrs = $z->getHeaderInfo();
```

This method returns either a hash reference (in scalar context) or a list or hash references (in array context) that contains information about each of the header fields in the compressed data stream(s).

tell

Usage is

```
$z->tell()
tell $z
```

Returns the uncompressed file offset.

eof

Usage is

```
$z->eof();
eof($z);
```

Returns true if the end of the compressed input stream has been reached.

seek

```
$z->seek($position, $whence);
seek($z, $position, $whence);
```

Provides a sub-set of the `seek` functionality, with the restriction that it is only legal to seek forward in the input file/buffer. It is a fatal error to attempt to seek backward.

Note that the implementation of `seek` in this module does not provide true random access to a compressed file/buffer. It works by uncompressing data from the current offset in the file/buffer until it reaches the uncompressed offset specified in the parameters to `seek`. For very small files this may be acceptable behaviour. For large files it may cause an unacceptable delay.

The `$whence` parameter takes one the usual values, namely SEEK_SET, SEEK_CUR or SEEK_END.

Returns 1 on success, 0 on failure.

binmode

Usage is

```
$z->binmode
binmode $z ;
```

This is a noop provided for completeness.

opened

```
$z->opened()
```

Returns true if the object currently refers to a opened file/buffer.

autoflush

```
my $prev = $z->autoflush()
my $prev = $z->autoflush(EXPR)
```

If the `$z` object is associated with a file or a filehandle, this method returns the current autoflush setting for the underlying filehandle. If `EXPR` is present, and is non-zero, it will enable flushing after every write/print operation.

If `$z` is associated with a buffer, this method has no effect and always returns `undef`.

Note that the special variable `$|` **cannot** be used to set or retrieve the autoflush setting.

input_line_number

```
$z->input_line_number()
$z->input_line_number(EXPR)
```

Returns the current uncompressed line number. If `EXPR` is present it has the effect of setting the line number. Note that setting the line number does not change the current position within the file/buffer being read.

The contents of `$/` are used to determine what constitutes a line terminator.

fileno

```
$z->fileno()
fileno($z)
```

If the `$z` object is associated with a file or a filehandle, `fileno` will return the underlying file descriptor. Once the `close` method is called `fileno` will return `undef`.

If the `$z` object is associated with a buffer, this method will return `undef`.

close

```
$z->close() ;
close $z ;
```

Closes the output file/buffer.

For most versions of Perl this method will be automatically invoked if the IO::Uncompress::RawInflate object is destroyed (either explicitly or by the variable with the reference to the object going out of scope). The exceptions are Perl versions 5.005 through 5.00504 and 5.8.0. In these cases, the `close` method will be called automatically, but not until global destruction of all live objects when the program is terminating.

Therefore, if you want your scripts to be able to run on all versions of Perl, you should call `close` explicitly and not rely on automatic closing.

Returns true on success, otherwise 0.

If the `AutoClose` option has been enabled when the IO::Uncompress::RawInflate object was created, and the object is associated with a file, the underlying file will also be closed.

nextStream

Usage is

```
my $status = $z->nextStream();
```

Skips to the next compressed data stream in the input file/buffer. If a new compressed data stream is found, the eof marker will be cleared and `$.` will be reset to 0.

Returns 1 if a new stream was found, 0 if none was found, and -1 if an error was encountered.

trailingData

Usage is

```
my $data = $z->trailingData();
```

Returns the data, if any, that is present immediately after the compressed data stream once uncompression is complete. It only makes sense to call this method once the end of the compressed data stream has been encountered.

This option can be used when there is useful information immediately following the compressed data stream, and you don't know the length of the compressed data stream.

If the input is a buffer, `trailingData` will return everything from the end of the compressed data stream to the end of the buffer.

If the input is a filehandle, `trailingData` will return the data that is left in the filehandle input buffer once the end of the compressed data stream has been reached. You can then use the filehandle to read the rest of the input file.

Don't bother using `trailingData` if the input is a filename.

If you know the length of the compressed data stream before you start uncompressing, you can avoid having to use `trailingData` by setting the `InputLength` option in the constructor.

Importing

No symbolic constants are required by IO::Uncompress::RawInflate at present.

- :all

  Imports `rawinflate` and `$RawInflateError`. Same as doing this

```
use IO::Uncompress::RawInflate qw(rawinflate $RawInflateError) ;
```

EXAMPLES

Working with Net::FTP

IO::Uncompress::Unzip

Read zip files/buffers

SYNOPSIS

```
use IO::Uncompress::Unzip qw(unzip $UnzipError) ;

my $status = unzip $input => $output [,OPTS]
    or die "unzip failed: $UnzipError\n";

my $z = IO::Uncompress::Unzip->new( $input [OPTS] )
    or die "unzip failed: $UnzipError\n";

$status = $z->read($buffer)
$status = $z->read($buffer, $length)
$status = $z->read($buffer, $length, $offset)
$line = $z->getline()
$char = $z->getc()
$char = $z->ungetc()
$char = $z->opened()

$status = $z->inflateSync()

$data = $z->trailingData()
$status = $z->nextStream()
$data = $z->getHeaderInfo()
$z->tell()
$z->seek($position, $whence)
$z->binmode()
$z->fileno()
$z->eof()
$z->close()

$UnzipError ;

(continues on next page)

(continued from previous page)

```
# IO::File mode

<$z>
read($z, $buffer);
read($z, $buffer, $length);
read($z, $buffer, $length, $offset);
tell($z)
seek($z, $position, $whence)
binmode($z)
fileno($z)
eof($z)
close($z)
```

DESCRIPTION

This module provides a Perl interface that allows the reading of zlib files/buffers.

For writing zip files/buffers, see the companion module IO::Compress::Zip.

The primary purpose of this module is to provide *streaming* read access to zip files and buffers.

At present the following compression methods are supported by IO::Uncompress::Unzip

- Store (0)
- Deflate (8)
- Bzip2 (12)

  To read Bzip2 content, the module `IO::Uncompress::Bunzip2` must be installed.
- Lzma (14)

  To read LZMA content, the module `IO::Uncompress::UnLzma` must be installed.
- Xz (95)

  To read Xz content, the module `IO::Uncompress::UnXz` must be installed.
- Zstandard (93)

  To read Zstandard content, the module `IO::Uncompress::UnZstd` must be installed.

Functional Interface

A top-level function, `unzip`, is provided to carry out "one-shot" uncompression between buffers and/or files. For finer control over the uncompression process, see the "OO Interface" section.

```
use IO::Uncompress::Unzip qw(unzip $UnzipError) ;

unzip $input_filename_or_reference => $output_filename_or_reference
```

(continues on next page)

(continued from previous page)

```
↪[,OPTS]
    or die "unzip failed: $UnzipError\n";
```

The functional interface needs Perl5.005 or better.

unzip $input_filename_or_reference => $output_filename_or_reference [, OPTS]

`unzip` expects at least two parameters, `$input_filename_or_reference` and `$output_filename_or_reference` and zero or more optional parameters (see "Optional Parameters")

The `$input_filename_or_reference` parameter

The parameter, `$input_filename_or_reference`, is used to define the source of the compressed data.

It can take one of the following forms:

- A filename

  If the `$input_filename_or_reference` parameter is a simple scalar, it is assumed to be a filename. This file will be opened for reading and the input data will be read from it.

- A filehandle

  If the `$input_filename_or_reference` parameter is a filehandle, the input data will be read from it. The string '-' can be used as an alias for standard input.

- A scalar reference

  If `$input_filename_or_reference` is a scalar reference, the input data will be read from `$$input_filename_or_reference`.

- An array reference

  If `$input_filename_or_reference` is an array reference, each element in the array must be a filename.

  The input data will be read from each file in turn.

  The complete array will be walked to ensure that it only contains valid filenames before any data is uncompressed.

- An Input FileGlob string

  If `$input_filename_or_reference` is a string that is delimited by the characters "<" and ">" `unzip` will assume that it is an *input fileglob string*. The input is the list of files that match the fileglob.

  See *File::GlobMapper* for more details.

If the `$input_filename_or_reference` parameter is any other type, `undef` will be returned.

The $output_filename_or_reference parameter

The parameter $output_filename_or_reference is used to control the destination of the uncompressed data. This parameter can take one of these forms.

- A filename

  If the $output_filename_or_reference parameter is a simple scalar, it is assumed to be a filename. This file will be opened for writing and the uncompressed data will be written to it.

- A filehandle

  If the $output_filename_or_reference parameter is a filehandle, the uncompressed data will be written to it. The string '-' can be used as an alias for standard output.

- A scalar reference

  If $output_filename_or_reference is a scalar reference, the uncompressed data will be stored in $$output_filename_or_reference.

- An Array Reference

  If $output_filename_or_reference is an array reference, the uncompressed data will be pushed onto the array.

- An Output FileGlob

  If $output_filename_or_reference is a string that is delimited by the characters "<" and ">" unzip will assume that it is an *output fileglob string*. The output is the list of files that match the fileglob.

  When $output_filename_or_reference is an fileglob string, $input_filename_or_reference must also be a fileglob string. Anything else is an error.

  See *File::GlobMapper* for more details.

If the $output_filename_or_reference parameter is any other type, undef will be returned.

Notes

When $input_filename_or_reference maps to multiple compressed files/buffers and $output_filename_or_reference is a single file/buffer, after uncompression $output_filename_or_reference will contain a concatenation of all the uncompressed data from each of the input files/buffers.

Optional Parameters

The optional parameters for the one-shot function unzip are (for the most part) identical to those used with the OO interface defined in the "Constructor Options" section. The exceptions are listed below

- AutoClose => 0|1

  This option applies to any input or output data streams to unzip that are filehandles.

If `AutoClose` is specified, and the value is true, it will result in all input and/or output filehandles being closed once `unzip` has completed.

This parameter defaults to 0.

- `BinModeOut => 0|1`

  This option is now a no-op. All files will be written in binmode.

- `Append => 0|1`

  The behaviour of this option is dependent on the type of output data stream.

  - A Buffer

    If Append is enabled, all uncompressed data will be append to the end of the output buffer. Otherwise the output buffer will be cleared before any uncompressed data is written to it.

  - A Filename

    If Append is enabled, the file will be opened in append mode. Otherwise the contents of the file, if any, will be truncated before any uncompressed data is written to it.

  - A Filehandle

    If Append is enabled, the filehandle will be positioned to the end of the file via a call to `seek` before any uncompressed data is written to it. Otherwise the file pointer will not be moved.

  When Append is specified, and set to true, it will *append* all uncompressed data to the output data stream.

  So when the output is a filehandle it will carry out a seek to the eof before writing any uncompressed data. If the output is a filename, it will be opened for appending. If the output is a buffer, all uncompressed data will be appended to the existing buffer.

  Conversely when Append is not specified, or it is present and is set to false, it will operate as follows.

  When the output is a filename, it will truncate the contents of the file before writing any uncompressed data. If the output is a filehandle its position will not be changed. If the output is a buffer, it will be wiped before any uncompressed data is output.

  Defaults to 0.

- `MultiStream => 0|1`

  If the input file/buffer contains multiple compressed data streams, this option will uncompress the whole lot as a single data stream.

  Defaults to 0.

- `TrailingData => $scalar`

  Returns the data, if any, that is present immediately after the compressed data stream once uncompression is complete.

This option can be used when there is useful information immediately following the compressed data stream, and you don't know the length of the compressed data stream.

If the input is a buffer, `trailingData` will return everything from the end of the compressed data stream to the end of the buffer.

If the input is a filehandle, `trailingData` will return the data that is left in the filehandle input buffer once the end of the compressed data stream has been reached. You can then use the filehandle to read the rest of the input file.

Don't bother using `trailingData` if the input is a filename.

If you know the length of the compressed data stream before you start uncompressing, you can avoid having to use `trailingData` by setting the `InputLength` option.

OneShot Examples

Say you have a zip file, `file1.zip`, that only contains a single member, you can read it and write the uncompressed data to the file `file1.txt` like this.

```
use strict ;
use warnings ;
use IO::Uncompress::Unzip qw(unzip $UnzipError) ;

my $input = "file1.zip";
my $output = "file1.txt";
unzip $input => $output
    or die "unzip failed: $UnzipError\n";
```

If you have a zip file that contains multiple members and want to read a specific member from the file, say `"data1"`, use the `Name` option

```
use strict ;
use warnings ;
use IO::Uncompress::Unzip qw(unzip $UnzipError) ;

my $input = "file1.zip";
my $output = "file1.txt";
unzip $input => $output, Name => "data1"
    or die "unzip failed: $UnzipError\n";
```

Alternatively, if you want to read the `"data1"` member into memory, use a scalar reference for the `output` parameter.

```
use strict ;
use warnings ;
use IO::Uncompress::Unzip qw(unzip $UnzipError) ;

my $input = "file1.zip";
my $output ;
unzip $input => \$output, Name => "data1"
```

(continues on next page)

(continued from previous page)

```
    or die "unzip failed: $UnzipError\n";
# $output now contains the uncompressed data
```

To read from an existing Perl filehandle, `$input`, and write the uncompressed data to a buffer, `$buffer`.

```
use strict ;
use warnings ;
use IO::Uncompress::Unzip qw(unzip $UnzipError) ;
use IO::File ;

my $input = IO::File->new( "<file1.zip" )
    or die "Cannot open 'file1.zip': $!\n" ;
my $buffer ;
unzip $input => \$buffer
    or die "unzip failed: $UnzipError\n";
```

OO Interface

Constructor

The format of the constructor for IO::Uncompress::Unzip is shown below

```
my $z = IO::Uncompress::Unzip->new( $input [OPTS] )
    or die "IO::Uncompress::Unzip failed: $UnzipError\n";
```

The constructor takes one mandatory parameter, `$input`, defined below, and zero or more `OPTS`, defined in “Constructor Options”.

Returns an `IO::Uncompress::Unzip` object on success and undef on failure. The variable `$UnzipError` will contain an error message on failure.

If you are running Perl 5.005 or better the object, `$z`, returned from IO::Uncompress::Unzip can be used exactly like an *IO::File* filehandle. This means that all normal input file operations can be carried out with `$z`. For example, to read a line from a compressed file/buffer you can use either of these forms

```
$line = $z->getline();
$line = <$z>;
```

Below is a simple exaple of using the OO interface to read the compressed file `myfile.zip` and write its contents to stdout.

```
my $filename = "myfile.zip";
my $z = IO::Uncompress::Unzip->new($filename)
    or die "IO::Uncompress::Unzip failed: $UnzipError\n";

while (<$z>) {
    print $_;
}
$z->close();
```

See “EXAMPLES” for further examples

The mandatory parameter `$input` is used to determine the source of the compressed data. This parameter can take one of three forms.

- A filename

  If the `$input` parameter is a scalar, it is assumed to be a filename. This file will be opened for reading and the compressed data will be read from it.

- A filehandle

  If the `$input` parameter is a filehandle, the compressed data will be read from it. The string ‘-’ can be used as an alias for standard input.

- A scalar reference

  If `$input` is a scalar reference, the compressed data will be read from `$$input`.

Constructor Options

The option names defined below are case insensitive and can be optionally prefixed by a ‘-’. So all of the following are valid

```
-AutoClose
-autoclose
AUTOCLOSE
autoclose
```

OPTS is a combination of the following options:

- `Name => "membername"`

  Open “membername” from the zip file for reading.

- `Efs => 0| 1`

  When this option is set to true AND the zip archive being read has the “Language Encoding Flag” (EFS) set, the member name is assumed to be encoded in UTF-8.

  If the member name in the zip archive is not valid UTF-8 when this optionn is true, the script will die with an error message.

  Note that this option only works with Perl 5.8.4 or better.

  This option defaults to **false**.

- `AutoClose => 0|1`

  This option is only valid when the `$input` parameter is a filehandle. If specified, and the value is true, it will result in the file being closed once either the `close` method is called or the IO::Uncompress::Unzip object is destroyed.

  This parameter defaults to 0.

- `MultiStream => 0|1`

  Treats the complete zip file/buffer as a single compressed data stream. When reading in multi-stream mode each member of the zip file/buffer will be uncompressed in turn until the end of the file/buffer is encountered.

This parameter defaults to 0.

- `Prime => $string`

  This option will uncompress the contents of `$string` before processing the input file/buffer.

  This option can be useful when the compressed data is embedded in another file/data structure and it is not possible to work out where the compressed data begins without having to read the first few bytes. If this is the case, the uncompression can be *primed* with these bytes using this option.

- `Transparent => 0|1`

  If this option is set and the input file/buffer is not compressed data, the module will allow reading of it anyway.

  In addition, if the input file/buffer does contain compressed data and there is non-compressed data immediately following it, setting this option will make this module treat the whole file/buffer as a single data stream.

  This option defaults to 1.

- `BlockSize => $num`

  When reading the compressed input data, IO::Uncompress::Unzip will read it in blocks of `$num` bytes.

  This option defaults to 4096.

- `InputLength => $size`

  When present this option will limit the number of compressed bytes read from the input file/buffer to `$size`. This option can be used in the situation where there is useful data directly after the compressed data stream and you know beforehand the exact length of the compressed data stream.

  This option is mostly used when reading from a filehandle, in which case the file pointer will be left pointing to the first byte directly after the compressed data stream.

  This option defaults to off.

- `Append => 0|1`

  This option controls what the `read` method does with uncompressed data.

  If set to 1, all uncompressed data will be appended to the output parameter of the `read` method.

  If set to 0, the contents of the output parameter of the `read` method will be overwritten by the uncompressed data.

  Defaults to 0.

- `Strict => 0|1`

  This option controls whether the extra checks defined below are used when carrying out the decompression. When Strict is on, the extra tests are carried out, when Strict is off they are not.

  The default for this option is off.

Methods

read

Usage is

```
$status = $z->read($buffer)
```

Reads a block of compressed data (the size of the compressed block is determined by the `Buffer` option in the constructor), uncompresses it and writes any uncompressed data into `$buffer`. If the `Append` parameter is set in the constructor, the uncompressed data will be appended to the `$buffer` parameter. Otherwise `$buffer` will be overwritten.

Returns the number of uncompressed bytes written to `$buffer`, zero if eof or a negative number on error.

read

Usage is

```
$status = $z->read($buffer, $length)
$status = $z->read($buffer, $length, $offset)

$status = read($z, $buffer, $length)
$status = read($z, $buffer, $length, $offset)
```

Attempt to read `$length` bytes of uncompressed data into `$buffer`.

The main difference between this form of the `read` method and the previous one, is that this one will attempt to return *exactly* `$length` bytes. The only circumstances that this function will not is if end-of-file or an IO error is encountered.

Returns the number of uncompressed bytes written to `$buffer`, zero if eof or a negative number on error.

getline

Usage is

```
$line = $z->getline()
$line = <$z>
```

Reads a single line.

This method fully supports the use of the variable `$/` (or `$INPUT_RECORD_SEPARATOR` or `$RS` when `English` is in use) to determine what constitutes an end of line. Paragraph mode, record mode and file slurp mode are all supported.

getc

Usage is

```
$char = $z->getc()
```

Read a single character.

ungetc

Usage is

```
$char = $z->ungetc($string)
```

inflateSync

Usage is

```
$status = $z->inflateSync()
```

TODO

getHeaderInfo

Usage is

```
$hdr  = $z->getHeaderInfo();
@hdrs = $z->getHeaderInfo();
```

This method returns either a hash reference (in scalar context) or a list or hash references (in array context) that contains information about each of the header fields in the compressed data stream(s).

tell

Usage is

```
$z->tell()
tell $z
```

Returns the uncompressed file offset.

eof

Usage is

```
$z->eof();
eof($z);
```

Returns true if the end of the compressed input stream has been reached.

seek

```
$z->seek($position, $whence);
seek($z, $position, $whence);
```

Provides a sub-set of the `seek` functionality, with the restriction that it is only legal to seek forward in the input file/buffer. It is a fatal error to attempt to seek backward.

Note that the implementation of `seek` in this module does not provide true random access to a compressed file/buffer. It works by uncompressing data from the current offset in the file/buffer until it reaches the uncompressed offset specified in the parameters to `seek`. For very small files this may be acceptable behaviour. For large files it may cause an unacceptable delay.

The `$whence` parameter takes one the usual values, namely SEEK_SET, SEEK_CUR or SEEK_END.

Returns 1 on success, 0 on failure.

binmode

Usage is

```
$z->binmode
binmode $z ;
```

This is a noop provided for completeness.

opened

```
$z->opened()
```

Returns true if the object currently refers to a opened file/buffer.

autoflush

```
my $prev = $z->autoflush()
my $prev = $z->autoflush(EXPR)
```

If the `$z` object is associated with a file or a filehandle, this method returns the current autoflush setting for the underlying filehandle. If `EXPR` is present, and is non-zero, it will enable flushing after every write/print operation.

If `$z` is associated with a buffer, this method has no effect and always returns `undef`.

Note that the special variable `$|` **cannot** be used to set or retrieve the autoflush setting.

input_line_number

```
$z->input_line_number()
$z->input_line_number(EXPR)
```

Returns the current uncompressed line number. If `EXPR` is present it has the effect of setting the line number. Note that setting the line number does not change the current position within the file/buffer being read.

The contents of `$/` are used to determine what constitutes a line terminator.

fileno

```
$z->fileno()
fileno($z)
```

If the `$z` object is associated with a file or a filehandle, `fileno` will return the underlying file descriptor. Once the `close` method is called `fileno` will return `undef`.

If the `$z` object is associated with a buffer, this method will return `undef`.

close

```
$z->close() ;
close $z ;
```

Closes the output file/buffer.

For most versions of Perl this method will be automatically invoked if the IO::Uncompress::Unzip object is destroyed (either explicitly or by the variable with the reference to the object going out of scope). The exceptions are Perl versions 5.005 through 5.00504 and 5.8.0. In these cases, the `close` method will be called automatically, but not until global destruction of all live objects when the program is terminating.

Therefore, if you want your scripts to be able to run on all versions of Perl, you should call `close` explicitly and not rely on automatic closing.

Returns true on success, otherwise 0.

If the `AutoClose` option has been enabled when the IO::Uncompress::Unzip object was created, and the object is associated with a file, the underlying file will also be closed.

nextStream

Usage is

```
my $status = $z->nextStream();
```

Skips to the next compressed data stream in the input file/buffer. If a new compressed data stream is found, the eof marker will be cleared and `$.` will be reset to 0.

If trailing data is present immediately after the zip archive and the `Transparent` option is enabled, this method will consider that trailing data to be another member of the zip archive.

Returns 1 if a new stream was found, 0 if none was found, and -1 if an error was encountered.

trailingData

Usage is

```
my $data = $z->trailingData();
```

Returns the data, if any, that is present immediately after the compressed data stream once uncompression is complete. It only makes sense to call this method once the end of the compressed data stream has been encountered.

This option can be used when there is useful information immediately following the compressed data stream, and you don't know the length of the compressed data stream.

If the input is a buffer, `trailingData` will return everything from the end of the compressed data stream to the end of the buffer.

If the input is a filehandle, `trailingData` will return the data that is left in the filehandle input buffer once the end of the compressed data stream has been reached. You can then use the filehandle to read the rest of the input file.

Don't bother using `trailingData` if the input is a filename.

If you know the length of the compressed data stream before you start uncompressing, you can avoid having to use `trailingData` by setting the `InputLength` option in the constructor.

Importing

No symbolic constants are required by IO::Uncompress::Unzip at present.

- :all

  Imports `unzip` and `$UnzipError`. Same as doing this

```
use IO::Uncompress::Unzip qw(unzip $UnzipError) ;
```

EXAMPLES

Simple Read

Say you have a zip file, `file1.zip`, that only contains a single member, you can read it and write the uncompressed data to the file `file1.txt` like this.

```
use strict ;
use warnings ;
use IO::Uncompress::Unzip qw(unzip $UnzipError) ;

my $filename = "file1.zip";
my $z = IO::Uncompress::Unzip->new($filename)
    or die "IO::Uncompress::Unzip failed: $UnzipError\n";
open my $out, ">", "file1.txt";

while (<$z>) {
    print $out $_;
}
$z->close();
```

If you have a zip file that contains multiple members and want to read a specific member from the file, say `"data1"`, use the `Name` option when constructing the

```
use strict ;
use warnings ;
use IO::Uncompress::Unzip qw(unzip $UnzipError) ;

my $filename = "file1.zip";
my $z = IO::Uncompress::Unzip->new($filename, Name => "data1")
    or die "IO::Uncompress::Unzip failed: $UnzipError\n";
```

Walking through a zip file

The code below can be used to traverse a zip file, one compressed data stream at a time.

```
use IO::Uncompress::Unzip qw($UnzipError);

my $zipfile = "somefile.zip";
my $u = IO::Uncompress::Unzip->new( $zipfile )
    or die "Cannot open $zipfile: $UnzipError";

my $status;
for ($status = 1; $status > 0; $status = $u->nextStream())
{

    my $name = $u->getHeaderInfo()->{Name};
    warn "Processing member $name\n" ;

    my $buff;
    while (($status = $u->read($buff)) > 0) {
        # Do something here
    }

    last if $status < 0;
}

die "Error processing $zipfile: $!\n"
    if $status < 0 ;
```

Each individual compressed data stream is read until the logical end-of-file is reached. Then `nextStream` is called. This will skip to the start of the next compressed data stream and clear the end-of-file flag.

It is also worth noting that `nextStream` can be called at any time – you don't have to wait until you have exhausted a compressed data stream before skipping to the next one.

Unzipping a complete zip file to disk

Daniel S. Sterling has written a script that uses `IO::Uncompress::UnZip` to read a zip file and unzip its contents to disk.

The script is available from https://gist.github.com/eqhmcow/5389877

Working with Net::FTP

IO::Zlib

IO:: style interface to *Compress::Zlib*

SYNOPSIS

With any version of Perl 5 you can use the basic OO interface:

```
use IO::Zlib;

$fh = new IO::Zlib;
if ($fh->open("file.gz", "rb")) {
    print <$fh>;
    $fh->close;
}

$fh = IO::Zlib->new("file.gz", "wb9");
if (defined $fh) {
    print $fh "bar\n";
    $fh->close;
}

$fh = IO::Zlib->new("file.gz", "rb");
if (defined $fh) {
    print <$fh>;
    undef $fh;       # automatically closes the file
}
```

With Perl 5.004 you can also use the TIEHANDLE interface to access compressed files just like ordinary files:

```
use IO::Zlib;

tie *FILE, 'IO::Zlib', "file.gz", "wb";
print FILE "line 1\nline2\n";

tie *FILE, 'IO::Zlib', "file.gz", "rb";
while (<FILE>) { print "LINE: ", $_ };
```

DESCRIPTION

`IO::Zlib` provides an IO:: style interface to *Compress::Zlib* and hence to gzip/zlib compressed files. It provides many of the same methods as the *IO::Handle* interface.

Starting from IO::Zlib version 1.02, IO::Zlib can also use an external `gzip` command. The default behaviour is to try to use an external `gzip` if no `Compress::Zlib` can be loaded, unless explicitly disabled by

```
use IO::Zlib qw(:gzip_external 0);
```

If explicitly enabled by

```
use IO::Zlib qw(:gzip_external 1);
```

then the external `gzip` is used **instead** of `Compress::Zlib`.

CONSTRUCTOR

- new ([ARGS])

  Creates an `IO::Zlib` object. If it receives any parameters, they are passed to the method open; if the open fails, the object is destroyed. Otherwise, it is returned to the caller.

OBJECT METHODS

- open (FILENAME, MODE)

  open takes two arguments. The first is the name of the file to open and the second is the open mode. The mode can be anything acceptable to *Compress::Zlib* and by extension anything acceptable to *zlib* (that basically means POSIX fopen() style mode strings plus an optional number to indicate the compression level).

- opened

  Returns true if the object currently refers to a opened file.

- close

  Close the file associated with the object and disassociate the file from the handle. Done automatically on destroy.

- getc

  Return the next character from the file, or undef if none remain.

- getline

  Return the next line from the file, or undef on end of string. Can safely be called in an array context. Currently ignores $/ ($INPUT_RECORD_SEPARATOR or $RS when *English* is in use) and treats lines as delimited by "\n".

- getlines

  Get all remaining lines from the file. It will croak() if accidentally called in a scalar context.

- print (ARGS...)

  Print ARGS to the file.

- read (BUF, NBYTES, [OFFSET])

  Read some bytes from the file. Returns the number of bytes actually read, 0 on end-of-file, undef on error.

- eof

  Returns true if the handle is currently positioned at end of file?

- seek (OFFSET, WHENCE)

  Seek to a given position in the stream. Not yet supported.

- tell

  Return the current position in the stream, as a numeric offset. Not yet supported.

- setpos (POS)

  Set the current position, using the opaque value returned by `getpos()`. Not yet supported.

- getpos (POS)

  Return the current position in the string, as an opaque object. Not yet supported.

USING THE EXTERNAL GZIP

If the external `gzip` is used, the following opens are used:

```
open(FH, "gzip -dc $filename |")  # for read opens
open(FH, " | gzip > $filename")   # for write opens
```

You can modify the 'commands' for example to hardwire an absolute path by e.g.

```
use IO::Zlib ':gzip_read_open'  => '/some/where/gunzip -c %s |';
use IO::Zlib ':gzip_write_open' => '| /some/where/gzip.exe > %s';
```

The `%s` is expanded to be the filename (`sprintf` is used, so be careful to escape any other % signs). The 'commands' are checked for sanity - they must contain the `%s`, and the read open must end with the pipe sign, and the write open must begin with the pipe sign.

CLASS METHODS

- has_Compress_Zlib

  Returns true if `Compress::Zlib` is available. Note that this does not mean that `Compress::Zlib` is being used: see "gzip_external" and gzip_used.

- gzip_external

  Undef if an external `gzip` **can** be used if `Compress::Zlib` is not available (see "has_Compress_Zlib"), true if an external `gzip` is explicitly used, false if an external `gzip` must not be used. See "gzip_used".

- gzip_used

  True if an external `gzip` is being used, false if not.

- gzip_read_open

  Return the 'command' being used for opening a file for reading using an external `gzip`.

- gzip_write_open

  Return the 'command' being used for opening a file for writing using an external `gzip`.

DIAGNOSTICS

- IO::Zlib::getlines: must be called in list context

  If you want read lines, you must read in list context.

- IO::Zlib::gzopen_external: mode '...' is illegal

  Use only modes 'rb' or 'wb' or /wb[1-9]/.

- IO::Zlib::import: '...' is illegal

  The known import symbols are the `:gzip_external`, `:gzip_read_open`, and `:gzip_write_open`. Anything else is not recognized.

- IO::Zlib::import: ':gzip_external' requires an argument

  The `:gzip_external` requires one boolean argument.

- IO::Zlib::import: 'gzip_read_open' requires an argument

  The `:gzip_external` requires one string argument.

- IO::Zlib::import: 'gzip_read' '...' is illegal

  The `:gzip_read_open` argument must end with the pipe sign (`|`) and have the `%s` for the filename. See "USING THE EXTERNAL GZIP".

- IO::Zlib::import: 'gzip_write_open' requires an argument

  The `:gzip_external` requires one string argument.

- IO::Zlib::import: 'gzip_write_open' '...' is illegal

  The `:gzip_write_open` argument must begin with the pipe sign (`|`) and have the `%s` for the filename. An output redirect (>) is also often a good idea, depending on your operating system shell syntax. See "USING THE EXTERNAL GZIP".

- IO::Zlib::import: no Compress::Zlib and no external gzip

  Given that we failed to load `Compress::Zlib` and that the use of an external `gzip` was disabled, IO::Zlib has not much chance of working.

- IO::Zlib::open: needs a filename

  No filename, no open.

- IO::Zlib::READ: NBYTES must be specified

  We must know how much to read.

- IO::Zlib::WRITE: too long LENGTH

  The LENGTH must be less than or equal to the buffer size.

5.2.58 IPC

Namespace containing the following modules:

- IPC::Cmd - finding and running system commands made easy
- IPC::Msg - SysV Msg IPC object class
- IPC::Open2 - open a process for both reading and writing using open2()
- IPC::Open3 - open a process for reading, writing, and error handling using open3()
- IPC::Semaphore - SysV Semaphore IPC object class
- IPC::SharedMem - SysV Shared Memory IPC object class
- IPC::SysV - System V IPC constants and the system calls Perl's builtins do not cover.

IPC::Cmd

finding and running system commands made easy

SYNOPSIS

```
use IPC::Cmd qw[can_run run run_forked];

my $full_path = can_run('wget') or warn 'wget is not installed!';

### commands can be arrayrefs or strings ###
my $cmd = "$full_path -b theregister.co.uk";
my $cmd = [$full_path, '-b', 'theregister.co.uk'];

### in scalar context ###
my $buffer;
if( scalar run( command => $cmd,
                verbose => 0,
                buffer  => \$buffer,
                timeout => 20 )
) {
    print "fetched webpage successfully: $buffer\n";
}
```

(continues on next page)

(continued from previous page)

```
### in list context ###
my( $success, $error_message, $full_buf, $stdout_buf, $stderr_buf )
 ↪=
        run( command => $cmd, verbose => 0 );

if( $success ) {
    print "this is what the command printed:\n";
    print join "", @$full_buf;
}

### run_forked example ###
my $result = run_forked("$full_path -q -O - theregister.co.uk", {
 ↪'timeout' => 20});
if ($result->{'exit_code'} eq 0 && !$result->{'timeout'}) {
    print "this is what wget returned:\n";
    print $result->{'stdout'};
}

### check for features
print "IPC::Open3 available: "   . IPC::Cmd->can_use_ipc_open3;
print "IPC::Run available: "     . IPC::Cmd->can_use_ipc_run;
print "Can capture buffer: "     . IPC::Cmd->can_capture_buffer;

### don't have IPC::Cmd be verbose, ie don't print to stdout or
### stderr when running commands -- default is '0'
$IPC::Cmd::VERBOSE = 0;
```

DESCRIPTION

IPC::Cmd allows you to run commands platform independently, interactively if desired, but have them still work.

The `can_run` function can tell you if a certain binary is installed and if so where, whereas the `run` function can actually execute any of the commands you give it and give you a clear return value, as well as adhere to your verbosity settings.

CLASS METHODS

$ipc_run_version = IPC::Cmd->can_use_ipc_run([VERBOSE])

Utility function that tells you if `IPC::Run` is available. If the `verbose` flag is passed, it will print diagnostic messages if IPC::Run can not be found or loaded.

$ipc_open3_version = IPC::Cmd->can_use_ipc_open3([VERBOSE])

Utility function that tells you if `IPC::Open3` is available. If the verbose flag is passed, it will print diagnostic messages if `IPC::Open3` can not be found or loaded.

$bool = IPC::Cmd->can_capture_buffer

Utility function that tells you if `IPC::Cmd` is capable of capturing buffers in it's current configuration.

$bool = IPC::Cmd->can_use_run_forked

Utility function that tells you if `IPC::Cmd` is capable of providing `run_forked` on the current platform.

FUNCTIONS

$path = can_run(PROGRAM);

`can_run` takes only one argument: the name of a binary you wish to locate. `can_run` works much like the unix binary `which` or the bash command `type`, which scans through your path, looking for the requested binary.

Unlike `which` and `type`, this function is platform independent and will also work on, for example, Win32.

If called in a scalar context it will return the full path to the binary you asked for if it was found, or `undef` if it was not.

If called in a list context and the global variable `$INSTANCES` is a true value, it will return a list of the full paths to instances of the binary where found in `PATH`, or an empty list if it was not found.

$ok | ($ok, $err, $full_buf, $stdout_buff, $stderr_buff) = run(command => COMMAND, [verbose => BOOL, buffer => \$SCALAR, timeout => DIGIT]);

`run` takes 4 arguments:

- command

  This is the command to execute. It may be either a string or an array reference. This is a required argument.

  See "Caveats" for remarks on how commands are parsed and their limitations.

- verbose

  This controls whether all output of a command should also be printed to STDOUT/STDERR or should only be trapped in buffers (NOTE: buffers require IPC::Run to be installed, or your system able to work with *IPC::Open3*).

  It will default to the global setting of `$IPC::Cmd::VERBOSE`, which by default is 0.

- buffer

  This will hold all the output of a command. It needs to be a reference to a scalar. Note that this will hold both the STDOUT and STDERR messages, and you have no

way of telling which is which. If you require this distinction, run the `run` command in list context and inspect the individual buffers.

Of course, this requires that the underlying call supports buffers. See the note on buffers above.

- timeout

  Sets the maximum time the command is allowed to run before aborting, using the built-in `alarm()` call. If the timeout is triggered, the `errorcode` in the return value will be set to an object of the `IPC::Cmd::TimeOut` class. See the "error message" section below for details.

  Defaults to `0`, meaning no timeout is set.

`run` will return a simple `true` or `false` when called in scalar context. In list context, you will be returned a list of the following items:

- success

  A simple boolean indicating if the command executed without errors or not.

- error message

  If the first element of the return value (`success`) was 0, then some error occurred. This second element is the error message the command you requested exited with, if available. This is generally a pretty printed value of `$?` or `$@`. See `perldoc perlvar` for details on what they can contain. If the error was a timeout, the `error message` will be prefixed with the string `IPC::Cmd::TimeOut`, the timeout class.

- full_buffer

  This is an array reference containing all the output the command generated. Note that buffers are only available if you have IPC::Run installed, or if your system is able to work with *IPC::Open3* – see below). Otherwise, this element will be `undef`.

- out_buffer

  This is an array reference containing all the output sent to STDOUT the command generated. The notes from "full_buffer" apply.

- error_buffer

  This is an arrayreference containing all the output sent to STDERR the command generated. The notes from "full_buffer" apply.

See the "HOW IT WORKS" section below to see how `IPC::Cmd` decides what modules or function calls to use when issuing a command.

$hashref = run_forked(COMMAND, { child_stdin => SCALAR, timeout => DIGIT, stdout_handler => CODEREF, stderr_handler => CODEREF});

`run_forked` is used to execute some program or a coderef, optionally feed it with some input, get its return code and output (both stdout and stderr into separate buffers). In addition, it allows to terminate the program if it takes too long to finish.

The important and distinguishing feature of run_forked is execution timeout which at first seems to be quite a simple task but if you think that the program which you're spawning might spawn some children itself (which in their turn could do the same and so on) it turns out to be not a simple issue.

`run_forked` is designed to survive and successfully terminate almost any long running task, even a fork bomb in case your system has the resources to survive during given timeout.

This is achieved by creating separate watchdog process which spawns the specified program in a separate process session and supervises it: optionally feeds it with input, stores its exit code, stdout and stderr, terminates it in case it runs longer than specified.

Invocation requires the command to be executed or a coderef and optionally a hashref of options:

- `timeout`

  Specify in seconds how long to run the command before it is killed with SIG_KILL (9), which effectively terminates it and all of its children (direct or indirect).

- `child_stdin`

  Specify some text that will be passed into the `STDIN` of the executed program.

- `stdout_handler`

  Coderef of a subroutine to call when a portion of data is received on STDOUT from the executing program.

- `stderr_handler`

  Coderef of a subroutine to call when a portion of data is received on STDERR from the executing program.

- `wait_loop_callback`

  Coderef of a subroutine to call inside of the main waiting loop (while `run_forked` waits for the external to finish or fail). It is useful to stop running external process before it ends by itself, e.g.

```
my $r = run_forked("some external command", {
        'wait_loop_callback' => sub {
        if (condition) {
            kill(1, $$);
        }
        },
        'terminate_on_signal' => 'HUP',
        });
```

  Combined with `stdout_handler` and `stderr_handler` allows terminating external command based on its output. Could also be used as a timer without engaging with alarm (signals).

  Remember that this code could be called every millisecond (depending on the output which external command generates), so try to make it as lightweight as possible.

- `discard_output`

  Discards the buffering of the standard output and standard errors for return by run_forked(). With this option you have to use the std*_handlers to read what the command outputs. Useful for commands that send a lot of output.

- `terminate_on_parent_sudden_death`

  Enable this option if you wish all spawned processes to be killed if the initially spawned process (the parent) is killed or dies without waiting for child processes.

`run_forked` will return a HASHREF with the following keys:

- `exit_code`

  The exit code of the executed program.

- `timeout`

  The number of seconds the program ran for before being terminated, or 0 if no timeout occurred.

- `stdout`

  Holds the standard output of the executed command (or empty string if there was no STDOUT output or if `discard_output` was used; it's always defined!)

- `stderr`

  Holds the standard error of the executed command (or empty string if there was no STDERR output or if `discard_output` was used; it's always defined!)

- `merged`

  Holds the standard output and error of the executed command merged into one stream (or empty string if there was no output at all or if `discard_output` was used; it's always defined!)

- `err_msg`

  Holds some explanation in the case of an error.

$q = QUOTE

Returns the character used for quoting strings on this platform. This is usually a `'` (single quote) on most systems, but some systems use different quotes. For example, `Win32` uses `"` (double quote).

You can use it as follows:

```
use IPC::Cmd qw[run QUOTE];
my $cmd = q[echo ] . QUOTE . q[foo bar] . QUOTE;
```

This makes sure that `foo bar` is treated as a string, rather than two separate arguments to the `echo` function.

HOW IT WORKS

`run` will try to execute your command using the following logic:

- If you have `IPC::Run` installed, and the variable `$IPC::Cmd::USE_IPC_RUN` is set to true (See the "Global Variables" section) use that to execute the command. You will have the full output available in buffers, interactive commands are sure to work and you are guaranteed to have your verbosity settings honored cleanly.

- Otherwise, if the variable `$IPC::Cmd::USE_IPC_OPEN3` is set to true (See the "Global Variables" section), try to execute the command using *IPC::Open3*. Buffers will be available on all platforms, interactive commands will still execute cleanly, and also your verbosity settings will be adhered to nicely;
- Otherwise, if you have the `verbose` argument set to true, we fall back to a simple `system()` call. We cannot capture any buffers, but interactive commands will still work.
- Otherwise we will try and temporarily redirect STDERR and STDOUT, do a `system()` call with your command and then re-open STDERR and STDOUT. This is the method of last resort and will still allow you to execute your commands cleanly. However, no buffers will be available.

Global Variables

The behaviour of IPC::Cmd can be altered by changing the following global variables:

$IPC::Cmd::VERBOSE

This controls whether IPC::Cmd will print any output from the commands to the screen or not. The default is 0.

$IPC::Cmd::USE_IPC_RUN

This variable controls whether IPC::Cmd will try to use IPC::Run when available and suitable.

$IPC::Cmd::USE_IPC_OPEN3

This variable controls whether IPC::Cmd will try to use *IPC::Open3* when available and suitable. Defaults to true.

$IPC::Cmd::WARN

This variable controls whether run-time warnings should be issued, like the failure to load an `IPC::*` module you explicitly requested.

Defaults to true. Turn this off at your own risk.

$IPC::Cmd::INSTANCES

This variable controls whether `can_run` will return all instances of the binary it finds in the `PATH` when called in a list context.

Defaults to false, set to true to enable the described behaviour.

$IPC::Cmd::ALLOW_NULL_ARGS

This variable controls whether `run` will remove any empty/null arguments it finds in command arguments.

Defaults to false, so it will remove null arguments. Set to true to allow them.

Caveats

- Whitespace and IPC::Open3 / system()

  When using `IPC::Open3` or `system`, if you provide a string as the `command` argument, it is assumed to be appropriately escaped. You can use the `QUOTE` constant to use as a portable quote character (see above). However, if you provide an array reference, special rules apply:

  If your command contains **special characters** (< > | &), it will be internally stringified before executing the command, to avoid that these special characters are escaped and passed as arguments instead of retaining their special meaning.

  However, if the command contained arguments that contained whitespace, stringifying the command would lose the significance of the whitespace. Therefore, `IPC::Cmd` will quote any arguments containing whitespace in your command if the command is passed as an arrayref and contains special characters.

- Whitespace and IPC::Run

  When using `IPC::Run`, if you provide a string as the `command` argument, the string will be split on whitespace to determine the individual elements of your command. Although this will usually just Do What You Mean, it may break if you have files or commands with whitespace in them.

  If you do not wish this to happen, you should provide an array reference, where all parts of your command are already separated out. Note however, if there are extra or spurious whitespaces in these parts, the parser or underlying code may not interpret it correctly, and cause an error.

  Example: The following code

```
gzip -cdf foo.tar.gz | tar -xf -
```

  should either be passed as

```
"gzip -cdf foo.tar.gz | tar -xf -"
```

  or as

```
['gzip', '-cdf', 'foo.tar.gz', '|', 'tar', '-xf', '-']
```

  But take care not to pass it as, for example

```
['gzip -cdf foo.tar.gz', '|', 'tar -xf -']
```

  Since this will lead to issues as described above.

- IO Redirect

  Currently it is too complicated to parse your command for IO redirections. For capturing STDOUT or STDERR there is a work around however, since you can just inspect your buffers for the contents.

- Interleaving STDOUT/STDERR

  Neither IPC::Run nor IPC::Open3 can interleave STDOUT and STDERR. For short bursts of output from a program, e.g. this sample,

```
for ( 1..4 ) {
    $_ % 2 ? print STDOUT $_ : print STDERR $_;
}
```

IPC::[Run|Open3] will first read all of STDOUT, then all of STDERR, meaning the output looks like '13' on STDOUT and '24' on STDERR, instead of

```
1
2
3
4
```

This has been recorded in rt.cpan.org as bug #37532: Unable to interleave STDOUT and STDERR.

IPC::Msg

SysV Msg IPC object class

SYNOPSIS

```
use IPC::SysV qw(IPC_PRIVATE S_IRUSR S_IWUSR);
use IPC::Msg;
```

(continues on next page)

(continued from previous page)

```
$msg = IPC::Msg->new(IPC_PRIVATE, S_IRUSR | S_IWUSR);

$msg->snd($msgtype, $msgdata);

$msg->rcv($buf, 256);

$ds = $msg->stat;

$msg->remove;
```

DESCRIPTION

A class providing an object based interface to SysV IPC message queues.

METHODS

- new (KEY , FLAGS)

  Creates a new message queue associated with `KEY`. A new queue is created if

  - `KEY` is equal to `IPC_PRIVATE`
  - `KEY` does not already have a message queue associated with it, and `_FLAGS_ & IPC_CREAT` is true.

  On creation of a new message queue `FLAGS` is used to set the permissions. Be careful not to set any flags that the Sys V IPC implementation does not allow: in some systems setting execute bits makes the operations fail.

- id

  Returns the system message queue identifier.

- rcv (BUF, LEN [, TYPE [, FLAGS]])

  Read a message from the queue. Returns the type of the message read. See msgrcv(2). The BUF becomes tainted.

- remove

  Remove and destroy the message queue from the system.

- set (STAT)

- set (NAME => VALUE [, NAME => VALUE ...])

  `set` will set the following values of the `stat` structure associated with the message queue.

  ```
  uid
  gid
  mode (oly the permission bits)
  qbytes
  ```

  `set` accepts either a stat object, as returned by the `stat` method, or a list of *name-value* pairs.

- snd (TYPE, MSG [, FLAGS])

  Place a message on the queue with the data from `MSG` and with type `TYPE`. See msgsnd(2).

- stat

  Returns an object of type `IPC::Msg::stat` which is a sub-class of `Class::Struct`. It provides the following fields. For a description of these fields see you system documentation.

```
uid
gid
cuid
cgid
mode
qnum
qbytes
lspid
lrpid
stime
rtime
ctime
```

IPC::Open2

open a process for both reading and writing using open2()

SYNOPSIS

```
use IPC::Open2;

my $pid = open2(my $chld_out, my $chld_in,
  'some', 'cmd', 'and', 'args');
# or passing the command through the shell
```

(continues on next page)

(continued from previous page)

```
my $pid = open2(my $chld_out, my $chld_in, 'some cmd and args');

# read from parent STDIN and write to already open handle
open my $outfile, '>', 'outfile.txt' or die "open failed: $!";
my $pid = open2(['&', $outfile], ['&', *STDIN],
  'some', 'cmd', 'and', 'args');

# read from already open handle and write to parent STDOUT
open my $infile, '<', 'infile.txt' or die "open failed: $!";
my $pid = open2(['&', *STDOUT], ['&', $infile],
  'some', 'cmd', 'and', 'args');

# reap zombie and retrieve exit status
waitpid( $pid, 0 );
my $child_exit_status = $? >> 8;
```

DESCRIPTION

The `open2()` function runs the given command and connects `$chld_out` for reading and `$chld_in` for writing. It's what you think should work when you try

```
my $pid = open(my $fh, "|cmd args|");  # ERROR
```

but you have to write it as:

```
my $pid = open2($chld_out, $chld_in, @command_and_args);
```

The `$chld_in` filehandle will have autoflush turned on.

By default, the filehandles you pass in are used as output parameters. open2 internally creates two pipes. The write end of the first pipe and the read end of the second pipe are connected to the command's standard output and input, respectively. The corresponding read and write ends are placed in the first and second argument to open2.

The filehandle arguments can take the following forms:

- An uninitialized variable (technically, either `undef` or the empty string will work): open2 generates a fresh filehandle and assigns it to the argument, which must be a modifiable variable for this work (otherwise an exception will be raised).
- An existing handle in the form of a typeglob like `*STDIN` or `*FOO` or a reference to such: open2 places the filehandle in the `IO` slot of the typeglob, which means the corresponding bareword filehandle (like `STDIN` or `FOO`) can be used for I/O from/to the child process. (If the handle is already open, it is automatically closed first.)
- A string containing the name of a bareword handle (like `'STDIN'` or `'FOO'`): Such strings are resolved to typeglobs at runtime and then act like the case described above.

However, it is possible to make open2 use an existing handle directly (as an input argument) and skip the creation of a pipe. To do this, the filehandle argument must have one of the following two forms:

- An array reference like `['&', $fh]`, i.e. the first element is the string `'&'` and the second element is the existing handle to use in the child process.
- A string of the form `'<&FOO'` or `'>&FOO'`, i.e. a string starting with the two characters <& (for input) or >& (for output), followed by the name of a bareword filehandle. (The string form cannot be used with handles stored in variables.)

If you use this form for `$chld_in`, the filehandle will be closed in the parent process.

open2 returns the process ID of the child process. It doesn't return on failure: it just raises an exception matching `/^open2:/`. However, `exec` failures in the child are not detected. You'll have to trap SIGPIPE yourself.

open2 does not wait for and reap the child process after it exits. Except for short programs where it's acceptable to let the operating system take care of this, you need to do this yourself. This is normally as simple as calling `waitpid $pid, 0` when you're done with the process. Failing to do this can result in an accumulation of defunct or "zombie" processes. See *"waitpid" in perlfunc* for more information.

This whole affair is quite dangerous, as you may block forever. It assumes it's going to talk to something like bc(1), both writing to it and reading from it. This is presumably safe because you "know" that commands like bc(1) will read a line at a time and output a line at a time. Programs like sort(1) that read their entire input stream first, however, are quite apt to cause deadlock.

The big problem with this approach is that if you don't have control over source code being run in the child process, you can't control what it does with pipe buffering. Thus you can't just open a pipe to `cat -v` and continually read and write a line from it.

The *IO::Pty* and Expect modules from CPAN can help with this, as they provide a real tty (well, a pseudo-tty, actually), which gets you back to line buffering in the invoked command again.

WARNING

The order of arguments differs from that of open3 from *IPC::Open3*.

SEE ALSO

See *IPC::Open3* for an alternative that handles `STDERR` as well. This function is really just a wrapper around open3.

IPC::Open3

open a process for reading, writing, and error handling using open3()

SYNOPSIS

```
use Symbol 'gensym'; # vivify a separate handle for STDERR
my $pid = open3(my $chld_in, my $chld_out, my $chld_err = gensym,
                'some', 'cmd', 'and', 'args');
# or pass the command through the shell
my $pid = open3(my $chld_in, my $chld_out, my $chld_err = gensym,
```

(continues on next page)

(continued from previous page)

```
                'some cmd and args');

# read from parent STDIN
# send STDOUT and STDERR to already open handle
open my $outfile, '>>', 'output.txt' or die "open failed: $!";
my $pid = open3(['&', *STDIN], ['&', $outfile], undef,
                'some', 'cmd', 'and', 'args');

# write to parent STDOUT and STDERR
my $pid = open3(my $chld_in, ['&', *STDOUT], ['&', *STDERR],
                'some', 'cmd', 'and', 'args');

# reap zombie and retrieve exit status
waitpid( $pid, 0 );
my $child_exit_status = $? >> 8;
```

DESCRIPTION

Extremely similar to open2 from *IPC::Open2*, open3 spawns the given command and provides filehandles for interacting with the command's standard I/O streams.

```
my $pid = open3($chld_in, $chld_out, $chld_err, @command_and_args);
```

It connects `$chld_in` for writing to the child's standard input, `$chld_out` for reading from the child's standard output, and `$chld_err` for reading from the child's standard error stream. If `$chld_err` is false, or the same file descriptor as `$chld_out`, then `STDOUT` and `STDERR` of the child are on the same filehandle. This means that you cannot pass an uninitialized variable for `$chld_err` and have open3 auto-generate a filehandle for you, but gensym from *Symbol* can be used to vivify a new glob reference; see "SYNOPSIS". The `$chld_in` handle will have autoflush turned on.

By default, the filehandles you pass in are used as output parameters. open3 internally creates three pipes. The write end of the first pipe and the read ends of the other pipes are connected to the command's standard input/output/error, respectively. The corresponding read and write ends are placed in the first three argument to open3.

The filehandle arguments can take the following forms:

- An uninitialized variable (technically, either `undef` or the empty string will work): open3 generates a fresh filehandle and assigns it to the argument, which must be a modifiable variable for this work (otherwise an exception will be raised).

  This does not work for `$chld_err`, however: If the `$chld_err` argument is a false value, the child's error stream is automatically redirected to its standard output.

- An existing handle in the form of a typeglob like `*STDIN` or `*FOO` or a reference to such: open3 places the filehandle in the `IO` slot of the typeglob, which means the corresponding bareword filehandle (like `STDIN` or `FOO`) can be used for I/O from/to the child process. (If the handle is already open, it is automatically closed first.)

- A string containing the name of a bareword handle (like `'STDIN'` or `'FOO'`): Such strings are resolved to typeglobs at runtime and then act like the case described above.

However, it is possible to make open3 use an existing handle directly (as an input argument) and skip the creation of a pipe. To do this, the filehandle argument must have one of the following two forms:

- An array reference like `['&', $fh]`, i.e. the first element is the string `'&'` and the second element is the existing handle to use in the child process.
- A string of the form `'<&FOO'` or `'>&FOO'`, i.e. a string starting with the two characters <& (for input) or >& (for output), followed by the name of a bareword filehandle. (The string form cannot be used with handles stored in variables.)

If you use this form for `$chld_in`, the filehandle will be closed in the parent process.

The filehandles may also be integers, in which case they are understood as file descriptors.

open3 returns the process ID of the child process. It doesn't return on failure: it just raises an exception matching `/^open3:/`. However, `exec` failures in the child (such as no such file or permission denied), are just reported to `$chld_err` under Windows and OS/2, as it is not possible to trap them.

If the child process dies for any reason, the next write to `$chld_in` is likely to generate a SIGPIPE in the parent, which is fatal by default, So you may wish to handle this signal.

Note: if you specify `-` as the command, in an analogous fashion to `open(my $fh, "-|")` the child process will just be the forked Perl process rather than an external command. This feature isn't yet supported on Win32 platforms.

open3 does not wait for and reap the child process after it exits. Except for short programs where it's acceptable to let the operating system take care of this, you need to do this yourself. This is normally as simple as calling `waitpid $pid, 0` when you're done with the process. Failing to do this can result in an accumulation of defunct or "zombie" processes. See *"waitpid" in perlfunc* for more information.

If you try to read from the child's stdout writer and their stderr writer, you'll have problems with blocking, which means you'll want to use `select` or *IO::Select*, which means you'd best use `sysread` instead of `readline` for normal stuff.

This is very dangerous, as you may block forever. open3 assumes it's going to talk to something like bc(1), both writing to it and reading from it. This is presumably safe because you "know" that commands like bc(1) will read a line at a time and output a line at a time. Programs like sort(1) that read their entire input stream first, however, are quite apt to cause deadlock.

The big problem with this approach is that if you don't have control over source code being run in the child process, you can't control what it does with pipe buffering. Thus you can't just open a pipe to `cat -v` and continually read and write a line from it.

  This is a CPAN module that has better error handling and more facilities than *IPC::Open3*.

WARNING

The order of arguments differs from that of open2.

IPC::Semaphore

SysV Semaphore IPC object class

SYNOPSIS

```
use IPC::SysV qw(IPC_PRIVATE S_IRUSR S_IWUSR IPC_CREAT);
use IPC::Semaphore;

$sem = IPC::Semaphore->new(IPC_PRIVATE, 10, S_IRUSR | S_IWUSR | IPC_
↪CREAT);

$sem->setall( (0) x 10);

@sem = $sem->getall;

$ncnt = $sem->getncnt;

$zcnt = $sem->getzcnt;

$ds = $sem->stat;

$sem->remove;
```

DESCRIPTION

A class providing an object based interface to SysV IPC semaphores.

METHODS

- new (KEY , NSEMS , FLAGS)

  Create a new semaphore set associated with KEY. NSEMS is the number of semaphores in the set. A new set is created if

  - KEY is equal to IPC_PRIVATE
  - KEY does not already have a semaphore identifier associated with it, and _FLAGS_ & IPC_CREAT is true.

  On creation of a new semaphore set FLAGS is used to set the permissions. Be careful not to set any flags that the Sys V IPC implementation does not allow: in some systems setting execute bits makes the operations fail.

- getall

  Returns the values of the semaphore set as an array.

- getncnt (SEM)

Returns the number of processes waiting for the semaphore SEM to become greater than its current value

- getpid (SEM)

  Returns the process id of the last process that performed an operation on the semaphore SEM.

- getval (SEM)

  Returns the current value of the semaphore SEM.

- getzcnt (SEM)

  Returns the number of processes waiting for the semaphore SEM to become zero.

- id

  Returns the system identifier for the semaphore set.

- op (OPLIST)

  OPLIST is a list of operations to pass to semop. OPLIST is a concatenation of smaller lists, each which has three values. The first is the semaphore number, the second is the operation and the last is a flags value. See semop(2) for more details. For example

```
$sem->op(
    0, -1, IPC_NOWAIT,
    1,  1, IPC_NOWAIT
);
```

- remove

  Remove and destroy the semaphore set from the system.

- set (STAT)

- set (NAME => VALUE [, NAME => VALUE ...])

  set will set the following values of the stat structure associated with the semaphore set.

```
uid
gid
mode (only the permission bits)
```

  set accepts either a stat object, as returned by the stat method, or a list of *name-value* pairs.

- setall (VALUES)

  Sets all values in the semaphore set to those given on the VALUES list. VALUES must contain the correct number of values.

- setval (N , VALUE)

  Set the Nth value in the semaphore set to VALUE

- stat

Returns an object of type `IPC::Semaphore::stat` which is a sub-class of `Class::Struct`. It provides the following fields. For a description of these fields see your system documentation.

```
uid
gid
cuid
cgid
mode
ctime
otime
nsems
```

IPC::SharedMem

SysV Shared Memory IPC object class

SYNOPSIS

```
use IPC::SysV qw(IPC_PRIVATE S_IRUSR S_IWUSR);
use IPC::SharedMem;

$shm = IPC::SharedMem->new(IPC_PRIVATE, 8, S_IRWXU);

$shm->write(pack("S", 4711), 2, 2);

$data = $shm->read(0, 2);

$ds = $shm->stat;

$shm->remove;
```

DESCRIPTION

A class providing an object based interface to SysV IPC shared memory.

METHODS

- new (KEY , SIZE , FLAGS)

  Creates a new shared memory segment of `SIZE` bytes size associated with `KEY`. A new segment is created if

  – `KEY` is equal to `IPC_PRIVATE`

  – `KEY` does not already have a shared memory segment associated with it, and `_FLAGS_ & IPC_CREAT` is true.

  On creation of a new shared memory segment `FLAGS` is used to set the permissions. Be careful not to set any flags that the Sys V IPC implementation does not allow: in some systems setting execute bits makes the operations fail.

- id

  Returns the shared memory identifier.

- read (POS, SIZE)

  Read `SIZE` bytes from the shared memory segment at `POS`. Returns the string read, or `undef` if there was an error. The return value becomes tainted. See shmread.

- write (STRING, POS, SIZE)

  Write `SIZE` bytes to the shared memory segment at `POS`. Returns true if successful, or false if there is an error. See shmwrite.

- remove

  Remove the shared memory segment from the system or mark it as removed as long as any processes are still attached to it.

- is_removed

  Returns true if the shared memory segment has been removed or marked for removal.

- stat

  Returns an object of type `IPC::SharedMem::stat` which is a sub-class of `Class::Struct`. It provides the following fields. For a description of these fields see you system documentation.

```
uid
gid
cuid
cgid
mode
segsz
lpid
cpid
nattch
```

(continues on next page)

(continued from previous page)

```
atime
dtime
ctime
```

- attach ([FLAG])

  Permanently attach to the shared memory segment. When a `IPC::SharedMem` object is attached, it will use memread and memwrite instead of shmread and shmwrite for accessing the shared memory segment. Returns true if successful, or false on error. See shmat(2).

- detach

  Detach from the shared memory segment that previously has been attached to. Returns true if successful, or false on error. See shmdt(2).

- addr

  Returns the address of the shared memory that has been attached to in a format suitable for use with `pack('P')`. Returns `undef` if the shared memory has not been attached.

IPC::SysV

System V IPC constants and the system calls Perl's builtins do not cover.

Perl's core already provides `msgget`/`msgctl`/`msgsnd`/`msgrcv`, `semget`/`semctl`/`semop` and `shmget`/`shmctl`/`shmread`/`shmwrite` as builtins. What `IPC::SysV` adds on top is the constant table (`IPC_CREAT`, `SEM_UNDO`, `SHM_RDONLY`, ...), the `ftok` key generator, shared-memory attach/detach, and the `pack`/`unpack` pair each of `IPC::Msg::stat`, `IPC::Semaphore::stat` and `IPC::SharedMem::stat` uses to move a `struct msqid_ds` / `semid_ds` / `shmid_ds` across the Perl boundary.

`IPC::Msg`, `IPC::Semaphore` and `IPC::SharedMem` are pure Perl on top of this module; `@EXPORT_OK`, `%EXPORT_TAGS` and the `AUTOLOAD` that resolves a constant name come from `IPC/SysV.pm`.

```
use IPC::SysV qw(IPC_PRIVATE IPC_CREAT IPC_RMID S_IRUSR S_IWUSR ftok␣
 ↪shmat shmdt memread memwrite);

my $key = ftok($0, 1);                        # a key derived from a␣
 ↪file
my $id = shmget(IPC_PRIVATE, 64, IPC_CREAT | S_IRUSR | S_IWUSR) //␣
 ↪die "shmget: $!";
my $addr = shmat($id, undef, 0) // die "shmat: $!";   # attach: an␣
 ↪address
memwrite($addr, "hello", 0, 5) or die;
memread($addr, my $buf, 0, 5) or die;
print "read back '$buf'\n";                   # read back 'hello'
shmdt($addr);
shmctl($id, IPC_RMID, 0);
```

This is a native implementation of the XS half of IPC::SysV 2.09; `IPC/SysV.pm` and the three object modules are used unchanged. Nothing is exported by default; ask for names, or for everything with `:all`.

Differences from upstream

None.

Functions

Keys

`ftok`

`ftok($path, $id = undef)` - derive a System V IPC key from an existing file and a project id.

Shared memory

`memread`

`memread($addr, $sv, $pos, $size)` - copy `$size` bytes out of an attached shared-memory segment into `$sv`.

`memwrite`

`memwrite($addr, $sv, $pos, $size)` - copy `$sv` into an attached shared-memory segment at byte offset `$pos`.

`shmat`

`shmat($id, $addr, $flag)` - attach the shared-memory segment `$id` and return an opaque address for it.

shmdt

`shmdt($addr)` - detach a shared-memory segment previously attached with `shmat`.

shmat

`shmat($id, $addr, $flag)` - attach the shared-memory segment `$id` and return an opaque address for it.

Pass `undef` as `$addr` to let the kernel choose where to attach; `$flag` takes `SHM_RDONLY`, `SHM_RND` and friends. The value that comes back is a string of raw address bytes, meaningful only to `memread`, `memwrite` and `shmdt` - do not print it or do arithmetic on it. Returns `undef` with `$!` set on failure; a negative `$id` sets `$!` to `EINVAL` without reaching the kernel.

5.2.59 Imager

Perl bindings for Imager, the raster graphics library.

This is the `Imager` module, version 1.037 of the CPAN API: the same packages, methods, arguments and return values that Perl code written against `Imager` already expects - for the part of it that is available so far (see below).

```
use Imager;

my $img = Imager->new(xsize => 4, ysize => 3, channels => 4) or die␣
↪Imager->errstr;
$img->setpixel(x => 1, y => 1, color => Imager::Color->new(255, 0,␣
↪0));
my $c = $img->getpixel(x => 1, y => 1);
printf "%dx%d, %d channels, pixel %s\n", $img->getwidth, $img->
↪getheight,
    $img->getchannels, join(",", $c->rgba);      # 4x3, 4 channels,␣
↪pixel 255,0,0,255
my @s = $img->getsamples(y => 1, x => 1, width => 1);   # 255 0 0␣
↪255
my $copy = $img->copy;
$img->settag(name => 'note', value => 'hello');
```

What is available

The image engine and the operations on it that are native so far: creating images of every kind below, `getpixel`/`setpixel`, `getsamples`/`setsamples`, `getscanline`/`setscanline`, `copy`, palettes (`addcolors`, `getcolors`, `colorcount` and the rest), tags, the channel mask, masked images, the colour classes, drawing (`box`, `line`, `arc`, `circle`, `polygon`, `polypolygon`, `flood_fill`, `polybezier`), fills, `paste`, `crop`, `rubthrough` and `compose`, `flip`, `convert`, `map` and `Imager->combine`, `to_paletted`, `Imager->make_palette`, `getcolorcount` and `getcolorusage`, `scale`, `scaleX` and `scaleY`, `rotate` and `matrix_transform`, `trim` and `trim_rect`, `transform` and `Imager::transform2`, the filters, `difference` and `rgb_difference`, the files below, and text through `Imager::Font::FT2`.

Not available: `Imager->load_plugin`, the loader for filter plugins compiled from C. It returns undef and sets `$Imager::ERRSTR` to "Couldn't load plugin '...'", as it does for a file that cannot be loaded. Imager's documentation has called that interface deprecated since 0.48 (2006).

Drawing

box, `line`, `arc`, `circle` and `polygon` draw in a colour or, where they fill an area, through a fill (below). `aa => 1` anti-aliases lines, arcs, circles and outlines; `filled => 0` gives the outline of a circle or an arc. A polygon is always anti-aliased, and `mode => 'nonzero'` fills it by the non-zero winding rule instead of the even-odd one; `polypolygon` takes several at once, so one can be a hole in another. `flood_fill` fills the region of one colour around a point, or with `border` everything up to that colour, and `polybezier` draws a Bezier curve through control points.

```
$img->circle(x => 50, y => 50, r => 30, color => 'red', aa => 1);
$img->arc(x => 50, y => 50, r => 40, d1 => 0, d2 => 90, filled => 0,␣
↪aa => 1);
$img->polygon(points => [ [ 10, 10 ], [ 90, 30 ], [ 40, 80 ] ],␣
↪color => 'green');
$img->flood_fill(x => 2, y => 2, color => 'blue') or die $img->
↪errstr;
```

Where Imager differs from the other raster modules

Imager is not a wrapper around one C library; its image engine is its own. That engine is what this module provides natively, and it is why Imager can do things the others cannot: an image may hold **8-bit, 16-bit or floating-point samples**, may be **paletted or direct**, and may have **one to four channels**, in any combination. A greyscale 16-bit image and an RGBA 8-bit image are both ordinary Imager images.

Every operation works on all of them, so code written for one kind of image works on another without change.

Four kinds of image

An image is described by three independent properties, and Imager supports the whole product of them:

Property	Values
sample size	8-bit, 16-bit, double
storage	direct, or paletted (up to 256 colours)
channels	1 (grey), 2 (grey+alpha), 3 (RGB), 4 (RGBA)

```
my $rgb   = Imager->new(xsize => 10, ysize => 10);
↪# 8-bit RGB
my $deep  = Imager->new(xsize => 10, ysize => 10, bits => 16);
my $float = Imager->new(xsize => 10, ysize => 10, bits => 'double');
my $pal   = Imager->new(xsize => 10, ysize => 10, type => 'paletted
```

(continues on next page)

(continued from previous page)

```
↪');
my $grey  = Imager->new(xsize => 10, ysize => 10, channels => 1);
```

Reading and writing a pixel works the same on all of them. `getpixel`/`setpixel` speak `Imager::Color` (bytes) or `Imager::Color::Float` (doubles); a 16-bit or floating-point image keeps its extra precision only if you use the float form.

Colours

A colour is four channels. `Imager::Color` holds them as bytes, 0 to 255, which is what most code wants; `Imager::Color::Float` holds them as floating-point numbers, nominally 0 to 1, which is what a 16-bit or floating-point image needs to keep its precision.

`Imager::Color->new` accepts the friendly spellings - a name, an HTML hex string, a channel list:

```
my $red   = Imager::Color->new('red');
my $red2  = Imager::Color->new('#FF0000');
my $red3  = Imager::Color->new(255, 0, 0);
my $trans = Imager::Color->new(255, 0, 0, 128);

my ($r, $g, $b, $a) = $red->rgba;
```

Anywhere a method takes `color =>`, an array reference works too and is the least ceremony for a one-off: `$img->setpixel(x => 0, y => 0, color => [0, 128, 255])`.

The channel mask

`$img->setmask(mask => 0x5)` makes subsequent writes touch only the channels whose bit is set - channel 0 and channel 2 here. Reads ignore it. It is how you draw into one channel of an image without disturbing the others.

Errors

Imager reports failure by returning false and leaving the reason in an error stack. `Imager->errstr` on the class gives the last error; `$img->errstr` gives that image's. Nothing croaks for an ordinary failure, so the idiom is to check and report:

```
my $img = Imager->new(xsize => 10, ysize => 10) or die Imager->
↪errstr;
```

Files

PNM files (PBM, PGM and PPM, ASCII and binary, 8 and 16 bit), Windows BMP files, Targa files and raw files (`type => 'raw'`, samples and nothing else) are read and written - the formats Imager has without any library. GIF, JPEG, PNG and TIFF are not available yet. BMP is read at 1, 4, 8, 16, 24 and 32 bits a pixel, run length encoded and with bit-field masks, and written uncompressed: 24 bits for a direct image, 1, 4 or 8 for a paletted one.

```
my $img = Imager->new(file => 'in.ppm') or die Imager->errstr;
$img->write(file => 'out.pgm', type => 'pnm') or die $img->errstr;
my @all = Imager->read_multi(file => 'frames.ppm');
```

Targa is read and written colour-mapped, direct and grey, run length encoded (`compress => 1`, the default) or not, with `wierdpack => 1` for 15 and 16 bits a pixel and `idstring` for the file's id.

Masked images

`$img->masked` gives a view of a rectangle of an image, optionally written through a mask: a pixel of the view is a pixel of the image, reads see all of it, and a write lands only where the mask's first channel is not zero. The view can be drawn into, copied and written to a file like any image.

```
my $mask = Imager->new(xsize => 100, ysize => 100, channels => 1);
$mask->box(filled => 1, color => 'white', xmin => 20, xmax => 79);
my $view = $img->masked(mask => $mask, left => 10, top => 10,
                        right => 110, bottom => 110);
$view->box(filled => 1, color => 'red');    # a red band in $img
```

Fills

box and `arc` take a `fill` instead of a colour: a hash of `Imager::Fill->new` parameters or such an object. A fill is a solid colour, one of the 32 named hatches or a custom 8x8 one (`hatch`, `fg`, `bg`, `dx`, `dy`), a tiled image (`image`, with `xoff`, `yoff` and a `matrix`), or another fill made more transparent (`type => 'opacity'`). `combine` says how it meets what is already there: `none`, `normal`, `multiply`, `dissolve`, `add`, `subtract`, `diff`, `lighten`, `darken`, `hue`, `saturation`, `value` or `color`. A fountain fill (`fountain => 'linear'`, `radial`, `conical` and the rest, with `segments` of colours as `Imager::Fountain` builds them) is a gradient between the points `xa`, `ya` and `xb`, `yb`; the `fountain` filter draws the same over a whole image.

```
$img->box(xmin => 10, ymin => 10, xmax => 90, ymax => 50,
          fill => { hatch => 'check2x2', fg => 'red', bg => 'white'␣
↪});
my $glass = Imager::Fill->new(solid => Imager::Color->new(0, 0, 255,␣
↪96),
                              combine => 'normal');
$img->arc(x => 50, y => 50, r => 30, fill => $glass);
```

One image onto another

`paste` copies a rectangle as it is. `rubthrough` lays the source over the target by the source's alpha channel. `compose` does the same with a combine mode (the names above) and an `opacity`, and with `mask` takes the coverage of each pixel from the first channel of a third image.

```
$img->rubthrough(src => $logo, tx => 10, ty => 10) or die $img->
↪errstr;
```

(continues on next page)

(continued from previous page)

```
$img->compose(src => $logo, tx => 10, ty => 10, combine => 'multiply
↪',
              opacity => 0.5, mask => $mask) or die $img->errstr;
```

`setsamples` writes samples of chosen channels, as 8-bit values, floating point (`type => 'float'`) or 16-bit (`type => '16bit'`, on a 16-bit image), and `getsamples` reads them in the same three forms.

An alpha channel is written over the colour of the `i_background` tag, black without one; `pnm_write_wide_data => 1` writes a 16-bit image with 16-bit samples. `Imager->set_file_limits` bounds the width, height and bytes of what `read` accepts, and `Imager->add_file_magic` teaches the format detection a new signature.

Channels

`convert` makes a new image whose channels are weighted sums of this one's, by a `matrix` or a `preset` (`grey`, `noalpha`, `rgb`, `addalpha`, `red`, `green`, `blue`, `alpha`); `Imager->combine` makes one from a channel each of several images; `map` runs the samples of chosen channels through lookup tables in place, and `flip` mirrors the image in place.

```
my $grey  = $img->convert(preset => 'grey') or die $img->errstr;
my $bgr   = $img->convert(matrix => [ [ 0, 0, 1 ], [ 0, 1, 0 ], [ 1,␣
↪0, 0 ] ]);
my $again = Imager->combine(src => [ $r, $g, $b ]) or die Imager->
↪errstr;
$img->map(red => [ reverse 0 .. 255 ]);
$img->flip(dir => 'h');
```

Scaling

`scale` returns a scaled copy: by `scalefactor`, or to `xpixels` and `ypixels`, where `type` says how the two combine (`max`, `min`, `nonprop`). `qtype` picks the method: `normal` (a Lanczos filter), `preview` (nearest neighbour) or `mixing` (the mean of the area each pixel covers). `normal` and `preview` give an 8-bit image whatever the source holds, as in Imager; `mixing` keeps the depth.

```
my $thumb = $img->scale(xpixels => 160, ypixels => 120, type => 'min
↪',
                        qtype => 'mixing') or die $img->errstr;
```

Rotation and matrix transforms

`rotate(right => 90)` (or 180, 270) turns the image exactly; `rotate(degrees => ...)` or `radians` rotates by any angle into an image large enough to hold the result, with `back` for the corners. `matrix_transform` maps the image through a 3 x 3 matrix, such as `Imager::Matrix2d` builds, with bilinear interpolation. A paletted image is not interpolated.

```
my $turned = $img->rotate(degrees => 30, back => 'white') or die
 ↪$img->errstr;
```

Expressions per pixel

`Imager::transform2` builds an image from an expression evaluated for every pixel, in postfix (`rpnexpr`) or, with Parse::RecDescent installed, infix (`expr`): arithmetic, comparisons, `getp1` to `getp3` for the pixels of up to three input images, `rgb`, `hsv` and their parts. `$img->transform` is the older form: two small stack programs give the source position of each pixel.

```
my $mirrored = Imager::transform2({ rpnexpr => 'w x - 1 - y getp1' }
 ↪, $img)
    or die Imager->errstr;
```

Filters

`$img->filter(type => ...)` changes the image in place, with every filter Imager has built in: `autolevels` and `autolevels_skew`, `bumpmap` and `bumpmap_complex`, `contrast`, `conv`, `fountain`, `gaussian` and `gaussian2`, `gradgen`, `hardinvert` and `hardinvertall`, `mosaic`, `nearest_color`, `noise`, `postlevels`, `radnoise`, `turbnoise`, `unsharpmask` and `watermark`. Many work through 8-bit samples, as in Imager, so a 16-bit or double image keeps 8 bits of precision afterwards. `$img->difference` and `rgb_difference` make a new image of where two images differ.

```
$img->filter(type => 'autolevels') or die $img->errstr;
$img->filter(type => 'mosaic', size => 8);
```

Paletted images from direct ones

`to_paletted` quantises an image. `make_colors` says where the palette comes from: `mediancut` (the default), `addi`, a fixed map (`webmap`, `mono`, `gray`, `gray4`, `gray16`) or none for the `colors` you give; `max_colors` bounds it. `translate` says how the pixels are matched to it: `closest`, `perturb`, or `errdiff` with an `errdiff` of `floyd`, `jarvis`, `stucki` or a custom map. `Imager->make_palette` makes one palette for several images, and `getcolorcount` and `getcolorusage` count the colours of an image.

```
my $pal = $img->to_paletted(make_colors => 'mediancut', max_colors
 ↪=> 16,
                            translate => 'errdiff') or die $img->
 ↪errstr;
my $n   = $img->getcolorcount(maxcolors => 256);   # undef if more
```

The `addi` palette and the `perturb` translation use the C library's random numbers, which Imager never seeds: the same image gives the same result every run.

Differences from upstream

Beyond `load_plugin` (above), eighteen:

- Where perl 5.44 with XS Imager reads freed memory: an `Imager::ImgRaw` or `Imager::IO` used after its `DESTROY` croaks "not a live Imager::ImgRaw" (or "Imager::IO") (t/64-auto-ffi/414-imager-or-better.t).
- `Imager::io_slurp` of an I/O object that is not a buffer chain croaks "io_slurp: called on a source that is not from a bufchain". Imager 1.037 ends the whole program there, silently and with exit status 0.
- Reading a row of a paletted image as floating point colours (`getscanline(type => 'float')`) returns its colours and leaves the image alone. Imager 1.037 writes where it should read there (image.c `i_glinf_fp` calls `i_plin` on an uninitialised buffer): the row comes back as whatever was in memory, and the image is overwritten with it and turned into a direct colour image.
- A grey image with an alpha channel written as BMP has its grey applied over the background by its own alpha. Imager 1.037 reads the wrong samples there (paste.im `i_gsamp_bg` asks for 2 a pixel and reads 4): every pixel takes its neighbour's grey as alpha and half the row is whatever was in memory.
- A masked image keeps its target and its mask alive, an image fill its image and an opacity fill its base fill. In Imager 1.037 that is done by `$img->masked` and `Imager::Fill->new`, which store them in the result; the objects themselves hold bare pointers, so one made with `Imager::i_img_masked_new` or `Imager::i_new_fill_image` directly reads freed memory once the other is gone.
- `paste` with a source rectangle that starts left of or above the source image writes black for the part outside it. Imager 1.037 writes whatever was in the memory it had just allocated.
- The hue combine mode leaves a grey pixel of an image without an alpha channel as it is. Imager 1.037 changes it to a colour that differs from run to run (it reads an alpha the image does not have).
- A custom hatch given as a string shorter than 8 bytes has empty rows for the missing bytes; Imager 1.037 takes them from whatever follows the string in memory.
- An image fill with a `matrix` drawn into a 16-bit or double image from a source without an alpha channel draws the source. In Imager 1.037 that fill comes out black.
- A polygon with a coordinate beyond 134 million pixels keeps its shape. Imager 1.037 converts such a coordinate to an `int` it does not fit in; on x86-64 the vertex lands far to the left of the image instead of far to the right.
- `compose` with a rectangle the target clips and a negative source or mask offset larger than what is left draws nothing and succeeds. Imager 1.037 prints "Out of memory" and aborts the program there.
- The fountain filter called as `Imager::i_fountain` with a super-sampling number it does not know draws without super-sampling, with a negative sample count draws nothing, and with segments that are not an array croaks. Imager 1.037 crashes in all three. A fountain fill none of whose samples has a colour draws transparent black where Imager draws what was in memory.

- `getsamples(type => '16bit')` of a negative sample in a double image gives 0. Imager 1.037 converts the negative number to an unsigned one, which on x86-64 gives a value near 4294967295.
- `to_paletted` with `make_colors => 'addi'` makes opaque colours. Imager 1.037 sets only their red, green and blue, so the palette of a four channel image has an alpha that is whatever was in memory.
- `transform` and `transform2` start from black and from empty registers, end a program that reaches outside its registers or its code, clamp `rgb()` of a number beyond the int range, and refuse a missing input image or a channel count outside 1 to 4. Imager 1.037 computes from memory it never set in the first cases and crashes in the last two.
- The `postlevels` filter with `levels => 0`, `autolevels_skew` on a channel whose range comes out empty, and `mosaic` with a `size` of 0 or less leave the image as it is. Imager 1.037 dies of a division by zero in the first two and never returns from the third. A negative bump map channel is refused; Imager reads outside the colour.
- `Imager::i_gradgen` with a distance measure other than 0, 1 or 2 croaks. Imager 1.037 ends the program with exit status 3.
- `Imager->set_out_of_memory_handler($code)` stores and returns the handler, but it is never called. An image whose pixel storage cannot be allocated fails with "Out of memory allocating image surface", as upstream; running out of memory for anything smaller ends the process, as upstream does when no handler is set.

Modules

- `Imager::Color` - Color handling for Imager.
- `Imager::Expr` - implements expression parsing and compilation for the expression evaluation engine used by Imager::transform2()
- `Imager::Fill` - general fill types
- `Imager::Font` - Font handling for Imager.
- `Imager::Fountain` - a class for building fountain fills suitable for use by the fountain filter.
- `Imager::Matrix2d` - simple wrapper for matrix construction
- `Imager::Regops` - generated information about the register based virtual machine
- `Imager::Test` - common functions used in testing Imager
- `Imager::Transform` - a library of register machine image transformations
- `Imager::TrimColorList` - represent a list of color ranges for Imager's trim() method.

Functions

Library information

i_list_formats

The image file formats this build can read and write, as a list of short names such as "png" and "jpeg".

Errors

i_clear_error

Discard any pending error.

i_push_error

Add a message to the error stack.

i_errors

The pending errors, newest first, each as an array reference [$message, $code]. Imager->errstr is built from this.

Imager::Color

Color handling for Imager.

SYNOPSIS

```
use Imager;

$color = Imager::Color->new($red, $green, $blue);
$color = Imager::Color->new($red, $green, $blue, $alpha);
$color = Imager::Color->new("#C0C0FF"); # html color specification

$color->set($red, $green, $blue);
$color->set($red, $green, $blue, $alpha);
$color->set("#C0C0FF"); # html color specification

($red, $green, $blue, $alpha) = $color->rgba();
@hsv = $color->hsv();

$color->info();

if ($color->equals(other=>$other_color)) {
  ...
}
```

DESCRIPTION

This module handles creating color objects used by Imager. The idea is that in the future this module will be able to handle color space calculations as well.

An Imager color consists of up to four components, each in the range 0 to 255. Unfortunately the meaning of the components can change depending on the type of image you're dealing with:

- for 3 or 4 channel images the color components are red, green, blue, alpha.
- for 1 or 2 channel images the color components are gray, alpha, with the other two components ignored.

An alpha value of zero is fully transparent, an alpha value of 255 is fully opaque.

METHODS

- new

  This creates a color object to pass to functions that need a color argument.

- set

  This changes an already defined color. Note that this does not affect any places where the color has been used previously.

- rgba()

  This returns the red, green, blue and alpha channels of the color the object contains.

- info

  Calling info merely dumps the relevant color to the log.

- equals(other=>$other_color)

- equals(other=>$other_color, ignore_alpha=>1)

  Compares $self and color $other_color returning true if the color components are the same.

  Compares all four channels unless `ignore_alpha` is set. If `ignore_alpha` is set only the first three channels are compared.

You can specify colors in several different ways, you can just supply simple values:

- an Imager::Color object
- an Imager::Color::Float object, the ranges of samples are translated from 0.0...1.0 to 0...255.
- simple numeric parameters - if you supply 3 or 4 numeric arguments, you get a color made up of those RGB (and possibly A) components.
- a six hex digit web color, either RRGGBB or #RRGGBB
- an eight hex digit web color, either RRGGBBAA or #RRGGBBAA.
- a CSS rgb() color, based on CSS Color 4. The none keyword is not supported and numbers must be simple decimals without exponents. eg.

```
rgb(50% 50% 100%)
rgb(0, 0, 255)
rgb(0.5 0.5 1.0 / 0.8)
rgb(50%, 50%, 100%, 80%)
```

Samples from percentages or decimals are rounded up per CSS Color 3 and 4.

This accepts some colors not accepted by the CSS rgb() specification, this may change.

- a 3 hex digit web color, `#RGB` - a value of F becomes 255.
- a color name, from whichever of the gimp `Named_Colors` file or X `rgb.txt` is found first. The same as using the `name` keyword.

You can supply named parameters:

- 'red', 'green' and 'blue', optionally shortened to 'r', 'g' and 'b'. The color components in the range 0 to 255.

```
# all of the following are equivalent
my $c1 = Imager::Color->new(red=>100, blue=>255, green=>0);
my $c2 = Imager::Color->new(r=>100, b=>255, g=>0);
my $c3 = Imager::Color->new(r=>100, blue=>255, g=>0);
```

- hue, `saturation` and `value`, optionally shortened to `h`, `s` and `v`, to specify a HSV color. 0 <= hue < 360, 0 <= s <= 1 and 0 <= v <= 1.

```
# the same as RGB(127,255,127)
my $c1 = Imager::Color->new(hue=>120, v=>1, s=>0.5);
my $c1 = Imager::Color->new(hue=>120, value=>1, saturation=>0.
↪5);
```

- `web`, which can specify a 6 or 3 hex digit web color, in any of the forms `#RRGGBB`, `#RGB`, `RRGGBB` or `RGB`.

```
my $c1 = Imager::Color->new(web=>'#FFC0C0'); # pale red
```

- `gray` or `grey` which specifies a single channel, from 0 to 255.

```
# exactly the same
my $c1 = Imager::Color->new(gray=>128);
my $c1 = Imager::Color->new(grey=>128);
```

- `rgb` which takes a 3 member arrayref, containing each of the red, green and blue values.

```
# the same
my $c1 = Imager::Color->new(rgb=>[255, 100, 0]);
my $c1 = Imager::Color->new(r=>255, g=>100, b=>0);
```

- `hsv` which takes a 3 member arrayref, containing each of hue, saturation and value.

```
# the same
my $c1 = Imager::Color->new(hsv=>[120, 0.5, 1]);
my $c1 = Imager::Color->new(hue=>120, v=>1, s=>0.5);
```

- gimp which specifies a color from a GIMP palette file. You can specify the file name of the palette file with the 'palette' parameter, or let Imager::Color look in various places, typically `$HOME/gimp-1.x/palettes/Named_Colors` with and without the version number, and in `/usr/share/gimp/palettes/`. The palette file must have color names.

```
my $c1 = Imager::Color->new(gimp=>'snow');
my $c1 = Imager::Color->new(gimp=>'snow', palette=>'testimg/
↪test_gimp_pal);
```

- xname which specifies a color from an X11 `rgb.txt` file. You can specify the file name of the `rgb.txt` file with the `palette` parameter, or let Imager::Color look in various places, typically `/usr/lib/X11/rgb.txt`.

```
my $c1 = Imager::Color->new(xname=>'blue') # usually RGB(0, 0,␣
↪255)
```

- builtin which specifies a color from the built-in color table in Imager::Color::Table. The colors in this module are the same as the default X11 `rgb.txt` file.

```
my $c1 = Imager::Color->new(builtin=>'black') # always RGB(0, 0,
↪ 0)
```

- name which specifies a name from either a GIMP palette, an X `rgb.txt` file or the built-in color table, whichever is found first.
- 'channel0', 'channel1', etc, each of which specifies a single channel. These can be abbreviated to 'c0', 'c1' etc.
- 'channels' which takes an arrayref of the channel values.

Optionally you can add an alpha channel to a color with the 'alpha' or 'a' parameter.

These color specifications can be used for both constructing new colors with the new() method and modifying existing colors with the set() method.

METHODS

- hsv()

```
my($h, $s, $v, $alpha) = $color->hsv();
```

  Returns the color as a Hue/Saturation/Value/Alpha tuple.

- red
- green
- blue
- alpha

Returns the respective component as an integer from 0 to 255.

- as_float

  Returns the color as a *Imager::Color::Float* object.

- as_css_rgb

  Returns the color as a CSS rgb() format color. This is always returned in the byte form, eg. rgb(255 128 64).

  If the alpha is not full coverage (255) it will be rounded if the result of converting the color back to an 8 bit color would return the same alpha, eg. if the color alpha is 128, it will be formatted as 0.5, not as the more precise 50.2%.

- `Imager::Color::Table` - built-in Imager color table

Imager::Color::Float

Rough floating point sample color handling

SYNOPSIS

```
$color = Imager::Color->new($red, $green, $blue);
$color = Imager::Color->new($red, $green, $blue, $alpha);
$color = Imager::Color->new("#C0C0FF"); # html color specification

$color->set($red, $green, $blue);
$color->set($red, $green, $blue, $alpha);
$color->set("#C0C0FF"); # html color specification

($red, $green, $blue, $alpha) = $color->rgba();
@hsv = $color->hsv(); # not implemented but proposed
my $c8 = $color->as_8bit;

$color->info();
```

DESCRIPTION

This module handles creating color objects used by Imager. The idea is that in the future this module will be able to handle color space calculations as well.

A floating point Imager color consists of up to four components, each in the range 0.0 to 1.0. Unfortunately the meaning of the components can change depending on the type of image you're dealing with:

- for 3 or 4 channel images the color components are red, green, blue, alpha.
- for 1 or 2 channel images the color components are gray, alpha, with the other two components ignored.

An alpha value of zero is fully transparent, an alpha value of 1.0 is fully opaque.

METHODS

- new

  This creates a color object to pass to functions that need a color argument.

- set

  This changes an already defined color. Note that this does not affect any places where the color has been used previously.

- rgba()

  This returns the red, green, blue and alpha channels of the color the object contains.

- info

  Calling info merely dumps the relevant color to the log.

- red
- green
- blue
- alpha

  Returns the respective component as a floating point value typically from 0 to 1.0.

- as_8bit

  Returns the color as the roughly equivalent 8-bit Imager::Color object. Samples below zero or above 1.0 are clipped.

- as_css_rgb

  Formats the color as a CSS rgb() style color. If the color is closely representable as byte style syntax, eg rgb(255, 128, 128), it will be returned in that form, otherwise the samples are formatted as percentages with up to 2 decimal places.

Setting colors

The new() and set() methods can accept the following parameters:

- an Imager::Color::Float object
- an Imager::Color object, the ranges of samples are translated from 0...255 to 0.0...1.0.
- 3 values, treated as red, green, blue
- 4 values, treated as red, green, blue, alpha
- an 8 character hex color, optionally preceded by #.
- a 6 character hex color, optionally preceded by #.
- a CSS rgb() color, based on CSS Color 4. The none keyword is not supported and numbers must be simple decimals without exponents. eg.

```
rgb(50% 50% 100%)
rgb(0, 0, 255)
rgb(0.5 0.5 1.0 / 0.8)
rgb(50%, 50%, 100%, 80%)
```

  This accepts some colors not accepted by the CSS rgb() specification, this may change.

Imager::Color::Table

built-in Imager color table

SYNOPSIS

```
use Imager::Color::Table;
my @rgb = Imager::Color::Table->get($name)
  or die "Color $name not found";
```

DESCRIPTION

This class provides a base color table for use in resolving color names.

The table contains the standard X11 `rgb.txt` colors.

This table is not included as part of Imager::Color itself since it's moderately large.

There is only one method:

- get

```
my @rgb = Imager::Color::Table->get('red')
  or die "No red found";
```

  Retrieves a color from Imager::Color::Tables built-in color table.

Imager::Expr

implements expression parsing and compilation for the expression evaluation engine used by Imager::transform2()

SYNOPSIS

my $code = Imager::Expr->new({rpnexpr=>$someexpr}) or die "Cannot compile $someexpr: ",Imager::Expr::error();

DESCRIPTION

This module is used internally by the Imager::transform2() function. You shouldn't have much need to use it directly, but you may want to extend it.

To create a new Imager::Expr object, call:

```
my %options;
my $expr = Imager::Expr->new(\%options)
  or die Imager::Expr::error();
```

You will need to set an expression value and you may set any of the following:

- constants

  A hashref defining extra constants for expression parsing. The names of the constants must be valid identifiers (/[^\W\d]\w*/) and the values must be valid numeric constants (that Perl recognizes in scalars).

  Imager::Expr may define it's own constants (currently just pi.)

- variables

  A reference to an array of variable names. These are allocated numeric registers starting from register zero.

By default you can define a `rpnexpr` key (which emulates RPN) or `expr` (an infix expression). It's also possible to write other expression parsers that will use other keys. Only one expression key should be defined.

Instance methods

The Imager::Expr::error() method is used to retrieve the error if the expression object cannot be created.

Methods

Imager::Expr provides only a few simple methods meant for external use:

- Imager::Expr->type_registered($keyword)

  Returns true if the given expression type is available. The parameter is the key supplied to the new() method.

  ```
  if (Imager::Expr->type_registered('expr')) {
    # use infix expressions
  }
  ```

- $expr->code()

  Returns the compiled code.

- $expr->nregs()

  Returns a reference to the array of numeric registers.

- $expr->cregs()

  Returns a reference to the array of color registers.

- $expr->dumpops()

  Returns a string with the generated VM “machine code”.

- $expr->dumpcode()

  Returns a string with the disassembled VM “machine code”.

Creating a new parser

I’ll write this one day.

Methods used by parsers:

- compile

  This is the main method you’ll need to implement in a parser. See the existing parsers for a guide.

  It’s supplied the following parameters:

  – $expr - the expression to be parsed

  – $options - the options hash supplied to transform2.

  Return an array ref of array refs containing opcodes and operands.

- @vars = $self->_variables()

  A list (not a reference) of the input variables. This should be used to allocate as many registers as there are variable as input registers.

- $self->error($message)

  Set the return value of Imager::Expr::error()

- @ops = $self->stack_to_reg(@stack_ops)

  Converts marginally parsed RPN to register code.

- assemble()

  Called to convert op codes into byte code.

- numre()

  Returns a regular expression that matches floating point numbers.

- optimize()

  Optimizes the assembly code, including attempting common subexpression elimination and strength reducing division by a constant into multiplication by a constant.

- register_type()

  Called by a new expression parser implementation to register itself, call as:

```
YourClassName->register_type('type code');
```

  where type code is the parameter that will accept the expression.

Future compatibility

Try to avoid doing your own optimization beyond literal folding - if we add some sort of jump, the existing optimizer will need to be rewritten, and any optimization you perform may well be broken too (well, your code generation will probably be broken anyway <sigh>).

AUTHOR

Tony Cook tonyc@cpan.org, Arnar M. Hrafnkelsson

Modules

- `Imager::Expr::Assem` - an assembler for producing code for the Imager register machine

Imager::Expr::Assem

an assembler for producing code for the Imager register machine

SYNOPSIS

```
use Imager::Expr::Assem;
my $expr = Imager::Expr->new(assem=>'...', ...)
```

DESCRIPTION

This module is a simple Imager::Expr compiler that compiles a low-level language that has a nearly 1-to-1 relationship to the internal representation used for compiled register machine code.

Syntax

Each line can contain multiple statements separated by semi-colons.

Anything after '#' in a line is ignored.

Types of statements:

- variable definition

  ```
  `var` _name_:_type_
  ```

  defines variable *name* to have *type*, which can be any of `n` or `num` for a numeric type or `pixel`, `p` or `c` for a pixel or color type.

  Variable names cannot include white-space.

- operators

  Operators can be split into 3 basic types, those that have a result value, those that don't and the null operator, eg. jump has no value.

  The format for operators that return a value is typically:

  ```
  _result_ = _operator_ _operand_ ...
  ```

  and for those that don't return a value:

  ```
  _operator_ _operand_
  ```

  where operator is any valid register machine operator, result is any variable defined with `var`, and operands are variables, constants or literals, or for jump operators, labels.

  The set operator can be simplified to:

  ```
  _result_ = _operator_
  ```

  All operators maybe preceded by a label, which is any non-white-space text immediately followed by a colon (':').

BUGS

Note that the current optimizer may produce incorrect optimization for your code, fortunately the optimizer will disable itself if you include any jump operator in your code. A single jump to anywhere after your final `ret` operator can be used to disable the optimizer without slowing down your code.

There's currently no high-level code generation that can generate code with loops or real conditions.

Tony Cook tony@develop-help.com

Imager::Fill

general fill types

SYNOPSIS

```
use Imager;
use Imager::Fill;

my $fill1 = Imager::Fill->new(solid=>$color, combine=>$combine);
my $fill2 = Imager::Fill->new(hatch=>'vline2', fg=>$color1, bg=>
 ↪$color2,
                               dx=>$dx, dy=>$dy);
my $fill3 = Imager::Fill->new(fountain=>$type, ...);
my $fill4 = Imager::Fill->new(image=>$img, ...);
my $fill5 = Imager::Fill->new(type => "opacity", other => $fill,
                               opacity => ...);
```

DESCRIPTION

Creates fill objects for use by most filled area drawing functions.

All fills are created with the new method.

- new

  ```
  my $fill = Imager::Fill->new(...);
  ```

  The parameters depend on the type of fill being created. See below for details.

The currently available fills are:

- solid
- hatch
- fountain (similar to gradients in paint software)
- image - fill with an image, possibly transformed
- opacity - a lower opacity version of some other fill

Common options

- combine

  The way in which the fill data is combined with the underlying image. See "Combine Types" in Imager::Draw.

In general colors can be specified as *Imager::Color* or *Imager::Color::Float* objects. The fill object will typically store both types and convert from one to the other. If a fill takes 2 color objects they should have the same type.

Solid fills

```
my $fill = Imager::Fill->new(solid=>$color, combine =>$combine)
```

Creates a solid fill, the only required parameter is `solid` which should be the color to fill with.

A translucent red fill:

```
my $red = Imager::Fill->new(solid => "FF000080", combine => "normal
↪");
```

Hatched fills

```
my $fill = Imager::Fill->new(hatch=>$type, fg=>$fgcolor, bg=>
↪$bgcolor,
                             dx=>$dx, $dy=>$dy);
```

Creates a hatched fill. You can specify the following keywords:

- `hatch` - The type of hatch to perform, this can either be the numeric index of the hatch (not recommended), the symbolic name of the hatch, or an array of 8 integers which specify the pattern of the hatch.

  Hatches are represented as cells 8x8 arrays of bits, which limits their complexity.

  Current hatch names are:

  - `check1x1`, `check2x2`, `check4x4` - checkerboards at various sizes
  - `vline1`, `vline2`, `vline4` - 1, 2, or 4 vertical lines per cell
  - `hline1`, `hline2`, `hline4` - 1, 2, or 4 horizontal lines per cell
  - `slash1`, `slash2` - 1 or 2 / lines per cell.
  - `slosh1`, `slosh2` - 1 or 2 \ lines per cell
  - `grid1`, `grid2`, `grid4` - 1, 2, or 4 vertical and horizontal lines per cell
  - `dots1`, `dots4`, `dots16` - 1, 4 or 16 dots per cell
  - `stipple`, `stipple2` - see the samples
  - `weave` - I hope this one is obvious.
  - `cross1`, `cross2` - 2 densities of crosshatch

  - `vlozenge`, `hlozenge` - something like lozenge tiles
  - `scalesdown`, `scalesup`, `scalesleft`, `scalesright` - Vaguely like fish scales in each direction.
  - `tile_L` - L-shaped tiles

- `fg`, bg - The `fg` color is rendered where bits are set in the hatch, and the bg where they are clear. If you use a transparent `fg` or bg, and set combine, you can overlay the hatch onto an existing image.

  `fg` defaults to black, bg to white.

- dx, dy - An offset into the hatch cell. Both default to zero.

A blue and white 4-pixel check pattern:

```
my $fill = Imager::Fill->new(hatch => "check2x2", fg => "blue");
```

You can call Imager::Fill->hatches for a list of hatch names.

Fountain fills

```
my $fill = Imager::Fill->new(fountain=>$ftype,
     xa=>$xa, ya=>$ya, xb=>$xb, yb=>$yb,
     segments=>$segments, repeat=>$repeat, combine=>$combine,
     super_sample=>$super_sample, ssample_param=>$ssample_param);
```

This fills the given region with a fountain fill. This is exactly the same fill as the `fountain` filter, but is restricted to the shape you are drawing, and the fountain parameter supplies the fill type, and is required.

A radial fill from white to transparent centered on (50, 50) with a 50 pixel radius:

```
use Imager::Fountain;
my $segs = Imager::Fountain->simple(colors => [ "FFFFFF", "FFFFFF00"␣
↪],
                                    positions => [ 0, 1 ]);
my $fill = Imager::Fill->new(fountain => "radial", segments =>
↪$segs,
                             xa => 50, ya => 50, xb => 0, yb => 50,
                             combine => "normal");
```

Image Fills

```
my $fill = Imager::Fill->new(image=>$src, xoff=>$xoff, yoff=>$yoff,
                             matrix=>$matrix, combine => $combine);
```

Fills the given image with a tiled version of the given image. The first non-zero value of `xoff` or `yoff` will provide an offset along the given axis between rows or columns of tiles respectively.

The matrix parameter performs a co-ordinate transformation from the co-ordinates in the target image to the fill image co-ordinates. Linear interpolation is used to determine the fill pixel. You can use the *Imager::Matrix2d* class to create transformation matrices.

The matrix parameter will significantly slow down the fill.

```
# some image to act as a texture
my $txim = Imager->new(...);

# simple tiling
my $fill = Imager::Fill->new(image => $txim);

# tile with a vertical offset
my $fill = Imager::Fill->new(image => $txim, yoff => 10);

# tile with a horizontal offset
my $fill = Imager::Fill->new(image => $txim, xoff => 10);

# rotated
use Imager::Matrix2d;
my $fill = Imager::Fill->new(image => $txim,
              matrix => Imager::Matrix2d->rotate(degrees => 20));
```

Opacity modification fill

```
my $fill = Imager::Fill->new(type => "opacity",
    other => $fill, opacity => 0.25);
```

This can be used to make a fill that is a more translucent or opaque version of an existing fill. This is intended for use where you receive a fill object as a parameter and need to change the opacity.

Parameters:

- type => “opacity” - Required
- other - the fill to produce a modified version of. This must be an Imager::Fill object. Required.
- opacity - multiplier for the source fill opacity. Default: 0.5.

The source fills combine mode is used.

```
my $hatch = Imager::Fill->new(hatch => "check4x4", combine =>
 ↪"normal");
my $fill = Imager::Fill->new(type => "opacity", other => $hatch);
```

OTHER METHODS

- Imager::Fill->hatches

  A list of all defined hatch names.

- Imager::Fill->combines

  A list of all combine types.

FUTURE PLANS

I'm planning on adding the following types of fills:

- `checkerboard` - combines 2 other fills in a checkerboard
- `combine` - combines 2 other fills using the levels of an image
- `regmach` - uses the transform2() register machine to create fills

my $bbox_object = $font->bounding_box(string=>"Foo");

# documented in Imager::Draw
$img->string(font  => $font,
           text  => "Model-XYZ",
           x     => 15,
           y     => 40,
```

(continues on next page)

(continued from previous page)

```
            size  => 40,
            color => $red,
            aa    => 1);
```

DESCRIPTION

This module manages, the font object returned by Imager::Font->new will typically be of a class derived from Imager::Font.

- new

  This creates a font object to pass to functions that take a font argument.

```
$font = Imager::Font->new(file  => 'denmark.ttf',
                          index => 0,
                          color => $blue,
                          size  => 30,
                          aa    => 1);
```

  This creates a font which is the TrueType font `denmark.ttf`. It's default color is $blue, default size is 30 pixels and it's rendered anti-aliased by default. Imager can see which type of font a file is by looking at the suffix of the file name for the font. A suffix of `ttf` is taken to mean a TrueType font while a suffix of `pfb` is taken to mean a Type 1 Postscript font. If Imager cannot tell which type a font is you can tell it explicitly by using the `type` parameter:

```
$t1font = Imager::Font->new(file => 'fruitcase', type => 't1');
$ttfont = Imager::Font->new(file => 'arglebarf', type => 'tt');
```

  The `index` parameter is used to select a single face from a font file containing more than one face, for example, from a Macintosh font suitcase or a `.dfont` file.

  If any of the `color`, `size` or `aa` parameters are omitted when calling `Imager::Font->new()` the they take the following values:

```
color => Imager::Color->new(255, 0, 0, 0);  # this default
↪should be changed
size  => 15
aa    => 0
index => 0
```

  To use Win32 fonts supply the face name of the font:

```
$font = Imager::Font->new(face=>'Arial Bold Italic');
```

  There isn't any access to other logical font attributes, but this typically isn't necessary for Win32 TrueType fonts, since you can construct the full name of the font as above.

  Other logical font attributes may be added if there is sufficient demand.

  Parameters:

- `file` - name of the file to load the font from.
-

```
 `face` - face name.  This is used only under Win32 to create␣
↪a GDI based
 font.  This is ignored if the `file` parameter is supplied.
```

- `type` - font driver to use. Currently the permitted values for this are:
  * `tt` - FreeType 1.x driver. Supports TrueType (`.ttf`) fonts.
  *

```
 `t1` - T1 Lib driver.  Supports Postscript Type 1 fonts. ␣
↪Allows for
 synthesis of underline, strikethrough and overline.
```

  * `ft2` - FreeType 2.x driver. Supports many different font formats. Also supports the transform() method.
- `color` - the default color used with this font. Default: red.
- `size` - the default size used with this font. Default: 15.
- `utf8` - if non-zero then text supplied to $img->string(...) and $font->bounding_box(...) is assumed to be UTF-8 encoded by default.
- `align` - the default value for the $img->string(...) `align` parameter. Default: 1.
- `vlayout` - the default value for the $img->string(...) `vlayout` parameter. Default: 0.
- `aa` - the default value for the $im->string(...) `aa` parameter. Default: 0.
- `index` - for font file containing multiple fonts this selects which font to use. This is useful for Macintosh `DFON` (`.dfont`) and suitcase font files.

  If you want to use a suitcase font you will need to tell Imager to use the FreeType 2.x driver by setting `type` to `'ft2'`:

```
my $font = Imager::Font->new(file=>$file, index => 1, type=>
↪'ft2')
  or die Imager->errstr;
```

Returns the new font object on success. Returns `undef` on failure and sets an error message readable with `Imager->errstr`.

- bounding_box()

Returns the bounding box for the specified string. Example:

```
my ($neg_width,
    $global_descent,
    $pos_width,
    $global_ascent,
    $descent,
```

(continues on next page)

(continued from previous page)

```
    $ascent,
    $advance_width,
    $right_bearing) = $font->bounding_box(string => "A Fool");

my $bbox_object = $font->bounding_box(string => "A Fool");
```

- `$neg_width`

  the relative start of a the string. In some cases this can be a negative number, in that case the first letter stretches to the left of the starting position that is specified in the string method of the Imager class

- `$global_descent`

  how far down the lowest letter of the entire font reaches below the baseline (this is often j).

- `$pos_width`

  how wide the string from the starting position is. The total width of the string is `$pos_width-$neg_width`.

- `$descent`

- `$ascent`

  the same as <$global_descent> and <$global_ascent> except that they are only for the characters that appear in the string.

- `$advance_width`

  the distance from the start point that the next string output should start at, this is often the same as `$pos_width`, but can be different if the final character overlaps the right side of its character cell.

- `$right_bearing`

  The distance from the right side of the final glyph to the end of the advance width. If the final glyph overflows the advance width this value is negative.

Obviously we can stuff all the results into an array just as well:

```
@metrics = $font->bounding_box(string => "testing 123");
```

Note that extra values may be added, so $metrics[-1] isn't supported. It's possible to translate the output by a passing coordinate to the bounding box method:

```
@metrics = $font->bounding_box(string => "testing 123", x=>45,␣
↪y=>34);
```

This gives the bounding box as if the string had been put down at `(x,y)` By giving bounding_box 'canon' as a true value it's possible to measure the space needed for the string:

```
@metrics = $font->bounding_box(string=>"testing",size=>15,
↪canon=>1);
```

This returns the same values in $metrics[0] and $metrics[1], but:

```
$bbox[2] - horizontal space taken by glyphs
$bbox[3] - vertical space taken by glyphs
```

Returns an *Imager::Font::BBox* object in scalar context, so you can avoid all those confusing indexes. This has methods as named above, with some extra convenience methods.

Parameters are:

- `string` - the string to calculate the bounding box for. Required.
- `size` - the font size to use. Default: value set in Imager::Font->new(), or 15.
- `sizew` - the font width to use. Default to the value of the `size` parameter.
- `utf8` - For drivers that support it, treat the string as UTF-8 encoded. For versions of perl that support Unicode (5.6 and later), this will be enabled automatically if the 'string' parameter is already a UTF-8 string. See "UTF-8" for more information. Default: the `utf8` value passed to Imager::Font->new(...) or 0.
- x, y - offsets applied to @box[0..3] to give you a adjusted bounding box. Ignored in scalar context.
- `canon` - if non-zero and the x, y parameters are not supplied, then $pos_width and $global_ascent values will returned as the width and height of the text instead.

On success returns either the list of bounds, or a bounding box object in scalar context. Returns an empty list or `undef` on failure and sets an error message readable with `Imager->errstr`.

The transformation matrix set by "transform()" has no effect on the result of this method - the bounds of the untransformed text is returned.

- string()

  The $img->string(...) method is now documented in "string()" in Imager::Draw

- align(string=>$text,size=>$size,x=>...,y=>...,valign => ...,halign=>...)

  Higher level text output - outputs the text aligned as specified around the given point (x,y).

```
# "Hello" centered at 100, 100 in the image.
my ($left, $top, $right, $bottom) =
  $font->align(string=>"Hello",
               x=>100, y=>100,
               halign=>'center', valign=>'center',
               image=>$image);
```

  Takes the same parameters as $font->draw(), and the following extra parameters:

  - `valign` - Possible values are:

    * `top`

      Point is at the top of the text.

        * `bottom`

          Point is at the bottom of the text.

        * `baseline`

          Point is on the baseline of the text (default.)

        * `center`

          Point is vertically centered within the text.

      - `halign`

        * `left` - the point is at the left of the text.

        * `start` - the point is at the start point of the text.

        * `center` - the point is horizontally centered within the text.

        * `right` - the point is at the right end of the text.

        * `end` - the point is at the end point of the text.

      - `image` - The image to draw to. Set to `undef` to avoid drawing but still calculate the bounding box.

    Returns a list specifying the bounds of the drawn text on success. Returns an empty list on failure, if an `image` parameter was supplied the error message can be read with `$image->errstr`, otherwise it's available as `Imager->errstr`.

- dpi()
- dpi(xdpi=>$xdpi, ydpi=>$ydpi)
- dpi(dpi=>$dpi)

  Set or retrieve the spatial resolution of the image in dots per inch. The default is 72 dpi.

  This isn't implemented for all font types yet.

  Possible parameters are:

  - `xdpi`, `ydpi` - set the horizontal and vertical resolution in dots per inch.
  - `dpi` - set both horizontal and vertical resolution to this value.

  Returns a list containing the previous `xdpi`, `ydpi` values on success. Returns an empty list on failure, with an error message returned in `Imager->errstr`.

- transform()

```
$font->transform(matrix=>$matrix);
```

  Applies a transformation to the font, where matrix is an array ref of numbers representing a 2 x 3 matrix:

```
[  $matrix->[0],  $matrix->[1],  $matrix->[2],
   $matrix->[3],  $matrix->[4],  $matrix->[5]   ]
```

  Not all font types support transformations, these will return false.

It's possible that a driver will disable hinting if you use a transformation, to prevent discontinuities in the transformations. See the end of the test script t/t38ft2font.t for an example.

Currently only the ft2 (FreeType 2.x) driver supports the transform() method.

See samples/slant_text.pl for a sample using this function.

Note that the transformation is done in font co-ordinates where y increases as you move up, not image co-ordinates where y decreases as you move up.

`transform()` has no effect on the results of "bounding_box()".

Returns true on success. Returns false on failure with the cause readable from `Imager->errstr`.

- has_chars(string=>$text)

  Checks if the characters in $text are defined by the font.

  In a list context returns a list of true or false value corresponding to the characters in $text, true if the character is defined, false if not. In scalar context returns a string of NUL or non-NUL characters. Supports UTF-8 where the font driver supports UTF-8.

  Not all fonts support this method (use $font->can("has_chars") to check.)

  On error, returns an empty list or undef in scalar context, and sets an error message readable with `Imager->errstr`.

  - `string` - string of characters to check for. Required. Must contain at least one character.
  - `utf8` - For drivers that support it, treat the string as UTF-8 encoded. For versions of perl that support Unicode (5.6 and later), this will be enabled automatically if the 'string' parameter is already a UTF-8 string. See "UTF-8" for more information. Default: the `utf8` value passed to Imager::Font->new(...) or 0.

- face_name()

  Returns the internal name of the face. Not all font types support this method yet, so you should check with `$font->can("face_name")` before calling `face_name`.

- glyph_names(string=>$string [, utf8=>$utf8][, reliable_only=>0]);

  Returns a list of glyph names for each of the characters in the string. If the character has no name then `undef` is returned for the character.

  Some font files do not include glyph names, in this case FreeType 2 will not return any names. FreeType 1 can return standard names even if there are no glyph names in the font.

  FreeType 2 has an API function that returns true only if the font has "reliable glyph names", unfortunately this always returns false for TrueType fonts. This can avoid the check of this API by supplying `reliable_only` as 0. The consequences of using this on an unknown font may be unpredictable, since the FreeType documentation doesn't say how those name tables are unreliable, or how FT2 handles them.

  Both FreeType 1.x and 2.x allow support for glyph names to not be included.

If the supplied `string` is marked as UTF-8 or the `utf8` parameter is true and the supplied string does not contain valid UTF-8, returns an empty string and set an error message readable from `Imager->errstr`,

- can_glyph_names()

  As a class method, returns true if the underlying library supports returning glyph names.

  As an object method, returns true if the supplied font supports returning glyph names.

- draw

  This is used by Imager's string() method to implement drawing text. See "string()" in Imager::Draw.

MULTIPLE MASTER FONTS

The FreeType 2 driver supports multiple master fonts:

- is_mm()

  Test if the font is a multiple master font.

- mm_axes()

  Returns a list of the axes that can be changes in the font. Each entry is an array reference which contains:

  1. Name of the axis.
  2. minimum value for this axis.
  3. maximum value for this axis

- set_mm_coords(coords=>\@values)

  Blends an interpolated design from the master fonts. @values must contain as many values as there are axes in the font.

For example, to select the minimum value in each axis:

```
my @axes = $font->mm_axes;
my @coords = map $_->[1], @axes;
$font->set_mm_coords(coords=>\@coords);
```

It's possible other drivers will support multiple master fonts in the future, check if your selected font object supports the is_mm() method using the can() method.

UTF-8

There are 2 ways of rendering Unicode characters with Imager:

- For versions of perl that support it, use perl's native UTF-8 strings. This is the simplest method.
- Hand build your own UTF-8 encoded strings. Only recommended if your version of perl has no UTF-8 support.

Imager won't construct characters for you, so if want to output Unicode character 00C3 "LATIN CAPITAL LETTER A WITH DIAERESIS", and your font doesn't support it, Imager will *not* build it from 0041 "LATIN CAPITAL LETTER A" and 0308 "COMBINING DIAERESIS".

To check if a driver supports UTF-8 call the utf8() method:

- utf8()

  Return true if the font supports UTF-8.

Native UTF-8 Support

If your version of perl supports UTF-8 and the driver supports UTF-8, just use the $im->string() method, and it should do the right thing.

Build your own

In this case you need to build your own UTF-8 encoded characters.

For example:

```
$x = pack("C*", 0xE2, 0x80, 0x90); # character code 0x2010 HYPHEN
```

You need to be careful with versions of perl that have UTF-8 support, since your string may end up doubly UTF-8 encoded.

For example:

```
$x = "A\xE2\x80\x90\x41\x{2010}";
substr($x, -1, 0) = "";
# at this point $x is has the UTF-8 flag set, but has 5 characters,
# none, of which is the constructed UTF-8 character
```

The test script t/t38ft2font.t has a small example of this after the comment:

```
# an attempt using emulation of UTF-8
```

DRIVER CONTROL

If you don't supply a 'type' parameter to Imager::Font->new(), but you do supply a 'file' parameter, Imager will attempt to guess which font driver to used based on the extension of the font file.

Since some formats can be handled by more than one driver, a priority list is used to choose which one should be used, if a given format can be handled by more than one driver.

- priorities

  The current priorities can be retrieved with:

  ```
  @drivers = Imager::Font->priorities();
  ```

  You can set new priorities and save the old priorities with:

```
@old = Imager::Font->priorities(@drivers);
```

If you supply driver names that are not currently supported, they will be ignored.

Note that by default the priority list no longer includes `tt` and `t1`, so typically you will need to have *Imager::Font::FT2* installed to create fonts with Imager.

```
my @old = Imager::Font->priorities(qw(tt ft2 t1));
```

- register

  Registers an extra font driver. Accepts the following parameters:

  - type - a brief identifier for the font driver. You can supply this value to `Imager::Font->new()` to create fonts of this type. Required.
  - class - the font class name. Imager will attempted to load this module by name. Required.
  - files - a regular expression to match against file names. If supplied this must be a valid perl regular expression. If not supplied you can only create fonts of this type by supplying the `type` parameter to `Imager::Font->new()`
  - description - a brief description of the font driver. Defaults to the value supplied in `class`.

AUTHOR

Arnar M. Hrafnkelsson, addi@umich.edu And a great deal of help from others - see the `README` for a complete list.

BUGS

The $pos_width member returned by the bounding_box() method has historically returned different values from different drivers. The FreeType 1.x and 2.x, and the Win32 drivers return the max of the advance width and the right edge of the right-most glyph. The Type 1 driver always returns the right edge of the right-most glyph.

The newer advance_width and right_bearing values allow access to any of the above.

Imager::Font::BBox

objects representing the bounding box of a string.

SYNOPSIS

```
use Imager::Font;

# get the object
my $font = Imager::Font->new(...);
my $bbox = $font->bounding_box(string=>$text, size=>$size);

# methods
my $start = $bbox->start_offset;
my $left_bearing = $bbox->left_bearing;
my $right_bearing = $bbox->right_bearing;
my $end = $bbox->end_offset;
my $gdescent = $box->global_descent;
my $gascent = $bbox->global_ascent;
my $ascent = $bbox->ascent;
my $decent = $bbox->descent;
my $total_width = $bbox->total_width;
my $fheight = $bbox->font_height;
my $theight = $bbox->text_height;
my $display_width = $bbox->display_width;
```

DESCRIPTION

Objects of this class are returned by the Imager::Font bounding_box() method when it is called in scalar context.

This will hopefully make the information from this method more accessible.

METHODS

- start_offset()
- neg_width
- left_bearing

Returns the horizontal offset from the selected drawing location to the left edge of the first character drawn. If this is positive, the first glyph is to the right of the drawing location.

The alias neg_width() is present to match the bounding_box() documentation for list context.

The alias left_bearing() is present to match font terminology.

- advance_width()

  The advance width of the string, if the driver supports that, otherwise the same as end_offset.

- right_bearing

  The distance from the right of the last glyph to the end of the advance point.

  If the glyph overflows the right side of the advance width this value is negative.

- display_width

  The distance from the left-most pixel of the left-most glyph to the right-most pixel of the right-most glyph.

  Equals advance_width - left_bearing - right_bearing (and implemented that way.)

- global_descent()

  The lowest position relative to the font baseline that any character in the font reaches in the character cell. Normally negative.

  At least one font we've seen has reported a positive number for this.

- global_ascent()

  The highest position relative to the font baseline that any character in the font reaches in the character cell. Normally positive.

- descent()

  The lowest position relative to the font baseline that any character in the supplied string reaches. Negative when any character's glyph reaches below the baseline.

- ascent()

  The highest position relative to the font baseline that any character in the supplied string reaches. Positive if any character's glyph reaches above the baseline.

- font_height()

  The maximum displayed height of any string using this font.

- text_height()

  The displayed height of the supplied string.

OBSOLETE METHODS

These methods include bugs kept for backwards compatibility and shouldn't be used in new code.

- total_width()

  The total displayed width of the string.

  New code should use display_width().

  This depends on end_offset(), and is limited by its backward compatibility.

- end_offset

- pos_width

  The offset from the selected drawing location to the right edge of the last character drawn. Should always be positive.

  You can use the alias pos_width() if you are used to the bounding_box() documentation for list context.

  For backwards compatibility this method returns the maximum of the advance width and the offset of the right edge of the last glyph.

INTERNAL FUNCTIONS

- new(...)

  Called by Imager::Font->bounding_box() to create the object.

BUGS

Doesn't reproduce the functionality that you get using the x and y parameters to Imager::Font->bounding_box(). I considered:

```
my ($left, $top, $right, $bottom) = $box->offset(x=>$x, y=>$y)
```

but this is about as clumsy as the original.

SEE ALSO

Imager(3), Imager::Font(3)

Imager::Font::FT2

FreeType 2 fonts for Imager: TrueType, OpenType, Type 1 and the other outline and bitmap formats FreeType reads.

`Imager::Font->new(file => ...)` picks this driver on its own when the FreeType library is installed; `type => 'ft2'` asks for it by name. Text is drawn with `$img->string`, measured with `$font->bounding_box`, and may be transformed (`$font->transform(matrix => ...)`), laid out vertically for fonts that carry vertical metrics, and drawn into a single channel with `channel =>`.

```
use Imager;

my $font = Imager::Font->new(file => 'DejaVuSans.ttf', size => 24)
    or die Imager->errstr;
$img->string(font => $font, text => 'Hello', x => 10, y => 40,
             color => 'black', aa => 1);
```

The FreeType library (`libfreetype.so.6`) is loaded when the module is; without it `require Imager::Font::FT2` fails and Imager reports the `ft2` format as unavailable, as a perl5 Imager built without FreeType does.

Drawing into a paletted image with a colour that is not in its palette goes through `Imager::Font::FT2` exactly as it does in perl5: the image becomes a direct RGB image. This is a native implementation of Imager::Font::FT2 1.005; its `.pm` is used unchanged.

Differences from upstream

`i_ft2_version(0)`, the version FreeType had when Imager was compiled, reports the version of the library actually loaded, because nothing here is compiled against FreeType.

Imager::Font::FreeType2

low-level functions for FreeType2 text output

DESCRIPTION

Imager::Font creates a Imager::Font::FreeType2 object when asked to.

See Imager::Font to see how to use this type.

This class provides low-level functions that require the caller to perform data validation.

This driver supports:

- transform()
- dpi()
- draw()

  The following parameters:

  - `utf8`
  - `vlayout`
  - `sizew`

Special behaviors

If you call transform() to set a transformation matrix, hinting will be switched off. This prevents sudden jumps in the size of the text caused by the hinting when the transformation is the identity matrix. If for some reason you want hinting enabled, use $font->hinting(hinting=>1) to re-enable hinting. This will need to be called after *each* call to transform().

AUTHOR

Addi, Tony

Imager::Font::Test

font driver producing consistent output for tests.

SYNOPSIS

```
my $font = Imager::Font::Test->new;

# use $font where you use other fonts
```

DESCRIPTION

Imager::Font::Test is intended to produce consistent output without being subject to the inconsistent output produced by different versions of font libraries.

The output is simple box for the whole string.

AUTHOR

Tony Cook tonyc@cpan.org

Imager::Font::Wrap

simple wrapped text output

SYNOPSIS

```
use Imager::Font::Wrap;

my $img = Imager->new(xsize=>$xsize, ysize=>$ysize);

my $font = Imager::Font->new(file=>$fontfile);

my $string = "..."; # text with or without newlines

Imager::Font::Wrap->wrap_text( image  => $img,
                               font   => $font,
                               string => $string,
                               x      => $left,
                               y      => $top,
                               width  => $width,
                               .... );
```

DESCRIPTION

This is a simple text wrapper with options to control the layout of text within the line.

You can control the position, width and height of the text with the `image`, `x`, `y`, `width` and `height` options.

You can simply calculate space usage by setting `image` to `undef`, or set `savepos` to see how much text can fit within the given `height`.

- wrap_text()

  Draw word-wrapped text.

  - `x`, `y` - The top-left corner of the rectangle the text is formatted into. Defaults to (0, 0).
  - `width` - The width of the formatted text in pixels. Defaults to the horizontal gap between the top-left corner and the right edge of the image. If no image is supplied then this is required.
  - `height` - The maximum height of the formatted text in pixels. Not required.
  - `savepos` - The amount of text consumed (as a count of characters) will be stored into the scalar this refers to.

```
my $pagenum = 1;
my $string = "...";
my $font = ...;
my $savepos;

while (length $string) {
  my $img = Imager->new(xsize=>$xsize, ysize=>$ysize);
  Imager::Font::Wrap->wrap_text(string=>$string, font=>$font,
↪
                                image=>$img, savepos => \
↪$savepos)
    or die $img->errstr;
  $savepos > 0
    or die "Could not fit any text on page\n";
  $string = substr($string, $savepos);
  $img->write(file=>"page$pagenum.ppm");
}
```

  - `image` - The image to render the text to. Can be supplied as `undef` or not provided to simply calculate the bounding box.
  - `font` - The font used to render the text. Required.
  - `size` - The size to render the font in. Defaults to the size stored in the font object. Required if it isn't stored in the font object.
  - `string` - The text to render. This can contain non-white-space, blanks (ASCII 0x20), and newlines.

    Newlines must match /(?:\x0A\x0D?|\x0D\x0A?)/. White-space other than blanks and newlines are completely ignored.

- justify

  The way text is formatted within each line. Possible values include:

  * left - left aligned against the left edge of the text box.
  * right - right aligned against the right edge of the text box.
  * center - centered horizontally in the text box.
  * fill - all but the final line of the paragraph has spaces expanded so that the line fills from the left to the right edge of the text box.

- linegap - Gap between lines of text in pixels. This is in addition to the size from $font->font_height. Can be positive or negative. Default 0.

Any other parameters are passed onto Imager::Font->draw().

Returns a list:

```
($left, $top, $right, $bottom)
```

which are the bounds of the space used to layout the text.

If height is set then this is the space used within that height.

You can use this to calculate the space required to format the text before doing it:

```
my ($left, $top, $right, $bottom) =
  Imager::Font::Wrap->wrap_text(string => $string,
                                font   => $font,
                                width  => $xsize);
my $img = Imager->new(xsize=>$xsize, ysize=>$bottom);
Imager::Font::Wrap->wrap_text(string => $string,
                              font   => $font,
                              width  => $xsize,
                              image  => $image);
```

BUGS

Imager::Font can handle UTF-8 encoded text itself, but this module doesn't support that (and probably won't). This could probably be done with regex magic.

Currently ignores the sizew parameter, if you supply one it will be supplied to the draw() function and the text will be too short or too long for the width.

Uses a simplistic text model, which is why there's no hyphenation, and no tabs.

Imager(3), Imager::Font(3)

Imager::Fountain

a class for building fountain fills suitable for use by the fountain filter.

SYNOPSIS

```
use Imager::Fountain;
my $f1 = Imager::Fountain->read(gimp=>$filename);
$f->write(gimp=>$filename);
my $f1 = Imager::Fountain->new;
$f1->add(start=>0, middle=>0.5, end=>1.0,
         c0=>Imager::Color->new(...),
         c1=>Imager::Color->new(...),
         type=>$trans_type, color=>$color_trans_type);
```

DESCRIPTION

Provide an interface to build arrays suitable for use by the Imager fountain filter. These can be loaded from or saved to a GIMP gradient file or you can build them from scratch.

- read(gimp=>$filename)
- read(gimp=>$filename, name=>\$name)

  Loads a gradient from the given GIMP gradient file, and returns a new Imager::Fountain object.

  If the name parameter is supplied as a scalar reference then any name field from newer GIMP gradient files will be returned in it.

  ```
  my $gradient = Imager::Fountain->read(gimp=>'foo.ggr');
  my $name;
  my $gradient2 = Imager::Fountain->read(gimp=>'bar.ggr', name=>\
  ↪$name);
  ```

- write(gimp=>$filename)
- write(gimp=>$filename, name=>$name)

  Save the gradient to a GIMP gradient file.

  The second variant allows the gradient name to be set (for newer versions of the GIMP).

  ```
  $gradient->write(gimp=>'foo.ggr')
    or die Imager->errstr;
  $gradient->write(gimp=>'bar.ggr', name=>'the bar gradient')
    or die Imager->errstr;
  ```

- new

  Create an empty fountain fill description.

- add(start=>$start, middle=>$middle, end=>1.0, c0=>$start_color, c1=>$end_color, type=>$trans_type, color=>$color_trans_type)

  Adds a new segment to the fountain fill, the possible options are:

  - `start` - the start position in the gradient where this segment takes effect between 0 and 1. Default: 0.
  - `middle` - the mid-point of the transition between the 2 colors, between 0 and 1. Default: average of `start` and end.
  - end - the end of the gradient, from 0 to 1. Default: 1.
  - `c0` - the color of the fountain fill where the fill parameter is equal to *start*. Default: opaque black.
  - `c1` - the color of the fountain fill where the fill parameter is equal to *end*. Default: opaque black.
  - `type` - the type of segment, controls the way in which the fill parameter moves from 0 to 1. Default: linear.

    This can take any of the following values:

    * `linear`
    * `curved` - unimplemented so far.
    * `sine`
    * `sphereup`
    * `spheredown`

  - `color` - the way in which the color transitions between `c0` and `c1`. Default: direct.

    This can take any of the following values:

    * `direct` - each channel is simple scaled between c0 and c1.
    * hueup - the color is converted to a HSV value and the scaling is done such that the hue increases as the fill parameter increases.
    * huedown - the color is converted to a HSV value and the scaling is done such that the hue decreases as the fill parameter increases.

  In most cases you can ignore some of the arguments, eg.

```
# assuming $f is a new Imager::Fountain in each case here
use Imager ':handy';
# simple transition from red to blue
$f->add(c0=>NC('#FF0000'), c1=>NC('#0000FF'));
# simple 2 stages from red to green to blue
$f->add(end=>0.5, c0=>NC('#FF0000'), c1=>NC('#00FF00'))
$f->add(start=>0.5, c0=>NC('#00FF00'), c1=>NC('#0000FF'));
```

- simple(positions=>[...], colors=>[...])

  Creates a simple fountain fill object consisting of linear segments.

  The array references passed as positions and colors must have the same number of elements. They must have at least 2 elements each.

  colors must contain Imager::Color or Imager::Color::Float objects.

  eg.

```
my $f = Imager::Fountain->simple(positions=>[0, 0.2, 1.0],
                                 colors=>[ NC(255,0,0), NC(0,
↪255,0),
                                           NC(0,0,255) ]);
```

Implementation Functions

Documented for internal use.

- _load_gimp_gradient($class, $fh, $name)

  Does the work of loading a GIMP gradient file.

- _save_gimp_gradient($self, $fh, $name)

  Does the work of saving to a GIMP gradient file.

FILL PARAMETER

The add() documentation mentions a fill parameter in a few places, this is as good a place as any to discuss it.

The process of deciding the color produced by the gradient works through the following steps:

1. calculate the base value, which is typically a distance or an angle of some sort. This can be positive or occasionally negative, depending on the type of fill being performed (linear, radial, etc).
2. clamp or convert the base value to the range 0 through 1, how this is done depends on the repeat parameter. I'm calling this result the fill parameter.
3. the appropriate segment is found. This is currently done with a linear search, and the first matching segment is used. If there is no matching segment the pixel is not touched.
4. the fill parameter is scaled from 0 to 1 depending on the segment type.
5. the color produced, depending on the segment color type.

Imager::Matrix2d

simple wrapper for matrix construction

SYNOPSIS

```
use Imager::Matrix2d;
$m1 = Imager::Matrix2d->identity;
$m2 = Imager::Matrix2d->rotate(radians=>$angle, x=>$cx, y=>$cy);
$m3 = Imager::Matrix2d->translate(x=>$dx, y=>$dy);
$m4 = Imager::Matrix2d->shear(x=>$sx, y=>$sy);
$m5 = Imager::Matrix2d->reflect(axis=>$axis);
$m6 = Imager::Matrix2d->scale(x=>$xratio, y=>$yratio);
$m8 = Imager::Matric2d->matrix($v11, $v12, $v13,
                               $v21, $v22, $v23,
                               $v31, $v32, $v33);
$m6 = $m1 * $m2;
$m7 = $m1 + $m2;
use Imager::Matrix2d qw(:handy);
# various m2d_* functions imported
# where m2d_(.*) calls Imager::Matrix2d->$1()
```

DESCRIPTION

This class provides a simple wrapper around a reference to an array of 9 coefficients, treated as a matrix:

```
[ 0, 1, 2,
  3, 4, 5,
  6, 7, 8 ]
```

Most of the methods in this class are constructors. The others are overloaded operators.

Note that since Imager represents images with y increasing from top to bottom, rotation angles are clockwise, rather than counter-clockwise.

- identity()

  Returns the identity matrix.

- rotate(radians=>$angle)
- rotate(degrees=>$angle)

  Creates a matrix that rotates around the origin, or around the point (x,y) if the 'x' and 'y' parameters are provided.

- translate(x=>$dx, y=>$dy)
- translate(x=>$dx)

- translate(y=>$dy)

  Translates by the specify amounts.

- shear(x=>$sx, y=>$sy)
- shear(x=>$sx)
- shear(y=>$sy)

  Shear by the given amounts.

- reflect(axis=>$axis)

  Reflect around the given axis, either 'x' or 'y'.

- reflect(radians=>$angle)
- reflect(degrees=>$angle)

  Reflect around a line drawn at the given angle from the origin.

- scale(x=>$xratio, y=>$yratio)

  Scales at the given ratios.

  You can also specify a center for the scaling with the `cx` and `cy` parameters.

- matrix($v11, $v12, $v13, $v21, $v22, $v23, $v31, $v32, $v33)

  Create a matrix with custom coefficients.

- transform($x, $y)

  Transform a point the same way matrix_transform does.

- compose(matrix...)

  Compose several matrices together for use in transformation.

  For example, for three matrices:

```
my $out = Imager::Matrix2d->compose($m1, $m2, $m3);
```

  is equivalent to:

```
my $out = $m3 * $m2 * $m1;
```

  Returns the identity matrix if no parameters are supplied.

  May return the supplied matrix if only one matrix is supplied.

- _mult()

  Implements the overloaded '*' operator. Internal use.

  Currently both the left and right-hand sides of the operator must be an Imager::Matrix2d.

  When composing a matrix for transformation you should multiply the matrices in the reverse order of the transformations:

```
my $shear = Imager::Matrix2d->shear(x => 0.1);
my $rotate = Imager::Matrix2d->rotate(degrees => 45);
my $shear_then_rotate = $rotate * $shear;
```

or use the compose method:

```
my $shear_then_rotate = Imager::Matrix2d->compose($shear,
 ↪$rotate);
```

- _add()

  Implements the overloaded binary '+' operator.

  Currently both the left and right sides of the operator must be Imager::Matrix2d objects.

- _string()

  Implements the overloaded stringification operator.

  This returns a string containing 3 lines of text with no terminating newline.

  I tried to make it fairly nicely formatted. You might disagree :)

- _eq

  Implement the overloaded equality operator.

  Provided for older perls that don't handle magic auto generation of eq from "".

The following functions are shortcuts to the various constructors.

These are not methods.

You can import these methods with:

```
use Imager::Matrix2d ':handy';
```

- m2d_identity
- m2d_rotate()
- m2d_translate()
- m2d_shear()
- m2d_reflect()
- m2d_scale()

Imager::Regops

generated information about the register based virtual machine

SYNOPSIS

```
use Imager::Regops;
$Imager::Regops::Attr{$opname}->{opcode} # opcode for given operator
$Imager::Regops::Attr{$opname}->{parms} # number of parameters
$Imager::Regops::Attr{$opname}->{types} # types of parameters
$Imager::Regops::Attr{$opname}->{func} # operator is a function
$Imager::Regops::Attr{$opname}->{result} # r for numeric, p for␣
↪pixel result
$Imager::Regops::MaxOperands; # maximum number of operands
```

DESCRIPTION

This module is generated automatically from `regmach.h` so we don't need to maintain the same information in at least one extra place.

At least that's the idea.

Imager::Test

common functions used in testing Imager

SYNOPSIS

```
use Imager::Test 'diff_text_with_nul';
diff_text_with_nul($test_name, $text1, $text2, @string_options);
```

DESCRIPTION

This is a repository of functions used in testing Imager.

Some functions will only be useful in testing Imager itself, while others should be useful in testing modules that use Imager.

No functions are exported by default.

FUNCTIONS

Test functions

- is_color1($color, $grey, $comment)

  Tests if the first channel of $color matches $grey.

- is_color3($color, $red, $green, $blue, $comment)

  Tests if $color matches the given ($red, $green, $blue)

- is_color4($color, $red, $green, $blue, $alpha, $comment)

  Tests if $color matches the given ($red, $green, $blue, $alpha)

- is_fcolor1($fcolor, $grey, $comment)

- is_fcolor1($fcolor, $grey, $epsilon, $comment)

  Tests if $fcolor's first channel is within $epsilon of ($grey). For the first form $epsilon is taken as 0.001.

- is_fcolor3($fcolor, $red, $green, $blue, $comment)

- is_fcolor3($fcolor, $red, $green, $blue, $epsilon, $comment)

  Tests if $fcolor's channels are within $epsilon of ($red, $green, $blue). For the first form $epsilon is taken as 0.001.

- is_fcolor4($fcolor, $red, $green, $blue, $alpha, $comment)

- is_fcolor4($fcolor, $red, $green, $blue, $alpha, $epsilon, $comment)

  Tests if $fcolor's channels are within $epsilon of ($red, $green, $blue, $alpha). For the first form $epsilon is taken as 0.001.

- is_image($im1, $im2, $comment)

  Tests if the 2 images have the same content. Both images must be defined, have the same width, height, channels and the same color in each pixel. The color comparison is done at 8-bits per pixel. The color representation such as direct vs paletted, bits per sample are not checked. Equivalent to is_image_similar($im1, $im2, 0, $comment).

- is_imaged($im, $im2, $comment)

- is_imaged($im, $im2, $epsilon, $comment)

  Tests if the two images have the same content at the double/sample level. `$epsilon` defaults to the platform DBL_EPSILON multiplied by four.

- is_image_similar($im1, $im2, $maxdiff, $comment)

  Tests if the 2 images have similar content. Both images must be defined, have the same width, height and channels. The sum of the squares of the differences of each sample are calculated and must be less than or equal to *$maxdiff* for the test to pass. The color comparison is done at 8-bits per pixel. The color representation such as direct vs paletted, bits per sample are not checked.

- isnt_image($im1, $im2, $comment)

  Tests that the two images are different. For regressions tests where something (like text output of "0") produced no change, but should have produced a change.

- test_colorf_gpix($im, $x, $y, $expected, $epsilon, $comment)

  Retrieves the pixel ($x,$y) from the low-level image $im and compares it to the floating point color $expected, with a tolerance of epsilon.

- test_color_gpix($im, $x, $y, $expected, $comment)

  Retrieves the pixel ($x,$y) from the low-level image $im and compares it to the floating point color $expected.

- test_colorf_glin($im, $x, $y, $pels, $comment)

  Retrieves the floating point pixels ($x, $y)-[$x+@$pels, $y] from the low level image $im and compares them against @$pels.

- is_color_close3($color, $red, $green, $blue, $tolerance, $comment)

  Tests if $color's first three channels are within $tolerance of ($red, $green, $blue).

Test suite functions

Functions that perform one or more tests, typically used to test various parts of Imager's implementation.

- std_image_tests(\%options)

  Performs various basic tests. Assumes you're doing modern `no_plan` testing.

- image_bounds_checks($im)

  Attempts to write to various pixel positions outside the edge of the image to ensure that it fails in those locations.

  Any new image type should pass these tests. Does 16 separate tests.

- mask_tests($im, $epsilon)

  Perform a standard set of mask tests on the OO image $im. Does 24 separate tests.

- diff_text_with_nul($test_name, $text1, $text2, @options)

  Creates 2 test images and writes $text1 to the first image and $text2 to the second image with the string() method. Each call adds 3 `ok`/`not ok` to the output of the test script.

  Extra options that should be supplied include the font and either a color or channel parameter.

  This was explicitly created for regression tests on #21770.

- std_font_tests({ font => $font })

  Perform standard font interface tests.

- std_font_test_count()

  The number of tests performed by std_font_tests().

Helper functions

- test_image_raw()

  Returns a 150x150x3 Imager::ImgRaw test image.

- test_image()

  Returns a 150x150x3 8-bit/sample OO test image. Name: `basic`.

- test_image_16()

  Returns a 150x150x3 16-bit/sample OO test image. Name: `basic16`

- test_image_double()

  Returns a 150x150x3 double/sample OO test image. Name: `basic_double`.

- test_image_gray()

  Returns a 150x150 single channel OO test image. Name: `gray`.

- test_image_gray_16()

  Returns a 150x150 16-bit/sample single channel OO test image. Name: `gray16`.

- test_image_mono()

  Returns a 150x150 bilevel image that passes the is_bilevel() test. Name: `mono`.

- test_image_named($name)

  Return one of the other test images above based on name.

- color_cmp($c1, $c2)

  Performs an ordering of 3-channel colors (like <=>).

- colorf_cmp($c1, $c2)

  Performs an ordering of 3-channel floating point colors (like <=>).

Imager::Transform

a library of register machine image transformations

SYNOPSIS

```
# get a list of transformations
my @funcs = Imager::Transform->list;
# create a transformation object
my $tran = Imager::Transform->new($name);
# describe it
print $tran->describe;
# a list of constant names
my @constants = $tran->constants;
# information about some of the constants
my @info = $tran->constants(@constants);
```

DESCRIPTION

This module provides a library of transformations that use the Imager transform2() function.

The aim is to provide a place to collect these transformations.

At some point there might be an interface to add new functions, but there's not a whole lot of point to that.

The interface is a little sparse as yet.

METHODS

- my @names = Imager::Transform->list

  Returns a list of the transformations.

- my $desc = Imager::Transform->describe($name);

- my $desc = $tran->describe()

  Describes a transformation specified either by name (as a class method) or by reference (as an instance method).

  The class method returns undef if there is no such transformation.

- my $tran = Imager::Transform->new($name)

  Create a new transformation object. Returns undef if there is no such transformation.

- my @inputs = $tran->inputs;

- my $inputs = $tran->inputs;

  Returns a list of input image descriptions, or the number of them, depending on context.

  The list contains hash references, which currently contain only one member, `desc`, a description of the use of the input image.

- $tran->constants

  Returns a list of names of constants that can be set for the transformation.

- $tran->constants($name, $name, ...)

  Returns a hashref for each named constant, which contains the default in key `default` and a description in key `desc`.

- my $out = $tran->transform(\%opts, \%constants, @imgs)

  Perform the image transformation.

  Returns the new image on success, or undef on failure, in which case you can use $tran->errstr to get an error message.

- $tran->errstr

  The error message, if any from the last image transformation.

BUGS

Needs more transformations.

Imager::TrimColorList

represent a list of color ranges for Imager's trim() method.

SYNOPSIS

```
use Imager::TrimColorList;

# empty list
my $tcl = Imager::TrimColorList->new;

# add an entry in a variety of forms
$tcl->add($entry);

# add an explicit color object entry
$tcl->add_color($c1, $c2);

# add an explicit floating color object entry
$tcl->add_fcolor($cf1, $cf2);

# number of entries
my $count = $tcl->count;

# fetch an entry
```

(continues on next page)

(continued from previous page)

```
my $entry = $tcl->get($index);

# fetch all entries
my @all = $tcl->all;

# make a list and populate it
my $tcl = Imager::TrimColorList->new($entry1, $entry2, ...);

# dump contents of the list as a string
print $tcl->describe;
```

DESCRIPTION

An Imager::TrimColorList represents a list of color ranges to supply to the trim() method.

Each range can be either an 8-bit color range, ie. *Imager::Color* objects, or a floating point color range, ie. *Imager::Color::Float* objects, these can be mixed freely in a single list but each range must be 8-bit or floating point.

You can supply an entry in a small variety of forms:

- a simple color object of either type, or something convertible to a color object such as a color name such as `"red"`, a hex color such as `"#FFF"`. Any of the forms that Imager::Color supports should work here *except* for the array form. This becomes a range of only that color.

  ```
  $tcl->add("#000");
  $tcl->add(Imager::Color->new(0, 0, 0));
  $tcl->add(Imager::Color::Float->new(0, 0, 0));
  ```

- an arrayref containing a single color object, or something convertible to a color object. This becomes a range of only that color.

  ```
  $tcl->add([ "#000" ]);
  $tcl->add([ Imager::Color->new(0, 0, 0) ]);
  $tcl->add([ Imager::Color::Float->new(0, 0, 0) ]);
  ```

- an arrayref containing two color objects of the same type, ie. both Imager::Color objects or convertible to Imager::Color objects, or two Imager::Color::Float objects. This becomes a range between those two colors inclusive.

  ```
  $tcl->add([ "#000", "#002" ]);
  $tcl->add([ Imager::Color->new(0, 0, 0), Imager::Color->new(0,␣
  ↪0, 2) ]);
  $tcl->add([ Imager::Color::Float->new(0, 0, 0),␣
  ↪Imager::Color::Float->new(0, 0, 2/255) ]);
  ```

- an arrayref containing a color object of either type and a number representing the variance within the color space on either side of the specified color to include.

```
$tcl->add([ "#000", 0.01 ])
$tcl->add([ Imager::Color->new(0, 0, 0), 0.01 ]);
$tcl->add([ Imager::Color::Float->new(0, 0, 0), 0.01 ]);
```

A range specified this way with an 8-bit color clips at the top and bottom of the sample ranges, so the example 8-bit range above goes from (0, 0, 0) to (2, 2, 2) inclusive, while the floating point range isn't clipped and results in the floating color range (-0.01, -0.01, -0.01) to (0.01, 0.01, 0.01) inclusive.

METHODS

- new()
- new($entry1, ...)

  Class method. Create a new Imager::TrimColorList object and optionally add some color ranges to it.

  Returns an optionally populated Imager::TrimColorList object, or an empty list (or undef) on failure.

- add($entry)

  Add a single range entry. Note that this accepts a single value which can be a color or convertible to a color, or a reference to an array as described above.

  Returns a true value on success and a false value on failure.

- add_color($color1, $color2)

  Add a single 8-bit color range going from the `$color1` object to the `$color2` object inclusive. Both parameters must be Imager::Color objects or an exception is thrown.

- add_fcolor($fcolor1, $fcolor2)

  Add a single floating point color range going from the `$fcolor1` object to the `$fcolor2` object inclusive. Both parameters must be Imager::Color::Float objects or an exception is thrown.

- count()

  Fetch the number of color ranges stored in the object.

- get($index)

  Fetch the color range at the given index. This returns a reference to an array containing either two Imager::Color objects or two Imager::Color::Float objects.

  Returns undef if `$index` is out of range and does not set `Imager->errstr`.

- all()

  Fetch all ranges from the object.

- describe()

  Return a string describing the color range as code that can create the object.

- clone()

  Duplicate the object.

- auto()

  Automatically produce a trim color list based on an input image.

  This is used to implement 'auto' for image trim() and trim_rect() methods.

  Parameters:

  - `image` - the image to base the color list on. Required.
  - `auto` - the mechanism used to produce the color list, one of:
    * 1 - a "best" mechanism is selected, this is currently the `center` method, but it subject to change.
    * `center`, `centre` - the pixels at the center of each side of the image are used.

    Default: 1.
  - `tolerance` - used to control the range of pixel colors to be accepted as part of the color list. Default: 0.01.
  - `name` - used internally to attribute errors back to the original method. Default: `auto`.

If any method returns an error you can fetch a diagnostic from `Imager->errstr`.

AUTHOR

Tony Cook tonyc@cpan.org

HISTORY

Originally the range handling for this was going to be embedded in the trim() method, but this meant that every call that used color ranges would pay some cost as the range list was checked for names (vs color objects) and non-standard forms such as single colors and the color plus variance.

The object allows a simple test for the trim() `colors` parameter that doesn't pay that cost, and still allows a caller to use the explicit convention.

5.2.60 JSON

Namespace containing the following modules:

- `JSON::PP` - Encode Perl data as JSON text and decode JSON text into Perl data, with JSON::PP's options and answers.
- `JSON::XS` - Encode Perl data as JSON text and decode JSON text into Perl data, in compiled code.

JSON::PP

Encode Perl data as JSON text and decode JSON text into Perl data, with JSON::PP's options and answers.

`encode_json` and `decode_json` convert between a Perl structure and UTF-8 encoded JSON. An object made with `JSON::PP->new` takes JSON::XS's options and JSON::PP's own - `allow_singlequote`, `allow_barekey`, `allow_bignum`, `loose`, `escape_slash`, `indent_length`, `sort_by`, `as_nonblessed`, `core_bools` - and parses incrementally with `incr_parse`. JSON `true` and `false` decode to `$JSON::PP::true` and `$JSON::PP::false`.

This is JSON::PP 4.16 over pperl's one JSON engine, the one under JSON::XS: the object and its option methods are JSON::PP's own (`JSON/PP.pm`), encoding and decoding are the engine's, in JSON::PP's dialect.

Synopsis

```
use JSON::PP;

my $text = encode_json { name => "caf\x{e9}", list => [1, 2.5, "x"]␣
 ↪};
my $data = decode_json '{"a":[1,true,null]}';

my $json = JSON::PP->new->pretty->canonical->escape_slash;
print $json->encode({ url => "http://example.com/" });

my $loose = JSON::PP->new->allow_singlequote->allow_barekey;
my $hash = $loose->decode("{key:'value'}");
```

Differences from upstream

- With `allow_tags`, the values a FREEZE method returns are encoded as JSON; JSON::PP joins them as they are, which is not JSON and loses references (`("T")[3,x,ARRAY(0x...)]`). A FREEZE that returns the object itself among them dies, as it would recurse.
- `decode_prefix` on a character string returns the number of characters it decoded, as its documentation says; JSON::PP returns the number of bytes of their UTF-8 encoding, and a caller that cuts the text there loses characters. `incr_parse` keeps the rest of its buffer as characters too; JSON::PP turns it into bytes.
- `incr_parse` on character strings takes the text as it is; JSON::PP decodes it as UTF-8 first, which changes Latin-1 text that happens to form UTF-8 (`"\xc3\xa9"` becomes `"\xe9"`).
- A bare key with non-ASCII characters under `allow_barekey` keeps them; JSON::PP gives the bytes of their UTF-8 (`{café:1}` decodes to the key "cafÃ©").
- A tag with no value under `allow_tags` - a lone `(`, or `(null)` - is an error; JSON::PP returns nothing for it, which decodes to undef or fails later with an unrelated message.

- A high surrogate escape followed by another (`"\ud800\ud83d\ude00"`) is an error; JSON::PP drops the first one and its character.
- A character from U+110000 on dies when encoded, as under JSON::XS; JSON::PP writes two `\u` escapes that decode to other characters.
- Errors perl itself raises on a wrong invocant (`Not a HASH reference` and the like) name the caller's line; JSON::PP's name a line in its own file.

Modules

- `JSON::PP::Boolean` - dummy module providing JSON::PP::Boolean

Functions

Data serialisation

encode

Perl data to JSON text, with this object's options.

Also available as `JSON::PP::PP_encode_json`.

decode

JSON text to Perl data, with this object's options.

decode_prefix

Decode the JSON text at the start of a string.

encode_json

Perl data to UTF-8 encoded JSON text.

decode_json

UTF-8 encoded JSON text to Perl data.

to_json

The old name of `encode_json`; it only dies, saying so.

What you get back

Nothing: it croaks "JSON::PP::to_json has been renamed to encode_json.". `from_json` does the same for `decode_json`.

from_json

The old name of `decode_json`; it only dies, saying so.

new

A new encoder/decoder with the defaults: `allow_nonref` on, a maximum depth of 512, an indent of 3, everything else off.

ascii

The option setters: `ascii`, `latin1`, `utf8`, `indent`, `canonical`, `space_before`, `space_after`, `allow_nonref`, `shrink`, `allow_blessed`, `convert_blessed`, `relaxed`, `allow_unknown`, `allow_tags`, and JSON::PP's own `allow_singlequote`, `allow_barekey`, `allow_bignum`, `loose`, `escape_slash` and `as_nonblessed`.

get_ascii

The option getters: `get_ascii`, `get_utf8`, `get_allow_barekey` and the others of each setter.

Synopsis

```
print JSON::PP->new->get_allow_nonref ? "on\n" : "off\n";   # on
```

What you get back

1 when the option is on, the empty string otherwise.

pretty

Set `indent`, `space_before` and `space_after` together.

Synopsis

```
print JSON::PP->new->pretty->encode({ a => [1, 2] });
```

What you get back

The object; `pretty(0)` turns the three off.

max_depth

The deepest nesting of arrays and objects that encode and decode accept.

get_max_depth

The limit `max_depth` set, as it was given.

max_size

The largest JSON text, in bytes, that decode accepts.

Synopsis

```
my $json = JSON::PP->new->max_size(1 << 20);
```

What you get back

The object. 0 (the default, and without an argument) means no limit, and so does 1. `get_max_size` returns the value as it was set.

get_max_size

The limit `max_size` set, as it was given.

boolean_values

The values JSON `false` and `true` decode to.

get_boolean_values

The values set by `boolean_values`, false first.

What you get back

The two values, or the empty list when none are set.

core_bools

Decode `true` and `false` to Perl's core booleans, `!!1` and `!!0`.

get_core_bools

Whether `core_bools` is on.

unblessed_bool

The same as `core_bools`.

get_unblessed_bool

The same as `get_core_bools`.

filter_json_object

A sub that each decoded object is passed to; what it returns takes the object's place.

filter_json_single_key_object

A sub for objects of a single key, by that key.

indent_length

The number of spaces each level indents by under `indent`, 0 to 15.

Synopsis

```
print JSON::PP->new->pretty->indent_length(2)->encode({ a => [1] });
```

What you get back

The object. A value outside 0 to 15 warns and leaves the length as it was; the default is 3.

get_indent_length

The indent `indent_length` set.

sort_by

The order in which an object's keys are written.

allow_bigint

The old name of `allow_bignum`: it warns and turns `allow_bignum` on.

incr_parse

Parse JSON texts as they arrive, a piece at a time.

incr_skip

Drop the text the incremental parser has looked at, after an error.

Synopsis

```
eval { $json->incr_parse };
$json->incr_skip if $@;
```

incr_reset

Forget everything the incremental parser holds.

incr_text

The text the incremental parser holds, as an lvalue.

Synopsis

```
$json->incr_text = '[1,2]';
my $data = $json->incr_parse;
```

What you get back

The buffer itself. It dies once parsing has started on its text.

is_bool

Whether a value is a JSON boolean.

true

`$JSON::PP::true`, the value JSON `true` decodes to.

false

`$JSON::PP::false`, the value JSON `false` decodes to.

null

undef, the value JSON `null` decodes to.

JSON::PP::Boolean

dummy module providing JSON::PP::Boolean

SYNOPSIS

```
# do not "use" yourself
```

DESCRIPTION

This module exists only to provide overload resolution for Storable and similar modules. See *JSON::PP* for more info about this class.

AUTHOR

This idea is from *JSON::XS::Boolean* written by Marc Lehmann <schmorp[at]schmorp.de>

LICENSE

This library is free software; you can redistribute it and/or modify it under the same terms as Perl itself.

encode

Perl data to JSON text, with this object's options.

Also available as `JSON::PP::PP_encode_json`.

Synopsis

```
my $text = JSON::PP->new->canonical->encode({ b => 1, a => [undef, \
↪1] });
# {"a":[null,true],"b":1}
```

What you get back

The JSON text: characters, or UTF-8 bytes under `utf8`. Dies on what JSON cannot represent unless an option allows it: a blessed object, a code reference, a reference to a scalar other than 0 or 1, nesting deeper than `max_depth`.

decode

JSON text to Perl data, with this object's options.

Synopsis

```
my $data = JSON::PP->new->relaxed->decode('[1, 2, // a comment
                                           3,]');
```

What you get back

The Perl structure: `true` and `false` as `$JSON::PP::true` and `$JSON::PP::false`, `null` as undef, numbers as numbers. Dies with the reason and the offset on text that is not valid JSON.

decode_prefix

Decode the JSON text at the start of a string.

Synopsis

```
my ($data, $chars) = JSON::PP->new->decode_prefix('[1,2] trailing␣
↪text');
# ([1, 2], 5)
```

What you get back

The Perl structure and the number of characters its text took; what follows is not looked at.

encode_json

Perl data to UTF-8 encoded JSON text.

Synopsis

```
use JSON::PP;
my $bytes = encode_json { name => "caf\x{e9}" };   # {"name":"caf\
↪xc3\xa9"}
```

What you get back

The JSON text as UTF-8 bytes: `JSON::PP->new->utf8->encode($data)`. Exported by default.

decode_json

UTF-8 encoded JSON text to Perl data.

Synopsis

```
use JSON::PP;
my $data = decode_json '{"list":[1,true,null]}';
```

What you get back

The Perl structure: `JSON::PP->new->utf8->decode($bytes)`. `true` and `false` are `$JSON::PP::true` and `$JSON::PP::false`. Exported by default.

new

A new encoder/decoder with the defaults: `allow_nonref` on, a maximum depth of 512, an indent of 3, everything else off.

Synopsis

```
my $json = JSON::PP->new->utf8->canonical->escape_slash;
```

What you get back

A hash blessed into the class it was called on, as JSON::PP's objects always are: a subclass may keep its own keys in it. The option methods return it again, so that they chain.

ascii

The option setters: `ascii`, `latin1`, `utf8`, `indent`, `canonical`, `space_before`, `space_after`, `allow_nonref`, `shrink`, `allow_blessed`, `convert_blessed`, `relaxed`, `allow_unknown`, `allow_tags`, and JSON::PP's own `allow_singlequote`, `allow_barekey`, `allow_bignum`, `loose`, `escape_slash` and `as_nonblessed`.

Synopsis

```
my $json = JSON::PP->new->allow_singlequote->allow_barekey;
my $data = $json->decode(q({key: 'value'}));
```

What you get back

The object itself, with the option on (no argument, or a defined true one) or off.

- `allow_singlequote`: strings may also be quoted with `'`.
- `allow_barekey`: an object's keys may be bare words of ASCII word characters, `$` and non-ASCII characters.
- `allow_bignum`: numbers too large or too precise for Perl decode to Math::BigInt and Math::BigFloat objects, and such objects encode as numbers.
- `loose`: unknown backslash escapes and control characters are taken as they are.
- `escape_slash`: `/` is written as `\/`.
- `as_nonblessed`: with `allow_blessed`, a blessed hash or array is encoded as if it were not blessed.
- `shrink` is accepted and changes nothing.

max_depth

The deepest nesting of arrays and objects that encode and decode accept.

Synopsis

```
my $json = JSON::PP->new->max_depth(16);
```

What you get back

The object. Without an argument the limit is 2**31; deeper data dies "json text or perl structure exceeds maximum nesting level (max_depth set too low?)". `get_max_depth` returns the value as it was set.

boolean_values

The values JSON `false` and `true` decode to.

Synopsis

```
my $json = JSON::PP->new->boolean_values(0, 1);
my ($false, $true) = $json->get_boolean_values;
```

What you get back

The object. With no arguments the default booleans, `$JSON::PP::false` and `$JSON::PP::true`, come back. Two core booleans (`!!0`, `!!1`) also turn `core_bools` on.

core_bools

Decode `true` and `false` to Perl's core booleans, `!!1` and `!!0`.

Synopsis

```
my $data = JSON::PP->new->core_bools->decode('[true]');
builtin::is_bool($data->[0]);   # true
```

What you get back

The object; `core_bools(0)` goes back to `$JSON::PP::true` and `$JSON::PP::false`. `unblessed_bool` is the same method, and core booleans always encode as `true` and `false`.

filter_json_object

A sub that each decoded object is passed to; what it returns takes the object's place.

Synopsis

```
my $json = JSON::PP->new->filter_json_object(sub { bless $_[0],
↪'Point' });
```

What you get back

The object. A filter that returns nothing leaves the object as it is; one that returns more than one value dies. A non-code argument removes the filter.

filter_json_single_key_object

A sub for objects of a single key, by that key.

Synopsis

```
my $json = JSON::PP->new->filter_json_single_key_object(
    '$date' => sub { Time::Piece->strptime($_[0], '%F') });
```

What you get back

The object. The sub gets the key's value; what it returns replaces the object. When it returns nothing, the object stays, and the `filter_json_object` filter is not called for it.

sort_by

The order in which an object's keys are written.

Synopsis

```
my $json = JSON::PP->new->sort_by(sub { $JSON::PP::b cmp
↪$JSON::PP::a });
```

What you get back

The object. A code reference, or the name of a sub in JSON::PP, sorts the keys, comparing `$JSON::PP::a` with `$JSON::PP::b`; any other true value sorts them as `canonical` does.

incr_parse

Parse JSON texts as they arrive, a piece at a time.

Synopsis

```
my $json = JSON::PP->new;
$json->incr_parse('[1,');              # append, nothing complete␣
↪yet
my @texts = $json->incr_parse('2][3]');   # ([1, 2], [3])
```

What you get back

In void context nothing: the text is only appended. In scalar context the first complete JSON text decoded, or undef while none is complete; in list context every complete one.

is_bool

Whether a value is a JSON boolean.

Synopsis

```
JSON::PP::is_bool(JSON::PP::true);    # true
JSON::PP::is_bool(!!1);               # true: a core boolean
JSON::PP::is_bool(1);                 # false
```

What you get back

True for an object of JSON::PP::Boolean, Types::Serialiser::BooleanBase or JSON::XS::Boolean, and for a core boolean.

JSON::XS

Encode Perl data as JSON text and decode JSON text into Perl data, in compiled code.

`encode_json` and `decode_json` convert between a Perl structure and UTF-8 encoded JSON. An object made with `JSON::XS->new` takes options

- `utf8`, `pretty`, `canonical`, `relaxed`, `allow_nonref`, `convert_blessed`, `allow_tags`, `max_depth`, `max_size`, filter callbacks - and parses incrementally from a stream with `incr_parse`. JSON `true` and `false` decode to `Types::Serialiser`'s booleans.

This is a native implementation of JSON::XS 4.04's `XS.xs`; its `JSON/XS.pm` is used unchanged.

Synopsis

```
use JSON::XS;

my $text = encode_json { name => "caf\x{e9}", list => [1, 2.5, "x"]␣
↪};
my $data = decode_json '{"a":[1,true,null]}';

my $json = JSON::XS->new->pretty->canonical;
print $json->encode($data);

$json->incr_parse('[1,2');
$json->incr_parse(',3]');
my $array = $json->incr_parse;           # [1, 2, 3]
```

Differences from upstream

- A method called on something blessed into `JSON::XS` that `JSON::XS->new` did not make - a hash, an array, a short string - dies "object is not of type JSON::XS"; perl crashes.
- After `JSON::XS::CLONE` has been called by hand, `new` and the decoding of `true` and `false` work as they do in a perl built with threads; a perl without threads crashes.

Modules

- `JSON::XS::Boolean` - dummy module providing JSON::XS::Boolean

Functions

Data serialisation

new

A new encoder/decoder with the defaults: `allow_nonref` on, a maximum depth of 512, everything else off.

Synopsis

```
my $json = JSON::XS->new->utf8->canonical;
```

What you get back

An object blessed into the class it was called on, whose option methods return it again, so that they chain.

allow_blessed

The option setters: `ascii`, `latin1`, `utf8`, `indent`, `canonical`, `space_before`, `space_after`, `pretty`, `allow_nonref`, `shrink`, `allow_blessed`, `convert_blessed`, `relaxed`, `allow_unknown` and `allow_tags`.

Also available as `JSON::XS::allow_nonref`, `JSON::XS::allow_tags`, `JSON::XS::allow_unknown`, `JSON::XS::ascii`, `JSON::XS::canonical`, `JSON::XS::convert_blessed`, `JSON::XS::indent`, `JSON::XS::latin1`, `JSON::XS::pretty`, `JSON::XS::relaxed`, `JSON::XS::shrink`, `JSON::XS::space_after`, `JSON::XS::space_before`, `JSON::XS::utf8`.

get_allow_blessed

The option getters: `get_ascii`, `get_utf8`, `get_canonical` and the others of each setter but `pretty`.

Also available as `JSON::XS::get_allow_nonref`, `JSON::XS::get_allow_tags`, `JSON::XS::get_allow_unknown`, `JSON::XS::get_ascii`, `JSON::XS::get_canonical`, `JSON::XS::get_convert_blessed`, `JSON::XS::get_indent`, `JSON::XS::get_latin1`, `JSON::XS::get_relaxed`, `JSON::XS::get_shrink`, `JSON::XS::get_space_after`, `JSON::XS::get_space_before`, `JSON::XS::get_utf8`.

Synopsis

```
print JSON::XS->new->get_allow_nonref ? "on\n" : "off\n";   # on
```

What you get back

True when the option is on, false otherwise.

encode

Perl data to JSON text, with this object's options.

decode

JSON text to Perl data, with this object's options.

decode_prefix

Decode the JSON text at the start of a string.

incr_parse

Parse JSON texts as they arrive, a piece at a time.

encode_json

Perl data to UTF-8 encoded JSON text.

Synopsis

```
use JSON::XS;
my $bytes = encode_json { name => "caf\x{e9}" };   # {"name":"caf\
↪xc3\xa9"}
```

What you get back

The JSON text as UTF-8 bytes: `JSON::XS->new->utf8->encode($data)`.

decode_json

UTF-8 encoded JSON text to Perl data.

JSON::XS::Boolean

dummy module providing JSON::XS::Boolean

SYNOPSIS

```
# do not "use" yourself
```

DESCRIPTION

This module exists only to provide overload resolution for Storable and similar modules. It's only needed for compatibility with data serialised (by other modules such as Storable) that was decoded by JSON::XS versions before 3.0.

Since 3.0, JSON::PP::Boolean has replaced it. Support for JSON::XS::Boolean will be removed in a future release.

AUTHOR

```
Marc Lehmann <schmorp@schmorp.de>
http://home.schmorp.de/
```

allow_blessed

The option setters: `ascii`, `latin1`, `utf8`, `indent`, `canonical`, `space_before`, `space_after`, `pretty`, `allow_nonref`, `shrink`, `allow_blessed`, `convert_blessed`, `relaxed`, `allow_unknown` and `allow_tags`.

Also available as `JSON::XS::allow_nonref`, `JSON::XS::allow_tags`, `JSON::XS::allow_unknown`, `JSON::XS::ascii`, `JSON::XS::canonical`, `JSON::XS::convert_blessed`, `JSON::XS::indent`, `JSON::XS::latin1`, `JSON::XS::pretty`, `JSON::XS::relaxed`, `JSON::XS::shrink`, `JSON::XS::space_after`, `JSON::XS::space_before`, `JSON::XS::utf8`.

Synopsis

```
my $json = JSON::XS->new->utf8->pretty->canonical(1)->relaxed(0);
```

What you get back

The object itself, with the option on (no argument, or a true one) or off (a false one). `pretty` sets `indent`, `space_before` and `space_after` together.

encode

Perl data to JSON text, with this object's options.

Synopsis

```
my $text = JSON::XS->new->canonical->encode({ b => 1, a => [undef, \
 ↪1] });
# {"a":[null,true],"b":1}
```

What you get back

The JSON text: characters, or UTF-8 bytes under `utf8`. Dies on what JSON cannot represent unless an option allows it: a blessed object, a code reference, a reference to a scalar other than 0 or 1, nesting deeper than `max_depth`.

decode

JSON text to Perl data, with this object's options.

Synopsis

```
my $data = JSON::XS->new->relaxed->decode('[1, 2, # a comment
                                           3,]');
```

What you get back

The Perl structure: `true` and `false` as `Types::Serialiser`'s booleans, `null` as undef, numbers as numbers. Dies with the reason and the character offset on text that is not valid JSON.

decode_prefix

Decode the JSON text at the start of a string.

Synopsis

```
my ($data, $chars) = JSON::XS->new->decode_prefix('[1,2] trailing␣
 ↪text');
# ([1, 2], 5)
```

What you get back

The Perl structure and the number of characters its text took; what follows is not looked at.

incr_parse

Parse JSON texts as they arrive, a piece at a time.

Synopsis

```
my $json = JSON::XS->new;
$json->incr_parse('[1,');           # append, nothing complete yet
my @texts = $json->incr_parse('2][3]');   # ([1, 2], [3])
```

What you get back

In void context nothing: the text is only appended. In scalar context the first complete JSON text decoded, or nothing while none is complete; in list context every complete one.

decode_json

UTF-8 encoded JSON text to Perl data.

Synopsis

```
use JSON::XS;
my $data = decode_json '{"list":[1,true,null]}';
```

What you get back

The Perl structure: `JSON::XS->new->utf8->decode($bytes)`. Dies on text that is not valid JSON, and on characters above 255 (the text must be bytes).

5.2.61 LMDB_File

Tie a Perl hash to an LMDB database, or drive LMDB's environments, transactions and cursors directly.

LMDB_File is the CPAN interface to OpenLDAP's Lightning Memory-Mapped Database. An environment is a directory (or, with `MDB_NOSUBDIR`, a file) holding one unnamed database and, with `maxdbs`, named ones. Every read and write happens in a transaction: read transactions see a snapshot and never block, and one write transaction at a time commits atomically.

The simplest use is a tied hash, which opens the environment, begins a transaction and commits it when the hash is untied. The object interface gives the environment (`LMDB::Env`), transactions (`LMDB::Txn`), databases (`LMDB_File`) and cursors (`LMDB::Cursor`) explicitly.

Synopsis

```
use LMDB_File qw(:flags :cursor_op);

tie my %h, 'LMDB_File', 'data-dir';
$h{greeting} = 'hello';
untie %h;

my $env = LMDB::Env->new('data-dir', { mapsize => 1 << 30, maxdbs =>
 ↪4 });
my $txn = $env->BeginTxn;
my $db  = $txn->OpenDB({ dbname => 'users', flags => MDB_CREATE });
$db->put(alice => 'admin');
$txn->commit;
```

The tie interface

```
tie %h, 'LMDB_File', $path;                    # options as below
tie %h, 'LMDB_File', $path, \%options;
tie %h, 'LMDB_File', $path, $flags, $mode;     # as other DBM
 ↪modules
tie %h, 'LMDB_File', $env, \%dboptions;        # in an environment
tie %h, 'LMDB_File', $txn, \%dboptions;        # in a transaction
```

The forms with a path open (and create) the environment, begin a transaction and open the database in it; `%options` takes the environment's options and the database's (`dbname`, `flags`). A transaction the tie begins commits when the hash is untied. `$path` is a directory, which must exist, unless `MDB_NOSUBDIR` is among the flags.

LMDB::Env

`LMDB::Env->new($path, \%options)` creates (if need be) and opens an environment. The options: `mapsize` (the most data it can hold, default 1 MiB - choose it large, it reserves address space only), `maxdbs` (named databases allowed, default 0), `maxreaders` (default 126), `mode` (of files created, default `0600`) and `flags`, the `:envflags` constants such as `MDB_NOSUBDIR`, `MDB_RDONLY`, `MDB_NOSYNC`, `MDB_WRITEMAP`.

- `$env->BeginTxn($flags)` - a new `LMDB::Txn`; `MDB_RDONLY` for a read transaction (the environment's own `MDB_RDONLY` is passed on).
- `$env->copy($path)`, `$env->copyfd($fh)` - a consistent copy of the environment, to a directory or an open file.
- `$env->stat` - the unnamed database's statistics, a hash reference (`psize`, `depth`, `branch_pages`, `leaf_pages`, `overflow_pages`, `entries`); `$env->info` - the map's `mapaddr`, `mapsize`, `last_pgno`, `last_txnid`, `maxreaders`, `numreaders`.
- `$env->sync($force)` - flush to disk (needed with `MDB_NOSYNC`).
- `$env->set_flags($flags, $on)`, `$env->get_flags($var)` - change or read the flags that can change while open.
- `$env->get_path($var)`, `$env->get_maxreaders($var)`, `$env->get_maxkeysize` - the path, the reader slots, the longest key (511 bytes with the usual liblmdb).
- `$env->set_mapsize($size)` - grow the map while no transaction is live.
- `$env->id` - a number identifying the environment.

The environment closes when its last reference goes.

LMDB::Txn

A transaction is `$env->BeginTxn` or `LMDB::Txn->new($env, $flags)`. A read transaction sees a snapshot and never blocks; one write transaction at a time sees its own writes and makes them all durable at `commit`. A transaction that goes out of scope is aborted, unless `$txn->AutoCommit(1)` asks for a commit.

- `$txn->commit`, `$txn->abort` - end it; afterwards only `env` may be called.
- `$txn->reset`, `$txn->renew` - let a read transaction's snapshot go, and take a fresh one later.
- `$txn->SubTxn($flags)` - a nested transaction, whose writes join the parent's at its commit and vanish at its abort.
- `$txn->OpenDB(\%dboptions)` or `$txn->OpenDB($dbname, $flags)` - an `LMDB_File` database object; `$txn->open($dbname, $flags)` - the bare database number. The `:dbflags` constants: `MDB_CREATE`, `MDB_DUPSORT`, `MDB_INTEGERKEY` and the like.

- `$txn->put($dbi, $key, $value, $flags)`, `$txn->get($dbi, $key, $value)` - the fast path, on a database number.
- `$txn->env` - the environment; `$txn->id` - the transaction's ID.

LMDB_File: a database in a transaction

`$txn->OpenDB(...)`, `LMDB_File->open($txn, $dbname, $flags)` or `LMDB_File->new($txn, $dbi)` give an object that pairs a database with a transaction.

- `$db->get($key)` - the value or undef; `$db->get($key, $value)` puts it in `$value` and reports a missing key as an error.
- `$db->put($key, $value, $flags)` - store; the `:writeflags` constants `MDB_NOOVERWRITE`, `MDB_NODUPDATA`, `MDB_APPEND`, `MDB_APPENDDUP`, and `MDB_RESERVE` with a length to write the value in place afterwards.
- `$db->del($key, $value)` - delete the key, or in an `MDB_DUPSORT` database one of its values.
- `$db->set_compare(sub { $a cmp $b })` - a sort sub for the keys, called with `$a` and `$b` as `sort` calls one; set it before any other use, the same every time.
- `$db->ReadMode(1)` - `get` returns the value in place, a read-only scalar over the map, without copying it (writable with `MDB_WRITEMAP` in a write transaction); it is valid until the transaction ends or, in a write transaction, the next write. `$db->Rget($key)` does the same for one call.
- `$db->UTF8(1)` - store character strings as UTF-8 and decode them on the way out (`use bytes` skips the decoding).
- `$db->stat`, `$db->flags`, `$db->drop($remove)` (empty, or delete the database), `$db->Alive`, `$db->Txn` (assignable), `$db->dbi` (assignable), `$db->Cursor`.

LMDB::Cursor

`$db->Cursor` opens a cursor. `$cursor->get($key, $value, $op)` moves it by one of the `:cursor_op` operations (`MDB_FIRST`, `MDB_NEXT`, `MDB_SET_RANGE`, `MDB_NEXT_DUP` ...) and puts the key and value it lands on in `$key` and `$value`; `$cursor->put($key, $value, $flags)` stores and leaves the cursor on the item; `$cursor->del($flags)` deletes where it stands (`MDB_NODUPDATA`: all the key's values). `count`, `renew($txn)`, `txn`, `dbi` and `close` complete it.

Errors

By default an LMDB error dies with LMDB's message in `$@`. With `$LMDB_File::die_on_err` false a call returns the error code instead; either way `$LMDB_File::last_err` holds the last code. `LMDB_File::strerror($code)` gives a code's message.

Two more functions, not exported: `LMDB_File::version(my $major, my $minor, my $patch)` returns liblmdb's version string ("LMDB 0.9.35: (Jan 27, 2026)") and sets the three numbers; and `LMDB_File::reader_check($env, my $dead)` clears the reader slots left behind by processes that died with a read transaction open, setting `$dead` to how many it cleared.

Constants

`use LMDB_File qw(...)` imports by tag: `:envflags`, `:dbflags`, `:writeflags`, `:flags` (all three), `:cursor_op`, `:error` (the `MDB_*` error codes) and `:version` (`MDB_VERSION_STRING` and the like, the version of the liblmdb in use).

Differences from upstream

Four, each where perl 5.44 with XS LMDB_File fails (t/15-modules/LMDB_File/150-or-better.t):

- `LMDB::Cursor::_put` with `MDB_RESERVE` takes the length as its fifth argument. Upstream demands five arguments and then reads a sixth, past the end of them, and dies "MDB_RESERVE length must be > 0".
- A failed `LMDB::Cursor::open` leaves its argument undef, which `LMDB_File.pm` checks for; upstream fills it with a pointer to nothing.
- `$env->close` leaves the environment closed for good: closing it again, as its `DESTROY` does, is harmless, and the same database can be opened again. Upstream frees the environment twice and aborts.
- `$env->close` with a transaction still open ends the transaction first, as dropping the environment does; using it afterwards dies "Not an active transaction" or "Terminated transaction". Upstream leaves it pointing at freed memory and crashes.

liblmdb is the system's library, loaded when first needed. Everything else behaves as with upstream's LMDB_File, as its own test suite shows: `t/15-modules/LMDB_File/100-upstream-00-basic.t` to `140-upstream-04-bigone.t`.

5.2.62 List

Namespace containing the following modules:

- `List::MoreUtils`
- `List::Util` - The standard library of list reductions and scanners.

List::MoreUtils

Namespace containing the following modules:

- `List::MoreUtils::XS` - The compiled implementation of List::MoreUtils: the list functions List::Util does not have - junctions (`any`, `all`, `none`, `notall`, one and their `_u` variants that answer undef for an empty list), index and value searches from either end (`firstidx`, `lastval`, `onlyres`, ...), slicing by a predicate (`after`, `before_incl`), iterators (`each_array`, `natatime`, `slideatatime`), merging (`mesh`, `zip6`, `pairwise`, `arrayify`), counting (`uniq`, `singleton`, `duplicates`, `frequency`, `occurrences`, `mode`), binary searches over sorted lists (`bsearch`, `lower_bound`, `equal_range`, `binsert`, `bremove`) and an in-place `qsort`.

List::MoreUtils::XS

The compiled implementation of List::MoreUtils: the list functions List::Util does not have - junctions (`any`, `all`, `none`, `notall`, `one` and their `_u` variants that answer undef for an empty list), index and value searches from either end (`firstidx`, `lastval`, `onlyres`, ...), slicing by a predicate (`after`, `before_incl`), iterators (`each_array`, `natatime`, `slideatatime`), merging (`mesh`, `zip6`, `pairwise`, `arrayify`), counting (`uniq`, `singleton`, `duplicates`, `frequency`, `occurrences`, `mode`), binary searches over sorted lists (`bsearch`, `lower_bound`, `equal_range`, `binsert`, `bremove`) and an in-place `qsort`.

This is a native implementation of List::MoreUtils::XS 0.430's `XS.xs`; its `List/MoreUtils/XS.pm` is used unchanged, and List::MoreUtils, which picks it as its backend, comes from CPAN.

Synopsis

```
use List::MoreUtils qw(firstidx pairwise natatime uniq);

my $i = firstidx { $_ eq 'b' } qw(a b c);       # 1
my @s = pairwise { $a + $b } @x, @y;
my $it = natatime 3, 1 .. 10;
while (my @chunk = $it->()) { print "@chunk\n" }
my $n = uniq 1, 1, 2, undef, undef;              # 3
```

Differences from upstream

- A block that is a compiled sub (any `\&Scalar::Util::blessed, ...`) is called; perl jumps into it as if it were Perl code and crashes.
- `minmax` over objects that overload only other operators, with `fallback => 1`, compares their numeric values as `<=>` would; perl crashes. An overloaded `<=>` that returns a string or a fraction is read as a number; perl reads an unrelated field and answers wrongly (the maximum of 3, 1, 2 comes out as 2).
- `reduce_u`, `reduce_0` and `reduce_1` leave the caller's `$_` alone; perl overwrites it with the last index, which changes the current element of an enclosing `for (@array)` and dies inside `for (1)` with "Modification of a read-only value attempted".
- `frequency` no longer leaks a scalar per call when the list holds undef.
- An object that overloads `@{}` over a hash or a scalar is read through its overloading by `arrayify`, `mesh`, `zip6`, `listcmp`, `each_array`, `insert_after` and `insert_after_string`; perl reads the hash as an array and crashes.
- An array with holes (`$a[5] = 1` on an empty array) is read with undef in the holes by `arrayify`, `each_array`, `insert_after` and `insert_after_string`; perl crashes.
- Calling the iterator bodies `List::MoreUtils::XS::_array_iterator` and `_slideatatime_iterator` directly returns an empty list; perl crashes.

List::Util

The standard library of list reductions and scanners.

`List::Util` is the first stop when you need to collapse a list to a single answer (`sum`, `max`, `product`, `reduce`), find or test elements by predicate (`first`, `any`, `all`, `none`, `notall`), strip duplicates (`uniq`, `uniqnum`, `uniqint`, `uniqstr`), or reshape an even-sized key/value list (`pairs`, `pairkeys`, `pairmap`, `pairgrep`). It also covers slicing (`head`, `tail`), randomisation (`shuffle`, `sample`), and lockstep iteration over multiple arrays (`zip`, `mesh`, and their `_shortest` / `_longest` variants).

The block-taking reductions - `reduce`, `reductions`, `pairmap`, `pairgrep`, `pairfirst` - expose the current pair or accumulator through `$a` and `$b`. The per-element scanners - `first`, `any`, `all`, `none`, `notall` - expose the current element through `$_`.

`Sub::Util` (`subname`, `set_subname`, `set_prototype`) ships with the same distribution and becomes available once `List::Util` is loaded; import it from `Sub::Util` as usual.

This is List::Util from Scalar-List-Utils 1.70; `List/Util.pm` is upstream's. Nothing is exported by default.

Synopsis

```
use List::Util qw(sum max first any reduce uniq pairs pairmap head
 ↪shuffle zip);

my @n = (3, 9, 4, 1, 9);
print sum(@n), ' ', max(@n), "\n";                    # 26 9
print first { $_ > 3 } @n;                            # 9
print((any { $_ == 4 } @n) ? "has 4\n" : "no 4\n");   # has 4
print reduce { $a * $b } 1 .. 5;                      # 120
print join(',', uniq @n), "\n";                       # 3,9,4,1

my %age = (alice => 30, bob => 25);
for my $p (sort { $a->key cmp $b->key } pairs %age) {
    printf "%s is %d\n", $p->key, $p->value;          # alice is 30,
 ↪bob is 25
}
print join(',', pairmap { "$a=$b" } %age), "\n";      # alice=30,
 ↪bob=25 (hash order)
print join(',', head 2, @n), "\n";                    # 3,9
print join(' ', map { "[@$_]" } zip [1, 2], ['a', 'b']), "\n";   #
 ↪[1 a] [2 b]
my @deck = shuffle 1 .. 52;
```

`sum`, `product`, `min` and `max` of a long list of plain integers (65536 elements and more) run on several cores; the answer is the one the single-core loop gives, the same element for `min` and `max`. `--no-parallel` turns that off.

Differences from upstream

Each where perl 5.44 with ListUtil.xs fails (t/81-xs-native/List-Util/151-or-better.t):

- `unpairs 42` croaks "Not a reference"; perl5 crashes.
- `unpairs` takes an array reference held in a variable that once held a string (`my $x = "abc"; $x = [1, 2]`); perl5 refuses it.
- `mesh` reads a hole in an input array (`my @h; $h[2] = 5`) as undef; perl5 crashes.

Modules

- `List::Util::XS` - Require List::Util's compiled implementation

Functions

Reductions

sum

Add up every value in the list and return the numerical total.

sum0

Add up every value in the list, returning `0` for an empty list.

min

Return the numerically smallest value in the list.

max

Return the numerically largest value in the list.

product

Multiply every value in the list and return the numerical product.

minstr

Return the lexically smallest value in the list.

maxstr

Return the lexically largest value in the list.

`reduce`

Collapse a list to a single value by repeated pairwise combination.

`reductions`

Like `reduce`, but also return every intermediate accumulator value.

Scanners

`first`

Return the first list element for which a block returns true.

`any`

True if the block returns true for at least one element.

`all`

True if the block returns true for every element (including empty list).

`none`

True if the block returns true for no element (including empty list).

`notall`

True if the block returns false for at least one element.

Pair handling

`pairs`

Group an even-sized list into key/value pair objects.

`unpairs`

Flatten a list of two-element arrayrefs into a key/value list.

`pairkeys`

Extract just the keys from an even-sized key/value list.

`pairvalues`

Extract just the values from an even-sized key/value list.

pairmap

Run a block for each pair and concatenate the results.

pairgrep

Keep the pairs for which a block returns true.

pairfirst

Return the first pair for which a block returns true.

Selection

head

Return the first `$size` elements of a list.

tail

Return the last `$size` elements of a list.

uniq

Remove subsequent duplicates by string equality, preserving order.

uniqstr

Remove subsequent duplicates by string equality, treating `undef` as the empty string.

uniqnum

Remove subsequent duplicates by numerical equality, preserving order.

uniqint

Remove subsequent duplicates by integer equality, preserving order.

Misc

shuffle

Return the input list in a uniformly random order.

sample

Pick `$count` distinct elements from the list at random.

mesh

Interleave multiple arrays, padding shorter ones with undef.

mesh_longest

The same as mesh, by the name that says what it does with lists of different lengths: the elements run to the longest input, the shorter ones padded with undef.

mesh_shortest

Interleave multiple arrays, stopping at the shortest.

zip

Walk multiple arrays in lockstep, returning one arrayref per row.

zip_longest

The same as zip, by the name that says what it does with lists of different lengths: rows run to the longest input, the shorter ones padded with undef.

zip_shortest

Walk multiple arrays in lockstep, stopping at the shortest.

List::Util::XS

Require List::Util's compiled implementation

SYNOPSIS

```
use List::Util::XS 1.20;
```

DESCRIPTION

use List::Util::XS 1.20; is a dependency check: it fails unless List::Util runs its compiled implementation rather than a pure-Perl fallback. Under pperl List::Util is native, so the check always holds, and $List::Util::XS::VERSION is List::Util's version.

SEE ALSO

Scalar::Util, *List::Util*, *List::MoreUtils*

COPYRIGHT

sum

Add up every value in the list and return the numerical total.

Synopsis

```
my $total = sum @values;
my $total = sum 1..10;           # 55
```

What you get back

A single number - an integer if every argument summed as an integer, a float otherwise. An integer total that would overflow continues as a float from the element that overflows. If any argument is an object with overloaded +, the total is built with that + and can be such an object. For an empty list, `sum` returns `undef` for backwards compatibility; if that is awkward use `sum0` instead.

Examples

```
my $n = sum 3, 9, 12;            # 24
my $n = sum @bar, @baz;          # concatenated lists
my $n = sum();                   # undef
my $n = sum map { length } @s;   # total length of all strings
```

Edge cases

- Empty list returns `undef`. Use `sum0` for a `0` default.
- Mixing ints and floats promotes the running total to a float.
- Non-numeric strings are coerced via the usual numification.

Differences from upstream

Fully compatible with upstream.

See also

- `sum0` - same as `sum`, but returns `0` for an empty list.
- `product` - multiplies rather than adds.
- `reduce` - the generic reduction when `sum` is not specific enough.

sum0

Add up every value in the list, returning `0` for an empty list.

Synopsis

```
my $total = sum0 @values;
my $total = sum0 ();              # 0, not undef
```

What you get back

The same number `sum` would produce, except that an empty list yields `0` instead of `undef`. This is almost always what callers want when adding up a list that may legitimately be empty.

Examples

```
my $n = sum0 1..10;               # 55
my $n = sum0 ();                  # 0
my $n = sum0 grep { $_ > 0 } @x; # total of positives, 0 if none
```

Differences from upstream

Fully compatible with upstream.

See also

- `sum` - the original; returns `undef` on empty input.
- `product` - identity element for multiplication (returns 1 on empty).

min

Return the numerically smallest value in the list.

Synopsis

```
my $lo = min @values;
my $lo = min 3, 9, 12;            # 3
```

What you get back

A single number. If every argument is an integer the result is returned as an integer; otherwise it is returned as a float. An empty list yields `undef`.

Examples

```
my $n = min 1..10;                # 1
my $n = min @bar, @baz;           # smallest across concatenated␣
↪lists
my $n = min();                    # undef
```

Edge cases

- Empty list returns `undef`.
- Strings are compared numerically (use `minstr` for lexical order).

Differences from upstream

Fully compatible with upstream.

See also

- `max` - the numerical maximum counterpart.
- `minstr` - string-wise minimum (`lt` semantics).
- `reduce` - custom minima (e.g. by a key function).

max

Return the numerically largest value in the list.

Synopsis

```
my $hi = max @values;
my $hi = max 3, 9, 12;          # 12
```

What you get back

A single number. If every argument is an integer the result is returned as an integer; otherwise it is returned as a float. An empty list yields `undef`.

Examples

```
my $n = max 1..10;              # 10
my $n = max @bar, @baz;         # largest across concatenated lists
my $n = max();                  # undef
```

Edge cases

- Empty list returns `undef`.
- Strings are compared numerically (use `maxstr` for lexical order).

Differences from upstream

Fully compatible with upstream.

See also

- `min` - the numerical minimum counterpart.
- `maxstr` - string-wise maximum (`gt` semantics).
- `reduce` - custom maxima (e.g. by a key function).

product

Multiply every value in the list and return the numerical product.

Synopsis

```
my $p = product @values;
my $p = product 1..10;          # 3628800
```

What you get back

A single number. Integer overflow is promoted to floating point transparently, so the result is an integer as long as the exact product fits in an `IV`. An empty list yields 1 (the multiplicative identity).

Examples

```
my $n = product 3, 9, 12;       # 324
my $n = product();              # 1
my $n = product map { $_->weight } @items;
```

Differences from upstream

Fully compatible with upstream.

See also

- `sum` - additive counterpart.
- `sum0` - additive counterpart that mirrors `product`'s identity-element behaviour on empty input.
- `reduce` - the generic reduction when `product` is not specific enough.

head

Return the first `$size` elements of a list.

Synopsis

```
my @first = head $size, @list;
my @first = head 2, qw( foo bar baz );   # ('foo', 'bar')
```

What you get back

A list of at most `$size` elements, taken from the start of the input. If `$size` is negative, head returns all but the last `-$size` elements - useful for dropping a tail.

Examples

```
my @r = head  2, qw( foo bar baz );   # ('foo', 'bar')
my @r = head -2, qw( foo bar baz );   # ('foo')
my @r = head  5, qw( a b c );         # ('a', 'b', 'c') - fewer than
 ↪$size
```

Edge cases

- `$size >= @list` returns the whole list.
- `$size == 0` or `-$size >= @list` returns the empty list.

Differences from upstream

Fully compatible with upstream.

See also

- `tail` - mirror operation, taking from the end.
- `sample` - random selection without positional bias.

tail

Return the last `$size` elements of a list.

Synopsis

```
my @last = tail $size, @list;
my @last = tail 2, qw( foo bar baz );    # ('bar', 'baz')
```

What you get back

A list of at most `$size` elements, taken from the end of the input. If `$size` is negative, `tail` returns all but the first `-$size` elements - useful for dropping a head.

Examples

```
my @r = tail  2, qw( foo bar baz );   # ('bar', 'baz')
my @r = tail -2, qw( foo bar baz );   # ('baz')
my @r = tail  5, qw( a b c );         # ('a', 'b', 'c') - fewer than
 ↪$size
```

Differences from upstream

Fully compatible with upstream.

See also

- `head` - mirror operation, taking from the start.
- `sample` - random selection without positional bias.

shuffle

Return the input list in a uniformly random order.

Synopsis

```
my @mixed = shuffle @values;
my @deck  = shuffle 0..51;       # a shuffled deck
```

What you get back

A new list with the same elements as the input, permuted by a Fisher-Yates shuffle. Each permutation is equally likely given a well-distributed random source. The source is the global `$List::Util::RAND`, or perl's built-in `rand()` when `$RAND` is undefined.

Examples

```
my @picked = shuffle @candidates;
my ($winner) = shuffle @entries;       # pick one at random
local $List::Util::RAND = sub { 0.5 }; # deterministic for tests
```

Differences from upstream

Fully compatible with upstream.

See also

- `sample` - take a fixed count without replacement.
- `head` - deterministic prefix selection.

sample

Pick `$count` distinct elements from the list at random.

Synopsis

```
my @picks = sample $count, @values;
my @three = sample 3, 1..100;
```

What you get back

A list of at most `$count` elements drawn without replacement. If `$count` is larger than the input, every element is returned in a random order - i.e. the function degrades to `shuffle`. The random source is `$List::Util::RAND` if set, otherwise perl's built-in `rand()`.

Examples

```
my @preview = sample 5, @articles;
my ($winner) = sample 1, @entries;
my @all     = sample 999, qw( a b c );   # ('c','a','b') say
```

Edge cases

- `$count <= 0` returns the empty list.
- Fewer inputs than `$count` returns all inputs, shuffled.

Differences from upstream

Fully compatible with upstream.

See also

- `shuffle` - permute the whole list.
- `head` - deterministic prefix (no randomness).

uniq

Remove subsequent duplicates by string equality, preserving order.

Elements are compared as strings: two values are the same when their stringifications are byte-for-byte identical. The first occurrence of any given value wins; later duplicates are dropped. `undef` is the one exception: it is distinct from the empty string, raises no warning, and is kept as `undef` in the result. That is the only difference from `uniqstr`.

Synopsis

```
my @subset = uniq @values;
my $count  = uniq @values;    # scalar context - count only
```

What you get back

In list context, the unique elements in first-seen order. In scalar context, the count of unique elements. `uniq undef, ''` returns both elements; later `undef`s are duplicates of the first.

Examples

```
my @u = uniq    qw( a b a c b );       # ('a', 'b', 'c')
my @u = uniqstr 'a', 'A';              # ('a', 'A') - case matters
my $n = uniq    qw( a b a c b );       # 3
```

Differences from upstream

Fully compatible with upstream.

See also

- `uniqnum` - compare as numbers rather than as strings.
- `uniqint` - compare as integers after truncation.

uniqstr

Remove subsequent duplicates by string equality, treating `undef` as the empty string.

Synopsis

```
my @subset = uniqstr @values;
my $count  = uniqstr @values;    # scalar context - count only
```

What you get back

In list context, the unique elements in first-seen order; in scalar context, their count. Unlike `uniq`, an `undef` element is indistinguishable from `""` and comes back as `""`.

See also

- `uniq` - identical, except `undef` is kept as `undef`.
- `uniqnum` / `uniqint` - numerical comparisons.

uniqnum

Remove subsequent duplicates by numerical equality, preserving order.

Synopsis

```
my @subset = uniqnum @values;
my $count  = uniqnum @values;    # scalar context - count only
```

What you get back

In list context, the unique numerical values in first-seen order. In scalar context, the count. `undef` is treated as `0` and coerced to `0` in the output (matching upstream's numerical handling). `+0.0` and `-0.0` are treated as equal. Every `NaN` is treated as a duplicate of every other `NaN`, despite `NaN != NaN`.

Examples

```
my @u = uniqnum  1, 1.0, '1', 2;   # (1, 2)
my @u = uniqnum  0, -0.0;          # (0)
my $n = uniqnum  1, 2, 3, 2, 1;    # 3
```

Differences from upstream

Fully compatible with upstream.

See also

- `uniq` - string-equality deduplication.
- `uniqint` - integer-equality deduplication (ignores fractions).

uniqint

Remove subsequent duplicates by integer equality, preserving order.

Synopsis

```
my @subset = uniqint @values;
my $count  = uniqint @values;    # scalar context - count only
```

What you get back

In list context, the unique integer values in first-seen order - every input is truncated to its integer part before comparison, and the returned list itself contains integers (not the original SVs). `undef` is treated as `0`.

Examples

```
my @u = uniqint 1.1, 1.9, 2.0;      # (1, 2)
my @u = uniqint '3', 3, 3.7;        # (3)
my $n = uniqint 1, 2, 2, 3;         # 3
```

Differences from upstream

Fully compatible with upstream.

See also

- `uniqnum` - full numerical (float) equality.
- `uniq` - string-equality deduplication.

minstr

Return the lexically smallest value in the list.

Synopsis

```
my $s = minstr @values;
my $s = minstr 'A'..'Z';          # 'A'
```

What you get back

The first (original) list element whose stringification compares less than every other element's stringification under `lt` (byte-wise comparison). Empty list yields `undef`.

Examples

```
my $s = minstr 'hello', 'world';    # 'hello'
my $s = minstr qw( foo bar baz );   # 'bar'
my $s = minstr ();                  # undef
```

Differences from upstream

Fully compatible with upstream.

See also

- `maxstr` - string-wise maximum.
- `min` - numerical minimum.

maxstr

Return the lexically largest value in the list.

Synopsis

```
my $s = maxstr @values;
my $s = maxstr 'A'..'Z';          # 'Z'
```

What you get back

The first (original) list element whose stringification compares greater than every other element's stringification under `gt` (byte-wise comparison). Empty list yields `undef`.

Examples

```
my $s = maxstr 'hello', 'world';    # 'world'
my $s = maxstr qw( foo bar baz );   # 'foo'
my $s = maxstr ();                  # undef
```

Differences from upstream

Fully compatible with upstream.

See also

- `minstr` - string-wise minimum.
- `max` - numerical maximum.

pairs

Group an even-sized list into key/value pair objects.

Synopsis

```
my @pairs = pairs @kvlist;
for my $p ( pairs %hash ) {
    my ($k, $v) = @$p;            # or $p->key / $p->value
}
```

What you get back

A list of two-element blessed array references (class `List::Util::_Pair`). Each pair responds to `->key`, `->value`, and `->TO_JSON`, and can also be dereferenced as a plain arrayref. For an odd-sized input, the final pair's value is `undef`.

Examples

```
for my $p ( pairs one => 1, two => 2 ) {
    print $p->key, '=', $p->value, "\n";
}
# one=1
# two=2
```

```
my @sorted = sort { $a->key cmp $b->key } pairs %h;
```

Differences from upstream

Fully compatible with upstream.

See also

- `unpairs` - inverse: flatten an arrayref list back to key/value.
- `pairkeys` / `pairvalues` - extract just one side.
- `pairmap` / `pairgrep` - transform or filter pairs in place.

unpairs

Flatten a list of two-element arrayrefs into a key/value list.

Synopsis

```
my @kvlist = unpairs @pairs;
my %hash   = unpairs @pairs;
```

What you get back

A flat list with exactly two elements per input arrayref: copies of `[0]` as the key and `[1]` as the value. Missing elements pad with `undef` so that the result is always even-sized; an argument that is not an ARRAY reference croaks.

Examples

```
my @kv = unpairs [a => 1], [b => 2];   # ('a', 1, 'b', 2)
my %h  = unpairs pairs %other;         # round-trip
my @kv = unpairs sort { $a->[0] cmp $b->[0] } pairs %h;
```

Differences from upstream

A plain integer argument croaks `Not a reference` where perl5 crashes, and an array reference held in a variable that once held a string is accepted where perl5 refuses it.

See also

- `pairs` - the inverse direction.

pairkeys

Extract just the keys from an even-sized key/value list.

Synopsis

```
my @keys = pairkeys @kvlist;
my @keys = pairkeys %hash;
```

What you get back

A list of every even-indexed element (indices `0`, 2, 4, ...). Equivalent to but more efficient than

```
pairmap { $a } @kvlist
```

Examples

```
my @k = pairkeys one => 1, two => 2;    # ('one', 'two')
my @k = pairkeys %ENV;                  # names of every env var
```

Differences from upstream

Fully compatible with upstream.

See also

- `pairvalues` - the value-side counterpart.
- `pairs` - keep keys and values bound together.

pairvalues

Extract just the values from an even-sized key/value list.

Synopsis

```
my @values = pairvalues @kvlist;
my @values = pairvalues %hash;
```

What you get back

A list of every odd-indexed element (indices 1, 3, 5, ...). If the input has an orphan key at the end, its corresponding value is `undef`. Equivalent to but more efficient than

```
pairmap { $b } @kvlist
```

Examples

```
my @v = pairvalues one => 1, two => 2;   # (1, 2)
my @v = pairvalues %ENV;                 # values of every env var
```

Differences from upstream

Fully compatible with upstream.

See also

- `pairkeys` - the key-side counterpart.
- `pairs` - keep keys and values bound together.

pairmap

Run a block for each pair and concatenate the results.

Synopsis

```
my @out   = pairmap { BLOCK } @kvlist;
my $count = pairmap { BLOCK } @kvlist;   # scalar context
```

For every pair the block is called in list context with `$a` set to the key and `$b` set to the value; its results are appended to the output list in order.

What you get back

In list context, the concatenation of everything every invocation of the block returned. In scalar context, the number of items that would have been returned in list context. `$a` and `$b` are aliased to the original list elements - modifications in the block are visible to the caller.

Examples

```
my @lines = pairmap { "The key $a has value $b" } %hash;
my @flat  = pairmap { ( $a, uc $b ) } %h;    # values upper-cased
my @pairs = pairmap { [ $a, $b ] } %h;       # equivalent to `pairs`
```

Differences from upstream

Fully compatible with upstream.

See also

- `pairgrep` - filter pairs by a predicate.
- `pairfirst` - stop at the first matching pair.
- `pairs` - bundle pairs into blessed arrayrefs.

pairgrep

Keep the pairs for which a block returns true.

Synopsis

```
my @kept  = pairgrep { BLOCK } @kvlist;
my $count = pairgrep { BLOCK } @kvlist;   # scalar context
```

For every pair the block is called in scalar context with `$a` set to the key and `$b` set to the value. Pairs for which the block returns true are included in the result; others are dropped.

What you get back

In list context, an even-sized list: the kept keys and values interleaved. In scalar context, the number of pairs (not elements) that matched - half of what the list-context length would be. `$a` and `$b` are aliased to the original list elements.

Examples

```
my %big     = pairgrep { $b > 100 } %totals;
my @uppers  = pairgrep { $a =~ /^[A-Z]/ } %h;
my $n_big   = pairgrep { $b > 100 } %totals;   # scalar: pair count
```

Differences from upstream

Fully compatible with upstream.

See also

- `pairmap` - transform pairs instead of filtering.
- `pairfirst` - find the first matching pair and stop.

pairfirst

Return the first pair for which a block returns true.

Synopsis

```
my ($k, $v) = pairfirst { BLOCK } @kvlist;
my $found   = pairfirst { BLOCK } @kvlist;   # scalar context
```

For each pair the block is called in scalar context with `$a` set to the key and `$b` set to the value. `pairfirst` stops at the first pair for which the block returns true.

What you get back

In list context, the matching `($key, $value)` pair, or an empty list if nothing matched. In scalar context, a boolean indicating whether any pair matched. `$a` and `$b` are aliased to the original list elements.

Examples

```
my ($k, $v) = pairfirst { $a =~ /^upper_/ } %config;
if ( pairfirst { $b > 1_000 } %totals ) {
    warn "at least one big entry";
}
```

Differences from upstream

Fully compatible with upstream.

See also

- `first` - non-pair equivalent, uses `$_`.
- `pairgrep` - collect every matching pair.

mesh

Interleave multiple arrays, padding shorter ones with `undef`.

Registered under both `mesh` and `mesh_longest`. Both forms stop at the length of the longest input and fill missing elements with `undef`.

Synopsis

```
my @out = mesh         \@a, \@b, \@c;
my @out = mesh_longest \@a, \@b, \@c;
my %h   = mesh \@keys, \@values;
```

What you get back

A flat list containing elements at position `0` from each input array, then position 1, and so on, up to the longest input. Missing positions are filled with `undef`.

Examples

```
my @r = mesh [1..3], ['a'..'c'];          # (1,'a', 2,'b', 3,'c')
my @r = mesh [1..3], ['a'..'b'];          # (1,'a', 2,'b', 3,undef)
my %h = mesh \@keys, \@values;            # build a hash
```

Edge cases

- An input that is not an arrayref croaks `Expected an ARRAY reference to mesh`.
- Empty input list returns an empty list.
- The elements are copies: modifying them leaves the inputs alone.

Differences from upstream

A hole in an input array reads as `undef`, where perl5 crashes.

See also

- `mesh_shortest` - stop at the shortest input.
- `zip` - same lockstep walk, but yields one arrayref per row.

mesh_shortest

Interleave multiple arrays, stopping at the shortest.

Synopsis

```
my @out = mesh_shortest \@a, \@b, \@c;
```

What you get back

A flat list containing elements at position `0` from each input, then 1, and so on - up to the length of the shortest input. No `undef` padding.

Examples

```
my @r = mesh_shortest [1..3], ['a','b'];   # (1,'a', 2,'b')
my @r = mesh_shortest [1..3], [];          # ()
```

Differences from upstream

Fully compatible with upstream.

See also

- `mesh` / `mesh_longest` - pad to longest instead.
- `zip_shortest` - same lockstep walk, but yields one arrayref per row.

zip

Walk multiple arrays in lockstep, returning one arrayref per row.

Registered under both `zip` and `zip_longest`. Both forms stop at the length of the longest input and fill missing positions with `undef`.

Synopsis

```
my @rows = zip         \@a, \@b, \@c;
my @rows = zip_longest \@a, \@b, \@c;
foreach ( zip \@xs, \@ys ) {
    my ($x, $y) = @$_;
}
```

What you get back

A list of arrayrefs, one per row. Row `i` contains the `i`-th element of each input array in order. Shorter inputs contribute `undef` beyond their own length.

Examples

```
my @r = zip [1..3], ['a'..'c'];   # ([1,'a'], [2,'b'], [3,'c'])
my @r = zip [1..3], ['a'..'b'];   # ([1,'a'], [2,'b'], [3,undef])
```

Differences from upstream

Fully compatible with upstream.

See also

- `zip_shortest` - stop at the shortest input.
- `mesh` - flatten the rows instead of wrapping in arrayrefs.

zip_shortest

Walk multiple arrays in lockstep, stopping at the shortest.

Synopsis

```
my @rows = zip_shortest \@a, \@b, \@c;
```

What you get back

A list of arrayrefs, one per row. Row `i` contains the `i`-th element of each input array - produced only while every input still has an `i`-th element. No `undef` padding.

Examples

```
my @r = zip_shortest [1..3], ['a','b'];   # ([1,'a'], [2,'b'])
my @r = zip_shortest [1..3], [];          # ()
```

Differences from upstream

Fully compatible with upstream.

See also

- `zip` / `zip_longest` - pad to longest instead.
- `mesh_shortest` - flatten the rows instead of wrapping in arrayrefs.

reduce

Collapse a list to a single value by repeated pairwise combination.

Synopsis

```
my $result = reduce { BLOCK } @list;
my $sum    = reduce { $a + $b } 1..10;       # 55
my $max    = reduce { $a > $b ? $a : $b } @xs;
```

The block is called in scalar context with `$a` set to the running accumulator and `$b` set to the next element. On the first call, `$a` and `$b` are the first two elements; on each subsequent call, `$a` is whatever the previous call returned.

What you get back

The value of the last block invocation. If the list is empty, `undef` is returned. If the list contains exactly one element, that element is returned and the block is not called.

Examples

```
my $concat = reduce { "$a,$b" } 'a'..'c';    # 'a,b,c'
my $best   = reduce { $a->score > $b->score ? $a : $b } @players;
```

(continues on next page)

(continued from previous page)

```
my $total  = reduce { $a + length $b } 0, @strings;   # sum of
 ↪lengths
```

```
# Guarantee a numeric identity so an empty @values doesn't yield
 ↪undef:
my $sum = reduce { $a + $b } 0, @values;
```

Differences from upstream

Fully compatible with upstream.

See also

- `reductions` - like `reduce`, but also keeps the intermediate values.
- `sum` / `product` / `min` / `max` - specialised, faster forms.
- `first` / any / `all` - element-test reductions over `$_`.

reductions

Like `reduce`, but also return every intermediate accumulator value.

Synopsis

```
my @steps = reductions { BLOCK } @list;
my @running = reductions { $a + $b } 1..4;   # (1, 3, 6, 10)
```

The block is called in the same way as for `reduce`: `$a` is the accumulator, `$b` is the next element. `reductions` differs in that it captures the accumulator at every step rather than just the final value.

What you get back

A list whose first element is the first input value and whose subsequent elements are each block invocation's return value in order. The last element equals what `reduce` would have returned for the same block and list.

Examples

```
reduce     { "$a-$b" }  'a'..'d';    # 'a-b-c-d'
reductions { "$a-$b" }  'a'..'d';    # ('a', 'a-b', 'a-b-c', 'a-b-c-
 ↪d')
```

```
my @running_sum = reductions { $a + $b } @values;
```

Differences from upstream

Fully compatible with upstream.

See also

- `reduce` - when only the final result is needed.

first

Return the first list element for which a block returns true.

Synopsis

```
my $val = first { BLOCK } @list;
my $d   = first { defined } @list;
my $big = first { $_ > 100 } @values;
```

For each element `first` sets `$_` to that element and calls the block in scalar context; the first element for which the block returns true is returned. Remaining elements are not examined.

What you get back

The matching element (the original value, not the block's return). If no element matches - or the list is empty - returns `undef`.

Examples

```
my $first_defined = first { defined $_ } @list;
my $first_big     = first { $_ > $threshold } @measurements;
my $first_admin   = first { $_->is_admin } @users;
```

Differences from upstream

Fully compatible with upstream.

See also

- any - boolean "at least one matches" test.
- `grep` - collect every matching element.
- `pairfirst` - pair-oriented counterpart.

any

True if the block returns true for at least one element.

Synopsis

```
my $bool = any { BLOCK } @list;
if ( any { length > 10 } @strings ) { ... }
```

For each element any sets `$_` to that element and calls the block in scalar context. It returns true as soon as the block returns true for any element, without examining the rest. For an empty list it returns false.

What you get back

1 if any element satisfied the block, `0` otherwise.

Examples

```
warn "has empty"   if any { $_ eq '' } @values;
die  "has admin"   if any { $_->is_admin } @users;
my $ok = any { /^--help$/ } @ARGV;
```

Differences from upstream

Fully compatible with upstream.

See also

- `all` - require every element to match.
- none - require no element to match.
- `first` - return the matching element itself.

all

True if the block returns true for every element (including empty list).

Synopsis

```
my $bool = all { BLOCK } @list;
if ( all { defined } @values ) { ... }
```

For each element `all` sets `$_` to that element and calls the block in scalar context. It returns false as soon as the block returns false for any element. An empty list yields true (the conventional “vacuous truth”).

What you get back

1 if every element satisfied the block, `0` otherwise.

Examples

```
die "found empty string" unless all { length } @strings;
my $ready = all { $_->is_ready } @workers;
my $yes   = all { $_ > 0 } ();           # 1 - vacuous truth
```

Differences from upstream

Fully compatible with upstream.

See also

- any - require at least one match.
- `notall` - inverse: at least one failure.
- none - inverse: zero matches.

none

True if the block returns true for no element (including empty list).

Synopsis

```
my $bool = none { BLOCK } @list;
if ( none { $_ < 0 } @measurements ) { ... }
```

For each element none sets `$_` to that element and calls the block in scalar context. It returns false as soon as the block returns true for any element. An empty list yields true.

What you get back

1 if every element failed the block, `0` otherwise.

Examples

```
die "negatives present" unless none { $_ < 0 } @measurements;
my $clean = none { /ERROR/ } @log_lines;
my $none  = none { 1 } ();               # 1 - nothing to fail
```

Differences from upstream

Fully compatible with upstream.

See also

- any - inverse: at least one match.
- `all` - require every element to match.
- `notall` - at least one failure.

notall

True if the block returns false for at least one element.

Synopsis

```
my $bool = notall { BLOCK } @list;
warn "some missing" if notall { defined } @values;
```

For each element `notall` sets `$_` to that element and calls the block in scalar context. It returns true as soon as the block returns false for any element. An empty list yields false.

What you get back

1 if at least one element failed the block, `0` otherwise.

Examples

```
my $incomplete = notall { defined } @row_cells;
warn "stale" if notall { $_->is_fresh } @entries;
my $false = notall { 1 } ();              # 0 - nothing to fail
```

Differences from upstream

Fully compatible with upstream.

See also

- `all` - inverse: require every element to match.
- any - at least one match.
- none - zero matches.

5.2.63 Locale

Namespace containing the following modules:

- `Locale::Maketext` - framework for localization

Locale::Maketext

framework for localization

SYNOPSIS

```
package MyProgram;
use strict;
use MyProgram::L10N;
 # ...which inherits from Locale::Maketext
my $lh = MyProgram::L10N->get_handle() || die "What language?";
...
# And then any messages your program emits, like:
warn $lh->maketext( "Can't open file [_1]: [_2]\n", $f, $! );
...
```

DESCRIPTION

It is a common feature of applications (whether run directly, or via the Web) for them to be "localized" – i.e., for them to a present an English interface to an English-speaker, a German interface to a German-speaker, and so on for all languages it's programmed with. Locale::Maketext is a framework for software localization; it provides you with the tools for organizing and accessing the bits of text and text-processing code that you need for producing localized applications.

In order to make sense of Maketext and how all its components fit together, you should probably go read Locale::Maketext::TPJ13, and *then* read the following documentation.

You may also want to read over the source for `File::Findgrep` and its constituent modules – they are a complete (if small) example application that uses Maketext.

QUICK OVERVIEW

The basic design of Locale::Maketext is object-oriented, and Locale::Maketext is an abstract base class, from which you derive a "project class". The project class (with a name like "TkBocciBall::Localize", which you then use in your module) is in turn the base class for all the "language classes" for your project (with names "TkBocciBall::Localize::it", "TkBocciBall::Localize::en", "TkBocciBall::Localize::fr", etc.).

A language class is a class containing a lexicon of phrases as class data, and possibly also some methods that are of use in interpreting phrases in the lexicon, or otherwise dealing with text in that language.

An object belonging to a language class is called a "language handle"; it's typically a flyweight object.

The normal course of action is to call:

```
use TkBocciBall::Localize;  # the localization project class
$lh = TkBocciBall::Localize->get_handle();
 # Depending on the user's locale, etc., this will
 # make a language handle from among the classes available,
 # and any defaults that you declare.
die "Couldn't make a language handle??" unless $lh;
```

From then on, you use the `maketext` function to access entries in whatever lexicon(s) belong to the language handle you got. So, this:

```
print $lh->maketext("You won!"), "\n";
```

...emits the right text for this language. If the object in `$lh` belongs to class "TkBocciBall::Localize::fr" and

=> "Tu as gagné!")`, then the above code happily tells the user "Tu as gagné!".

METHODS

Locale::Maketext offers a variety of methods, which fall into three categories:

- Methods to do with constructing language handles.
- `maketext` and other methods to do with accessing %Lexicon data for a given language handle.
- Methods that you may find it handy to use, from routines of yours that you put in %Lexicon entries.

These are covered in the following section.

Construction Methods

These are to do with constructing a language handle:

- $lh = YourProjClass->get_handle(...langtags...) || die "lg-handle?";

  This tries loading classes based on the language-tags you give (like `("en-US", "sk", "kon", "es-MX", "ja", "i-klingon")`, and for the first class that succeeds, returns YourProjClass::*language*->new().

  If it runs thru the entire given list of language-tags, and finds no classes for those exact terms, it then tries "superordinate" language classes. So if no "en-US" class (i.e., YourProjClass::en_us) was found, nor classes for anything else in that list, we then try its superordinate, "en" (i.e., YourProjClass::en), and so on thru the other language-tags in the given list: "es". (The other language-tags in our example list: happen to have no superordinates.)

  If none of those language-tags leads to loadable classes, we then try classes derived from YourProjClass->fallback_languages() and then if nothing comes of that, we use classes named by YourProjClass->fallback_language_classes(). Then in the (probably quite unlikely) event that that fails, we just return undef.

- $lh = YourProjClass->get_handle**()** || die "lg-handle?";

  When `get_handle` is called with an empty parameter list, magic happens:

  If `get_handle` senses that it's running in program that was invoked as a CGI, then it tries to get language-tags out of the environment variable "HTTP_ACCEPT_LANGUAGE", and it pretends that those were the languages passed as parameters to `get_handle`.

  Otherwise (i.e., if not a CGI), this tries various OS-specific ways to get the language-tags for the current locale/language, and then pretends that those were the value(s) passed to `get_handle`.

Currently this OS-specific stuff consists of looking in the environment variables "LANG" and "LANGUAGE"; and on MSWin machines (where those variables are typically unused), this also tries using the module Win32::Locale to get a language-tag for whatever language/locale is currently selected in the "Regional Settings" (or "International"?) Control Panel. I welcome further suggestions for making this do the Right Thing under other operating systems that support localization.

If you're using localization in an application that keeps a configuration file, you might consider something like this in your project class:

```
sub get_handle_via_config {
  my $class = $_[0];
  my $chosen_language = $Config_settings{'language'};
  my $lh;
  if($chosen_language) {
    $lh = $class->get_handle($chosen_language)
     || die "No language handle for \"$chosen_language\""
          . " or the like";
  } else {
    # Config file missing, maybe?
    $lh = $class->get_handle()
     || die "Can't get a language handle";
  }
  return $lh;
}
```

- $lh = YourProjClass::langname->new();

  This constructs a language handle. You usually **don't** call this directly, but instead let `get_handle` find a language class to `use` and to then call ->new on.

- $lh->init();

  This is called by ->new to initialize newly-constructed language handles. If you define an init method in your class, remember that it's usually considered a good idea to call $lh->SUPER::init in it (presumably at the beginning), so that all classes get a chance to initialize a new object however they see fit.

- YourProjClass->fallback_languages()

  `get_handle` appends the return value of this to the end of whatever list of languages you pass `get_handle`. Unless you override this method, your project class will inherit Locale::Maketext's `fallback_languages`, which currently returns `('i-default', 'en', 'en-US')`. ("i-default" is defined in RFC 2277).

  This method (by having it return the name of a language-tag that has an existing language class) can be used for making sure that `get_handle` will always manage to construct a language handle (assuming your language classes are in an appropriate @INC directory). Or you can use the next method:

- YourProjClass->fallback_language_classes()

  `get_handle` appends the return value of this to the end of the list of classes it will try using. Unless you override this method, your project class will inherit Locale::Maketext's `fallback_language_classes`, which currently returns

an empty list, `()`. By setting this to some value (namely, the name of a loadable language class), you can be sure that `get_handle` will always manage to construct a language handle.

The "maketext" Method

This is the most important method in Locale::Maketext:

```
$text = $lh->maketext(I<key>, ...parameters for this phrase...);
```

This looks in the %Lexicon of the language handle $lh and all its superclasses, looking for an entry whose key is the string *key*. Assuming such an entry is found, various things then happen, depending on the value found:

If the value is a scalarref, the scalar is dereferenced and returned (and any parameters are ignored).

If the value is a coderef, we return &$value($lh, ...parameters...).

If the value is a string that *doesn't* look like it's in Bracket Notation, we return it (after replacing it with a scalarref, in its %Lexicon).

If the value *does* look like it's in Bracket Notation, then we compile it into a sub, replace the string in the %Lexicon with the new coderef, and then we return &$new_sub($lh, ...parameters...).

Bracket Notation is discussed in a later section. Note that trying to compile a string into Bracket Notation can throw an exception if the string is not syntactically valid (say, by not balancing brackets right.)

Also, calling &$coderef($lh, ...parameters...) can throw any sort of exception (if, say, code in that sub tries to divide by zero). But a very common exception occurs when you have Bracket Notation text that says to call a method "foo", but there is no such method. (E.g., "You have [quat**n**,_1,ball]." will throw an exception on trying to call $lh->quat**n**($_[1],'ball') – you presumably meant "quant".) `maketext` catches these exceptions, but only to make the error message more readable, at which point it rethrows the exception.

An exception *may* be thrown if *key* is not found in any of $lh's %Lexicon hashes. What happens if a key is not found, is discussed in a later section, "Controlling Lookup Failure".

Note that you might find it useful in some cases to override the `maketext` method with an "after method", if you want to translate encodings, or even scripts:

```
package YrProj::zh_cn; # Chinese with PRC-style glyphs
use base ('YrProj::zh_tw');  # Taiwan-style
sub maketext {
  my $self = shift(@_);
  my $value = $self->maketext(@_);
  return Chineeze::taiwan2mainland($value);
}
```

Or you may want to override it with something that traps any exceptions, if that's critical to your program:

```
sub maketext {
  my($lh, @stuff) = @_;
  my $out;
  eval { $out = $lh->SUPER::maketext(@stuff) };
  return $out unless $@;
  ...otherwise deal with the exception...
}
```

Other than those two situations, I don't imagine that it's useful to override the `maketext` method. (If you run into a situation where it is useful, I'd be interested in hearing about it.)

- $lh->fail_with *or* $lh->fail_with(*PARAM*)
- $lh->failure_handler_auto

  These two methods are discussed in the section "Controlling Lookup Failure".

- $lh->denylist(@list) <or> $lh->blacklist(@list)
- $lh->allowlist(@list) <or> $lh->whitelist(@list)

  These methods are discussed in the section "Bracket Notation Security".

Utility Methods

These are methods that you may find it handy to use, generally from %Lexicon routines of yours (whether expressed as Bracket Notation or not).

- $language->quant($number, $singular)
- $language->quant($number, $singular, $plural)
- $language->quant($number, $singular, $plural, $negative)

  This is generally meant to be called from inside Bracket Notation (which is discussed later), as in

  ```
  "Your search matched [quant,_1,document]!"
  ```

  It's for *quantifying* a noun (i.e., saying how much of it there is, while giving the correct form of it). The behavior of this method is handy for English and a few other Western European languages, and you should override it for languages where it's not suitable. You can feel free to read the source, but the current implementation is basically as this pseudocode describes:

  ```
  if $number is 0 and there's a $negative,
     return $negative;
  elsif $number is 1,
     return "1 $singular";
  elsif there's a $plural,
     return "$number $plural";
  else
     return "$number " . $singular . "s";
  #
  ```

(continues on next page)

(continued from previous page)

```
# ...except that we actually call numf to
#  stringify $number before returning it.
```

So for English (with Bracket Notation) "...[quant,_1,file]..." is fine (for 0 it returns "0 files", for 1 it returns "1 file", and for more it returns "2 files", etc.)

But for "directory", you'd want "[quant,_1,directory,directories]" so that our elementary quant method doesn't think that the plural of "directory" is "directorys". And you might find that the output may sound better if you specify a negative form, as in:

```
"[quant,_1,file,files,No files] matched your query.\n"
```

Remember to keep in mind verb agreement (or adjectives too, in other languages), as in:

```
"[quant,_1,document] were matched.\n"
```

Because if _1 is one, you get "1 document **were** matched". An acceptable hack here is to do something like this:

```
"[quant,_1,document was, documents were] matched.\n"
```

- $language->numf($number)

  This returns the given number formatted nicely according to this language's conventions. Maketext's default method is mostly to just take the normal string form of the number (applying sprintf "%G" for only very large numbers), and then to add commas as necessary. (Except that we apply `tr/,././` if $language->{'numf_comma'} is true; that's a bit of a hack that's useful for languages that express two million as "2.000.000" and not as "2,000,000").

  If you want anything fancier, consider overriding this with something that uses Number::Format, or does something else entirely.

  Note that numf is called by quant for stringifying all quantifying numbers.

- $language->numerate($number, $singular, $plural, $negative)

  This returns the given noun form which is appropriate for the quantity `$number` according to this language's conventions. `numerate` is used internally by `quant` to quantify nouns. Use it directly – usually from bracket notation – to avoid `quant`'s implicit call to `numf` and output of a numeric quantity.

- $language->sprintf($format, @items)

  This is just a wrapper around Perl's normal `sprintf` function. It's provided so that you can use "sprintf" in Bracket Notation:

```
"Couldn't access datanode [sprintf,%10x=~[%s~],_1,_2]!\n"
```

  returning...

```
Couldn't access datanode      Stuff=[thangamabob]!
```

- $language->language_tag()

  Currently this just takes the last bit of `ref($language)`, turns underscores to dashes, and returns it. So if $language is an object of class Hee::HOO::Haw::en_us, $language->language_tag() returns "en-us". (Yes, the usual representation for that language tag is "en-US", but case is *never* considered meaningful in language-tag comparison.)

  You may override this as you like; Maketext doesn't use it for anything.

- $language->encoding()

  Currently this isn't used for anything, but it's provided (with default value of `(ref($language) && $language->{'encoding'}) or "iso-8859-1"`) as a sort of suggestion that it may be useful/necessary to associate encodings with your language handles (whether on a per-class or even per-handle basis.)

Language Handle Attributes and Internals

A language handle is a flyweight object – i.e., it doesn't (necessarily) carry any data of interest, other than just being a member of whatever class it belongs to.

A language handle is implemented as a blessed hash. Subclasses of yours can store whatever data you want in the hash. Currently the only hash entry used by any crucial Maketext method is "fail", so feel free to use anything else as you like.

Remember: Don't be afraid to read the Maketext source if there's any point on which this documentation is unclear. This documentation is vastly longer than the module source itself.

LANGUAGE CLASS HIERARCHIES

These are Locale::Maketext's assumptions about the class hierarchy formed by all your language classes:

- You must have a project base class, which you load, and which you then use as the first argument in the call to YourProjClass->get_handle(...). It should derive (whether directly or indirectly) from Locale::Maketext. It **doesn't matter** how you name this class, although assuming this is the localization component of your Super Mega Program, good names for your project class might be SuperMegaProgram::Localization, SuperMegaProgram::L10N, SuperMegaProgram::I18N, SuperMegaProgram::International, or even SuperMegaProgram::Languages or SuperMegaProgram::Messages.

- Language classes are what YourProjClass->get_handle will try to load. It will look for them by taking each language-tag (**skipping** it if it doesn't look like a language-tag or locale-tag!), turning it to all lowercase, turning dashes to underscores, and appending it to YourProjClass . "::". So this:

```
$lh = YourProjClass->get_handle(
  'en-US', 'fr', 'kon', 'i-klingon', 'i-klingon-romanized'
);
```

will try loading the classes YourProjClass::en_us (note lowercase!), YourProjClass::fr, YourProjClass::kon, YourProjClass::i_klingon and YourProjClass::i_klingon_romanized. (And it'll stop at the first one that actually loads.)

- I assume that each language class derives (directly or indirectly) from your project class, and also defines its @ISA, its %Lexicon, or both. But I anticipate no dire consequences if these assumptions do not hold.
- Language classes may derive from other language classes (although they should have "use *Thatclassname*" or "use base qw(...*classes*...)"). They may derive from the project class. They may derive from some other class altogether. Or via multiple inheritance, it may derive from any mixture of these.
- I foresee no problems with having multiple inheritance in your hierarchy of language classes. (As usual, however, Perl will complain bitterly if you have a cycle in the hierarchy: i.e., if any class is its own ancestor.)

ENTRIES IN EACH LEXICON

A typical %Lexicon entry is meant to signify a phrase, taking some number (0 or more) of parameters. An entry is meant to be accessed by via a string *key* in $lh->maketext(*key*, ...parameters...), which should return a string that is generally meant for be used for "output" to the user – regardless of whether this actually means printing to STDOUT, writing to a file, or putting into a GUI widget.

While the key must be a string value (since that's a basic restriction that Perl places on hash keys), the value in the lexicon can currently be of several types: a defined scalar, scalarref, or coderef. The use of these is explained above, in the section 'The "maketext" Method', and Bracket Notation for strings is discussed in the next section.

While you can use arbitrary unique IDs for lexicon keys (like "_min_larger_max_error"), it is often useful for if an entry's key is itself a valid value, like this example error message:

```
"Minimum ([_1]) is larger than maximum ([_2])!\n",
```

Compare this code that uses an arbitrary ID...

```
die $lh->maketext( "_min_larger_max_error", $min, $max )
 if $min > $max;
```

...to this code that uses a key-as-value:

```
die $lh->maketext(
 "Minimum ([_1]) is larger than maximum ([_2])!\n",
 $min, $max
) if $min > $max;
```

The second is, in short, more readable. In particular, it's obvious that the number of parameters you're feeding to that phrase (two) is the number of parameters that it *wants* to be fed. (Since you see _1 and a _2 being used in the key there.)

Also, once a project is otherwise complete and you start to localize it, you can scrape together all the various keys you use, and pass it to a translator; and then the translator's work will go faster if what he's presented is this:

```
"Minimum ([_1]) is larger than maximum ([_2])!\n",
 => "",   # fill in something here, Jacques!
```

rather than this more cryptic mess:

```
"_min_larger_max_error"
 => "",   # fill in something here, Jacques
```

I think that keys as lexicon values makes the completed lexicon entries more readable:

```
"Minimum ([_1]) is larger than maximum ([_2])!\n",
 => "Le minimum ([_1]) est plus grand que le maximum ([_2])!\n",
```

Also, having valid values as keys becomes very useful if you set up an _AUTO lexicon. _AUTO lexicons are discussed in a later section.

I almost always use keys that are themselves valid lexicon values. One notable exception is when the value is quite long. For example, to get the screenful of data that a command-line program might return when given an unknown switch, I often just use a brief, self-explanatory key such as "_USAGE_MESSAGE". At that point I then go and immediately to define that lexicon entry in the ProjectClass::L10N::en lexicon (since English is always my "project language"):

```
'_USAGE_MESSAGE' => <<'EOSTUFF',
...long long message...
EOSTUFF
```

and then I can use it as:

```
getopt('oDI', \%opts) or die $lh->maketext('_USAGE_MESSAGE');
```

Incidentally, note that each class's `%Lexicon` inherits-and-extends the lexicons in its superclasses. This is not because these are special hashes *per se*, but because you access them via the `maketext` method, which looks for entries across all the `%Lexicon` hashes in a language class *and* all its ancestor classes. (This is because the idea of "class data" isn't directly implemented in Perl, but is instead left to individual class-systems to implement as they see fit..)

Note that you may have things stored in a lexicon besides just phrases for output: for example, if your program takes input from the keyboard, asking a "(Y/N)" question, you probably need to know what the equivalent of "Y[es]/N[o]" is in whatever language. You probably also need to know what the equivalents of the answers "y" and "n" are. You can store that information in the lexicon (say, under the keys "~answer_y" and "~answer_n", and the long forms as "~answer_yes" and "~answer_no", where "~" is just an ad-hoc character meant to indicate to programmers/translators that these are not phrases for output).

Or instead of storing this in the language class's lexicon, you can (and, in some cases, really should) represent the same bit of knowledge as code in a method in the language class. (That leaves a tidy distinction between the lexicon as the things we know how to *say*, and the rest of the things in the lexicon class as things that we know how to *do*.) Consider this example of a processor for responses to French "oui/non" questions:

```
sub y_or_n {
  return undef unless defined $_[1] and length $_[1];
  my $answer = lc $_[1];  # smash case
  return 1 if $answer eq 'o' or $answer eq 'oui';
  return 0 if $answer eq 'n' or $answer eq 'non';
  return undef;
}
```

...which you'd then call in a construct like this:

```
my $response;
until(defined $response) {
  print $lh->maketext("Open the pod bay door (y/n)? ");
  $response = $lh->y_or_n( get_input_from_keyboard_somehow() );
}
if($response) { $pod_bay_door->open()         }
else          { $pod_bay_door->leave_closed() }
```

Other data worth storing in a lexicon might be things like filenames for language-targetted resources:

```
...
"_main_splash_png"
  => "/styles/en_us/main_splash.png",
"_main_splash_imagemap"
  => "/styles/en_us/main_splash.incl",
"_general_graphics_path"
  => "/styles/en_us/",
"_alert_sound"
  => "/styles/en_us/hey_there.wav",
"_forward_icon"
 => "left_arrow.png",
"_backward_icon"
 => "right_arrow.png",
# In some other languages, left equals
#  BACKwards, and right is FOREwards.
...
```

You might want to do the same thing for expressing key bindings or the like (since hard-wiring "q" as the binding for the function that quits a screen/menu/program is useful only if your language happens to associate "q" with "quit"!)

BRACKET NOTATION

Bracket Notation is a crucial feature of Locale::Maketext. I mean Bracket Notation to provide a replacement for the use of sprintf formatting. Everything you do with Bracket Notation could be done with a sub block, but bracket notation is meant to be much more concise.

Bracket Notation is a like a miniature "template" system (in the sense of Text::Template, not in the sense of C++ templates), where normal text is passed thru basically as is, but

text in special regions is specially interpreted. In Bracket Notation, you use square brackets ("[...]"), not curly braces ("{...}") to note sections that are specially interpreted.

For example, here all the areas that are taken literally are underlined with a "^", and all the in-bracket special regions are underlined with an X:

```
"Minimum ([_1]) is larger than maximum ([_2])!\n",
 ^^^^^^^^^ XX ^^^^^^^^^^^^^^^^^^^^^^^^^ XX ^^^^
```

When that string is compiled from bracket notation into a real Perl sub, it's basically turned into:

```
sub {
  my $lh = $_[0];
  my @params = @_;
  return join '',
    "Minimum (",
    ...some code here...
    ") is larger than maximum (",
    ...some code here...
    ")!\n",
}
# to be called by $lh->maketext(KEY, params...)
```

In other words, text outside bracket groups is turned into string literals. Text in brackets is rather more complex, and currently follows these rules:

- Bracket groups that are empty, or which consist only of whitespace, are ignored. (Examples: "[]", "[ ]", or a [and a] with returns and/or tabs and/or spaces between them.

  Otherwise, each group is taken to be a comma-separated group of items, and each item is interpreted as follows:

- An item that is "*_digits*" or "*_-digits*" is interpreted as $_[*value*]. I.e., "_1" becomes with $_[1], and "_-3" is interpreted as $_[-3] (in which case @_ should have at least three elements in it). Note that $_[0] is the language handle, and is typically not named directly.

- An item "_*" is interpreted to mean "all of @_ except $_[0]". I.e., `@_[1..$#_]`. Note that this is an empty list in the case of calls like $lh->maketext(*key*) where there are no parameters (except $_[0], the language handle).

- Otherwise, each item is interpreted as a string literal.

The group as a whole is interpreted as follows:

- If the first item in a bracket group looks like a method name, then that group is interpreted like this:

  ```
  $lh->that_method_name(
    ...rest of items in this group...
  ),
  ```

- If the first item in a bracket group is "*", it's taken as shorthand for the so commonly called "quant" method. Similarly, if the first item in a bracket group is "#", it's taken

to be shorthand for "numf".

- If the first item in a bracket group is the empty-string, or "_*" or "*_digits*" or "*_-digits*", then that group is interpreted as just the interpolation of all its items:

```
join('',
  ...rest of items in this group...
),
```

  Examples: "[_1]" and "[,_1]", which are synonymous; and "`[,ID-(,_4,-,_2,)]`", which compiles as `join "", "ID-(", $_[4], "-", $_[2], ")"`.

- Otherwise this bracket group is invalid. For example, in the group "[!@#,whatever]", the first item "`!@#`" is neither the empty-string, "*_number*", "*_-number*", "_*", nor a valid method name; and so Locale::Maketext will throw an exception of you try compiling an expression containing this bracket group.

Note, incidentally, that items in each group are comma-separated, not `/\s*,\s*/`-separated. That is, you might expect that this bracket group:

```
"Hoohah [foo, _1 , bar ,baz]!"
```

would compile to this:

```
sub {
  my $lh = $_[0];
  return join '',
    "Hoohah ",
    $lh->foo( $_[1], "bar", "baz"),
    "!",
}
```

But it actually compiles as this:

```
sub {
  my $lh = $_[0];
  return join '',
    "Hoohah ",
    $lh->foo(" _1 ", " bar ", "baz"),  # note the <space> in " bar "
    "!",
}
```

In the notation discussed so far, the characters "[" and "]" are given special meaning, for opening and closing bracket groups, and "," has a special meaning inside bracket groups, where it separates items in the group. This begs the question of how you'd express a literal "[" or "]" in a Bracket Notation string, and how you'd express a literal comma inside a bracket group. For this purpose I've adopted "~" (tilde) as an escape character: "~[" means a literal '[' character anywhere in Bracket Notation (i.e., regardless of whether you're in a bracket group or not), and ditto for "~]" meaning a literal ']', and "~," meaning a literal comma. (Altho "," means a literal comma outside of bracket groups – it's only inside bracket groups that commas are special.)

And on the off chance you need a literal tilde in a bracket expression, you get it with "~~".

Currently, an unescaped "~" before a character other than a bracket or a comma is taken to mean just a "~" and that character. I.e., "~X" means the same as "~~X" – i.e., one literal tilde, and then one literal "X". However, by using "~X", you are assuming that no future version of Maketext will use "~X" as a magic escape sequence. In practice this is not a great problem, since first off you can just write "~~X" and not worry about it; second off, I doubt I'll add lots of new magic characters to bracket notation; and third off, you aren't likely to want literal "~" characters in your messages anyway, since it's not a character with wide use in natural language text.

Brackets must be balanced – every openbracket must have one matching closebracket, and vice versa. So these are all **invalid**:

```
"I ate [quant,_1,rhubarb pie."
"I ate [quant,_1,rhubarb pie[."
"I ate quant,_1,rhubarb pie]."
"I ate quant,_1,rhubarb pie[."
```

Currently, bracket groups do not nest. That is, you **cannot** say:

```
"Foo [bar,baz,[quux,quuux]]\n";
```

If you need a notation that's that powerful, use normal Perl:

```
%Lexicon = (
  ...
  "some_key" => sub {
    my $lh = $_[0];
    join '',
      "Foo ",
      $lh->bar('baz', $lh->quux('quuux')),
      "\n",
  },
  ...
);
```

Or write the "bar" method so you don't need to pass it the output from calling quux.

I do not anticipate that you will need (or particularly want) to nest bracket groups, but you are welcome to email me with convincing (real-life) arguments to the contrary.

BRACKET NOTATION SECURITY

Locale::Maketext does not use any special syntax to differentiate bracket notation methods from normal class or object methods. This design makes it vulnerable to format string attacks whenever it is used to process strings provided by untrusted users.

Locale::Maketext does support denylist and allowlist functionality to limit which methods may be called as bracket notation methods.

By default, Locale::Maketext denies all methods in the Locale::Maketext namespace that begin with the '_' character, and all methods which include Perl's namespace separator characters.

The default denylist for Locale::Maketext also prevents use of the following methods in bracket notation:

```
denylist
encoding
fail_with
failure_handler_auto
fallback_language_classes
fallback_languages
get_handle
init
language_tag
maketext
new
allowlist
whitelist
blacklist
```

This list can be extended by either deny-listing additional “known bad” methods, or allow-listing only “known good” methods.

To prevent specific methods from being called in bracket notation, use the denylist() method:

```
my $lh = MyProgram::L10N->get_handle();
$lh->denylist(qw{my_internal_method my_other_method});
$lh->maketext('[my_internal_method]'); # dies
```

To limit the allowed bracked notation methods to a specific list, use the allowlist() method:

```
my $lh = MyProgram::L10N->get_handle();
$lh->allowlist('numerate', 'numf');
$lh->maketext('[_1] [numerate, _1,shoe,shoes]', 12); # works
$lh->maketext('[my_internal_method]'); # dies
```

The denylist() and allowlist() methods extend their internal lists whenever they are called. To reset the denylist or allowlist, create a new maketext object.

```
my $lh = MyProgram::L10N->get_handle();
$lh->denylist('numerate');
$lh->denylist('numf');
$lh->maketext('[_1] [numerate,_1,shoe,shoes]', 12); # dies
```

For lexicons that use an internal cache, translations which have already been cached in their compiled form are not affected by subsequent changes to the allowlist or denylist settings. Lexicons that use an external cache will have their cache cleared whenever the allowlist or denylist settings change. The difference between the two types of caching is explained in the “Readonly Lexicons” section.

Methods disallowed by the denylist cannot be permitted by the allowlist.

NOTE: denylist() is the preferred method name to use instead of the historical and non-inclusive method blacklist(). blacklist() may be removed in a future release of this

package and so it's use should be removed from usage.

NOTE: allowlist() is the preferred method name to use instead of the historical and non-inclusive method whitelist(). whitelist() may be removed in a future release of this package and so it's use should be removed from usage.

AUTO LEXICONS

If maketext goes to look in an individual %Lexicon for an entry for *key* (where *key* does not start with an underscore), and sees none, **but does see** an entry of "_AUTO" => *some_true_value*, then we actually define $Lexicon{*key*} = *key* right then and there, and then use that value as if it had been there all along. This happens before we even look in any superclass %Lexicons!

(This is meant to be somewhat like the AUTOLOAD mechanism in Perl's function call system – or, looked at another way, like the *AutoLoader* module.)

I can picture all sorts of circumstances where you just do not want lookup to be able to fail (since failing normally means that maketext throws a `die`, although see the next section for greater control over that). But here's one circumstance where _AUTO lexicons are meant to be *especially* useful:

As you're writing an application, you decide as you go what messages you need to emit. Normally you'd go to write this:

```
if(-e $filename) {
  go_process_file($filename)
} else {
  print qq{Couldn't find file "$filename"!\n};
}
```

but since you anticipate localizing this, you write:

```
use ThisProject::I18N;
my $lh = ThisProject::I18N->get_handle();
 # For the moment, assume that things are set up so
 # that we load class ThisProject::I18N::en
 # and that that's the class that $lh belongs to.
...
if(-e $filename) {
  go_process_file($filename)
} else {
  print $lh->maketext(
    qq{Couldn't find file "[_1]"!\n}, $filename
  );
}
```

Now, right after you've just written the above lines, you'd normally have to go open the file ThisProject/I18N/en.pm, and immediately add an entry:

```
"Couldn't find file \"[_1]\"!\n"
=> "Couldn't find file \"[_1]\"!\n",
```

But I consider that somewhat of a distraction from the work of getting the main code working – to say nothing of the fact that I often have to play with the program a few times before I can decide exactly what wording I want in the messages (which in this case would require me to go changing three lines of code: the call to maketext with that key, and then the two lines in ThisProject/I18N/en.pm).

However, if you set "_AUTO => 1" in the %Lexicon in, ThisProject/I18N/en.pm (assuming that English (en) is the language that all your programmers will be using for this project's internal message keys), then you don't ever have to go adding lines like this

```
"Couldn't find file \"[_1]\"!\n"
=> "Couldn't find file \"[_1]\"!\n",
```

to ThisProject/I18N/en.pm, because if _AUTO is true there, then just looking for an entry with the key "Couldn't find file "[_1]"!\n" in that lexicon will cause it to be added, with that value!

Note that the reason that keys that start with "_" are immune to _AUTO isn't anything generally magical about the underscore character – I just wanted a way to have most lexicon keys be autoable, except for possibly a few, and I arbitrarily decided to use a leading underscore as a signal to distinguish those few.

READONLY LEXICONS

If your lexicon is a tied hash the simple act of caching the compiled value can be fatal.

For example a *GDBM_File* GDBM_READER tied hash will die with something like:

```
gdbm store returned -1, errno 2, key "..." at ...
```

All you need to do is turn on caching outside of the lexicon hash itself like so:

```
sub init {
    my ($lh) = @_;
    ...
    $lh->{'use_external_lex_cache'} = 1;
    ...
}
```

And then instead of storing the compiled value in the lexicon hash it will store it in $lh->{'_external_lex_cache'}

CONTROLLING LOOKUP FAILURE

If you call $lh->maketext(*key*, ...parameters...), and there's no entry *key* in $lh's class's %Lexicon, nor in the superclass %Lexicon hash, *and* if we can't auto-make *key* (because either it starts with a "_", or because none of its lexicons have `_AUTO => 1`,), then we have failed to find a normal way to maketext *key*. What then happens in these failure conditions, depends on the $lh object's "fail" attribute.

If the language handle has no "fail" attribute, maketext will simply throw an exception (i.e., it calls `die`, mentioning the *key* whose lookup failed, and naming the line number where the calling $lh->maketext(*key*,...) was.

If the language handle has a "fail" attribute whose value is a coderef, then $lh->maketext(*key*,...params...) gives up and calls:

```
return $that_subref->($lh, $key, @params);
```

Otherwise, the "fail" attribute's value should be a string denoting a method name, so that $lh->maketext(*key*,...params...) can give up with:

```
return $lh->$that_method_name($phrase, @params);
```

The "fail" attribute can be accessed with the `fail_with` method:

```
# Set to a coderef:
$lh->fail_with( \&failure_handler );

# Set to a method name:
$lh->fail_with( 'failure_method' );

# Set to nothing (i.e., so failure throws a plain exception)
$lh->fail_with( undef );

# Get the current value
$handler = $lh->fail_with();
```

Now, as to what you may want to do with these handlers: Maybe you'd want to log what key failed for what class, and then die. Maybe you don't like `die` and instead you want to send the error message to STDOUT (or wherever) and then merely `exit()`.

Or maybe you don't want to `die` at all! Maybe you could use a handler like this:

```
# Make all lookups fall back onto an English value,
#  but only after we log it for later fingerpointing.
my $lh_backup = ThisProject->get_handle('en');
open(LEX_FAIL_LOG, ">>wherever/lex.log") || die "GNAARGH $!";
sub lex_fail {
  my($failing_lh, $key, $params) = @_;
  print LEX_FAIL_LOG scalar(localtime), "\t",
     ref($failing_lh), "\t", $key, "\n";
  return $lh_backup->maketext($key,@params);
}
```

Some users have expressed that they think this whole mechanism of having a "fail" attribute at all, seems a rather pointless complication. But I want Locale::Maketext to be usable for software projects of *any* scale and type; and different software projects have different ideas of what the right thing is to do in failure conditions. I could simply say that failure always throws an exception, and that if you want to be careful, you'll just have to wrap every call to $lh->maketext in an eval { }. However, I want programmers to reserve the right (via the "fail" attribute) to treat lookup failure as something other than an exception of the same level of severity as a config file being unreadable, or some essential resource being inaccessible.

One possibly useful value for the "fail" attribute is the method name "failure_handler_auto". This is a method defined in the class Locale::Maketext itself. You set it with:

```
$lh->fail_with('failure_handler_auto');
```

Then when you call $lh->maketext(*key*, ...parameters...) and there's no *key* in any of those lexicons, maketext gives up with

```
return $lh->failure_handler_auto($key, @params);
```

But failure_handler_auto, instead of dying or anything, compiles $key, caching it in

```
$lh->{'failure_lex'}{$key} = $compiled
```

and then calls the compiled value, and returns that. (I.e., if $key looks like bracket notation, $compiled is a sub, and we return &{$compiled}(@params); but if $key is just a plain string, we just return that.)

The effect of using "failure_auto_handler" is like an AUTO lexicon, except that it 1) compiles $key even if it starts with "_", and 2) you have a record in the new hashref $lh->{'failure_lex'} of all the keys that have failed for this object. This should avoid your program dying – as long as your keys aren't actually invalid as bracket code, and as long as they don't try calling methods that don't exist.

"failure_auto_handler" may not be exactly what you want, but I hope it at least shows you that maketext failure can be mitigated in any number of very flexible ways. If you can formalize exactly what you want, you should be able to express that as a failure handler. You can even make it default for every object of a given class, by setting it in that class's init:

```
sub init {
  my $lh = $_[0];  # a newborn handle
  $lh->SUPER::init();
  $lh->fail_with('my_clever_failure_handler');
  return;
}
sub my_clever_failure_handler {
  ...you clever things here...
}
```

HOW TO USE MAKETEXT

Here is a brief checklist on how to use Maketext to localize applications:

- Decide what system you'll use for lexicon keys. If you insist, you can use opaque IDs (if you're nostalgic for `catgets`), but I have better suggestions in the section "Entries in Each Lexicon", above. Assuming you opt for meaningful keys that double as values (like "Minimum ([_1]) is larger than maximum ([_2])!\n"), you'll have to settle on what language those should be in. For the sake of argument, I'll call this English, specifically American English, "en-US".
- Create a class for your localization project. This is the name of the class that you'll use in the idiom:

  ```
  use Projname::L10N;
  my $lh = Projname::L10N->get_handle(...) || die "Language?";
  ```

Assuming you call your class Projname::L10N, create a class consisting minimally of:

```
package Projname::L10N;
use base qw(Locale::Maketext);
...any methods you might want all your languages to share...

# And, assuming you want the base class to be an _AUTO lexicon,
# as is discussed a few sections up:

1;
```

- Create a class for the language your internal keys are in. Name the class after the language-tag for that language, in lowercase, with dashes changed to underscores. Assuming your project's first language is US English, you should call this Projname::L10N::en_us. It should consist minimally of:

```
package Projname::L10N::en_us;
use base qw(Projname::L10N);
%Lexicon = (
  '_AUTO' => 1,
);
1;
```

(For the rest of this section, I'll assume that this "first language class" of Projname::L10N::en_us has _AUTO lexicon.)

- Go and write your program. Everywhere in your program where you would say:

```
print "Foobar $thing stuff\n";
```

instead do it thru maketext, using no variable interpolation in the key:

```
print $lh->maketext("Foobar [_1] stuff\n", $thing);
```

If you get tired of constantly saying `print $lh->maketext`, consider making a functional wrapper for it, like so:

```
use Projname::L10N;
our $lh;
$lh = Projname::L10N->get_handle(...) || die "Language?";
sub pmt (@) { print( $lh->maketext(@_)) }
 # "pmt" is short for "Print MakeText"
$Carp::Verbose = 1;
 # so if maketext fails, we see made the call to pmt
```

Besides whole phrases meant for output, anything language-dependent should be put into the class Projname::L10N::en_us, whether as methods, or as lexicon entries – this is discussed in the section "Entries in Each Lexicon", above.

- Once the program is otherwise done, and once its localization for the first language works right (via the data and methods in Projname::L10N::en_us), you can get together the data for translation. If your first language lexicon isn't an _AUTO lexicon, then you already have all the messages explicitly in the lexicon (or else you'd be

getting exceptions thrown when you call $lh->maketext to get messages that aren't in there). But if you were (advisedly) lazy and are using an _AUTO lexicon, then you've got to make a list of all the phrases that you've so far been letting _AUTO generate for you. There are very many ways to assemble such a list. The most straightforward is to simply grep the source for every occurrence of "maketext" (or calls to wrappers around it, like the above `pmt` function), and to log the following phrase.

- You may at this point want to consider whether your base class (Projname::L10N), from which all lexicons inherit from (Projname::L10N::en, Projname::L10N::es, etc.), should be an _AUTO lexicon. It may be true that in theory, all needed messages will be in each language class; but in the presumably unlikely or "impossible" case of lookup failure, you should consider whether your program should throw an exception, emit text in English (or whatever your project's first language is), or some more complex solution as described in the section "Controlling Lookup Failure", above.

- Submit all messages/phrases/etc. to translators.

  (You may, in fact, want to start with localizing to *one* other language at first, if you're not sure that you've properly abstracted the language-dependent parts of your code.)

  Translators may request clarification of the situation in which a particular phrase is found. For example, in English we are entirely happy saying "*n* files found", regardless of whether we mean "I looked for files, and found *n* of them" or the rather distinct situation of "I looked for something else (like lines in files), and along the way I saw *n* files." This may involve rethinking things that you thought quite clear: should "Edit" on a toolbar be a noun ("editing") or a verb ("to edit")? Is there already a conventionalized way to express that menu option, separate from the target language's normal word for "to edit"?

  In all cases where the very common phenomenon of quantification (saying "*N* files", for **any** value of N) is involved, each translator should make clear what dependencies the number causes in the sentence. In many cases, dependency is limited to words adjacent to the number, in places where you might expect them ("I found the-?PLURAL *N* empty-?PLURAL directory-?PLURAL"), but in some cases there are unexpected dependencies ("I found-?PLURAL ..."!) as well as long-distance dependencies "The *N* directory-?PLURAL could not be deleted-?PLURAL"!).

  Remind the translators to consider the case where N is 0: "0 files found" isn't exactly natural-sounding in any language, but it may be unacceptable in many – or it may condition special kinds of agreement (similar to English "I didN'T find ANY files").

  Remember to ask your translators about numeral formatting in their language, so that you can override the `numf` method as appropriate. Typical variables in number formatting are: what to use as a decimal point (comma? period?); what to use as a thousands separator (space? nonbreaking space? comma? period? small middot? prime? apostrophe?); and even whether the so-called "thousands separator" is actually for every third digit – I've heard reports of two hundred thousand being expressible as "2,00,000" for some Indian (Subcontinental) languages, besides the less surprising "200 000", "200.000", "200,000", and "200'000". Also, using a set of numeral glyphs other than the usual ASCII "0"-"9" might be appreciated, as via `tr/0-9/\x{0966}-\x{096F}/` for getting digits in Devanagari script (for Hindi,

Konkani, others).

The basic `quant` method that Locale::Maketext provides should be good for many languages. For some languages, it might be useful to modify it (or its constituent `numerate` method) to take a plural form in the two-argument call to `quant` (as in "[quant,_1,files]") if it's all-around easier to infer the singular form from the plural, than to infer the plural form from the singular.

But for other languages (as is discussed at length in Locale::Maketext::TPJ13), simple `quant`/`numf` is not enough. For the particularly problematic Slavic languages, what you may need is a method which you provide with the number, the citation form of the noun to quantify, and the case and gender that the sentence's syntax projects onto that noun slot. The method would then be responsible for determining what grammatical number that numeral projects onto its noun phrase, and what case and gender it may override the normal case and gender with; and then it would look up the noun in a lexicon providing all needed inflected forms.

- You may also wish to discuss with the translators the question of how to relate different subforms of the same language tag, considering how this reacts with `get_handle`'s treatment of these. For example, if a user accepts interfaces in "en, fr", and you have interfaces available in "en-US" and "fr", what should they get? You may wish to resolve this by establishing that "en" and "en-US" are effectively synonymous, by having one class zero-derive from the other.

  For some languages this issue may never come up (Danish is rarely expressed as "da-DK", but instead is just "da"). And for other languages, the whole concept of a "generic" form may verge on being uselessly vague, particularly for interfaces involving voice media in forms of Arabic or Chinese.

- Once you've localized your program/site/etc. for all desired languages, be sure to show the result (whether live, or via screenshots) to the translators. Once they approve, make every effort to have it then checked by at least one other speaker of that language. This holds true even when (or especially when) the translation is done by one of your own programmers. Some kinds of systems may be harder to find testers for than others, depending on the amount of domain-specific jargon and concepts involved – it's easier to find people who can tell you whether they approve of your translation for "delete this message" in an email-via-Web interface, than to find people who can give you an informed opinion on your translation for "attribute value" in an XML query tool's interface.

SEE ALSO

I recommend reading all of these:

Locale::Maketext::TPJ13 – my *The Perl Journal* article about Maketext. It explains many important concepts underlying Locale::Maketext's design, and some insight into why Maketext is better than the plain old approach of having message catalogs that are just databases of sprintf formats.

File::Findgrep is a sample application/module that uses Locale::Maketext to localize its messages. For a larger internationalized system, see also Apache::MP3.

I18N::LangTags.

Win32::Locale.

RFC 3066, *Tags for the Identification of Languages*, as at http://sunsite.dk/RFC/rfc/rfc3066.html

RFC 2277, *IETF Policy on Character Sets and Languages* is at http://sunsite.dk/RFC/rfc/rfc2277.html – much of it is just things of interest to protocol designers, but it explains some basic concepts, like the distinction between locales and language-tags.

The manual for GNU `gettext`. The gettext dist is available in `ftp://prep.ai.mit.edu/pub/gnu/` – get a recent gettext tarball and look in its "doc/" directory, there's an easily browsable HTML version in there. The gettext documentation asks lots of questions worth thinking about, even if some of their answers are sometimes wonky, particularly where they start talking about pluralization.

The Locale/Maketext.pm source. Observe that the module is much shorter than its documentation!

Locale::Maketext::Guts

Deprecated module to load Locale::Maketext utf8 code

SYNOPSIS

```
# Do this instead please
use Locale::Maketext
```

DESCRIPTION

Previously Local::Maketext::GutsLoader performed some magic to load Locale::Maketext when utf8 was unavailable. The subs this module provided were merged back into Locale::Maketext

Locale::Maketext::GutsLoader

Deprecated module to load Locale::Maketext utf8 code

SYNOPSIS

```
# Do this instead please
use Locale::Maketext
```

DESCRIPTION

Previously Locale::Maketext::Guts performed some magic to load Locale::Maketext when utf8 was unavailable. The subs this module provided were merged back into Locale::Maketext.

Locale::Maketext::Simple

Simple interface to Locale::Maketext::Lexicon

VERSION

This document describes version 0.18 of Locale::Maketext::Simple, released Septermber 8, 2006.

SYNOPSIS

Minimal setup (looks for `auto/Foo/*.po` and `auto/Foo/*.mo`):

```
package Foo;
use Locale::Maketext::Simple;       # exports 'loc'
loc_lang('fr');                     # set language to French
sub hello {
    print loc("Hello, [_1]!", "World");
}
```

More sophisticated example:

```
package Foo::Bar;
use Locale::Maketext::Simple (
    Class       => 'Foo',       # search in auto/Foo/
    Style       => 'gettext',   # %1 instead of [_1]
    Export      => 'maketext',  # maketext() instead of loc()
    Subclass    => 'L10N',      # Foo::L10N instead of Foo::I18N
```

(continues on next page)

(continued from previous page)

```
    Decode      => 1,           # decode entries to unicode-strings
    Encoding    => 'locale',    # but encode lexicons in current␣
↪locale
                                # (needs Locale::Maketext::Lexicon␣
↪0.36)
);
sub japh {
    print maketext("Just another %1 hacker", "Perl");
}
```

DESCRIPTION

This module is a simple wrapper around **Locale::Maketext::Lexicon**, designed to alleviate the need of creating *Language Classes* for module authors.

The language used is chosen from the loc_lang call. If a lookup is not possible, the i-default language will be used. If the lookup is not in the i-default language, then the key will be returned.

If **Locale::Maketext::Lexicon** is not present, it implements a minimal localization function by simply interpolating `[_1]` with the first argument, `[_2]` with the second, etc. Interpolated function like `[quant,_1]` are treated as `[_1]`, with the sole exception of `[tense,_1,X]`, which will append `ing` to `_1` when X is `present`, or appending `ed` to <_1> otherwise.

OPTIONS

All options are passed either via the `use` statement, or via an explicit `import`.

Class

By default, **Locale::Maketext::Simple** draws its source from the calling package's `auto/` directory; you can override this behaviour by explicitly specifying another package as `Class`.

Path

If your PO and MO files are under a path elsewhere than `auto/`, you may specify it using the `Path` option.

Style

By default, this module uses the `maketext` style of `[_1]` and `[quant,_1]` for interpolation. Alternatively, you can specify the `gettext` style, which uses `%1` and `%quant(%1)` for interpolation.

This option is case-insensitive.

Export

By default, this module exports a single function, `loc`, into its caller's namespace. You can set it to another name, or set it to an empty string to disable exporting.

Subclass

By default, this module creates an `::I18N` subclass under the caller's package (or the package specified by `Class`), and stores lexicon data in its subclasses. You can assign a name other than `I18N` via this option.

Decode

If set to a true value, source entries will be converted into utf8-strings (available in Perl 5.6.1 or later). This feature needs the **Encode** or **Encode::compat** module.

Encoding

Specifies an encoding to store lexicon entries, instead of utf8-strings. If set to `locale`, the encoding from the current locale setting is used. Implies a true value for `Decode`.

ACKNOWLEDGMENTS

Thanks to Jos I. Boumans for suggesting this module to be written.

Thanks to Chia-Liang Kao for suggesting `Path` and `loc_lang`.

5.2.64 MIME

Namespace containing the following modules:

- `MIME::Base64` - Encode and decode base64 strings - the standard MIME flavour plus the URL-safe variant and cheap length helpers.
- `MIME::Charset` - Charset Information for MIME
- `MIME::QuotedPrint` - Quoted-printable encoding and decoding as specified by RFC 2045.

MIME::Base64

Encode and decode base64 strings - the standard MIME flavour plus the URL-safe variant and cheap length helpers.

`MIME::Base64` turns arbitrary byte strings into the 65-character ASCII subset defined by RFC 2045 (`[A-Za-z0-9+/=]`) and back. Most callers reach for it for one of a handful of jobs:

- writing MIME-style bodies where encoded output must be wrapped at 76 characters per line (the default `encode_base64` form);
- producing a single unwrapped token for an HTTP header, a credential, or a config file - `encode_base64($bytes, "");`
- building URL-safe tokens (JWT payloads, signed cookies, opaque identifiers) where `+` and `/` would need percent-escaping - `encode_base64url`;
- sizing a buffer without paying the cost of the full encode or decode - `encoded_base64_length` and `decoded_base64_length`.

Line-length wrapping

`encode_base64` breaks the output into lines of **at most 76 characters**, each terminated by the caller’s end-of-line sequence (default `"\n"`). Pass `""` as the second argument to suppress wrapping entirely; pass `"\r\n"` for CRLF output suitable for raw MIME transport. The URL-safe encoder never wraps and never pads.

Decode leniency

decode_base64 is deliberately forgiving. Any character outside the 65-character alphabet is silently skipped, so embedded whitespace, line breaks, and MIME boilerplate pass through harmlessly. Decoding stops at the first = padding group - data after padding is never consumed. The URL-safe decoder accepts input with or without padding and translates -/_ back to +// before running the same state machine.

Who calls this

Most real-world consumers are Authen::* (HTTP Basic auth), Email::MIME and friends (message bodies), JWT/JOSE libraries (via the URL-safe variant), and anything that needs to round-trip binary through a text channel. encode_base64 and decode_base64 are exported by default; the URL-safe and length helpers are exported on request.

URL-safe variant

encode_base64url($bytes) encodes with the URL- and filename-safe alphabet (- and _ in place of + and /), strips the trailing = padding and never wraps, so the result drops into URLs, cookies and JWT segments unescaped. decode_base64url($token) maps - and _ back, restores the padding and decodes; input with or without padding, or with + and /, is accepted.

This is MIME::Base64 from MIME-Base64 3.16_01; MIME/Base64.pm is upstream's. encode_base64 and decode_base64 are exported by default.

Synopsis

```
use MIME::Base64 qw(encode_base64 decode_base64 encode_base64url␣
↪decode_base64url);

my $enc = encode_base64("Aladdin:open sesame");
print $enc;                                    #␣
↪QWxhZGRpbjpvcGVuIHNlc2FtZQ==\n
print decode_base64($enc), "\n";               # Aladdin:open␣
↪sesame
print encode_base64("\xff\xfe binary", ''), "\n";  # //4gYmluYXJ5 -␣
↪one line

my $token = encode_base64url("\xfb\xff");          # -_8: no + / or␣
↪= padding
print length decode_base64url($token), "\n";       # 2
```

Strings must be bytes: a character above 0xFF dies "Wide character"; encode text first (encode_base64(Encode::encode_utf8($text))).

Differences from upstream

One, where perl 5.44 with Base64.xs fails (t/81-xs-native/MIME-Base64/130-or-better.t): `encoded_base64_length` and `decoded_base64_length` given a number or undef measure its string value, as for any other value. perl5 reads a length that number never had - `encoded_base64_length(12345)` gave 485286422 - or crashes on undef.

Functions

Standard encoding

encode_base64

Encode a byte string as standard RFC 2045 base64, optionally wrapping at 76 characters.

decode_base64

Decode a base64 string back to the original byte sequence, tolerating stray whitespace and line breaks.

Length helpers

encoded_base64_length

Return the length `encode_base64` would produce, without doing the encoding.

decoded_base64_length

Return the length `decode_base64` would produce, without doing the decoding.

Other Functions

encode_base64url

Encode bytes using the URL- and filename-safe base64 alphabet, with no padding and no line breaks.

decode_base64url

Decode a URL-safe base64 string, accepting input with or without trailing padding.

encode_base64

Encode a byte string as standard RFC 2045 base64, optionally wrapping at 76 characters.

Synopsis

```
use MIME::Base64;
my $encoded = encode_base64($bytes);          # wrapped at 76, "\n"-
 ↪terminated
```

(continues on next page)

(continued from previous page)

```
my $oneline = encode_base64($bytes, "");     # no wrapping, no␣
↪trailing EOL
my $crlf    = encode_base64($bytes, "\r\n"); # MIME-style CRLF␣
↪wrapping
```

What you get back

A plain (non-UTF8) ASCII string containing only characters from `[A-Za-z0-9+/=]` plus the caller's end-of-line sequence. With the default `"\n"` terminator, every 76-character line - including the final short one - ends with `"\n"`. Pass `""` to get a single unbroken token with no trailing newline; useful for HTTP headers, credential strings, and anywhere a single atomic value is expected. The output always pads to a multiple of four characters with `=`.

Examples

```
encode_base64("Aladdin:open sesame");
# "QWxhZGRpbjpvcGVuIHNlc2FtZQ==\n"

encode_base64("Aladdin:open sesame", "");
# "QWxhZGRpbjpvcGVuIHNlc2FtZQ=="

encode_base64("\x00\x00\x00");
# "AAAA\n"
```

Edge cases

- Empty input returns the empty string.
- A single character (or any input whose length is not a multiple of 3) is padded with `=` so the output length is a multiple of four.
- Binary bytes are encoded as-is; there is no byte-order or encoding transformation.
- Input with code points above 255 is a programming error in the caller; base64 is defined over octets only. Encode to UTF-8 first if the source is a text string.

Differences from upstream

Fully compatible with upstream `MIME::Base64` 3.16_01.

See also

- `decode_base64` - the inverse operation.
- `encode_base64url` - the URL-safe variant, no padding, no wrapping.
- `encoded_base64_length` - size the output without encoding.

decode_base64

Decode a base64 string back to the original byte sequence, tolerating stray whitespace and line breaks.

Synopsis

```
use MIME::Base64;
my $bytes = decode_base64($encoded);
```

What you get back

A byte string carrying the decoded octets. The result is binary; treat it as bytes, not text. If the input was the output of `encode_base64`, the result is byte-for-byte what was encoded.

The decoder silently skips any character outside the 65-character base64 subset, so wrapped lines, CRLFs, leading/trailing whitespace, and MIME header remnants are handled without special preprocessing. Decoding stops at the first = padding group; data appearing after padding is ignored.

Examples

```
decode_base64("QWxhZGRpbjpvcGVuIHNlc2FtZQ==");
# "Aladdin:open sesame"

decode_base64("QWxh\nZGRp\nbjpv\ncGVu\nIHNl\nc2Ft\nZQ==\n");
# "Aladdin:open sesame"   (wrapped input decodes identically)

decode_base64("AAAA");
# "\x00\x00\x00"
```

Edge cases

- Empty input returns the empty string.
- Input of all-whitespace returns the empty string.
- A truncated final group (1 valid character) produces no output for that group; 2 valid characters produce 1 byte, 3 produce 2 bytes.
- Characters after the first = padding group are discarded.
- Non-alphabet characters anywhere in the input are silently skipped, including control characters and punctuation.

Differences from upstream

Fully compatible with upstream `MIME::Base64` 3.16_01.

See also

- encode_base64 - the inverse operation.
- decode_base64url - the URL-safe variant, accepts -/_ and missing padding.
- decoded_base64_length - size the output without decoding.

encoded_base64_length

Return the length encode_base64 would produce, without doing the encoding.

Synopsis

```
use MIME::Base64 qw(encoded_base64_length);
my $n = encoded_base64_length($bytes);           # wrapping with "\n"
my $m = encoded_base64_length($bytes, "");       # no wrapping
my $k = encoded_base64_length($bytes, "\r\n");  # CRLF wrapping
```

What you get back

An integer: the exact number of bytes encode_base64($bytes, $eol) would produce, including every end-of-line sequence. Equivalent to length(encode_base64($bytes, $eol)) but avoids allocating and building the encoded string - preferred when you need to pre-size a buffer or report progress on a large payload.

Examples

```
encoded_base64_length("");                  # 0
encoded_base64_length("A");                 # 5   ("QQ==\n")
encoded_base64_length("A", "");             # 4   ("QQ==")
encoded_base64_length("A" x 57);            # 77  (one full 76-char␣
↪line + "\n")
encoded_base64_length("A" x 57, "\r\n");    # 78  (one full 76-char␣
↪line + "\r\n")
```

Edge cases

- Empty input returns 0 regardless of the $eol argument.
- The formula is ceil(n/3) * 4 + lines * length($eol) where lines = ceil(base_len / 76).
- An undefined or missing $eol counts as "\n" (length 1) to match encode_base64's default.

Differences from upstream

Fully compatible with upstream `MIME::Base64` 3.16_01.

See also

- `encode_base64` - the function whose output length is being computed.
- `decoded_base64_length` - the companion predictor for the decoder.

decoded_base64_length

Return the length `decode_base64` would produce, without doing the decoding.

Synopsis

```
use MIME::Base64 qw(decoded_base64_length);
my $n = decoded_base64_length($encoded);
```

What you get back

An integer: the exact number of bytes `decode_base64($encoded)` would produce. Equivalent to `length(decode_base64($encoded))` but avoids building the decoded string. Useful when validating that a payload fits a size limit, or pre-sizing a destination buffer.

The same leniency rules as `decode_base64` apply: stray whitespace and non-alphabet characters are ignored, and the count stops at the first = padding group.

Examples

```
decoded_base64_length("");                                  # 0
decoded_base64_length("QQ==");                              # 1
decoded_base64_length("QWxhZGRpbjpvcGVuIHNlc2FtZQ==");  # 19
decoded_base64_length("QWxh\nZGRp\nbjpv\ncGVu\n");     # 12 (newlines
↪ignored)
```

Edge cases

- Empty input, or input with no alphabet characters, returns `0`.
- A lone trailing character that would decode to no output (a group of exactly 1 valid character) contributes `0` bytes.
- Characters after the first = are not counted.

Differences from upstream

Fully compatible with upstream `MIME::Base64` 3.16_01.

See also

- `decode_base64` - the function whose output length is being computed.
- `encoded_base64_length` - the companion predictor for the encoder.

encode_base64url

Encode bytes using the URL- and filename-safe base64 alphabet, with no padding and no line breaks.

Synopsis

```
use MIME::Base64 qw(encode_base64url);
my $token = encode_base64url($bytes);
```

What you get back

A single unbroken ASCII string using the alphabet `[A-Za-z0-9-_]`. Trailing = padding is stripped. The result is safe to drop into URLs, path segments, cookie values, and JWT components without percent-escaping. The output is always one line - never wrapped.

Examples

```
encode_base64url("Aladdin:open sesame");
# "QWxhZGRpbjpvcGVuIHNlc2FtZQ"

encode_base64url("\xFB\xFF");
# "-_8"                 (note the '-' and '_' where '+' and '/' would
 ↪appear)

encode_base64url("");
# ""
```

Edge cases

- Empty input returns the empty string.
- Bytes that would encode to + under standard base64 become -; bytes that would encode to / become _.
- No = appears in the output under any input length.

Differences from upstream

Fully compatible with upstream `MIME::Base64` 3.16_01.

See also

- `decode_base64url` - the inverse operation.
- `encode_base64` - standard variant with wrapping and padding.

decode_base64url

Decode a URL-safe base64 string, accepting input with or without trailing padding.

Synopsis

```
use MIME::Base64 qw(decode_base64url);
my $bytes = decode_base64url($token);
```

What you get back

The decoded byte string. `-` and `_` in the input are mapped back to `+` and `/` before decoding, and any missing trailing padding is reconstructed. The decoder inherits `decode_base64`'s tolerance: characters outside the alphabet are silently skipped, and decoding stops at the first padding group.

Examples

```
decode_base64url("QWxhZGRpbjpvcGVuIHNlc2FtZQ");
# "Aladdin:open sesame"

decode_base64url("-_8");
# "\xFB\xFF"

decode_base64url("QWxhZGRpbjpvcGVuIHNlc2FtZQ==");   # padding also␣
↪OK
# "Aladdin:open sesame"
```

Edge cases

- Empty input returns the empty string.
- Input with stray `+` or `/` is accepted (those are valid under standard base64); the URL-safe decoder is a superset of the standard decoder for input characters.
- Truncated input (length not a multiple of four, no padding) is padded internally and decoded; the last partial group follows the same "1 char gives 0 bytes, 2 gives 1, 3 gives 2" rule as `decode_base64`.

Differences from upstream

Fully compatible with upstream `MIME::Base64` 3.16_01.

See also

- `encode_base64url` - the inverse operation.
- `decode_base64` - standard variant.

MIME::Charset

Charset Information for MIME

SYNOPSIS

```
use MIME::Charset;

$charset = MIME::Charset->new("euc-jp");
```

Getting charset information:

```
$benc = $charset->body_encoding; # e.g. "Q"
$cset = $charset->as_string; # e.g. "US-ASCII"
$henc = $charset->header_encoding; # e.g. "S"
$cset = $charset->output_charset; # e.g. "ISO-2022-JP"
```

Translating text data:

```
($text, $charset, $encoding) =
    $charset->header_encode(
       "\xc9\xc2\xc5\xaa\xc0\xde\xc3\xef\xc5\xaa".
       "\xc7\xd1\xca\xaa\xbd\xd0\xce\xcf\xb4\xef",
       Charset => 'euc-jp');
# ...returns e.g. (<converted>, "ISO-2022-JP", "B").

($text, $charset, $encoding) =
    $charset->body_encode(
        "Collectioneur path\xe9tiquement ".
        "\xe9clectique de d\xe9chets",
        Charset => 'latin1');
# ...returns e.g. (<original>, "ISO-8859-1", "QUOTED-PRINTABLE").

$len = $charset->encoded_header_len(
    "Perl\xe8\xa8\x80\xe8\xaa\x9e",
    Charset => 'utf-8',
    Encoding => "b");
# ...returns e.g. 28.
```

Manipulating module defaults:

```
MIME::Charset::alias("csEUCKR", "euc-kr");
MIME::Charset::default("iso-8859-1");
MIME::Charset::fallback("us-ascii");
```

Non-OO functions (may be deprecated in near future):

```
use MIME::Charset qw(:info);

$benc = body_encoding("iso-8859-2"); # "Q"
$cset = canonical_charset("ANSI X3.4-1968"); # "US-ASCII"
$henc = header_encoding("utf-8"); # "S"
$cset = output_charset("shift_jis"); # "ISO-2022-JP"

use MIME::Charset qw(:trans);

($text, $charset, $encoding) =
    header_encode(
       "\xc9\xc2\xc5\xaa\xc0\xde\xc3\xef\xc5\xaa".
       "\xc7\xd1\xca\xaa\xbd\xd0\xce\xcf\xb4\xef",
       "euc-jp");
# ...returns (<converted>, "ISO-2022-JP", "B");

($text, $charset, $encoding) =
    body_encode(
        "Collectioneur path\xe9tiquement ".
        "\xe9clectique de d\xe9chets",
        "latin1");
# ...returns (<original>, "ISO-8859-1", "QUOTED-PRINTABLE");

$len = encoded_header_len(
    "Perl\xe8\xa8\x80\xe8\xaa\x9e", "b", "utf-8"); # 28
```

DESCRIPTION

MIME::Charset provides information about character sets used for MIME messages on Internet.

Definitions

The **charset** is ``character set'' used in MIME to refer to a method of converting a sequence of octets into a sequence of characters. It includes both concepts of ``coded character set'' (CCS) and ``character encoding scheme'' (CES) of ISO/IEC.

The **encoding** is that used in MIME to refer to a method of representing a body part or a header body as sequence(s) of printable US-ASCII characters.

Constructor

- $charset = MIME::Charset->new([CHARSET [, OPTS]])

  Create charset object.

  OPTS may accept following key-value pair. **NOTE**: When Unicode/multibyte support is disabled (see "USE_ENCODE"), conversion will not be performed. So this option do not have any effects.

  – Mapping => MAPTYPE

    Whether to extend mappings actually used for charset names or not. `"EXTENDED"` uses extended mappings. `"STANDARD"` uses standardized strict mappings. Default is `"EXTENDED"`.

Getting Information of Charsets

- $charset->body_encoding
- body_encoding CHARSET

  Get recommended transfer-encoding of CHARSET for message body.

  Returned value will be one of `"B"` (BASE64), `"Q"` (QUOTED-PRINTABLE), `"S"` (shorter one of either) or `undef` (might not be transfer-encoded; either 7BIT or 8BIT). This may not be same as encoding for message header.

- $charset->as_string
- canonical_charset CHARSET

  Get canonical name for charset.

- $charset->decoder

  Get "Encode::Encoding" object to decode strings to Unicode by charset. If charset is not specified or not known by this module, undef will be returned.

- $charset->dup

  Get a copy of charset object.

- $charset->encoder([CHARSET])

  Get "Encode::Encoding" object to encode Unicode string using compatible charset recommended to be used for messages on Internet.

  If optional CHARSET is specified, replace encoder (and output charset name) of $charset object with those of CHARSET, therefore, $charset object will be a converter between original charset and new CHARSET.

- $charset->header_encoding
- header_encoding CHARSET

  Get recommended encoding scheme of CHARSET for message header.

  Returned value will be one of `"B"`, `"Q"`, `"S"` (shorter one of either) or `undef` (might not be encoded). This may not be same as encoding for message body.

- $charset->output_charset

- output_charset CHARSET

  Get a charset which is compatible with given CHARSET and is recommended to be used for MIME messages on Internet (if it is known by this module).

  When Unicode/multibyte support is disabled (see "USE_ENCODE"), this function will simply return the result of "canonical_charset".

Translating Text Data

- $charset->body_encode(STRING [, OPTS])
- body_encode STRING, CHARSET [, OPTS]

  Get converted (if needed) data of STRING and recommended transfer-encoding of that data for message body. CHARSET is the charset by which STRING is encoded.

  OPTS may accept following key-value pairs. **NOTE**: When Unicode/multibyte support is disabled (see "USE_ENCODE"), conversion will not be performed. So these options do not have any effects.

  – Detect7bit => YESNO

    Try auto-detecting 7-bit charset when CHARSET is not given. Default is `"YES"`.

  – Replacement => REPLACEMENT

    Specifies error handling scheme. See "Error Handling".

  3-item list of (*converted string*, *charset for output*, *transfer-encoding*) will be returned. *Transfer-encoding* will be either `"BASE64"`, `"QUOTED-PRINTABLE"`, `"7BIT"` or `"8BIT"`. If *charset for output* could not be determined and *converted string* contains non-ASCII byte(s), *charset for output* will be `undef` and *transfer-encoding* will be `"BASE64"`. *Charset for output* will be `"US-ASCII"` if and only if string does not contain any non-ASCII bytes.

- $charset->decode(STRING [,CHECK])

  Decode STRING to Unicode.

  Note: When Unicode/multibyte support is disabled (see "USE_ENCODE"), this function will die.

- detect_7bit_charset STRING

  Guess 7-bit charset that may encode a string STRING. If STRING contains any 8-bit bytes, `undef` will be returned. Otherwise, Default Charset will be returned for unknown charset.

- $charset->encode(STRING [, CHECK])

  Encode STRING (Unicode or non-Unicode) using compatible charset recommended to be used for messages on Internet (if this module knows it). Note that string will be decoded to Unicode then encoded even if compatible charset was equal to original charset.

  Note: When Unicode/multibyte support is disabled (see "USE_ENCODE"), this function will die.

- $charset->encoded_header_len(STRING [, ENCODING])

- encoded_header_len STRING, ENCODING, CHARSET

  Get length of encoded STRING for message header (without folding).

  ENCODING may be one of `"B"`, `"Q"` or `"S"` (shorter one of either `"B"` or `"Q"`).

- $charset->header_encode(STRING [, OPTS])
- header_encode STRING, CHARSET [, OPTS]

  Get converted (if needed) data of STRING and recommended encoding scheme of that data for message headers. CHARSET is the charset by which STRING is encoded.

  OPTS may accept following key-value pairs. **NOTE**: When Unicode/multibyte support is disabled (see "USE_ENCODE"), conversion will not be performed. So these options do not have any effects.

  – Detect7bit => YESNO

    Try auto-detecting 7-bit charset when CHARSET is not given. Default is `"YES"`.

  – Replacement => REPLACEMENT

    Specifies error handling scheme. See "Error Handling".

  3-item list of (*converted string*, *charset for output*, *encoding scheme*) will be returned. *Encoding scheme* will be either `"B"`, `"Q"` or `undef` (might not be encoded). If *charset for output* could not be determined and *converted string* contains non-ASCII byte(s), *charset for output* will be `"8BIT"` (this is *not* charset name but a special value to represent unencodable data) and *encoding scheme* will be `undef` (should not be encoded). *Charset for output* will be `"US-ASCII"` if and only if string does not contain any non-ASCII bytes.

- $charset->undecode(STRING [,CHECK])

  Encode Unicode string STRING to byte string by input charset of $charset. This is equivalent to `$charset->decoder->encode()`.

  Note: When Unicode/multibyte support is disabled (see "USE_ENCODE"), this function will die.

Manipulating Module Defaults

- alias ALIAS [, CHARSET]

  Get/set charset alias for canonical names determined by "canonical_charset".

  If CHARSET is given and isn't false, ALIAS will be assigned as an alias of CHARSET. Otherwise, alias won't be changed. In both cases, current charset name that ALIAS is assigned will be returned.

- default [CHARSET]

  Get/set default charset.

  Default charset is used by this module when charset context is unknown. Modules using this module are recommended to use this charset when charset context is unknown or implicit default is expected. By default, it is `"US-ASCII"`.

If CHARSET is given and isn't false, it will be set to default charset. Otherwise, default charset won't be changed. In both cases, current default charset will be returned.

NOTE: Default charset *should not* be changed.

- fallback [CHARSET]

  Get/set fallback charset.

  Fallback charset is used by this module when conversion by given charset is failed and `"FALLBACK"` error handling scheme is specified. Modules using this module may use this charset as last resort of charset for conversion. By default, it is `"UTF-8"`.

  If CHARSET is given and isn't false, it will be set to fallback charset. If CHARSET is `"NONE"`, fallback charset will be undefined. Otherwise, fallback charset won't be changed. In any cases, current fallback charset will be returned.

  NOTE: It *is* useful that `"US-ASCII"` is specified as fallback charset, since result of conversion will be readable without charset information.

- recommended CHARSET [, HEADERENC, BODYENC [, ENCCHARSET]]

  Get/set charset profiles.

  If optional arguments are given and any of them are not false, profiles for CHARSET will be set by those arguments. Otherwise, profiles won't be changed. In both cases, current profiles for CHARSET will be returned as 3-item list of (HEADERENC, BODYENC, ENCCHARSET).

  HEADERENC is recommended encoding scheme for message header. It may be one of `"B"`, `"Q"`, `"S"` (shorter one of either) or `undef` (might not be encoded).

  BODYENC is recommended transfer-encoding for message body. It may be one of `"B"`, `"Q"`, `"S"` (shorter one of either) or `undef` (might not be transfer-encoded).

  ENCCHARSET is a charset which is compatible with given CHARSET and is recommended to be used for MIME messages on Internet. If conversion is not needed (or this module doesn't know appropriate charset), ENCCHARSET is `undef`.

  NOTE: This function in the future releases can accept more optional arguments (for example, properties to handle character widths, line folding behavior, ...). So format of returned value may probably be changed. Use "header_encoding", "body_encoding" or "output_charset" to get particular profile.

Constants

- USE_ENCODE

  Unicode/multibyte support flag. Non-empty string will be set when Unicode and multibyte support is enabled. Currently, this flag will be non-empty on Perl 5.7.3 or later and empty string on earlier versions of Perl.

Error Handling

“body_encode” and “header_encode” accept following `Replacement` options:

- `"DEFAULT"`

  Put a substitution character in place of a malformed character. For UCM-based encodings, <subchar> will be used.

- `"FALLBACK"`

  Try `"DEFAULT"` scheme using *fallback charset* (see “fallback”). When fallback charset is undefined and conversion causes error, code will die on error with an error message.

- `"CROAK"`

  Code will die on error immediately with an error message. Therefore, you should trap the fatal error with eval{} unless you really want to let it die on error. Synonym is `"STRICT"`.

- `"PERLQQ"`

- `"HTMLCREF"`

- `"XMLCREF"`

  Use `FB_PERLQQ`, `FB_HTMLCREF` or `FB_XMLCREF` scheme defined by *Encode* module.

- numeric values

  Numeric values are also allowed. For more details see *“Handling Malformed Data” in Encode*.

If error handling scheme is not specified or unknown scheme is specified, `"DEFAULT"` will be assumed.

Configuration File

Built-in defaults for option parameters can be overridden by configuration file: `MIME/Charset/Defaults.pm`. For more details read `MIME/Charset/Defaults.pm.sample`.

VERSION

Consult $VERSION variable.

Development versions of this module may be found at http://hatuka.nezumi.nu/repos/MIME-Charset/.

Incompatible Changes

- Release 1.001
  - new() method returns an object when CHARSET argument is not specified.
- Release 1.005
  - Restrict characters in encoded-word according to RFC 2047 section 5 (3). This also affects return value of encoded_header_len() method.

- Release 1.008.2
  - body_encoding() method may also returns "S".
  - Return value of body_encode() method for UTF-8 may include "QUOTED-PRINTABLE" encoding item that in earlier versions was fixed to "BASE64".

MIME::QuotedPrint

Quoted-printable encoding and decoding as specified by RFC 2045.

Quoted-printable is the encoding of choice for mail bodies that are *mostly* ASCII with the occasional non-ASCII byte - long passages of plain text stay readable, and only the unsafe bytes turn into =XX hex triplets. For content that is truly binary, prefer base64 via MIME::Base64.

The encoder keeps lines at most 76 characters long by inserting soft line breaks (= at end of line, then the $eol sequence). Pass a $binmode flag when you want \n itself to be encoded - useful when the decoded output must be byte-for-byte identical regardless of the receiver's line-ending conventions. An $eol of "" disables both soft breaks and \n rewriting.

The decoder always produces \n-terminated output, even when the input used \r\n line endings.

This is MIME::QuotedPrint from MIME-Base64 3.16_01; MIME/QuotedPrint.pm is upstream's. encode_qp and decode_qp are exported by default.

Synopsis

```
use MIME::QuotedPrint;

my $qp = encode_qp("caf\xe9 = coffee\n");
print $qp;                                  # caf=E9 =3D coffee
print decode_qp($qp) eq "caf\xe9 = coffee\n" ? "round trip\n" : "";

print encode_qp('x' x 80);    # 75 x's and "=", then "xxxxx=":
                              # text without a final newline ends in␣
 ↪a soft break
```

Differences from upstream

None: upstream's tests pass unchanged (t/81-xs-native/MIME-Base64/230-upstream-quoted-print.t), and t/81-xs-native/MIME-QuotedPrint checks the rest against perl 5.44.

Functions

Encoding and decoding

encode_qp

Encode a string as quoted-printable.

decode_qp

Decode a quoted-printable string back to plain bytes.

encode_qp

Encode a string as quoted-printable.

Synopsis

```
$encoded = encode_qp($str);
$encoded = encode_qp($str, $eol);
$encoded = encode_qp($str, $eol, $binmode);
```

What you get back

A scalar holding the quoted-printable encoding of `$str`. Printable ASCII bytes (plus `\t`) pass through unchanged; every other byte, and `=` itself, becomes a `=XX` triplet with uppercase hex digits. Lines are kept at most 76 characters by inserting soft breaks: a trailing `=` followed by the `$eol` sequence.

`$eol` defaults to `"\n"`. Pass `"\015\012"` to produce output suitable for direct transmission over the wire. Pass `""` to suppress soft breaks and force binary-mode behavior for `\n`.

`$binmode`, when true, encodes `\n` and `\r` as `=0A` / `=0D` rather than passing them through as line terminators. Use this when the decoded form must match the input byte for byte on every platform.

Examples

```
use MIME::QuotedPrint;
print encode_qp("Hello, world!\n");       # Hello, world!\n
print encode_qp("caf\xe9\n");             # caf=E9\n
print encode_qp("\x00\x01\x02", "", 1);   # =00=01=02
print encode_qp("x" x 80 . "\n");         # wraps at col 75 with =\n
↪soft break
```

Edge cases

- Empty `$str` returns the empty string.
- `$eol` of `""` disables soft line breaks and encodes every `\n`.
- Trailing spaces and tabs on a line are always encoded so they survive transports that strip trailing whitespace.

Differences from upstream

Fully compatible with upstream `MIME::QuotedPrint` 3.16.

See also

- `decode_qp` - reverse the encoding.
- `MIME::Base64::encode_base64` - better choice for fully binary data.

decode_qp

Decode a quoted-printable string back to plain bytes.

Synopsis

```
$decoded = decode_qp($encoded);
```

What you get back

A scalar holding the decoded byte string. Every =XX triplet is replaced by the byte whose hex value is XX; soft line breaks (a = immediately before `\r\n` or `\n`) are removed.

Line terminators are normalized: whether the input used `\n` or `\r\n`, each line in the result ends with `\n`.

Examples

```
use MIME::QuotedPrint;
print decode_qp("Hello, world!\n");     # Hello, world!\n
print decode_qp("caf=E9\n");            # "caf\xe9" (the Latin-1␣
↪byte E9)
print decode_qp("line =\r\ncontinued"); # line continued
print decode_qp("=00=01=02");           # three bytes: 00 01 02
```

Edge cases

- A stray = not followed by two hex digits or a line break is passed through literally, matching the upstream decoder.
- Trailing whitespace on a decoded line is stripped, matching the encoder's soft-break contract.

- Lowercase hex digits are accepted even though the encoder only emits uppercase.

Differences from upstream

Fully compatible with upstream `MIME::QuotedPrint` 3.16.

See also

- `encode_qp` - produce the encoded form.
- `MIME::Base64::decode_base64` - the counterpart for binary payloads.

5.2.65 Math

Namespace containing the following modules:

- `Math::BigFloat` - arbitrary size floating point math package
- `Math::BigInt` - arbitrary size integer math package
- `Math::BigRat` - arbitrary size rational number math package
- `Math::Complex` - complex numbers and associated mathematical functions
- `Math::GMP` - Arbitrary-precision integer arithmetic backed by GNU `libgmp`.
- `Math::Random`
- `Math::Trig` - trigonometric functions

Math::BigFloat

arbitrary size floating point math package

SYNOPSIS

```
use Math::BigFloat;

# Configuration methods (may be used as class methods and instance
 ↪methods)

Math::BigFloat->accuracy($n);       # set accuracy
Math::BigFloat->accuracy();         # get accuracy
Math::BigFloat->precision($n);      # set precision
Math::BigFloat->precision();        # get precision
Math::BigFloat->round_mode($m);     # set rounding mode, must be
                                    # 'even', 'odd', '+inf', '-inf',
                                    # 'zero', 'trunc', or 'common'
Math::BigFloat->round_mode();       # get class rounding mode
Math::BigFloat->div_scale($n);      # set fallback accuracy
Math::BigFloat->div_scale();        # get fallback accuracy
Math::BigFloat->trap_inf($b);       # trap infinities or not
Math::BigFloat->trap_inf();         # get trap infinities status
```

(continues on next page)

(continued from previous page)

```
Math::BigFloat->trap_nan($b);       # trap NaNs or not
Math::BigFloat->trap_nan();         # get trap NaNs status
Math::BigFloat->config($par, $val); # set configuration parameter
Math::BigFloat->config($par);       # get configuration parameter
Math::BigFloat->config();           # get hash with configuration
Math::BigFloat->config("lib");      # get name of backend library

# Generic constructor method (always returns a new object)

$x = Math::BigFloat->new($str);               # defaults to 0
$x = Math::BigFloat->new('256');              # from decimal
$x = Math::BigFloat->new('0256');             # from decimal
$x = Math::BigFloat->new('0xcafe');           # from hexadecimal
$x = Math::BigFloat->new('0x1.cafep+7');      # from hexadecimal
$x = Math::BigFloat->new('0o377');            # from octal
$x = Math::BigFloat->new('0o1.3571p+6');      # from octal
$x = Math::BigFloat->new('0b101');            # from binary
$x = Math::BigFloat->new('0b1.101p+3');       # from binary

# Specific constructor methods (no prefix needed; when used as
# instance method, the value is assigned to the invocand)

$x = Math::BigFloat->from_dec('234');         # from decimal
$x = Math::BigFloat->from_hex('c.afep+3');    # from hexadecimal
$x = Math::BigFloat->from_hex('cafe');        # from hexadecimal
$x = Math::BigFloat->from_oct('1.3267p-4');   # from octal
$x = Math::BigFloat->from_oct('377');         # from octal
$x = Math::BigFloat->from_bin('0b1.1001p-4'); # from binary
$x = Math::BigFloat->from_bin('0101');        # from binary
$x = Math::BigFloat->from_bytes($bytes);      # from byte string
$x = Math::BigFloat->from_base('why', 36);    # from any base
$x = Math::BigFloat->from_ieee754($b, $fmt);  # from IEEE-754 bytes
$x = Math::BigFloat->from_fp80($b);           # from x86 80-bit
$x = Math::BigFloat->bzero();                 # create a +0
$x = Math::BigFloat->bone();                  # create a +1
$x = Math::BigFloat->bone('-');               # create a -1

↪underflow)
```

DESCRIPTION

Math::BigFloat provides support for arbitrary precision floating point. Overloading is also provided for Perl operators.

All operators (including basic math operations) are overloaded if you declare your big floating point numbers as

```
$x = Math::BigFloat -> new('12_3.456_789_123_456_789E-2');
```

Operations with overloaded operators preserve the arguments, which is exactly what you expect.

Input

Input values to these routines may be any scalar number or string that looks like a number. Anything that is accepted by Perl as a literal numeric constant should be accepted by this module.

- Leading and trailing whitespace is ignored.
- Leading zeros are ignored, except for floating point numbers with a binary exponent, in which case the number is interpreted as an octal floating point number. For example, “01.4p+0” gives 1.5, “00.4p+0” gives 0.5, but “0.4p+0” gives a NaN. And while “0377” gives 255, “0377p0” gives 255.
- If the string has a “0x” or “0X” prefix, it is interpreted as a hexadecimal number.
- If the string has a “0o” or “0O” prefix, it is interpreted as an octal number. A floating point literal with a “0” prefix is also interpreted as an octal number.
- If the string has a “0b” or “0B” prefix, it is interpreted as a binary number.
- Underline characters are allowed in the same way as they are allowed in literal numerical constants.
- If the string can not be interpreted, NaN is returned.
- For hexadecimal, octal, and binary floating point numbers, the exponent must be separated from the significand (mantissa) by the letter “p” or “P”, not “e” or “E” as with decimal numbers.

Some examples of valid string input

```
Input string                 Resulting value

123                          123
1.23e2                       123

0b1.1001p-4                  9.765625e-2
```

Output

Output values are usually Math::BigFloat objects.

Boolean operators *is_zero()*, *is_one()*, *is_inf()*, etc. return true or false.

Comparison operators *bcmp()* and *bacmp()*) return -1, 0, 1, or undef.

METHODS

Math::BigFloat supports all methods that Math::BigInt supports, except it calculates non-integer results when possible. Please see *Math::BigInt* for a full description of each method. Below are just the most important differences:

Configuration methods

- accuracy()

```
$x->accuracy(5);           # local for $x
CLASS->accuracy(5);        # global for all members of CLASS
                           # Note: This also applies to new()!

$A = $x->accuracy();       # read out accuracy that affects $x
$A = CLASS->accuracy();    # read out global accuracy
```

Set or get the global or local accuracy, aka how many significant digits the results have. If you set a global accuracy, then this also applies to new()!

Warning! The accuracy *sticks*, e.g. once you created a number under the influence of `CLASS->accuracy($A)`, all results from math operations with that number will also be rounded.

In most cases, you should probably round the results explicitly using one of *"round()" in Math::BigInt*, *"bround()" in Math::BigInt* or *"bfround()" in Math::BigInt* or by passing the desired accuracy to the math operation as additional parameter:

```
my $x = Math::BigInt->new(30000);
my $y = Math::BigInt->new(7);
print scalar $x->copy()->bdiv($y, 2);           # print 4300
print scalar $x->copy()->bdiv($y)->bround(2);   # print 4300
```

- precision()

```
$x->precision(-2);         # local for $x, round at the second
                           # digit right of the dot
$x->precision(2);          # ditto, round at the second digit
                           # left of the dot

CLASS->precision(5);       # Global for all members of CLASS
                           # This also applies to new()!
CLASS->precision(-5);      # ditto

$P = CLASS->precision();   # read out global precision
$P = $x->precision();      # read out precision that affects $x
```

Note: You probably want to use "accuracy()" instead. With "accuracy()" you set the number of digits each result should have, with "precision()" you set the place where to round!

Constructor methods

- from_dec()

```
$x -> from_hex("314159");
$x = Math::BigInt -> from_hex("314159");
```

Interpret input as a decimal. It is equivalent to new(), but does not accept anything but strings representing finite, decimal numbers.

- from_hex()

```
$x -> from_hex("0x1.921fb54442d18p+1");
$x = Math::BigFloat -> from_hex("0x1.921fb54442d18p+1");
```

Interpret input as a hexadecimal string.A prefix ("0x", "x", ignoring case) is optional. A single underscore character ("_") may be placed between any two digits. If the input is invalid, a NaN is returned. The exponent is in base 2 using decimal digits.

If called as an instance method, the value is assigned to the invocand.

- from_oct()

```
$x -> from_oct("1.3267p-4");
$x = Math::BigFloat -> from_oct("1.3267p-4");
```

Interpret input as an octal string. A single underscore character ("_") may be placed between any two digits. If the input is invalid, a NaN is returned. The exponent is in base 2 using decimal digits.

If called as an instance method, the value is assigned to the invocand.

- from_bin()

```
$x -> from_bin("0b1.1001p-4");
$x = Math::BigFloat -> from_bin("0b1.1001p-4");
```

Interpret input as a hexadecimal string. A prefix ("0b" or "b", ignoring case) is optional. A single underscore character ("_") may be placed between any two digits. If the input is invalid, a NaN is returned. The exponent is in base 2 using decimal digits.

If called as an instance method, the value is assigned to the invocand.

- from_bytes()

```
$x = Math::BigFloat->from_bytes("\xf3\x6b");  # $x = 62315
```

Interpret the input as a byte string, assuming big endian byte order. The output is always a non-negative, finite integer.

See *"from_bytes()" in Math::BigInt*.

- from_ieee754()

Interpret the input as a value encoded as described in IEEE754-2008. The input can be given as a byte string, hex string, or binary string. The input is assumed to be in big-endian byte-order.

```
# Both $dbl, $xr, $xh, and $xb below are 3.141592...

$dbl = unpack "d>", "\x40\x09\x21\xfb\x54\x44\x2d\x18";
```

(continues on next page)

(continued from previous page)

```
$raw = "\x40\x09\x21\xfb\x54\x44\x2d\x18";           # raw bytes
$xr  = Math::BigFloat -> from_ieee754($raw, "binary64");

$hex = "400921fb54442d18";
$xh  = Math::BigFloat -> from_ieee754($hex, "binary64");

$bin =
 ↪"0100000000001001001000011111101101010100010001000010110100011000
 ↪";
$xb  = Math::BigFloat -> from_ieee754($bin, "binary64");
```

Supported formats are all IEEE 754 binary formats: “binary16”, “binary32”, “binary64”, “binary128”, “binary160”, “binary192”, “binary224”, “binary256”, etc. where the number of bits is a multiple of 32 for all formats larger than “binary128”. Aliases are “half” (“binary16”), “single” (“binary32”), “double” (“binary64”), “quadruple” (“binary128”), “octuple” (“binary256”), and “sexdecuple” (“binary512”).

See also “to_ieee754()”.

- from_fp80()

  Interpret the input as a value encoded as an x86 80-bit floating point number. The input can be given as a 10 character byte string, 20 character hex string, or 80 character binary string. The input is assumed to be in big-endian byte-order.

```
    # Both $xr, $xh, and $xb below are 3.141592...

    $dbl = unpack "d>", "\x40\x09\x21\xfb\x54\x44\x2d\x18";

    $raw = "\x40\x00\xc9\x0f\xda\xa2\x21\x68\xc2\x35";  # raw␣
 ↪bytes
    $xr  = Math::BigFloat -> from_fp80($raw);

    $hex = "4000c90fdaa22168c235";
    $xh  = Math::BigFloat -> from_fp80($hex);

    $bin = "0100000000000000110010010000111111011010"
         . "1010001000100001011010001100001000110101";
    $xb  = Math::BigFloat -> from_fp80($bin);
See also L</to_ieee754()>.
```

- from_base()

  See *“from_base()” in Math::BigInt*.

- bpi()

```
print Math::BigFloat->bpi(100), "\n";
```

Calculate PI to N digits (including the 3 before the dot). The result is rounded according to the current rounding mode, which defaults to “even”.

This method was added in v1.87 of Math::BigInt (June 2007).

- as_int()

```
$y = $x -> as_int();        # $y is a Math::BigInt
```

Returns $x as a Math::BigInt object regardless of upgrading and downgrading. If $x is finite, but not an integer, $x is truncated.

- as_rat()

```
$y = $x -> as_rat();        # $y is a Math::BigRat
```

Returns $x a Math::BigRat object regardless of upgrading and downgrading. The invocand is not modified.

- as_float()

```
$y = $x -> as_float();      # $y is a Math::BigFloat
```

Returns $x a Math::BigFloat object regardless of upgrading and downgrading. The invocand is not modified.

Arithmetic methods

- bdiv()

```
$x->bdiv($y);               # set $x to quotient
($q, $r) = $x->bdiv($y);    # also remainder
```

This is an alias for "bfdiv()".

- bmod()

```
$x->bmod($y);
```

Returns $x modulo $y. When $x is finite, and $y is finite and non-zero, the result is identical to the remainder after floored division (F-division). If, in addition, both $x and $y are integers, the result is identical to the result from Perl's % operator.

- bfdiv()

```
$q = $x->bfdiv($y);
($q, $r) = $x->bfdiv($y);
```

In scalar context, divides $x by $y and returns the result to the given accuracy or precision or the default accuracy. In list context, does floored division (F-division), returning an integer $q and a remainder $r

```
$q = floor($x / $y)
$r = $x - $q * $y
```

so that the following relationship always holds

```
$x = $q * $y + $r
```

The remainer (modulo) is equal to what is returned by `$x->bmod($y)`.

- binv()

```
$x->binv();
```

Invert the value of $x, i.e., compute 1/$x.

- bmuladd()

```
$x->bmuladd($y,$z);
```

Multiply $x by $y, and then add $z to the result.

This method was added in v1.87 of Math::BigInt (June 2007).

- bexp()

```
$x->bexp($accuracy);            # calculate e ** X
```

Calculates the expression `e ** $x` where e is Euler's number.

This method was added in v1.82 of Math::BigInt (April 2007).

- bnok()

See *"bnok()" in Math::BigInt*.

- bperm()

See *"bperm()" in Math::BigInt*.

- bsin()

```
my $x = Math::BigFloat->new(1);
print $x->bsin(100), "\n";
```

Calculate the sinus of $x, modifying $x in place.

This method was added in v1.87 of Math::BigInt (June 2007).

- bcos()

```
my $x = Math::BigFloat->new(1);
print $x->bcos(100), "\n";
```

Calculate the cosinus of $x, modifying $x in place.

This method was added in v1.87 of Math::BigInt (June 2007).

- batan()

```
my $x = Math::BigFloat->new(1);
print $x->batan(100), "\n";
```

Calculate the arcus tanges of $x, modifying $x in place. See also "batan2()".

This method was added in v1.87 of Math::BigInt (June 2007).

- batan2()

```
my $y = Math::BigFloat->new(2);
my $x = Math::BigFloat->new(3);
print $y->batan2($x), "\n";
```

Calculate the arcus tanges of $y divided by $x, modifying $y in place. See also "batan()".

This method was added in v1.87 of Math::BigInt (June 2007).

- bgcd()

```
$x -> bgcd($y);               # GCD of $x and $y
$x -> bgcd($y, $z, ...);      # GCD of $x, $y, $z, ...
```

Returns the greatest common divisor (GCD), which is the number with the largest absolute value such that $x/$gcd, $y/$gcd, ... is an integer. For example, when the operands are 0.8 and 1.2, the GCD is 0.4. This is a generalisation of the ordinary GCD for integers. See *"gcd()" in Math::BigInt*.

String conversion methods

- bstr()

```
my $x = Math::BigRat->new('8/4');
print $x->bstr(), "\n";             # prints 1/2
```

Returns a string representing the number.

- bsstr()

  See *"bsstr()" in Math::BigInt*.

- bnstr()

  See *"bnstr()" in Math::BigInt*.

- bestr()

  See *"bestr()" in Math::BigInt*.

- bdstr()

  See *"bdstr()" in Math::BigInt*.

- to_bytes()

  See *"to_bytes()" in Math::BigInt*.

- to_ieee754()

  Encodes the invocand as a byte string in the given format as specified in IEEE 754-2008. Note that the encoded value is the nearest possible representation of the value. This value might not be exactly the same as the value in the invocand.

```
# $x = 3.14159265358979323
$x = Math::BigFloat -> bpi(30);

```

(continues on next page)

(continued from previous page)

```
$b = $x -> to_ieee754("binary64");  # encode as 8 bytes
$h = unpack "H*", $b;               # "400921fb54442d18"

# 3.14159265358979311599796 3...
$y = Math::BigFloat -> from_ieee754($h, "binary64");
```

All binary formats in IEEE 754-2008 are accepted. For convenience, som aliases are recognized: “half” for “binary16”, “single” for “binary32”, “double” for “binary64”, “quadruple” for “binary128”, “octuple” for “binary256”, and “sexdecuple” for “binary512”.

See also “from_ieee754()”, https://en.wikipedia.org/wiki/IEEE_754.

ACCURACY AND PRECISION

See also: Rounding.

Math::BigFloat supports both precision (rounding to a certain place before or after the dot) and accuracy (rounding to a certain number of digits). For a full documentation, examples and tips on these topics please see the large section about rounding in *Math::BigInt*.

Since things like `sqrt(2)` or `1 / 3` must presented with a limited accuracy lest a operation consumes all resources, each operation produces no more than the requested number of digits.

If there is no global precision or accuracy set, **and** the operation in question was not called with a requested precision or accuracy, **and** the input $x has no accuracy or precision set, then a fallback parameter will be used. For historical reasons, it is called `div_scale` and can be accessed via:

```
$d = Math::BigFloat->div_scale();       # query
Math::BigFloat->div_scale($n);          # set to $n digits
```

The default value for `div_scale` is 40.

In case the result of one operation has more digits than specified, it is rounded. The rounding mode taken is either the default mode, or the one supplied to the operation after the *scale*:

```
$x = Math::BigFloat->new(2);
Math::BigFloat->accuracy(5);              # 5 digits max
$y = $x->copy()->bdiv(3);                 # gives 0.66667
$y = $x->copy()->bdiv(3,6);               # gives 0.666667
$y = $x->copy()->bdiv(3,6,undef,'odd');   # gives 0.666667
Math::BigFloat->round_mode('zero');
$y = $x->copy()->bdiv(3,6);               # will also give 0.666667
```

Note that `Math::BigFloat->accuracy()` and `Math::BigFloat->precision()` set the global variables, and thus **any** newly created number will be subject to the global rounding **immediately**. This means that in the examples above, the 3 as argument to “bdiv()” will also get an accuracy of **5**.

It is less confusing to either calculate the result fully, and afterwards round it explicitly, or use the additional parameters to the math functions like so:

```
use Math::BigFloat;
$x = Math::BigFloat->new(2);
$y = $x->copy()->bdiv(3);
print $y->bround(5),"\n";                # gives 0.66667

or

use Math::BigFloat;
$x = Math::BigFloat->new(2);
$y = $x->copy()->bdiv(3,5);              # gives 0.66667
print "$y\n";
```

Rounding

- bfround (+$scale)

  Rounds to the $scale'th place left from the '.', counting from the dot. The first digit is numbered 1.

- bfround (-$scale)

  Rounds to the $scale'th place right from the '.', counting from the dot.

- bfround (0)

  Rounds to an integer.

- bround (+$scale)

  Preserves accuracy to $scale digits from the left (aka significant digits) and pads the rest with zeros. If the number is between 1 and -1, the significant digits count from the first non-zero after the '.'

- bround (-$scale) and bround (0)

  These are effectively no-ops.

All rounding functions take as a second parameter a rounding mode from one of the following: 'even', 'odd', '+inf', '-inf', 'zero', 'trunc' or 'common'.

The default rounding mode is 'even'. By using `Math::BigFloat->round_mode($round_mode);` you can get and set the default mode for subsequent rounding. The usage of `$Math::BigFloat::$round_mode` is no longer supported. The second parameter to the round functions then overrides the default temporarily.

The "as_int()" method returns a BigInt from a Math::BigFloat. It uses 'trunc' as rounding mode to make it equivalent to:

```
$x = 2.5;
$y = int($x) + 2;
```

You can override this by passing the desired rounding mode as parameter to "as_int()":

```
$x = Math::BigFloat->new(2.5);
$y = $x->as_number('odd');      # $y = 3
```

NUMERIC LITERALS

After `use Math::BigFloat ':constant'` all numeric literals in the given scope are converted to `Math::BigFloat` objects. This conversion happens at compile time.

For example,

```
perl -MMath::BigFloat=:constant -le 'print 2e-150'
```

prints the exact value of `2e-150`. Note that without conversion of constants the expression `2e-150` is calculated using Perl scalars, which leads to an inaccuracte result.

Note that strings are not affected, so that

```
use Math::BigFloat qw/:constant/;

$y = "1234567890123456789012345678901234567890"
        + "123456789123456789";
```

does not give you what you expect. You need an explicit Math::BigFloat->new() around at least one of the operands. You should also quote large constants to prevent loss of precision:

```
use Math::BigFloat;

$x = Math::BigFloat->new("123456788912345678912345678912345678 9");
```

Without the quotes Perl converts the large number to a floating point constant at compile time, and then converts the result to a Math::BigFloat object at runtime, which results in an inaccurate result.

Hexadecimal, octal, and binary floating point literals

Perl (and this module) accepts hexadecimal, octal, and binary floating point literals, but use them with care with Perl versions before v5.32.0, because some versions of Perl silently give the wrong result. Below are some examples of different ways to write the number decimal 314.

Hexadecimal floating point literals:

```
0x1.3ap+8          0X1.3AP+8
0x1.3ap8           0X1.3AP8
0x13a0p-4          0X13A0P-4
```

Octal floating point literals (with “0” prefix):

```
01.164p+8          01.164P+8
01.164p8           01.164P8
011640p-4          011640P-4
```

Octal floating point literals (with "0o" prefix) (requires v5.34.0):

```
0o1.164p+8          0O1.164P+8
0o1.164p8           0O1.164P8
0o11640p-4          0O11640P-4
```

Binary floating point literals:

```
0b1.0011101p+8      0B1.0011101P+8
0b1.0011101p8       0B1.0011101P8
0b10011101000p-2    0B10011101000P-2
```

Math library

Math with the numbers is done (by default) by a module called Math::BigInt::Calc. This is equivalent to saying:

```
use Math::BigFloat lib => "Calc";
```

You can change this by using:

```
use Math::BigFloat lib => "GMP";
```

Note: General purpose packages should not be explicit about the library to use; let the script author decide which is best.

Note: The keyword 'lib' will warn when the requested library could not be loaded. To suppress the warning use 'try' instead:

```
use Math::BigFloat try => "GMP";
```

If your script works with huge numbers and Calc is too slow for them, you can also for the loading of one of these libraries and if none of them can be used, the code will die:

```
use Math::BigFloat only => "GMP,Pari";
```

The following would first try to find Math::BigInt::Foo, then Math::BigInt::Bar, and when this also fails, revert to Math::BigInt::Calc:

```
use Math::BigFloat lib => "Foo,Math::BigInt::Bar";
```

See the respective low-level library documentation for further details.

See *Math::BigInt* for more details about using a different low-level library.

EXPORTS

`Math::BigFloat` exports nothing by default, but can export the "bpi()" method:

```
use Math::BigFloat qw/bpi/;

print bpi(10), "\n";
```

- Modifying and =

  Beware of:

```
$x = Math::BigFloat->new(5);
$y = $x;
```

  It will not do what you think, e.g. making a copy of $x. Instead it just makes a second reference to the **same** object and stores it in $y. Thus anything that modifies $x will modify $y (except overloaded math operators), and vice versa. See *Math::BigInt* for details and how to avoid that.

- precision() vs. accuracy()

  A common pitfall is to use "precision()" when you want to round a result to a certain number of digits:

```
use Math::BigFloat;

Math::BigFloat->precision(4);           # does not do what you
                                        # think it does
my $x = Math::BigFloat->new(12345);     # rounds $x to "12000"!
print "$x\n";                           # print "12000"
my $y = Math::BigFloat->new(3);         # rounds $y to "0"!
print "$y\n";                           # print "0"
$z = $x / $y;                           # 12000 / 0 => NaN!
print "$z\n";
print $z->precision(),"\n";             # 4
```

  Replacing "precision()" with "accuracy()" is probably not what you want, either:

```
use Math::BigFloat;

Math::BigFloat->accuracy(4);          # enables global rounding:
my $x = Math::BigFloat->new(123456);  # rounded immediately
                                      #   to "12350"
print "$x\n";                         # print "123500"
my $y = Math::BigFloat->new(3);       # rounded to "3
print "$y\n";                         # print "3"
print $z = $x->copy()->bdiv($y),"\n"; # 41170
print $z->accuracy(),"\n";            # 4
```

  What you want to use instead is:

```
use Math::BigFloat;

my $x = Math::BigFloat->new(123456);    # no rounding
print "$x\n";                           # print "123456"
my $y = Math::BigFloat->new(3);         # no rounding
print "$y\n";                           # print "3"
print $z = $x->copy()->bdiv($y,4),"\n"; # 41150
print $z->accuracy(),"\n";              # undef
```

  In addition to computing what you expected, the last example also does **not** "taint"

the result with an accuracy or precision setting, which would influence any further operation.

BUGS

Please report any bugs or feature requests to `bug-math-bigint at rt.cpan.org`, or through the web interface at https://rt.cpan.org/Ticket/Create.html?Queue=Math-BigInt (requires login). We will be notified, and then you'll automatically be notified of progress on your bug as I make changes.

SUPPORT

You can find documentation for this module with the perldoc command.

```

Math::BigInt

arbitrary size integer math package

SYNOPSIS

```
use Math::BigInt;

# or make it faster with huge numbers: install (optional)
# Math::BigInt::GMP and always use (it falls back to
# pure Perl if the GMP library is not installed):
# (See also the L</Math Library> section!)

# to warn if Math::BigInt::GMP cannot be found, use
use Math::BigInt lib => 'GMP';

# to suppress the warning if Math::BigInt::GMP cannot be found, use
# use Math::BigInt try => 'GMP';

# to die if Math::BigInt::GMP cannot be found, use
# use Math::BigInt only => 'GMP';

# Configuration methods (may be used as class methods and instance
 ↪methods)

Math::BigInt->accuracy($n);       # set accuracy
Math::BigInt->accuracy();         # get accuracy
Math::BigInt->precision($n);      # set precision
Math::BigInt->precision();        # get precision
Math::BigInt->round_mode($m);     # set rounding mode, must be
                                  # 'even', 'odd', '+inf', '-inf',
                                  # 'zero', 'trunc', or 'common'
Math::BigInt->round_mode();       # get class rounding mode
Math::BigInt->div_scale($n);      # set fallback accuracy
Math::BigInt->div_scale();        # get fallback accuracy
Math::BigInt->trap_inf($b);       # trap infinities or not
Math::BigInt->trap_inf();         # get trap infinities status
Math::BigInt->trap_nan($b);       # trap NaNs or not
Math::BigInt->trap_nan();         # get trap NaNs status
Math::BigInt->config($par, $val); # set configuration parameter
Math::BigInt->config($par);       # get configuration parameter
Math::BigInt->config();           # get hash with configuration
Math::BigFloat->config("lib");    # get name of backend library

# Generic constructor method (always returns a new object)

$x = Math::BigInt->new($str);             # defaults to 0
$x = Math::BigInt->new('256');            # from decimal
$x = Math::BigInt->new('0256');           # from decimal
$x = Math::BigInt->new('0xcafe');         # from hexadecimal
```

(continues on next page)

(continued from previous page)

```
$x = Math::BigInt->new('0x1.fap+7');      # from hexadecimal
$x = Math::BigInt->new('0o377');          # from octal
$x = Math::BigInt->new('0o1.35p+6');      # from octal
$x = Math::BigInt->new('0b101');          # from binary
$x = Math::BigInt->new('0b1.101p+3');     # from binary

# Specific constructor methods (no prefix needed; when used as
# instance method, the value is assigned to the invocand)

$x = Math::BigInt->from_dec('234');       # from decimal
$x = Math::BigInt->from_hex('cafe');      # from hexadecimal
$x = Math::BigInt->from_hex('1.fap+7');   # from hexadecimal
$x = Math::BigInt->from_oct('377');       # from octal
$x = Math::BigInt->from_oct('1.35p+6');   # from octal
$x = Math::BigInt->from_bin('1101');      # from binary
$x = Math::BigInt->from_bin('1.101p+3');  # from binary
$x = Math::BigInt->from_bytes($bytes);    # from byte string
$x = Math::BigInt->from_base('why', 36);  # from any base
$x = Math::BigInt->from_base_num([1, 0], 2);  # from any base
$x = Math::BigInt->from_ieee754($b, $fmt);    # from IEEE-754 bytes
$x = Math::BigInt->from_fp80($b);         # from x86 80-bit
$x = Math::BigInt->bzero();               # create a +0
$x = Math::BigInt->bone();                # create a +1
$x = Math::BigInt->bone('-');             # create a -1
$x = Math::BigInt->binf();                # create a +inf
$x = Math::BigInt->binf('-');             # create a -inf
$x = Math::BigInt->bnan();                # create a Not-A-Number
$x = Math::BigInt->bpi();                 # returns pi

$y = $x->copy();        # make a copy (unlike $y = $x)
$y = $x->as_int();      # return as a Math::BigInt
$y = $x->as_float();    # return as a Math::BigFloat
$y = $x->as_rat();      # return as a Math::BigRat

# Boolean methods (these don't modify the invocand)

$x->is_zero();          # true if $x is 0
$x->is_one();           # true if $x is +1
$x->is_one("+");        # true if $x is +1
$x->is_one("-");        # true if $x is -1
$x->is_inf();           # true if $x is +inf or -inf
$x->is_inf("+");        # true if $x is +inf
$x->is_inf("-");        # true if $x is -inf
$x->is_nan();           # true if $x is NaN

$x->is_finite();        # true if -inf < $x < inf
$x->is_positive();      # true if $x > 0
$x->is_pos();           # true if $x > 0
$x->is_negative();      # true if $x < 0
```

(continues on next page)

(continued from previous page)

```
$x->is_neg();           # true if $x < 0
$x->is_non_positive()   # true if $x <= 0
$x->is_non_negative()   # true if $x >= 0

$x->is_odd();           # true if $x is odd
$x->is_even();          # true if $x is even
$x->is_int();           # true if $x is an integer

# Comparison methods (these don't modify the invocand)

$x->bcmp($y);           # compare numbers (undef, < 0, == 0, > 0)
$x->bacmp($y);          # compare abs values (undef, < 0, == 0, > 0)
$x->beq($y);            # true if $x == $y
$x->bne($y);            # true if $x != $y
$x->blt($y);            # true if $x < $y
$x->ble($y);            # true if $x <= $y
$x->bgt($y);            # true if $x > $y
$x->bge($y);            # true if $x >= $y

# Arithmetic methods (these modify the invocand)

$x->bneg();             # negation
$x->babs();             # absolute value
$x->bsgn();             # sign function (-1, 0, 1, or NaN)
$x->bdigitsum();        # sum of decimal digits
$x->binc();             # increment $x by 1
$x->bdec();             # decrement $x by 1
$x->badd($y);           # addition (add $y to $x)
$x->bsub($y);           # subtraction (subtract $y from $x)
$x->bmul($y);           # multiplication (multiply $x by $y)
$x->bmuladd($y, $z);    # $x = $x * $y + $z
$x->bdiv($y);           # division (floored)
$x->bmod($y);           # modulus (x % y)
$x->bmodinv($mod);      # modular multiplicative inverse
$x->bmodpow($y, $mod);  # modular exponentiation (($x ** $y) % $mod)
$x->btdiv($y);          # division (truncated), set $x to quotient
$x->btmod($y);          # modulus (truncated)

DESCRIPTION

Math::BigInt provides support for arbitrary precision integers. Overloading is also provided for Perl operators.

Input

Input values to these routines may be any scalar number or string that looks like a number and represents an integer. Anything that is accepted by Perl as a literal numeric constant should be accepted by this module, except that finite non-integers return NaN.

- Leading and trailing whitespace is ignored.
- Leading zeros are ignored, except for floating point numbers with a binary exponent, in which case the number is interpreted as an octal floating point number. For example, “01.4p+0” gives 1.5, “00.4p+0” gives 0.5, but “0.4p+0” gives a NaN. And while “0377” gives 255, “0377p0” gives 255.
- If the string has a “0x” or “0X” prefix, it is interpreted as a hexadecimal number.
- If the string has a “0o” or “0O” prefix, it is interpreted as an octal number. A floating point literal with a “0” prefix is also interpreted as an octal number.
- If the string has a “0b” or “0B” prefix, it is interpreted as a binary number.
- Underline characters are allowed in the same way as they are allowed in literal numerical constants.
- If the string can not be interpreted, or does not represent a finite integer, NaN is returned.
- For hexadecimal, octal, and binary floating point numbers, the exponent must be separated from the significand (mantissa) by the letter “p” or “P”, not “e” or “E” as with decimal numbers.

Some examples of valid string input

```
Input string                Resulting value

123                         123
1.23e2                      123
12300e-2                    123

67_538_754                  67538754
-4_5_6.7_8_9e+0_1_0         -4567890000000

0x13a                       314
```

(continues on next page)

(continued from previous page)

0x1.3ap+8                       314
0x0.00013ap+24                  314
0x13a000p-12                    314

0o472                           314
0o1.164p+8                      314
0o0.0001164p+20                 314
0o1164000p-10                   314

0472                            472     Note!
01.164p+8                       314
00.0001164p+20                  314
01164000p-10                    314

0b100111010                     314
0b1.0011101p+8                  314
0b0.00010011101p+12             314
0b100111010000p-3               314
```

Input given as scalar numbers might lose precision. Quote your input to ensure that no digits are lost:

```
$x = Math::BigInt->new( 56789012345678901234 );   # bad
$x = Math::BigInt->new('56789012345678901234');   # good
```

Currently, `Math::BigInt-new()>` (no input argument) and `Math::BigInt-new("")>` return 0. This might change in the future, so always use the following explicit forms to get a zero:

```
$zero = Math::BigInt->bzero();
```

Output

Output values are usually Math::BigInt objects.

Boolean operators "is_zero()", "is_one()", "is_inf()", etc. return true or false.

Comparison operators "bcmp()" and "bacmp()") return -1, 0, 1, or undef.

METHODS

Configuration methods

Each of the methods below (except "config()", "accuracy()" and "precision()") accepts three additional parameters. These arguments `$A`, `$P` and `$R` are `accuracy`, `precision` and `round_mode`. Please see the section about "ACCURACY AND PRECISION" for more information.

Setting a class variable effects all object instance that are created afterwards.

- accuracy()

```
Math::BigInt->accuracy(5);      # set class accuracy
$x->accuracy(5);                # set instance accuracy

$A = Math::BigInt->accuracy();  # get class accuracy
$A = $x->accuracy();            # get instance accuracy
```

Set or get the accuracy, i.e., the number of significant digits. The accuracy must be an integer. If the accuracy is set to `undef`, no rounding is done.

Alternatively, one can round the results explicitly using one of "round()", "bround()" or "bfround()" or by passing the desired accuracy to the method as an additional parameter:

```
my $x = Math::BigInt->new(30000);
my $y = Math::BigInt->new(7);
print scalar $x->copy()->bdiv($y, 2);               # prints␣
↪4300
print scalar $x->copy()->bdiv($y)->bround(2);       # prints␣
↪4300
```

Please see the section about "ACCURACY AND PRECISION" for further details.

```
$y = Math::BigInt->new(1234567);    # $y is not rounded
Math::BigInt->accuracy(4);          # set class accuracy to 4
$x = Math::BigInt->new(1234567);    # $x is rounded␣
↪automatically
print "$x $y";                      # prints "1235000 1234567"

print $x->accuracy();       # prints "4"
print $y->accuracy();       # also prints "4", since
                            #   class accuracy is 4

Math::BigInt->accuracy(5);  # set class accuracy to 5
print $x->accuracy();       # prints "4", since instance
                            #   accuracy is 4
print $y->accuracy();       # prints "5", since no instance
                            #   accuracy, and class accuracy is␣
↪5
```

Note: Each class has it's own globals separated from Math::BigInt, but it is possible to subclass Math::BigInt and make the globals of the subclass aliases to the ones from Math::BigInt.

- precision()

```
Math::BigInt->precision(-2);     # set class precision
$x->precision(-2);               # set instance precision

$P = Math::BigInt->precision();  # get class precision
$P = $x->precision();            # get instance precision
```

Set or get the precision, i.e., the place to round relative to the decimal point. The precision must be a integer. Setting the precision to $P means that each number is

rounded up or down, depending on the rounding mode, to the nearest multiple of 10**$P. If the precision is set to `undef`, no rounding is done.

You might want to use "accuracy()" instead. With "accuracy()" you set the number of digits each result should have, with "precision()" you set the place where to round.

Please see the section about "ACCURACY AND PRECISION" for further details.

```
$y = Math::BigInt->new(1234567);    # $y is not rounded
Math::BigInt->precision(4);         # set class precision to 4
$x = Math::BigInt->new(1234567);    # $x is rounded
 ↪automatically
print $x;                           # prints "1230000"
```

Note: Each class has its own globals separated from Math::BigInt, but it is possible to subclass Math::BigInt and make the globals of the subclass aliases to the ones from Math::BigInt.

- round_mode()

  Set/get the rounding mode.

- div_scale()

  Set/get the fallback accuracy. This is the accuracy used when neither accuracy nor precision is set explicitly. It is used when a computation might otherwise attempt to return an infinite number of digits.

- trap_inf()

  Set/get the value determining whether infinities should cause a fatal error or not.

- trap_nan()

  Set/get the value determining whether NaNs should cause a fatal error or not.

- upgrade()

  Set/get the class for upgrading. When a computation might result in a non-integer, the operands are upgraded to this class. This is used for instance by *bignum*. The default is `undef`, i.e., no upgrading.

```
# with no upgrading
$x = Math::BigInt->new(12);
$y = Math::BigInt->new(5);
print $x / $y, "\n";                # 2 as a Math::BigInt

# with upgrading to Math::BigFloat
Math::BigInt -> upgrade("Math::BigFloat");
print $x / $y, "\n";                # 2.4 as a Math::BigFloat

# with upgrading to Math::BigRat (after loading Math::BigRat)
Math::BigInt -> upgrade("Math::BigRat");
print $x / $y, "\n";                # 12/5 as a Math::BigRat
```

- downgrade()

Set/get the class for downgrading. The default is undef, i.e., no downgrading. Downgrading is not done by Math::BigInt.

- modify()

```
$x->modify('bpowd');
```

This method returns 0 if the object can be modified with the given operation, or 1 if not.

This is used for instance by Math::BigInt::Constant.

- config()

```
Math::BigInt->config("trap_nan" => 1);      # set
$accu = Math::BigInt->config("accuracy");   # get
```

Set or get class variables. Read-only parameters are marked as RO. Read-write parameters are marked as RW. The following parameters are supported.

```
Parameter       RO/RW   Description
                        Example
============================================================

                        undef
```

Constructor methods

- new()

```
$x = Math::BigInt->new($str,$A,$P,$R);
```

Creates a new Math::BigInt object from a scalar or another Math::BigInt object. The input is accepted as decimal, hexadecimal (with leading '0x'), octal (with leading ('0o') or binary (with leading '0b').

See "Input" for more info on accepted input formats.

- from_dec()

```
$x = Math::BigInt->from_dec("314159");    # input is decimal
```

Interpret input as a decimal. It is equivalent to "new()", but does not accept anything but strings representing finite, decimal numbers.

- from_hex()

```
$x = Math::BigInt->from_hex("0xcafe");    # input is hexadecimal
```

Interpret input as a hexadecimal string. A "0x" or "x" prefix is optional. A single underscore character may be placed right after the prefix, if present, or between any two digits. If the input is invalid, a NaN is returned.

- from_oct()

```
$x = Math::BigInt->from_oct("0775");      # input is octal
```

Interpret the input as an octal string and return the corresponding value. A "0" (zero) prefix is optional. A single underscore character may be placed right after the prefix, if present, or between any two digits. If the input is invalid, a NaN is returned.

- from_bin()

```
$x = Math::BigInt->from_bin("0b10011");   # input is binary
```

Interpret the input as a binary string. A "0b" or "b" prefix is optional. A single underscore character may be placed right after the prefix, if present, or between any two digits. If the input is invalid, a NaN is returned.

- from_bytes()

```
$x = Math::BigInt->from_bytes("\xf3\x6b");  # $x = 62315
```

Interpret the input as a byte string, assuming big endian byte order. The output is always a non-negative, finite integer.

In some special cases, "from_bytes()" matches the conversion done by unpack():

```
$b = "\x4e";                              # one char byte string
$x = Math::BigInt->from_bytes($b);        # = 78
$y = unpack "C", $b;                      # ditto, but scalar
```

(continues on next page)

(continued from previous page)

```
$b = "\xf3\x6b";                          # two char byte string
$x = Math::BigInt->from_bytes($b);        # = 62315
$y = unpack "S>", $b;                     # ditto, but scalar

$b = "\x2d\xe0\x49\xad";                  # four char byte string
$x = Math::BigInt->from_bytes($b);        # = 769673645
$y = unpack "L>", $b;                     # ditto, but scalar

$b = "\x2d\xe0\x49\xad\x2d\xe0\x49\xad"; # eight char byte␣
↪string
$x = Math::BigInt->from_bytes($b);        # = 3305723134637787565
$y = unpack "Q>", $b;                     # ditto, but scalar
```

- from_ieee754()

```
# set $x to 314159
$x = Math::BigInt -> from_ieee754("40490fdb", "binary32");
```

Interpret the input as a value encoded as described in IEEE754-2008. NaN is returned if the value is neither +/-infinity nor an integer.

See *“from_ieee754()” in Math::BigFloat*.

- from_fp80()

```
# set $x to 314159
$x = Math::BigInt -> from_fp80("40119965e00000000000");
```

Interpret the input as a value encoded in the x86 extended-precision 80-bit format.

See *“from_fp80()” in Math::BigFloat*.

- from_base()

Given a string, a base, and an optional collation sequence, interpret the string as a number in the given base. The collation sequence describes the value of each character in the string.

If a collation sequence is not given, a default collation sequence is used. If the base is less than or equal to 36, the collation sequence is the string consisting of the 36 characters “0” to “9” and “A” to “Z”. In this case, the letter case in the input is ignored. If the base is greater than 36, and smaller than or equal to 62, the collation sequence is the string consisting of the 62 characters “0” to “9”, “A” to “Z”, and “a” to “z”. A base larger than 62 requires the collation sequence to be specified explicitly.

These examples show standard binary, octal, and hexadecimal conversion. All cases return 250.

```
$x = Math::BigInt->from_base("11111010", 2);
$x = Math::BigInt->from_base("372", 8);
$x = Math::BigInt->from_base("fa", 16);
```

When the base is less than or equal to 36, and no collation sequence is given, the letter case is ignored, so both of these also return 250:

```
$x = Math::BigInt->from_base("6Y", 16);
$x = Math::BigInt->from_base("6y", 16);
```

When the base greater than 36, and no collation sequence is given, the default collation sequence contains both uppercase and lowercase letters, so the letter case in the input is not ignored:

```
$x = Math::BigInt->from_base("6S", 37);         # $x is 250
$x = Math::BigInt->from_base("6s", 37);         # $x is 276
$x = Math::BigInt->from_base("121", 3);         # $x is 16
$x = Math::BigInt->from_base("XYZ", 36);        # $x is 44027
$x = Math::BigInt->from_base("Why", 42);        # $x is 58314
```

The collation sequence can be any set of unique characters. These two cases are equivalent

```
$x = Math::BigInt->from_base("100", 2, "01");   # $x is 4
$x = Math::BigInt->from_base("|--", 2, "-|");   # $x is 4
```

- from_base_num()

  Returns a new Math::BigInt object given an array of values and a base. This method is equivalent to "from_base()", but works on numbers in an array rather than characters in a string. Unlike "from_base()", all input values may be arbitrarily large.

```
$x = Math::BigInt->from_base_num([1, 1, 0, 1], 2)     # $x is 13
$x = Math::BigInt->from_base_num([3, 125, 39], 128)   # $x is␣
↪65191
```

- bzero()

```
$x = Math::BigInt->bzero();
$x->bzero();
```

  Returns a new Math::BigInt object representing zero. If used as an instance method, assigns the value to the invocand.

- bone()

```
$x = Math::BigInt->bone();            # +1
$x = Math::BigInt->bone("+");         # +1
$x = Math::BigInt->bone("-");         # -1
$x->bone();                           # +1
$x->bone("+");                        # +1
$x->bone('-');                        # -1
```

  Creates a new Math::BigInt object representing one. The optional argument is either '-' or '+', indicating whether you want plus one or minus one. If used as an instance method, assigns the value to the invocand.

- binf()

```
$x = Math::BigInt->binf($sign);
```

Creates a new Math::BigInt object representing infinity. The optional argument is either '-' or '+', indicating whether you want infinity or minus infinity. If used as an instance method, assigns the value to the invocand.

```
$x->binf();
$x->binf('-');
```

- bnan()

```
$x = Math::BigInt->bnan();
```

Creates a new Math::BigInt object representing NaN (Not A Number). If used as an instance method, assigns the value to the invocand.

```
$x->bnan();
```

- bpi()

```
$x = Math::BigInt->bpi(100);        # 3
$x->bpi(100);                       # 3
```

Creates a new Math::BigInt object representing PI. If used as an instance method, assigns the value to the invocand. With Math::BigInt this always returns 3.

If upgrading is in effect, returns PI, rounded to N digits with the current rounding mode:

```
use Math::BigFloat;
use Math::BigInt upgrade => "Math::BigFloat";
print Math::BigInt->bpi(3), "\n";           # 3.14
print Math::BigInt->bpi(100), "\n";         # 3.1415....
```

- copy()

```
$x->copy();         # make a true copy of $x (unlike $y = $x)
```

- as_int()

```
$y = $x -> as_int();        # $y is a Math::BigInt
```

Returns $x as a Math::BigInt object regardless of upgrading and downgrading. If $x is finite, but not an integer, $x is truncated.

- as_rat()

```
$y = $x -> as_rat();        # $y is a Math::BigRat
```

Returns $x a Math::BigRat object regardless of upgrading and downgrading. The invocand is not modified.

- as_float()

```
$y = $x -> as_float();      # $y is a Math::BigFloat
```

Returns $x a Math::BigFloat object regardless of upgrading and downgrading. The invocand is not modified.

Boolean methods

None of these methods modify the invocand object.

- is_zero()

```
$x->is_zero();              # true if $x is 0
```

Returns true if the invocand is zero and false otherwise.

- is_one()

```
$x->is_one();               # true if $x is +1
$x->is_one("+");            # ditto
$x->is_one("-");            # true if $x is -1
```

Returns true if the invocand is one and false otherwise.

- is_finite()

```
$x->is_finite();    # true if $x is not +inf, -inf or NaN
```

Returns true if the invocand is a finite number, i.e., it is neither +inf, -inf, nor NaN.

- is_inf()

```
$x->is_inf();               # true if $x is +inf or -inf
$x->is_inf("+");            # true if $x is +inf
$x->is_inf("-");            # true if $x is -inf
```

Returns true if the invocand is infinite and false otherwise.

- is_nan()

```
$x->is_nan();               # true if $x is NaN
```

- is_positive()
- is_pos()

```
$x->is_positive();          # true if > 0
$x->is_pos();               # ditto
```

Returns true if the invocand is positive and false otherwise. A NaN is neither positive nor negative.

- is_negative()
- is_neg()

```
$x->is_negative();          # true if < 0
$x->is_neg();               # ditto
```

Returns true if the invocand is negative and false otherwise. A NaN is neither positive nor negative.

- is_non_positive()

```
$x->is_non_positive();      # true if <= 0
```

Returns true if the invocand is negative or zero.

- is_non_negative()

```
$x->is_non_negative();      # true if >= 0
```

Returns true if the invocand is positive or zero.

- is_odd()

```
$x->is_odd();               # true if odd, false for even
```

Returns true if the invocand is odd and false otherwise. NaN, +inf, and -inf are neither odd nor even.

- is_even()

```
$x->is_even();              # true if $x is even
```

Returns true if the invocand is even and false otherwise. NaN, +inf, -inf are not integers and are neither odd nor even.

- is_int()

```
$x->is_int();               # true if $x is an integer
```

Returns true if the invocand is an integer and false otherwise. NaN, +inf, -inf are not integers.

Comparison methods

None of these methods modify the invocand object. Note that a NaN is neither less than, greater than, or equal to anything else, even a NaN.

- bcmp()

```
$x->bcmp($y);
```

Returns -1, 0, 1 depending on whether $x is less than, equal to, or grater than $y. Returns undef if any operand is a NaN.

- bacmp()

```
$x->bacmp($y);
```

Returns -1, 0, 1 depending on whether the absolute value of $x is less than, equal to, or grater than the absolute value of $y. Returns undef if any operand is a NaN.

- beq()

```
$x -> beq($y);
```

Returns true if and only if $x is equal to $y, and false otherwise.

- bne()

```
$x -> bne($y);
```

Returns true if and only if $x is not equal to $y, and false otherwise.

- blt()

```
$x -> blt($y);
```

Returns true if and only if $x is equal to $y, and false otherwise.

- ble()

```
$x -> ble($y);
```

Returns true if and only if $x is less than or equal to $y, and false otherwise.

- bgt()

```
$x -> bgt($y);
```

Returns true if and only if $x is greater than $y, and false otherwise.

- bge()

```
$x -> bge($y);
```

Returns true if and only if $x is greater than or equal to $y, and false otherwise.

Arithmetic methods

These methods modify the invocand object and returns it.

- bneg()

```
$x->bneg();
```

Negate the number, e.g. change the sign between '+' and '-', or between '+inf' and '-inf', respectively. Does nothing for NaN or zero.

- babs()

```
$x->babs();
```

Set the number to its absolute value, e.g. change the sign from '-' to '+' and from '-inf' to '+inf', respectively. Does nothing for NaN or positive numbers.

- bsgn()

```
$x->bsgn();
```

Signum function. Set the number to -1, 0, or 1, depending on whether the number is negative, zero, or positive, respectively. Does not modify NaNs.

- bnorm()

```
$x->bnorm();                    # normalize (no-op)
```

Normalize the number. This is a no-op and is provided only for backwards compatibility.

- binc()

```
$x->binc();                     # increment x by 1
```

- bdec()

```
$x->bdec();                     # decrement x by 1
```

- badd()

```
$x->badd($y);                   # addition (add $y to $x)
```

- bsub()

```
$x->bsub($y);                   # subtraction (subtract $y from $x)
```

- bmul()

```
$x->bmul($y);                   # multiplication (multiply $x by $y)
```

- bdiv()

```
$x->bdiv($y);                   # set $x to quotient
($q, $r) = $x->bdiv($y);        # also return remainder
```

The behaviour of “bdiv()” and “bmod()” is based on Perl’s % operator, which is the remainder after performing floored division.

Because of this, “bdiv()” and “bmod()” are aliases for “bfdiv()” and “bfmod()”, respectively.

- bmod()

```
$x->bmod($y);                   # modulus (x % y)
```

This is an alias for “bfmod()”.

- bfdiv()

```
$x->bfdiv($y);                  # return quotient
($q, $r) = $x->bfdiv($y);       # return quotient and remainder
```

Divides $x by $y by doing floored division (F-division), where the quotient is the floored (rounded towards negative infinity) quotient of the two operands. In list context, returns the quotient and the remainder. In scalar context, only the quotient is returned.

```
$q = floor($x / $y)          # quotient
$r = $x - $q * $y            # remainder
```

With F-division, the remainder is either zero or has the same sign as the divisor.

```
 7 /  4 => ( 1,  3)
-7 /  4 => (-2,  1)
-7 / -4 => ( 1, -3)
 7 / -4 => (-2, -1)
```

The behavior of the overloaded operator % agrees with the behavior of Perl's built-in % operator (as documented in the perlop manpage), and the equation

```
$x == ($x / $y) * $y + ($x % $y)
```

holds true for any finite $x and finite, non-zero $y.

Perl's "use integer" might change the behaviour of % and / for scalars. This is because under 'use integer' Perl does what the underlying C library thinks is right, and this varies. However, "use integer" does not change the way things are done with Math::BigInt objects.

- bfmod()

```
$x->bfmod($y);               # floored modulus (x % y)
```

Returns $x modulo $y, i.e., the remainder after floored division (F-division). This method is like Perl's % operator. See "bfdiv()".

- btdiv()

```
$x->btdiv($y);               # divide, set $x to quotient
```

Divides $x by $y by doing truncated division (T-division), where quotient is the truncated (rouneded towards zero) quotient of the two operands. In list context, returns the quotient and the remainder. The remainder is either zero or has the same sign as the first operand. In scalar context, only the quotient is returned.

- btmod()

```
$x->btmod($y);               # modulus
```

Returns the remainer after truncated division (T-division). See "btdiv()".

- binv()

```
$x->binv();
```

Invert the value of $x, i.e., compute 1/$x.

- bsqrt()

```
$x->bsqrt();                    # calculate square root
```

Returns the square root truncated to an integer.

If you want a better approximation of the square root, then use:

```
$x = Math::BigFloat->new(12);
Math::BigFloat->precision(0);
Math::BigFloat->round_mode("even");
print $x->copy->bsqrt(),"\n";           # 4

Math::BigFloat->precision(2);
print $x->bsqrt(),"\n";                 # 3.46
print $x->bsqrt(3),"\n";                # 3.464
```

- bpow()

```
$x->bpow($y);                   # power of arguments (x ** y)
```

Returns $x raised to the power of $y. The first two modifies $x, the last one doesn't:

```
print $x->bpow($i),"\n";        # modifies $x
print $x **= $i,"\n";           # ditto
print $x ** $i,"\n";            # leaves $x alone
```

The form `$x **= $y` is faster than `$x = $x ** $y;`, though.

- broot()

```
$x->broot($N);
```

Calculates the $N'th root of `$x`.

- bmuladd()

```
$x->bmuladd($y,$z);
```

Multiply $x by $y, and then add $z to the result,

This method was added in v1.88 of Math::BigInt.

- bmodpow()

```
$num->bmodpow($exp,$mod);           # modular exponentiation
                                    # ($num**$exp % $mod)
```

Returns the value of `$num` taken to the power `$exp` in the modulus `$mod` using binary exponentiation. `bmodpow` is far superior to writing

```
$num ** $exp % $mod
```

because it is much faster - it reduces internal variables into the modulus whenever possible, so it operates on smaller numbers.

`bmodpow` also supports negative exponents.

```
bmodpow($num, -1, $mod)
```

is exactly equivalent to

```
bmodinv($num, $mod)
```

- bmodinv()

```
$x->bmodinv($mod);          # modular multiplicative inverse
```

Returns the multiplicative inverse of $x modulo $mod. If

```
$y = $x -> copy() -> bmodinv($mod)
```

then $y is the number closest to zero, and with the same sign as $mod, satisfying

```
($x * $y) % $mod = 1 % $mod
```

If $x and $y are non-zero, they must be relative primes, i.e., bgcd($y, $mod)==1. 'NaN' is returned when no modular multiplicative inverse exists.

- blog()

```
$x->blog($base, $accuracy);         # logarithm of x to the
↪base $base
```

If $base is not defined, Euler's number (e) is used:

```
print $x->blog(undef, 100);         # log(x) to 100 digits
```

- bexp()

```
$x->bexp($accuracy);                # calculate e ** X
```

Calculates the expression e ** $x where e is Euler's number.

This method was added in v1.82 of Math::BigInt (April 2007).

See also "blog()".

- bilog2()

Base 2 logarithm rounded down towards the nearest integer.

```
$x->bilog2();               # int(log2(x)) = int(log(x)/log(2))
```

In list context a second argument is returned. This is 1 if the result is exact, i.e., the input is an exact power of 2, and 0 otherwise.

- bilog10()

Base 10 logarithm rounded down towards the nearest integer.

```
$x->bilog10();              # int(log10(x)) = int(log(x)/
↪log(10))
```

In list context a second argument is returned. This is 1 if the result is exact, i.e., the input is an exact power of 10, and 0 otherwise.

- bclog2()

  Base 2 logarithm rounded up towards the nearest integer.

```
$x->bclog2();               # ceil(log2(x)) = ceil(log(x)/
 ↪log(2))
```

  In list context a second argument is returned. This is 1 if the result is exact, i.e., the input is an exact power of 2, and 0 otherwise.

- bclog10()

  Base 10 logarithm rounded up towards the nearest integer.

```
$x->bclog10();              # ceil(log10(x)) = ceil(log(x)/
 ↪log(10))
```

  In list context a second argument is returned. This is 1 if the result is exact, i.e., the input is an exact power of 10, and 0 otherwise.

- bnok()

  Combinations.

```
$n->bnok($k);               # binomial coefficient n over k
```

  Calculates the binomial coefficient n over k, also called the "choose" function, which is the number of ways to choose a sample of k elements from a set of n distinct objects where order does not matter and replacements are not allowed. The result is equivalent to

```
          / n \      n!
C(n, k) = |   | = --------  where 0 <= k <= n
          \ k /   k!(n-k)!
```

  when n and k are non-negative. This method implements the full Kronenburg extension (Kronenburg, M.J. "The Binomial Coefficient for Negative Arguments." 18 May 2011. http://arxiv.org/abs/1105.3689/) illustrated by the following pseudo-code:

```
if n >= 0 and k >= 0:
    return binomial(n, k)
if k >= 0:
    return (-1)^k*binomial(-n+k-1, k)
if k <= n:
    return (-1)^(n-k)*binomial(-k-1, n-k)
else
    return 0
```

  The behaviour is identical to the behaviour of the Maple and Mathematica function for negative integers n, k.

- bperm()

  Permutations

```
$n->bperm($k);
```

Calculates the number of ways to choose a sample of k elements from a set of n distinct objects where order does matter and replacements are not allowed.

```
            n!
P(n, k) = ------  where 0 <= k <= n
          (n-k)!
```

- bhyperop()
- hyperop()

```
$a -> bhyperop($n, $b);          # modifies $a
$x = $a -> hyperop($n, $b);      # does not modify $a
```

H_n(a, b) = a[n]b is the _n_th hyperoperator,

```
n = 0 : succession (b + 1)
n = 1 : addition (a + b)
n = 2 : multiplication (a * b)
n = 3 : exponentiation (a ** b)
n = 4 : tetration (a ** a ** ... ** a) (b occurrences of a)
...

                    / b+1                       if n = 0
                    | a                         if n = 1 and b = 0
H_n(a, b) = a[n]b = | 0                         if n = 2 and b = 0
                    | 1                         if n >= 3 and b =␣
 ↪0
                    \ H_(n-1)(a, H_n(a, b-1)) otherwise
```

Note that the result can be a very large number, even for small operands. Also note that the backend library `Math::BigInt::GMP` silently returns the incorrect result when the numbers are larger than it can handle. It is better to use `Math::BigInt::GMPz` or `Math::BigInt::Pari`; they throw an error if they can't handle the number.

See also "buparrow()", https://en.wikipedia.org/wiki/Hyperoperation.

- buparrow()
- uparrow()

```
$a -> buparrow($n, $b);          # modifies $a
$x = $a -> uparrow($n, $b);      # does not modify $a
```

This method implements Knuth's up-arrow notation, where $n is a non-negative integer representing the number of up-arrows. $n = 0 gives multiplication, $n = 1 gives exponentiation, $n = 2 gives tetration, $n = 3 gives hexation etc. The following illustrates the relation between the first values of $n.

The "buparrow()" method is equivalent to the "bhyperop()" method with an offset of two. The following two give the same result:

```
$x -> buparrow($n, $b);
$x -> bhyperop($n + 2, $b);
```

See also "bhyperop()", https://en.wikipedia.org/wiki/Knuth%27s_up-arrow_notation.

- backermann()
- ackermann()

```
$m -> backermann($n);           # modifies $a
$x = $m -> ackermann($n);       # does not modify $a
```

This method implements the Ackermann function:

```
          / n + 1               if m = 0
A(m, n) = | A(m-1, 1)           if m > 0 and n = 0
          \ A(m-1, A(m, n-1))   if m > 0 and n > 0
```

Its value grows rapidly, even for small inputs. For example, A(4, 2) is an integer of 19729 decimal digits.

See https://en.wikipedia.org/wiki/Ackermann_function

- bsin()

```
my $x = Math::BigInt->new(1);
print $x->bsin(100), "\n";
```

Calculate the sine of $x, modifying $x in place.

In Math::BigInt, unless upgrading is in effect, the result is truncated to an integer.

This method was added in v1.87 of Math::BigInt (June 2007).

- bcos()

```
my $x = Math::BigInt->new(1);
print $x->bcos(100), "\n";
```

Calculate the cosine of $x, modifying $x in place.

In Math::BigInt, unless upgrading is in effect, the result is truncated to an integer.

This method was added in v1.87 of Math::BigInt (June 2007).

- batan()

```
my $x = Math::BigFloat->new(0.5);
print $x->batan(100), "\n";
```

Calculate the arcus tangens of $x, modifying $x in place.

In Math::BigInt, unless upgrading is in effect, the result is truncated to an integer.

This method was added in v1.87 of Math::BigInt (June 2007).

- batan2()

```
my $x = Math::BigInt->new(1);
my $y = Math::BigInt->new(1);
print $y->batan2($x), "\n";
```

Calculate the arcus tangens of $y divided by $x, modifying $y in place.

In Math::BigInt, unless upgrading is in effect, the result is truncated to an integer.

This method was added in v1.87 of Math::BigInt (June 2007).

- bfac()

```
$x->bfac();               # factorial of $x
```

Returns the factorial of $x, i.e., $x*($x-1)*($x-2)*...*2*1, the product of all positive integers up to and including $x. $x must be > -1. The factorial of N is commonly written as N!, or N!1, when using the multifactorial notation.

- bdfac()

```
$x->bdfac();                # double factorial of $x
```

Returns the double factorial of $x, i.e., $x*($x-2)*($x-4)*... $x must be > -2. The double factorial of N is commonly written as N!!, or N!2, when using the multifactorial notation.

- btfac()

```
$x->btfac();               # triple factorial of $x
```

Returns the triple factorial of $x, i.e., $x*($x-3)*($x-6)*... $x must be > -3. The triple factorial of N is commonly written as N!!!, or N!3, when using the multifactorial notation.

- bmfac()

```
$x->bmfac($k);           # $k'th multifactorial of $x
```

Returns the multi-factorial of $x, i.e., $x*($x-$k)*($x-2*$k)*... $x must be > -$k. The multi-factorial of N is commonly written as N!K.

- bfib()

```
$F = $n->bfib();            # a single Fibonacci number
@F = $n->bfib();            # a list of Fibonacci numbers
```

In scalar context, returns a single Fibonacci number. In list context, returns a list of Fibonacci numbers. The invocand is the last element in the output.

The Fibonacci sequence is defined by

```
F(0) = 0
F(1) = 1
F(n) = F(n-1) + F(n-2)
```

In list context, F(0) and F(n) is the first and last number in the output, respectively. For example, if $n is 12, then `@F = $n->bfib()` returns the following values, F(0) to F(12):

```
0, 1, 1, 2, 3, 5, 8, 13, 21, 34, 55, 89, 144
```

The sequence can also be extended to negative index n using the re-arranged recurrence relation

```
F(n-2) = F(n) - F(n-1)
```

giving the bidirectional sequence

```
  n  -7  -6  -5  -4  -3  -2  -1   0   1   2   3   4   5   6   7
F(n)  13  -8   5  -3   2  -1   1   0   1   1   2   3   5   8  13
```

If $n is -12, the following values, F(0) to F(12), are returned:

```
0, 1, -1, 2, -3, 5, -8, 13, -21, 34, -55, 89, -144
```

- blucas()

```
$F = $n->blucas();          # a single Lucas number
@F = $n->blucas();          # a list of Lucas numbers
```

In scalar context, returns a single Lucas number. In list context, returns a list of Lucas numbers. The invocand is the last element in the output.

The Lucas sequence is defined by

```
L(0) = 2
L(1) = 1
L(n) = L(n-1) + L(n-2)
```

In list context, L(0) and L(n) is the first and last number in the output, respectively. For example, if $n is 12, then `@L = $n->blucas()` returns the following values, L(0) to L(12):

```
2, 1, 3, 4, 7, 11, 18, 29, 47, 76, 123, 199, 322
```

The sequence can also be extended to negative index n using the re-arranged recurrence relation

```
L(n-2) = L(n) - L(n-1)
```

giving the bidirectional sequence

```
  n  -7  -6  -5  -4  -3  -2  -1   0   1   2   3   4   5   6   7
L(n)  29 -18  11  -7   4  -3   1   2   1   3   4   7  11  18  29
```

If $n is -12, the following values, L(0) to L(-12), are returned:

```
2, 1, -3, 4, -7, 11, -18, 29, -47, 76, -123, 199, -322
```

- blsft()

  Left shift.

```
$x->blsft($n);               # left shift $n places in base 2
$x->blsft($n, $b);           # left shift $n places in base $b
```

  The latter is equivalent to

```
$x -> bmul($b -> copy() -> bpow($n));
```

- brsft()

  Right shift.

```
$x->brsft($n);               # right shift $n places in base 2
$x->brsft($n, $b);           # right shift $n places in base $b
```

  The latter is equivalent to

```
$x -> bdiv($b -> copy() -> bpow($n));
```

Bitwise methods

For all bitwise methods, the operands are truncated to integers, i.e., rounded towards zero, if necessary, before the method is applied. The bitwise methods never upgrade, and they always return an integer.

- bblsft()

  Bitwise left shift. This is equivalent to Perl's << operator.

```
$x -> bblsft($n);            # left shift $n places in base 2
```

  If $n is negative, the shifting is done in the opposite direction, so these two are equivalent for all $x and $n

```
$y = $x -> bblsft($n);
$y = $x -> bbrsft(-$n);
```

  and also equivalent to

```
$y = $x -> bmul(ref($x) -> new(2) -> bpow($n));   # if $n > 0
$y = $x -> bdiv(ref($x) -> new(2) -> bpow($n));   # if $n < 0
```

- bbrsft()

  Bitwise right shift. This is equivalent to Perl's >> operator.

```
$x -> bbrsft($n);            # right shift $n places in base 2
```

  If $n is negative, the shifting is done in the opposite direction, so these two are equivalent for all $x and $n

```
$y = $x -> bbrsft($n);
$y = $x -> bblsft(-$n);
```

and also equivalent to

```
$y = $x -> bdiv(ref($x) -> new(2) -> bpow($n));   # if $n > 0
$y = $x -> bmul(ref($x) -> new(2) -> bpow(-$n));  # if $n < 0
```

- band()

```
$x->band($y);                 # bitwise and
```

- bior()

```
$x->bior($y);                 # bitwise inclusive or
```

- bxor()

```
$x->bxor($y);                 # bitwise exclusive or
```

- bnot()

```
$x->bnot();                   # bitwise not (two's complement)
```

Two's complement (bitwise not). This is equivalent to, but faster than,

```
$x->binc()->bneg();
```

Rounding methods

- round()

```
$x->round($A,$P,$round_mode);
```

Round $x to accuracy $A or precision $P using the round mode $round_mode.

- bround()

```
$x->bround($N);               # accuracy: preserve $N digits
```

Rounds $x to an accuracy of $N digits.

- bfround()

```
$x->bfround($N);
```

Rounds to a multiple of 10**$N. Examples:

```
Input           N          Result

123456.123456   3          123500
123456.123456   2          123450
```

(continues on next page)

(continued from previous page)

```
123456.123456   -2          123456.12
123456.123456   -3          123456.123
```

- bfloor()

```
$x->bfloor();
```

Round $x towards minus infinity, i.e., set $x to the largest integer less than or equal to $x.

- bceil()

```
$x->bceil();
```

Round $x towards plus infinity, i.e., set $x to the smallest integer greater than or equal to $x.

- bint()

```
$x->bint();
```

Round $x towards zero.

Other mathematical methods

- bgcd()

```
$x -> bgcd($y);             # GCD of $x and $y
$x -> bgcd($y, $z, ...);    # GCD of $x, $y, $z, ...
```

Returns the greatest common divisor (GCD), which is the largest positive integer that divides each of the operands.

- blcm()

```
$x -> blcm($y);             # LCM of $x and $y
$x -> blcm($y, $z, ...);    # LCM of $x, $y, $z, ...
```

Returns the least common multiple (LCM).

Object property methods

- sign()

```
$x->sign();
```

Return the sign, of $x, meaning either +, -, -inf, +inf or NaN.

If you want $x to have a certain sign, use one of the following methods:

```
$x->babs();                 # '+'
$x->babs()->bneg();         # '-'
```

(continues on next page)

(continued from previous page)

```
$x->bnan();                    # 'NaN'
$x->binf();                    # '+inf'
$x->binf('-');                 # '-inf'
```

- digit()

```
$x->digit($n);       # return the nth digit, counting from right
```

If $n is negative, returns the digit counting from left.

- bdigitsum()

```
$x->bdigitsum();
```

Computes the sum of the base 10 digits and assigns the result to the invocand.

- digitsum()

```
$x->digitsum();
```

Computes the sum of the base 10 digits and returns it.

- length()

```
$x->length();
($xl, $fl) = $x->length();
```

Returns the number of digits in the decimal representation of the number. In list context, returns the length of the integer and fraction part. For Math::BigInt objects, the length of the fraction part is always 0.

The following probably doesn't do what you expect:

```
$c = Math::BigInt->new(123);
print $c->length(),"\n";                # prints 30
```

It prints both the number of digits in the number and in the fraction part since print calls "length()" in list context. Use something like:

```
print scalar $c->length(),"\n";         # prints 3
```

- mantissa()

```
$x->mantissa();
```

Return the signed mantissa of $x as a Math::BigInt.

- exponent()

```
$x->exponent();
```

Return the exponent of $x as a Math::BigInt.

- parts()

```
$x->parts();
```

Returns the significand (mantissa) and the exponent as integers. In Math::BigFloat, both are returned as Math::BigInt objects.

- sparts()

  Returns the significand (mantissa) and the exponent as integers. In scalar context, only the significand is returned. The significand is the integer with the smallest absolute value. The output of "sparts()" corresponds to the output from "bsstr()".

  In Math::BigInt, this method is identical to "parts()".

- nparts()

  Returns the significand (mantissa) and exponent corresponding to normalized notation. In scalar context, only the significand is returned. For finite non-zero numbers, the significand's absolute value is greater than or equal to 1 and less than 10. The output of "nparts()" corresponds to the output from "bnstr()". In Math::BigInt, if the significand can not be represented as an integer, upgrading is performed or NaN is returned.

- eparts()

  Returns the significand (mantissa) and exponent corresponding to engineering notation. In scalar context, only the significand is returned. For finite non-zero numbers, the significand's absolute value is greater than or equal to 1 and less than 1000, and the exponent is a multiple of 3. The output of "eparts()" corresponds to the output from "bestr()". In Math::BigInt, if the significand can not be represented as an integer, upgrading is performed or NaN is returned.

- dparts()

  Returns the integer part and the fraction part. If the fraction part can not be represented as an integer, upgrading is performed or NaN is returned. The output of "dparts()" corresponds to the output from "bdstr()".

- fparts()

  Returns the smallest possible numerator and denominator so that the numerator divided by the denominator gives back the original value. For finite numbers, both values are integers. Mnemonic: fraction.

- numerator()

  Together with "denominator()", returns the smallest integers so that the numerator divided by the denominator reproduces the original value. With Math::BigInt, "numerator()" simply returns a copy of the invocand.

- denominator()

  Together with "numerator()", returns the smallest integers so that the numerator divided by the denominator reproduces the original value. With Math::BigInt, "denominator()" always returns either a 1 or a NaN.

String conversion methods

- bstr()

  Returns a string representing the number using decimal notation. In Math::BigFloat, the output is zero padded according to the current accuracy or precision, if any of those are defined.

- bsstr()

  Returns a string representing the number using scientific notation where both the significand (mantissa) and the exponent are integers. The output corresponds to the output from "sparts()".

```
  123 is returned as "123e+0"
 1230 is returned as "123e+1"
12300 is returned as "123e+2"
12000 is returned as "12e+3"
10000 is returned as "1e+4"
```

- bnstr()

  Returns a string representing the number using normalized notation, the most common variant of scientific notation. For finite non-zero numbers, the absolute value of the significand is greater than or equal to 1 and less than 10. The output corresponds to the output from "nparts()".

```
  123 is returned as "1.23e+2"
 1230 is returned as "1.23e+3"
12300 is returned as "1.23e+4"
12000 is returned as "1.2e+4"
10000 is returned as "1e+4"
```

- bestr()

  Returns a string representing the number using engineering notation. For finite non-zero numbers, the absolute value of the significand is greater than or equal to 1 and less than 1000, and the exponent is a multiple of 3. The output corresponds to the output from "eparts()".

```
  123 is returned as "123e+0"
 1230 is returned as "1.23e+3"
12300 is returned as "12.3e+3"
12000 is returned as "12e+3"
10000 is returned as "10e+3"
```

- bdstr()

  Returns a string representing the number using decimal notation. The output corresponds to the output from "dparts()".

```
  123 is returned as "123"
 1230 is returned as "1230"
12300 is returned as "12300"
```

(continues on next page)

(continued from previous page)

```
12000 is returned as "12000"
10000 is returned as "10000"
```

- bfstr()

  Returns a string representing the number using fractional notation. The output corresponds to the output from "fparts()".

```
    12.345 is returned as "2469/200"
   123.45 is returned as "2469/20"
  1234.5 is returned as "2469/2"
 12345 is returned as "12345"
123450 is returned as "123450"
```

- to_hex()

```
$x->to_hex();
```

  Returns a hexadecimal string representation of the number. See also "from_hex()".

- to_oct()

```
$x->to_oct();
```

  Returns an octal string representation of the number. See also "from_oct()".

- to_bin()

```
$x->to_bin();
```

  Returns a binary string representation of the number. See also "from_bin()".

- to_bytes()

```
$x = Math::BigInt->new("1667327589");
$s = $x->to_bytes();                    # $s = "cafe"
```

  Returns a byte string representation of the number using big endian byte order. The invocand must be a non-negative, finite integer. See also "from_bytes()".

- to_ieee754()

  See *"to_ieee754()" in Math::BigFloat*.

- to_fp80()

  See *"to_fp80()" in Math::BigFloat*.

- to_base()

```
$x = Math::BigInt->new("250");
$x->to_base(2);     # returns "11111010"
$x->to_base(8);     # returns "372"
$x->to_base(16);    # returns "fa"
```

Returns a string representation of the number in the given base. If a collation sequence is given, the collation sequence determines which characters are used in the output.

Here are some more examples

```
$x = Math::BigInt->new("16")->to_base(3);       # returns "121"
$x = Math::BigInt->new("44027")->to_base(36);   # returns "XYZ"
$x = Math::BigInt->new("58314")->to_base(42);   # returns "Why"
$x = Math::BigInt->new("4")->to_base(2, "-|");  # returns "|--"
```

If the collation sequence are the bytes from "\x00" to "\xff", and the base is 256, then "to_base()" returns the same output as "to_bytes()". In the following example, $x and $y are identical:

```
$cs = join "", map chr, 0 .. 255;  # collation sequence
$x = Math::BigInt -> to_base("1230129310", 256, $cs)
$y = Math::BigInt -> to_bytes("1230129310");
```

See "from_base()" for information and examples.

- to_base_num()

  Converts the given number to the given base. This method is equivalent to "to_base()", but returns numbers in an array rather than characters in a string. In the output, the first element is the most significant.

```
$x = Math::BigInt->new(13);          # decimal 13 is binary 1101
$x->to_base_num(2);                  # returns [1, 1, 0, 1]

$x = Math::BigInt->new(65191);
$x->to_base_num(128);                # returns [3, 125, 39]
```

- as_hex()

```
$x->as_hex();
```

  As, "to_hex()", but with a "0x" prefix.

- as_oct()

```
$x->as_oct();
```

  As, "to_oct()", but with a "0" prefix.

- as_bin()

```
$x->as_bin();
```

  As, "to_bin()", but with a "0b" prefix.

- as_bytes()

  This is an alias for "to_bytes()".

Other conversion methods

- numify()

```
print $x->numify();
```

  Returns a Perl scalar from $x. It is used automatically whenever a scalar is needed, for instance in array index operations.

Utility methods

These utility methods are made public

- dec_str_to_dec_flt_str()

  Takes a string representing any valid number using decimal notation and converts it to a string representing the same number using decimal floating point notation. The output consists of five parts joined together: the sign of the significand, the absolute value of the significand as the smallest possible integer, the letter “e”, the sign of the exponent, and the absolute value of the exponent. If the input is invalid, nothing is returned.

```
$str2 = $class -> dec_str_to_dec_flt_str($str1);
```

  Some examples

```
Input           Output
31400.00e-4     +314e-2
-0.00012300e8   -123e+2
0               +0e+0
```

- hex_str_to_dec_flt_str()

  Takes a string representing any valid number using hexadecimal notation and converts it to a string representing the same number using decimal floating point notation. The output has the same format as that of “dec_str_to_dec_flt_str()”.

```
$str2 = $class -> hex_str_to_dec_flt_str($str1);
```

  Some examples

```
Input           Output
0xff            +255e+0
```

  Some examples

- oct_str_to_dec_flt_str()

  Takes a string representing any valid number using octal notation and converts it to a string representing the same number using decimal floating point notation. The output has the same format as that of “dec_str_to_dec_flt_str()”.

```
$str2 = $class -> oct_str_to_dec_flt_str($str1);
```

- bin_str_to_dec_flt_str()

Takes a string representing any valid number using binary notation and converts it to a string representing the same number using decimal floating point notation. The output has the same format as that of "dec_str_to_dec_flt_str()".

```
$str2 = $class -> bin_str_to_dec_flt_str($str1);
```

- dec_str_to_dec_str()

  Takes a string representing any valid number using decimal notation and converts it to a string representing the same number using decimal notation. If the number represents an integer, the output consists of a sign and the absolute value. If the number represents a non-integer, the output consists of a sign, the integer part of the number, the decimal point ".", and the fraction part of the number without any trailing zeros. If the input is invalid, nothing is returned.

- hex_str_to_dec_str()

  Takes a string representing any valid number using hexadecimal notation and converts it to a string representing the same number using decimal notation. The output has the same format as that of "dec_str_to_dec_str()".

- oct_str_to_dec_str()

  Takes a string representing any valid number using octal notation and converts it to a string representing the same number using decimal notation. The output has the same format as that of "dec_str_to_dec_str()".

- bin_str_to_dec_str()

  Takes a string representing any valid number using binary notation and converts it to a string representing the same number using decimal notation. The output has the same format as that of "dec_str_to_dec_str()".

ACCURACY AND PRECISION

Math::BigInt and Math::BigFloat have full support for accuracy and precision based rounding, both automatically after every operation, as well as manually.

This section describes the accuracy/precision handling in Math::BigInt and Math::BigFloat as it used to be and as it is now, complete with an explanation of all terms and abbreviations.

Not yet implemented things (but with correct description) are marked with '!', things that need to be answered are marked with '?'.

In the next paragraph follows a short description of terms used here (because these may differ from terms used by others people or documentation).

During the rest of this document, the shortcuts A (for accuracy), P (for precision), R (rounding mode), and F (fallback) are be used.

Accuracy A

Number of significant digits. Leading zeros are not counted. A number may have an accuracy greater than the non-zero digits when there are zeros in it or trailing zeros. For example, 123.456 has A of 6, 10203 has 5, 123.0506 has 7, 123.45000 has 8 and 0.000123 has 3.

The string output (of floating point numbers) is padded with zeros:

```
Initial value    P      A       Result          String
------------------------------------------------------------
1234.01                 3       1230            1230
1234.01                 6       1234.01         1234.01
1234.1                  8       1234.1          1234.1000
```

For Math::BigInt objects, no padding occurs.

Precision P

Precision is a fixed number of digits before (positive) or after (negative) the decimal point. For example, 123.45 has a precision of -2. 0 means an integer like 123 (or 120). A precision of 2 means at least two digits to the left of the decimal point are zero, so 123 with P = 1 becomes 120. Note that numbers with zeros before the decimal point may have different precisions, because 1200 can have P = 0, 1 or 2 (depending on what the initial value was). It could also have p < 0, when the digits after the decimal point are zero.

The string output (of floating point numbers) is padded with zeros:

```
Initial value    P      A       Result          String
------------------------------------------------------------
1234.01         -3              1000            1000
1234            -2              1200            1200
1234.5          -1              1230            1230
1234.001         1              1234            1234.0
1234.01          0              1234            1234
1234.01          2              1234.01         1234.01
1234.01          5              1234.01         1234.01000
```

For Math::BigInt objects, no padding occurs.

Rounding mode R

When rounding a number, different 'styles' or 'kinds' of rounding are possible. (Note that random rounding, as in Math::Round, is not implemented.)

Directed rounding

These round modes always round in the same direction.

- 'trunc'

  Round towards zero. Remove all digits following the rounding place, i.e., replace them with zeros. Thus, 987.65 rounded to tens (P=1) becomes 980, and rounded to the fourth significant digit becomes 987.6 (A=4). 123.456 rounded to the second place after the decimal point (P=-2) becomes 123.46. This corresponds to the IEEE 754 rounding mode 'roundTowardZero'.

Rounding to nearest

These rounding modes round to the nearest digit. They differ in how they determine which way to round in the ambiguous case when there is a tie.

- 'even'

  Round towards the nearest even digit, e.g., when rounding to nearest integer, -5.5 becomes -6, 4.5 becomes 4, but 4.501 becomes 5. This corresponds to the IEEE 754 rounding mode 'roundTiesToEven'.

- 'odd'

  Round towards the nearest odd digit, e.g., when rounding to nearest integer, 4.5 becomes 5, -5.5 becomes -5, but 5.501 becomes 6. This corresponds to the IEEE 754 rounding mode 'roundTiesToOdd'.

- '+inf'

  Round towards plus infinity, i.e., always round up. E.g., when rounding to the nearest integer, 4.5 becomes 5, -5.5 becomes -5, and 4.501 also becomes 5. This corresponds to the IEEE 754 rounding mode 'roundTiesToPositive'.

- '-inf'

  Round towards minus infinity, i.e., always round down. E.g., when rounding to the nearest integer, 4.5 becomes 4, -5.5 becomes -6, but 4.501 becomes 5. This corresponds to the IEEE 754 rounding mode 'roundTiesToNegative'.

- 'zero'

  Round towards zero, i.e., round positive numbers down and negative numbers up. E.g., when rounding to the nearest integer, 4.5 becomes 4, -5.5 becomes -5, but 4.501 becomes 5. This corresponds to the IEEE 754 rounding mode 'roundTiesToZero'.

- 'common'

  Round away from zero, i.e., round to the number with the largest absolute value. E.g., when rounding to the nearest integer, -1.5 becomes -2, 1.5 becomes 2 and 1.49 becomes 1. This corresponds to the IEEE 754 rounding mode 'roundTiesToAway'.

Fallback F

When neither A nor P are defined, the fallback accuracy is used when computing values that would potentially give an infinite number of digits, e.g., division, roots, logarithms, trigonometric functions etc.

More details on rounding

The handling of A & P in MBI/MBF (the old core code shipped with Perl versions <= 5.7.2) is like this:

- Precision

```
* bfround($p) is able to round to $p number of digits after the␣
↪decimal
```

(continues on next page)

(continued from previous page)

```
  point
* otherwise P is unused
```

- Accuracy (significant digits)

```
 * bround($a) rounds to $a significant digits
 * only bdiv() and bsqrt() take A as (optional) parameter
   + other operations simply create the same number (bneg etc), or
     more (bmul) of digits
   + rounding/truncating is only done when explicitly calling one
     of bround or bfround, and never for Math::BigInt (not implemented)
 * bsqrt() simply hands its accuracy argument over to bdiv.
 * the documentation and the comment in the code indicate two
   different ways on how bdiv() determines the maximum number
   of digits it should calculate, and the actual code does yet
   another thing
   POD:
     max($Math::BigFloat::div_scale, length(dividend)+length(divisor))
   Comment:
     result has at most max(scale, length(dividend), length(divisor)) digits
   Actual code:
     scale = max(scale, length(dividend)-1,length(divisor)-1);
     scale += length(divisor) - length(dividend);
   So for lx = 3, ly = 9, scale = 10, scale will actually be 16 (10
   So for lx = 3, ly = 9, scale = 10, scale will actually be 16
   (10+9-3). Actually, the 'difference' added to the scale is cal-
   culated from the number of "significant digits" in dividend and
   divisor, which is derived by looking at the length of the man-
   tissa. Which is wrong, since it includes the + sign (oops) and
   actually gets 2 for '+100' and 4 for '+101'. Oops again. Thus
   124/3 with div_scale=1 will get you '41.3' based on the strange
   assumption that 124 has 3 significant digits, while 120/7 will
   get you '17', not '17.1' since 120 is thought to have 2 signif-
   icant digits. The rounding after the division then uses the
   remainder and $y to determine whether it must round up or down.
```

(continues on next page)

(continued from previous page)

```
?  I have no idea which is the right way. That's why I used a␣
↪slightly more
?  simple scheme and tweaked the few failing testcases to match␣
↪it.
```

This is how it works now:

- Setting/Accessing

```
* You can set the A global via Math::BigInt->accuracy() or
  Math::BigFloat->accuracy() or whatever class you are using.
* You can also set P globally by using Math::SomeClass->
↪precision()
  likewise.
* Globals are classwide, and not inherited by subclasses.
* to undefine A, use Math::SomeClass->accuracy(undef);
* to undefine P, use Math::SomeClass->precision(undef);
* Setting Math::SomeClass->accuracy() clears automatically
  Math::SomeClass->precision(), and vice versa.
* To be valid, A must be > 0, P can have any value.
* If P is negative, this means round to the P'th place to the␣
↪right of the
  decimal point; positive values mean to the left of the␣
↪decimal point.
  P of 0 means round to integer.
* to find out the current global A, use Math::SomeClass->
↪accuracy()
* to find out the current global P, use Math::SomeClass->
↪precision()
* use $x->accuracy() respective $x->precision() for the local
  setting of $x.
* Please note that $x->accuracy() respective $x->precision()
  return eventually defined global A or P, when $x's A or P is␣
↪not
  set.
```

- Creating numbers

```
* When you create a number, you can give the desired A or P via:
  $x = Math::BigInt->new($number,$A,$P);
* Only one of A or P can be defined, otherwise the result is NaN
* If no A or P is give ($x = Math::BigInt->new($number) form),␣
↪then the
  globals (if set) will be used. Thus changing the global␣
↪defaults later on
  will not change the A or P of previously created numbers (i.e.
↪, A and P of
  $x will be what was in effect when $x was created)
* If given undef for A and P, NO rounding will occur, and the␣
↪globals will
```

(continues on next page)

(continued from previous page)

```
  NOT be used. This is used by subclasses to create numbers␣
↪without
  suffering rounding in the parent. Thus a subclass is able to␣
↪have its own
  globals enforced upon creation of a number by using
  $x = Math::BigInt->new($number,undef,undef):

      use Math::BigInt::SomeSubclass;
      use Math::BigInt;

      Math::BigInt->accuracy(2);
      Math::BigInt::SomeSubclass->accuracy(3);
      $x = Math::BigInt::SomeSubclass->new(1234);

  $x is now 1230, and not 1200. A subclass might choose to␣
↪implement
  this otherwise, e.g. falling back to the parent's A and P.
```

- Usage

```
* If A or P are enabled/defined, they are used to round the␣
↪result of each
  operation according to the rules below
* Negative P is ignored in Math::BigInt, since Math::BigInt␣
↪objects never
  have digits after the decimal point
* Math::BigFloat uses Math::BigInt internally, but setting A or␣
↪P inside
  Math::BigInt as globals does not tamper with the parts of a␣
↪Math::BigFloat.
  A flag is used to mark all Math::BigFloat numbers as 'never␣
↪round'.
```

- Precedence

```
 * It only makes sense that a number has only one of A or P at␣
↪a time.
   If you set either A or P on one object, or globally, the␣
↪other one will
   be automatically cleared.
 * If two objects are involved in an operation, and one of them␣
↪has A in
   effect, and the other P, this results in an error (NaN).
 * A takes precedence over P (Hint: A comes before P).
   If neither of them is defined, nothing is used, i.e. the␣
↪result will have
   as many digits as it can (with an exception for bdiv/bsqrt)␣
↪and will not
   be rounded.
 * There is another setting for bdiv() (and thus for bsqrt()).␣
```

(continues on next page)

(continued from previous page)

```
↪If neither of
  A or P is defined, bdiv() will use a fallback (F) of $div_
↪scale digits.
  If either the dividend's or the divisor's mantissa has more␣
↪digits than
  the value of F, the higher value will be used instead of F.
  This is to limit the digits (A) of the result (just consider␣
↪what would
  happen with unlimited A and P in the case of 1/3 :-)
* bdiv will calculate (at least) 4 more digits than required␣
↪(determined by
  A, P or F), and, if F is not used, round the result
  (this will still fail in the case of a result like 0.
↪12345000000001 with A
  or P of 5, but this can not be helped - or can it?)
* Thus you can have the math done by on Math::Big* class in␣
↪two modi:
  + never round (this is the default):
    This is done by setting A and P to undef. No math operation
    will round the result, with bdiv() and bsqrt() as␣
↪exceptions to guard
    against overflows. You must explicitly call bround(),␣
↪bfround() or
    round() (the latter with parameters).
    Note: Once you have rounded a number, the settings will
↪'stick' on it
    and 'infect' all other numbers engaged in math operations␣
↪with it, since
    local settings have the highest precedence. So, to get␣
↪SaferRound[tm],
    use a copy() before rounding like this:

      $x = Math::BigFloat->new(12.34);
      $y = Math::BigFloat->new(98.76);
      $z = $x * $y;                           # 1218.6984
      print $x->copy()->bround(3);            # 12.3 (but A is␣
↪now 3!)
      $z = $x * $y;                           # still 1218.
↪6984, without
                                              # copy would␣
↪have been 1210!

  + round after each op:
    After each single operation (except for testing like is_
↪zero()), the
    method round() is called and the result is rounded␣
↪appropriately. By
    setting proper values for A and P, you can have all-the-
↪same-A or
```

(continues on next page)

(continued from previous page)

```
    all-the-same-P modes. For example, Math::Currency might␣
↪set A to undef,
    and P to -2, globally.

?Maybe an extra option that forbids local A & P settings would␣
↪be in order,
?so that intermediate rounding does not 'poison' further math?
```

- Overriding globals

```
* you will be able to give A, P and R as an argument to all the␣
↪calculation
  routines; the second parameter is A, the third one is P, and␣
↪the fourth is
  R (shift right by one for binary operations like badd). P is␣
↪used only if
  the first parameter (A) is undefined. These three parameters␣
↪override the
  globals in the order detailed as follows, i.e. the first␣
↪defined value
  wins:
  (local: per object, global: global default, parameter:␣
↪argument to sub)
    + parameter A
    + parameter P
    + local A (if defined on both of the operands: smaller one␣
↪is taken)
    + local P (if defined on both of the operands: bigger one␣
↪is taken)
    + global A
    + global P
    + global F
* bsqrt() will hand its arguments to bdiv(), as it used to,␣
↪only now for two
  arguments (A and P) instead of one
```

- Local settings

```
* You can set A or P locally by using $x->accuracy() or
  $x->precision()
  and thus force different A and P for different objects/
↪numbers.
* Setting A or P this way immediately rounds $x to the new␣
↪value.
* $x->accuracy() clears $x->precision(), and vice versa.
```

- Rounding

```
* the rounding routines will use the respective global or local␣
↪settings.
```

(continues on next page)

(continued from previous page)

```
  bround() is for accuracy rounding, while bfround() is for
↪precision
* the two rounding functions take as the second parameter one
↪of the
  following rounding modes (R):
  'even', 'odd', '+inf', '-inf', 'zero', 'trunc', 'common'
* you can set/get the global R by using Math::SomeClass->round_
↪mode()
  or by setting $Math::SomeClass::round_mode
* after each operation, $result->round() is called, and the
↪result may
  eventually be rounded (that is, if A or P were set either
↪locally,
  globally or as parameter to the operation)
* to manually round a number, call $x->round($A,$P,$round_mode);
  this will round the number by using the appropriate rounding
↪function
  and then normalize it.
* rounding modifies the local settings of the number:

      $x = Math::BigFloat->new(123.456);
      $x->accuracy(5);
      $x->bround(4);

  Here 4 takes precedence over 5, so 123.5 is the result and $x-
↪>accuracy()
  will be 4 from now on.
```

- Default values

```
* A: undef
* P: undef
* R: 'even'
* F: 40
```

- Remarks

```
* The defaults are set up so that the new code gives the same
↪results as
  the old code (except in a few cases on bdiv):
  + Both A and P are undefined and thus will not be used for
↪rounding
    after each operation.
  + round() is thus a no-op, unless given extra parameters A
↪and P
```

INTERNALS

You should neither care about nor depend on the internal representation; it might change without notice. Use **ONLY** method calls like `$x->sign();` instead relying on the internal representation.

Math Library

The mathematical computations are performed by a backend library. It is not required to specify which backend library to use, but some backend libraries are much faster than the default library.

The default library

The default library is *Math::BigInt::Calc*, which is implemented in pure Perl and hence does not require a compiler.

Specifying a library

The simple case

```
use Math::BigInt;
```

is equivalent to saying

```
use Math::BigInt try => 'Calc';
```

You can use a different backend library with, e.g.,

```
use Math::BigInt try => 'GMP';
```

which attempts to load the Math::BigInt::GMP library, and falls back to the default library if the specified library can't be loaded.

Multiple libraries can be specified by separating them by a comma, e.g.,

```
use Math::BigInt try => 'GMP,Pari';
```

If you request a specific set of libraries and do not allow fallback to the default library, specify them using "only",

```
use Math::BigInt only => 'GMP,Pari';
```

If you prefer a specific set of libraries, but want to see a warning if the fallback library is used, specify them using "lib",

```
use Math::BigInt lib => 'GMP,Pari';
```

The following first tries to find Math::BigInt::Foo, then Math::BigInt::Bar, and if this also fails, reverts to Math::BigInt::Calc:

```
use Math::BigInt try => 'Foo,Math::BigInt::Bar';
```

Which library to use?

Note: General purpose packages should not be explicit about the library to use; let the script author decide which is best.

Math::BigInt::GMP, Math::BigInt::Pari, and Math::BigInt::GMPz are in cases involving big numbers much faster than *Math::BigInt::Calc*. However these libraries are slower when dealing with very small numbers (less than about 20 digits) and when converting very large numbers to decimal (for instance for printing, rounding, calculating their length in decimal etc.).

So please select carefully what library you want to use.

Different low-level libraries use different formats to store the numbers, so mixing them won't work. You should not depend on the number having a specific internal format.

See the respective math library module documentation for further details.

Loading multiple libraries

The first library that is successfully loaded is the one that will be used. Any further attempts at loading a different module will be ignored. This is to avoid the situation where module A requires math library X, and module B requires math library Y, causing modules A and B to be incompatible. For example,

```
use Math::BigInt;                    # loads default "Calc"
use Math::BigFloat only => "GMP";    # ignores "GMP"
```

Sign

The sign is either '+', '-', 'NaN', '+inf' or '-inf'.

A sign of 'NaN' is used to represent values that are not numbers, e.g., the result of 0/0. '+inf' and '-inf' represen positive and negative infinity, respectively. For example you get '+inf' when dividing a positive number by 0, and '-inf' when dividing any negative number by 0.

EXAMPLES

```
use Math::BigInt;

sub bigint { Math::BigInt->new(shift); }

$x = Math::BigInt->bstr("1234")       # string "1234"
$x = "$x";                            # same as bstr()
$x = Math::BigInt->bneg("1234");      # Math::BigInt "-1234"
$x = Math::BigInt->babs("-12345");    # Math::BigInt "12345"
$x = Math::BigInt->bnorm("-0.00");    # Math::BigInt "0"
$x = bigint(1) + bigint(2);           # Math::BigInt "3"
$x = bigint(1) + "2";                 # ditto ("2" becomes a␣
↪Math::BigInt)
$x = bigint(1);                       # Math::BigInt "1"
```

(continues on next page)

(continued from previous page)

```
$x = $x + 5 / 2;                        # Math::BigInt "3"
$x = $x ** 3;                           # Math::BigInt "27"
$x *= 2;                                # Math::BigInt "54"
$x = Math::BigInt->new(0);              # Math::BigInt "0"
$x--;                                   # Math::BigInt "-1"
$x = Math::BigInt->badd(4,5)            # Math::BigInt "9"
print $x->bsstr();                      # 9e+0
```

Examples for rounding:

```
use Math::BigFloat;
use Test::More;

$x = Math::BigFloat->new(123.4567);
$y = Math::BigFloat->new(123.456789);
Math::BigFloat->accuracy(4);            # no more A than 4

is ($x->copy()->bround(),123.4);        # even rounding
print $x->copy()->bround(),"\n";        # 123.4
Math::BigFloat->round_mode('odd');      # round to odd
print $x->copy()->bround(),"\n";        # 123.5
Math::BigFloat->accuracy(5);            # no more A than 5
Math::BigFloat->round_mode('odd');      # round to odd
print $x->copy()->bround(),"\n";        # 123.46
$y = $x->copy()->bround(4),"\n";        # A = 4: 123.4
print "$y, ",$y->accuracy(),"\n";       # 123.4, 4

Math::BigFloat->accuracy(undef);        # A not important now
Math::BigFloat->precision(2);           # P important
print $x->copy()->bnorm(),"\n";         # 123.46
print $x->copy()->bround(),"\n";        # 123.46
```

Examples for converting:

```
my $x = Math::BigInt->new('0b1'.'01' x 123);
print "bin: ",$x->as_bin()," hex:",$x->as_hex()," dec: ",$x,"\n";
```

NUMERIC LITERALS

After `use Math::BigInt ':constant'` all numeric literals in the given scope are converted to `Math::BigInt` objects. This conversion happens at compile time. Every non-integer is convert to a NaN.

For example,

```
perl -MMath::BigInt=:constant -le 'print 2**150'
```

prints the exact value of `2**150`. Note that without conversion of constants to objects the expression `2**150` is calculated using Perl scalars, which leads to an inaccurate result.

Please note that strings are not affected, so that

```
use Math::BigInt qw/:constant/;

$x = "12345678901234567890123456789012345678890"
        + "123456789123456789";
```

does give you what you expect. You need an explicit Math::BigInt->new() around at least one of the operands. You should also quote large constants to prevent loss of precision:

```
use Math::BigInt;

$x = Math::BigInt->new("123456788912345678912345678912345678889");
```

Without the quotes Perl first converts the large number to a floating point constant at compile time, and then converts the result to a Math::BigInt object at run time, which results in an inaccurate result.

Hexadecimal, octal, and binary floating point literals

Perl (and this module) accepts hexadecimal, octal, and binary floating point literals, but use them with care with Perl versions before v5.32.0, because some versions of Perl silently give the wrong result. Below are some examples of different ways to write the number decimal 314.

Hexadecimal floating point literals:

```
0x1.3ap+8          0X1.3AP+8
0x1.3ap8           0X1.3AP8
0x13a0p-4          0X13A0P-4
```

Octal floating point literals (with “0” prefix):

```
01.164p+8          01.164P+8
01.164p8           01.164P8
011640p-4          011640P-4
```

Octal floating point literals (with “0o” prefix) (requires v5.34.0):

```
0o1.164p+8         0O1.164P+8
0o1.164p8          0O1.164P8
0o11640p-4         0O11640P-4
```

Binary floating point literals:

```
0b1.0011101p+8     0B1.0011101P+8
0b1.0011101p8      0B1.0011101P8
0b10011101000p-2   0B10011101000P-2
```

PERFORMANCE

Using the form $x += $y; etc over $x = $x + $y is faster, since a copy of $x must be made in the second case. For long numbers, the copy can eat up to 20% of the work (in the case of addition/subtraction, less for multiplication/division). If $y is very small compared to $x, the form $x += $y is MUCH faster than $x = $x + $y since making the copy of $x takes more time then the actual addition.

With a technique called copy-on-write, the cost of copying with overload could be minimized or even completely avoided. A test implementation of COW did show performance gains for overloaded math, but introduced a performance loss due to a constant overhead for all other operations. So Math::BigInt does currently not COW.

The rewritten version of this module (vs. v0.01) is slower on certain operations, like "new()", "bstr()" and "numify()". The reason are that it does now more work and handles much more cases. The time spent in these operations is usually gained in the other math operations so that code on the average should get (much) faster. If they don't, please contact the author.

Some operations may be slower for small numbers, but are significantly faster for big numbers. Other operations are now constant (O(1), like "bneg()", "babs()" etc), instead of O(N) and thus nearly always take much less time. These optimizations were done on purpose.

If you find the Calc module to slow, try to install any of the replacement modules and see if they help you.

Alternative math libraries

You can use an alternative library to drive Math::BigInt. See the section "Math Library" for more information.

For more benchmark results see http://bloodgate.com/perl/benchmarks.html.

SUBCLASSING

Subclassing Math::BigInt

The basic design of Math::BigInt allows simple subclasses with very little work, as long as a few simple rules are followed:

- The public API must remain consistent, i.e. if a sub-class is overloading addition, the sub-class must use the same name, in this case badd(). The reason for this is that Math::BigInt is optimized to call the object methods directly.
- The private object hash keys like `$x->{sign}` may not be changed, but additional keys can be added, like `$x->{_custom}`.
- Accessor functions are available for all existing object hash keys and should be used instead of directly accessing the internal hash keys. The reason for this is that Math::BigInt itself has a pluggable interface which permits it to support different storage methods.

More complex sub-classes may have to replicate more of the logic internal of Math::BigInt if they need to change more basic behaviors. A subclass that needs to merely change the output only needs to overload "bstr()".

All other object methods and overloaded functions can be directly inherited from the parent class.

At the very minimum, any subclass needs to provide its own "new()" and can store additional hash keys in the object. There are also some package globals that must be defined, e.g.:

```
# Globals
our $accuracy = 2;          # round to 2 decimal places
our $precision = undef;
our $round_mode = 'even';
our $div_scale = 40;
```

Additionally, you might want to provide the following two globals to allow auto-upgrading and auto-downgrading:

```
our $upgrade = undef;
our $downgrade = undef;
```

This allows Math::BigInt to correctly retrieve package globals from the subclass, like `$SubClass::precision`. See `t/Math/BigInt/Subclass.pm`, `t/Math/BigFloat/SubClass.pm`, or `t/Math/BigRat/SubClass.pm` for subclass examples.

Don't forget to

```
use overload;
```

in your subclass to automatically inherit the overloading from the parent. If you like, you can change part of the overloading, look at Math::String for an example.

UPGRADING

When used like this:

```
use Math::BigInt upgrade => 'Foo::Bar';

use Math::BigInt;
Math::BigInt -> upgrade('Foo::Bar');
```

any operation whose result cannot be represented as an Math::BigInt object is upgraded to the class Foo::Bar. Usually this is used in conjunction with Math::BigRat or Math::BigFloat:

```
use Math::BigInt upgrade => 'Math::BigFloat';
```

For example, the following returns 3 as a Math::BigInt when no upgrading is defined, and 3.125 as a Math::BigFloat if Math::BigInt is set to upgrade to Math::BigFloat:

```
$x = Math::BigInt -> new(25) -> bdiv(8);
```

As a shortcut, you can use the module *bignum*:

```
use bignum;
```

which is also good for one-liners:

```
perl -Mbignum -le 'print 2 ** 255'
```

This makes it possible to mix arguments of different classes (as in 2.5 + 2) as well as preserve accuracy (as in sqrt(3)).

Auto-upgrade

The following methods upgrade themselves unconditionally; that is if upgrade is in effect, they always hands up their work:

```
bdiv bfdiv btdiv bsqrt blog bexp bpi bsin bcos batan batan2
```

All other methods upgrade themselves only when one (or all) of their arguments are of the class mentioned in $upgrade.

EXPORTS

`Math::BigInt` exports nothing by default, but can export the following methods:

```
bgcd
blcm
```

CAVEATS

Some things might not work as you expect them. Below is documented what is known to be troublesome:

- Comparing numbers as strings

  Both "bstr()" and "bsstr()" as well as stringify via overload drop the leading '+'. This is to be consistent with Perl and to make `cmp` (especially with overloading) to work as you expect. It also solves problems with `Test.pm` and *Test::More*, which stringify arguments before comparing them.

  Mark Biggar said, when asked about to drop the '+' altogether, or make only `cmp` work:

  ```
  I agree (with the first alternative), don't add the '+' on␣
  ↪positive
  numbers.  It's not as important anymore with the new internal␣
  ↪form
  for numbers.  It made doing things like abs and neg easier, but
  those have to be done differently now anyway.
  ```

  So, the following examples now works as expected:

  ```
  use Test::More tests => 1;
  use Math::BigInt;

  my $x = Math::BigInt -> new(3*3);
  ```

(continues on next page)

(continued from previous page)

```
my $y = Math::BigInt -> new(3*3);

is($x,3*3, 'multiplication');
print "$x eq 9" if $x eq $y;
print "$x eq 9" if $x eq '9';
print "$x eq 9" if $x eq 3*3;
```

Additionally, the following still works:

```
print "$x == 9" if $x == $y;
print "$x == 9" if $x == 9;
print "$x == 9" if $x == 3*3;
```

There is now a "bsstr()" method to get the string in scientific notation aka 1e+2 instead of 100. Be advised that overloaded 'eq' always uses bstr() for comparison, but Perl represents some numbers as 100 and others as 1e+308. If in doubt, convert both arguments to Math::BigInt before comparing them as strings:

```
use Test::More tests => 3;
use Math::BigInt;

$x = Math::BigInt->new('1e56');
$y = 1e56;
is($x,$y);                      # fails
is($x->bsstr(), $y);            # okay
$y = Math::BigInt->new($y);
is($x, $y);                     # okay
```

Alternatively, simply use <=> for comparisons, this always gets it right. There is not yet a way to get a number automatically represented as a string that matches exactly the way Perl represents it.

- oct()/hex()

  These perl routines currently (as of Perl v.5.8.6) cannot handle passed inf.

```
te@linux:~> perl -wle 'print 2 ** 3333'
Inf
te@linux:~> perl -wle 'print 2 ** 3333 == 2 ** 3333'
1
te@linux:~> perl -wle 'print oct(2 ** 3333)'
0
te@linux:~> perl -wle 'print hex(2 ** 3333)'
Illegal hexadecimal digit 'I' ignored at -e line 1.
0
```

  The same problems occur if you pass them Math::BigInt->binf() objects. Since overloading these routines is not possible, this cannot be fixed from Math::BigInt.

- int()

  "int()" returns (at least for Perl v5.7.1 and up) another Math::BigInt, not a Perl scalar:

```
$x = Math::BigInt->new(123);
$y = int($x);                           # 123 as a Math::BigInt
$x = Math::BigFloat->new(123.45);
$y = int($x);                           # 123 as a␣
↪Math::BigFloat
```

If you want a real Perl scalar, use "numify()":

```
$y = $x->numify();                      # 123 as a scalar
```

This is seldom necessary, though, because this is done automatically, like when you access an array:

```
$z = $array[$x];                        # does work␣
↪automatically
```

- Modifying and =

  Beware of:

```
$x = Math::BigFloat->new(5);
$y = $x;
```

  This makes a second reference to the **same** object and stores it in $y. Thus anything that modifies $x (except overloaded operators) also modifies $y, and vice versa. Or in other words, = is only safe if you modify your Math::BigInt objects only via overloaded math. As soon as you use a method call it breaks:

```
$x->bmul(2);
print "$x, $y\n";       # prints '10, 10'
```

  If you want a true copy of $x, use:

```
$y = $x->copy();
```

  You can also chain the calls like this, this first makes a copy and then multiply it by 2:

```
$y = $x->copy()->bmul(2);
```

  See also the documentation for overload.pm regarding =.

- Overloading -$x

  The following:

```
$x = -$x;
```

  is slower than

```
$x->bneg();
```

  since overload calls `sub($x,0,1);` instead of `neg($x)`. The first variant needs to preserve $x since it does not know that it later gets overwritten. This makes a copy

of $x and takes O(N), but $x->bneg() is O(1).

- Mixing different object types

  With overloaded operators, it is the first (dominating) operand that determines which method is called. Here are some examples showing what actually gets called in various cases.

```
use Math::BigInt;
use Math::BigFloat;

$mbf  = Math::BigFloat->new(5);
$mbi2 = Math::BigInt->new(5);
$mbi  = Math::BigInt->new(2);
                                  # what actually gets called:
$float = $mbf + $mbi;             # $mbf->badd($mbi)
$float = $mbf / $mbi;             # $mbf->bdiv($mbi)
$integer = $mbi + $mbf;           # $mbi->badd($mbf)
$integer = $mbi2 / $mbi;          # $mbi2->bdiv($mbi)
$integer = $mbi2 / $mbf;          # $mbi2->bdiv($mbf)
```

  For instance, Math::BigInt->bdiv() always returns a Math::BigInt, regardless of whether the second operant is a Math::BigFloat. To get a Math::BigFloat you either need to call the operation manually, make sure each operand already is a Math::BigFloat, or cast to that type via Math::BigFloat->new():

```
$float = Math::BigFloat->new($mbi2) / $mbi;      # = 2.5
```

  Beware of casting the entire expression, as this would cast the result, at which point it is too late:

```
$float = Math::BigFloat->new($mbi2 / $mbi);      # = 2
```

  Beware also of the order of more complicated expressions like:

```
$integer = ($mbi2 + $mbi) / $mbf;                # int / float =>
 ↪ int
$integer = $mbi2 / Math::BigFloat->new($mbi);    # ditto
```

  If in doubt, break the expression into simpler terms, or cast all operands to the desired resulting type.

  Scalar values are a bit different, since:

```
$float = 2 + $mbf;
$float = $mbf + 2;
```

  both result in the proper type due to the way the overloaded math works.

  This section also applies to other overloaded math packages, like Math::String.

  One solution to you problem might be autoupgrading|upgrading. See the pragmas *bignum*, *bigint* and *bigrat* for an easy way to do this.

BUGS

Please report any bugs or feature requests to `bug-math-bigint at rt.cpan.org`, or through the web interface at https://rt.cpan.org/Ticket/Create.html?Queue=Math-BigInt (requires login). We will be notified, and then you'll automatically be notified of progress on your bug as I make changes.

SUPPORT

You can find documentation for this module with the perldoc command.

Math::BigInt::Calc

pure Perl module to support Math::BigInt

SYNOPSIS

```
# to use it with Math::BigInt
use Math::BigInt lib => 'Calc';

# to use it with Math::BigFloat
use Math::BigFloat lib => 'Calc';

# to use it with Math::BigRat
use Math::BigRat lib => 'Calc';

# explicitly set base length and whether to "use integer"
use Math::BigInt::Calc base_len => 4, use_int => 1;
use Math::BigInt lib => 'Calc';
```

DESCRIPTION

Math::BigInt::Calc inherits from Math::BigInt::Lib.

In this library, the numbers are represented interenally in base B = 10**N, where N is the largest possible integer that does not cause overflow in the intermediate computations. The base B elements are stored in an array, with the least significant element stored in array element zero. There are no leading zero elements, except a single zero element when the number is zero. For instance, if B = 10000, the number 1234567890 is represented internally as [7890, 3456, 12].

OPTIONS

When the module is loaded, it computes the maximum exponent, i.e., power of 10, that can be used with and without "use integer" in the computations. The default is to use this maximum exponent. If the combination of the 'base_len' value and the 'use_int' value exceeds the maximum value, an error is thrown.

- base_len

  The base length can be specified explicitly with the 'base_len' option. The value must be a positive integer.

```
use Math::BigInt::Calc base_len => 4;  # use 10000 as internal␣
↪base
```

- use_int

  This option is used to specify whether “use integer” should be used in the internal computations. The value is interpreted as a boolean value, so use 0 or “” for false and anything else for true. If the ‘base_len’ is not specified together with ‘use_int’, the current value for the base length is used.

```
use Math::BigInt::Calc use_int => 1;   # use "use integer"␣
↪internally
```

METHODS

This overview constains only the methods that are specific to `Math::BigInt::Calc`. For the other methods, see *Math::BigInt::Lib*.

- _base_len()

  Specify the desired base length and whether to enable “use integer” in the computations.

```
Math::BigInt::Calc -> _base_len($base_len, $use_int);
```

  Note that it is better to specify the base length and whether to use integers as options when the module is loaded, for example like this

```
use Math::BigInt::Calc base_len => 6, use_int => 1;
```

SEE ALSO

Math::BigInt::Lib for a description of the API.

Alternative libraries *Math::BigInt::FastCalc*, Math::BigInt::GMP, Math::BigInt::Pari, Math::BigInt::GMPz, and Math::BigInt::BitVect.

Some of the modules that use these libraries *Math::BigInt*, *Math::BigFloat*, and *Math::BigRat*.

Math::BigInt::FastCalc

The XS half of Math::BigInt::FastCalc 0.5020: the hot primitives of Math::BigInt’s default library, in C.

`Math/BigInt/FastCalc.pm` is upstream’s, a subclass of Math::BigInt::Calc, which stores a number as an array of base-10**N “parts”, least significant first. These XSUBs replace Calc’s Perl for creating, copying, incrementing, decrementing, comparing and testing such arrays; everything else is Calc’s.

```
use Math::BigInt lib => 'FastCalc';
print Math::BigInt->new("123456789012345678901234567890") + 1;
# 123456789012345678901234567891
```

Nothing calls these XSUBs but the library itself. `Math::BigInt` uses FastCalc when asked to, with `lib => 'FastCalc'` (or `try` / `only`); its default library is plain `Math::BigInt::Calc`.

Differences from upstream

None.

Math::BigInt::Lib

virtual parent class for Math::BigInt libraries

SYNOPSIS

```
# In the backend library for Math::BigInt et al.

package Math::BigInt::MyBackend;

use Math::BigInt::Lib;
our @ISA = qw< Math::BigInt::Lib >;

sub _new { ... }
sub _str { ... }
sub _add { ... }
str _sub { ... }
...

# In your main program.

use Math::BigInt lib => 'MyBackend';
```

DESCRIPTION

This module provides support for big integer calculations. It is not intended to be used directly, but rather as a parent class for backend libraries used by Math::BigInt, Math::BigFloat, Math::BigRat, and related modules.

Other backend libraries include Math::BigInt::Calc, Math::BigInt::FastCalc, Math::BigInt::GMP, and Math::BigInt::Pari.

In order to allow for multiple big integer libraries, Math::BigInt was rewritten to use a plug-in library for core math routines. Any module which conforms to the API can be used by Math::BigInt by using this in your program:

```
use Math::BigInt lib => 'libname';
```

'libname' is either the long name, like 'Math::BigInt::Pari', or only the short version, like 'Pari'.

General Notes

A library only needs to deal with unsigned big integers. Testing of input parameter validity is done by the caller, so there is no need to worry about underflow (e.g., in `_sub()` and `_dec()`) or about division by zero (e.g., in `_div()` and `_mod()`)) or similar cases.

Some libraries use methods that don't modify their argument, and some libraries don't even use objects, but rather unblessed references. Because of this, liberary methods are always called as class methods, not instance methods:

```
$x = Class -> method($x, $y);     # like this
$x = $x -> method($y);            # not like this ...
$x -> method($y);                 # ... or like this
```

And with boolean methods

```
$bool = Class -> method($x, $y);  # like this
$bool = $x -> method($y);         # not like this
```

Return values are always objects, strings, Perl scalars, or true/false for comparison routines.

API version

- CLASS->api_version()

  This method is no longer used and can be omitted. Methods that are not implemented by a subclass will be inherited from this class.

Constructors

The following methods are mandatory: _new(), _str(), _add(), and _sub(). However, computations will be very slow without _mul() and _div().

- CLASS->_new(STR)

  Convert a string representing an unsigned decimal number to an object representing the same number. The input is normalized, i.e., it matches `^(0|[1-9]\d*)$`.

- CLASS->_zero()

  Return an object representing the number zero.

- CLASS->_one()

  Return an object representing the number one.

- CLASS->_two()

  Return an object representing the number two.

- CLASS->_ten()

  Return an object representing the number ten.

- CLASS->_from_bin(STR)

  Return an object given a string representing a binary number. The input has a '0b' prefix and matches the regular expression `^0[bB](0|1[01]*)$`.

- CLASS->_from_oct(STR)

  Return an object given a string representing an octal number. The input has a '0' prefix and matches the regular expression `^0[1-7]*$`.

- CLASS->_from_hex(STR)

  Return an object given a string representing a hexadecimal number. The input has a '0x' prefix and matches the regular expression `^0x(0|[1-9a-fA-F][\da-fA-F]*)$`.

- CLASS->_from_bytes(STR)

  Returns an object given a byte string representing the number. The byte string is in big endian byte order, so the two-byte input string "\x01\x00" should give an output value representing the number 256.

- CLASS->_from_base(STR, BASE, COLLSEQ)

  Returns an object given a string STR, a base BASE, and a collation sequence COLLSEQ. Each character in STR represents a numerical value identical to the character's position in COLLSEQ. All characters in STR must be present in COLLSEQ.

  If BASE is less than or equal to 94, and a collation sequence is not specified, the following default collation sequence is used. It contains of all the 94 printable ASCII characters except space/blank:

```
0123456789                  # ASCII  48 to  57
ABCDEFGHIJKLMNOPQRSTUVWXYZ  # ASCII  65 to  90
abcdefghijklmnopqrstuvwxyz  # ASCII  97 to 122
!"#$%&'()*+,-./             # ASCII  33 to  47
:;<=>?@                     # ASCII  58 to  64
[\]^_`                      # ASCII  91 to  96
{|}~                        # ASCII 123 to 126
```

  If the default collation sequence is used, and the BASE is less than or equal to 36, the letter case in STR is ignored.

  For instance, with base 3 and collation sequence "-/|", the character "-" represents 0, "/" represents 1, and "|" represents 2. So if STR is "/|-", the output is 1 * 3**2 + 2 * 3**1 + 0 * 3**0 = 15.

  The following examples show standard binary, octal, decimal, and hexadecimal conversion. All examples return 250.

```
$x = $class -> _from_base("11111010", 2)
$x = $class -> _from_base("372", 8)
$x = $class -> _from_base("250", 10)
$x = $class -> _from_base("FA", 16)
```

  Some more examples, all returning 250:

```
$x = $class -> _from_base("100021", 3)
$x = $class -> _from_base("3322", 4)
$x = $class -> _from_base("2000", 5)
$x = $class -> _from_base("caaa", 5, "abcde")
```

(continues on next page)

(continued from previous page)

```
$x = $class -> _from_base("42", 62)
$x = $class -> _from_base("2!", 94)
```

- CLASS->_from_base_num(ARRAY, BASE)

  Returns an object given an array of values and a base. This method is equivalent to `_from_base()`, but works on numbers in an array rather than characters in a string. Unlike `_from_base()`, all input values may be arbitrarily large.

```
$x = $class -> _from_base_num([1, 1, 0, 1], 2)    # $x is 13
$x = $class -> _from_base_num([3, 125, 39], 128)  # $x is 65191
```

Mathematical functions

- CLASS->_add(OBJ1, OBJ2)

  Addition. Returns the result of adding OBJ2 to OBJ1.

- CLASS->_mul(OBJ1, OBJ2)

  Multiplication. Returns the result of multiplying OBJ2 and OBJ1.

- CLASS->_div(OBJ1, OBJ2)

  Division. In scalar context, returns the quotient after dividing OBJ1 by OBJ2 and truncating the result to an integer. In list context, return the quotient and the remainder.

- CLASS->_sub(OBJ1, OBJ2, FLAG)

- CLASS->_sub(OBJ1, OBJ2)

  Subtraction. Returns the result of subtracting OBJ2 by OBJ1. If `flag` is false or omitted, OBJ1 might be modified. If `flag` is true, OBJ2 might be modified.

- CLASS->_sadd(OBJ1, SIGN1, OBJ2, SIGN2)

  Signed addition. Returns the result of adding OBJ2 with sign SIGN2 to OBJ1 with sign SIGN1.

```
($obj3, $sign3) = $class -> _sadd($obj1, $sign1, $obj2, $sign2);
```

- CLASS->_ssub(OBJ1, SIGN1, OBJ2, SIGN2)

  Signed subtraction. Returns the result of subtracting OBJ2 with sign SIGN2 to OBJ1 with sign SIGN1.

```
($obj3, $sign3) = $class -> _sadd($obj1, $sign1, $obj2, $sign2);
```

- CLASS->_dec(OBJ)

  Returns the result after decrementing OBJ by one.

- CLASS->_inc(OBJ)

  Returns the result after incrementing OBJ by one.

- CLASS->_mod(OBJ1, OBJ2)

  Returns OBJ1 modulo OBJ2, i.e., the remainder after dividing OBJ1 by OBJ2.

- CLASS->_sqrt(OBJ)

  Returns the square root of OBJ, truncated to an integer.

- CLASS->_root(OBJ, N)

  Returns the Nth root of OBJ, truncated to an integer.

- CLASS->_fac(OBJ)

  Returns the factorial of OBJ, i.e., the product of all positive integers up to and including OBJ.

- CLASS->_dfac(OBJ)

  Returns the double factorial of OBJ. If OBJ is an even integer, returns the product of all positive, even integers up to and including OBJ, i.e., 2*4*6*...*OBJ. If OBJ is an odd integer, returns the product of all positive, odd integers, i.e., 1*3*5*...*OBJ.

- CLASS->_pow(OBJ1, OBJ2)

  Returns OBJ1 raised to the power of OBJ2. By convention, 0**0 = 1.

- CLASS->_modinv(OBJ1, OBJ2)

  Returns the modular multiplicative inverse, i.e., return OBJ3 so that

  ```
  (OBJ3 * OBJ1) % OBJ2 = 1 % OBJ2
  ```

  The result is returned as two arguments. If the modular multiplicative inverse does not exist, both arguments are undefined. Otherwise, the arguments are a number (object) and its sign ("+" or "-").

  The output value, with its sign, must either be a positive value in the range 1,2,...,OBJ2-1 or the same value subtracted OBJ2. For instance, if the input arguments are objects representing the numbers 7 and 5, the method must either return an object representing the number 3 and a "+" sign, since (3*7) % 5 = 1

- CLASS->_modpow(OBJ1, OBJ2, OBJ3)

  Returns the modular exponentiation, i.e., (OBJ1 ** OBJ2) % OBJ3.

- CLASS->_rsft(OBJ, N, B)

  Returns the result after shifting OBJ N digits to thee right in base B. This is equivalent to performing integer division by B**N and discarding the remainder, except that it might be much faster.

  For instance, if the object $obj represents the hexadecimal number 0xabcde, then `_rsft($obj, 2, 16)` returns an object representing the number 0xabc. The "remainer", 0xde, is discarded and not returned.

- CLASS->_lsft(OBJ, N, B)

  Returns the result after shifting OBJ N digits to the left in base B. This is equivalent to multiplying by B**N, except that it might be much faster.

- CLASS->_log_int(OBJ, B)

  Returns the logarithm of OBJ to base BASE truncted to an integer. This method has two output arguments, the OBJECT and a STATUS. The STATUS is Perl scalar; it is 1 if OBJ is the exact result, 0 if the result was truncted to give OBJ, and undef if it is unknown whether OBJ is the exact result.

- CLASS->_ilog2(OBJ)

  Returns the base 2 logarithm of OBJ rounded downwards to the nearest integer, i.e., `int(log2(OBJ))`. In list context, this method returns two output arguments, the OBJECT and a STATUS. The STATUS is Perl scalar; it is 1 if OBJ is the exact result, 0 if the result was truncted to give OBJ, and undef if it is unknown whether OBJ is the exact result.

  This method is equivalent to the more general method _log_int() when it is used with base 2 argument, but _ilog2() method might be faster.

- CLASS->_ilog10(OBJ)

  Returns the base 10 logarithm of OBJ rounded downwards to the nearest integer, i.e., `int(log2(OBJ))`. In list context, this method returns two output arguments, the OBJECT and a STATUS. The STATUS is Perl scalar; it is 1 if OBJ is the exact result, 0 if the result was truncted to give OBJ, and undef if it is unknown whether OBJ is the exact result.

  This method is equivalent to the more general method _log_int() when it is used with base 10 argument, but _ilog10() method might be faster.

  Also, the output from _ilog10() is always 1 smaller than the output from _len().

- CLASS->_clog2(OBJ)

  Returns the base 2 logarithm of OBJ rounded upwards to the nearest integer, i.e., `ceil(log2(OBJ))`. In list context, this method returns two output arguments, the OBJECT and a STATUS. The STATUS is Perl scalar; it is 1 if OBJ is the exact result, 0 if the result was truncted to give OBJ, and undef if it is unknown whether OBJ is the exact result.

- CLASS->_clog10(OBJ)

  Returns the base 10 logarithm of OBJ rounded upnwards to the nearest integer, i.e., `ceil(log2(OBJ))`. In list context, this method returns two output arguments, the OBJECT and a STATUS. The STATUS is Perl scalar; it is 1 if OBJ is the exact result, 0 if the result was truncted to give OBJ, and undef if it is unknown whether OBJ is the exact result.

- CLASS->_gcd(OBJ1, OBJ2)

  Returns the greatest common divisor of OBJ1 and OBJ2.

- CLASS->_lcm(OBJ1, OBJ2)

  Return the least common multiple of OBJ1 and OBJ2.

- CLASS->_fib(OBJ)

  In scalar context, returns the nth Fibonacci number: _fib(0) returns 0, _fib(1) returns 1, _fib(2) returns 1, _fib(3) returns 2 etc. In list context, returns the Fibonacci numbers from F(0) to F(n): 0, 1, 1, 2, 3, 5, 8, 13, 21, 34, ...

- CLASS->_lucas(OBJ)

  In scalar context, returns the nth Lucas number: _lucas(0) returns 2, _lucas(1) returns 1, _lucas(2) returns 3, etc. In list context, returns the Lucas numbers from L(0) to L(n): 2, 1, 3, 4, 7, 11, 18, 29,47, 76, ...

Bitwise operators

- CLASS->_and(OBJ1, OBJ2)

  Returns bitwise and.

- CLASS->_or(OBJ1, OBJ2)

  Returns bitwise or.

- CLASS->_xor(OBJ1, OBJ2)

  Returns bitwise exclusive or.

- CLASS->_sand(OBJ1, OBJ2, SIGN1, SIGN2)

  Returns bitwise signed and.

- CLASS->_sor(OBJ1, OBJ2, SIGN1, SIGN2)

  Returns bitwise signed or.

- CLASS->_sxor(OBJ1, OBJ2, SIGN1, SIGN2)

  Returns bitwise signed exclusive or.

Boolean operators

- CLASS->_is_zero(OBJ)

  Returns a true value if OBJ is zero, and false value otherwise.

- CLASS->_is_one(OBJ)

  Returns a true value if OBJ is one, and false value otherwise.

- CLASS->_is_two(OBJ)

  Returns a true value if OBJ is two, and false value otherwise.

- CLASS->_is_ten(OBJ)

  Returns a true value if OBJ is ten, and false value otherwise.

- CLASS->_is_even(OBJ)

  Return a true value if OBJ is an even integer, and a false value otherwise.

- CLASS->_is_odd(OBJ)

  Return a true value if OBJ is an even integer, and a false value otherwise.

- CLASS->_acmp(OBJ1, OBJ2)

  Compare OBJ1 and OBJ2 and return -1, 0, or 1, if OBJ1 is numerically less than, equal to, or larger than OBJ2, respectively.

- CLASS->_scmp(OBJ1, SIGN1, OBJ2, SIGN2)

  Compare OBJ1 and OBJ2 and return -1, 0, or 1, if OBJ1 is numerically less than, equal to, or larger than OBJ2, respectively.

String conversion

- CLASS->_str(OBJ)

  Returns a string representing OBJ in decimal notation. The returned string should have no leading zeros, i.e., it should match `^(0|[1-9]\d*)$`.

- CLASS->_to_bin(OBJ)

  Returns the binary string representation of OBJ.

- CLASS->_to_oct(OBJ)

  Returns the octal string representation of the number.

- CLASS->_to_hex(OBJ)

  Returns the hexadecimal string representation of the number.

- CLASS->_to_bytes(OBJ)

  Returns a byte string representation of OBJ. The byte string is in big endian byte order, so if OBJ represents the number 256, the output should be the two-byte string "\x01\x00".

- CLASS->_to_base(OBJ, BASE, COLLSEQ)

  Returns a string representation of OBJ in base BASE with collation sequence COLLSEQ.

```
$val = $class -> _new("210");
$str = $class -> _to_base($val, 10, "xyz")  # $str is "zyx"

$val = $class -> _new("32");
$str = $class -> _to_base($val, 2, "-|")  # $str is "|-----"
```

  See _from_base() for more information.

- CLASS->_to_base_num(OBJ, BASE)

  Converts the given number to the given base. This method is equivalent to `_to_base()`, but returns numbers in an array rather than characters in a string. In the output, the first element is the most significant. Unlike `_to_base()`, all input values may be arbitrarily large.

```
$x = $class -> _to_base_num(13, 2)        # $x is [1, 1, 0, 1]
$x = $class -> _to_base_num(65191, 128)   # $x is [3, 125, 39]
```

- CLASS->_as_bin(OBJ)

  Like `_to_bin()` but with a '0b' prefix.

- CLASS->_as_oct(OBJ)

  Like `_to_oct()` but with a '0' prefix.

- CLASS->_as_hex(OBJ)

  Like `_to_hex()` but with a '0x' prefix.

- CLASS->_as_bytes(OBJ)

  This is an alias to `_to_bytes()`.

Numeric conversion

- CLASS->_num(OBJ)

  Returns a Perl scalar number representing the number OBJ as close as possible. Since Perl scalars have limited precision, the returned value might not be exactly the same as OBJ.

Miscellaneous

- CLASS->_copy(OBJ)

  Returns a true copy OBJ.

- CLASS->_len(OBJ)

  Returns the number of the decimal digits in OBJ. The output is a Perl scalar.

- CLASS->_zeros(OBJ)

  Returns the number of trailing decimal zeros. The output is a Perl scalar. The number zero has no trailing decimal zeros.

- CLASS->_digit(OBJ, N)

  Returns the Nth digit in OBJ as a Perl scalar. N is a Perl scalar, where zero refers to the rightmost (least significant) digit, and negative values count from the left (most significant digit). If $obj represents the number 123, then

```
CLASS->_digit($obj,  0)     # returns 3
CLASS->_digit($obj,  1)     # returns 2
CLASS->_digit($obj,  2)     # returns 1
CLASS->_digit($obj, -1)     # returns 1
```

- CLASS->_digitsum(OBJ)

  Returns the sum of the base 10 digits.

- CLASS->_check(OBJ)

  Returns true if the object is invalid and false otherwise. Preferably, the true value is a string describing the problem with the object. This is a check routine to test the internal state of the object for corruption.

- CLASS->_set(OBJ)

  xxx

API version 2

The following methods are required for an API version of 2 or greater.

Constructors

- CLASS->_1ex(N)

  Return an object representing the number 10**N where N >= 0 is a Perl scalar.

Mathematical functions

- CLASS->_nok(OBJ1, OBJ2)

  Return the binomial coefficient OBJ1 over OBJ1.

Miscellaneous

- CLASS->_alen(OBJ)

  Return the approximate number of decimal digits of the object. The output is a Perl scalar.

WRAP YOUR OWN

If you want to port your own favourite C library for big numbers to the Math::BigInt interface, you can take any of the already existing modules as a rough guideline. You should really wrap up the latest Math::BigInt and Math::BigFloat testsuites with your module, and replace in them any of the following:

```
use Math::BigInt;
```

by this:

```
use Math::BigInt lib => 'yourlib';
```

This way you ensure that your library really works 100% within Math::BigInt.

BUGS

Please report any bugs or feature requests to `bug-math-bigint at rt.cpan.org`, or through the web interface at https://rt.cpan.org/Ticket/Create.html?Queue=Math-BigInt (requires login). We will be notified, and then you'll automatically be notified of progress on your bug as I make changes.

SUPPORT

You can find documentation for this module with the perldoc command.

```
perldoc Math::BigInt::Calc
```

You can also look for information at:

- GitHub Source Repository

  https://github.com/pjacklam/p5-Math-BigInt

- RT: CPAN's request tracker

  https://rt.cpan.org/Public/Dist/Display.html?Name=Math-BigInt

- MetaCPAN

  https://metacpan.org/release/Math-BigInt

- CPAN Testers Matrix

Math::BigRat

arbitrary size rational number math package

SYNOPSIS

```
use Math::BigRat;

# Generic constructor method (always returns a new object)

$x = Math::BigRat->new($str);              # defaults to 0
$x = Math::BigRat->new('256');             # from decimal
$x = Math::BigRat->new('0256');            # from decimal
$x = Math::BigRat->new('0xcafe');          # from hexadecimal
$x = Math::BigRat->new('0x1.fap+7');       # from hexadecimal
$x = Math::BigRat->new('0o377');           # from octal
$x = Math::BigRat->new('0o1.35p+6');       # from octal
$x = Math::BigRat->new('0b101');           # from binary
$x = Math::BigRat->new('0b1.101p+3');      # from binary
```

(continues on next page)

(continued from previous page)

```
# Specific constructor methods (no prefix needed; when used as
# instance method, the value is assigned to the invocand)

$x = Math::BigRat->from_dec('234');       # from decimal
$x = Math::BigRat->from_hex('cafe');      # from hexadecimal
$x = Math::BigRat->from_hex('1.fap+7');   # from hexadecimal
$x = Math::BigRat->from_oct('377');       # from octal
$x = Math::BigRat->from_oct('1.35p+6');   # from octal
$x = Math::BigRat->from_bin('1101');      # from binary
$x = Math::BigRat->from_bin('1.101p+3');  # from binary
$x = Math::BigRat->from_bytes($bytes);    # from byte string
$x = Math::BigRat->from_base('why', 36);  # from any base
$x = Math::BigRat->from_base_num([1, 0], 2);  # from any base
$x = Math::BigRat->from_ieee754($b, $fmt);    # from IEEE-754 bytes
$x = Math::BigRat->from_fp80($b);         # from x86 80-bit
$x = Math::BigRat->bzero();               # create a +0
$x = Math::BigRat->bone();                # create a +1
$x = Math::BigRat->bone('-');             # create a -1
$x = Math::BigRat->binf();                # create a +inf
$x = Math::BigRat->binf('-');             # create a -inf
$x = Math::BigRat->bnan();                # create a Not-A-Number
$x = Math::BigRat->bpi();                 # returns pi

$y = $x->copy();         # make a copy (unlike $y = $x)
$y = $x->as_int();       # return as a Math::BigInt
$y = $x->as_float();     # return as a Math::BigFloat
$y = $x->as_rat();       # return as a Math::BigRat

# Boolean methods (these don't modify the invocand)

$x->is_zero();           # true if $x is 0
$x->is_one();            # true if $x is +1
$x->is_one("+");         # true if $x is +1
$x->is_one("-");         # true if $x is -1
$x->is_inf();            # true if $x is +inf or -inf
$x->is_inf("+");         # true if $x is +inf
$x->is_inf("-");         # true if $x is -inf
$x->is_nan();            # true if $x is NaN

$x->is_finite();         # true if -inf < $x < inf
$x->is_positive();       # true if $x > 0
$x->is_pos();            # true if $x > 0
$x->is_negative();       # true if $x < 0
$x->is_neg();            # true if $x < 0
$x->is_non_positive()    # true if $x <= 0
$x->is_non_negative()    # true if $x >= 0

$x->is_odd();            # true if $x is odd
$x->is_even();           # true if $x is even
```

(continues on next page)

(continued from previous page)

```
$x->is_int();           # true if $x is an integer

# Comparison methods (these don't modify the invocand)

$x->bcmp($y);           # compare numbers (undef, < 0, == 0, > 0)
$x->bacmp($y);          # compare abs values (undef, < 0, == 0, > 0)
$x->beq($y);            # true if $x == $y
$x->bne($y);            # true if $x != $y
$x->blt($y);            # true if $x < $y
$x->ble($y);            # true if $x <= $y
$x->bgt($y);            # true if $x > $y
$x->bge($y);            # true if $x >= $y

# Arithmetic methods (these modify the invocand)

$x->bneg();             # negation
$x->babs();             # absolute value
$x->bsgn();             # sign function (-1, 0, 1, or NaN)
$x->bdigitsum();        # sum of decimal digits
$x->binc();             # increment $x by 1
$x->bdec();             # decrement $x by 1
$x->badd($y);           # addition (add $y to $x)
$x->bsub($y);           # subtraction (subtract $y from $x)
$x->bmul($y);           # multiplication (multiply $x by $y)
$x->bmuladd($y, $z);    # $x = $x * $y + $z

$x->bior($y);           # bitwise inclusive or
$x->bxor($y);           # bitwise exclusive or
$x->bnot();             # bitwise not (two's complement)

# Rounding methods (these modify the invocand)

$x->round($A, $P, $R);  # round to accuracy or precision using
                        #   rounding mode $R
$x->bround($n);         # accuracy: preserve $n digits
$x->bfround($n);        # $n > 0: round to $nth digit left of dec. point
                        # $n < 0: round to $nth digit right of dec. point
$x->bfloor();           # round towards minus infinity
$x->bceil();            # round towards plus infinity
$x->bint();             # round towards zero

# Other mathematical methods (these don't modify the invocand)

$x->bgcd($y);           # greatest common divisor
$x->blcm($y);           # least common multiple

# Object property methods (these don't modify the invocand)
```

(continues on next page)

(continued from previous page)

```
$x->sign();             # the sign, either +, - or NaN
$x->digit($n);          # the nth digit, counting from the right
$x->digit(-$n);         # the nth digit, counting from the left
$x->digitsum();         # sum of decimal digits
$x->length();           # return number of digits in number
$x->mantissa();         # return (signed) mantissa as a Math::BigInt
$x->exponent();         # return exponent as a Math::BigInt
$x->parts();            # return (mantissa,exponent) as a␣
↪Math::BigInt
$x->sparts();           # mantissa and exponent (as integers)
$x->nparts();           # mantissa and exponent (normalised)
$x->eparts();           # mantissa and exponent (engineering␣
↪notation)
$x->dparts();           # integer and fraction part
$x->fparts();           # numerator and denominator
$x->numerator();        # numerator
$x->denominator();      # denominator

# Conversion methods (these don't modify the invocand)

$x->bstr();             # decimal notation (possibly zero padded)
$x->bnstr();            # string in normalized notation
$x->bestr();            # string in engineering notation
$x->bdstr();            # string in decimal notation (no padding)
$x->bfstr();            # string in fractional notation

$x->to_hex();           # as signed hexadecimal string
$x->to_bin();           # as signed binary string
$x->to_oct();           # as signed octal string
$x->to_bytes();         # as byte string
$x->to_base($b);        # as string in any base
$x->to_base_num($b);    # as array of integers in any base
$x->to_ieee754($fmt);   # to bytes encoded according to IEEE 754-
↪2008
$x->to_fp80();          # encode value in x86 80-bit format

$x->as_hex();           # as signed hexadecimal string with "0x"␣
↪prefix
$x->as_bin();           # as signed binary string with "0b" prefix
$x->as_oct();           # as signed octal string with "0" prefix

# Other conversion methods (these don't modify the invocand)

$x->numify();           # return as scalar (might overflow or␣
↪underflow)
```

DESCRIPTION

Math::BigRat complements *Math::BigInt* and *Math::BigFloat* by providing support for arbitrary big rational numbers.

Math Library

You can change the underlying module that does the low-level math operations by using:

```
use Math::BigRat try => 'GMP';
```

Note: This needs Math::BigInt::GMP installed.

The following would first try to find Math::BigInt::Foo, then Math::BigInt::Bar, and when this also fails, revert to Math::BigInt::Calc:

```
use Math::BigRat try => 'Foo,Math::BigInt::Bar';
```

If you want to get warned when the fallback occurs, replace “try” with “lib”:

```
use Math::BigRat lib => 'Foo,Math::BigInt::Bar';
```

If you want the code to die instead, replace “try” with “only”:

```
use Math::BigRat only => 'Foo,Math::BigInt::Bar';
```

METHODS

Any methods not listed here are derived from Math::BigFloat (or Math::BigInt), so make sure you check these two modules for further information.

- new()

  ```
  $x = Math::BigRat->new('1/3');
  ```

  Create a new Math::BigRat object. Input can come in various forms:

  ```
  $x = Math::BigRat->new(123);                                #␣
  ↪scalars
  $x = Math::BigRat->new('inf');                              #␣
  ↪infinity
  $x = Math::BigRat->new('123.3');                            # float
  $x = Math::BigRat->new('1/3');                              #␣
  ↪simple string
  $x = Math::BigRat->new('1 / 3');                            # spaced
  $x = Math::BigRat->new('1 / 0.1');                          # w/␣
  ↪floats
  $x = Math::BigRat->new(Math::BigInt->new(3));               # BigInt
  $x = Math::BigRat->new(Math::BigFloat->new('3.1'));         #␣
  ↪BigFloat
  $x = Math::BigRat->new(Math::BigInt::Lite->new('2'));       #␣
  ↪BigLite
  ```

(continues on next page)

(continued from previous page)

```
# You can also give D and N as different objects:
$x = Math::BigRat->new(
        Math::BigInt->new(-123),
        Math::BigInt->new(7),
     );                         # => -123/7
```

- from_dec()

```
my $h = Math::BigRat->from_dec("1.2");
```

Create a BigRat from a decimal number in string form. It is equivalent to "new()", but does not accept anything but strings representing finite, decimal numbers.

- from_hex()

```
my $h = Math::BigRat->from_hex("0x10");
```

Create a BigRat from a hexadecimal number in string form.

- from_oct()

```
my $o = Math::BigRat->from_oct("020");
```

Create a BigRat from an octal number in string form.

- from_bin()

```
my $b = Math::BigRat->from_bin("0b10000000");
```

Create a BigRat from an binary number in string form.

- from_bytes()

```
$x = Math::BigRat->from_bytes("\xf3\x6b");  # $x = 62315
```

Interpret the input as a byte string, assuming big endian byte order. The output is always a non-negative, finite integer.

See *"from_bytes()" in Math::BigInt*.

- from_ieee754()

```
# set $x to 13176795/4194304, the closest value to pi that can␣
↪be
# represented in the binary32 (single) format
$x = Math::BigRat -> from_ieee754("40490fdb", "binary32");
```

Interpret the input as a value encoded as described in IEEE754-2008.

See *"from_ieee754()" in Math::BigFloat*.

- from_fp80()

```
# set $x to 14488038916154245685/4611686018427387904, the
 ↪closest value
# to pi that can be represented in the x86 80-bit format
$x = Math::BigRat -> from_fp80("4000c90fdaa22168c235");
```

Interpret the input as a value encoded in the x86 extended-precision 80-bit format.

See *"from_fp80()" in Math::BigFloat*.

- from_base()

  See *"from_base()" in Math::BigInt*.

- bzero()

```
$x = Math::BigRat->bzero();
```

Creates a new BigRat object representing zero. If used on an object, it will set it to zero:

```
$x->bzero();
```

- bone()

```
$x = Math::BigRat->bone($sign);
```

Creates a new BigRat object representing one. The optional argument is either '-' or '+', indicating whether you want one or minus one. If used on an object, it will set it to one:

```
$x->bone();                 # +1
$x->bone('-');              # -1
```

- binf()

```
$x = Math::BigRat->binf($sign);
```

Creates a new BigRat object representing infinity. The optional argument is either '-' or '+', indicating whether you want infinity or minus infinity. If used on an object, it will set it to infinity:

```
$x->binf();
$x->binf('-');
```

- bnan()

```
$x = Math::BigRat->bnan();
```

Creates a new BigRat object representing NaN (Not A Number). If used on an object, it will set it to NaN:

```
$x->bnan();
```

- bpi()

```
$x = Math::BigRat -> bpi();         # default accuracy
$x = Math::BigRat -> bpi(7);        # specified accuracy
```

Returns a rational approximation of PI accurate to the specified accuracy or the default accuracy if no accuracy is specified. If called as an instance method, the value is assigned to the invocand.

```
$x = Math::BigRat -> bpi(1);        # returns "3"
$x = Math::BigRat -> bpi(3);        # returns "22/7"
$x = Math::BigRat -> bpi(7);        # returns "355/113"
```

- copy()

```
my $z = $x->copy();
```

Makes a deep copy of the object.

Please see the documentation in *Math::BigInt* for further details.

- as_int()

```
$y = $x -> as_int();        # $y is a Math::BigInt
```

Returns $x as a Math::BigInt object regardless of upgrading and downgrading. If $x is finite, but not an integer, $x is truncated.

- as_rat()

```
$y = $x -> as_rat();        # $y is a Math::BigRat
```

Returns $x a Math::BigRat object regardless of upgrading and downgrading. The invocand is not modified.

- as_float()

```
$x = Math::BigRat->new('13/7');
print $x->as_float(), "\n";             # '1'

$x = Math::BigRat->new('2/3');
print $x->as_float(5), "\n";            # '0.66667'
```

Returns a copy of the object as Math::BigFloat object regardless of upgrading and downgrading, preserving the accuracy as wanted, or the default of 40 digits.

- bround()/round()/bfround()

Are not yet implemented.

- is_zero()

```
print "$x is 0\n" if $x->is_zero();
```

Return true if $x is exactly zero, otherwise false.

- is_one()

```
print "$x is 1\n" if $x->is_one();
```

Return true if $x is exactly one, otherwise false.

- is_finite()

```
$x->is_finite();    # true if $x is not +inf, -inf or NaN
```

Returns true if the invocand is a finite number, i.e., it is neither +inf, -inf, nor NaN.

- is_positive()
- is_pos()

```
print "$x is >= 0\n" if $x->is_positive();
```

Return true if $x is positive (greater than or equal to zero), otherwise false. Please note that '+inf' is also positive, while 'NaN' and '-inf' aren't.

"is_positive()" is an alias for "is_pos()".

- is_negative()
- is_neg()

```
print "$x is < 0\n" if $x->is_negative();
```

Return true if $x is negative (smaller than zero), otherwise false. Please note that '-inf' is also negative, while 'NaN' and '+inf' aren't.

"is_negative()" is an alias for "is_neg()".

- is_odd()

```
print "$x is odd\n" if $x->is_odd();
```

Return true if $x is odd, otherwise false.

- is_even()

```
print "$x is even\n" if $x->is_even();
```

Return true if $x is even, otherwise false.

- is_int()

```
print "$x is an integer\n" if $x->is_int();
```

Return true if $x has a denominator of 1 (e.g. no fraction parts), otherwise false. Please note that '-inf', 'inf' and 'NaN' aren't integer.

Comparison methods

None of these methods modify the invocand object. Note that a `NaN` is neither less than, greater than, or equal to anything else, even a `NaN`.

- bcmp()

```
$x->bcmp($y);
```

Compares $x with $y and takes the sign into account. Returns -1, 0, 1 or undef.

- bacmp()

```
$x->bacmp($y);
```

Compares $x with $y while ignoring their sign. Returns -1, 0, 1 or undef.

- beq()

```
$x -> beq($y);
```

Returns true if and only if $x is equal to $y, and false otherwise.

- bne()

```
$x -> bne($y);
```

Returns true if and only if $x is not equal to $y, and false otherwise.

- blt()

```
$x -> blt($y);
```

Returns true if and only if $x is equal to $y, and false otherwise.

- ble()

```
$x -> ble($y);
```

Returns true if and only if $x is less than or equal to $y, and false otherwise.

- bgt()

```
$x -> bgt($y);
```

Returns true if and only if $x is greater than $y, and false otherwise.

- bge()

```
$x -> bge($y);
```

Returns true if and only if $x is greater than or equal to $y, and false otherwise.

- blsft()/brsft()

Used to shift numbers left/right.

Please see the documentation in *Math::BigInt* for further details.

- bneg()

```
$x->bneg();
```

Used to negate the object in-place.

- bnorm()

```
$x->bnorm();
```

Reduce the number to the shortest form. This routine is called automatically whenever it is needed.

- binc()

```
$x->binc();
```

Increments $x by 1 and returns the result.

- bdec()

```
$x->bdec();
```

Decrements $x by 1 and returns the result.

- badd()

```
$x->badd($y);
```

Adds $y to $x and returns the result.

- bsub()

```
$x->bsub($y);
```

Subtracts $y from $x and returns the result.

- bmul()

```
$x->bmul($y);
```

Multiplies $y to $x and returns the result.

- bdiv()

```
$q = $x->bdiv($y);
($q, $r) = $x->bdiv($y);
```

In scalar context, divides $x by $y and returns the result. In list context, does floored division (F-division), returning an integer $q and a remainder $r so that `$x = $q * $y + $r`. The remainer (modulo) is equal to what is returned by `$x->bmod($y)`.

- bmod()

```
$x->bmod($y);
```

Returns $x modulo $y. When $x is finite, and $y is finite and non-zero, the result is identical to the remainder after floored division (F-division). If, in addition, both $x and $y are integers, the result is identical to the result from Perl's % operator.

- binv()

```
$x->binv();
```

Inverse of $x.

- bsqrt()

```
$x->bsqrt();
```

Calculate the square root of $x.

- bpow()

```
$x->bpow($y);
```

Compute $x ** $y.

Please see the documentation in *Math::BigInt* for further details.

- broot()

```
$x->broot($n);
```

Calculate the N'th root of $x.

- bmodpow()

```
$num->bmodpow($exp,$mod);           # modular exponentiation
                                    # ($num**$exp % $mod)
```

Returns the value of `$num` taken to the power `$exp` in the modulus `$mod` using binary exponentiation. `bmodpow` is far superior to writing

```
$num ** $exp % $mod
```

because it is much faster - it reduces internal variables into the modulus whenever possible, so it operates on smaller numbers.

`bmodpow` also supports negative exponents.

```
bmodpow($num, -1, $mod)
```

is exactly equivalent to

```
bmodinv($num, $mod)
```

- bmodinv()

```
$x->bmodinv($mod);          # modular multiplicative inverse
```

Returns the multiplicative inverse of `$x` modulo `$mod`. If

```
$y = $x -> copy() -> bmodinv($mod)
```

then `$y` is the number closest to zero, and with the same sign as `$mod`, satisfying

```
($x * $y) % $mod = 1 % $mod
```

If $x and $y are non-zero, they must be relative primes, i.e., bgcd($y, $mod)==1. 'NaN' is returned when no modular multiplicative inverse exists.

- blog()

```
$x->blog($base, $accuracy);         # logarithm of x to the
 ↪base $base
```

If $base is not defined, Euler's number (e) is used:

```
print $x->blog(undef, 100);         # log(x) to 100 digits
```

- bexp()

```
$x->bexp($accuracy);        # calculate e ** X
```

Calculates two integers A and B so that A/B is equal to e ** $x, where e is Euler's number.

This method was added in v0.20 of Math::BigRat (May 2007).

See also "blog()".

- bnok()

See *"bnok()" in Math::BigInt*.

- bperm()

See *"bperm()" in Math::BigInt*.

- bfac()

```
$x->bfac();
```

Calculates the factorial of $x. For instance:

```
print Math::BigRat->new('3/1')->bfac(), "\n";   # 1*2*3
print Math::BigRat->new('5/1')->bfac(), "\n";   # 1*2*3*4*5
```

Works currently only for integers.

- band()

```
$x->band($y);               # bitwise and
```

- bior()

```
$x->bior($y);               # bitwise inclusive or
```

- bxor()

```
$x->bxor($y);               # bitwise exclusive or
```

- bnot()

```
$x->bnot();                    # bitwise not (two's complement)
```

- bfloor()

```
$x->bfloor();
```

Round $x towards minus infinity, i.e., set $x to the largest integer less than or equal to $x.

- bceil()

```
$x->bceil();
```

Round $x towards plus infinity, i.e., set $x to the smallest integer greater than or equal to $x.

- bint()

```
$x->bint();
```

Round $x towards zero.

- bgcd()

```
$x -> bgcd($y);               # GCD of $x and $y
$x -> bgcd($y, $z, ...);      # GCD of $x, $y, $z, ...
```

Returns the greatest common divisor (GCD), which is the number with the largest absolute value such that $x/$gcd, $y/$gcd, ... is an integer. For example, when the operands are 4/5 and 6/5, the GCD is 2/5. This is a generalisation of the ordinary GCD for integers. See *"gcd()" in Math::BigInt*.

- digit()

```
print Math::BigRat->new('123/1')->digit(1);     # 1
print Math::BigRat->new('123/1')->digit(-1);    # 3
```

Return the N'ths digit from X when X is an integer value.

- length()

```
$len = $x->length();
```

Return the length of $x in digits for integer values.

- parts()

```
($n, $d) = $x->parts();
```

Return a list consisting of (signed) numerator and (unsigned) denominator as BigInts.

- dparts()

Returns the integer part and the fraction part.

- fparts()

  Returns the smallest possible numerator and denominator so that the numerator divided by the denominator gives back the original value. For finite numbers, both values are integers. Mnemonic: fraction.

- numerator()

```
$n = $x->numerator();
```

  Returns a copy of the numerator (the part above the line) as signed BigInt.

- denominator()

```
$d = $x->denominator();
```

  Returns a copy of the denominator (the part under the line) as positive BigInt.

String conversion methods

- bstr()

```
my $x = Math::BigRat->new('8/4');
print $x->bstr(), "\n";             # prints 1/2
```

  Returns a string representing the number.

- bnstr()

  See *“bnstr()” in Math::BigInt*.

- bestr()

  See *“bestr()” in Math::BigInt*.

- bdstr()

  See *“bdstr()” in Math::BigInt*.

- to_bytes()

  See *“to_bytes()” in Math::BigInt*.

- to_ieee754()

  See *“to_ieee754()” in Math::BigFloat*.

- to_fp80()

  See *“to_fp80()” in Math::BigFloat*.

- as_hex()

```
$x = Math::BigRat->new('13');
print $x->as_hex(), "\n";               # '0xd'
```

  Returns the BigRat as hexadecimal string. Works only for integers.

- as_oct()

```
$x = Math::BigRat->new('13');
print $x->as_oct(), "\n";               # '015'
```

Returns the BigRat as octal string. Works only for integers.

- as_bin()

```
$x = Math::BigRat->new('13');
print $x->as_bin(), "\n";               # '0x1101'
```

Returns the BigRat as binary string. Works only for integers.

- numify()

```
my $y = $x->numify();
```

Returns the object as a scalar. This will lose some data if the object cannot be represented by a normal Perl scalar (integer or float), so use "as_int()" or "as_float()" instead.

This routine is automatically used whenever a scalar is required:

```
my $x = Math::BigRat->new('3/1');
@array = (0, 1, 2, 3);
$y = $array[$x];                # set $y to 3
```

- config()

```
Math::BigRat->config("trap_nan" => 1);      # set
$accu = Math::BigRat->config("accuracy");   # get
```

Set or get configuration parameter values. Read-only parameters are marked as RO. Read-write parameters are marked as RW. The following parameters are supported.

```
Parameter       RO/RW   Description
                        Example
============================================================
lib             RO      Name of the math backend library
                        Math::BigInt::Calc
lib_version     RO      Version of the math backend library
                        0.30
class           RO      The class of config you just called
                        Math::BigRat
version         RO      version number of the class you used
                        0.10
upgrade         RW      To which class numbers are upgraded
                        undef
downgrade       RW      To which class numbers are downgraded
                        undef
precision       RW      Global precision
                        undef
accuracy        RW      Global accuracy
```

(continues on next page)

(continued from previous page)

```
                        undef
round_mode      RW      Global round mode
                        even
div_scale       RW      Fallback accuracy for div, sqrt etc.
                        40
trap_nan        RW      Trap NaNs
                        undef
trap_inf        RW      Trap +inf/-inf
                        undef
```

NUMERIC LITERALS

After `use Math::BigRat ':constant'` all numeric literals in the given scope are converted to `Math::BigRat` objects. This conversion happens at compile time. Every non-integer is convert to a NaN.

For example,

```
perl -MMath::BigRat=:constant -le 'print 2**150'
```

prints the exact value of `2**150`. Note that without conversion of constants to objects the expression `2**150` is calculated using Perl scalars, which leads to an inaccurate result.

Please note that strings are not affected, so that

```
use Math::BigRat qw/:constant/;

$x = "12345678901234567890123456789012345678901234567890"
        + "123456789123456789";
```

does give you what you expect. You need an explicit Math::BigRat->new() around at least one of the operands. You should also quote large constants to prevent loss of precision:

```
use Math::BigRat;

$x = Math::BigRat->new("12345678891234567891234567891234567891234567890");
```

Without the quotes Perl first converts the large number to a floating point constant at compile time, and then converts the result to a Math::BigRat object at run time, which results in an inaccurate result.

Hexadecimal, octal, and binary floating point literals

Perl (and this module) accepts hexadecimal, octal, and binary floating point literals, but use them with care with Perl versions before v5.32.0, because some versions of Perl silently give the wrong result. Below are some examples of different ways to write the number decimal 314.

Hexadecimal floating point literals:

```
0x1.3ap+8          0X1.3AP+8
0x1.3ap8           0X1.3AP8
0x13a0p-4          0X13A0P-4
```

Octal floating point literals (with "0" prefix):

```
01.164p+8          01.164P+8
01.164p8           01.164P8
011640p-4          011640P-4
```

Octal floating point literals (with "0o" prefix) (requires v5.34.0):

```
0o1.164p+8         0O1.164P+8
0o1.164p8          0O1.164P8
0o11640p-4         0O11640P-4
```

Binary floating point literals:

```
0b1.0011101p+8     0B1.0011101P+8
0b1.0011101p8      0B1.0011101P8
0b10011101000p-2   0B10011101000P-2
```

BUGS

Please report any bugs or feature requests to `bug-math-bigint at rt.cpan.org`, or through the web interface at https://rt.cpan.org/Ticket/Create.html?Queue=Math-BigInt (requires login). We will be notified, and then you'll automatically be notified of progress on your bug as I make changes.

SUPPORT

You can find documentation for this module with the perldoc command.

Math::Complex

complex numbers and associated mathematical functions

SYNOPSIS

```
use Math::Complex;

$z = Math::Complex->make(5, 6);
$t = 4 - 3*i + $z;
$j = cplxe(1, 2*pi/3);
```

DESCRIPTION

This package lets you create and manipulate complex numbers. By default, *Perl* limits itself to real numbers, but an extra `use` statement brings full complex support, along with a full set of mathematical functions typically associated with and/or extended to complex numbers.

If you wonder what complex numbers are, they were invented to be able to solve the following equation:

```
x*x = -1
```

and by definition, the solution is noted *i* (engineers use *j* instead since *i* usually denotes an intensity, but the name does not matter). The number *i* is a pure *imaginary* number.

The arithmetics with pure imaginary numbers works just like you would expect it with real numbers... you just have to remember that

```
i*i = -1
```

so you have:

```
5i + 7i = i * (5 + 7) = 12i
4i - 3i = i * (4 - 3) = i
4i * 2i = -8
6i / 2i = 3
1 / i = -i
```

Complex numbers are numbers that have both a real part and an imaginary part, and are usually noted:

```
a + bi
```

where a is the *real* part and b is the *imaginary* part. The arithmetic with complex numbers is straightforward. You have to keep track of the real and the imaginary parts, but otherwise the rules used for real numbers just apply:

```
(4 + 3i) + (5 - 2i) = (4 + 5) + i(3 - 2) = 9 + i
(2 + i) * (4 - i) = 2*4 + 4i -2i -i*i = 8 + 2i + 1 = 9 + 2i
```

A graphical representation of complex numbers is possible in a plane (also called the *complex plane*, but it's really a 2D plane). The number

```
z = a + bi
```

is the point whose coordinates are (a, b). Actually, it would be the vector originating from (0, 0) to (a, b). It follows that the addition of two complex numbers is a vectorial addition.

Since there is a bijection between a point in the 2D plane and a complex number (i.e. the mapping is unique and reciprocal), a complex number can also be uniquely identified with polar coordinates:

```
[rho, theta]
```

where rho is the distance to the origin, and theta the angle between the vector and the *x* axis. There is a notation for this using the exponential form, which is:

```
rho * exp(i * theta)
```

where *i* is the famous imaginary number introduced above. Conversion between this form and the cartesian form a + bi is immediate:

```
a = rho * cos(theta)
b = rho * sin(theta)
```

which is also expressed by this formula:

```
z = rho * exp(i * theta) = rho * (cos theta + i * sin theta)
```

In other words, it's the projection of the vector onto the *x* and *y* axes. Mathematicians call *rho* the *norm* or *modulus* and *theta* the *argument* of the complex number. The *norm* of z is marked here as abs(z).

The polar notation (also known as the trigonometric representation) is much more handy for performing multiplications and divisions of complex numbers, whilst the cartesian notation is better suited for additions and subtractions. Real numbers are on the *x* axis, and therefore *y* or *theta* is zero or *pi*.

All the common operations that can be performed on a real number have been defined to work on complex numbers as well, and are merely *extensions* of the operations defined on real numbers. This means they keep their natural meaning when there is no imaginary part, provided the number is within their definition set.

For instance, the `sqrt` routine which computes the square root of its argument is only defined for non-negative real numbers and yields a non-negative real number (it is an application from **R**+ to **R**+). If we allow it to return a complex number, then it can be extended to negative real numbers to become an application from **R** to **C** (the set of complex numbers):

```
sqrt(x) = x >= 0 ? sqrt(x) : sqrt(-x)*i
```

It can also be extended to be an application from **C** to **C**, whilst its restriction to **R** behaves as defined above by using the following definition:

```
sqrt(z = [r,t]) = sqrt(r) * exp(i * t/2)
```

Indeed, a negative real number can be noted `[x,pi]` (the modulus *x* is always non-negative, so `[x,pi]` is really `-x`, a negative number) and the above definition states that

```
sqrt([x,pi]) = sqrt(x) * exp(i*pi/2) = [sqrt(x),pi/2] = sqrt(x)*i
```

which is exactly what we had defined for negative real numbers above. The `sqrt` returns only one of the solutions: if you want the both, use the `root` function.

All the common mathematical functions defined on real numbers that are extended to complex numbers share that same property of working *as usual* when the imaginary part is zero (otherwise, it would not be called an extension, would it?).

A *new* operation possible on a complex number that is the identity for real numbers is called the *conjugate*, and is noted with a horizontal bar above the number, or `~z` here.

```
 z = a + bi
~z = a - bi
```

Simple... Now look:

```
z * ~z = (a + bi) * (a - bi) = a*a + b*b
```

We saw that the norm of `z` was noted `abs(z)` and was defined as the distance to the origin, also known as:

```
rho = abs(z) = sqrt(a*a + b*b)
```

so

```
z * ~z = abs(z) ** 2
```

If z is a pure real number (i.e. `b == 0`), then the above yields:

```
a * a = abs(a) ** 2
```

which is true (`abs` has the regular meaning for real number, i.e. stands for the absolute value). This example explains why the norm of `z` is noted `abs(z)`: it extends the `abs` function to complex numbers, yet is the regular `abs` we know when the complex number actually has no imaginary part... This justifies *a posteriori* our use of the `abs` notation for the norm.

OPERATIONS

Given the following notations:

```
z1 = a + bi = r1 * exp(i * t1)
z2 = c + di = r2 * exp(i * t2)
z = <any complex or real number>
```

the following (overloaded) operations are supported on complex numbers:

```
z1 + z2 = (a + c) + i(b + d)
z1 - z2 = (a - c) + i(b - d)
z1 * z2 = (r1 * r2) * exp(i * (t1 + t2))
z1 / z2 = (r1 / r2) * exp(i * (t1 - t2))
z1 ** z2 = exp(z2 * log z1)
~z = a - bi
abs(z) = r1 = sqrt(a*a + b*b)
sqrt(z) = sqrt(r1) * exp(i * t/2)
exp(z) = exp(a) * exp(i * b)
log(z) = log(r1) + i*t
sin(z) = 1/2i (exp(i * z1) - exp(-i * z))
cos(z) = 1/2 (exp(i * z1) + exp(-i * z))
atan2(y, x) = atan(y / x) # Minding the right quadrant, note the␣
↪order.
```

The definition used for complex arguments of atan2() is

```
-i log((x + iy)/sqrt(x*x+y*y))
```

Note that atan2(0, 0) is not well-defined.

The following extra operations are supported on both real and complex numbers:

```
Re(z) = a
Im(z) = b
arg(z) = t
abs(z) = r

cbrt(z) = z ** (1/3)
log10(z) = log(z) / log(10)
logn(z, n) = log(z) / log(n)
```

(continues on next page)

(continued from previous page)

```
tan(z) = sin(z) / cos(z)

csc(z) = 1 / sin(z)
sec(z) = 1 / cos(z)
cot(z) = 1 / tan(z)

asin(z) = -i * log(i*z + sqrt(1-z*z))
acos(z) = -i * log(z + i*sqrt(1-z*z))
atan(z) = i/2 * log((i+z) / (i-z))

acsc(z) = asin(1 / z)
asec(z) = acos(1 / z)
acot(z) = atan(1 / z) = -i/2 * log((i+z) / (z-i))

sinh(z) = 1/2 (exp(z) - exp(-z))
cosh(z) = 1/2 (exp(z) + exp(-z))
tanh(z) = sinh(z) / cosh(z) = (exp(z) - exp(-z)) / (exp(z) + exp(-
 ↪z))

csch(z) = 1 / sinh(z)
sech(z) = 1 / cosh(z)
coth(z) = 1 / tanh(z)

asinh(z) = log(z + sqrt(z*z+1))
acosh(z) = log(z + sqrt(z*z-1))
atanh(z) = 1/2 * log((1+z) / (1-z))

acsch(z) = asinh(1 / z)
asech(z) = acosh(1 / z)
acoth(z) = atanh(1 / z) = 1/2 * log((1+z) / (z-1))
```

arg, *abs*, *log*, *csc*, *cot*, *acsc*, *acot*, *csch*, *coth*, *acosech*, *acotanh*, have aliases *rho*, *theta*, *ln*, *cosec*, *cotan*, *acosec*, *acotan*, *cosech*, *cotanh*, *acosech*, *acotanh*, respectively. `Re`, `Im`, `arg`, `abs`, `rho`, and `theta` can be used also as mutators. The `cbrt` returns only one of the solutions: if you want all three, use the `root` function.

The *root* function is available to compute all the *n* roots of some complex, where *n* is a strictly positive integer. There are exactly *n* such roots, returned as a list. Getting the number mathematicians call `j` such that:

```
1 + j + j*j = 0;
```

is a simple matter of writing:

```
$j = (root(1, 3))[1];
```

The _k_th root for `z = [r,t]` is given by:

```
(root(z, n))[k] = r**(1/n) * exp(i * (t + 2*k*pi)/n)
```

You can return the _k_th root directly by `root(z, n, k)`, indexing starting from *zero*

and ending at *n - 1*.

The *spaceship* numeric comparison operator, <=>, is also defined. In order to ensure its restriction to real numbers is conform to what you would expect, the comparison is run on the real part of the complex number first, and imaginary parts are compared only when the real parts match.

CREATION

To create a complex number, use either:

```
$z = Math::Complex->make(3, 4);
$z = cplx(3, 4);
```

if you know the cartesian form of the number, or

```
$z = 3 + 4*i;
```

if you like. To create a number using the polar form, use either:

```
$z = Math::Complex->emake(5, pi/3);
$x = cplxe(5, pi/3);
```

instead. The first argument is the modulus, the second is the angle (in radians, the full circle is 2*pi). (Mnemonic: `e` is used as a notation for complex numbers in the polar form).

It is possible to write:

```
$x = cplxe(-3, pi/4);
```

but that will be silently converted into `[3,-3pi/4]`, since the modulus must be non-negative (it represents the distance to the origin in the complex plane).

It is also possible to have a complex number as either argument of the `make`, `emake`, `cplx`, and `cplxe`: the appropriate component of the argument will be used.

```
$z1 = cplx(-2,  1);
$z2 = cplx($z1, 4);
```

The `new`, `make`, `emake`, `cplx`, and `cplxe` will also understand a single (string) argument of the forms

```
2-3i
-3i
[2,3]
[2,-3pi/4]
[2]
```

in which case the appropriate cartesian and exponential components will be parsed from the string and used to create new complex numbers. The imaginary component and the theta, respectively, will default to zero.

The `new`, `make`, `emake`, `cplx`, and `cplxe` will also understand the case of no arguments: this means plain zero or (0, 0).

DISPLAYING

When printed, a complex number is usually shown under its cartesian style *a+bi*, but there are legitimate cases where the polar style *[r,t]* is more appropriate. The process of converting the complex number into a string that can be displayed is known as *stringification*.

By calling the class method `Math::Complex::display_format` and supplying either `"polar"` or `"cartesian"` as an argument, you override the default display style, which is `"cartesian"`. Not supplying any argument returns the current settings.

This default can be overridden on a per-number basis by calling the `display_format` method instead. As before, not supplying any argument returns the current display style for this number. Otherwise whatever you specify will be the new display style for *this* particular number.

For instance:

```
use Math::Complex;

Math::Complex::display_format('polar');
$j = (root(1, 3))[1];
print "j = $j\n";               # Prints "j = [1,2pi/3]"
$j->display_format('cartesian');
print "j = $j\n";               # Prints "j = -0.5+0.
 ↪866025403784439i"
```

The polar style attempts to emphasize arguments like *k*pi/n* (where *n* is a positive integer and *k* an integer within [-9, +9]), this is called *polar pretty-printing*.

For the reverse of stringifying, see the `make` and `emake`.

CHANGED IN PERL 5.6

The `display_format` class method and the corresponding `display_format` object method can now be called using a parameter hash instead of just a one parameter.

The old display format style, which can have values `"cartesian"` or `"polar"`, can be changed using the `"style"` parameter.

```
$j->display_format(style => "polar");
```

The one parameter calling convention also still works.

```
$j->display_format("polar");
```

There are two new display parameters.

The first one is `"format"`, which is a sprintf()-style format string to be used for both numeric parts of the complex number(s). The is somewhat system-dependent but most often it corresponds to `"%.15g"`. You can revert to the default by setting the `format` to `undef`.

```
# the $j from the above example

$j->display_format('format' => '%.5f');
print "j = $j\n";               # Prints "j = -0.50000+0.86603i"
$j->display_format('format' => undef);
print "j = $j\n";               # Prints "j = -0.5+0.86603i"
```

Notice that this affects also the return values of the `display_format` methods: in list context the whole parameter hash will be returned, as opposed to only the style parameter value. This is a potential incompatibility with earlier versions if you have been calling the `display_format` method in list context.

The second new display parameter is `"polar_pretty_print"`, which can be set to true or false, the default being true. See the previous section for what this means.

USAGE

Thanks to overloading, the handling of arithmetics with complex numbers is simple and almost transparent.

Here are some examples:

```
use Math::Complex;

$j = cplxe(1, 2*pi/3);  # $j ** 3 == 1
print "j = $j, j**3 = ", $j ** 3, "\n";
print "1 + j + j**2 = ", 1 + $j + $j**2, "\n";

$z = -16 + 0*i;                 # Force it to be a complex
print "sqrt($z) = ", sqrt($z), "\n";

$k = exp(i * 2*pi/3);
print "$j - $k = ", $j - $k, "\n";

$z->Re(3);                      # Re, Im, arg, abs,
$j->arg(2);                     # (the last two aka rho, theta)
                                # can be used also as mutators.
```

CONSTANTS

PI

The constant `pi` and some handy multiples of it (pi2, pi4, and pip2 (pi/2) and pip4 (pi/4)) are also available if separately exported:

```
use Math::Complex ':pi';
$third_of_circle = pi2 / 3;
```

Inf

The floating point infinity can be exported as a subroutine Inf():

```
use Math::Complex qw(Inf sinh);
my $AlsoInf = Inf() + 42;
my $AnotherInf = sinh(1e42);
print "$AlsoInf is $AnotherInf\n" if $AlsoInf == $AnotherInf;
```

Note that the stringified form of infinity varies between platforms: it can be for example any of

```
inf
infinity
INF
1.#INF
```

or it can be something else.

Also note that in some platforms trying to use the infinity in arithmetic operations may result in Perl crashing because using an infinity causes SIGFPE or its moral equivalent to be sent. The way to ignore this is

```
local $SIG{FPE} = sub { };
```

ERRORS DUE TO DIVISION BY ZERO OR LOGARITHM OF ZERO

The division (/) and the following functions

```
log     ln      log10   logn
tan     sec     csc     cot
atan    asec    acsc    acot
tanh    sech    csch    coth
atanh   asech   acsch   acoth
```

cannot be computed for all arguments because that would mean dividing by zero or taking logarithm of zero. These situations cause fatal runtime errors looking like this

```
cot(0): Division by zero.
(Because in the definition of cot(0), the divisor sin(0) is 0)
Died at ...
```

or

```
atanh(-1): Logarithm of zero.
Died at...
```

For the `csc`, `cot`, `asec`, `acsc`, `acot`, `csch`, `coth`, `asech`, `acsch`, the argument cannot be `0` (zero). For the logarithmic functions and the `atanh`, `acoth`, the argument cannot be `1` (one). For the `atanh`, `acoth`, the argument cannot be `-1` (minus one). For the `atan`, `acot`, the argument cannot be `i` (the imaginary unit). For the `atan`, `acoth`, the argument cannot be `-i` (the negative imaginary unit). For the `tan`, `sec`, `tanh`, the argument cannot

be *pi/2 + k * pi*, where *k* is any integer. atan2(0, 0) is undefined, and if the complex arguments are used for atan2(), a division by zero will happen if z1**2+z2**2 == 0.

Note that because we are operating on approximations of real numbers, these errors can happen when merely `too close' to the singularities listed above.

ERRORS DUE TO INDIGESTIBLE ARGUMENTS

The `make` and `emake` accept both real and complex arguments. When they cannot recognize the arguments they will die with error messages like the following

```
Math::Complex::make: Cannot take real part of ...
Math::Complex::make: Cannot take real part of ...
Math::Complex::emake: Cannot take rho of ...
Math::Complex::emake: Cannot take theta of ...
```

BUGS

Saying `use Math::Complex;` exports many mathematical routines in the caller environment and even overrides some (`sqrt`, `log`, `atan2`). This is construed as a feature by the Authors, actually... ;-)

All routines expect to be given real or complex numbers. Don't attempt to use BigFloat, since Perl has currently no rule to disambiguate a '+' operation (for instance) between two overloaded entities.

In Cray UNICOS there is some strange numerical instability that results in root(), cos(), sin(), cosh(), sinh(), losing accuracy fast. Beware. The bug may be in UNICOS math libs, in UNICOS C compiler, in Math::Complex. Whatever it is, it does not manifest itself anywhere else where Perl runs.

Math::GMP

Arbitrary-precision integer arithmetic backed by GNU `libgmp`.

`Math::GMP` lets you work with integers of unlimited size. The interpreter's native integer tops out somewhere around `2**63`; pass anything bigger through a `Math::GMP` object and every arithmetic operator keeps working, up to the memory you have.

Build a value with `Math::GMP->new`, then use it like a normal number - the module overloads `+ - * / % ** <=> == & | ^ << >>` so `$x * $y` and `$x ** 1000` Do The Right Thing. Only the final stringification crosses back into ordinary Perl:

```
use Math::GMP;
my $x = Math::GMP->new('2');
my $huge = $x ** 1024;                    # a 309-digit integer
print "$huge\n";
```

A `Math::GMP` value is a blessed reference whose underlying scalar holds a pointer to a GMP `mpz_t`. Passing one to `ref` returns `"Math::GMP"`; passing it to a stringifying or numifying operator goes through the overloaded `op_stringify` / `op_numify`.

The `:constant` pragma extends the overloading to bare integer literals in your source:

```
use Math::GMP qw(:constant);
my $n = 2 ** (256 * 1024);                # evaluated in GMP, not␣
↪doubles
```

Without `:constant` the exponent `256 * 1024` would be computed as a C `double` and overflow to infinity before `Math::GMP` ever sees it.

Division by zero

`libgmp` raises `SIGFPE` on division by zero instead of returning a Perl-level error. On Perl 5.36 and later you can trap it with a `$SIG{FPE}` handler; on older Perls use `POSIX::sigaction`. Returning from the handler re-raises the signal, so use it for diagnostics (`Carp::confess`) rather than recovery.

libgmp itself is the system's `libgmp.so.10`, loaded with the module. This is a native implementation of the XS half of Math::GMP 2.25; its `Math/GMP.pm` is used unchanged, and nothing is exported by default.

Differences from upstream

`_gmp_build_version` reports the libgmp actually loaded, which is the library this module is built on; upstream reports the GMP headers it was compiled against, which there are none of here.

Functions

Construction

new_from_scalar

Build a `Math::GMP` object from a decimal/auto-detected string.

new_from_scalar_with_base

Build a `Math::GMP` object from a string in the given base.

destroy

Release the `mpz_t` backing a `Math::GMP` object.

gmp_copy

Return an independent copy of `$x`.

Conversion

stringify

Return the decimal string representation of a `Math::GMP` value.

get_str_gmp

Return the string representation of `$x` in the given base.

sizeinbase_gmp

Return the number of digits `$x` would take in the given base.

uintify

Return the low bits of `$x` as a plain unsigned Perl integer.

intify

Return `$x` as a plain signed Perl integer.

Arithmetic

add_ui_gmp

Add an unsigned integer to `$x` in place.

op_add

Overloaded `+` - return `$m + $n` as a new `Math::GMP`.

op_sub

Overloaded `-` - return `$m - $n` as a new `Math::GMP`.

op_mul

Overloaded `*` - return `$m * $n` as a new `Math::GMP`.

bmulf

Return `$x` multiplied by a floating-point value, truncated to an integer.

op_div

Overloaded `/` - integer division `int($m / $n)`, truncated toward zero.

bdiv

Return the quotient and remainder of `$m / $n` as a two-element list.

op_mod

Overloaded `%` - remainder of `$m / $n`, sign follows the dividend.

op_pow

Overloaded `**` - return `$m` raised to the integer power `$n`.

Comparison

op_spaceship

Overloaded `<=>` - signed comparison returning `-1`, `0`, or `1`.

op_eq

Overloaded `==` - return `1` when `$m` equals `$n`, else `0`.

Bitwise

mul_2exp_gmp

Return `$x` shifted left by `$e` bits (`$x * 2**$e`).

Synopsis

```
Math::GMP->new(0b1011)->mul_2exp_gmp(4);   # 0b10110000
```

Equivalent to `$x << $e` on a `Math::GMP` value; the operator form goes through `blshift`. `$e` is a plain non-negative integer.

div_2exp_gmp

Return `$x` shifted right by `$e` bits (`int($x / 2**$e)`).

Synopsis

```
Math::GMP->new(200)->div_2exp_gmp(2);      # 50
```

Truncates toward zero, matching `libgmp`'s `mpz_tdiv_q_2exp`. Use `brshift` for the overloaded-operator spelling.

mod_2exp_gmp

Return the low `$cnt` bits of `$x` (`$x mod 2**$cnt`).

Synopsis

```
Math::GMP->new(0b10001011)->mod_2exp_gmp(4);    # 0b1011
```

Does not modify `$x`. The sign of the result matches `$x` - this is truncated (`tdiv`) rather than Euclidean (`mmod`) semantics.

band

Bit-wise AND of `$m` and `$n`.

Synopsis

```
Math::GMP->new(6)->band(3);      # 0b110 & 0b011 = 0b010 = 2
```

Overload hook for `&`. The optional third argument (`swap`) is accepted and ignored.

bxor

Bit-wise XOR of `$m` and `$n`.

bior

Bit-wise inclusive OR of `$m` and `$n`.

blshift

Return `$m << $n` - left shift by `$n` bits.

brshift

Return `$m >> $n` - right shift by `$n` bits, truncating toward zero.

gmp_tstbit

Return bit `$n` of `$x` (0-indexed, from the least significant end).

Number theory

powm_gmp

Compute `$base ** $exp mod $mod` without building the full power.

`mmod_gmp`

Return the non-negative remainder of `$a / $b`.

`bmodinv`

Return the modular inverse of `$x` mod `$y`.

`legendre`

Return the Legendre symbol `($m / $n)` as `-1`, `0`, or `1`.

`jacobi`

Return the Jacobi symbol `($m / $n)` as `-1`, `0`, or `1`.

`probab_prime`

Probabilistic primality test: return `0`, `1`, or `2`.

`bgcd`

Return the greatest common divisor of `$m` and `$n`.

`blcm`

Return the least common multiple of `$m` and `$n`.

`fibonacci`

Return the `$n`-th Fibonacci number.

`bfac`

Return `$n!` - the factorial of a non-negative integer.

`bnok`

Return the binomial coefficient `$n choose $k`.

Roots and powers

`broot`

Return the integer `$n`-th root of `$x`, truncated toward zero.

brootrem

Return the integer $n-th root of $x and the shortfall.

bsqrt

Return the integer square root of $x.

bsqrtrem

Return the integer square root of $x and the shortfall.

Synopsis

```
my ($r, $q) = Math::GMP->new(7)->bsqrtrem;   # 2, 3
# because 2**2 + 3 == 7
```

The returned list satisfies `$r ** 2 + $q == $x`.

is_perfect_power

Return 1 when $x is a perfect power `$a ** $b` with `$b > 1`.

is_perfect_square

Return 1 when $x is the square of an integer, else `0`.

Synopsis

```
Math::GMP->new(49)->is_perfect_square;   # 1
Math::GMP->new(50)->is_perfect_square;   # 0
```

Overload glue

op_stringify

Overloaded `""` - stringify a `Math::GMP` as its decimal digits.

op_numify

Overloaded `0+` - convert a `Math::GMP` to a plain Perl number.

op_bool

Overloaded `bool` - true when $x is non-zero.

Library info

_gmp_build_version

Return the version of `libgmp` this module is built on, as a v-string.

_gmp_lib_version

Return the version of `libgmp` currently loaded into the process.

Other Functions

new

Build a `Math::GMP` object from a string or integer scalar.

_gmp_build_version

Return the version of `libgmp` this module is built on, as a v-string.

```
printf "built on libgmp %vd\n", Math::GMP::_gmp_build_version();   #␣
 ↪6.3.0
```

Upstream reports the GMP headers it was compiled against. libgmp is bound here when the module loads, not at compile time, so the library it is built on is the one loaded: this is `_gmp_lib_version`'s value.

_gmp_lib_version

Return the version of `libgmp` currently loaded into the process.

Synopsis

```
my $v = Math::GMP::_gmp_lib_version();
printf "running libgmp %vd\n", $v;   # e.g. "running libgmp 6.3.0"
```

What you get back

A v-string, as `v6.3.0` would be: its characters are the version numbers, so it is formatted with `sprintf "%vd"`, compared with `lt`/`gt` against another v-string, and accepted by `version->parse`. Printed as it is, it shows those characters, not the dotted digits.

Differences from upstream

Fully compatible with upstream.

get_str_gmp

Return the string representation of `$x` in the given base.

Synopsis

```
my $x = Math::GMP->new(3 * 7 + 2 * 7**2 + 6 * 7**3);
print $x->get_str_gmp(7);      # "6230"
print $x->get_str_gmp(16);     # hex
```

Base is 2 through 36 for lowercase digits or `-2` through `-36` for uppercase, matching `libgmp`'s `mpz_get_str` convention.

sizeinbase_gmp

Return the number of digits `$x` would take in the given base.

Synopsis

```
Math::GMP->new(10**100)->sizeinbase_gmp(10);    # 101
Math::GMP->new(255)->sizeinbase_gmp(2);         # 8
```

The count may be off by one on the high side - this is `libgmp`'s documented behaviour for `mpz_sizeinbase`, which trades accuracy for speed. Use it for buffer sizing, not for exact digit counts.

intify

Return `$x` as a plain signed Perl integer.

Synopsis

```
my $n = Math::GMP->new(-42)->intify;    # -42
```

Truncates when `$x` does not fit in a platform `signed long`. For values outside that range use `get_str_gmp` or stringify to preserve precision.

add_ui_gmp

Add an unsigned integer to `$x` in place.

Synopsis

```
my $x = Math::GMP->new(1_000_000);
$x->add_ui_gmp(7);
print $x;                   # 1000007
```

Mutates `$x` and returns nothing. The second argument must be a non-negative plain Perl integer. Useful in tight counting loops where allocating a new `Math::GMP` per `+=` would dominate the cost.

powm_gmp

Compute `$base ** $exp mod $mod` without building the full power.

Synopsis

```
my $base = Math::GMP->new(157);
my $exp  = Math::GMP->new(100);
my $mod  = Math::GMP->new(5013);
my $r    = $base->powm_gmp($exp, $mod);   # 157**100 mod 5013
```

The workhorse of RSA-style modular exponentiation: fast enough for thousand-bit exponents, and never materialises the intermediate `$base ** $exp`. Behaviour is undefined when `$mod` is `0`.

mmod_gmp

Return the non-negative remainder of `$a / $b`.

Synopsis

```
Math::GMP->new(-7)->mmod_gmp(3);        # 2, not -1
```

Unlike `%` on `Math::GMP` (which uses truncated division and follows the sign of the dividend), `mmod_gmp` always returns a result in `[0, abs($b))`. This matches the mathematical "mod" operation used in number-theory work.

op_numify

Overloaded `0+` - convert a `Math::GMP` to a plain Perl number.

Invoked when a `Math::GMP` is used in numeric context outside of the overloaded arithmetic operators (for example, passed to a function that does `$arg + 0`). Precision is limited to what an `IV` or `UV` can hold; for large values the top bits are lost. Call `intify` or `uintify` if you want to be explicit about the cast, or stringify if you want to keep all the digits.

bmulf

Return `$x` multiplied by a floating-point value, truncated to an integer.

Synopsis

```
my $x = Math::GMP->new(3)->bpow(100);
my $y = $x->bmulf(1.5);                 # floor(3**100 * 1.5)
```

The double `$float` is converted to a GMP float, multiplied, then truncated toward zero. Internal precision is raised just enough to hold both operands exactly; the default `mpf` precision is restored before returning.

Edge cases

- `$float == 0.0` gives a `Math::GMP` of `0`.
- Negative `$float` gives a result with the expected sign.
- `NaN` / infinity gives an implementation-defined result; do not rely on it.

bdiv

Return the quotient and remainder of `$m / $n` as a two-element list.

Synopsis

```
my $x = Math::GMP->new(7);
my ($q, $r) = $x->bdiv(3);      # $q = 2, $r = 1
```

Division truncates toward zero, and the remainder has the same sign as the dividend - the `tdiv_qr` convention. For non-negative remainders, combine with `mmod_gmp`.

bmodinv

Return the modular inverse of `$x` mod `$y`.

Synopsis

```
my $x = Math::GMP->new(5);
my $inv = $x->bmodinv(7);      # 3, because 5 * 3 == 1 (mod 7)
```

When `$x` has no inverse modulo `$y` (i.e. `gcd($x, $y) != 1`), returns `0`. Behaviour is undefined when `$y` is `0`.

Edge cases

- `bmodinv` returning `0` is ambiguous: `0` is never a valid inverse, so treat it as "no inverse exists".

legendre

Return the Legendre symbol `($m / $n)` as `-1`, `0`, or `1`.

Synopsis

```
Math::GMP->new(6)->legendre(Math::GMP->new(11));   # -1, 0, or 1
```

Defined only when `$n` is an odd prime. When `$n` is not an odd prime the result is currently `0`, but do not rely on that - upstream documents this as "may change in the future".

probab_prime

Probabilistic primality test: return `0`, 1, or 2.

Synopsis

```
my $x = Math::GMP->new(7);
my $v = $x->probab_prime(10);   # 2 - definitely prime
```

What you get back

- `0` - definitely composite.
- 1 - probably prime (no witness found in `$reps` rounds).
- 2 - definitely prime (small numbers, or `libgmp` proved it).

`$reps` is the Miller-Rabin round count; higher values cost more but tighten the confidence on a 1 answer. A round count of 25 is a common default for cryptographic work.

bgcd

Return the greatest common divisor of `$m` and `$n`.

Synopsis

```
my $x = Math::GMP->new(6);
print $x->bgcd(4);              # 2
```

Also registered as `gcd`. Result is always non-negative; `bgcd(0, 0)` is `0`.

blcm

Return the least common multiple of `$m` and `$n`.

Synopsis

```
my $x = Math::GMP->new(6);
print $x->blcm(4);              # 12
```

Also registered as `lcm`. Result is always non-negative; `blcm($x, 0)` is `0`.

fibonacci

Return the $n-th Fibonacci number.

Synopsis

```
my $f = Math::GMP::fibonacci(100);    # 354224848179261915075
```

Called as a function, not a method. `$n` is a plain Perl non-negative integer. `libgmp`'s recursive doubling algorithm handles indices in the millions in fractions of a second.

blshift

Return `$m << $n` - left shift by `$n` bits.

Synopsis

```
Math::GMP->new(0b11) << 4;                # 0b110000 = 48
Math::GMP->new(0b11)->blshift(4, 0);      # same; the third argument
↪is
                                          # the overload swap flag
```

Overload hook for <<. Only the low bits of `$n` that fit in an `unsigned long` count, because it is passed through `mpz_get_ui`: the shift is `abs($n)` modulo 2**64, so a negative `$n` shifts left by its magnitude and `2**64 + 1` shifts by 1.

brshift

Return `$m >> $n` - right shift by `$n` bits, truncating toward zero.

Synopsis

```
Math::GMP->new(0b11001) >> 3;               # 0b11 = 3
Math::GMP->new(0b11001)->brshift(3, 0);     # same; the third
↪argument
                                            # is the overload swap
↪flag
```

Overload hook for >>. Uses truncated division, so negative values shift toward zero rather than toward minus infinity.

bfac

Return `$n!` - the factorial of a non-negative integer.

Synopsis

```
my $x = Math::GMP->new(5);
print $x->bfac;                 # 1*2*3*4*5 = 120
```

The receiver is read as an `unsigned long` - factorials larger than that range are out of reach of a single call. In practice this is rarely limiting: `libgmp` struggles with memory long before `LONG_MAX` enters the picture.

bnok

Return the binomial coefficient `$n choose $k`.

Synopsis

```
my $x = Math::GMP->new(5);
print $x->bnok(2);              # 10
```

Equivalent to `$n! / ($k! * ($n - $k)!)`, but computed without building the factorials - suitable for counting problems where `$n` is large.

gmp_copy

Return an independent copy of `$x`.

Because `Math::GMP` values are references to heap-allocated `mpz_t` structures, two Perl variables can share the same underlying integer. For the overloaded arithmetic operators that does not matter - they always allocate a fresh result. If you are about to call an in-place mutator (currently just `add_ui_gmp`) and want to keep the original intact, copy first.

gmp_tstbit

Return bit `$n` of `$x` (0-indexed, from the least significant end).

Synopsis

```
my $x = Math::GMP->new(0b1010);
print $x->gmp_tstbit(1);        # 1
print $x->gmp_tstbit(2);        # 0
```

For negative values, `libgmp` uses a two's-complement view. Bits above the most significant set bit of a positive value read as `0`.

broot

Return the integer `$n`-th root of `$x`, truncated toward zero.

Synopsis

```
my $x = Math::GMP->new(100);
print $x->broot(3);             # 4, since 4**3 = 64 and 5**3 = 125
```

`$n` must be a positive integer. For odd `$n` negative values of `$x` are fine; for even `$n` they croak inside `libgmp`.

brootrem

Return the integer $n-th root of $x and the shortfall.

Synopsis

```
my $x = Math::GMP->new(100);
my ($root, $rem) = $x->brootrem(3);    # 4, 36
# because 4**3 + 36 == 100
```

The returned list satisfies `$root ** $n + $rem == $x` exactly. Use when you need both pieces in one pass - calling `broot` and computing the remainder yourself doubles the work.

Differences from upstream

Replicates upstream's explicit workaround for `libgmp` versions earlier than `5.1.0`, where `mpz_rootrem` returned wrong results for negative arguments with odd $n. Modern `libgmp` builds skip the workaround automatically.

bsqrt

Return the integer square root of $x.

Synopsis

```
Math::GMP->new(6)->bsqrt;      # 2 - int(sqrt(6))
Math::GMP->new(49)->bsqrt;     # 7
```

Equivalent to `broot(2)` but noticeably faster. Croaks on negative arguments inside `libgmp`.

is_perfect_power

Return 1 when $x is a perfect power `$a ** $b` with `$b > 1`.

Synopsis

```
Math::GMP->new(27)->is_perfect_power;    # 1 (3**3)
Math::GMP->new(28)->is_perfect_power;    # 0
```

Returns `0` otherwise. Detects any exponent - squares, cubes, fifth powers, and so on.

new

Build a `Math::GMP` object from a string or integer scalar.

Synopsis

```
my $x = Math::GMP->new(123);
my $y = Math::GMP->new('12345678901234567890123456789O');
my $z = Math::GMP->new('abcd', 36);          # base 36
```

What you get back

A blessed reference of class `Math::GMP`. You can feed it to any overloaded operator, or to the named methods on this page.

The first argument is read as a string. A leading `+` is stripped, and embedded spaces and underscores are removed - so `'1_000_000'` and `' 1 000 000 '` both parse. When no base is given every character must be a digit, `-`, `x` or a hex letter, which admits the usual `0x`-prefixed hex form; any other character dies with `Argument to Math::GMP->new is not a string representing an integer`. A string that passes this check but is not a valid number, such as `'abc'` or `'1-2'`, gives `0`. With an explicit base (2 to 62) the usual GMP digit-set applies.

Edge cases

- Missing or false first argument gives `Math::GMP` of `0`.
- Floating-point input is not special-cased here; a stringified value with a decimal point or an exponent sign fails the character check and dies.
- Base `0` (the default) means "guess from the prefix": `0x` for hex, `0` for octal, otherwise decimal.

Math::Random

Namespace containing the following modules:

- `Math::Random::MT` - The Mersenne Twister pseudo-random number generator, MT19937: a long period (2**19937 - 1), fast, and the same sequence on every platform for the same seed.

Math::Random::MT

The Mersenne Twister pseudo-random number generator, MT19937: a long period (2**19937 - 1), fast, and the same sequence on every platform for the same seed. It is not for cryptography.

`Math::Random::MT->new(@seeds)` makes a generator; one seed is a 32-bit integer, several are an array of them, and none takes a seed from perl's own `rand`. `$gen->rand($n)` returns a number in `[0, $n)` (`$n` defaults to 1), `$gen->irand` an integer in `[0, 2**32)`, and `$gen->get_seed` the seed. Imported, `srand`, `rand` and `irand` work on one generator of the module's own, as perl's built-ins do.

This is a native implementation of Math::Random::MT 1.17's `MT.xs` and `_mt.c` (Matsumoto and Nishimura's mt19937ar.c); its `Math/Random/MT.pm` is used unchanged.

Synopsis

```
use Math::Random::MT;

my $gen = Math::Random::MT->new(5489);
print $gen->irand, "\n";        # 3499211612, mt19937ar's first␣
↪output
my $die = 1 + int $gen->rand(6);

use Math::Random::MT qw(srand rand);
srand(42);
print rand(10), "\n";
```

Functions

Generators

init

`Math::Random::MT::init()`: a new generator object, not yet seeded; new seeds it.

genrand

`$gen->genrand`: the next number in `[0, 1)`.

genirand

`$gen->genirand`: the next integer in `[0, 2**32)`.

Seeding

init_seed

`$gen->init_seed($seed)`: seed with one 32-bit integer.

setup_array

`$gen->setup_array(@seeds)`: seed with an array of 32-bit integers.

get_seed

`$gen->get_seed`: the seed it was given with `init_seed`, or 19650218 after `setup_array`.

Math::Trig

trigonometric functions

SYNOPSIS

```
use Math::Trig;

$x = tan(0.9);
$y = acos(3.7);
$z = asin(2.4);

$halfpi = pi/2;

$rad = deg2rad(120);

# Import constants pi2, pi4, pip2, pip4 (2*pi, 4*pi, pi/2, pi/4).
use Math::Trig ':pi';

# Import the conversions between cartesian/spherical/cylindrical.
use Math::Trig ':radial';

    # Import the great circle formulas.
use Math::Trig ':great_circle';
```

DESCRIPTION

`Math::Trig` defines many trigonometric functions not defined by the core Perl which defines only the `sin()` and `cos()`. The constant **pi** is also defined as are a few convenience functions for angle conversions, and *great circle formulas* for spherical movement.

TRIGONOMETRIC FUNCTIONS

The tangent

- **tan**

The cofunctions of the sine, cosine, and tangent (cosec/csc and cotan/cot are aliases)

csc, **cosec**, **sec**, **sec**, **cot**, **cotan**

The arcus (also known as the inverse) functions of the sine, cosine, and tangent

asin, **acos**, **atan**

The principal value of the arc tangent of y/x

atan2(y, x)

The arcus cofunctions of the sine, cosine, and tangent (acosec/acsc and acotan/acot are aliases). Note that atan2(0, 0) is not well-defined.

acsc, **acosec**, **asec**, **acot**, **acotan**

The hyperbolic sine, cosine, and tangent

sinh, **cosh**, **tanh**

The cofunctions of the hyperbolic sine, cosine, and tangent (cosech/csch and cotanh/coth are aliases)

csch, **cosech**, **sech**, **coth**, **cotanh**

The area (also known as the inverse) functions of the hyperbolic sine, cosine, and tangent

asinh, **acosh**, **atanh**

The area cofunctions of the hyperbolic sine, cosine, and tangent (acsch/acosech and acoth/acotanh are aliases)

acsch, **acosech**, **asech**, **acoth**, **acotanh**

The trigonometric constant **pi** and some of handy multiples of it are also defined.

pi, pi2, pi4, pip2, pip4

ERRORS DUE TO DIVISION BY ZERO

The following functions

```
acoth
acsc
acsch
asec
asech
atanh
cot
coth
csc
csch
sec
sech
tan
tanh
```

cannot be computed for all arguments because that would mean dividing by zero or taking logarithm of zero. These situations cause fatal runtime errors looking like this

```
cot(0): Division by zero.
(Because in the definition of cot(0), the divisor sin(0) is 0)
Died at ...
```

or

```
atanh(-1): Logarithm of zero.
Died at...
```

For the `csc`, `cot`, `asec`, `acsc`, `acot`, `csch`, `coth`, `asech`, `acsch`, the argument cannot be `0` (zero). For the `atanh`, `acoth`, the argument cannot be 1 (one). For the `atanh`, `acoth`, the argument cannot be `-1` (minus one). For the `tan`, `sec`, `tanh`, `sech`, the argument cannot be *pi/2 + k * pi*, where *k* is any integer.

Note that atan2(0, 0) is not well-defined.

SIMPLE (REAL) ARGUMENTS, COMPLEX RESULTS

Please note that some of the trigonometric functions can break out from the **real axis** into the **complex plane**. For example `asin(2)` has no definition for plain real numbers but it has definition for complex numbers.

In Perl terms this means that supplying the usual Perl numbers (also known as scalars, please see *perldata*) as input for the trigonometric functions might produce as output results that no more are simple real numbers: instead they are complex numbers.

The `Math::Trig` handles this by using the `Math::Complex` package which knows how to handle complex numbers, please see *Math::Complex* for more information. In practice you need not to worry about getting complex numbers as results because the `Math::Complex` takes care of details like for example how to display complex numbers. For example:

```
print asin(2), "\n";
```

should produce something like this (take or leave few last decimals):

```
1.5707963267949-1.31695789692482i
```

That is, a complex number with the real part of approximately `1.571` and the imaginary part of approximately `-1.317`.

PLANE ANGLE CONVERSIONS

(Plane, 2-dimensional) angles may be converted with the following functions.

- deg2rad

```
$radians  = deg2rad($degrees);
```

- grad2rad

```
$radians  = grad2rad($gradians);
```

- rad2deg

```
$degrees  = rad2deg($radians);
```

- grad2deg

```
$degrees  = grad2deg($gradians);
```

- deg2grad

```
$gradians = deg2grad($degrees);
```

- rad2grad

```
$gradians = rad2grad($radians);
```

The full circle is 2 *pi* radians or *360* degrees or *400* gradians. The result is by default wrapped to be inside the [0, {2pi,360,400}) circle. If you don't want this, supply a true second argument:

```
$zillions_of_radians  = deg2rad($zillions_of_degrees, 1);
$negative_degrees     = rad2deg($negative_radians, 1);
```

You can also do the wrapping explicitly by rad2rad(), deg2deg(), and grad2grad().

- rad2rad

  ```
  $radians_wrapped_by_2pi = rad2rad($radians);
  ```

- deg2deg

  ```
  $degrees_wrapped_by_360 = deg2deg($degrees);
  ```

- grad2grad

  ```
  $gradians_wrapped_by_400 = grad2grad($gradians);
  ```

RADIAL COORDINATE CONVERSIONS

Radial coordinate systems are the **spherical** and the **cylindrical** systems, explained shortly in more detail.

You can import radial coordinate conversion functions by using the `:radial` tag:

```
use Math::Trig ':radial';

($rho, $theta, $z)     = cartesian_to_cylindrical($x, $y, $z);
($rho, $theta, $phi)   = cartesian_to_spherical($x, $y, $z);
($x, $y, $z)           = cylindrical_to_cartesian($rho, $theta, $z);
($rho_s, $theta, $phi) = cylindrical_to_spherical($rho_c, $theta,
 ↪$z);
($x, $y, $z)           = spherical_to_cartesian($rho, $theta, $phi);
($rho_c, $theta, $z)   = spherical_to_cylindrical($rho_s, $theta,
 ↪$phi);
```

All angles are in radians.

COORDINATE SYSTEMS

Cartesian coordinates are the usual rectangular *(x, y, z)*-coordinates.

Spherical coordinates, *(rho, theta, phi)*, are three-dimensional coordinates which define a point in three-dimensional space. They are based on a sphere surface. The radius of the sphere is **rho**, also known as the *radial* coordinate. The angle in the *xy*-plane (around the *z*-axis) is **theta**, also known as the *azimuthal* coordinate. The angle from the *z*-axis is **phi**, also known as the *polar* coordinate. The North Pole is therefore *rho, 0, 0*, and the Gulf of Guinea (think of the missing big chunk of Africa) *rho, 0, pi/2*. In geographical terms *phi* is latitude (northward positive, southward negative) and *theta* is longitude (eastward positive, westward negative).

BEWARE: some texts define *theta* and *phi* the other way round, some texts define the *phi* to start from the horizontal plane, some texts use *r* in place of *rho*.

Cylindrical coordinates, *(rho, theta, z)*, are three-dimensional coordinates which define a point in three-dimensional space. They are based on a cylinder surface. The radius of the cylinder is **rho**, also known as the *radial* coordinate. The angle in the *xy*-plane (around the *z*-axis) is **theta**, also known as the *azimuthal* coordinate. The third coordinate is the *z*, pointing up from the **theta**-plane.

3-D ANGLE CONVERSIONS

Conversions to and from spherical and cylindrical coordinates are available. Please notice that the conversions are not necessarily reversible because of the equalities like *pi* angles being equal to *-pi* angles.

- cartesian_to_cylindrical

```
($rho, $theta, $z) = cartesian_to_cylindrical($x, $y, $z);
```

- cartesian_to_spherical

```
($rho, $theta, $phi) = cartesian_to_spherical($x, $y, $z);
```

- cylindrical_to_cartesian

```
($x, $y, $z) = cylindrical_to_cartesian($rho, $theta, $z);
```

- cylindrical_to_spherical

```
($rho_s, $theta, $phi) = cylindrical_to_spherical($rho_c,
↪$theta, $z);
```

  Notice that when `$z` is not 0 `$rho_s` is not equal to `$rho_c`.

- spherical_to_cartesian

```
($x, $y, $z) = spherical_to_cartesian($rho, $theta, $phi);
```

- spherical_to_cylindrical

```
($rho_c, $theta, $z) = spherical_to_cylindrical($rho_s, $theta,
↪$phi);
```

  Notice that when `$z` is not 0 `$rho_c` is not equal to `$rho_s`.

GREAT CIRCLE DISTANCES AND DIRECTIONS

A great circle is section of a circle that contains the circle diameter: the shortest distance between two (non-antipodal) points on the spherical surface goes along the great circle connecting those two points.

great_circle_distance

Returns the great circle distance between two points on a sphere.

```
$distance = great_circle_distance($theta0, $phi0, $theta1, $phi1, [,
↪$rho]);
```

Where ($theta0, $phi0) and ($theta1, $phi1) are the spherical coordinates of the two points, respectively. The distance is in $rho units. The $rho is optional. It defaults to 1 (the unit sphere).

If you are using geographic coordinates, latitude and longitude, you need to adjust for the fact that latitude is zero at the equator increasing towards the north and decreasing towards the south. Assuming ($lat0, $lon0) and ($lat1, $lon1) are the geographic coordinates in radians of the two points, the distance can be computed with

```
$distance = great_circle_distance($lon0, pi/2 - $lat0,
                                  $lon1, pi/2 - $lat1, $rho);
```

great_circle_direction

The direction you must follow the great circle (also known as *bearing*) can be computed by the great_circle_direction() function:

```
use Math::Trig 'great_circle_direction';

$direction = great_circle_direction($theta0, $phi0, $theta1, $phi1);
```

great_circle_bearing

Alias 'great_circle_bearing' for 'great_circle_direction' is also available.

```
use Math::Trig 'great_circle_bearing';

$direction = great_circle_bearing($theta0, $phi0, $theta1, $phi1);
```

The result of great_circle_direction is in radians, zero indicating straight north, pi or -pi straight south, pi/2 straight west, and -pi/2 straight east.

great_circle_destination

You can inversely compute the destination if you know the starting point, direction, and distance:

```
use Math::Trig 'great_circle_destination';

# $diro is the original direction,
# for example from great_circle_bearing().
# $distance is the angular distance in radians,
# for example from great_circle_distance().
# $thetad and $phid are the destination coordinates,
```

(continues on next page)

(continued from previous page)

```
# $dird is the final direction at the destination.

($thetad, $phid, $dird) =
  great_circle_destination($theta, $phi, $diro, $distance);
```

or the midpoint if you know the end points:

great_circle_midpoint

```
use Math::Trig 'great_circle_midpoint';

($thetam, $phim) =
  great_circle_midpoint($theta0, $phi0, $theta1, $phi1);
```

The great_circle_midpoint() is just a special case of

great_circle_waypoint

```
use Math::Trig 'great_circle_waypoint';

($thetai, $phii) =
  great_circle_waypoint($theta0, $phi0, $theta1, $phi1, $way);
```

Where $way indicates the position of the waypoint along the great circle arc through the starting point ($theta0, $phi0) and the end point ($theta1, $phi1) relative to the distance from the starting point to the end point. So $way = 0 gives the starting point, $way = 1 gives the end point, $way < 0 gives a point "behind" the starting point, and $way > 1 gives a point beyond the end point. $way defaults to 0.5 if not given.

Note that antipodal points (where their distance is *pi* radians) do not have unique waypoints between them, and therefore `undef` is returned in such cases. If the points are the same, so the distance between them is zero, all waypoints are identical to the starting/end point.

The thetas, phis, direction, and distance in the above are all in radians.

You can import all the great circle formulas by

```
use Math::Trig ':great_circle';
```

Notice that the resulting directions might be somewhat surprising if you are looking at a flat worldmap: in such map projections the great circles quite often do not look like the shortest routes – but for example the shortest possible routes from Europe or North America to Asia do often cross the polar regions. (The common Mercator projection does **not** show great circles as straight lines: straight lines in the Mercator projection are lines of constant bearing.)

EXAMPLES

To calculate the distance between London (51.3N 0.5W) and Tokyo (35.7N 139.8E) in kilometers:

```
use Math::Trig qw(great_circle_distance deg2rad);

# Notice the 90 - latitude: phi zero is at the North Pole.
sub NESW { deg2rad($_[0]), deg2rad(90 - $_[1]) }
my @L = NESW( -0.5, 51.3);
my @T = NESW(139.8, 35.7);
my $km = great_circle_distance(@L, @T, 6378); # About 9600 km.
```

The direction you would have to go from London to Tokyo (in radians, straight north being zero, straight east being pi/2).

```
use Math::Trig qw(great_circle_direction);

my $rad = great_circle_direction(@L, @T); # About 0.547 or 0.174 pi.
```

The midpoint between London and Tokyo being

```
use Math::Trig qw(great_circle_midpoint rad2deg);

my @M = great_circle_midpoint(@L, @T);
sub SWNE { rad2deg( $_[0] ), 90 - rad2deg( $_[1] ) }
my @lonlat = SWNE(@M);
```

or about 69 N 89 E, on the Putorana Plateau of Siberia.

NOTE: you **cannot** get from A to B like this:

```
Dist = great_circle_distance(A, B)
Dir  = great_circle_direction(A, B)
C    = great_circle_destination(A, Dist, Dir)
```

and expect C to be B, because the bearing constantly changes when going from A to B (except in some special case like the meridians or the circles of latitudes) and in great_circle_destination() one gives a **constant** bearing to follow.

CAVEAT FOR GREAT CIRCLE FORMULAS

The answers may be off by few percentages because of the irregular (slightly aspherical) form of the Earth. The errors are at worst about 0.55%, but generally below 0.3%.

Real-valued asin and acos

For small inputs asin() and acos() may return complex numbers even when real numbers would be enough and correct, this happens because of floating-point inaccuracies. You can see these inaccuracies for example by trying theses:

```
print cos(1e-6)**2+sin(1e-6)**2 - 1,"\n";
printf "%.20f", cos(1e-6)**2+sin(1e-6)**2,"\n";
```

which will print something like this

```
-1.11022302462516e-16
0.99999999999999988898
```

even though the expected results are of course exactly zero and one. The formulas used to compute asin() and acos() are quite sensitive to this, and therefore they might accidentally slip into the complex plane even when they should not. To counter this there are two interfaces that are guaranteed to return a real-valued output.

- asin_real

  ```
  use Math::Trig qw(asin_real);

  $real_angle = asin_real($input_sin);
  ```

  Return a real-valued arcus sine if the input is between [-1, 1], **inclusive** the endpoints. For inputs greater than one, pi/2 is returned. For inputs less than minus one, -pi/2 is returned.

- acos_real

  ```
  use Math::Trig qw(acos_real);

  $real_angle = acos_real($input_cos);
  ```

  Return a real-valued arcus cosine if the input is between [-1, 1], **inclusive** the endpoints. For inputs greater than one, zero is returned. For inputs less than minus one, pi is returned.

BUGS

Saying `use Math::Trig;` exports many mathematical routines in the caller environment and even overrides some (`sin`, `cos`). This is construed as a feature by the Authors, actually... ;-)

The code is not optimized for speed, especially because we use `Math::Complex` and thus go quite near complex numbers while doing the computations even when the arguments are not. This, however, cannot be completely avoided if we want things like `asin(2)` to give an answer instead of giving a fatal runtime error.

Do not attempt navigation using these formulas.

5.2.66 Memoize

Make functions faster by trading space for time - cache a function's results by its arguments and return the cached result on a repeated call.

`memoize('f')` replaces `f` with a wrapper that remembers every result it has computed. The next call with the same arguments returns the remembered result without running `f` again. This is only sound for a function whose result depends on nothing but its arguments and which has no side effects; the call to `memoize` is your assertion that it is such a function.

The wrapper is installed under the function's own name, so existing callers hit the cache transparently, and it is returned as a code reference. `INSTALL => 'other'` installs it under another name, `INSTALL => undef` installs nothing and only returns it. Scalar- and list-context results are cached separately, because a function may return different things in each; `SCALAR_CACHE` and `LIST_CACHE` choose the storage per context: `MEMORY` (in-process, the default), `[HASH => \%h]` (a hash you supply, possibly tied to a DBM file so the cache persists across runs), `FAULT` (croak if called in that context) and `MERGE` (one cache for both contexts). `NORMALIZER` names a function that turns the argument list into the cache key when the default key, the arguments joined with `chr(28)`, is not the right notion of "same arguments".

`flush_cache('f')` empties a function's cache; `unmemoize('f')` restores the original function. Both are exported on request only.

The cache is native: nothing here is a Perl closure, the key is built and probed in the runtime, and a hit costs one hash probe and a copy of the stored result.

A pure numeric function is memoized further down still. It is compiled, its results are kept in a native table, and `memoize` puts the compiled function itself under the name rather than anything wrapped around it - so a loop calling it can be compiled too, and a repeated call is then a table probe in registers with no call at all. This covers one to four numeric arguments and recursion (the compiled body's recursive calls probe the same table), so `memoize('fib')`, and equally a two- or three-argument recurrence, run compiled, memoized and - for a repeated call - allocation- and call-free. Deep recursion behaves as in perl: it is limited by memory, not by a fixed depth, and the `Deep recursion` warning appears as usual under `use warnings`. Anything outside that shape - five or more arguments, a non-numeric argument, a `NORMALIZER`, list context - uses the general cache above, which is correct for every function `memoize` accepts.

Synopsis

```
use Memoize;
memoize('slow_function');
slow_function(@args);          # computed
slow_function(@args);          # returned from the cache

use Memoize qw(memoize flush_cache unmemoize);
```

(continues on next page)

(continued from previous page)

```
memoize('fib', NORMALIZER => sub { $_[0] });
flush_cache('fib');
unmemoize('fib');
```

Differences from upstream

Upstream Memoize is pure Perl and wraps each function in a Perl closure; here the wrapper is native, and that shows in four places. From inside the memoized function `caller` sees its own caller directly, with no `Memoize::__ANON__` frame in between - there is no Perl closure to make one. For the same reason the `Deep recursion` warning names the memoized function (`subroutine "main::fib"`) where the pure-Perl module's recursion is first counted on its wrapper (`anonymous subroutine`). A `die` from `flush_cache` or `unmemoize` reports the caller's location, as XS errors do, rather than a line inside `Memoize.pm`. The module does not define `CLONE`, because this runtime has no interpreter threads.

Modules

- `Memoize::AnyDBM_File` - glue to provide EXISTS for AnyDBM_File for Storable use
- `Memoize::Expire` - Plug-in module for automatic expiration of memoized values
- `Memoize::NDBM_File` - glue to provide EXISTS for NDBM_File for Storable use
- `Memoize::SDBM_File` - DEPRECATED compatibility shim
- `Memoize::Storable` - store Memoized data in Storable database

Functions

Memoization

memoize

Memoize a function: `memoize('name', %options)` or `memoize(\&code, %options)`.

flush_cache

Empty a memoized function's caches: `flush_cache('name')` or `flush_cache(\&wrapper)`.

unmemoize

Undo `memoize`: `unmemoize('name')` or `unmemoize(\&wrapper)`.

Memoize::AnyDBM_File

glue to provide EXISTS for AnyDBM_File for Storable use

DESCRIPTION

This class does the same thing as *AnyDBM_File*, except that instead of *NDBM_File* itself it loads *Memoize::NDBM_File* if *NDBM_File* lacks EXISTS support.

Code which requires perl 5.37.3 or newer should simply use AnyBDM_File directly.

Memoize::Expire

Plug-in module for automatic expiration of memoized values

SYNOPSIS

```
use Memoize;
use Memoize::Expire;
tie my %cache => 'Memoize::Expire',
                   LIFETIME => $lifetime,    # In seconds
                   NUM_USES => $n_uses;

memoize 'function', SCALAR_CACHE => [HASH => \%cache ];
```

DESCRIPTION

Memoize::Expire is a plug-in module for Memoize. It allows the cached values for memoized functions to expire automatically. This manual assumes you are already familiar with the Memoize module. If not, you should study that manual carefully first, paying particular attention to the HASH feature.

Memoize::Expire is a layer of software that you can insert in between Memoize itself and whatever underlying package implements the cache. The layer presents a hash variable whose values expire whenever they get too old, have been used too often, or both. You tell `Memoize` to use this forgetful hash as its cache instead of the default, which is an ordinary hash.

To specify a real-time timeout, supply the `LIFETIME` option with a numeric value. Cached data will expire after this many seconds, and will be looked up afresh when it expires. When a data item is looked up afresh, its lifetime is reset.

If you specify `NUM_USES` with an argument of *n*, then each cached data item will be discarded and looked up afresh after the _n_th time you access it. When a data item is looked up afresh, its number of uses is reset.

If you specify both arguments, data will be discarded from the cache when either expiration condition holds.

Memoize::Expire uses a real hash internally to store the cached data. You can use the `HASH` option to Memoize::Expire to supply a tied hash in place of the ordinary hash that Memoize::Expire will normally use. You can use this feature to add Memoize::Expire as a

layer in between a persistent disk hash and Memoize. If you do this, you get a persistent disk cache whose entries expire automatically. For example:

```
#   Memoize
#      |
#   Memoize::Expire  enforces data expiration policy
#      |
#   DB_File  implements persistence of data in a disk file
#      |
#   Disk file

use Memoize;
use Memoize::Expire;
use DB_File;

# Set up persistence
tie my %disk_cache => 'DB_File', $filename, O_CREAT|O_RDWR, 0666];

# Set up expiration policy, supplying persistent hash as a target
tie my %cache => 'Memoize::Expire',
                   LIFETIME => $lifetime,    # In seconds
                   NUM_USES => $n_uses,
                   HASH => \%disk_cache;

# Set up memoization, supplying expiring persistent hash for cache
memoize 'function', SCALAR_CACHE => [ HASH => \%cache ];
```

INTERFACE

There is nothing special about Memoize::Expire. It is just an example. If you don't like the policy that it implements, you are free to write your own expiration policy module that implements whatever policy you desire. Here is how to do that. Let us suppose that your module will be named MyExpirePolicy.

Short summary: You need to create a package that defines four methods:

-

TIEHASH

```
Construct and return cache object.
```

-

EXISTS

```
Given a function argument, is the corresponding function value in␣
↪the
cache, and if so, is it fresh enough to use?
```

-

FETCH

```
Given a function argument, look up the corresponding function value␣
 ↪in
the cache and return it.
```

-

STORE

```
Given a function argument and the corresponding function value,␣
 ↪store
them into the cache.
```

-

CLEAR

```
(Optional.)  Flush the cache completely.
```

The user who wants the memoization cache to be expired according to your policy will say so by writing

```
tie my %cache => 'MyExpirePolicy', args...;
memoize 'function', SCALAR_CACHE => [HASH => \%cache];
```

This will invoke `MyExpirePolicy->TIEHASH(args)`. MyExpirePolicy::TIEHASH should do whatever is appropriate to set up the cache, and it should return the cache object to the caller.

For example, MyExpirePolicy::TIEHASH might create an object that contains a regular Perl hash (which it will to store the cached values) and some extra information about the arguments and how old the data is and things like that. Let us call this object `C`.

When Memoize needs to check to see if an entry is in the cache already, it will invoke `C->EXISTS(key)`. `key` is the normalized function argument. MyExpirePolicy::EXISTS should return 0 if the key is not in the cache, or if it has expired, and 1 if an unexpired value is in the cache. It should *not* return `undef`, because there is a bug in some versions of Perl that will cause a spurious FETCH if the EXISTS method returns `undef`.

If your EXISTS function returns true, Memoize will try to fetch the cached value by invoking `C->FETCH(key)`. MyExpirePolicy::FETCH should return the cached value. Otherwise, Memoize will call the memoized function to compute the appropriate value, and will store it into the cache by calling `C->STORE(key, value)`.

Here is a very brief example of a policy module that expires each cache item after ten seconds.

```
package Memoize::TenSecondExpire;

sub TIEHASH {
  my ($package, %args) = @_;
  my $cache = $args{HASH} || {};
  bless $cache => $package;
}
```

(continues on next page)

(continued from previous page)

```
sub EXISTS {
  my ($cache, $key) = @_;
  if (exists $cache->{$key} &&
      $cache->{$key}{EXPIRE_TIME} > time) {
    return 1
  } else {
    return 0;  # Do NOT return undef here
  }
}

sub FETCH {
  my ($cache, $key) = @_;
  return $cache->{$key}{VALUE};
}

sub STORE {
  my ($cache, $key, $newvalue) = @_;
  $cache->{$key}{VALUE} = $newvalue;
  $cache->{$key}{EXPIRE_TIME} = time + 10;
}
```

To use this expiration policy, the user would say

```
use Memoize;
tie my %cache10sec => 'Memoize::TenSecondExpire';
memoize 'function', SCALAR_CACHE => [HASH => \%cache10sec];
```

Memoize would then call `function` whenever a cached value was entirely absent or was older than ten seconds.

You should always support a `HASH` argument to `TIEHASH` that ties the underlying cache so that the user can specify that the cache is also persistent or that it has some other interesting semantics. The example above demonstrates how to do this, as does `Memoize::Expire`.

Another sample module, Memoize::Saves, is available in a separate distribution on CPAN. It implements a policy that allows you to specify that certain function values would always be looked up afresh. See the documentation for details.

ALTERNATIVES

Brent Powers has a Memoize::ExpireLRU module that was designed to work with Memoize and provides expiration of least-recently-used data. The cache is held at a fixed number of entries, and when new data comes in, the least-recently used data is expired.

Joshua Chamas's Tie::Cache module may be useful as an expiration manager. (If you try this, let me know how it works out.)

If you develop any useful expiration managers that you think should be distributed with Memoize, please let me know.

CAVEATS

This module is experimental, and may contain bugs. Please report bugs to the address below.

Number-of-uses is stored as a 16-bit unsigned integer, so can't exceed 65535.

Because of clock granularity, expiration times may occur up to one second sooner than you expect. For example, suppose you store a value with a lifetime of ten seconds, and you store it at 12:00:00.998 on a certain day. Memoize will look at the clock and see 12:00:00. Then 9.01 seconds later, at 12:00:10.008 you try to read it back. Memoize will look at the clock and see 12:00:10 and conclude that the value has expired. This will probably not occur if you have `Time::HiRes` installed.

Memoize::NDBM_File

glue to provide EXISTS for NDBM_File for Storable use

DESCRIPTION

This class provides EXISTS support for *NDBM_File*.

In Perl 5.37.3, support for `EXISTS` was added to *NDBM_File* itself. Any code which already requires perl >= 5.37.3 should be rewritten to use *NDBM_File* directly.

Memoize::SDBM_File

DEPRECATED compatibility shim

DESCRIPTION

This class used to provide EXISTS support for *SDBM_File* before support for `EXISTS` was added to *SDBM_File* itself in Perl 5.6.0.

Any code still using this class should be rewritten to use *SDBM_File* directly.

Memoize::Storable

store Memoized data in Storable database

DESCRIPTION

See *Memoize*.

memoize

Memoize a function: `memoize('name', %options)` or `memoize(\&code, %options)`.

Returns a code reference to the memoized wrapper. Given a name, the wrapper is also installed under that name (qualified with the caller's package unless it contains `::`), so every existing caller now goes through the cache; `\&name` changes accordingly. Given a code reference, nothing is installed unless `INSTALL` says so.

Options:

- `INSTALL => 'name'` installs the wrapper under `name` instead; `INSTALL => undef` installs it nowhere.
- `NORMALIZER => 'name'` or `=> \&code` computes the cache key from the argument list (called in the same context as the wrapper; in list context its first return value is the key). Without it the key is the arguments joined with `chr(28)`, so `f(1, 2)` and `f("1", "2")` share an entry and references are keyed by address.
- `SCALAR_CACHE` and `LIST_CACHE` choose the storage for results computed in scalar and list context: `MEMORY` (the default), `[HASH => \%hash]` to use your hash (tie it to a DBM file for a persistent cache), `FAULT` to croak when called in that context, and `MERGE` to share one cache between the two contexts. `TIE` is accepted for compatibility and warns that it is deprecated.

Croaks `Cannot operate on nonexistent function` for a name that does not name a defined sub, and `Usage: memoize 'functionname'|coderef {OPTIONS}` for anything that is neither a name nor a plain code reference.

A `die` inside the function propagates and caches nothing. A recursive function benefits fully: its recursive calls reach the cache too, so `fib(50)` becomes linear. Only memoize functions whose result depends solely on their arguments and that have no side effects - that is your assertion, not something the module checks.

flush_cache

Empty a memoized function's caches: `flush_cache('name')` or `flush_cache(\&wrapper)`.

Both the scalar- and the list-context cache are cleared; the function stays memoized and starts refilling on the next call. Croaks `... not memoized` for a function that is not currently memoized, and `Tied cache hash for ... does not support flushing` when a `HASH` cache is tied to a class without a `CLEAR` method. Not exported by default: `use Memoize qw(flush_cache)`.

unmemoize

Undo `memoize`: `unmemoize('name')` or `unmemoize(\&wrapper)`.

Reinstalls the original function under the name the wrapper was installed at and returns a code reference to the original. The cache is discarded with the wrapper; a wrapper reference you still hold keeps working but can no longer be flushed or unmemoized. Croaks `Could not unmemoize function ..., because it was not memoized to begin with` otherwise. Not exported by default: `use Memoize qw(unmemoize)`.

5.2.67 Module

Namespace containing the following modules:

- `Module::CoreList` - what modules shipped with versions of perl
- `Module::Load` - runtime require of both modules and files
- `Module::Loaded` - mark modules as loaded or unloaded
- `Module::Metadata` - Gather package and POD information from perl module files

Module::CoreList

what modules shipped with versions of perl

SYNOPSIS

```
use Module::CoreList;

print $Module::CoreList::version{5.00503}{CPAN}; # prints 1.48

print Module::CoreList->first_release('File::Spec');
# prints 5.00405

print Module::CoreList->first_release_by_date('File::Spec');
# prints 5.005

print Module::CoreList->first_release('File::Spec', 0.82);
# prints 5.006001

if (Module::CoreList::is_core('File::Spec')) {
  print "File::Spec is a core module\n";
}

print join ', ', Module::CoreList->find_modules(qr/Data/);
   # prints 'Data::Dumper'
print join ', ',
         Module::CoreList->find_modules(qr/test::h.*::.*s/i, 5.
↪008008);
   # prints 'Test::Harness::Assert, Test::Harness::Straps'
```

(continues on next page)

(continued from previous page)

```
print join ", ", @{ $Module::CoreList::families{5.005} };
   # prints "5.005, 5.00503, 5.00504"
```

DESCRIPTION

Module::CoreList provides information on which core and dual-life modules shipped with each version of perl.

It provides a number of mechanisms for querying this information.

There is a utility called corelist provided with this module which is a convenient way of querying from the command-line.

There is a functional programming API available for programmers to query information.

Programmers may also query the contained hash structures to find relevant information.

FUNCTIONS API

These are the functions that are available, they may either be called as functions or class methods:

```
Module::CoreList::first_release('File::Spec'); # as a function

Module::CoreList->first_release('File::Spec'); # class method
```

- `first_release( MODULE )`

  Behaviour since version 2.11

  Requires a MODULE name as an argument, returns the perl version when that module first appeared in core as ordered by perl version number or undef (in scalar context) or an empty list (in list context) if that module is not in core.

- `first_release_by_date( MODULE )`

  Requires a MODULE name as an argument, returns the perl version when that module first appeared in core as ordered by release date or undef (in scalar context) or an empty list (in list context) if that module is not in core.

- `find_modules( REGEX, [ LIST OF PERLS ] )`

  Takes a regex as an argument, returns a list of modules that match the regex given. If only a regex is provided applies to all modules in all perl versions. Optionally you may provide a list of perl versions to limit the regex search.

- `find_version( PERL_VERSION )`

  Takes a perl version as an argument. Upon successful completion, returns a reference to a hash. Each element of that hash has a key which is the name of a module (*e.g.,* 'File::Path') shipped with that version of perl and a value which is the version number (*e.g.,* '2.09') of that module which shipped with that version of perl . Returns `undef` otherwise.

- `is_core( MODULE, [ MODULE_VERSION, [ PERL_VERSION ] ] )`

  Available in version 2.99 and above.

  Returns true if MODULE was bundled with the specified version of Perl. You can optionally specify a minimum version of the module, and can also specify a version of Perl. If a version of Perl isn't specified, `is_core()` will use the numeric version of Perl that is running (ie `$]`).

  If you want to specify the version of Perl, but don't care about the version of the module, pass `undef` for the module version:

- `is_deprecated( MODULE, PERL_VERSION )`

  Available in version 2.22 and above.

  Returns true if MODULE is marked as deprecated in PERL_VERSION. If PERL_VERSION is omitted, it defaults to the current version of Perl.

- `deprecated_in( MODULE )`

  Available in version 2.77 and above.

  Returns the first perl version where the MODULE was marked as deprecated. Returns `undef` if the MODULE has not been marked as deprecated.

- `removed_from( MODULE )`

  Available in version 2.32 and above

  Takes a module name as an argument, returns the first perl version where that module was removed from core. Returns undef if the given module was never in core or remains in core.

- `removed_from_by_date( MODULE )`

  Available in version 2.32 and above

  Takes a module name as an argument, returns the first perl version by release date where that module was removed from core. Returns undef if the given module was never in core or remains in core.

- `changes_between( PERL_VERSION, PERL_VERSION )`

  Available in version 2.66 and above.

  Given two perl versions, this returns a list of pairs describing the changes in core module content between them. The list is suitable for storing in a hash. The keys are library names and the values are hashrefs. Each hashref has an entry for one or both of `left` and `right`, giving the versions of the library in each of the left and right perl distributions.

  For example, it might return these data (among others) for the difference between 5.008000 and 5.008001:

```
'Pod::ParseLink'  => { left => '1.05', right => '1.06' },
'Pod::ParseUtils' => { left => '0.22', right => '0.3'  },
'Pod::Perldoc'    => {                 right => '3.10' },
'Pod::Perldoc::BaseTo' => {            right => undef  },
```

This shows us two libraries being updated and two being added, one of which has an undefined version in the right-hand side version.

DATA STRUCTURES

These are the hash data structures that are available:

- `%Module::CoreList::version`

  A hash of hashes that is keyed on perl version as indicated in $]. The second level hash is module => version pairs.

  Note, it is possible for the version of a module to be unspecified, whereby the value is `undef`, so use `exists $version{$foo}{$bar}` if that's what you're testing for.

  Starting with 2.10, the special module name `Unicode` refers to the version of the Unicode Character Database bundled with Perl.

- `%Module::CoreList::delta`

  Available in version 3.00 and above.

  It is a hash of hashes that is keyed on perl version. Each keyed hash will have the following keys:

```
delta_from - a previous perl version that the changes are based
 ↪on
changed    - a hash of module/versions that have changed
removed    - a hash of modules that have been removed
```

- `%Module::CoreList::released`

  Keyed on perl version this contains ISO formatted versions of the release dates, as gleaned from perlhist.

- `%Module::CoreList::families`

  New, in 1.96, a hash that clusters known perl releases by their major versions.

- `%Module::CoreList::deprecated`

  A hash of hashes keyed on perl version and on module name. If a module is defined it indicates that that module is deprecated in that perl version and is scheduled for removal from core at some future point.

- `%Module::CoreList::upstream`

  A hash that contains information on where patches should be directed for each core module.

  UPSTREAM indicates where patches should go. `undef` implies that this hasn't been discussed for the module at hand. `blead` indicates that the copy of the module in the blead sources is to be considered canonical, `cpan` means that the module on CPAN is to be patched first. `first-come` means that blead can be patched freely if it is in sync with the latest release on CPAN.

- `%Module::CoreList::bug_tracker`

  A hash that contains information on the appropriate bug tracker for each core module.

BUGS is an email or url to post bug reports. For modules with UPSTREAM => 'blead', use mailto:perl5-porters@perl.org. rt.cpan.org appears to automatically provide a URL for CPAN modules; any value given here overrides the default: http://rt.cpan.org/Public/Dist/Display.html?Name=\protect\TU\textdollarModuleName

CAVEATS

Module::CoreList currently covers the 5.000, 5.001, 5.002, 5.003_07, 5.004, 5.004_05, 5.005, 5.005_03, 5.005_04 and 5.7.3 releases of perl.

All stable releases of perl since 5.6.0 are covered.

All development releases of perl since 5.9.0 are covered.

HISTORY

Moved to Changes file.

Modules

- `Module::CoreList::Utils` - what utilities shipped with versions of perl

Module::CoreList::Utils

what utilities shipped with versions of perl

SYNOPSIS

```
use Module::CoreList::Utils;

print $Module::CoreList::Utils::utilities{5.009003}{ptar}; # prints␣
 ↪1

print Module::CoreList::Utils->first_release('corelist');
```

(continues on next page)

(continued from previous page)

```
# prints 5.008009

print Module::CoreList::Utils->first_release_by_date('corelist');
# prints 5.009002
```

DESCRIPTION

Module::CoreList::Utils provides information on which core and dual-life utilities shipped with each version of perl.

It provides a number of mechanisms for querying this information.

There is a functional programming API available for programmers to query information.

Programmers may also query the contained hash structure to find relevant information.

FUNCTIONS API

These are the functions that are available, they may either be called as functions or class methods:

```
Module::CoreList::Utils::first_release('corelist'); # as a function

Module::CoreList::Utils->first_release('corelist'); # class method
```

- `utilities`

  Requires a perl version as an argument, returns a list of utilities that shipped with that version of perl, or undef/empty list if that perl doesn't exist.

- `first_release( UTILITY )`

  Requires a UTILITY name as an argument, returns the perl version when that utility first appeared in core as ordered by perl version number or undef (in scalar context) or an empty list (in list context) if that utility is not in core.

- `first_release_by_date( UTILITY )`

  Requires a UTILITY name as an argument, returns the perl version when that utility first appeared in core as ordered by release date or undef (in scalar context) or an empty list (in list context) if that utility is not in core.

- `removed_from( UTILITY )`

  Takes a UTILITY name as an argument, returns the first perl version where that utility was removed from core. Returns undef if the given utility was never in core or remains in core.

- `removed_from_by_date( UTILITY )`

  Takes a UTILITY name as an argument, returns the first perl version by release date where that utility was removed from core. Returns undef if the given utility was never in core or remains in core.

DATA STRUCTURES

These are the hash data structures that are available:

- `%Module::CoreList::Utils::utilities`

  A hash of hashes that is keyed on perl version as indicated in $]. The second level hash is utility / defined pairs.

Module::Load

runtime require of both modules and files

SYNOPSIS

```
use Module::Load;

my $module = 'Data::Dumper';

load Data::Dumper;     # loads that module, but not import any␣
↪functions
                       # -> cannot use 'Dumper' function

load 'Data::Dumper';   # ditto
load $module           # tritto

autoload Data::Dumper; # loads that module and imports the default␣
↪functions
                       # -> can use 'Dumper' function

my $script = 'some/script.pl'
load $script;
```

(continues on next page)

(continued from previous page)

```
load 'some/script.pl';  # use quotes because of punctuations

load thing;             # try 'thing' first, then 'thing.pm'

load CGI, ':all';       # like 'use CGI qw[:standard]'
```

DESCRIPTION

`Module::Load` eliminates the need to know whether you are trying to require either a file or a module.

If you consult `perldoc -f require` you will see that `require` will behave differently when given a bareword or a string.

In the case of a string, `require` assumes you are wanting to load a file. But in the case of a bareword, it assumes you mean a module.

This gives nasty overhead when you are trying to dynamically require modules at runtime, since you will need to change the module notation (`Acme::Comment`) to a file notation fitting the particular platform you are on.

`Module::Load` eliminates the need for this overhead and will just DWYM.

Difference between `load` and `autoload`

`Module::Load` imports the two functions - `load` and `autoload`

`autoload` imports the default functions automatically, but `load` do not import any functions.

`autoload` is usable under `BEGIN{};`.

Both the functions can import the functions that are specified.

Following codes are same.

```
load File::Spec::Functions, qw/splitpath/;

autoload File::Spec::Functions, qw/splitpath/;
```

FUNCTIONS

- load

  Loads a specified module.

  See “Rules” for detailed loading rule.

- autoload

  Loads a specified module and imports the default functions.

  Except importing the functions, ‘autoload’ is same as ‘load’.

- load_remote

  Loads a specified module to the specified package.

```
use Module::Load 'load_remote';

my $pkg = 'Other::Package';

load_remote $pkg, 'Data::Dumper'; # load a module to
 ↪'Other::Package'
                                  # but do not import 'Dumper'␣
 ↪function
```

  A module for loading must be quoted.

  Except specifing the package and quoting module name, 'load_remote' is same as 'load'.

- autoload_remote

  Loads a specified module and imports the default functions to the specified package.

```
use Module::Load 'autoload_remote';

my $pkg = 'Other::Package';

autoload_remote $pkg, 'Data::Dumper'; # load a module to
 ↪'Other::Package'
                                      # and imports 'Dumper'␣
 ↪function
```

  A module for loading must be quoted.

  Except specifing the package and quoting module name, 'autoload_remote' is same as 'load_remote'.

Rules

All functions have the following rules to decide what it thinks you want:

- If the argument has any characters in it other than those matching `\w`, `:` or `'`, it must be a file
- If the argument matches only `[\w:']`, it must be a module
- If the argument matches only `\w`, it could either be a module or a file. We will try to find `file.pm` first in `@INC` and if that fails, we will try to find `file` in @INC. If both fail, we die with the respective error messages.

IMPORTS THE FUNCTIONS

'load' and 'autoload' are imported by default, but 'load_remote' and 'autoload_remote' are not imported.

To use 'load_remote' or 'autoload_remote', specify at 'use'.

- “load”,”autoload”,”load_remote”,”autoload_remote”

  Imports the selected functions.

```
# imports 'load' and 'autoload' (default)
use Module::Load;

# imports 'autoload' only
use Module::Load 'autoload';

# imports 'autoload' and 'autoload_remote', but don't import
 ↪'load';
use Module::Load qw/autoload autoload_remote/;
```

- ‘all’

  Imports all the functions.

```
use Module::Load 'all'; # imports load, autoload, load_remote,␣
 ↪autoload_remote
```

- ‘’,’none’,undef

  Not import any functions (`load` and `autoload` are not imported).

```
use Module::Load '';

use Module::Load 'none';

use Module::Load undef;
```

Caveats

Because of a bug in perl (#19213), at least in version 5.6.1, we have to hardcode the path separator for a require on Win32 to be `/`, like on Unix rather than the Win32 `\`. Otherwise perl will not read its own %INC accurately double load files if they are required again, or in the worst case, core dump.

`Module::Load` cannot do implicit imports, only explicit imports. (in other words, you always have to specify explicitly what you wish to import from a module, even if the functions are in that modules’ `@EXPORT`)

SEE ALSO

Module::Runtime provides functions for loading modules, checking the validity of a module name, converting a module name to partial `.pm` path, and related utility functions.

“require” in perlfunc and “use” in perlfunc.

Mojo::Loader is a “class loader and plugin framework”, and is included in the Mojolicious distribution.

Module::Loader is a module for finding and loading modules in a given namespace, inspired by `Mojo::Loader`.

ACKNOWLEDGEMENTS

Thanks to Jonas B. Nielsen for making explicit imports work.

Modules

- `Module::Load::Conditional` - Looking up module information / loading at runtime

Module::Load::Conditional

Looking up module information / loading at runtime

SYNOPSIS

```
use Module::Load::Conditional qw[can_load check_install requires];

my $use_list = {
        CPANPLUS        => 0.05,
        LWP             => 5.60,
        'Test::More'    => undef,
};

print can_load( modules => $use_list )
        ? 'all modules loaded successfully'
        : 'failed to load required modules';

my $rv = check_install( module => 'LWP', version => 5.60 )
            or print 'LWP is not installed!';

print 'LWP up to date' if $rv->{uptodate};
print "LWP version is $rv->{version}\n";
print "LWP is installed as file $rv->{file}\n";
```

(continues on next page)

(continued from previous page)

```
print "LWP requires the following modules to be installed:\n";
print join "\n", requires('LWP');

### allow M::L::C to peek in your %INC rather than just
### scanning @INC
$Module::Load::Conditional::CHECK_INC_HASH = 1;

### reset the 'can_load' cache
undef $Module::Load::Conditional::CACHE;

### don't have Module::Load::Conditional issue warnings --
### default is '1'
$Module::Load::Conditional::VERBOSE = 0;

### The last error that happened during a call to 'can_load'
my $err = $Module::Load::Conditional::ERROR;
```

DESCRIPTION

Module::Load::Conditional provides simple ways to query and possibly load any of the modules you have installed on your system during runtime.

It is able to load multiple modules at once or none at all if one of them was not able to load. It also takes care of any error checking and so forth.

Methods

$href = check_install(module => NAME [, version => VERSION, verbose => BOOL]);

`check_install` allows you to verify if a certain module is installed or not. You may call it with the following arguments:

- module

  The name of the module you wish to verify – this is a required key

- version

  The version this module needs to be – this is optional

- verbose

  Whether or not to be verbose about what it is doing – it will default to $Module::Load::Conditional::VERBOSE

It will return undef if it was not able to find where the module was installed, or a hash reference with the following keys if it was able to find the file:

- file

  Full path to the file that contains the module

- dir

Directory, or more exact the `@INC` entry, where the module was loaded from.

- version

  The version number of the installed module - this will be `undef` if the module had no (or unparsable) version number, or if the variable `$Module::Load::Conditional::FIND_VERSION` was set to true. (See the `GLOBAL VARIABLES` section below for details)

- uptodate

  A boolean value indicating whether or not the module was found to be at least the version you specified. If you did not specify a version, uptodate will always be true if the module was found. If no parsable version was found in the module, uptodate will also be true, since `check_install` had no way to verify clearly.

  See also `$Module::Load::Conditional::DEPRECATED`, which affects the outcome of this value.

$bool = can_load(modules => { NAME => VERSION [,NAME => VERSION] }, [verbose => BOOL, nocache => BOOL, autoload => BOOL])

`can_load` will take a list of modules, optionally with version numbers and determine if it is able to load them. If it can load *ALL* of them, it will. If one or more are unloadable, none will be loaded.

This is particularly useful if you have More Than One Way (tm) to solve a problem in a program, and only wish to continue down a path if all modules could be loaded, and not load them if they couldn't.

This function uses the `load` function or the `autoload_remote` function from Module::Load under the hood.

`can_load` takes the following arguments:

- modules

  This is a hashref of module/version pairs. The version indicates the minimum version to load. If no version is provided, any version is assumed to be good enough.

- verbose

  This controls whether warnings should be printed if a module failed to load. The default is to use the value of $Module::Load::Conditional::VERBOSE.

- nocache

  `can_load` keeps its results in a cache, so it will not load the same module twice, nor will it attempt to load a module that has already failed to load before. By default, `can_load` will check its cache, but you can override that by setting `nocache` to true.

- autoload

  This controls whether imports the functions of a loaded modules to the caller package. The default is no importing any functions.

  See the `autoload` function and the `autoload_remote` function from *Module::Load* for details.

@list = requires(MODULE);

`requires` can tell you what other modules a particular module requires. This is particularly useful when you're intending to write a module for public release and are listing its prerequisites.

`requires` takes but one argument: the name of a module. It will then first check if it can actually load this module, and return undef if it can't. Otherwise, it will return a list of modules and pragmas that would have been loaded on the module's behalf.

Note: The list `require` returns has originated from your current perl and your current install.

Global Variables

The behaviour of Module::Load::Conditional can be altered by changing the following global variables:

$Module::Load::Conditional::VERBOSE

This controls whether Module::Load::Conditional will issue warnings and explanations as to why certain things may have failed. If you set it to 0, Module::Load::Conditional will not output any warnings. The default is 0;

$Module::Load::Conditional::FIND_VERSION

This controls whether Module::Load::Conditional will try to parse (and eval) the version from the module you're trying to load.

If you don't wish to do this, set this variable to `false`. Understand then that version comparisons are not possible, and Module::Load::Conditional can not tell you what module version you have installed. This may be desirable from a security or performance point of view. Note that `$FIND_VERSION` code runs safely under `taint mode`.

The default is 1;

$Module::Load::Conditional::CHECK_INC_HASH

This controls whether `Module::Load::Conditional` checks your `%INC` hash to see if a module is available. By default, only `@INC` is scanned to see if a module is physically on your filesystem, or available via an `@INC-hook`. Setting this variable to `true` will trust any entries in `%INC` and return them for you.

The default is 0;

$Module::Load::Conditional::FORCE_SAFE_INC

This controls whether `Module::Load::Conditional` sanitises `@INC` by removing ".". The current default setting is `0`, but this may change in a future release.

$Module::Load::Conditional::CACHE

This holds the cache of the `can_load` function. If you explicitly want to remove the current cache, you can set this variable to `undef`

$Module::Load::Conditional::ERROR

This holds a string of the last error that happened during a call to `can_load`. It is useful to inspect this when `can_load` returns `undef`.

$Module::Load::Conditional::DEPRECATED

This controls whether `Module::Load::Conditional` checks if a dual-life core module has been deprecated. If this is set to true `check_install` will return false to `uptodate`, if a dual-life module is found to be loaded from `$Config{privlibexp}`

The default is 0;

Module::Loaded

mark modules as loaded or unloaded

SYNOPSIS

```
use Module::Loaded;

$bool = mark_as_loaded('Foo');   # Foo.pm is now marked as loaded
$loc  = is_loaded('Foo');        # location of Foo.pm set to the
                                 # loaders location
eval "require 'Foo'";            # is now a no-op

$bool = mark_as_unloaded('Foo'); # Foo.pm no longer marked as loaded
eval "require 'Foo'";            # Will try to find Foo.pm in @INC
```

DESCRIPTION

When testing applications, often you find yourself needing to provide functionality in your test environment that would usually be provided by external modules. Rather than munging the `%INC` by hand to mark these external modules as loaded, so they are not attempted to be loaded by perl, this module offers you a very simple way to mark modules as loaded and/or unloaded.

FUNCTIONS

$bool = mark_as_loaded(PACKAGE);

Marks the package as loaded to perl. `PACKAGE` can be a bareword or string.

If the module is already loaded, `mark_as_loaded` will carp about this and tell you from where the `PACKAGE` has been loaded already.

$bool = mark_as_unloaded(PACKAGE);

Marks the package as unloaded to perl, which is the exact opposite of `mark_as_loaded`. `PACKAGE` can be a bareword or string.

If the module is already unloaded, `mark_as_unloaded` will carp about this and tell you the `PACKAGE` has been unloaded already.

$loc = is_loaded(PACKAGE);

`is_loaded` tells you if `PACKAGE` has been marked as loaded yet. `PACKAGE` can be a bareword or string.

It returns falls if `PACKAGE` has not been loaded yet and the location from where it is said to be loaded on success.

Module::Metadata

Gather package and POD information from perl module files

VERSION

version 1.000039

SYNOPSIS

```
use Module::Metadata;

# information about a .pm file
my $info = Module::Metadata->new_from_file( $file );
my $version = $info->version;

# CPAN META 'provides' field for .pm files in a directory
my $provides = Module::Metadata->provides(
  dir => 'lib', version => 2
);
```

DESCRIPTION

This module provides a standard way to gather metadata about a .pm file through (mostly) static analysis and (some) code execution. When determining the version of a module, the `$VERSION` assignment is `eval`ed, as is traditional in the CPAN toolchain.

CLASS METHODS

new_from_file($filename, collect_pod => 1, decode_pod => 1)

Constructs a `Module::Metadata` object given the path to a file. Returns undef if the filename does not exist.

`collect_pod` is a optional boolean argument that determines whether POD data is collected and stored for reference. POD data is not collected by default. POD headings are always collected.

If the file begins by an UTF-8, UTF-16BE or UTF-16LE byte-order mark, then it is skipped before processing, and the content of the file is also decoded appropriately starting from perl 5.8.

Alternatively, if `decode_pod` is set, it will decode the collected pod sections according to the `=encoding` declaration.

new_from_handle($handle, $filename, collect_pod => 1, decode_pod => 1)

This works just like `new_from_file`, except that a handle can be provided as the first argument.

Note that there is no validation to confirm that the handle is a handle or something that can act like one. Passing something that isn't a handle will cause a exception when trying to read from it. The `filename` argument is mandatory or undef will be returned.

You are responsible for setting the decoding layers on `$handle` if required.

new_from_module($module, collect_pod => 1, inc => \@dirs, decode_pod => 1)

Constructs a `Module::Metadata` object given a module or package name. Returns undef if the module cannot be found.

In addition to accepting the `collect_pod` and `decode_pod` arguments as described above, this method accepts a `inc` argument which is a reference to an array of directories to search for the module. If none are given, the default is @INC.

If the file that contains the module begins by an UTF-8, UTF-16BE or UTF-16LE byte-order mark, then it is skipped before processing, and the content of the file is also decoded appropriately starting from perl 5.8.

find_module_by_name($module, \@dirs)

Returns the path to a module given the module or package name. A list of directories can be passed in as an optional parameter, otherwise @INC is searched.

Can be called as either an object or a class method.

find_module_dir_by_name($module, \@dirs)

Returns the entry in `@dirs` (or `@INC` by default) that contains the module `$module`. A list of directories can be passed in as an optional parameter, otherwise @INC is searched.

Can be called as either an object or a class method.

provides(%options)

This is a convenience wrapper around `package_versions_from_directory` to generate a CPAN META `provides` data structure. It takes key/value pairs. Valid option keys include:

- version **(required)**

  Specifies which version of the *CPAN::Meta::Spec* should be used as the format of the `provides` output. Currently only '1.4' and '2' are supported (and their format is identical). This may change in the future as the definition of `provides` changes.

  The `version` option is required. If it is omitted or if an unsupported version is given, then `provides` will throw an error.

- dir

  Directory to search recursively for `.pm` files. May not be specified with `files`.

- files

  Array reference of files to examine. May not be specified with `dir`.

- prefix

  String to prepend to the `file` field of the resulting output. This defaults to `lib`, which is the common case for most CPAN distributions with their `.pm` files in `lib`. This option ensures the META information has the correct relative path even when

the `dir` or `files` arguments are absolute or have relative paths from a location other than the distribution root.

For example, given `dir` of 'lib' and `prefix` of 'lib', the return value is a hashref of the form:

```
{
  'Package::Name' => {
    version => '0.123',
    file => 'lib/Package/Name.pm'
  },
  'OtherPackage::Name' => ...
}
```

package_versions_from_directory($dir, \@files?)

Scans `$dir` for .pm files (unless `@files` is given, in which case looks for those files in `$dir` - and reads each file for packages and versions, returning a hashref of the form:

```
{
  'Package::Name' => {
    version => '0.123',
    file => 'Package/Name.pm'
  },
  'OtherPackage::Name' => ...
}
```

The `DB` and `main` packages are always omitted, as are any "private" packages that have leading underscores in the namespace (e.g. `Foo::_private`)

Note that the file path is relative to `$dir` if that is specified. This **must not** be used directly for CPAN META `provides`. See the `provides` method instead.

log_info (internal)

Used internally to perform logging; imported from Log::Contextual if Log::Contextual has already been loaded, otherwise simply calls warn.

OBJECT METHODS

name()

Returns the name of the package represented by this module. If there is more than one package, it makes a best guess based on the filename. If it's a script (i.e. not a *.pm) the package name is 'main'.

version($package)

Returns the version as defined by the $VERSION variable for the package as returned by the `name` method if no arguments are given. If given the name of a package it will attempt to return the version of that package if it is specified in the file.

`filename()`

Returns the absolute path to the file. Note that this file may not actually exist on disk yet, e.g. if the module was read from an in-memory filehandle.

`packages_inside()`

Returns a list of packages. Note: this is a raw list of packages discovered (or assumed, in the case of `main`). It is not filtered for `DB`, `main` or private packages the way the `provides` method does. Invalid package names are not returned, for example "Foo:Bar". Strange but valid package names are returned, for example "Foo::Bar::", and are left up to the caller on how to handle.

`pod_inside()`

Returns a list of POD sections.

`contains_pod()`

Returns true if there is any POD in the file.

`pod($section)`

Returns the POD data in the given section.

`is_indexable($package)` or `is_indexable()`

Available since version 1.000020.

Returns a boolean indicating whether the package (if provided) or any package (otherwise) is eligible for indexing by PAUSE, the Perl Authors Upload Server. Note This only checks for valid `package` declarations, and does not take any ownership information into account.

GIVING THANKS

If you found this module to be useful, please show your appreciation by adding a +1 in MetaCPAN and a star in GitHub.

SUPPORT

Bugs may be submitted through the RT bug tracker (or bug-Module-Metadata@rt.cpan.org).

There is also a mailing list available for users of this distribution, at http://lists.perl.org/list/cpan-workers.html.

There is also an irc channel available for users of this distribution, at `#toolchain` on `irc.perl.org`.

5.2.68 Moose

The compiled part of Moose and Class::MOP: the attribute readers of the metaclass objects, the method map cache, and a few helpers of Moose::Exporter, the type constraints and role application.

Moose's own `.pm` files load this when `Class::MOP` is loaded; it is not used directly. `Class::MOP::get_code_info` is the one function meant to be called by other code.

This is a native implementation of Moose 2.4001's `mop.c` and `xs/*.xs`; its `.pm` files are used unchanged.

Synopsis

```
use Class::MOP;

my ($package, $name) = Class::MOP::get_code_info(\&Foo::bar);  # (
↪'Foo', 'bar')
my $meta = Class::MOP::Class->initialize('Foo');
print $meta->name, "\n";                          # Foo
print $meta->get_method('bar')->is_stub ? "stub\n" : "defined\n";
```

Differences from upstream

- `_method_map` and `is_stub` called on something that is not a reference to a hash die with the readers' messages, "can't call _method_map as a class method" and "object is not a hashref"; perl crashes. `_method_map` on an object with no `package` entry treats it as undefined, as perl does for an undefined one; perl crashes.
- `is_stub` on a method whose body is not a code reference dies "method body is not a CODE reference"; perl crashes, or reads the value as code and answers at random.
- Moose::Exporter's `_flag_as_reexport` does nothing to what is not a reference, and `_export_is_flagged` answers false for it; perl crashes on both.
- Applying a role to an instance that is not a blessed reference (`_reset_amagic`) does nothing; perl crashes.
- `_reset_amagic` no longer walks every scalar of the program looking for other references to the object: in perl 5.44 the overloading flag it sets on each of them lives on the class, which the first one has already set. The result is the same, without a cost that grows with the size of the program.

5.2.69 NDBM_File

Tie a Perl hash to an ndbm database file, so keys and values persist between runs.

NDBM_File is a tied-hash interface: bind a hash to a database with `tie`, and from then on `$h{key}`, `delete`, `exists`, `keys` and `each` read and write the file. Most programs reach it through `AnyDBM_File`, which picks NDBM_File first.

Synopsis

```
use Fcntl;
use NDBM_File;

tie my %h, 'NDBM_File', 'mydb', O_RDWR|O_CREAT, 0640
    or die "tie failed: $!";
$h{greeting} = 'hello';
untie %h;
```

Opening a database

```
tie %h, 'NDBM_File', $basename, $flags, $mode;
```

`$flags` are `Fcntl`'s `O_RDONLY`, `O_RDWR`, `O_CREAT`, `O_TRUNC`; `$mode` is the permission of the files it creates. `tie` returns the database object, or undef with `$!` set when the file cannot be opened.

DBM filters

`(tied %h)->filter_store_key(sub {...})`, `filter_store_value`, `filter_fetch_key` and `filter_fetch_value` install a sub that rewrites every key or value on its way into, or out of, the database. The sub changes `$_` in place; a store filter works on a copy, so your own variable keeps its value. Each method returns the filter it replaces (or undef), and `undef` as the argument removes the filter. The `DBM_Filter` module offers ready-made ones (`utf8`, `null`, `int32` and others). A filter that uses the same database croaks `recursion detected in filter_store_key` (or the filter's own name).

Files

pperl keeps the data in an LMDB file, `NAME.pag`, with an empty `NAME.dir` beside it, as ndbm has the two, and LMDB's lock file `NAME.pag-lock`. The ndbm library is not used, and its files cannot be read: tying a real gdbm or Berkeley DB file croaks, naming what the file is, and the file is left as it was. A key may be at most 511 bytes, 510 if it starts with a NUL byte; a longer one croaks.

Writes reach the file when the hash is untied: until then the tie holds the file's one writer slot, and another process that writes the file waits for it (readers never wait). Set `$Peta::FFI::LMDB::DBM_WRITE = 'through'` before `tie` to commit every write as it happens, for files that several processes write; see `Peta::FFI::LMDB`.

Differences from upstream

- The files are LMDB files: real ndbm (gdbm) and Berkeley DB files are refused, and pperl's files cannot be read by perl 5's NDBM_File. Covered by `t/82-native/Peta-FFI-LMDB/060-store.t`.
- Keys are limited to 511 bytes. Covered by `t/82-native/Peta-FFI-LMDB/060-store.t`.
- Writes reach the file at `untie` (or each one, with `$Peta::FFI::LMDB::DBM_WRITE = 'through'`), and a writer holds the file until then. Covered by `t/82-native/Peta-FFI-LMDB/060-store.t`.
- Deleting the key `each` just returned is safe: the walk goes on with the next key. Covered by `t/82-native/Peta-FFI-LMDB/060-store.t`.

Everything else behaves as with perl 5's NDBM_File. Covered by its own test, `t/81-xs-native/NDBM_File/100-upstream-ndbm.t`.

Functions

Errors

error

`(tied %h)->error`: true when an operation on the database has failed since it was tied or since the last `clearerr` - a `delete` on a database tied `O_RDONLY`, for one.

clearerr

`(tied %h)->clearerr`: reset the failure flag `error` reports.

5.2.70 NEXT

Provide a pseudo-class NEXT (et al) that allows method redispatch

SYNOPSIS

```
use NEXT;

package P;
sub P::method   { print "$_[0]: P method\n";   $_[0]->NEXT::method()
 ↪}
sub P::DESTROY  { print "$_[0]: P dtor\n";     $_[0]->
 ↪NEXT::DESTROY() }

package Q;
use base qw( P );
sub Q::AUTOLOAD { print "$_[0]: Q AUTOLOAD\n"; $_[0]->
 ↪NEXT::AUTOLOAD() }
sub Q::DESTROY  { print "$_[0]: Q dtor\n";     $_[0]->
 ↪NEXT::DESTROY() }
```

(continues on next page)

(continued from previous page)

```
package R;
sub R::method   { print "$_[0]: R method\n";   $_[0]->NEXT::method()␣
↪}
sub R::AUTOLOAD { print "$_[0]: R AUTOLOAD\n"; $_[0]->
↪NEXT::AUTOLOAD() }
sub R::DESTROY  { print "$_[0]: R dtor\n";     $_[0]->
↪NEXT::DESTROY() }

package S;
use base qw( Q R );
sub S::method   { print "$_[0]: S method\n";   $_[0]->NEXT::method()␣
↪}
sub S::AUTOLOAD { print "$_[0]: S AUTOLOAD\n"; $_[0]->
↪NEXT::AUTOLOAD() }
sub S::DESTROY  { print "$_[0]: S dtor\n";     $_[0]->
↪NEXT::DESTROY() }

package main;

my $obj = bless {}, "S";

$obj->method();             # Calls S::method, P::method, R::method
$obj->missing_method(); # Calls S::AUTOLOAD, Q::AUTOLOAD,␣
↪R::AUTOLOAD

# Clean-up calls S::DESTROY, Q::DESTROY, P::DESTROY, R::DESTROY
```

DESCRIPTION

The NEXT module adds a pseudoclass named NEXT to any program that uses it. If a method m calls `$self->NEXT::m()`, the call to m is redispatched as if the calling method had not originally been found.

Note: before using this module, you should look at next::method in the core *mro* module. mro has been a core module since Perl 5.9.5.

In other words, a call to `$self->NEXT::m()` resumes the depth-first, left-to-right search of `$self`'s class hierarchy that resulted in the original call to m.

Note that this is not the same thing as `$self->SUPER::m()`, which begins a new dispatch that is restricted to searching the ancestors of the current class. `$self->NEXT::m()` can backtrack past the current class – to look for a suitable method in other ancestors of `$self` – whereas `$self->SUPER::m()` cannot.

A typical use would be in the destructors of a class hierarchy, as illustrated in the SYNOPSIS above. Each class in the hierarchy has a DESTROY method that performs some class-specific action and then redispatches the call up the hierarchy. As a result, when an object of class S is destroyed, the destructors of *all* its parent classes are called (in depth-first, left-to-right order).

Another typical use of redispatch would be in AUTOLOAD'ed methods. If such a method determined that it was not able to handle a particular call, it might choose to redispatch

that call, in the hope that some other AUTOLOAD (above it, or to its left) might do better.

By default, if a redispatch attempt fails to find another method elsewhere in the objects class hierarchy, it quietly gives up and does nothing (but see "Enforcing redispatch"). This gracious acquiescence is also unlike the (generally annoying) behaviour of SUPER, which throws an exception if it cannot redispatch.

Note that it is a fatal error for any method (including AUTOLOAD) to attempt to redispatch any method that does not have the same name. For example:

```
sub S::oops { print "oops!\n"; $_[0]->NEXT::other_method() }
```

Enforcing redispatch

It is possible to make NEXT redispatch more demandingly (i.e. like SUPER does), so that the redispatch throws an exception if it cannot find a "next" method to call.

To do this, simple invoke the redispatch as:

```
$self->NEXT::ACTUAL::method();
```

rather than:

```
$self->NEXT::method();
```

The ACTUAL tells NEXT that there must actually be a next method to call, or it should throw an exception.

NEXT::ACTUAL is most commonly used in AUTOLOAD methods, as a means to decline an AUTOLOAD request, but preserve the normal exception-on-failure semantics:

```
sub AUTOLOAD {
        if ($AUTOLOAD =~ /foo|bar/) {
                # handle here
        }
        else {  # try elsewhere
                shift()->NEXT::ACTUAL::AUTOLOAD(@_);
        }
}
```

By using NEXT::ACTUAL, if there is no other AUTOLOAD to handle the method call, an exception will be thrown (as usually happens in the absence of a suitable AUTOLOAD).

Avoiding repetitions

If NEXT redispatching is used in the methods of a "diamond" class hierarchy:

```
#     A   B
#    / \ /
#   C   D
#    \ /
#     E
```

(continues on next page)

(continued from previous page)

```
use NEXT;

package A;
sub foo { print "called A::foo\n"; shift->NEXT::foo() }

package B;
sub foo { print "called B::foo\n"; shift->NEXT::foo() }

package C; @ISA = qw( A );
sub foo { print "called C::foo\n"; shift->NEXT::foo() }

package D; @ISA = qw(A B);
sub foo { print "called D::foo\n"; shift->NEXT::foo() }

package E; @ISA = qw(C D);
sub foo { print "called E::foo\n"; shift->NEXT::foo() }

E->foo();
```

then derived classes may (re-)inherit base-class methods through two or more distinct paths (e.g. in the way `E` inherits `A::foo` twice – through `C` and `D`). In such cases, a sequence of `NEXT` redispatches will invoke the multiply inherited method as many times as it is inherited. For example, the above code prints:

```
called E::foo
called C::foo
called A::foo
called D::foo
called A::foo
called B::foo
```

(i.e. `A::foo` is called twice).

In some cases this *may* be the desired effect within a diamond hierarchy, but in others (e.g. for destructors) it may be more appropriate to call each method only once during a sequence of redispatches.

To cover such cases, you can redispatch methods via:

```
$self->NEXT::DISTINCT::method();
```

rather than:

```
$self->NEXT::method();
```

This causes the redispatcher to only visit each distinct `method` method once. That is, to skip any classes in the hierarchy that it has already visited during redispatch. So, for example, if the previous example were rewritten:

```
package A;
sub foo { print "called A::foo\n"; shift->NEXT::DISTINCT::foo() }
```

(continues on next page)

(continued from previous page)

```
package B;
sub foo { print "called B::foo\n"; shift->NEXT::DISTINCT::foo() }

package C; @ISA = qw( A );
sub foo { print "called C::foo\n"; shift->NEXT::DISTINCT::foo() }

package D; @ISA = qw(A B);
sub foo { print "called D::foo\n"; shift->NEXT::DISTINCT::foo() }

package E; @ISA = qw(C D);
sub foo { print "called E::foo\n"; shift->NEXT::DISTINCT::foo() }

E->foo();
```

then it would print:

```
called E::foo
called C::foo
called A::foo
called D::foo
called B::foo
```

and omit the second call to `A::foo` (since it would not be distinct from the first call to `A::foo`).

Note that you can also use:

```
$self->NEXT::DISTINCT::ACTUAL::method();
```

or:

```
$self->NEXT::ACTUAL::DISTINCT::method();
```

to get both unique invocation *and* exception-on-failure.

Note that, for historical compatibility, you can also use `NEXT::UNSEEN` instead of `NEXT::DISTINCT`.

Invoking all versions of a method with a single call

Yet another pseudo-class that `NEXT` provides is `EVERY`. Its behaviour is considerably simpler than that of the `NEXT` family. A call to:

```
$obj->EVERY::foo();
```

calls *every* method named `foo` that the object in `$obj` has inherited. That is:

```
use NEXT;

package A; @ISA = qw(B D X);
```

(continues on next page)

(continued from previous page)

```
sub foo { print "A::foo " }

package B; @ISA = qw(D X);
sub foo { print "B::foo " }

package X; @ISA = qw(D);
sub foo { print "X::foo " }

package D;
sub foo { print "D::foo " }

package main;

my $obj = bless {}, 'A';
$obj->EVERY::foo();        # prints" A::foo B::foo X::foo D::foo
```

Prefixing a method call with `EVERY::` causes every method in the object's hierarchy with that name to be invoked. As the above example illustrates, they are not called in Perl's usual "left-most-depth-first" order. Instead, they are called "breadth-first-dependency-wise".

That means that the inheritance tree of the object is traversed breadth-first and the resulting order of classes is used as the sequence in which methods are called. However, that sequence is modified by imposing a rule that the appropriate method of a derived class must be called before the same method of any ancestral class. That's why, in the above example, `X::foo` is called before `D::foo`, even though `D` comes before `X` in `@B::ISA`.

In general, there's no need to worry about the order of calls. They will be left-to-right, breadth-first, most-derived-first. This works perfectly for most inherited methods (including destructors), but is inappropriate for some kinds of methods (such as constructors, cloners, debuggers, and initializers) where it's more appropriate that the least-derived methods be called first (as more-derived methods may rely on the behaviour of their "ancestors"). In that case, instead of using the `EVERY` pseudo-class:

```
$obj->EVERY::foo();        # prints" A::foo B::foo X::foo D::foo
```

you can use the `EVERY::LAST` pseudo-class:

```
$obj->EVERY::LAST::foo();  # prints" D::foo X::foo B::foo A::foo
```

which reverses the order of method call.

Whichever version is used, the actual methods are called in the same context (list, scalar, or void) as the original call via `EVERY`, and return:

- A hash of array references in list context. Each entry of the hash has the fully qualified method name as its key and a reference to an array containing the method's list-context return values as its value.
- A reference to a hash of scalar values in scalar context. Each entry of the hash has the fully qualified method name as its key and the method's scalar-context return values as its value.

- Nothing in void context (obviously).

Using EVERY methods

The typical way to use an EVERY call is to wrap it in another base method, that all classes inherit. For example, to ensure that every destructor an object inherits is actually called (as opposed to just the left-most-depth-first-est one):

```
package Base;
sub DESTROY { $_[0]->EVERY::Destroy }

package Derived1;
use base 'Base';
sub Destroy {...}

package Derived2;
use base 'Base', 'Derived1';
sub Destroy {...}
```

et cetera. Every derived class than needs its own clean-up behaviour simply adds its own Destroy method (*not* a DESTROY method), which the call to EVERY::LAST::Destroy in the inherited destructor then correctly picks up.

Likewise, to create a class hierarchy in which every initializer inherited by a new object is invoked:

```
package Base;
sub new {
        my ($class, %args) = @_;
        my $obj = bless {}, $class;
        $obj->EVERY::LAST::Init(\%args);
}

package Derived1;
use base 'Base';
sub Init {
        my ($argsref) = @_;
        ...
}

package Derived2;
use base 'Base', 'Derived1';
sub Init {
        my ($argsref) = @_;
        ...
}
```

et cetera. Every derived class than needs some additional initialization behaviour simply adds its own Init method (*not* a new method), which the call to EVERY::LAST::Init in the inherited constructor then correctly picks up.

SEE ALSO

mro (in particular next::method), which has been a core module since Perl 5.9.5.

Damian Conway (damian@conway.org)

BUGS AND IRRITATIONS

Because it's a module, not an integral part of the interpreter, NEXT has to guess where the surrounding call was found in the method look-up sequence. In the presence of diamond inheritance patterns it occasionally guesses wrong.

It's also too slow (despite caching).

Comment, suggestions, and patches welcome.

5.2.71 Net

Namespace containing the following modules:

- Net::Cmd - Network Command class (as used by FTP, SMTP etc)
- Net::Config - Local configuration data for libnet
- Net::Domain - Attempt to evaluate the current host's internet name and domain
- Net::FTP - FTP Client class
- Net::NNTP - NNTP Client class
- Net::Netrc - OO interface to users netrc file
- Net::POP3 - Post Office Protocol 3 Client class (RFC1939)
- Net::Ping - check a remote host for reachability
- Net::SMTP - Simple Mail Transfer Protocol Client
- Net::SSLeay - Perl bindings for OpenSSL's libssl and libcrypto
- Net::Time - time and daytime network client interface
- Net::hostent - by-name interface to Perl's built-in gethost*() functions
- Net::netent - by-name interface to Perl's built-in getnet*() functions
- Net::protoent - by-name interface to Perl's built-in getproto*() functions
- Net::servent - by-name interface to Perl's built-in getserv*() functions

Net::Cmd

Network Command class (as used by FTP, SMTP etc)

SYNOPSIS

```
use Net::Cmd;

@ISA = qw(Net::Cmd);
```

DESCRIPTION

`Net::Cmd` is a collection of methods that can be inherited by a sub-class of `IO::Socket::INET`. These methods implement the functionality required for a command based protocol, for example FTP and SMTP.

If your sub-class does not also derive from `IO::Socket::INET` or similar (e.g. `IO::Socket::IP`, `IO::Socket::INET6` or `IO::Socket::SSL`) then you must provide the following methods by other means yourself: `close()` and `timeout()`.

Public Methods

These methods provide a user interface to the `Net::Cmd` object.

- `debug($level)`

  Set the level of debug information for this object. If `$level` is not given then the current state is returned. Otherwise the state is changed to `$level` and the previous state returned.

  Different packages may implement different levels of debug but a non-zero value results in copies of all commands and responses also being sent to STDERR.

  If `$level` is `undef` then the debug level will be set to the default debug level for the class.

  This method can also be called as a *static* method to set/get the default debug level for a given class.

- `message()`

  Returns the text message returned from the last command. In a scalar context it returns a single string, in a list context it will return each line as a separate element. (See "PSEUDO RESPONSES" below.)

- `code()`

  Returns the 3-digit code from the last command. If a command is pending then the value 0 is returned. (See "PSEUDO RESPONSES" below.)

- `ok()`

  Returns non-zero if the last code value was greater than zero and less than 400. This holds true for most command servers. Servers where this does not hold may override this method.

- `status()`

  Returns the most significant digit of the current status code. If a command is pending then `CMD_PENDING` is returned.

- `datasend($data)`

  Send data to the remote server, converting LF to CRLF. Any line starting with a '.' will be prefixed with another '.'. `$data` may be an array or a reference to an array. The `$data` passed in must be encoded by the caller to octets of whatever encoding is required, e.g. by using the Encode module's `encode()` function.

- `dataend()`

  End the sending of data to the remote server. This is done by ensuring that the data already sent ends with CRLF then sending '.CRLF' to end the transmission. Once this data has been sent `dataend` calls `response` and returns true if `response` returns CMD_OK.

Protected Methods

These methods are not intended to be called by the user, but used or over-ridden by a sub-class of `Net::Cmd`

- `debug_print($dir, $text)`

  Print debugging information. `$dir` denotes the direction *true* being data being sent to the server. Calls `debug_text` before printing to STDERR.

- `debug_text($dir, $text)`

  This method is called to print debugging information. `$text` is the text being sent. The method should return the text to be printed.

  This is primarily meant for the use of modules such as FTP where passwords are sent, but we do not want to display them in the debugging information.

- `command($cmd[, $args, ... ])`

  Send a command to the command server. All arguments are first joined with a space character and CRLF is appended, this string is then sent to the command server.

  Returns undef upon failure.

- `unsupported()`

  Sets the status code to 580 and the response text to 'Unsupported command'. Returns zero.

- `response()`

  Obtain a response from the server. Upon success the most significant digit of the status code is returned. Upon failure, timeout etc., *CMD_ERROR* is returned.

- `parse_response($text)`

  This method is called by `response` as a method with one argument. It should return an array of 2 values, the 3-digit status code and a flag which is true when this is part of a multi-line response and this line is not the last.

- `getline()`

  Retrieve one line, delimited by CRLF, from the remote server. Returns *undef* upon failure.

  NOTE: If you do use this method for any reason, please remember to add some `debug_print` calls into your method.

- `ungetline($text)`

  Unget a line of text from the server.

- `rawdatasend($data)`

  Send data to the remote server without performing any conversions. `$data` is a scalar. As with `datasend()`, the `$data` passed in must be encoded by the caller to octets of whatever encoding is required, e.g. by using the Encode module's `encode()` function.

- `read_until_dot()`

  Read data from the remote server until a line consisting of a single '.'. Any lines starting with '..' will have one of the '.'s removed.

  Returns a reference to a list containing the lines, or *undef* upon failure.

- `tied_fh()`

  Returns a filehandle tied to the Net::Cmd object. After issuing a command, you may read from this filehandle using read() or <>. The filehandle will return EOF when the final dot is encountered. Similarly, you may write to the filehandle in order to send data to the server after issuing a command that expects data to be written.

  See the Net::POP3 and Net::SMTP modules for examples of this.

Pseudo Responses

Normally the values returned by `message()` and `code()` are obtained from the remote server, but in a few circumstances, as detailed below, `Net::Cmd` will return values that it sets. You can alter this behavior by overriding DEF_REPLY_CODE() to specify a different default reply code, or overriding one of the specific error handling methods below.

- Initial value

  Before any command has executed or if an unexpected error occurs `code()` will return "421" (temporary connection failure) and `message()` will return undef.

- Connection closed

  If the underlying `IO::Handle` is closed, or if there are any read or write failures, the file handle will be forced closed, and `code()` will return "421" (temporary connection failure) and `message()` will return "[$pkg] Connection closed" (where $pkg is the name of the class that subclassed `Net::Cmd`). The _set_status_closed() method can be overridden to set a different message (by calling set_status()) or otherwise trap this error.

- Timeout

  If there is a read or write timeout `code()` will return "421" (temporary connection failure) and `message()` will return "[$pkg] Timeout" (where $pkg is the name

of the class that subclassed `Net::Cmd`). The _set_status_timeout() method can be overridden to set a different message (by calling set_status()) or otherwise trap this error.

EXPORTS

The following symbols are, or can be, exported by this module:

- Default Exports

  `CMD_INFO`, `CMD_OK`, `CMD_MORE`, `CMD_REJECT`, `CMD_ERROR`, `CMD_PENDING`.

  (These correspond to possible results of `response()` and `status()`.)

- Optional Exports

  None.

- Export Tags

  None.

Net::Config

Local configuration data for libnet

SYNOPSIS

```
use Net::Config qw(%NetConfig);
```

DESCRIPTION

`Net::Config` holds configuration data for the modules in the libnet distribution. During installation you will be asked for these values.

The configuration data is held globally in a file in the perl installation tree, but a user may override any of these values by providing their own. This can be done by having a `.libnetrc` file in their home directory. This file should return a reference to a HASH containing the keys described below. For example

```
# .libnetrc
{
    nntp_hosts => [ "my_preferred_host" ],
    ph_hosts   => [ "my_ph_server" ],
}
__END__
```

Class Methods

`Net::Config` defines the following methods. They are methods as they are invoked as class methods. This is because `Net::Config` inherits from `Net::LocalCfg` so you can override these methods if you want.

- `requires_firewall($host)`

  Attempts to determine if a given host is outside your firewall. Possible return values are.

  ```
  -1  Cannot lookup hostname
   0  Host is inside firewall (or there is no ftp_firewall entry)
   1  Host is outside the firewall
  ```

  This is done by using hostname lookup and the `local_netmask` entry in the configuration data.

NetConfig Values

- nntp_hosts
- snpp_hosts
- pop3_hosts
- smtp_hosts
- ph_hosts
- daytime_hosts
- time_hosts

  Each is a reference to an array of hostnames (in order of preference), which should be used for the given protocol

- inet_domain

  Your internet domain name

- ftp_firewall

  If you have an FTP proxy firewall (**NOT** an HTTP or SOCKS firewall) then this value should be set to the firewall hostname. If your firewall does not listen to port 21, then this value should be set to `"hostname:port"` (eg `"hostname:99"`)

- ftp_firewall_type

  There are many different ftp firewall products available. But unfortunately there is no standard for how to traverse a firewall. The list below shows the sequence of commands that Net::FTP will use

```
user        Username for remote host
pass        Password for remote host
fwuser      Username for firewall
fwpass      Password for firewall
remote.host The hostname of the remote ftp server
```

  – 0

    There is no firewall

  – 1

```
USER user@remote.host
PASS pass
```

  – 2

```
USER fwuser
PASS fwpass
USER user@remote.host
PASS pass
```

  – 3

```
USER fwuser
PASS fwpass
SITE remote.site
USER user
PASS pass
```

– 4

```
USER fwuser
PASS fwpass
OPEN remote.site
USER user
PASS pass
```

– 5

```
USER user@fwuser@remote.site
PASS pass@fwpass
```

– 6

```
USER fwuser@remote.site
PASS fwpass
USER user
PASS pass
```

– 7

```
USER user@remote.host
PASS pass
AUTH fwuser
RESP fwpass
```

- ftp_ext_passive
- ftp_int_passive

  FTP servers can work in passive or active mode. Active mode is when you want to transfer data you have to tell the server the address and port to connect to. Passive mode is when the server provide the address and port and you establish the connection.

  With some firewalls active mode does not work as the server cannot connect to your machine (because you are behind a firewall) and the firewall does not re-write the command. In this case you should set `ftp_ext_passive` to a *true* value.

  Some servers are configured to only work in passive mode. If you have one of these you can force `Net::FTP` to always transfer in passive mode; when not going via a firewall, by setting `ftp_int_passive` to a *true* value.

- local_netmask

  A reference to a list of netmask strings in the form `"134.99.4.0/24"`. These are used by the `requires_firewall` function to determine if a given host is inside or outside your firewall.

The following entries are used during installation & testing on the libnet package

- test_hosts

  If true then `make test` may attempt to connect to hosts given in the configuration.

- test_exists

  If true then `Configure` will check each hostname given that it exists

EXPORTS

Net::Domain

Attempt to evaluate the current host's internet name and domain

SYNOPSIS

```
use Net::Domain qw(hostname hostfqdn hostdomain domainname);
```

DESCRIPTION

Using various methods **attempt** to find the Fully Qualified Domain Name (FQDN) of the current host. From this determine the host-name and the host-domain.

Each of the functions will return *undef* if the FQDN cannot be determined.

Functions

- `hostfqdn()`

  Identify and return the FQDN of the current host.

- `domainname()`

  An alias for hostfqdn().

- `hostname()`

  Returns the smallest part of the FQDN which can be used to identify the host.

- `hostdomain()`

  Returns the remainder of the FQDN after the *hostname* has been removed.

EXPORTS

The following symbols are, or can be, exported by this module:

- Default Exports

  None.

- Optional Exports

  `hostname`, `hostdomain`, `hostfqdn`, `domainname`.

Net::FTP

FTP Client class

SYNOPSIS

```
use Net::FTP;

$ftp = Net::FTP->new("some.host.name", Debug => 0)
  or die "Cannot connect to some.host.name: $@";

$ftp->login("anonymous",'-anonymous@')
  or die "Cannot login ", $ftp->message;
```

(continues on next page)

(continued from previous page)

```
$ftp->cwd("/pub")
  or die "Cannot change working directory ", $ftp->message;

$ftp->get("that.file")
  or die "get failed ", $ftp->message;

$ftp->quit;
```

DESCRIPTION

`Net::FTP` is a class implementing a simple FTP client in Perl as described in RFC959. It provides wrappers for the commonly used subset of the RFC959 commands. If *IO::Socket::IP* or IO::Socket::INET6 is installed it also provides support for IPv6 as defined in RFC2428. And with *IO::Socket::SSL* installed it provides support for implicit FTPS and explicit FTPS as defined in RFC4217.

The Net::FTP class is a subclass of Net::Cmd and (depending on avaibility) of IO::Socket::IP, IO::Socket::INET6 or IO::Socket::INET.

Overview

FTP stands for File Transfer Protocol. It is a way of transferring files between networked machines. The protocol defines a client (whose commands are provided by this module) and a server (not implemented in this module). Communication is always initiated by the client, and the server responds with a message and a status code (and sometimes with data).

The FTP protocol allows files to be sent to or fetched from the server. Each transfer involves a **local file** (on the client) and a **remote file** (on the server). In this module, the same file name will be used for both local and remote if only one is specified. This means that transferring remote file `/path/to/file` will try to put that file in `/path/to/file` locally, unless you specify a local file name.

The protocol also defines several standard **translations** which the file can undergo during transfer. These are ASCII, EBCDIC, binary, and byte. ASCII is the default type, and indicates that the sender of files will translate the ends of lines to a standard representation which the receiver will then translate back into their local representation. EBCDIC indicates the file being transferred is in EBCDIC format. Binary (also known as image) format sends the data as a contiguous bit stream. Byte format transfers the data as bytes, the values of which remain the same regardless of differences in byte size between the two machines (in theory - in practice you should only use this if you really know what you're doing). This class does not support the EBCDIC or byte formats, and will default to binary instead if they are attempted.

Class Methods

- `new([$host][, %options])`

  This is the constructor for a new Net::FTP object. `$host` is the name of the remote host to which an FTP connection is required.

`$host` is optional. If `$host` is not given then it may instead be passed as the `Host` option described below.

`%options` are passed in a hash like fashion, using key and value pairs. Possible options are:

Host - FTP host to connect to. It may be a single scalar, as defined for the `PeerAddr` option in *IO::Socket::INET*, or a reference to an array with hosts to try in turn. The "host" method will return the value which was used to connect to the host.

Firewall - The name of a machine which acts as an FTP firewall. This can be overridden by an environment variable `FTP_FIREWALL`. If specified, and the given host cannot be directly connected to, then the connection is made to the firewall machine and the string `@hostname` is appended to the login identifier. This kind of setup is also referred to as an ftp proxy.

FirewallType - The type of firewall running on the machine indicated by **Firewall**. This can be overridden by an environment variable `FTP_FIREWALL_TYPE`. For a list of permissible types, see the description of ftp_firewall_type in *Net::Config*.

BlockSize - This is the block size that Net::FTP will use when doing transfers. (defaults to 10240)

Port - The port number to connect to on the remote machine for the FTP connection

SSL - If the connection should be done from start with SSL, contrary to later upgrade with `starttls`.

SSL_* - SSL arguments which will be applied when upgrading the control or data connection to SSL. You can use SSL arguments as documented in *IO::Socket::SSL*, but it will usually use the right arguments already.

Timeout - Set a timeout value in seconds (defaults to 120)

Debug - debug level (see the debug method in *Net::Cmd*)

Passive - If set to a non-zero value then all data transfers will be done using passive mode. If set to zero then data transfers will be done using active mode. If the machine is connected to the Internet directly, both passive and active mode should work equally well. Behind most firewall and NAT configurations passive mode has a better chance of working. However, in some rare firewall configurations, active mode actually works when passive mode doesn't. Some really old FTP servers might not implement passive transfers. If not specified, then the transfer mode is set by the environment variable `FTP_PASSIVE` or if that one is not set by the settings done by the `libnetcfg` utility. If none of these apply then passive mode is used.

Hash - If given a reference to a file handle (e.g., `\*STDERR`), print hash marks (#) on that filehandle every 1024 bytes. This simply invokes the `hash()` method for you, so that hash marks are displayed for all transfers. You can, of course, call `hash()` explicitly whenever you'd like.

LocalAddr - Local address to use for all socket connections. This argument will be passed to the super class, i.e. *IO::Socket::INET* or *IO::Socket::IP*.

Domain - Domain to use, i.e. AF_INET or AF_INET6. This argument will be passed to the IO::Socket super class. This can be used to enforce IPv4 even with *IO::Socket::IP* which would default to IPv6. **Family** is accepted as alternative name for **Domain**.

If the constructor fails undef will be returned and an error message will be in $@

Object Methods

Unless otherwise stated all methods return either a *true* or *false* value, with *true* meaning that the operation was a success. When a method states that it returns a value, failure will be returned as *undef* or an empty list.

`Net::FTP` inherits from `Net::Cmd` so methods defined in `Net::Cmd` may be used to send commands to the remote FTP server in addition to the methods documented here.

- `login([$login[, $password[, $account]]])`

  Log into the remote FTP server with the given login information. If no arguments are given then the `Net::FTP` uses the `Net::Netrc` package to lookup the login information for the connected host. If no information is found then a login of *anonymous* is used. If no password is given and the login is *anonymous* then *anonymous@* will be used for password.

  If the connection is via a firewall then the `authorize` method will be called with no arguments.

- `starttls()`

  Upgrade existing plain connection to SSL. The SSL arguments have to be given in `new` already because they are needed for data connections too.

- `stoptls()`

  Downgrade existing SSL connection back to plain. This is needed to work with some FTP helpers at firewalls, which need to see the PORT and PASV commands and responses to dynamically open the necessary ports. In this case `starttls` is usually only done to protect the authorization.

- `prot($level)`

  Set what type of data channel protection the client and server will be using. Only `$level`s "C" (clear) and "P" (private) are supported.

- `host()`

  Returns the value used by the constructor, and passed to the IO::Socket super class to connect to the host.

- `account($acct)`

  Set a string identifying the user's account.

- `authorize([$auth[, $resp]])`

  This is a protocol used by some firewall ftp proxies. It is used to authorise the user to send data out. If both arguments are not specified then `authorize` uses `Net::Netrc` to do a lookup.

- `site($args)`

  Send a SITE command to the remote server and wait for a response.

  Returns most significant digit of the response code.

- `ascii()`

  Transfer file in ASCII. CRLF translation will be done if required

- `binary()`

  Transfer file in binary mode. No transformation will be done.

  Hint: If both server and client machines use the same line ending for text files, then it will be faster to transfer all files in binary mode.

- `type([$type])`

  Set or get if files will be transferred in ASCII or binary mode.

- `rename($oldname, $newname)`

  Rename a file on the remote FTP server from `$oldname` to `$newname`. This is done by sending the RNFR and RNTO commands.

- `delete($filename)`

  Send a request to the server to delete `$filename`.

- `cwd([$dir])`

  Attempt to change directory to the directory given in `$dir`. If `$dir` is `"..`", the FTP `CDUP` command is used to attempt to move up one directory. If no directory is given then an attempt is made to change the directory to the root directory.

- `cdup()`

  Change directory to the parent of the current directory.

- `passive([$passive])`

  Set or get if data connections will be initiated in passive mode.

- `pwd()`

  Returns the full pathname of the current directory.

- `restart($where)`

  Set the byte offset at which to begin the next data transfer. Net::FTP simply records this value and uses it when during the next data transfer. For this reason this method will not return an error, but setting it may cause a subsequent data transfer to fail.

- `rmdir($dir[, $recurse])`

  Remove the directory with the name `$dir`. If `$recurse` is *true* then `rmdir` will attempt to delete everything inside the directory.

- `mkdir($dir[, $recurse])`

  Create a new directory with the name `$dir`. If `$recurse` is *true* then `mkdir` will attempt to create all the directories in the given path.

  Returns the full pathname to the new directory.

- `alloc($size[, $record_size])`

  The alloc command allows you to give the ftp server a hint about the size of the file about to be transferred using the ALLO ftp command. Some storage systems use

this to make intelligent decisions about how to store the file. The `$size` argument represents the size of the file in bytes. The `$record_size` argument indicates a maximum record or page size for files sent with a record or page structure.

The size of the file will be determined, and sent to the server automatically for normal files so that this method need only be called if you are transferring data from a socket, named pipe, or other stream not associated with a normal file.

- `ls([$dir])`

  Get a directory listing of `$dir`, or the current directory.

  In an array context, returns a list of lines returned from the server. In a scalar context, returns a reference to a list.

- `dir([$dir])`

  Get a directory listing of `$dir`, or the current directory in long format.

  In an array context, returns a list of lines returned from the server. In a scalar context, returns a reference to a list.

- `get($remote_file[, $local_file[, $where]])`

  Get `$remote_file` from the server and store locally. `$local_file` may be a filename or a filehandle. If not specified, the file will be stored in the current directory with the same leafname as the remote file.

  If `$where` is given then the first `$where` bytes of the file will not be transferred, and the remaining bytes will be appended to the local file if it already exists.

  Returns `$local_file`, or the generated local file name if `$local_file` is not given. If an error was encountered undef is returned.

- `put($local_file[, $remote_file])`

  Put a file on the remote server. `$local_file` may be a name or a filehandle. If `$local_file` is a filehandle then `$remote_file` must be specified. If `$remote_file` is not specified then the file will be stored in the current directory with the same leafname as `$local_file`.

  Returns `$remote_file`, or the generated remote filename if `$remote_file` is not given.

  NOTE: If for some reason the transfer does not complete and an error is returned then the contents that had been transferred will not be remove automatically.

- `put_unique($local_file[, $remote_file])`

  Same as put but uses the `STOU` command.

  Returns the name of the file on the server.

- `append($local_file[, $remote_file])`

  Same as put but appends to the file on the remote server.

  Returns `$remote_file`, or the generated remote filename if `$remote_file` is not given.

- `unique_name()`

  Returns the name of the last file stored on the server using the `STOU` command.

- `mdtm($file)`

  Returns the *modification time* of the given file

- `size($file)`

  Returns the size in bytes for the given file as stored on the remote server.

  NOTE: The size reported is the size of the stored file on the remote server. If the file is subsequently transferred from the server in ASCII mode and the remote server and local machine have different ideas about "End Of Line" then the size of file on the local machine after transfer may be different.

- `supported($cmd)`

  Returns TRUE if the remote server supports the given command.

- `hash([$filehandle_glob_ref[, $bytes_per_hash_mark]])`

  Called without parameters, or with the first argument false, hash marks are suppressed. If the first argument is true but not a reference to a file handle glob, then *STDERR is used. The second argument is the number of bytes per hash mark printed, and defaults to 1024. In all cases the return value is a reference to an array of two: the filehandle glob reference and the bytes per hash mark.

- `feature($name)`

  Determine if the server supports the specified feature. The return value is a list of lines the server responded with to describe the options that it supports for the given feature. If the feature is unsupported then the empty list is returned.

```
if ($ftp->feature( 'MDTM' )) {
  # Do something
}

if (grep { /\bTLS\b/ } $ftp->feature('AUTH')) {
  # Server supports TLS
}
```

The following methods can return different results depending on how they are called. If the user explicitly calls either of the `pasv` or `port` methods then these methods will return a *true* or *false* value. If the user does not call either of these methods then the result will be a reference to a `Net::FTP::dataconn` based object.

- `nlst([$dir])`

  Send an `NLST` command to the server, with an optional parameter.

- `list([$dir])`

  Same as `nlst` but using the `LIST` command

- `retr($file)`

  Begin the retrieval of a file called `$file` from the remote server.

- `stor($file)`

  Tell the server that you wish to store a file. `$file` is the name of the new file that should be created.

- `stou($file)`

  Same as `stor` but using the `STOU` command. The name of the unique file which was created on the server will be available via the `unique_name` method after the data connection has been closed.

- `appe($file)`

  Tell the server that we want to append some data to the end of a file called `$file`. If this file does not exist then create it.

If for some reason you want to have complete control over the data connection, this includes generating it and calling the `response` method when required, then the user can use these methods to do so.

However calling these methods only affects the use of the methods above that can return a data connection. They have no effect on methods `get`, `put`, `put_unique` and those that do not require data connections.

- `port([$port])`
- `eprt([$port])`

  Send a `PORT` (IPv4) or `EPRT` (IPv6) command to the server. If `$port` is specified then it is sent to the server. If not, then a listen socket is created and the correct information sent to the server.

- `pasv()`
- `epsv()`

  Tell the server to go into passive mode (`pasv` for IPv4, `epsv` for IPv6). Returns the text that represents the port on which the server is listening, this text is in a suitable form to send to another ftp server using the `port` or `eprt` method.

The following methods can be used to transfer files between two remote servers, providing that these two servers can connect directly to each other.

- `pasv_xfer($src_file, $dest_server[, $dest_file ])`

  This method will do a file transfer between two remote ftp servers. If `$dest_file` is omitted then the leaf name of `$src_file` will be used.

- `pasv_xfer_unique($src_file, $dest_server[, $dest_file ])`

  Like `pasv_xfer` but the file is stored on the remote server using the STOU command.

- `pasv_wait($non_pasv_server)`

  This method can be used to wait for a transfer to complete between a passive server and a non-passive server. The method should be called on the passive server with the `Net::FTP` object for the non-passive server passed as an argument.

- `abort()`

  Abort the current data transfer.

- `quit()`

  Send the QUIT command to the remote FTP server and close the socket connection.

Methods for the Adventurous

- `quot($cmd[, $args])`

  Send a command, that Net::FTP does not directly support, to the remote server and wait for a response.

  Returns most significant digit of the response code.

  WARNING This call should only be used on commands that do not require data connections. Misuse of this method can hang the connection.

- `can_inet6()`

  Returns whether we can use IPv6.

- `can_ssl()`

  Returns whether we can use SSL.

The dataconn Class

Some of the methods defined in `Net::FTP` return an object which will be derived from the `Net::FTP::dataconn` class. See *Net::FTP::dataconn* for more details.

Unimplemented

The following RFC959 commands have not been implemented:

- `SMNT`

  Mount a different file system structure without changing login or accounting information.

- `HELP`

  Ask the server for "helpful information" (that's what the RFC says) on the commands it accepts.

- `MODE`

  Specifies transfer mode (stream, block or compressed) for file to be transferred.

- `SYST`

  Request remote server system identification.

- `STAT`

  Request remote server status.

- `STRU`

  Specifies file structure for file to be transferred.

- `REIN`

  Reinitialize the connection, flushing all I/O and account information.

EXPORTS

None.

KNOWN BUGS

See https://rt.cpan.org/Dist/Display.html?Status=Active&Queue=libnet.

Reporting Bugs

When reporting bugs/problems please include as much information as possible. It may be difficult for me to reproduce the problem as almost every setup is different.

A small script which yields the problem will probably be of help. It would also be useful if this script was run with the extra options `Debug => 1` passed to the constructor, and the output sent with the bug report. If you cannot include a small script then please include a Debug trace from a run of your program which does yield the problem.

Modules

- `Net::FTP::dataconn` - FTP Client data connection class

Net::FTP::dataconn

FTP Client data connection class

SYNOPSIS

```
# Perform IO operations on an FTP client data connection object:

$num_bytes_read = $obj->read($buffer, $size);
$num_bytes_read = $obj->read($buffer, $size, $timeout);

$num_bytes_written = $obj->write($buffer, $size);
$num_bytes_written = $obj->write($buffer, $size, $timeout);

$num_bytes_read_so_far = $obj->bytes_read();

$obj->abort();

$closed_successfully = $obj->close();
```

DESCRIPTION

Some of the methods defined in `Net::FTP` return an object which will be derived from this class. The dataconn class itself is derived from the `IO::Socket::INET` class, so any normal IO operations can be performed. However the following methods are defined in the dataconn class and IO should be performed using these.

- `read($buffer, $size[, $timeout])`

  Read `$size` bytes of data from the server and place it into `$buffer`, also performing any translation necessary. `$timeout` is optional, if not given, the timeout value from the command connection will be used.

  Returns the number of bytes read before any translation.

- `write($buffer, $size[, $timeout])`

  Write `$size` bytes of data from `$buffer` to the server, also performing any translation necessary. `$timeout` is optional, if not given, the timeout value from the command connection will be used.

  Returns the number of bytes written before any translation.

- `bytes_read()`

  Returns the number of bytes read so far.

- `abort()`

  Abort the current data transfer.

- `close()`

  Close the data connection and get a response from the FTP server. Returns *true* if the connection was closed successfully and the first digit of the response from the server was a '2'.

EXPORTS

None.

KNOWN BUGS

None.

Net::NNTP

NNTP Client class

SYNOPSIS

```
use Net::NNTP;

$nntp = Net::NNTP->new("some.host.name");
$nntp->quit;

# start with SSL, e.g. nntps
$nntp = Net::NNTP->new("some.host.name", SSL => 1);

# start with plain and upgrade to SSL
$nntp = Net::NNTP->new("some.host.name");
$nntp->starttls;
```

DESCRIPTION

`Net::NNTP` is a class implementing a simple NNTP client in Perl as described in RFC977 and RFC4642. With *IO::Socket::SSL* installed it also provides support for implicit and explicit TLS encryption, i.e. NNTPS or NNTP+STARTTLS.

The Net::NNTP class is a subclass of Net::Cmd and (depending on avaibility) of IO::Socket::IP, IO::Socket::INET6 or IO::Socket::INET.

Class Methods

- `new([$host][, %options])`

  This is the constructor for a new Net::NNTP object. `$host` is the name of the remote host to which a NNTP connection is required. If not given then it may be passed as the `Host` option described below. If no host is passed then two environment variables are checked, first `NNTPSERVER` then `NEWSHOST`, then `Net::Config` is checked, and if a host is not found then `news` is used.

  `%options` are passed in a hash like fashion, using key and value pairs. Possible options are:

  Host - NNTP host to connect to. It may be a single scalar, as defined for the `PeerAddr` option in *IO::Socket::INET*, or a reference to an array with hosts to try in turn. The "host" method will return the value which was used to connect to the host.

Port - port to connect to. Default - 119 for plain NNTP and 563 for immediate SSL (nntps).

SSL - If the connection should be done from start with SSL, contrary to later upgrade with `starttls`. You can use SSL arguments as documented in *IO::Socket::SSL*, but it will usually use the right arguments already.

Timeout - Maximum time, in seconds, to wait for a response from the NNTP server, a value of zero will cause all IO operations to block. (default: 120)

Debug - Enable the printing of debugging information to STDERR

Reader - If the remote server is INN then initially the connection will be to innd, by default `Net::NNTP` will issue a `MODE READER` command so that the remote server becomes nnrpd. If the `Reader` option is given with a value of zero, then this command will not be sent and the connection will be left talking to innd.

LocalAddr and **LocalPort** - These parameters are passed directly to IO::Socket to allow binding the socket to a specific local address and port.

Domain - This parameter is passed directly to IO::Socket and makes it possible to enforce IPv4 connections even if *IO::Socket::IP* is used as super class. Alternatively **Family** can be used.

Object Methods

Unless otherwise stated all methods return either a *true* or *false* value, with *true* meaning that the operation was a success. When a method states that it returns a value, failure will be returned as *undef* or an empty list.

`Net::NNTP` inherits from `Net::Cmd` so methods defined in `Net::Cmd` may be used to send commands to the remote NNTP server in addition to the methods documented here.

- `host()`

  Returns the value used by the constructor, and passed to IO::Socket::INET, to connect to the host.

- `starttls()`

  Upgrade existing plain connection to SSL. Any arguments necessary for SSL must be given in `new` already.

- `article([{$msgid|$msgnum}[, $fh]])`

  Retrieve the header, a blank line, then the body (text) of the specified article.

  If `$fh` is specified then it is expected to be a valid filehandle and the result will be printed to it, on success a true value will be returned. If `$fh` is not specified then the return value, on success, will be a reference to an array containing the article requested, each entry in the array will contain one line of the article.

  If no arguments are passed then the current article in the currently selected newsgroup is fetched.

  `$msgnum` is a numeric id of an article in the current newsgroup, and will change the current article pointer. `$msgid` is the message id of an article as shown in that article's header. It is anticipated that the client will obtain the `$msgid` from a list

provided by the newnews command, from references contained within another article, or from the message-id provided in the response to some other commands.

If there is an error then undef will be returned.

- body([{$msgid|$msgnum}[, [$fh]])

  Like article but only fetches the body of the article.

- head([{$msgid|$msgnum}[, [$fh]])

  Like article but only fetches the headers for the article.

- articlefh([{$msgid|$msgnum}])
- bodyfh([{$msgid|$msgnum}])
- headfh([{$msgid|$msgnum}])

  These are similar to article(), body() and head(), but rather than returning the requested data directly, they return a tied filehandle from which to read the article.

- nntpstat([{$msgid|$msgnum}])

  The nntpstat command is similar to the article command except that no text is returned. When selecting by message number within a group, the nntpstat command serves to set the "current article pointer" without sending text.

  Using the nntpstat command to select by message-id is valid but of questionable value, since a selection by message-id does **not** alter the "current article pointer".

  Returns the message-id of the "current article".

- group([$group])

  Set and/or get the current group. If $group is not given then information is returned on the current group.

  In a scalar context it returns the group name.

  In an array context the return value is a list containing, the number of articles in the group, the number of the first article, the number of the last article and the group name.

- help()

  Request help text (a short summary of commands that are understood by this implementation) from the server. Returns the text or undef upon failure.

- ihave($msgid[, $message])

  The ihave command informs the server that the client has an article whose id is $msgid. If the server desires a copy of that article and $message has been given then it will be sent.

  Returns *true* if the server desires the article and $message was successfully sent, if specified.

  If $message is not specified then the message must be sent using the datasend and dataend methods from *Net::Cmd*

`$message` can be either an array of lines or a reference to an array and must be encoded by the caller to octets of whatever encoding is required, e.g. by using the Encode module's `encode()` function.

- `last()`

  Set the "current article pointer" to the previous article in the current newsgroup.

  Returns the message-id of the article.

- `date()`

  Returns the date on the remote server. This date will be in a UNIX time format (seconds since 1970)

- `postok()`

  `postok` will return *true* if the servers initial response indicated that it will allow posting.

- `authinfo($user, $pass)`

  Authenticates to the server (using the original AUTHINFO USER / AUTHINFO PASS form, defined in RFC2980) using the supplied username and password. Please note that the password is sent in clear text to the server. This command should not be used with valuable passwords unless the connection to the server is somehow protected.

- `authinfo_simple($user, $pass)`

  Authenticates to the server (using the proposed NNTP V2 AUTHINFO SIMPLE form, defined and deprecated in RFC2980) using the supplied username and password. As with "authinfo" the password is sent in clear text.

- `list()`

  Obtain information about all the active newsgroups. The results is a reference to a hash where the key is a group name and each value is a reference to an array. The elements in this array are:- the last article number in the group, the first article number in the group and any information flags about the group.

- `newgroups($since[, $distributions])`

  `$since` is a time value and `$distributions` is either a distribution pattern or a reference to a list of distribution patterns. The result is the same as `list`, but the groups return will be limited to those created after `$since` and, if specified, in one of the distribution areas in `$distributions`.

- `newnews($since[, $groups[, $distributions]])`

  `$since` is a time value. `$groups` is either a group pattern or a reference to a list of group patterns. `$distributions` is either a distribution pattern or a reference to a list of distribution patterns.

  Returns a reference to a list which contains the message-ids of all news posted after `$since`, that are in a groups which matched `$groups` and a distribution which matches `$distributions`.

- `next()`

  Set the "current article pointer" to the next article in the current newsgroup.

Returns the message-id of the article.

- `post([$message])`

  Post a new article to the news server. If `$message` is specified and posting is allowed then the message will be sent.

  If `$message` is not specified then the message must be sent using the `datasend` and `dataend` methods from *Net::Cmd*

  `$message` can be either an array of lines or a reference to an array and must be encoded by the caller to octets of whatever encoding is required, e.g. by using the Encode module's `encode()` function.

  The message, either sent via `datasend` or as the `$message` parameter, must be in the format as described by RFC822 and must contain From:, Newsgroups: and Subject: headers.

- `postfh()`

  Post a new article to the news server using a tied filehandle. If posting is allowed, this method will return a tied filehandle that you can print() the contents of the article to be posted. You must explicitly close() the filehandle when you are finished posting the article, and the return value from the close() call will indicate whether the message was successfully posted.

- `slave()`

  Tell the remote server that I am not a user client, but probably another news server.

- `quit()`

  Quit the remote server and close the socket connection.

- `can_inet6()`

  Returns whether we can use IPv6.

- `can_ssl()`

  Returns whether we can use SSL.

Extension Methods

These methods use commands that are not part of the RFC977 documentation. Some servers may not support all of them.

- `newsgroups([$pattern])`

  Returns a reference to a hash where the keys are all the group names which match `$pattern`, or all of the groups if no pattern is specified, and each value contains the description text for the group.

- `distributions()`

  Returns a reference to a hash where the keys are all the possible distribution names and the values are the distribution descriptions.

- `distribution_patterns()`

  Returns a reference to an array where each element, itself an array reference, consists of the three fields of a line of the distrib.pats list maintained by some NNTP

servers, namely: a weight, a wildmat and a value which the client may use to construct a Distribution header.

- `subscriptions()`

  Returns a reference to a list which contains a list of groups which are recommended for a new user to subscribe to.

- `overview_fmt()`

  Returns a reference to an array which contain the names of the fields returned by `xover`.

- `active_times()`

  Returns a reference to a hash where the keys are the group names and each value is a reference to an array containing the time the groups was created and an identifier, possibly an Email address, of the creator.

- `active([$pattern])`

  Similar to `list` but only active groups that match the pattern are returned. `$pattern` can be a group pattern.

- `xgtitle($pattern)`

  Returns a reference to a hash where the keys are all the group names which match `$pattern` and each value is the description text for the group.

- `xhdr($header, $message_spec)`

  Obtain the header field `$header` for all the messages specified.

  The return value will be a reference to a hash where the keys are the message numbers and each value contains the text of the requested header for that message.

- `xover($message_spec)`

  The return value will be a reference to a hash where the keys are the message numbers and each value contains a reference to an array which contains the overview fields for that message.

  The names of the fields can be obtained by calling `overview_fmt`.

- `xpath($message_id)`

  Returns the path name to the file on the server which contains the specified message.

- `xpat($header, $pattern, $message_spec)`

  The result is the same as `xhdr` except the is will be restricted to headers where the text of the header matches `$pattern`

- `xrover($message_spec)`

  The XROVER command returns reference information for the article(s) specified.

  Returns a reference to a HASH where the keys are the message numbers and the values are the References: lines from the articles

- `listgroup([$group])`

Returns a reference to a list of all the active messages in `$group`, or the current group if `$group` is not specified.

- `reader()`

  Tell the server that you are a reader and not another server.

  This is required by some servers. For example if you are connecting to an INN server and you have transfer permission your connection will be connected to the transfer daemon, not the NNTP daemon. Issuing this command will cause the transfer daemon to hand over control to the NNTP daemon.

  Some servers do not understand this command, but issuing it and ignoring the response is harmless.

Unsupported

The following NNTP command are unsupported by the package, and there are no plans to do so.

```
AUTHINFO GENERIC
XTHREAD
XSEARCH
XINDEX
```

Definitions

- $message_spec

  `$message_spec` is either a single message-id, a single message number, or a reference to a list of two message numbers.

  If `$message_spec` is a reference to a list of two message numbers and the second number in a range is less than or equal to the first then the range represents all messages in the group after the first message number.

  NOTE For compatibility reasons only with earlier versions of Net::NNTP a message spec can be passed as a list of two numbers, this is deprecated and a reference to the list should now be passed

- $pattern

  The `NNTP` protocol uses the `WILDMAT` format for patterns. The WILDMAT format was first developed by Rich Salz based on the format used in the UNIX "find" command to articulate file names. It was developed to provide a uniform mechanism for matching patterns in the same manner that the UNIX shell matches filenames.

  Patterns are implicitly anchored at the beginning and end of each string when testing for a match.

  There are five pattern matching operations other than a strict one-to-one match between the pattern and the source to be checked for a match.

  The first is an asterisk * to match any sequence of zero or more characters.

  The second is a question mark ? to match any single character. The third specifies a specific set of characters.

The set is specified as a list of characters, or as a range of characters where the beginning and end of the range are separated by a minus (or dash) character, or as any combination of lists and ranges. The dash can also be included in the set as a character it if is the beginning or end of the set. This set is enclosed in square brackets. The close square bracket] may be used in a set if it is the first character in the set.

The fourth operation is the same as the logical not of the third operation and is specified the same way as the third with the addition of a caret character ^ at the beginning of the test string just inside the open square bracket.

The final operation uses the backslash character to invalidate the special meaning of an open square bracket [, the asterisk, backslash or the question mark. Two backslashes in sequence will result in the evaluation of the backslash as a character with no special meaning.

- Examples
- `[^]-]`

  matches any single character other than a close square bracket or a minus sign/dash.
- `*bdc`

  matches any string that ends with the string “bdc” including the string “bdc” (without quotes).
- `[0-9a-zA-Z]`

  matches any single printable alphanumeric ASCII character.
- `a??d`

  matches any four character string which begins with a and ends with d.

Net::Netrc

OO interface to users netrc file

SYNOPSIS

```
use Net::Netrc;

$mach = Net::Netrc->lookup('some.machine');
$login = $mach->login;
($login, $password, $account) = $mach->lpa;
```

DESCRIPTION

`Net::Netrc` is a class implementing a simple interface to the .netrc file used as by the ftp program.

`Net::Netrc` also implements security checks just like the ftp program, these checks are, first that the .netrc file must be owned by the user and second the ownership permissions should be such that only the owner has read and write access. If these conditions are not met then a warning is output and the .netrc file is not read.

The `.netrc` File

The .netrc file contains login and initialization information used by the auto-login process. It resides in the user's home directory. The following tokens are recognized; they may be separated by spaces, tabs, or new-lines:

- machine name

  Identify a remote machine name. The auto-login process searches the .netrc file for a machine token that matches the remote machine specified. Once a match is made, the subsequent .netrc tokens are processed, stopping when the end of file is reached or an- other machine or a default token is encountered.

- default

  This is the same as machine name except that default matches any name. There can be only one default token, and it must be after all machine tokens. This is normally used as:

  ```
  default login anonymous password user@site
  ```

  thereby giving the user automatic anonymous login to machines not specified in .netrc.

- login name

  Identify a user on the remote machine. If this token is present, the auto-login process will initiate a login using the specified name.

- password string

  Supply a password. If this token is present, the auto-login process will supply the specified string if the remote server requires a password as part of the login process.

- account string

  Supply an additional account password. If this token is present, the auto-login process will supply the specified string if the remote server requires an additional account password.

- macdef name

  Define a macro. `Net::Netrc` only parses this field to be compatible with *ftp*.

Class Methods

The constructor for a `Net::Netrc` object is not called new as it does not really create a new object. But instead is called `lookup` as this is essentially what it does.

- `lookup($machine[, $login])`

  Lookup and return a reference to the entry for `$machine`. If `$login` is given then the entry returned will have the given login. If `$login` is not given then the first entry in the .netrc file for `$machine` will be returned.

  If a matching entry cannot be found, and a default entry exists, then a reference to the default entry is returned.

If there is no matching entry found and there is no default defined, or no .netrc file is found, then `undef` is returned.

Object Methods

- `login()`

  Return the login id for the netrc entry

- `password()`

  Return the password for the netrc entry

- `account()`

  Return the account information for the netrc entry

- `lpa()`

  Return a list of login, password and account information for the netrc entry

EXPORTS

None.

Net::POP3

Post Office Protocol 3 Client class (RFC1939)

SYNOPSIS

```
use Net::POP3;

# Constructors
$pop = Net::POP3->new('pop3host');
$pop = Net::POP3->new('pop3host', Timeout => 60);
$pop = Net::POP3->new('pop3host', SSL => 1, Timeout => 60);

if ($pop->login($username, $password) > 0) {
  my $msgnums = $pop->list; # hashref of msgnum => size
  foreach my $msgnum (keys %$msgnums) {
    my $msg = $pop->get($msgnum);
    print @$msg;
    $pop->delete($msgnum);
  }
}

$pop->quit;
```

DESCRIPTION

This module implements a client interface to the POP3 protocol, enabling a perl5 application to talk to POP3 servers. This documentation assumes that you are familiar with the POP3 protocol described in RFC1939. With *IO::Socket::SSL* installed it also provides support for implicit and explicit TLS encryption, i.e. POP3S or POP3+STARTTLS.

A new Net::POP3 object must be created with the *new* method. Once this has been done, all POP3 commands are accessed via method calls on the object.

The Net::POP3 class is a subclass of Net::Cmd and (depending on avaibility) of IO::Socket::IP, IO::Socket::INET6 or IO::Socket::INET.

Class Methods

- `new([$host][, %options])`

  This is the constructor for a new Net::POP3 object. `$host` is the name of the remote host to which an POP3 connection is required.

  `$host` is optional. If `$host` is not given then it may instead be passed as the `Host` option described below. If neither is given then the `POP3_Hosts` specified in `Net::Config` will be used.

  `%options` are passed in a hash like fashion, using key and value pairs. Possible options are:

  Host - POP3 host to connect to. It may be a single scalar, as defined for the `PeerAddr` option in *IO::Socket::INET*, or a reference to an array with hosts to try in turn. The "host" method will return the value which was used to connect to the host.

  Port - port to connect to. Default - 110 for plain POP3 and 995 for POP3s (direct SSL).

  SSL - If the connection should be done from start with SSL, contrary to later upgrade with `starttls`. You can use SSL arguments as documented in *IO::Socket::SSL*, but it will usually use the right arguments already.

  LocalAddr and **LocalPort** - These parameters are passed directly to IO::Socket to allow binding the socket to a specific local address and port. For compatibility with older versions **ResvPort** can be used instead of **LocalPort**.

  Domain - This parameter is passed directly to IO::Socket and makes it possible to enforce IPv4 connections even if *IO::Socket::IP* is used as super class. Alternatively **Family** can be used.

  Timeout - Maximum time, in seconds, to wait for a response from the POP3 server (default: 120)

  Debug - Enable debugging information

Object Methods

Unless otherwise stated all methods return either a *true* or *false* value, with *true* meaning that the operation was a success. When a method states that it returns a value, failure will be returned as *undef* or an empty list.

`Net::POP3` inherits from `Net::Cmd` so methods defined in `Net::Cmd` may be used to send commands to the remote POP3 server in addition to the methods documented here.

- `host()`

  Returns the value used by the constructor, and passed to IO::Socket::INET, to connect to the host.

- `auth($username, $password)`

  Attempt SASL authentication.

- `user($user)`

  Send the USER command.

- `pass($pass)`

  Send the PASS command. Returns the number of messages in the mailbox.

- `login([$user[, $pass]])`

  Send both the USER and PASS commands. If `$pass` is not given the `Net::POP3` uses `Net::Netrc` to lookup the password using the host and username. If the username is not specified then the current user name will be used.

  Returns the number of messages in the mailbox. However if there are no messages on the server the string `"0E0"` will be returned. This is will give a true value in a boolean context, but zero in a numeric context.

  If there was an error authenticating the user then *undef* will be returned.

- `starttls(%sslargs)`

  Upgrade existing plain connection to SSL. You can use SSL arguments as documented in *IO::Socket::SSL*, but it will usually use the right arguments already.

- `apop([$user[, $pass]])`

  Authenticate with the server identifying as `$user` with password `$pass`. Similar to "login", but the password is not sent in clear text.

  To use this method you must have the Digest::MD5 or the MD5 module installed, otherwise this method will return *undef*.

- `banner()`

  Return the sever's connection banner

- `capa()`

  Return a reference to a hash of the capabilities of the server. APOP is added as a pseudo capability. Note that I've been unable to find a list of the standard capability values, and some appear to be multi-word and some are not. We make an attempt at intelligently parsing them, but it may not be correct.

- `capabilities()`

  Just like capa, but only uses a cache from the last time we asked the server, so as to avoid asking more than once.

- `top($msgnum[, $numlines])`

  Get the header and the first `$numlines` of the body for the message `$msgnum`. Returns a reference to an array which contains the lines of text read from the server.

- `list([$msgnum])`

  If called with an argument the `list` returns the size of the message in octets.

  If called without arguments a reference to a hash is returned. The keys will be the `$msgnum`'s of all undeleted messages and the values will be their size in octets.

- `get($msgnum[, $fh])`

  Get the message `$msgnum` from the remote mailbox. If `$fh` is not given then get returns a reference to an array which contains the lines of text read from the server. If `$fh` is given then the lines returned from the server are printed to the filehandle `$fh`.

- `getfh($msgnum)`

  As per get(), but returns a tied filehandle. Reading from this filehandle returns the requested message. The filehandle will return EOF at the end of the message and should not be reused.

- `last()`

  Returns the highest `$msgnum` of all the messages accessed.

- `popstat()`

  Returns a list of two elements. These are the number of undeleted elements and the size of the mbox in octets.

- `ping($user)`

  Returns a list of two elements. These are the number of new messages and the total number of messages for `$user`.

- `uidl([$msgnum])`

  Returns a unique identifier for `$msgnum` if given. If `$msgnum` is not given `uidl` returns a reference to a hash where the keys are the message numbers and the values are the unique identifiers.

- `delete($msgnum)`

  Mark message `$msgnum` to be deleted from the remote mailbox. All messages that are marked to be deleted will be removed from the remote mailbox when the server connection closed.

- `reset()`

  Reset the status of the remote POP3 server. This includes resetting the status of all messages to not be deleted.

- `quit()`

  Quit and close the connection to the remote POP3 server. Any messages marked as deleted will be deleted from the remote mailbox.

- `can_inet6()`

  Returns whether we can use IPv6.

- `can_ssl()`

  Returns whether we can use SSL.

Notes

If a `Net::POP3` object goes out of scope before `quit` method is called then the `reset` method will called before the connection is closed. This means that any messages marked to be deleted will not be.

EXPORTS

None.

Net::Ping

check a remote host for reachability

SYNOPSIS

```
use Net::Ping;

my $p = Net::Ping->new();
print "$host is alive.\n" if $p->ping($host);
$p->close();

my $p = Net::Ping->new("icmp");
$p->bind($my_addr); # Specify source interface of pings
foreach my $host (@host_array)
{
    print "$host is ";
    print "NOT " unless $p->ping($host, 2);
    print "reachable.\n";
    sleep(1);
}
$p->close();

my $p = Net::Ping->new("icmpv6");
my $ip = "[fd00:dead:beef::4e]";
print "$ip is alive.\n" if $p->ping($ip);

my $p = Net::Ping->new("tcp", 2);
# Try connecting to the www port instead of the echo port
$p->port_number(scalar(getservbyname("http", "tcp")));
while ($stop_time > time())
{
    print "$host not reachable ", scalar(localtime()), "\n"
        unless $p->ping($host);
    sleep(300);
}
undef($p);

# Like tcp protocol, but with many hosts
my $p = Net::Ping->new("syn");
$p->port_number(getservbyname("http", "tcp"));
foreach my $host (@host_array) {
  $p->ping($host);
}
while (my ($host, $rtt, $ip) = $p->ack) {
  print "HOST: $host [$ip] ACKed in $rtt seconds.\n";
}

# High precision syntax (requires Time::HiRes)
my $p = Net::Ping->new();
$p->hires();
my ($ret, $duration, $ip) = $p->ping($host, 5.5);
printf("$host [ip: $ip] is alive (packet return time: %.2f ms)\n",
        1000 * $duration)
```

(continues on next page)

(continued from previous page)

```
  if $ret;
$p->close();

# For backward compatibility
print "$host is alive.\n" if pingecho($host);
```

DESCRIPTION

This module contains methods to test the reachability of remote hosts on a network. A ping object is first created with optional parameters, a variable number of hosts may be pinged multiple times and then the connection is closed.

You may choose one of six different protocols to use for the ping. The "tcp" protocol is the default. Note that a live remote host may still fail to be pingable by one or more of these protocols. For example, www.microsoft.com is generally alive but not "icmp" pingable.

With the "tcp" protocol the ping() method attempts to establish a connection to the remote host's echo port. If the connection is successfully established, the remote host is considered reachable. No data is actually echoed. This protocol does not require any special privileges but has higher overhead than the "udp" and "icmp" protocols.

Specifying the "udp" protocol causes the ping() method to send a udp packet to the remote host's echo port. If the echoed packet is received from the remote host and the received packet contains the same data as the packet that was sent, the remote host is considered reachable. This protocol does not require any special privileges. It should be borne in mind that, for a udp ping, a host will be reported as unreachable if it is not running the appropriate echo service. For Unix-like systems see inetd(8) for more information.

If the "icmp" protocol is specified, the ping() method sends an icmp echo message to the remote host, which is what the UNIX ping program does. If the echoed message is received from the remote host and the echoed information is correct, the remote host is considered reachable. Specifying the "icmp" protocol requires that the program be run as root or that the program be setuid to root.

If the "external" protocol is specified, the ping() method attempts to use the `Net::Ping::External` module to ping the remote host. `Net::Ping::External` interfaces with your system's default `ping` utility to perform the ping, and generally produces relatively accurate results. If `Net::Ping::External` if not installed on your system, specifying the "external" protocol will result in an error.

If the "syn" protocol is specified, the "ping" method will only send a TCP SYN packet to the remote host then immediately return. If the syn packet was sent successfully, it will return a true value, otherwise it will return false. NOTE: Unlike the other protocols, the return value does NOT determine if the remote host is alive or not since the full TCP three-way handshake may not have completed yet. The remote host is only considered reachable if it receives a TCP ACK within the timeout specified. To begin waiting for the ACK packets, use the "ack" method as explained below. Use the "syn" protocol instead the "tcp" protocol to determine reachability of multiple destinations simultaneously by sending parallel TCP SYN packets. It will not block while testing each remote host. This protocol does not require any special privileges.

Functions

- Net::Ping->new([proto, timeout, bytes, device, tos, ttl, family, host, port, bind, gateway, retrans, pingstring, source_verify econnrefused dontfrag IPV6_USE_MIN_MTU IPV6_RECVPATHMTU])

  Create a new ping object. All of the parameters are optional and can be passed as hash ref. All options besides the first 7 must be passed as hash ref.

  `proto` specifies the protocol to use when doing a ping. The current choices are "tcp", "udp", "icmp", "icmpv6", "stream", "syn", or "external". The default is "tcp".

  If a `timeout` in seconds is provided, it is used when a timeout is not given to the ping() method (below). The timeout must be greater than 0 and the default, if not specified, is 5 seconds.

  If the number of data bytes (`bytes`) is given, that many data bytes are included in the ping packet sent to the remote host. The number of data bytes is ignored if the protocol is "tcp". The minimum (and default) number of data bytes is 1 if the protocol is "udp" and 0 otherwise. The maximum number of data bytes that can be specified is 65535, but staying below the MTU (1472 bytes for ICMP) is recommended. Many small devices cannot deal with fragmented ICMP packets.

  If `device` is given, this device is used to bind the source endpoint before sending the ping packet. I believe this only works with superuser privileges and with udp and icmp protocols at this time.

  If <tos> is given, this ToS is configured into the socket.

  For icmp, `ttl` can be specified to set the TTL of the outgoing packet.

  Valid `family` values for IPv4:

```
4, v4, ip4, ipv4, AF_INET (constant)
```

  Valid `family` values for IPv6:

```
6, v6, ip6, ipv6, AF_INET6 (constant)
```

  The `host` argument implicitly specifies the family if the family argument is not given.

  The `port` argument is only valid for a udp, tcp or stream ping, and will not do what you think it does. ping returns true when we get a "Connection refused"! The default is the echo port.

  The `bind` argument specifies the local_addr to bind to. By specifying a bind argument you don't need the bind method.

  The `gateway` argument is only valid for IPv6, and requires a IPv6 address.

  The `retrans` argument the exponential backoff rate, default 1.2. It matches the $def_factor global.

  The `dontfrag` argument sets the IP_DONTFRAG bit, but note that IP_DONTFRAG is not yet defined by Socket, and not available on many systems. Then it is ignored. On linux it also sets IP_MTU_DISCOVER to IP_PMTUDISC_DO but need we don't chunk oversized packets. You need to set $data_size manually.

- $p->ping($host [, $timeout [, $family]]);

  Ping the remote host and wait for a response. $host can be either the hostname or the IP number of the remote host. The optional timeout must be greater than 0 seconds and defaults to whatever was specified when the ping object was created. Returns a success flag. If the hostname cannot be found or there is a problem with the IP number, the success flag returned will be undef. Otherwise, the success flag will be 1 if the host is reachable and 0 if it is not. For most practical purposes, undef and 0 and can be treated as the same case. In array context, the elapsed time as well as the string form of the ip the host resolved to are also returned. The elapsed time value will be a float, as returned by the Time::HiRes::time() function, if hires() has been previously called, otherwise it is returned as an integer.

- $p->source_verify({ 0 | 1 });

  Allows source endpoint verification to be enabled or disabled. This is useful for those remote destinations with multiples interfaces where the response may not originate from the same endpoint that the original destination endpoint was sent to. This only affects udp and icmp protocol pings.

  This is enabled by default.

- $p->service_check({ 0 | 1 });

  Set whether or not the connect behavior should enforce remote service availability as well as reachability. Normally, if the remote server reported ECONNREFUSED, it must have been reachable because of the status packet that it reported. With this option enabled, the full three-way tcp handshake must have been established successfully before it will claim it is reachable. NOTE: It still does nothing more than connect and disconnect. It does not speak any protocol (i.e., HTTP or FTP) to ensure the remote server is sane in any way. The remote server CPU could be grinding to a halt and unresponsive to any clients connecting, but if the kernel throws the ACK packet, it is considered alive anyway. To really determine if the server is responding well would be application specific and is beyond the scope of Net::Ping. For udp protocol, enabling this option demands that the remote server replies with the same udp data that it was sent as defined by the udp echo service.

  This affects the “udp”, “tcp”, and “syn” protocols.

  This is disabled by default.

- $p->tcp_service_check({ 0 | 1 });

  Deprecated method, but does the same as service_check() method.

- $p->hires({ 0 | 1 });

  With 1 causes this module to use Time::HiRes module, allowing milliseconds to be returned by subsequent calls to ping().

- $p->time

  The current time, hires or not.

- $p->socket_blocking_mode($fh, $mode);

  Sets or clears the O_NONBLOCK flag on a file handle.

- $p->IPV6_USE_MIN_MTU

With argument sets the option. Without returns the option value.

- $p->IPV6_RECVPATHMTU

  Notify an according IPv6 MTU.

  With argument sets the option. Without returns the option value.

- $p->IPV6_HOPLIMIT

  With argument sets the option. Without returns the option value.

- $p->IPV6_REACHCONF *NYI*

  Sets ipv6 reachability IPV6_REACHCONF was removed in RFC3542. ping6 -R supports it. IPV6_REACHCONF requires root/admin permissions.

  With argument sets the option. Without returns the option value.

  Not yet implemented.

- $p->bind($local_addr);

  Sets the source address from which pings will be sent. This must be the address of one of the interfaces on the local host. $local_addr may be specified as a hostname or as a text IP address such as "192.168.1.1".

  If the protocol is set to "tcp", this method may be called any number of times, and each call to the ping() method (below) will use the most recent $local_addr. If the protocol is "icmp" or "udp", then bind() must be called at most once per object, and (if it is called at all) must be called before the first call to ping() for that object.

  The bind() call can be omitted when specifying the `bind` option to new().

- $p->message_type([$ping_type]);

  When you are using the "icmp" protocol, this call permit to change the message type to 'echo' or 'timestamp' (only for IPv4, see RFC 792).

  Without argument, it returns the currently used icmp protocol message type. By default, it returns 'echo'.

- $p->open($host);

  When you are using the "stream" protocol, this call pre-opens the tcp socket. It's only necessary to do this if you want to provide a different timeout when creating the connection, or remove the overhead of establishing the connection from the first ping. If you don't call `open()`, the connection is automatically opened the first time `ping()` is called. This call simply does nothing if you are using any protocol other than stream.

  The $host argument can be omitted when specifying the `host` option to new().

- $p->ack([$host]);

  When using the "syn" protocol, use this method to determine the reachability of the remote host. This method is meant to be called up to as many times as ping() was called. Each call returns the host (as passed to ping()) that came back with the TCP ACK. The order in which the hosts are returned may not necessarily be the same order in which they were SYN queued using the ping() method. If the timeout is reached before the TCP ACK is received, or if the remote host is not listening on the port attempted, then the TCP connection will not be established and ack() will

return undef. In list context, the host, the ack time, the dotted ip string, and the port number will be returned instead of just the host. If the optional `$host` argument is specified, the return value will be pertaining to that host only. This call simply does nothing if you are using any protocol other than "syn".

When "new" had a host option, this host will be used. Without `$host` argument, all hosts are scanned.

- $p->nack($failed_ack_host);

  The reason that `host $failed_ack_host` did not receive a valid ACK. Useful to find out why when `ack($fail_ack_host)` returns a false value.

- $p->ack_unfork($host)

  The variant called by "ack" with the "syn" protocol and `$syn_forking` enabled.

- $p->ping_icmp([$host, $timeout, $family])

  The "ping" method used with the icmp protocol. Under Linux under a non-root account this uses now SOCK_DGRAM.

- $p->ping_icmpv6([$host, $timeout, $family])

  The "ping" method used with the icmpv6 protocol. Under Linux under a non-root account this uses now SOCK_DGRAM.

- $p->ping_stream([$host, $timeout, $family])

  The "ping" method used with the stream protocol.

  Perform a stream ping. If the tcp connection isn't already open, it opens it. It then sends some data and waits for a reply. It leaves the stream open on exit.

- $p->ping_syn([$host, $ip, $start_time, $stop_time])

  The "ping" method used with the syn protocol. Sends a TCP SYN packet to host specified.

- $p->ping_syn_fork([$host, $timeout, $family])

  The "ping" method used with the forking syn protocol.

- $p->ping_tcp([$host, $timeout, $family])

  The "ping" method used with the tcp protocol.

- $p->ping_udp([$host, $timeout, $family])

  The "ping" method used with the udp protocol.

  Perform a udp echo ping. Construct a message of at least the one-byte sequence number and any additional data bytes. Send the message out and wait for a message to come back. If we get a message, make sure all of its parts match. If they do, we are done. Otherwise go back and wait for the message until we run out of time. Return the result of our efforts.

- $p->ping_external([$host, $timeout, $family])

  The "ping" method used with the external protocol. Uses Net::Ping::External to do an external ping.

- $p->tcp_connect([$ip, $timeout])

  Initiates a TCP connection, for a tcp ping.

- $p->tcp_echo([$ip, $timeout, $pingstring])

  Performs a TCP echo. It writes the given string to the socket and then reads it back. It returns 1 on success, 0 on failure.

- $p->close();

  Close the network connection for this ping object. The network connection is also closed by "undef $p". The network connection is automatically closed if the ping object goes out of scope (e.g. $p is local to a subroutine and you leave the subroutine).

- $p->port_number([$port_number])

  When called with a port number, the port number used to ping is set to `$port_number` rather than using the echo port. It also has the effect of calling `$p->service_check(1)` causing a ping to return a successful response only if that specific port is accessible. This function returns the value of the port that "ping" will connect to.

- $p->mselect

  A `select()` wrapper that compensates for platform peculiarities.

- $p->ntop

  Platform abstraction over `inet_ntop()`

- $p->checksum($msg)

  Do a checksum on the message. Basically sum all of the short words and fold the high order bits into the low order bits.

- $p->icmp_result

  Returns a list of addr, type, subcode.

- pingecho($host [, $timeout]);

  To provide backward compatibility with the previous version of *Net::Ping*, a `pingecho()` subroutine is available with the same functionality as before. `pingecho()` uses the tcp protocol. The return values and parameters are the same as described for the "ping" method. This subroutine is obsolete and may be removed in a future version of *Net::Ping*.

- wakeonlan($mac, [$host, [$port]])

  Emit the popular wake-on-lan magic udp packet to wake up a local device. See also Net::Wake, but this has the mac address as 1st arg. `$host` should be the local gateway. Without it will broadcast.

  Default host: '255.255.255.255' Default port: 9

```
perl -MNet::Ping=wakeonlan -e'wakeonlan "e0:69:95:35:68:d2"'
```

NOTES

There will be less network overhead (and some efficiency in your program) if you specify either the udp or the icmp protocol. The tcp protocol will generate 2.5 times or more traffic for each ping than either udp or icmp. If many hosts are pinged frequently, you may wish to implement a small wait (e.g. 25ms or more) between each ping to avoid flooding your network with packets.

The icmp and icmpv6 protocols requires that the program be run as root or that it be setuid to root. The other protocols do not require special privileges, but not all network devices implement tcp or udp echo.

Local hosts should normally respond to pings within milliseconds. However, on a very congested network it may take up to 3 seconds or longer to receive an echo packet from the remote host. If the timeout is set too low under these conditions, it will appear that the remote host is not reachable (which is almost the truth).

Reachability doesn't necessarily mean that the remote host is actually functioning beyond its ability to echo packets. tcp is slightly better at indicating the health of a system than icmp because it uses more of the networking stack to respond.

Because of a lack of anything better, this module uses its own routines to pack and unpack ICMP packets. It would be better for a separate module to be written which understands all of the different kinds of ICMP packets.

INSTALL

The latest source tree is available via git:

```
git clone https://github.com/rurban/Net-Ping.git
cd Net-Ping
```

The tarball can be created as follows:

```
perl Makefile.PL ; make ; make dist
```

The latest Net::Ping releases are included in cperl and perl5.

Net::SMTP

Simple Mail Transfer Protocol Client

SYNOPSIS

```
use Net::SMTP;

# Constructors
$smtp = Net::SMTP->new('mailhost');
$smtp = Net::SMTP->new('mailhost', Timeout => 60);
```

DESCRIPTION

This module implements a client interface to the SMTP and ESMTP protocol, enabling a perl5 application to talk to SMTP servers. This documentation assumes that you are familiar with the concepts of the SMTP protocol described in RFC2821. With *IO::Socket::SSL* installed it also provides support for implicit and explicit TLS encryption, i.e. SMTPS or SMTP+STARTTLS.

The Net::SMTP class is a subclass of Net::Cmd and (depending on avaibility) of IO::Socket::IP, IO::Socket::INET6 or IO::Socket::INET.

Class Methods

- `new([$host][, %options])`

  This is the constructor for a new Net::SMTP object. `$host` is the name of the remote host to which an SMTP connection is required.

  On failure `undef` will be returned and `$@` will contain the reason for the failure.

  `$host` is optional. If `$host` is not given then it may instead be passed as the `Host` option described below. If neither is given then the `SMTP_Hosts` specified in `Net::Config` will be used.

  `%options` are passed in a hash like fashion, using key and value pairs. Possible options are:

  Hello - SMTP requires that you identify yourself. This option specifies a string to pass as your mail domain. If not given localhost.localdomain will be used.

  SendHello - If false then the EHLO (or HELO) command that is normally sent when constructing the object will not be sent. In that case the command will have to be sent manually by calling `hello()` instead.

  Host - SMTP host to connect to. It may be a single scalar (hostname[:port]), as defined for the `PeerAddr` option in *IO::Socket::INET*, or a reference to an array with hosts to try in turn. The "host" method will return the value which was used to connect to the host. Format - `PeerHost` from *IO::Socket::INET* new method.

  Port - port to connect to. Default - 25 for plain SMTP and 465 for immediate SSL.

  SSL - If the connection should be done from start with SSL, contrary to later upgrade with `starttls`. You can use SSL arguments as documented in *IO::Socket::SSL*, but it will usually use the right arguments already.

  LocalAddr and **LocalPort** - These parameters are passed directly to IO::Socket to allow binding the socket to a specific local address and port.

  Domain - This parameter is passed directly to IO::Socket and makes it possible to enforce IPv4 connections even if *IO::Socket::IP* is used as super class. Alternatively **Family** can be used.

  Timeout - Maximum time, in seconds, to wait for a response from the SMTP server (default: 120)

  ExactAddresses - If true then all `$address` arguments must be as defined by `addr-spec` in RFC2822. If not given, or false, then Net::SMTP will attempt to extract the address from the value passed.

Debug - Enable debugging information

Example:

```
$smtp = Net::SMTP->new('mailhost',
                       Hello => 'my.mail.domain',
                       Timeout => 30,
                       Debug   => 1,
                      );

# the same
$smtp = Net::SMTP->new(
                       Host => 'mailhost',
                       Hello => 'my.mail.domain',
                       Timeout => 30,
                       Debug   => 1,
                      );

# the same with direct SSL
$smtp = Net::SMTP->new('mailhost',
                       Hello => 'my.mail.domain',
                       Timeout => 30,
                       Debug   => 1,
                       SSL     => 1,
                      );

# Connect to the default server from Net::config
$smtp = Net::SMTP->new(
                       Hello => 'my.mail.domain',
                       Timeout => 30,
                      );
```

Object Methods

Unless otherwise stated all methods return either a *true* or *false* value, with *true* meaning that the operation was a success. When a method states that it returns a value, failure will be returned as *undef* or an empty list.

`Net::SMTP` inherits from `Net::Cmd` so methods defined in `Net::Cmd` may be used to send commands to the remote SMTP server in addition to the methods documented here.

- `banner()`

  Returns the banner message which the server replied with when the initial connection was made.

- `domain()`

  Returns the domain that the remote SMTP server identified itself as during connection.

- `hello($domain)`

  Tell the remote server the mail domain which you are in using the EHLO command (or HELO if EHLO fails). Since this method is invoked automatically when

the Net::SMTP object is constructed the user should normally not have to call it manually.

- `host()`

  Returns the value used by the constructor, and passed to IO::Socket::INET, to connect to the host.

- `etrn($domain)`

  Request a queue run for the `$domain` given.

- `starttls(%sslargs)`

  Upgrade existing plain connection to SSL. You can use SSL arguments as documented in *IO::Socket::SSL*, but it will usually use the right arguments already.

- `auth($username, $password)`

- `auth($sasl)`

  Attempt SASL authentication. Requires Authen::SASL module. The first form constructs a new Authen::SASL object using the given username and password; the second form uses the given Authen::SASL object.

- `mail($address[, %options])`

- `send($address)`

- `send_or_mail($address)`

- `send_and_mail($address)`

  Send the appropriate command to the server MAIL, SEND, SOML or SAML. `$address` is the address of the sender. This initiates the sending of a message. The method `recipient` should be called for each address that the message is to be sent to.

  The `mail` method can take some additional ESMTP `%options` which is passed in hash like fashion, using key and value pairs. Possible options are:

```
Size        => <bytes>
Return      => "FULL" | "HDRS"
Bits        => "7" | "8" | "binary"
Transaction => <ADDRESS>
Envelope    => <ENVID>     # xtext-encodes its argument
ENVID       => <ENVID>     # similar to Envelope, but expects␣
↪argument encoded
XVERP       => 1
AUTH        => <submitter> # encoded address according to RFC␣
↪2554
```

  The `Return` and `Envelope` parameters are used for DSN (Delivery Status Notification).

  The submitter address in `AUTH` option is expected to be in a format as required by RFC 2554, in an RFC2821-quoted form and xtext-encoded, or <> .

- `reset()`

Reset the status of the server. This may be called after a message has been initiated, but before any data has been sent, to cancel the sending of the message.

- `recipient($address[, $address[, ...]][, %options])`

  Notify the server that the current message should be sent to all of the addresses given. Each address is sent as a separate command to the server. Should the sending of any address result in a failure then the process is aborted and a *false* value is returned. It is up to the user to call `reset` if they so desire.

  The `recipient` method can also pass additional case-sensitive `%options` as an anonymous hash using key and value pairs. Possible options are:

```
Notify  => ['NEVER'] or ['SUCCESS','FAILURE','DELAY']  (see
↪below)
ORcpt   => <ORCPT>
SkipBad => 1        (to ignore bad addresses)
```

  If `SkipBad` is true the `recipient` will not return an error when a bad address is encountered and it will return an array of addresses that did succeed.

```
$smtp->recipient($recipient1,$recipient2);  # Good
$smtp->recipient($recipient1,$recipient2, { SkipBad => 1 });  #
↪Good
$smtp->recipient($recipient1,$recipient2, { Notify => ['FAILURE
↪','DELAY'], SkipBad => 1 });  # Good
@goodrecips=$smtp->recipient(@recipients, { Notify => ['FAILURE
↪'], SkipBad => 1 });  # Good
$smtp->recipient("$recipient,$recipient2"); # BAD
```

  Notify is used to request Delivery Status Notifications (DSNs), but your SMTP/ESMTP service may not respect this request depending upon its version and your site's SMTP configuration.

  Leaving out the Notify option usually defaults an SMTP service to its default behavior equivalent to ['FAILURE'] notifications only, but again this may be dependent upon your site's SMTP configuration.

  The NEVER keyword must appear by itself if used within the Notify option and "requests that a DSN not be returned to the sender under any conditions."

```
{Notify => ['NEVER']}

$smtp->recipient(@recipients, { Notify => ['NEVER'], SkipBad =>
↪1 });  # Good
```

  You may use any combination of these three values 'SUCCESS','FAILURE','DELAY' in the anonymous array reference as defined by RFC3461 (see https://www.ietf.org/rfc/rfc3461.txt for more information. Note: quotations in this topic from same.).

  A Notify parameter of 'SUCCESS' or 'FAILURE' "requests that a DSN be issued on successful delivery or delivery failure, respectively."

  A Notify parameter of 'DELAY' "indicates the sender's willingness to receive delayed DSNs. Delayed DSNs may be issued if delivery of a message has been delayed for an unusual amount of time (as determined by the Message Transfer Agent

(MTA) at which the message is delayed), but the final delivery status (whether successful or failure) cannot be determined. The absence of the DELAY keyword in a NOTIFY parameter requests that a "delayed" DSN NOT be issued under any conditions."

```
{Notify => ['SUCCESS','FAILURE','DELAY']}

$smtp->recipient(@recipients, { Notify => ['FAILURE','DELAY'],␣
↪SkipBad => 1 });  # Good
```

ORcpt is also part of the SMTP DSN extension according to RFC3461. It is used to pass along the original recipient that the mail was first sent to. The machine that generates a DSN will use this address to inform the sender, because he can't know if recipients get rewritten by mail servers. It is expected to be in a format as required by RFC3461, xtext-encoded.

- `to($address[, $address[, ...]])`
- `cc($address[, $address[, ...]])`
- `bcc($address[, $address[, ...]])`

  Synonyms for `recipient`.

- `data([$data])`

  Initiate the sending of the data from the current message.

  `$data` may be a reference to a list or a list and must be encoded by the caller to octets of whatever encoding is required, e.g. by using the Encode module's `encode()` function.

  If specified the contents of `$data` and a termination string `".\r\n"` is sent to the server. The result will be true if the data was accepted.

  If `$data` is not specified then the result will indicate that the server wishes the data to be sent. The data must then be sent using the `datasend` and `dataend` methods described in *Net::Cmd*.

- `bdat($data)`
- `bdatlast($data)`

  Use the alternate `$data` command "BDAT" of the data chunking service extension defined in RFC1830 for efficiently sending large MIME messages.

- `expand($address)`

  Request the server to expand the given address Returns an array which contains the text read from the server.

- `verify($address)`

  Verify that `$address` is a legitimate mailing address.

  Most sites usually disable this feature in their SMTP service configuration. Use "Debug => 1" option under new() to see if disabled.

- `help([$subject])`

  Request help text from the server. Returns the text or undef upon failure

- `quit()`

  Send the QUIT command to the remote SMTP server and close the socket connection.

- `can_inet6()`

  Returns whether we can use IPv6.

- `can_ssl()`

  Returns whether we can use SSL.

Addresses

Net::SMTP attempts to DWIM with addresses that are passed. For example an application might extract The From: line from an email and pass that to mail(). While this may work, it is not recommended. The application should really use a module like Mail::Address to extract the mail address and pass that.

If `ExactAddresses` is passed to the constructor, then addresses should be a valid rfc2821-quoted address, although Net::SMTP will accept the address surrounded by angle brackets.

```
funny user@domain       WRONG
"funny user"@domain     RIGHT, recommended
<"funny user"@domain>   OK
```

EXAMPLES

This example prints the mail domain name of the SMTP server known as mailhost:

```
#!/usr/local/bin/perl -w

use Net::SMTP;

$smtp = Net::SMTP->new('mailhost');
print $smtp->domain,"\n";
$smtp->quit;
```

This example sends a small message to the postmaster at the SMTP server known as mailhost:

```
#!/usr/local/bin/perl -w

use Net::SMTP;

my $smtp = Net::SMTP->new('mailhost');

$smtp->mail($ENV{USER});
if ($smtp->to('postmaster')) {
 $smtp->data();
 $smtp->datasend("To: postmaster\n");
```

(continues on next page)

(continued from previous page)

```
 $smtp->datasend("\n");
 $smtp->datasend("A simple test message\n");
 $smtp->dataend();
} else {
 print "Error: ", $smtp->message();
}

$smtp->quit;
```

EXPORTS

None.

Net::SSLeay

Net::SSLeay - Perl bindings for OpenSSL's libssl and libcrypto.

TLS connections, certificates, keys, digests and the rest of OpenSSL, one Perl function per C function: `Net::SSLeay::CTX_new` is `SSL_CTX_new`, `Net::SSLeay::X509_get_subject_name` is `X509_get_subject_name`, with the same arguments, return values and constants. Objects are passed around as plain integers (the C pointers) and freed explicitly, as in C. Most programs use it through IO::Socket::SSL or AnyEvent::TLS, which are built on it; use it directly for what they do not expose.

This is Net::SSLeay 1.96: all 709 functions and 769 constants of the CPAN distribution, and its Perl half (`Net/SSLeay.pm`, `Net/SSLeay/Handle.pm`) unchanged. Because each function is its C namesake, OpenSSL's manual pages (`man SSL_CTX_new`) describe what it does; the overview below says where to look.

Requirements

OpenSSL 3.0 or newer, as `libssl.so.3` and `libcrypto.so.3`, loaded when the module is: nothing is linked into pperl. Without them, `use Net::SSLeay` dies naming the package to install. The module is part of the `native-max` build.

Synopsis

A certificate's subject, expiry and fingerprint - no network needed:

```
use Net::SSLeay;

my $bio  = Net::SSLeay::BIO_new_file('cert.pem', 'r') or die "cert.
 ↪pem: $!";
my $x509 = Net::SSLeay::PEM_read_bio_X509($bio);
Net::SSLeay::BIO_free($bio);

print Net::SSLeay::X509_NAME_oneline(Net::SSLeay::X509_get_subject_
 ↪name($x509)), "\n";
print Net::SSLeay::P_ASN1_TIME_get_isotime(Net::SSLeay::X509_get_
 ↪notAfter($x509)), "\n";
print unpack('H*', Net::SSLeay::X509_digest($x509,
    Net::SSLeay::EVP_get_digestbyname('sha256'))), "\n";
Net::SSLeay::X509_free($x509);
```

A TLS client over a socket of your own:

```
use Socket;
use Net::SSLeay qw(die_now die_if_ssl_error);

my ($host, $port) = ('example.com', 443);
Net::SSLeay::initialize();
```

(continues on next page)

(continued from previous page)

```
socket(my $sock, PF_INET, SOCK_STREAM, getprotobyname('tcp')) or die␣
↪"socket: $!";
connect($sock, sockaddr_in($port, inet_aton($host))) or die
↪"connect: $!";

my $ctx = Net::SSLeay::CTX_new() or die_now("CTX_new: $!");
Net::SSLeay::CTX_set_options($ctx, Net::SSLeay::OP_ALL());
my $ssl = Net::SSLeay::new($ctx) or die_now("new: $!");
Net::SSLeay::set_tlsext_host_name($ssl, $host);    # SNI
Net::SSLeay::set_fd($ssl, fileno $sock);
Net::SSLeay::connect($ssl) == 1 or die_if_ssl_error('connect');
print 'cipher: ', Net::SSLeay::get_cipher($ssl), "\n";

Net::SSLeay::write($ssl, "GET / HTTP/1.0\r\nHost: $host\r\n\r\n");
my $reply = '';
while (defined(my $chunk = Net::SSLeay::read($ssl))) {
    last unless length $chunk;
    $reply .= $chunk;
}
Net::SSLeay::free($ssl);
Net::SSLeay::CTX_free($ctx);
```

This client does not verify the server's certificate. To do so, before `connect`:

```
Net::SSLeay::CTX_set_default_verify_paths($ctx);   # the system's␣
↪CAs
Net::SSLeay::set_verify($ssl, Net::SSLeay::VERIFY_PEER(), undef);
Net::SSLeay::X509_VERIFY_PARAM_set1_host(Net::SSLeay::get0_param(
↪$ssl), $host);
```

`connect` then fails for a certificate that does not chain to a trusted CA or does not name `$host`. IO::Socket::SSL does all of this by default.

The functions, by family

The name says which C object a function works on; strip the prefix the C function had (`SSL_`, sometimes `SSL_CTX_` becomes `CTX_`) and look it up in OpenSSL's manual.

- **Contexts** - `CTX_*` (112): `CTX_new`, the protocol versions, ciphers, certificates and keys a context offers, verification, sessions, and every callback (`CTX_set_verify`, `CTX_set_alpn_select_cb`, `CTX_set_tlsext_servername_callback`).
- **Connections** - functions without a prefix: `new`, `set_fd`, `connect`, `accept`, `read`, `write`, `shutdown`, `free`, and the `get_*`/`set_*` accessors of a connection (`get_peer_certificate`, `get_cipher`, `set_tlsext_host_name`).
- **Sessions** - `SESSION_*`, `get_session`, `set_session`.
- **Certificates** - `X509_*` (162): names, extensions, stores and verification, CRLs, requests; `P_X509_*` are Net::SSLeay's own helpers that return Perl lists (`P_X509_get_crl_distribution_points`, `P_X509_get_ext_key_usage`).
- **Keys and digests** - `EVP_*`, `RSA_*`, `EC_*`, `BN_*`; `RAND_*` for random bytes.

- **Files and encodings** - `PEM_*`, `d2i_*`/`i2d_*` (DER), `BIO_*` (memory and file buffers), `ASN1_*` and `P_ASN1_*` (times and integers).
- **Errors** - `ERR_get_error`, `ERR_error_string`, and the module's `die_now`, `die_if_ssl_error` and `print_errs`.
- **The rest** - `OCSP_*`, `OBJ_*`, `OSSL_PROVIDER_*`, `OPENSSL_*` (version and initialisation).

Constants are functions too, named without their C prefix: `Net::SSLeay::VERIFY_PEER()`, `Net::SSLeay::OP_ALL()`, `Net::SSLeay::ERROR_WANT_READ()`.

Written in Perl

`Net/SSLeay.pm` adds whole-request helpers: `get_https`, `post_https`, `sslcat`, `make_headers`, `make_form`, and `Net::SSLeay::Handle`, a tied filehandle over a connection.

```
my ($page, $response, %headers) = Net::SSLeay::get_https('example.
↪com', 443, '/');
```

Differences from upstream

- Which functions exist is decided by the OpenSSL loaded, not by the one the module was compiled against. Upstream compiles a function only for an OpenSSL that has its feature; here a function is defined only when the loaded library has every C function it needs - so `defined &Net::SSLeay::client_hello_get_extension_order` is false under OpenSSL 3.0 and 3.1, as it is for a Net::SSLeay built there (t/81-xs-native/Net-SSLeay/660-xsub-set-follows-openssl.t). On this machine's OpenSSL it is upstream's set of 709 (600-xsub-set.t).
- The functions an OpenSSL can provide only when built with options off by default (MD2, SSLv3 methods) are not provided, whatever is loaded.
- OpenSSL before 3.0 and LibreSSL are not supported; upstream builds against them too.
- `RAND_bytes`, `RAND_priv_bytes` and `RAND_pseudo_bytes` with a negative count return 0 and leave the buffer empty, where perl exits "Out of memory" (670-or-better.t).

Modules

- `Net::SSLeay::Handle` - Perl module that lets SSL (HTTPS) sockets be handled as standard file handles.

Net::SSLeay::Handle

Perl module that lets SSL (HTTPS) sockets be handled as standard file handles.

SYNOPSIS

```
use Net::SSLeay::Handle qw/shutdown/;
my ($host, $port) = ("localhost", 443);

tie(*SSL, "Net::SSLeay::Handle", $host, $port);

print SSL "GET / HTTP/1.0\r\n";
shutdown(\*SSL, 1);
print while (<SSL>);
close SSL;
```

DESCRIPTION

Net::SSLeay::Handle allows you to request and receive HTTPS web pages using "old-fashion" file handles as in:

```
print SSL "GET / HTTP/1.0\r\n";
```

and

```
print while (<SSL>);
```

If you export the shutdown routine, then the only extra code that you need to add to your program is the tie function as in:

```
my $socket;
if ($scheme eq "https") {
    tie(*S2, "Net::SSLeay::Handle", $host, $port);
    $socket = \*S2;
else {
    $socket = Net::SSLeay::Handle->make_socket($host, $port);
}
print $socket $request_headers;
...
```

FUNCTIONS

- shutdown

  ```
  shutdown(\*SOCKET, $mode)
  ```

  Calls to the main shutdown() don't work with tied sockets created with this module. This shutdown should be able to distinquish between tied and untied sockets and do the right thing.

- debug

  ```
  my $debug = Net::SSLeay::Handle->debug()
  Net::SSLeay::Handle->debug(1)
  ```

Get/set debugging mode. Always returns the debug value before the function call. if an additional argument is given the debug option will be set to this value.

- make_socket

```
my $sock = Net::SSLeay::Handle->make_socket($host, $port);
```

Creates a socket that is connected to $post using $port. It uses $Net::SSLeay::proxyhost and proxyport if set and authentificates itself against this proxy depending on $Net::SSLeay::proxyauth. It also turns autoflush on for the created socket.

USING EXISTING SOCKETS

One of the motivations for writing this module was to avoid duplicating socket creation code (which is mostly error handling). The calls to tie() above where it is passed a $host and $port is provided for convenience testing. If you already have a socket connected to the right host and port, S1, then you can do something like:

```
my $socket \*S1;
if ($scheme eq "https") {
    tie(*S2, "Net::SSLeay::Handle", $socket);
    $socket = \*S2;
}
my $last_sel = select($socket); $| = 1; select($last_sel);
print $socket $request_headers;
...
```

Note: As far as I know you must be careful with the globs in the tie() function. The first parameter must be a glob (*SOMETHING) and the last parameter must be a reference to a glob (*SOMETHING_ELSE) or a scaler that was assigned to a reference to a glob (as in the example above)

Also, the two globs must be different. When I tried to use the same glob, I got a core dump.

EXPORT

None by default.

You can export the shutdown() function.

It is suggested that you do export shutdown() or use the fully qualified Net::SSLeay::Handle::shutdown() function to shutdown SSL sockets. It should be smart enough to distinguish between SSL and non-SSL sockets and do the right thing.

EXAMPLES

```
use Net::SSLeay::Handle qw/shutdown/;
my ($host, $port) = ("localhost", 443);

tie(*SSL, "Net::SSLeay::Handle", $host, $port);

```

(continues on next page)

(continued from previous page)

```
print SSL "GET / HTTP/1.0\r\n";
shutdown(\*SSL, 1);
print while (<SSL>);
close SSL;
```

TODO

Better error handling. Callback routine?

CAVEATS

Tying to a file handle is a little tricky (for me at least).

The first parameter to tie() must be a glob (*SOMETHING) and the last parameter must be a reference to a glob (*SOMETHING_ELSE) or a scaler that was assigned to a reference to a glob ($s = *SOMETHING_ELSE). Also, the two globs must be different. When I tried to use the same glob, I got a core dump.

I was able to associate attributes to globs created by this module (like *SSL above) by making a hash of hashes keyed by the file head1.

CHANGES

Please see Net-SSLeay-Handle-0.50/Changes file.

BUGS

If you encounter a problem with this module that you believe is a bug, please create a new issue in the Net-SSLeay GitHub repository. Please make sure your bug report includes the following information:

- the code you are trying to run;
- your operating system name and version;
- the output of `perl -V`;
- the version of OpenSSL or LibreSSL you are using.

Net::Time

time and daytime network client interface

SYNOPSIS

```
use Net::Time qw(inet_time inet_daytime);

print inet_time();          # use default host from Net::Config
print inet_time('localhost');
print inet_time('localhost', 'tcp');

print inet_daytime();       # use default host from Net::Config
print inet_daytime('localhost');
print inet_daytime('localhost', 'tcp');
```

DESCRIPTION

`Net::Time` provides subroutines that obtain the time on a remote machine.

Functions

- `inet_time([$host[, $protocol[, $timeout]]])`

  Obtain the time on `$host`, or some default host if `$host` is not given or not defined, using the protocol as defined in RFC868. The optional argument `$protocol` should

define the protocol to use, either `tcp` or udp. The result will be a time value in the same units as returned by time() or *undef* upon failure.

- `inet_daytime([$host[, $protocol[, $timeout]]])`

  Obtain the time on `$host`, or some default host if `$host` is not given or not defined, using the protocol as defined in RFC867. The optional argument `$protocol` should define the protocol to use, either `tcp` or udp. The result will be an ASCII string or *undef* upon failure.

EXPORTS

The following symbols are, or can be, exported by this module:

- Default Exports

  None.

- Optional Exports

  `inet_time`, `inet_daytime`.

- Export Tags

  None.

KNOWN BUGS

None.

Net::hostent

by-name interface to Perl's built-in gethost*() functions

SYNOPSIS

```
use Net::hostent;
```

DESCRIPTION

This module's default exports override the core gethostbyname() and gethostbyaddr() functions, replacing them with versions that return "Net::hostent" objects. This object has methods that return the similarly named structure field name from the C's hostent structure from `netdb.h`; namely name, aliases, addrtype, length, and addr_list. The aliases and addr_list methods return array reference, the rest scalars. The addr method is equivalent to the zeroth element in the addr_list array reference.

You may also import all the structure fields directly into your namespace as regular variables using the :FIELDS import tag. (Note that this still overrides your core functions.) Access these fields as variables named with a preceding `h_`. Thus, `$host_obj->name()` corresponds to $h_name if you import the fields. Array references are available as regular array variables, so for example `@{ $host_obj->aliases() }` would be simply @h_aliases.

The gethost() function is a simple front-end that forwards a numeric argument to gethostbyaddr() by way of Socket::inet_aton, and the rest to gethostbyname().

To access this functionality without the core overrides, pass the `use` an empty import list, and then access the functions with their full qualified names. On the other hand, the built-ins are still available via the `CORE::` pseudo-package.

EXAMPLES

```
use Net::hostent;
use Socket;

@ARGV = ('netscape.com') unless @ARGV;

for $host ( @ARGV ) {

   unless ($h = gethost($host)) {
       warn "$0: no such host: $host\n";
```

(continues on next page)

(continued from previous page)

```
        next;
    }

    printf "\n%s is %s%s\n",
           $host,
           lc($h->name) eq lc($host) ? "" : "*really* ",
           $h->name;

    print "\taliases are ", join(", ", @{$h->aliases}), "\n"
                if @{$h->aliases};

    if ( @{$h->addr_list} > 1 ) {
        my $i;
        for $addr ( @{$h->addr_list} ) {
            printf "\taddr #%d is [%s]\n", $i++, inet_ntoa($addr);
        }
    } else {
        printf "\taddress is [%s]\n", inet_ntoa($h->addr);
    }

    if ($h = gethostbyaddr($h->addr)) {
        if (lc($h->name) ne lc($host)) {
            printf "\tThat addr reverses to host %s!\n", $h->name;
            $host = $h->name;
            redo;
        }
    }
}
```

NOTE

While this class is currently implemented using the Class::Struct module to build a struct-like class, you shouldn't rely upon this.

Net::netent

by-name interface to Perl's built-in getnet*() functions

SYNOPSIS

```
use Net::netent qw(:FIELDS);
getnetbyname("loopback")               or die "bad net";
printf "%s is %08X\n", $n_name, $n_net;
```

(continues on next page)

(continued from previous page)

```
use Net::netent;

$n = getnetbyname("loopback")          or die "bad net";
{ # there's gotta be a better way, eh?
    @bytes = unpack("C4", pack("N", $n->net));
    shift @bytes while @bytes && $bytes[0] == 0;
}
printf "%s is %08X [%d.%d.%d.%d]\n", $n->name, $n->net, @bytes;
```

DESCRIPTION

This module's default exports override the core getnetbyname() and getnetbyaddr() functions, replacing them with versions that return "Net::netent" objects. This object has methods that return the similarly named structure field name from the C's netent structure from `netdb.h`; namely name, aliases, addrtype, and net. The aliases method returns an array reference, the rest scalars.

You may also import all the structure fields directly into your namespace as regular variables using the :FIELDS import tag. (Note that this still overrides your core functions.) Access these fields as variables named with a preceding `n_`. Thus, `$net_obj->name()` corresponds to $n_name if you import the fields. Array references are available as regular array variables, so for example `@{ $net_obj->aliases() }` would be simply @n_aliases.

The getnet() function is a simple front-end that forwards a numeric argument to getnetbyaddr(), and the rest to getnetbyname().

To access this functionality without the core overrides, pass the `use` an empty import list, and then access the functions with their full qualified names. On the other hand, the built-ins are still available via the `CORE::` pseudo-package.

EXAMPLES

The getnet() functions do this in the Perl core:

```
sv_setiv(sv, (I32)nent->n_net);
```

The gethost() functions do this in the Perl core:

```
sv_setpvn(sv, hent->h_addr, len);
```

That means that the address comes back in binary for the host functions, and as a regular perl integer for the net ones. This seems a bug, but here's how to deal with it:

```
use strict;
use Socket;
use Net::netent;

@ARGV = ('loopback') unless @ARGV;
```

(continues on next page)

(continued from previous page)

```
my($n, $net);

for $net ( @ARGV ) {

    unless ($n = getnetbyname($net)) {
       warn "$0: no such net: $net\n";
       next;
    }

    printf "\n%s is %s%s\n",
           $net,
           lc($n->name) eq lc($net) ? "" : "*really* ",
           $n->name;

    print "\taliases are ", join(", ", @{$n->aliases}), "\n"
                if @{$n->aliases};

    # this is stupid; first, why is this not in binary?
    # second, why am i going through these convolutions
    # to make it looks right
    {
       my @a = unpack("C4", pack("N", $n->net));
       shift @a while @a && $a[0] == 0;
       printf "\taddr is %s [%d.%d.%d.%d]\n", $n->net, @a;
    }

    if ($n = getnetbyaddr($n->net)) {
       if (lc($n->name) ne lc($net)) {
           printf "\tThat addr reverses to net %s!\n", $n->name;
           $net = $n->name;
           redo;
       }
    }
}
```

NOTE

While this class is currently implemented using the Class::Struct module to build a struct-like class, you shouldn't rely upon this.

Net::protoent

by-name interface to Perl's built-in getproto*() functions

SYNOPSIS

```
use Net::protoent;
my $p = getprotobyname(shift || 'tcp') || die "no proto";
printf "proto for %s is %d, aliases are %s\n",
   $p->name, $p->proto, "@{$p->aliases}";

use Net::protoent qw(:FIELDS);
getprotobyname(shift || 'tcp') || die "no proto";
print "proto for $p_name is $p_proto, aliases are @p_aliases\n";
```

DESCRIPTION

This module's default exports override the core getprotoent(), getprotobyname(), and getprotobynumber() functions, replacing them with versions that return "Net::protoent" objects. This object has methods that return the similarly named structure field name from the C's protoent structure from `netdb.h`; namely name, aliases, and proto. The aliases method returns an array reference, the rest scalars.

You may also import all the structure fields directly into your namespace as regular variables using the :FIELDS import tag. (Note that this still overrides your core functions.) Access these fields as variables named with a preceding `p_`. Thus, `$proto_obj->name()` corresponds to $p_name if you import the fields. Array references are available as regular array variables, so for example `@{ $proto_obj->aliases() }` would be simply @p_aliases.

The getproto() function is a simple front-end that forwards a numeric argument to getprotobynumber(), and the rest to getprotobyname().

To access this functionality without the core overrides, pass the `use` an empty import list, and then access the functions with their full qualified names. On the other hand, the built-ins are still available via the `CORE::` pseudo-package.

NOTE

While this class is currently implemented using the Class::Struct module to build a struct-like class, you shouldn't rely upon this.

AUTHOR

Net::servent

by-name interface to Perl's built-in getserv*() functions

SYNOPSIS

```
use Net::servent;
my $s = getservbyname(shift || 'ftp') || die "no service";
printf "port for %s is %s, aliases are %s\n",
   $s->name, $s->port, "@{$s->aliases}";

use Net::servent qw(:FIELDS);
getservbyname(shift || 'ftp') || die "no service";
print "port for $s_name is $s_port, aliases are @s_aliases\n";
```

DESCRIPTION

This module's default exports override the core getservent(), getservbyname(), and getnetbyport() functions, replacing them with versions that return "Net::servent" objects. They take default second arguments of "tcp". This object has methods that return the similarly named structure field name from the C's servent structure from `netdb.h`; namely name, aliases, port, and proto. The aliases method returns an array reference, the rest scalars.

You may also import all the structure fields directly into your namespace as regular variables using the :FIELDS import tag. (Note that this still overrides your core functions.) Access these fields as variables named with a preceding `s_`. Thus, `$serv_obj->name()` corresponds to $s_name if you import the fields. Array references are available as regular array variables, so for example `@{ $serv_obj->aliases()}` would be simply @s_aliases.

The getserv() function is a simple front-end that forwards a numeric argument to getservbyport(), and the rest to getservbyname().

To access this functionality without the core overrides, pass the `use` an empty import list, and then access the functions with their full qualified names. On the other hand, the built-ins are still available via the `CORE::` pseudo-package.

EXAMPLES

```
use Net::servent qw(:FIELDS);

while (@ARGV) {
    my ($service, $proto) = ((split m!/!, shift), 'tcp');
    my $valet = getserv($service, $proto);
    unless ($valet) {
        warn "$0: No service: $service/$proto\n"
        next;
    }
    printf "service $service/$proto is port %d\n", $valet->port;
    print "alias are @s_aliases\n" if @s_aliases;
}
```

NOTE

While this class is currently implemented using the Class::Struct module to build a struct-like class, you shouldn't rely upon this.

5.2.72 O

Generic interface to Perl Compiler backends

SYNOPSIS

```
perl -MO=[-q,]Backend[,OPTIONS] foo.pl
```

DESCRIPTION

This is the module that is used as a frontend to the Perl Compiler.

If you pass the `-q` option to the module, then the STDOUT filehandle will be redirected into the variable `$O::BEGIN_output` during compilation. This has the effect that any output printed to STDOUT by BEGIN blocks or use'd modules will be stored in this variable rather than printed. It's useful with those backends which produce output themselves (`Deparse`, `Concise` etc), so that their output is not confused with that generated by the code being compiled.

The `-qq` option behaves like `-q`, except that it also closes STDERR after deparsing has finished. This suppresses the "Syntax OK" message normally produced by perl.

CONVENTIONS

Most compiler backends use the following conventions: OPTIONS consists of a comma-separated list of words (no white-space). The `-v` option usually puts the backend into verbose mode. The `-ofile` option generates output to **file** instead of stdout. The `-D` option followed by various letters turns on various internal debugging flags. See the documentation for the desired backend (named `B::Backend` for the example above) to find out about that backend.

IMPLEMENTATION

This section is only necessary for those who want to write a compiler backend module that can be used via this module.

The command-line mentioned in the SYNOPSIS section corresponds to the Perl code

```
use O ("Backend", OPTIONS);
```

The `O::import` function loads the appropriate `B::Backend` module and calls its `compile` function, passing it OPTIONS. That function is expected to return a sub reference which we'll call CALLBACK. Next, the "compile-only" flag is switched on (equivalent to

the command-line option `-c`) and a CHECK block is registered which calls CALLBACK. Thus the main Perl program mentioned on the command-line is read in, parsed and compiled into internal syntax tree form. Since the `-c` flag is set, the program does not start running (excepting BEGIN blocks of course) but the CALLBACK function registered by the compiler backend is called.

In summary, a compiler backend module should be called "B::Foo" for some foo and live in the appropriate directory for that name. It should define a function called `compile`. When the user types

```
perl -MO=Foo,OPTIONS foo.pl
```

that function is called and is passed those OPTIONS (split on commas). It should return a sub ref to the main compilation function. After the user's program is loaded and parsed, that returned sub ref is invoked which can then go ahead and do the compilation, usually by making use of the `B` module's functionality.

BUGS

The `-q` and `-qq` options don't work correctly if perl isn't compiled with PerlIO support : STDOUT will be closed instead of being redirected to `$O::BEGIN_output`.

Malcolm Beattie, `mbeattie@sable.ox.ac.uk`

5.2.73 ODBM_File

Tie a Perl hash to an old-style dbm database file.

ODBM_File is the tied-hash interface to the original Unix dbm: one database per process, keys and values of bytes. Bind a hash with `tie`; `$h{key}`, `delete`, `keys` and `each` then read and write the file. It has no `exists`.

Synopsis

```
use Fcntl;
use ODBM_File;

tie my %h, 'ODBM_File', 'mydb', O_RDWR|O_CREAT, 0640
    or die "tie failed: $!";
$h{greeting} = 'hello';
untie %h;
```

Opening a database

```
tie %h, 'ODBM_File', $basename, $flags, $mode;
```

With `O_CREAT` in `$flags` the files are created if missing, with the permission `$mode`; without it they must exist, or `tie` croaks `ODBM_FILE: Can't open NAME`. Only one database can be tied at a time in a process: a second `tie` croaks `Old dbm can only open one database` until the first is untied.

DBM filters

`(tied %h)->filter_store_key(sub {...})`, `filter_store_value`, `filter_fetch_key` and `filter_fetch_value` install a sub that rewrites every key or value on its way into, or out of, the database. The sub changes `$_` in place; a store filter works on a copy, so your own variable keeps its value. Each method returns the filter it replaces (or undef), and `undef` as the argument removes the filter. A filter that uses the same database croaks `recursion detected in filter_store_key` (or the filter's own name).

Files

pperl keeps the data in an LMDB file, `NAME.pag`, with `NAME.dir` beside it, as old dbm has the two, and LMDB's lock file `NAME.pag-lock`. The dbm library is not used, and its files cannot be read: tying a real dbm (gdbm) or Berkeley DB file croaks, naming what the file is, and the file is left as it was. A key may be at most 511 bytes, 510 if it starts with a NUL byte; a longer one croaks.

Writes reach the file when the hash is untied: until then the tie holds the file's one writer slot, and another process that writes the file waits for it (readers never wait). Set `$Peta::FFI::LMDB::DBM_WRITE = 'through'` before `tie` to commit every write as it happens; see `Peta::FFI::LMDB`.

Differences from upstream

- The files are LMDB files: real dbm and Berkeley DB files are refused, and pperl's files cannot be read by perl 5's ODBM_File. Covered by `t/82-native/Peta-FFI-LMDB/080-odbm.t`.
- Keys are limited to 511 bytes. Covered by `t/82-native/Peta-FFI-LMDB/080-odbm.t`.
- Writes reach the file at `untie` (or each one, with `$Peta::FFI::LMDB::DBM_WRITE = 'through'`), and a writer holds the file until then. Covered by `t/82-native/Peta-FFI-LMDB/080-odbm.t`.
- `tie` with `O_CREAT` opens a database that already exists, where perl 5 croaks `ODBM_File: Can't create NAME`. Covered by `t/82-native/Peta-FFI-LMDB/080-odbm.t`.
- A `tie` that fails does not keep later ones from opening a database; in perl 5 every later `tie` in the process croaks `Old dbm can only open one database`. Covered by `t/82-native/Peta-FFI-LMDB/080-odbm.t`.

Everything else behaves as with perl 5's ODBM_File. Covered by its own test, `t/81-xs-native/ODBM_File/100-upstream-odbm.t`.

5.2.74 Opcode

Name, group and mask the interpreter's opcodes - the machinery `Safe` compartments are built from.

An *opset* is a bit string with one bit per opcode, `(MAXO + 7) / 8` bytes wide. Operators are named individually (`"print"`, `"backtick"`) or by tag (`":base_core"`, `":subpro-`

cess"); Opcode converts between names, tags and opsets, and installs an opset into PL_op_mask, which the compiler consults to refuse masked ops.

use Opcode gives you the whole interface: the opset constructors and conversions (opset, ops_to_opset, opset_to_ops, opset_to_hex, invert_opset, empty_opset, full_opset, verify_opset), the operator queries (opdesc, opcodes, opdump), the tag builder define_optag, and the mask accessors opmask and opmask_add. Nothing is exported by default - name what you want on the use line. The predefined tags (:base_core, :default, :subprocess and the rest) are defined when the module loads.

```
use Opcode qw(opset opset_to_ops opdesc invert_opset opcodes);
use Safe;

my $io = opset(qw(:filesys_open print));
my @names = opset_to_ops($io);
print scalar(@names), " ops: @names[0..2] ...\n";   # 8 ops: open␣
↪close umask ...
print join(", ", opdesc(qw(print backtick))), "\n";  # print, quoted␣
↪execution (``, qx)
printf "%d opcodes, the rest of the set: %d\n",
    scalar(opcodes()), scalar(() = opset_to_ops(invert_opset($io)));␣
↪  # 429, 421

my $c = Safe->new;
Opcode::deny($c, 'print');
print $c->reval('1 + 2'), "\n";                      # 3
print defined $c->reval('print "x"') ? "printed\n" : "refused: $@";
# refused: 'print' trapped by operation mask at (eval 9) line 1.
```

The opcodes are perl 5.44's, so opsets, tags and masks mean what they mean there, and a Safe compartment refuses the same code.

This is a native implementation of the XS half of Opcode 1.71; its Opcode.pm, which defines the tags and opset_to_hex, opdump and ops_to_opset, is used unchanged.

Differences from upstream

None.

Functions

Opsets

verify_opset

Check that a scalar really is an opset, optionally croaking if it is not.

invert_opset

Return the complement of an opset - every operator it selects deselected, and vice versa.

opset_to_ops

List the operators an opset selects, by name or by description.

opset

Build an opset from operator names, `:tag` names and other opsets.

empty_opset

Return an opset with no operators selected.

full_opset

Return an opset with every operator selected.

Operators and tags

opdesc

Return the human-readable description of each named operator.

define_optag

Give a name to an opset so it can be used as a `:tag` afterwards.

opcodes

Return the number of operators the interpreter knows about.

Masking

opmask_add

Mask the operators an opset selects, on top of whatever is already masked. The compiler refuses a masked operator.

opmask

Return the currently masked operators as an opset.

Safe compartments

permit_only

`Opcode::permit_only($safe, @ops)`, `Opcode::permit($safe, @ops)`, `Opcode::deny_only($safe, @ops)`, `Opcode::deny($safe, @ops)`: change the

operator mask of a compartment object - any blessed hash, such as a `Safe`, whose `Mask` entry is an opset (created when missing). The operators are given as names, `:tags` and opsets; a name with a leading `!` counts inverted.

Also available as `Opcode::permit`, `Opcode::deny_only`, `Opcode::deny`.

permit_only

`Opcode::permit_only($safe, @ops)`, `Opcode::permit($safe, @ops)`, `Opcode::deny_only($safe, @ops)`, `Opcode::deny($safe, @ops)`: change the operator mask of a compartment object - any blessed hash, such as a `Safe`, whose `Mask` entry is an opset (created when missing). The operators are given as names, `:tags` and opsets; a name with a leading `!` counts inverted.

Also available as `Opcode::permit`, `Opcode::deny_only`, `Opcode::deny`.

- `permit` allows the named operators, deny forbids them, both on top of the current mask;
- `permit_only` allows the named operators and forbids every other; `deny_only` forbids the named ones and allows every other.

```
my $c = Safe->new;
Opcode::permit_only($c, ':default');
Opcode::deny($c, 'print');
$c->reval('print "x"');     # 'print' trapped by operation mask
```

`Safe`'s methods of the same names are its own Perl code over `opset`; these are the older XS versions. Anything but a blessed hash dies "Not a Safe object".

5.2.75 PDL

PDL - the Perl Data Language: fast, vectorised, multidimensional arrays for scientific and bulk numeric work.

```
use PDL;
my $x = sequence(3, 2);                          # 3 columns, 2 rows:
↪0 .. 5
print +($x * 2 + 1)->flat, "\n";                  # [1 3 5 7 9 11]
print $x->sumover, " ", $x->max, " ", $x->type, "\n";    # [3 12] 5
↪double
my $col = $x->slice("(1),:");                    # a view of column 1
$col .= -1;
print $x->flat, " ", $x->where($x > 3), "\n";             # [0 -1 2 3
↪-1 5] [5]
print float(1.5) + byte(2), " ", (float(1.5) + byte(2))->type, "\n";
↪  # 3.5 float
```

An ndarray is a blessed scalar holding a dense, typed, multidimensional block of numbers. Operators and functions apply to the whole block at once - `$x * 2 + 1` works on every element without a Perl loop - and slices such as `$x->slice(...)` are live views onto the parent's data rather than copies, so writing through a view writes to the parent. Functions broadcast: an operation on one dimension runs over all the others, and operands of different shapes are matched dimension by dimension.

The element type is chosen per ndarray. The constructors named after each type - `sbyte`, `byte`, `short`, `ushort`, `long`, `ulong`, `indx`, `longlong`, `ulonglong`, `float`, `double`, `ldouble`, `cfloat`, `cdouble`, `cldouble` - both build an ndarray of that type and, called with no arguments, name the type itself.

`use PDL` loads and imports PDL::Core (constructors, dimensions, types), PDL::Ops (the operators), PDL::Primitive (products, selecting, searching, interpolation), PDL::Ufunc (reductions and sorting), PDL::Basic (sequences and coordinates), PDL::Slices (views and indexing), PDL::Bad (bad values), PDL::MatrixOps (linear algebra), PDL::Math (mathematical functions), and the IO modules: PDL::IO::Misc (columns of text, byte swapping), PDL::IO::FITS, PDL::IO::Pic (images, through PDL::IO::Pnm and PDL::ImageRGB) and PDL::IO::Storable. PDL::Lite and PDL::LiteF load fewer; PDL::FFT, PDL::Image2D, PDL::ImageND, PDL::Transform and PDL::Compression are loaded on their own.

This is PDL 2.106: its Perl is upstream's, unchanged, and its compiled kernels are PDL's own C, run by pperl's engine. The XS that binds them is pperl's. `use PDL` needs pperl built with PDL (the `pdl` feature).

As upstream, an operation on large ndarrays (by default from 1 Mi elements) is split across threads: `set_autopthread_targ` and `set_autopthread_size` in PDL::Core control it. The threads are pperl's own pool, sized by `--threads`; `--no-parallel` keeps PDL on one thread.

Differences from upstream

Where perl5 with PDL fails, pperl does better:

- `broadcast` with a dimension the ndarray does not have croaks "Error in broadcastI:Invalid dim N (ndarray has M dims)" when first computed. Upstream reads outside the dimension array: memory before it for a negative dim (a garbage result), and for `broadcast(99)` it runs out of memory (t/81-xs-native/PDL/380-broadcast-methods.t).

Not there yet:

- `isnan` (PDL::Bad) and `casinh` (PDL::Math), both new in PDL 2.105.

t/81-xs-native/PDL/838-open-differences.t holds one case for every difference from upstream, open or closed; a new one goes there first.

Modules

- `PDL::Bad` - Bad values: PDL's marker for missing data, and the functions that find, make and replace them.
- `PDL::Basic` - PDL's basic constructors: counting sequences, coordinate values along a dimension, evenly spaced ranges, distances from a centre and histograms.
- `PDL::Complex`
- `PDL::Compression` - Rice compression of integer ndarrays, as FITS files use it.
- `PDL::Constants` - basic compile time constants for PDL
- `PDL::Core` - Build ndarrays, ask them about themselves, and convert between types.
- `PDL::Exporter` - PDL export control

- PDL::FFT - Fast Fourier transforms of PDL's ndarrays, in place, in one or more dimensions.
- PDL::IO
- PDL::Image2D - Two-dimensional image processing: median filters, polygon filling, connected components, rotation and warping.
- PDL::ImageND - Image processing in any number of dimensions: convolution, rebinning, interpolation, circular masks, contours and graph layout forces.
- PDL::ImageRGB - Utility functions for RGB image data: palette quantisation, palette lookup, conversion to grey, and scaling to bytes.
- PDL::Lite - PDL with methods only: the core modules loaded, four names imported.
- PDL::LiteF - The core PDL modules, with their functions imported.
- PDL::Math - PDL's mathematical functions: trigonometric and hyperbolic, rounding, error and Bessel functions, log gamma, complex square roots, logarithms and inverses, and polynomials.
- PDL::MatrixOps - Linear algebra on PDL's ndarrays: determinants, inverses, LU, singular value and eigen decompositions, linear systems, triangular storage.
- PDL::Ops - PDL's operators: arithmetic, comparison, bitwise and the unary functions, element by element, as the functions behind Perl's operators on ndarrays.
- PDL::Options - simplifies option passing by hash in PerlDL
- PDL::PP
- PDL::Primitive - PDL's primitives: products, selecting by a mask, clipping, searching sorted data, interpolation, set operations on vectors, statistics.
- PDL::Slices - Take pieces of an ndarray, and rearrange the pieces you take.
- PDL::Trans
- PDL::Transform - Coordinate transformations as objects, and the resampling of images through them.
- PDL::Types - define fundamental PDL Datatypes
- PDL::Ufunc - Reductions of PDL's ndarrays: sums, products, means, extrema, medians, percentiles, logical and bitwise folds, running sums and products, and sorting.

Functions

Contours and paths

contour_segments

`($segs, $cnt) = contour_segments($c, $data, $points)` - the line segments of the contour of `$data` at the level `$c`, in the coordinates `$points` gives each data point; `$cnt` is the index of the last segment end in `$segs`.

contour_polylines

`($pathendindex, $paths) = contour_polylines($c, $data, $points)` - the contour of `$data` at the level `$c` as polylines: `$paths` holds the points and `$pathendindex` the index of each polyline's last point, -1 after the last.

path_join

`($pathendindex, $paths) = path_join($edges, $nvertices, $directed)` - the edges `$edges` (pairs of vertex numbers) joined into paths: `$paths` holds the vertices and `$pathendindex` the index of each path's last vertex. `$directed` is true by default.

Graph layout

combcoords

`combcoords($x, $y, $z)` - the three coordinates packed into one float ndarray with a leading dimension of 3.

repulse

`repulse($coords, $boxsize, $dmult, $a, $b, $c, $d)` - the repulsive force on each point of `$coords` from the points near it, for a spring-embedded graph layout. The points are sorted into boxes of side `$boxsize`, `$dmult` of them along each of three dimensions, and only points in neighbouring boxes interact. With `s = 1 / (r + $d)` for two points at distance `r`, each pushes the other along their difference vector, scaled by `$c * sqrt(s) + $b * s + $a * s**2`.

attract

`attract($coords, $from, $to, $strength, $m, $ms)` - the attractive force on each point of `$coords` from the links `$from` to `$to` of the given `$strength`, for a spring-embedded graph layout.

First-dimension reductions

sumover

`sumover($a)` - the sum along the first dimension.

prodover

`prodover($a)` - the product along the first dimension.

dprodover

`dprodover($a)` - the product along the first dimension, computed in double precision.

dsumover

`dsumover($a)` - the sum along the first dimension, computed in double precision.

average

`average($a)` - the mean along the first dimension.

daverage

`daverage($a)` - the mean along the first dimension, computed in double precision.

caverage

`caverage($a)` - the mean along the first dimension as a complex value (`cfloat` for `float` input, `cdouble` otherwise); `cavgover` is the same function.

intover

`intover($a)` - the integral along the first dimension, for a point spacing of one: scale the result by the real spacing.

magnover

`magnover($a)` - the Euclidean length along the first dimension, `sqrt(sumover($a ** 2))`.

minimum

`minimum($a)` - the smallest value along the first dimension.

minimum_ind

`minimum_ind($a)` - the position of the smallest value along the first dimension.

maximum

`maximum($a)` - the largest value along the first dimension.

maximum_ind

`maximum_ind($a)` - the position of the largest value along the first dimension.

medover

`medover($a)` - the median along the first dimension; for an even count, the mean of the two middle values.

oddmedover

`oddmedover($a)` - the median along the first dimension; for an even count, the lower of the two middle values.

modeover

`modeover($data)` - the most frequent value along the first dimension. Meant for integer types: floating-point values are demoted to integers first.

minmaximum

`minmaximum($x)` - `($min, $max, $min_ind, $max_ind)` along the first dimension, broadcasting over the rest.

pctover

`pctover($pdl, $percentile)` - the given percentile along the first dimension, broadcasting over the others. `$percentile` is between 0.0 and 1.0; values outside are clipped to that range. Between data points the result is interpolated, by the variant Microsoft Excel uses and NIST recommends. Bad values are skipped.

oddpctover

`oddpctover($pdl, $percentile)` - like `pctover`, but when the percentile falls between data points the result is the nearest data value rather than an interpolation.

Logical and bitwise reductions

andover

`andover($a)` - 1 where every value along the first dimension is true, else 0.

orover

`orover($a)` - 1 where any value along the first dimension is true, else 0.

xorover

`xorover($a)` - the logical exclusive or along the first dimension.

zcover

`zcover($a)` - 1 where every value along the first dimension is zero, else 0.

bandover

`bandover($a)` - the bitwise and along the first dimension (integer types).

borover

`borover($a)` - the bitwise or along the first dimension (integer types).

bxorover

`bxorover($a)` - the bitwise exclusive or along the first dimension (integer types).

firstnonzeroover

`firstnonzeroover($a)` - the first non-zero value along the first dimension, or 0.

zcheck

`$pdl->zcheck` - 1 if every value is zero, else 0.

and

`$pdl->and` - 1 if every value is true, else 0.

or

`$pdl->or` - 1 if any value is true, else 0.

xorall

`$pdl->xorall` - the logical exclusive or of all the values.

band

`$pdl->band` - the bitwise and of all the values.

bor

`$pdl->bor` - the bitwise or of all the values.

bxor

`$pdl->bxor` - the bitwise exclusive or of all the values.

Cumulative operations

cumusumover

`cumusumover($a)` - the running sum along the first dimension.

dcumusumover

`dcumusumover($a)` - the running sum along the first dimension, in double precision.

cumuprodover

`cumuprodover($a)` - the running product along the first dimension.

dcumuprodover

`dcumuprodover($a)` - the running product along the first dimension, in double precision.

numdiff

`numdiff($x)` - the differences of neighbouring values along the first dimension, the first value kept: the inverse of `cumusumover`. Works in place.

diffcentred

`diffcentred($a)` - the centred difference along the first dimension, `($a[i+1] - $a[i-1]) / 2`, wrapping around at the ends. `partial($f, $dim)` takes it along dimension `$dim`; with `{ dir => 'f' }` or `'b'` it takes the forward or backward difference instead.

diff2

`diff2($a)` - the differences of neighbouring values along the first dimension, `$a[i+1] - $a[i]`: one element shorter than `$a`.

Sorting

qsort

`qsort($a)` - the values sorted along the first dimension, bad values last. Works in place.

qsorti

`qsorti($a)` - the indices that sort the values along the first dimension.

qsortvec

`qsortvec($a)` - a list of vectors sorted lexicographically: each vector runs along the first dimension, the list along the second. Works in place.

qsortveci

`qsortveci($a)` - the indices that would sort a list of vectors lexicographically, as `qsortvec` does.

Whole-array reductions

avg

`$pdl->avg` - the mean of all the values, as a 0-dim ndarray.

sum

`$pdl->sum` - the sum of all the values.

prod

`$pdl->prod` - the product of all the values.

davg

`$pdl->davg` - the mean of all the values, in double precision.

dsum

`$pdl->dsum` - the sum of all the values, in double precision.

dprod

`$pdl->dprod` - the product of all the values, in double precision.

min

`$pdl->min` - the smallest of all the values.

max

`$pdl->max` - the largest of all the values.

median

`$pdl->median` - the median of all the values.

oddmedian

`$pdl->oddmedian` - the median of all the values; for an even count, the lower middle value.

mode

`$pdl->mode` - the most frequent of all the values.

pct

`pct($pdl, $p)` - the given percentile of all the values of `$pdl`, whatever its dimensions, as a 0-dimensional PDL. Interpolated between data points, as `pctover`; bad values are skipped.

oddpct

`oddpct($pdl, $p)` - like `pct`, but when the percentile falls between data points the result is the nearest data value.

Making values bad

setinftobad

`$pdl->setinftobad` - infinities made bad values; works in place.

setnonfinitetobad

`$pdl->setnonfinitetobad` - infinities and NaNs made bad values; works in place.

setnantobad

`$pdl->setnantobad` - NaNs made bad values; works in place.

setbadif

`setbadif($a, $mask)` - `$a` with the elements bad where `$mask` is true.

copybad

`copybad($a, $mask)` - `$a` with the elements bad where `$mask` is bad; works in place.

setvaltobad

`setvaltobad($pdl, $val)` - elements equal to `$val` made bad; works in place.

Finding bad values

isbad

`isbad($a)` - 1 where the element is bad, 0 elsewhere.

isgood

`isgood($a)` - 1 where the element is good, 0 elsewhere.

nbadover

nbadover($a) - the number of bad elements along the first dimension.

ngoodover

ngoodover($a) - the number of good elements along the first dimension.

Replacing bad values

setbadtonan

$pdl->setbadtonan - bad values made NaN; works in place.

locf

locf($a) - each bad value replaced by the last good one before it.

setbadtoval

setbadtoval($pdl, $val) - bad values replaced with $val; works in place.

badmask

badmask($a, $b) - $a with each bad value replaced by $b's; works in place.

Indexing

index2d

index2d($a, $inda, $indb) - the elements of the 2-D $a at the coordinate pairs ($inda, $indb), as a child linked both ways.

index1d

index1d($a, $ind): the elements of $a along dim 0 at each of the indices in $ind, as a child linked both ways.

rangeb

$source->rangeb($index, $size, $boundary) - the kernel under range: the elements, or with $size the rectangular blocks, of $source at the coordinates in $index (its first dimension runs over the dimensions of $source), as a child linked both ways. $boundary says what lies outside $source: forbid (the default), truncate, extend, periodic or mirror, one for all dimensions or one each. range is the same with optional arguments, and indexND is range without a size.

Run-length encoding

rlevec

`($counts, $rows) = rlevec($c)` - run-length encode the rows of `$c`: how often each row repeats, and the rows that start each run.

rleseq

`($counts, $starts) = rleseq($c)` - run-length encode `$c` as runs of consecutive values: the length of each run and the value it starts at.

Views

rotate

`rotate($pdl, $shift)`

make_physdims

Force the ndarray's dimensions to be worked out, and return it.

xchg

`$pdl->xchg($n1, $n2)` - a view with dimensions `$n1` and `$n2` exchanged.

mv

`$pdl->mv($n1, $n2)` - a view with dimension `$n1` moved to position `$n2`, the others shifted.

lags

`$pdl->lags($nthdim, $step, $nlags)` - a view of lagged copies of one dimension, one per lag.

splitdim

`$pdl->splitdim($nthdim, $nsp)` - a view with dimension `$nthdim` split into two, the first of size `$nsp`.

unbroadcast

`$pdl->unbroadcast($atind)` - a view with the broadcast dimensions moved back to position `$atind`.

broadcastI

`$pdl->broadcastI($id, [@dims])` - a view with `@dims` made broadcast dimensions of group `$id`.

Decompositions and solving

svd

`($u, $s, $v) = svd($a)` - singular value decomposition `a = u * diag(s) * transpose(v)`; `svd($a, 1)` for the full decomposition.

simq

`($x, $ips) = simq($a, $b, $flag)` - solve the linear system `a x = b` by LU decomposition; `$a` is replaced by its decomposition.

Triangular storage

squaretotri

Convert the lower triangle of a square matrix to triangular vector storage: `squaretotri($a)` or `squaretotri($a, $b)`.

tritosquare

Convert triangular vector storage to the lower triangle of a square matrix; the upper half of the output is left alone.

tricpy

`tricpy($A, $uplo = 0, $C)`: copy a triangular part of `$A` - uplo -1 strict upper, 0 upper, 1 lower, 2 strict lower.

Building matrices

mstack

Stack two matrices along dim 1: `x(n,m)` and `y(n,p)` give `out(n,m+p)`.

augment

Join two ndarrays along dim 0: `x(n)` and `y(p)` give `out(n+p)`.

Complex numbers

re

`$z->re` - the real part of each complex element; assigning to it writes back into `$z`.

im

`$z->im` - the imaginary part of each complex element; assigning to it writes back into `$z`.

carg

`carg($z)` - the polar angle of each complex element, real.

conj

`conj($z)` - the complex conjugate; `$z->inplace->conj` works.

czip

`czip($re, $im)` - a complex ndarray from its real and imaginary parts.

Arithmetic

plus

`plus($a, $b)` - `$a + $b`, element by element.

minus

`minus($a, $b)` - `$a - $b`.

mult

`mult($a, $b)` - `$a * $b`.

divide

`divide($a, $b)` - `$a / $b`.

power

`power($a, $b)` - `$a ** $b`.

modulo

`modulo($a, $b)` - `$a % $b`, with the sign of `$b` as Perl's `%`.

atan2

`atan2($a, $b)` - the angle of the point `($b, $a)`, element by element.

ipow

`ipow($a, $b)` - `$a` to the integer power `$b`, by repeated multiplication.

pow

`pow($a, $b)` - `$a` to the power `$b`, element by element, the result in the input type (`pow(byte(2), 3)` is a byte); `$a->inplace->pow($b)` works in place.

Comparison

eq

`eq($a, $b)` - `$a == $b`: 1 or 0 per element.

ne

`ne($a, $b)` - `$a != $b`.

gt

`gt($a, $b)` - `$a > $b`.

lt

`lt($a, $b)` - `$a < $b`.

ge

`ge($a, $b)` - `$a >= $b`.

le

`le($a, $b)` - `$a <= $b`.

spaceship

`spaceship($a, $b)` - `$a <=> $b`: -1, 0 or 1 per element.

in

`in($a, $b)` - for each element of `$a`, whether it occurs in `$b`.

approx_artol

`approx_artol($got, $expected, $atol, $rtol)` - 1 where `$got` is within `$atol` of `$expected`, or within `$rtol` relative to it, else 0 (`$atol` 1e-6 and `$rtol` 0 by default). Two NaNs, or two bad values, are approximately equal.

Bitwise

and2

`and2($a, $b)` - `$a & $b`, bitwise.

or2

`or2($a, $b)` - `$a | $b`, bitwise.

xor

`xor($a, $b)` - `$a ^ $b`, bitwise.

shiftleft

`shiftleft($a, $b)` - `$a << $b`.

shiftright

`shiftright($a, $b)` - `$a >> $b`.

bitnot

`bitnot($a)` - bitwise negation.

Unary functions

sqrt

`sqrt($a)` - the element-wise square root.

abs2

`abs2($a)` - the squared absolute value, real.

not

`not($a)` - logical negation: 1 where `$a` is 0, else 0.

sin

`sin($a)`, element-wise.

cos

`cos($a)`, element-wise.

exp

`exp($a)`, element-wise.

log

`log($a)`, element-wise natural logarithm.

Assignment

assgn

`assgn($a, $b)` - copies `$a` into `$b`, broadcasting, and returns `$b` when it was not given: the operation behind `.=`. Into a view the copy reaches the parent, as every write through a view does.

Miscellaneous

hclip

`hclip($a, $b)` - `$a` with every value above `$b` replaced by `$b`: `$b` is the upper bound. Works in place.

lclip

`lclip($a, $b)` - `$a` with every value below `$b` replaced by `$b`: `$b` is the lower bound. Works in place.

axisvalues

`$pdl->inplace->axisvalues` - each element set to its index along the first dimension; broadcasts over the rest.

indadd

`indadd($input, $ind, $sum)` – broadcasting index-add.

broadcastids

`$pdl->broadcastids` - where each broadcast group starts among the dimensions, in list context; how many ids there are, in scalar context.

flags

`$pdl->flags` - the names of the state flags set on the ndarray, such as `PDL_ALLOCATED` or `PDL_PARENTDIMSCHANGED`. For debugging.

dump

`$pdl->dump` - print the engine's view of the ndarray to standard output: its state flags, dimensions, data and the transformations attached to it. For debugging; `PDL::Core::pdump` returns much the same as a string.

broadcastover_n

`PDL::broadcastover_n($code, $pdl1, ...)` - call `$code` once per element of the ndarrays broadcast against each other. Each call gets the number of the outermost dimension that just changed, then the current element of each ndarray as a plain number.

broadcastover

`PDL::broadcastover($code, \@realdims, \@creating, $nothers, $pdl1, ..., @others)` - call `$code` once per broadcast step, with a view of each ndarray that has the dimensions named in `\@realdims`, followed by the `$nothers` trailing arguments. An ndarray whose `\@creating` flag is set is created to fit; its dimensions follow the flags in `\@creating`. This is what `broadcast_define` builds its subs on.

Vectors

eqvec

`eqvec($a, $b)` - whether two vectors are equal.

enumvec

`enumvec($v)` - number each vector by its position within its run of equal vectors.

enumvecg

`enumvecg($v)` - number each vector by the group of equal vectors it belongs to.

vsearchvec

`vsearchvec($find, $which)` - binary search of vectors in a sorted list of vectors.

vcos

`vcos($a, $b)` - the cosine of the angle between each vector of `$a` (its rows along the second dimension) and the vector `$b`.

cmpvec

`cmpvec($a, $b)` - lexicographic comparison of two vectors: -1, 0 or 1.

Searching

vsearch_sample

`vsearch_sample($vals, $x)` - where each value falls in the sorted `$x`, as `vsearch` with `mode => 'sample'`.

vsearch_insert_leftmost

`vsearch_insert_leftmost($vals, $x)` - the leftmost insertion point of each value in the sorted `$x`.

vsearch_insert_rightmost

`vsearch_insert_rightmost($vals, $x)` - the rightmost insertion point of each value in the sorted `$x`.

vsearch_match

`vsearch_match($vals, $x)` - the index of each value in the sorted `$x`, or a negative insertion point where it is missing.

vsearch_bin_inclusive

`vsearch_bin_inclusive($vals, $x)` - the bin of each value, bins closed at their lower edge.

vsearch_bin_exclusive

`vsearch_bin_exclusive($vals, $x)` - the bin of each value, bins open at their lower edge.

Interpolation

pchip_chim

`pchip_chim($x, $f)` - derivatives for a monotone piecewise cubic Hermite interpolant.

pchip_chsp

`pchip_chsp($ic, $vc, $x, $f)` - derivatives for a cubic spline interpolant.

pchip_chfd

`pchip_chfd($x, $f, $d, $xe)` - the Hermite interpolant and its derivative at the points `$xe`.

pchip_chfe

`pchip_chfe($x, $f, $d, $xe)` - the Hermite interpolant at the points `$xe`.

pchip_chia

`pchip_chia($x, $f, $d, $la, $lb)` - the integral of the Hermite interpolant between two abscissae.

pchip_chid

`pchip_chid($x, $f, $d, $ia, $ib)` - the integral of the Hermite interpolant between two data points.

pchip_chbs

`pchip_chbs($x, $f, $d, $knotyp)` - the B-spline representation of the Hermite interpolant.

pchip_bvalu

`pchip_bvalu($t, $a, $ideriv, $x)` - a B-spline or one of its derivatives at `$x`.

pchip_chic

`($d, $ierr) = pchip_chic($ic, $vc, $mflag, $x, $f)` - the derivatives for a monotone piecewise cubic Hermite interpolant, with control over the end conditions (SLATEC PCHIC).

interpolate

`($yi, $err) = interpolate($xi, $x, $y)` - linear interpolation of `$y` over `$x` at the positions `$xi`. `$x` must be monotonic. A position outside `$x` is extrapolated from the two nearest knots, and its `$err` is 1.

Products

inner

`inner($a, $b)` – inner (dot) product along the first dimension.

outer

`outer($a, $b)` - the outer product: `c(n,m) = a(n) * b(m)`.

norm

`norm($vec)` - each vector along the first dimension scaled to unit length. Works in place.

inner2

`inner2($a, $b, $c)` - the inner product of a vector, a matrix and a vector: `$a x $b x $c`.

inner2d

`inner2d($a, $b)` - the inner product over the first two dimensions: the sum of `$a * $b` over a 2-D slice.

inner2t

`inner2t($a, $b, $c)` - the matrix product `$a x $b x $c` for matrices, through a temporary.

innerwt

`innerwt($a, $b, $c)` - the weighted inner product: the sum of `$a * $b * $c` along the first dimension.

crossp

`crossp($a, $b)` - the cross product of two 3-vectors; broadcasts over further dimensions.

Selecting

whichover

`whichover($mask)` - along the first dimension, the positions of the true elements first and -1 for the rest, broadcasting over the other dimensions. Works in place.

index

`index($a, $ind)`: the elements of `$a` along dim 0 at `$ind`, broadcasting over the rest, as a child linked both ways - a write into it reaches `$a`.

Complex functions

csqrt

`csqrt($z)` - the square root, taking real input as complex.

clog

`clog($z)` - the natural logarithm, taking real input as complex.

cacos

`cacos($z)` - the inverse cosine, taking real input as complex.

casin

`casin($z)` - the inverse sine, taking real input as complex.

cacosh

`cacosh($z)` - the inverse hyperbolic cosine, taking real input as complex.

catanh

`catanh($z)` - the inverse hyperbolic tangent, taking real input as complex.

csqrt_up

`csqrt_up($z)` - the square root with its imaginary part non-negative.

Classification

isfinite

`isfinite($pdl)` - 1 where the element is finite (and good), 0 elsewhere, as an int ndarray.

Trigonometric and hyperbolic

asin

`asin($a)` - the arc sine, in radians.

acos

`acos($a)` - the arc cosine, in radians.

atan

`atan($a)` - the arc tangent, in radians.

tan

`tan($a)` - the tangent.

sinh

`sinh($a)` - the hyperbolic sine.

cosh

`cosh($a)` - the hyperbolic cosine.

tanh

`tanh($a)` - the hyperbolic tangent.

asinh

`asinh($a)` - the inverse hyperbolic sine.

acosh

`acosh($a)` - the inverse hyperbolic cosine.

atanh

`atanh($a)` - the inverse hyperbolic tangent.

Rounding

ceil

`ceil($a)` - rounded up to an integer value.

floor

`floor($a)` - rounded down to an integer value.

rint

`rint($a)` - rounded to the nearest integer value, halves to even (C99 `rint`).

Special functions

erf

`erf($a)` - the error function.

erfc

`erfc($a)` - the complementary error function, `1 - erf($a)`.

erfi

`erfi($a)` - the inverse of the error function.

ndtri

`ndtri($a)` - the inverse of the standard normal distribution function: `ndtri(0.975)` is 1.96.

bessj0

`bessj0($a)` - the Bessel function of the first kind, order 0.

bessj1

`bessj1($a)` - the Bessel function of the first kind, order 1.

bessy0

`bessy0($a)` - the Bessel function of the second kind, order 0.

bessy1

`bessy1($a)` - the Bessel function of the second kind, order 1.

lgamma

`lgamma($a)` - the log of the absolute value of the gamma function, and its sign: `($l, $s) = lgamma($a)`.

bessjn

`bessjn($a, $n)` - the Bessel function of the first kind of integer order `$n`.

bessyn

`bessyn($a, $n)` - the Bessel function of the second kind of integer order `$n`.

Constructors

pdl

`$class->pdl(...)`: `$class->new(...)`.

topdl

Core.xs `topdl(klass, arg1, ...)`: `arg1` itself when it is an object; otherwise `klass->new(...)` of all the arguments - several of them, a plain scalar or an array ref.

null

`null()` - create a null (typeless, dimensionless) PDL placeholder.

new

`PDL->new(...)` - an ndarray from a number, a list of numbers, a (nested) array ref, a Matlab-style string (`"[1 2; 3 4]"`), a Math::Complex, or another ndarray (copied); a leading `PDL::Type` object sets the type.

initialize

`$class->initialize`: a new null ndarray blessed into `$class` (a class name, or the class of a reference). `new` calls it on the class it was invoked on, so a subclass - or a subclass's own `initialize` - decides what `My->new(...)` gives back.

zeroes

Core.xs `new_from_specification(invoc, ...)`, `ALIAS: PDL::zeroes = 1`.

Also available as `PDL::new_from_specification`.

set_sv_to_null_pdl

Turn an existing scalar into a null ndarray.

new_around_datasv

`PDL->new_around_datasv($address, $offset)` - an ndarray whose data is the string of the Perl scalar at `$address` (`0 + \$scalar`), from byte `$offset` (default 0) on. The scalar is kept alive, not copied. The result still needs its type and dimensions:

new_around_pointer

`PDL->new_around_pointer($pointer, $nbytes)` - an ndarray whose data is the `$nbytes` bytes of memory at `$pointer`, which it neither copies nor frees. The result still needs its type and dimensions.

Elements and data

get_dataref

Return a reference to the scalar holding the ndarray's raw bytes.

upd_data

Tell the ndarray that the scalar `get_dataref` returned was changed.

update_data_from

Replace the ndarray's contents with the bytes of a scalar.

at

Return a single element of an ndarray as a plain Perl scalar.

set

`set($pdl, @indices, $value)` - set the element at the given indices.

unpdl

Return the ndarray as nested Perl arrayrefs, shape and all.

string

`string($pdl)` - return the PDL's string representation.

sclr

`sclr($pdl)` - return the only element as a plain Perl scalar.

set_donttouchdata

Declare that the ndarray's storage belongs to someone else.

datasv_refcount

Return how many references are held to the ndarray's data scalar.

firstvals_nophys

`$pdl->firstvals_nophys` - up to the first ten elements of the ndarray's own data. Dies when it has none, as a view does.

Dimensions

dims

`dims($pdl)` - return the list of dimension sizes. Also aliased as shape().

getndims

Return how many dimensions the ndarray has.

Also available as `PDL::ndims`.

nelem

Return the total number of elements in the ndarray.

dim

`dim($pdl, $n)` - return the size of dimension `$n`. A negative `$n` counts from the last dimension; one past the last dimension is 1.

Also available as `PDL::getdim`.

dimincs

`dimincs($pdl)` - return the list of stride increments.

isnull

`isnull($pdl)` - return 1 if the PDL is a null placeholder.

setdims

Give an ndarray a new shape, in place.

nbytes

`nbytes($pdl)` - return the number of bytes in the pdl's data buffer.

nelem_nophys

`$pdl->nelem_nophys` - the number of elements as currently recorded, without computing a pending view first.

dims_nophys

`$pdl->dims_nophys` - the dimensions as currently recorded, without computing a pending view first. Always a list.

dimincs_nophys

`$pdl->dimincs_nophys` - the step in elements along each dimension as currently recorded. Always a list.

broadcastids_nophys

`$pdl->broadcastids_nophys` - the broadcast ids as currently recorded. Always a list.

getnbroadcastids

`$pdl->getnbroadcastids` - how many broadcast ids the ndarray has.

getbroadcastid

`$pdl->getbroadcastid($n)` - broadcast id number `$n`: the dimension where that broadcast group starts.

Parallel processing

set_autopthread_targ

`set_autopthread_targ($n)` - the number of threads an operation is split across, at most; 0 turns the splitting off. Returns `$n`.

get_autopthread_targ

`get_autopthread_targ()` - the target set by `set_autopthread_targ`.

set_autopthread_size

`set_autopthread_size($n)` - the size, in Mi elements of the largest ndarray, from which an operation is split across threads (default 1; `PDL_AUTOPTHREAD_SIZE` in the environment sets it when PDL loads). Returns `$n`.

get_autopthread_size

`get_autopthread_size()` - the size set by `set_autopthread_size`.

get_autopthread_actual

`get_autopthread_actual()` - how many threads the most recently set up operation was split across; 0 when it was not split.

get_autopthread_dim

`get_autopthread_dim()` - the dimension the most recently set up operation was split along; -1 when it was not split.

add_threading_magic

`$pdl->add_threading_magic($dim, $nthreads)` - have operations on this ndarray split dimension `$dim` across `$nthreads` threads, whatever the automatic setting would do.

remove_threading_magic

`$pdl->remove_threading_magic` - undo `add_threading_magic`.

Dataflow and views

inplace

`$pdl->inplace` - mark the ndarray so that the next operation on it that can work in place writes its result into it; returns `$pdl`.

flowing

Turn on dataflow, so ndarrays derived from this one track its changes.

sever

Detach a view from its parent, keeping the values it has right now.

dog

`$pdl->dog` - the ndarray as a list of views, one per element of its last dimension; `$pdl->dog({Break => 1})` severs them from it.

readonly

Mark the ndarray read-only and return it.

make_physical

Give the ndarray data of its own - a view (slice, dice, ...) gets its elements computed and stored - and return it.

has_vafftrans

`$pdl->has_vafftrans` - 1 when the ndarray is a view that reads its data from another ndarray's memory, 0 otherwise.

vaffine_from

`$pdl->vaffine_from` - the address of the ndarray a view reads its data from. Dies when the ndarray is not such a view.

make_physvaffine

`$pdl->make_physvaffine` - compute a view far enough that its elements can be read from its parent's memory, without copying them. Returns the ndarray.

trans_parent

`$pdl->trans_parent` - the transformation that produces this ndarray, a `PDL::Trans` object, or undef when it has none.

trans_children

`$pdl->trans_children` - the transformations that read this ndarray, as `PDL::Trans` objects; in scalar context, how many there are.

bind

`$pdl->bind($code)` - have `$code` called, without arguments, after the ndarray's data changed. The calls are collected and made by the next `PDL::dowhenidle()`.

dowhenidle

`PDL::dowhenidle()` - call the subs bound with `bind` to ndarrays that changed since the last call.

Bad values

badflag

`badflag($pdl, $flag?)` - get or set the bad-value flag.

has_badvalue

`$pdl->has_badvalue` - 1 when the ndarray has a bad value of its own instead of its type's, 0 otherwise.

Types

set_datatype

Change the element type of an ndarray in place.

get_datatype

`get_datatype($pdl)` - return the datatype as integer type code.

Headers

sethdr

`$pdl->sethdr($hashref)` - give the ndarray a header: any hash, such as the one `rfits` reads. `sethdr(undef)` removes it.

hdr

`$pdl->hdr` - the header, a hash reference; an ndarray without one gets an empty header first.

gethdr

`$pdl->gethdr` - the header, a hash reference, or undef when the ndarray has none.

hdrcpy

Get or set whether the header travels with derived ndarrays.

Filtering

box2d

`box2d($a, $wx, $wy, $edgezero)` - each pixel replaced by the mean of the `$wx` by `$wy` box around it. The pixels nearer to the edge than half a box are set to 0 if `$edgezero` is true and copied otherwise.

patch2d

`patch2d($a, $bad)` - `$a` with each pixel where `$bad` is true replaced by the mean of its good neighbours in the 3 by 3 box around it; a pixel with no good neighbour is kept.

patchbad2d

`patchbad2d($a)` - `$a` with each bad value replaced by the mean of its good neighbours in the 3 by 3 box around it; one with no good neighbour stays bad.

Resampling

bilin2d

`bilin2d($in, $out)` - `$in` stretched to the size of `$out` by bilinear interpolation and added to `$out`, which must not be smaller.

rescale2d

`rescale2d($in, $out)` - `$in` scaled to the size of `$out`, larger or smaller, each output pixel the area-weighted mean of the input it covers, and added to `$out`.

Other Functions

rice_expand

`rice_expand($in, $len, $dim0, $blocksize?)` - the rows `rice_compress` squeezed into `$in`, restored to `$dim0` elements each.

cquant_c

`cquant_c($a, $b, $c, $psz)` - the kernel under `cquant`: the palette image `$b` and the colour table `$c` (of `$psz` colours) for the RGB byte image `$a`.

wtstat

`wtstat($a, $wt, $avg, $deg)` - the weighted moment of degree `$deg` of `$a` about `$avg` along the first dimension: the sum of `$wt * ($a - $avg) ** $deg` over the sum of `$wt`.

histogram

`histogram($data, $step, $min, $numbins)` - the number of values of `$data` in each of `$numbins` bins of width `$step` starting at `$min`, along the first dimension. A value below the first bin counts in the first, one above the last in the last.

whistogram

`whistogram($data, $weight, $step, $min, $numbins)` - as `histogram`, each value counting with its weight.

histogram2d

`histogram2d($a, $b, $stepa, $mina, $na, $stepb, $minb, $nb)` - the two-dimensional histogram of the pairs (`$a`, `$b`).

whistogram2d

`whistogram2d($a, $b, $weight, $stepa, $mina, $na, $stepb, $minb, $nb)` - as `histogram2d`, each pair counting with its weight.

t_spherical_inv

`t_spherical_inv($in, $origin, $angunit)` - the kernel under the inverse of `t_spherical`: (longitude, latitude, radius) to Cartesian (x, y, z), the angles multiplied by `$angunit` (1 by default) to give radians. Works in place.

max2d_ind

`($val, $x, $y) = max2d_ind($img)` - the largest value of an image and its position.

centroid2d

`($xcen, $ycen) = centroid2d($img, $x, $y, $box)` - the centroid of the `$box`-wide square around `($x, $y)`.

ccNcompt

`ccNcompt($img, $con)` - the connected components of an image, `$con` 4 or 8 for the neighbourhood, each numbered from 1.

rot2d

`rot2d($img, $angle, $bg, $aa)` - a byte image turned by `$angle` degrees (-90 to 90), uncovered pixels set to `$bg`, antialiased when `$aa` is true.

pnminraw

`pnminraw($type, $im, $ms, $ns, $isbin, $fh)` - read a raw PNM image of `$ms` by `$ns` pixels from `$fh`, bits (`$isbin`) or bytes, into `$im`.

pnminascii

`pnminascii($type, $im, $ms, $ns, $format, $fh)` - read an ASCII PNM image of `$ms` by `$ns` pixels from `$fh` into `$im`.

pnmout

`pnmout($im, $israw, $isbin, $fh)` - write the pixels of `$im` to `$fh`, raw or ASCII, as bits (`$isbin`) or bytes.

bswap2

`bswap2($x)` - the bytes of each 2-byte element of `$x` reversed, in place.

bswap4

`bswap4($x)` - the bytes of each 4-byte element reversed, in place.

bswap8

`bswap8($x)` - the bytes of each 8-byte element reversed, in place.

bswap12

`bswap12($x)` - the bytes of each 12-byte element reversed, in place.

bswap16

`bswap16($x)` - the bytes of each 16-byte element reversed, in place.

bswap24

`bswap24($x)` - the bytes of each 24-byte element reversed, in place.

bswap32

`bswap32($x)` - the bytes of each 32-byte element reversed, in place.

PDL::Bad

Bad values: PDL's marker for missing data, and the functions that find, make and replace them.

```
use PDL;
my $x = pdl(1, 2, -1, 4);
$x->inplace->setvaltobad(-1);
print "$x ", $x->nbad, " ", $x->ngood, " ", $x->badflag, "\n";     #␣
↪[1 2 BAD 4] 1 3 1
print isbad($x), " ", $x->setbadtoval(0), " ", locf($x), "\n";   #␣
↪[0 0 1 0] [1 2 0 4] [1 2 2 4]
print $x->sum, " ", $x->avg, "\n";                                # 7␣
↪2.33333333333333
print setbadif(pdl(1, 2, 3), pdl(0, 1, 0)), " ", pdl(1, 9**9**9)->
↪setinftobad, "\n";   # [1 BAD 3] [1 BAD]
```

An element is bad when it holds its type's bad value and the ndarray's bad flag is set (`badflag`). Operations skip bad elements - `sum` and `avg` above count the three good ones - and a result computed from a bad element is bad. Each type has a default bad value, which an ndarray can override for itself: `badvalue` reads or sets either, called on an ndarray or on a type, and `orig_badvalue` gives a type's built-in default. Floating-point types can use NaN instead. nbad and ngood count, `check_badflag` clears the flag of an ndarray that has no bad element left.

This is PDL::Bad of PDL 2.106. The kernels are PDL's own, through pperl's engine; `badvalue`, `orig_badvalue`, `check_badflag`, nbad, ngood and `setbadat` (one element made bad, by position) are upstream's Perl unchanged.

PDL::Basic

PDL's basic constructors: counting sequences, coordinate values along a dimension, evenly spaced ranges, distances from a centre and histograms.

```
use PDL;
print sequence(5), " ", sequence(byte, 2, 2)->type, "\n";         #␣
↪[0 1 2 3 4] byte
print xvals(3, 2)->flat, " ", yvals(3, 2)->flat, "\n";            #␣
↪[0 1 2 0 1 2] [0 0 0 1 1 1]
print zeroes(4)->xlinvals(0, 1), " ", rvals(3), "\n";             #␣
↪[0 0.333333333333333 0.666666666666667 1] [1 0 1]
my ($centres, $counts) = hist(pdl(1, 2, 2, 3), 0, 4, 1);
print "$centres $counts\n";                                       #␣
```

(continues on next page)

(continued from previous page)

```
 ↪[0.5 1.5 2.5 3.5] [0 1 2 1]
print zeroes(2, 3)->ndcoords->dims, " ", ndcoords(2)->dims, "\n";
 ↪# 223 12
```

All of it is upstream's Perl, unchanged: `sequence`, `xvals`, `yvals`, `zvals` and `axisvals` (each element its index along a dimension), `xlinvals`, `ylinvals`, `zlinvals`, `xlogvals`, `ylogvals`, `zlogvals`, `axislinvals`, `axislogvals`, `allaxislinvals` and `allaxislogvals` (evenly spaced, linearly or logarithmically, between two values), `rvals` (the distance of each element from the centre), `ndcoords` (the coordinates of each element), `transpose`, `sec`, `ins` and `similar_assign`. Each takes dimensions, or an ndarray whose dimensions to use, and an optional type first.

`($centres, $counts) = hist($data, $min, $max, $step)` is the histogram of `$data`, the bin centres and the count in each bin; without `$min`, `$max` and `$step` the bins are chosen from the data. In scalar context it returns the counts alone. `whist($data, $weight, ...)` counts each value with its weight.

This is PDL::Basic of PDL 2.106.

PDL::Complex

Namespace containing the following modules:

- `PDL::Complex::Overloads` - subclass of Math::Complex with overload fallbacks

PDL::Complex::Overloads

subclass of Math::Complex with overload fallbacks

SYNOPSIS

```
require PDL::Complex::Overloads;
my $same = PDL::Complex::Overloads::cplx(1, 2) eq '1+2i';
```

DESCRIPTION

This is a subclass whose only purpose is to provide *Math::Complex*'s overloads but with `fallback` true, mainly to allow string-comparison for backwards compatibility.

AUTHOR

Ed J

SEE ALSO

Math::Complex

PDL::Compression

Rice compression of integer ndarrays, as FITS files use it.

```
use PDL;
use PDL::Compression;
my $x = long(1, 2, 3, 4, 5, 4, 3, 2, 1, 0);
my ($y, $n, $blocksize, $len) = $x->rice_compress;
print $y->rice_expand($len, $n), "\n";     # [1 2 3 4 5 4 3 2 1 0]
```

`rice_compress` squeezes each row of a byte, short, ushort or long ndarray; in list context it also returns the row length, the block size and each row's compressed length, which `rice_expand` needs to restore the data. The algorithm is the RICE_1 compression of CFITSIO, so PDL::IO::FITS reads and writes RICE-compressed images with it.

This is PDL::Compression of PDL 2.106: upstream's Perl, unchanged, over PDL's own kernels run by pperl's engine.

PDL::Constants

basic compile time constants for PDL

DESCRIPTION

This module is used to define compile time constant values for PDL. It uses Perl's *constant* pragma for simplicity and availability.

SYNOPSIS

```
use PDL::Constants qw(PI E);
print 'PI is ' . PI . "\n";
print 'E  is ' .  E . "\n";
```

PI

The ratio of a circle's circumference to its diameter

DEGRAD

The number of degrees of arc per radian (180/PI)

DEG2RAD

The constant to convert degrees of arc into radians (PI/180)

```
$radians = DEG2RAD * $degrees;
```

RAD2DEG

The constant to convert radians into degrees of arc (180/PI)

```
$degrees = RAD2DEG * $radians;
```

E

The base of the natural logarithms or Euler's number

PDL::Core

Build ndarrays, ask them about themselves, and convert between types.

```
use PDL;
my $x = pdl([1, 2, 3], [4, 5, 6]);
print join(",", $x->dims), " ", $x->nelem, " ", $x->type, " ", $x->
 ↪at(2, 1), "\n";   # 3,2 6 double 6
print $x->info, "\n";                                    # PDL:␣
 ↪Double D [3,2]
print zeroes(byte, 2), ones(2), " ", sequence(3)->convert(float)->
 ↪type, "\n";   # [0 0][1 1] float
my @l = $x->list;
print "@l ", short(1.7), " ", pdl(5)->sclr + 1, "\n";       # 1 2 3␣
 ↪4 5 6 1 6
my $v = $x->slice(":,(0)");
$v .= 0;
print $x->flat, " ", $x->copy->sever->isnull, "\n";          # [0 0␣
 ↪0 4 5 6] 0
print cat(pdl(1, 2), pdl(3, 4))->flat, " ", $x->badflag, "\n";   #␣
 ↪[1 2 3 4] 0
```

`PDL::Core` is the foundation the rest of PDL rests on. It holds the constructors (`pdl`, `null`, `zeroes`, `ones`, `empty`, `cat`), the accessors that report shape and contents (`dims`, `shape`, `ndims`, `nelem`, `at`, `set`, `list`, `unpdl`, `info`), the type system (`type`, `convert`, `get_datatype`, `howbig`), and the bad-value flag (`badflag`; the rest of the bad-value machinery is PDL::Bad).

Two ideas run through all of it. Ndarrays are typed: an ndarray of `byte` and one of `double` hold different things, and `convert` moves between them. And ndarrays can share data: a slice or a reshape is a view onto its parent, so `sever` and `copy` exist for the times you want a snapshot that stops tracking the original.

The types and their constructors, each `type(...)` an ndarray of that type and a bare `type` the type itself (as in `zeroes(float, 3)`): `sbyte`, `byte`, `short`, `ushort`, `long`, `ulong`, `indx`, `ulonglong`, `longlong`, `float`, `double`, `ldouble`, `cfloat`, `cdouble`, `cldouble`. `piddle` is the old name of `pdl`.

The state of an ndarray, as methods returning 0 or 1: `allocated`, `anychgd`, `datachgd`, `dimschgd`, `donttouch`, `fflows`, `is_inplace`, `is_readonly`, `vaffine`; `set_inplace` changes it, and `getdim` and `getndims` are `dim` and `ndims`. `address`, `address_data` and `address_datasv` are the memory addresses behind an ndarray, for debugging, `new_from_specification` is `zeroes`' engine, `is_scalar_SvPOK` is a helper of `pdl`'s, and `howbig_c` is the one of `howbig`.

This is PDL::Core of PDL 2.106. Its XS is pperl's, native; its Perl (`cat`, `ones`, `empty`, `info`, `convert`, `copy`, `reshape`, `squeeze`, `dummy`, `clump`, `mslice`, `barf`, `approx`, `howbig`, `isempty`, `shape`, `type`, `list`, `fhdr` and the rest) is upstream's, unchanged.

Functions

Constructors

alltopdl

`PDL::Core::alltopdl($class, $value, $type)`, see [`alltopdl`].

pdl_avref

Core.xs `pdl_avref(array_ref, class, type)`.

Elements and data

at_bad_c

`PDL::Core::at_bad_c($pdl, [@pos])` (also `at_c`): the element at `@pos`, "BAD" for a bad value - what `$pdl->at(@pos)` is built on.

set_c

`PDL::Core::set_c($pdl, [@pos], $value)`: store `$value` at `@pos` - what `$pdl->set(@pos, $value)` is built on.

listref_c

`PDL::Core::listref_c($pdl)`: the elements as a nested array ref, "BAD" for bad values - what `list` is built on.

Parallel processing

online_cpus

`PDL::Core::online_cpus()` - how many threads PDL can split an operation across.

pthreads_enabled

`PDL::Core::pthreads_enabled()` - 1: operations can be split across threads.

Miscellaneous

seed

`PDL::Core::seed()`: a seed for the random number generators, from the time and the process id.

set_debugging

`PDL::Core::set_debugging($on)` - set the engine's debugging flag and return its previous value.

PDL::Exporter

PDL export control

DESCRIPTION

Implements the standard conventions for import of PDL modules in to the namespace

Hopefully will be extended to allow fine control of which namespace is used.

SYNOPSIS

use PDL::Exporter;

```
use PDL::MyModule;       # Import default function list ':Func'
use PDL::MyModule '';    # Import nothing (OO)
use PDL::MyModule '...'; # Same behaviour as Exporter
```

SUMMARY

`PDL::Exporter` is a drop-in replacement for the *Exporter* module. It confers the standard PDL export conventions to your module. Usage is fairly straightforward and best illustrated by an example. The following shows typical usage near the top of a simple PDL module:

```
package PDL::MyMod;

use strict;

# For Perl 5.6:
use vars qw($VERSION @ISA @EXPORT @EXPORT_OK %EXPORT_TAGS);
# For more modern Perls:
our ($VERSION, @ISA, @EXPORT, @EXPORT_OK, %EXPORT_TAGS);
```

(continues on next page)

(continued from previous page)

```
require PDL::Exporter;

@ISA = qw(PDL::Exporter);
@EXPORT_OK = qw(inc myfunc); # these will be exported by default
%EXPORT_TAGS = (Func=>[@EXPORT_OK],
                Internal => [qw/internfunc1 internfunc2/],
               );

 # ... body of your module

1; # end of simple module
```

SEE ALSO

Exporter

AUTHOR

Copyright (C) Karl Glazebrook (kgb@aaoepp.aao.gov.au). Some docs by Christian Soeller. All rights reserved. There is no warranty. PDL::FFT

Fast Fourier transforms of PDL's ndarrays, in place, in one or more dimensions.

```
use PDL;
use PDL::FFT;
my ($re, $im) = (pdl(1, 2, 3, 4), zeroes(4));
fft($re, $im);
print "$re $im\n";                  # [10 -2 -2 -2] [0 2 0 -2]
```

`fft($re, $im)` and `ifft($re, $im)` transform the real and imaginary parts in place along the first dimension, broadcasting over the rest; `realfft`/`realifft` work on real data, `fftnd`/`ifftnd` in every dimension, and `fftconvolve` convolves two ndarrays through the transform. All of these are upstream's Perl, unchanged, over the kernels; this is PDL::FFT of PDL 2.106.

PDL::IO

Namespace containing the following modules:

- `PDL::IO::FITS` - Simple FITS support for PDL
- `PDL::IO::Misc` - Reading and writing ndarrays as text, and byte-order swapping.
- `PDL::IO::Pic` - image I/O for PDL

- `PDL::IO::Pnm` - Reading and writing images in the PNM formats: PBM, PGM and PPM.
- `PDL::IO::Storable` - helper functions to make PDL usable with serialisation packages

PDL::IO::FITS

Simple FITS support for PDL

SYNOPSIS

```
use PDL;
use PDL::IO::FITS;

$x = rfits('foo.fits');          # read a FITS file
$x->wfits('bar.fits');           # write a FITS file
```

DESCRIPTION

This module provides basic FITS support for PDL, in the sense of reading and writing whole FITS files. For more complex operations, such as prefiltering rows out of tables or performing operations on the FITS file in-place on disk, you can use the Astro::FITS::CFITSIO module that is available on CPAN.

Basic FITS image files are supported, along with BINTABLE and IMAGE extensions. ASCII Table support is planned, as are the HEASARC bintable extensions that are recommended in the 1999 FITS standard.

Table support is based on hashes and named columns, rather than the less convenient (but slightly more congruent) technique of perl lists of numbered columns.

The principle interface routines are `rfits` and `wfits`, for reading and writing respectively. FITS headers are returned as perl hashes or (if the module is present) Astro::FITS::Header objects that are tied to perl hashes. Astro::FITS::Header objects provide convenient access through the tied hash interface, but also allow you to control the card structure in more detail using a separate method interface; see the Astro::FITS::Header documentation for details.

FUNCTIONS

rfits()

Simple ndarray FITS reader.

```
$pdl = rfits('file.fits');   # Read a simple FITS image
```

Suffix magic:

```
$pdl = rfits('file.fits.gz'); # Read a file with gunzip(1)
$pdl = rfits('file.fits.Z');  # Read a file with uncompress(1)

$pdl = rfits('file.fits[2]');    # Read 2nd extension
$pdl = rfits('file.fits.gz[3]'); # Read 3rd extension
@pdls = rfits('file.fits');      # Read primary data and extensions
```

Tilde expansion:

```
#expand leading ~ to home directory (using glob())
$pdl = rfits '~/filename.fits';

$hdr = rfits('file.fits',{data=>0});  # Options hash changes␣
↪behavior
```

In list context, `rfits` reads the primary image and all possible extensions, returning them in the same order that they occurred in the file – except that, by default, the primary HDU is skipped if it contains no data. In scalar context, the default is to read the first HDU that contains data. One can read other HDU's by using the [n] syntax. Using the [0] syntax forces a read of the first HDU, regardless of whether it contains data or no. Currently recognized extensions are IMAGE and BINTABLE. (See the addendum on EXTENSIONS for details).

`rfits` accepts several options that may be passed in as a hash ref if desired:

- bscale (default=1)

  Determines whether the data are linearly scaled using the BSCALE/BZERO keywords in the FITS header. To read in the exact data values in the file, set this to 0.

- data (default=1)

  Determines whether to read the data, or just the header. If you set this to 0, you will get back the FITS header rather than the data themselves. (Note that the header is normally returned as the `hdr` field of the returned PDL; this causes it to be returned as a hash ref directly.)

- hdrcpy (default=0)

  Determines whether the *hdrcpy* flag is set in the returned PDL. Setting the flag will cause an explicit deep copy of the header whenever you use the returned PDL in an arithmetic or slicing operation. That is useful in many circumstances but also causes a hit in speed. When two or more PDLs with hdrcpy set are used in an expression, the result gets the header of the first PDL in the expression. See *hdrcpy* for an example.

- expand (default=1)

  Determines whether auto-expansion of tile-compressed images should happen. Tile-compressed images are transmitted as binary tables with particular fields

("ZIMAGE") set. Leaving this alone does what you want most of the time, unpacking such images transparently and returning the data and header as if they were part of a normal IMAGE extension. Setting "expand" to 0 delivers the binary table, rather than unpacking it into an image.

- afh (default=1)

  By default rfits uses Astro::FITS::Header tied-hash objects to contain the FITS header information. This permits explicit control over FITS card information, and conforms well with the FITS specification. But Astro::FITS::Header objects are about 40-60x more memory intensive than comparable perl hashes, and also use ~10x more CPU to manage. For jobs where header processing performance is important (e.g. reading just the headers of 1,000 FITS files), set afh to 0 to use the legacy parser and get a large boost in speed.

FITS image headers are stored in the output PDL and can be retrieved with *hdr* or *gethdr*. The *hdrcpy* flag of the PDL is set so that the header is copied to derived ndarrays by default. (This is inefficient if you are planning to do lots of small operations on the data; clear the flag with "->hcpy(0)" or via the options hash if that's the case.)

The header is a hash whose keys are the keywords in the FITS header. If you have the "Astro::FITS::Header" module installed, the header is actually a tied hash to a FITS header object, which can give you more control over card order, comment fields, and variable types. (see Astro::FITS::Header for details).

The header keywords are converted to *uppercase* per the FITS standard. Access is case-insensitive on the perl side, provided that Astro::FITS::Header is installed.

If Astro::FITS::Header is not installed, then a built-in legacy parser is used to generate the header hash. Keyword-associated comments in the headers are stored under the hash key `<keyword>_COMMENT>`. All HISTORY cards in the header are collected into a single multiline string stored in the `HISTORY` key. All COMMENT cards are similarly collected under the `COMMENT` key.

BSCALE/BZERO

If the BSCALE and/or BZERO keywords are set, they are applied to the image before it is returned. The returned PDL is promoted as necessary to contain the multiplied values, and the BSCALE and BZERO keywords are deleted from the header for clarity. If you don't want this type of processing, set 'bscale=>0' in the options hash.

EXTENSIONS

Sometimes a FITS file contains only extensions and a stub header in the first header/data unit ("primary HDU"). In scalar context, you normally only get back the primary HDU – but in this special case, you get back the first extension HDU. You can force a read of the primary HDU by adding a '[0]' suffix to the file name.

BINTABLE EXTENSIONS

Binary tables are handled. Currently only the following PDL datatypes are supported: byte, short, ushort, long, float, and double. At present ushort() data is written as a long rather than as a short with TSCAL/ZERO; this may change.

The return value for a binary table is a hash ref containing the names of the columns in the table (in UPPER CASE as per the FITS standard). Each element of the hash contains a PDL (for numerical values) or a perl list (for string values). The PDL's 0th dimension runs across rows; the 1st dimension runs across the repeat index within the row (for rows with more than one value). (Note that this is different from standard broadcasting order - but it allows Least Surprise to work when adding more complicated objects such as collections of numbers (via the repeat count) or variable length arrays.)

Thus, if your table contains a column named FOO with type 5D, the expression

```
$x->{FOO}->((2))
```

returns a 5-element double-precision PDL containing the values of FOO from the third row of the table.

The header of the table itself is parsed as with a normal FITS HDU, and is returned in the element 'hdr' of the returned hash. You can use that to preserve the original column order or access the table at a low level, if you like.

Scaling and zero-point adjustment are performed as with BSCALE/BZERO: the appropriate keywords are deleted from the as-returned header. To avoid this behavior, set 'bscale=>0' in the options hash.

As appropriate, TSCAL/ZERO and TUNIT are copied into each column-PDL's header as BSCALE/BZERO and BUNIT.

The main hash also contains the element 'tbl', which is set to 'binary' to distinguish it from an ASCII table.

Because different columns in the table might have identical names in a FITS file, the binary table reader practices collision avoidance. If you have multiple columns named "FOO", then the first one encountered (numerically) gets the name "FOO", the next one gets "FOO_1", and the next "FOO_2", etc. The appropriate TTYPEn fields in the header are changed to match the renamed column fields.

Columns with no name are assigned the name "COL_<n>", where <n> starts at 1 and increments for each no-name column found.

Variable-length arrays are supported for reading. They are unpacked into PDLs that appear exactly the same as the output for fixed-length rows, except that each row is padded to the maximum length given in the extra characters – e.g. a row with TFORM of 1PB(300) will yield an NAXIS2x300 output field in the final hash. The padding uses the TNULn keyword for the column, or 0 if TNULn is not present. The output hash also gets an additional field, "len_<name>", that contains the number of elements in each table row.

TILE-COMPRESSED IMAGES

CFITSIO and several large projects (including NASA's Solar Dynamics Observatory) now support an unofficial extension to FITS that stores images as a collection of individually compressed tiles within a BINTABLE extension. These images are automagically uncompressed by default, and delivered as if they were normal image files. You can override this behavior by supplying the "expand" key in the options hash.

Currently, only Rice compression is supported, though there is a framework in place for adding other compression schemes.

BAD VALUE HANDLING

If a FITS file contains the BLANK keyword (and has BITPIX > 0), the ndarray will have its bad flag set, and those elements which equal the BLANK value will be set bad. For BITPIX < 0, any NaN's are converted to bad (if necessary).

rfitshdr()

Read only the header of a FITS file or an extension within it.

This is syntactic sugar for the data=>0 option to rfits.

See rfits for details on header handling. rfitshdr() runs the same code to read the header, but returns it rather than reading in a data structure as well.

wfits()

Simple PDL FITS writer

```
wfits $pdl, 'filename.fits', [$BITPIX], [$COMPRESSION_OPTIONS];
wfits $hash, 'filename.fits', [$OPTIONS];
$pdl->wfits('foo.fits',-32);
```

Suffix magic:

```
# Automatically compress through pipe to gzip
wfits $pdl, 'filename.fits.gz';
# Automatically compress through pipe to compress
wfits $pdl, 'filename.fits.Z';
```

Tilde expansion:

```
#expand leading ~ to home directory (using glob())
wfits $pdl, '~/filename.fits';
```

- Ordinary (PDL) data handling:

  If the first argument is a PDL, then the PDL is written out as an ordinary FITS file with a single Header/Data Unit of data.

  $BITPIX is then optional and coerces the output data type according to the standard FITS convention for the BITPIX field (with positive values representing integer types and negative values representing floating-point types).

  If $pdl has a FITS header attached to it (actually, any hash that contains a SIMPLE=>T keyword), then that FITS header is written out to the file. The image dimension tags are adjusted to the actual dataset. If there's a mismatch between the dimensions of the data and the dimensions in the FITS header, then the header gets corrected and a warning is printed.

  If $pdl is a slice of another PDL with a FITS header already present (and header copying enabled), then you must be careful. wfits will remove any extraneous NAXISn keywords (per the FITS standard), and also remove the other keywords associated with that axis: CTYPEn, CRPIXn, CRVALn, CDELTn, and CROTAn. This

may cause confusion if the slice is NOT out of the last dimension: `wfits($x(:,(0),:),'file.fits');` and you would be best off adjusting the header yourself before calling `wfits`.

You can tile-compress images according to the CFITSIO extension to the FITS standard, by adding an option hash to the arguments:

- compress

  This can be either unity, in which case Rice compression is used, or a (case-insensitive) string matching the CFITSIO compression type names. Currently supported compression algorithms are:

  * RICE_1 - linear Rice compression

    This uses limited-symbol-length Rice compression, which works well on low entropy image data (where most pixels differ from their neighbors by much less than the dynamic range of the image).

- BLOCKSIZE (RICE_1 only; default 32)

  For RICE_1, indicates the number of pixel samples to use for each compression block within the compression algorithm. The blocksize is independent of the tile dimensions. For RICE compression the pixels from each tile are arranged in normal pixel order (early dims fastest) and compressed as a linear stream.

- Table handling:

  If you feed in a hash ref instead of a PDL, then the hash ref is written out as a binary table extension. The hash ref keys are treated as column names, and their values are treated as the data to be put in each column.

  For numeric information, the hash values should contain PDLs. The 0th dim of the PDL runs across rows, and higher dims are written as multi-value entries in the table (e.g. a 7x5 PDL will yield a single named column with 7 rows and 5 numerical entries per row, in a binary table). Note that this is slightly different from the usual concept of broadcasting, in which dimension 1 runs across rows.

  ASCII tables only allow one entry per column in each row, so if you plan to write an ASCII table then all of the values of `$hash` should have at most one dim.

  All of the columns' 0 dims must agree in the broadcasting sense. That is to say, the 0th dimension of all of the values of `$hash` should be the same (indicating that all columns have the same number of rows). As an exception, if the 0th dim of any of the values is 1, or if that value is a PDL scalar (with 0 dims), then that value is "broadcasted" over – copied into all rows.

  Data dimensions higher than 2 are preserved in binary tables, via the TDIMn field (e.g. a 7x5x3 PDL is stored internally as seven rows with 15 numerical entries per row, and reconstituted as a 7x5x3 PDL on read).

  Non-PDL Perl scalars are treated as strings, even if they contain numerical values. For example, a list ref containing 7 values is treated as 7 rows containing one string each. There is no such thing as a multi-string column in FITS tables, so any non-scalar values in the list are stringified before being written. For example, if you pass in a perl list of 7 PDLs, each PDL will be stringified before being written, just as if you printed it to the screen. This is probably not what you want – you should

use “glue” to connect the separate PDLs into a single one. (e.g. `$x->glue(1,$y,$c)->mv(1,0)`)

The column names are case-insensitive, but by convention the keys of `$hash` should normally be ALL CAPS, containing only digits, capital letters, hyphens, and underscores. If you include other characters, then case is smashed to ALL CAPS, whitespace is converted to underscores, and unrecognized characters are ignored – so if you include the key “Au Purity (%)”, it will be written to the file as a column that is named “AU_PURITY”. Since this is not guaranteed to produce unique column names, subsequent columns by the same name are disambiguated by the addition of numbers.

You can specify the use of variable-length rows in the output, saving space in the file. To specify variable length rows for a column named “FOO”, you can include a separate key “len_FOO” in the hash to be written. The key’s value should be a PDL containing the number of actual samples in each row. The result is a FITS P-type variable length column that, upon read with `rfits()`, will restore to a field named FOO and a corresponding field named “len_FOO”. Invalid data in the final PDL consist of a padding value (which defaults to 0 but which you may set by including a TNULL field in the hdr specificaion). Variable length arrays must be 2-D PDLs, with the variable length in the 1 dimension.

Two further special keys, ‘hdr’ and ‘tbl’, can contain meta-information about the type of table you want to write. You may override them by including an `$OPTIONS` hash with a ‘hdr’ and/or ‘tbl’ key.

The ‘tbl’ key, if it exists, must contain either ‘ASCII’ or ‘binary’ (case-insensitive), indicating whether to write an ascii or binary table. The default is binary. [ASCII table writing is planned but does not yet exist].

You can specify the format of the table quite specifically with the ‘hdr’ key or option field. If it exists, then the ‘hdr’ key should contain fields appropriate to the table extension being used. Any field information that you don’t specify will be filled in automatically, so (for example) you can specify that a particular column name goes in a particular position, but allow `wfits` to arrange the other columns in the usual alphabetical order into any unused slots that you leave behind. The `TFORMn`, `TFIELDS`, `PCOUNT`, `GCOUNT`, `NAXIS`, and `NAXISn` keywords are ignored: their values are calculated based on the hash that you supply. Any other fields are passed into the final FITS header verbatim.

As an example, the following

```
$x = long(1,2,4);
$y = double(1,2,4);
wfits { 'COLA'=>$x, 'COLB'=>$y }, "table1.fits";
```

will create a binary FITS table called `table1.fits` which contains two columns called `COLA` and `COLB`. The order of the columns is controlled by setting the `TTYPEn` keywords in the header array, so

```
$h = { 'TTYPE1'=>'Y', 'TTYPE2'=>'X' };
wfits { 'X'=>$x, 'Y'=>$y, hdr=>$h }, "table2.fits";
```

creates `table2.fits` where the first column is called `Y` and the second column is `X`.

- multi-value handling

  If you feed in a perl array-ref rather than a PDL or a hash, then each element is written out as a separate HDU in the FITS file. Each element of the list must be a PDL or a hash.

- DEVEL NOTES

  ASCII tables are not yet handled but should be.

  Binary tables currently only handle one vector (up to 1-D array) per table entry; the standard allows more, and should be fully implemented.

  Handling multidim arrays implies that perl multidim lists should also be handled.

For integer types (ie `BITPIX > 0`), the `BLANK` keyword is set to the bad value. For floating-point types, the bad value is converted to NaN (if necessary) before writing.

fits_field_cmp

fits_field_cmp

Sorting comparison routine that makes proper sense of the digits at the end of some FITS header fields. Sort your hash keys using "fits_field_cmp" and you will get (e.g.) your "TTYPE" fields in the correct order even if there are 140 of them.

This is a standard perl comparison sub – it uses the magical $a and $b variables, rather than normal argument passing.

_rows()

Return the number of rows in a variable for table entry

You feed in a PDL or a list ref, and you get back the 0th dimension.

_prep_table()

Accept a hash ref containing a table, and return a header describing the table and a string to be written out as the table, or barf.

You can indicate whether the table should be binary or ascii. The default is binary; it can be overridden by the "tbl" field of the hash (if present) or by parameter.

PDL::IO::Misc

Reading and writing ndarrays as text, and byte-order swapping.

```
use PDL;
my $x = short(1, 256);
bswap2($x);
print "$x ", isbigendian() ? "big" : "little", "-endian\n";   # [256␣
 ↪1] little-endian
```

`rcols` reads columns of numbers from a file into ndarrays and `wcols` writes ndarrays as columns; `swcols` writes them to a string, `rgrep` pulls values out of lines matching a pattern, `rasc` reads numbers from an ASCII file into an existing ndarray, and `rcube`

stacks images into a cube. `bswap2`, `bswap4`, `bswap8`, `bswap12`, `bswap16`, `bswap24` and `bswap32` reverse the bytes of each element in place; `isbigendian` reports the host's byte order.

This is PDL::IO::Misc of PDL 2.106: upstream's Perl, unchanged, over PDL's own kernels run by pperl's engine. `use PDL` loads it.

PDL::IO::Pic

image I/O for PDL

DESCRIPTION

This package implements I/O for a number of popular image formats by exploiting the xxxtopnm and pnmtoxxx converters from the netpbm package (which is based on the original pbmplus by Jef Poskanzer).

Netpbm is available at ftp://wuarchive.wustl.edu/graphics/graphics/packages/NetPBM/ Pbmplus (on which netpbm is based) might work as well, I haven't tried it. If you want to read/write JPEG images you additionally need the two converters cjpeg/djpeg which come with the libjpeg distribution (the "official" archive site for this software is ftp://ftp.uu.net/graphics/jpeg).

Image I/O for all formats is established by reading and writing only the PNM format directly while the netpbm standalone apps take care of the necessary conversions. In accordance with netpbm parlance PNM stands here for 'portable any map' meaning any of the PBM/PGM/PPM formats.

As it appeared to be a reasonable place this package also contains the routine wmpeg to write mpeg movies from PDLs representing image stacks (the image stack is first written as a sequence of PPM images into some temporary directory). For this to work you need the program ffmpeg also.

Configuration

The executables from the netpbm package are assumed to be in your path. Problems in finding the executables may show up as PNM format errors when calling wpic/rpic. If you run into this kind of problem run your program with perl `-w` so that perl prints a message if it can't find the filter when trying to open the pipe. [']

FUNCTIONS

rpiccan, wpiccan

Test which image formats can be read/written

```
$im = PDL->rpic('PDL.jpg') if PDL->rpiccan('JPEG');
@wformats = PDL->wpiccan();
```

finds out if PDL::IO::Pic can read/write certain image formats. When called without arguments returns a list of supported formats. When called with an argument returns true if format is supported on your computer (requires appropriate filters in your path), false otherwise.

rpic

Read images in many formats with automatic format detection.

```
$im = rpic $file;
$im = PDL->rpic 'PDL.jpg' if PDL->rpiccan('JPEG');
```

Options

```
FORMAT  =>  'JPEG'   # explicitly read this format
XTRAFLAGS => '-nolut'  # additional flags for converter
```

Reads image files in most of the formats supported by netpbm. You can explicitly specify a supported format by additionally passing a hash containing the FORMAT key as in

```
$im = rpic ($file, {FORMAT => 'GIF'});
```

This is especially useful if the particular format isn't identified by a magic number and doesn't have the 'typical' extension or you want to avoid the check of the magic number if your data comes in from a pipe. The function returns a pdl of the appropriate type upon completion. Option parsing uses the *PDL::Options* module and therefore supports minimal options matching.

You can also read directly into an existing pdl that has to have the right size(!). This can come in handy when you want to read a sequence of images into a datacube, e.g.

```
$stack = zeroes(byte,3,500,300,4);
rpic $stack->slice(':,:,:,(0)'),"PDL.jpg";
```

reads an rgb image (that had better be of size (500,300)) into the first plane of a 3D RGB datacube (=4D pdl datacube). You can also do transpose/inversion upon read that way.

wpic

Write images in many formats with automatic format selection.

```
Usage: wpic($pdl,$filename[,{ options... }])
```

```
wpic $pdl, $file;
$im->wpic('web.gif',{LUT => $lut});
for (@images) {
  $_->wpic($name[0],{CONVERTER => 'ppmtogif'})
}
```

Write out an image file. Function will try to guess correct image format from the filename extension, e.g.

```
$pdl->wpic("image.gif")
```

will write a gif file. The data written out will be scaled to byte if input is of type float/double. Input data that is of a signed integer type and contains negative numbers will be rejected (assuming the user should have the desired conversion to an unsigned type al-

ready). A number of options can be specified (as a hash reference) to get more direct control of the image format that is being written. Valid options are (key => example_value):

```
CONVERTER  => 'ppmtogif',   # explicitly specify pbm converter
FLAGS      => '-interlaced -transparent 0',  # flags for converter
IFORM      => 'PGM',        # explicitly specify intermediate format
XTRAFLAGS  => '-imagename iris', # additional flags to defaultflags
FORMAT     => 'PCX',        # explicitly specify output image format
COLOR      => 'bw',         # specify color conversion
LUT        => $lut,         # use color table information
```

Option parsing uses the *PDL::Options* module and therefore supports minimal options matching. A detailed explanation of supported options follows.

- CONVERTER

  directly specify the converter, you had better know what you are doing, e.g.

  ```
  CONVERTER  => 'ppmtogif',
  ```

- FLAGS

  flags to use with the converter; ignored if !defined($$hints{CONVERTER}), e.g. with the gif format

  ```
  FLAGS      => '-interlaced -transparent 0',
  ```

- IFORM

  intermediate PNM/PPM/PGM/PBM format to use; you can append the strings 'RAW' or 'ASCII' to enforce those modes, eg IFORMAT=>'PGMRAW' or

  ```
  IFORM    => 'PGM',
  ```

- XTRAFLAGS

  additional flags to use with an automatically chosen converter, this example works when you write SGI files (but will give an error otherwise)

  ```
  XTRAFLAGS => '-imagename iris',
  ```

- FORMAT

  explicitly select the format you want to use. Required if wpic cannot figure out the desired format from the file name extension. Supported types are currently TIFF,GIF,SGI,PNM,JPEG,PS,RAST(Sun Raster),IFF,PCX, e.g.

  ```
  FORMAT     => 'PCX',
  ```

- COLOR

  you want black and white (value **bw**), other possible value is **bwdither** which will write a dithered black&white image from the input data, data conversion will be done appropriately, e.g.

```
COLOR       => 'bw',
```

- LUT

  This is a palette image and the value of this key should be a pdl containing an RGB lookup table (3,x), e.g.

```
LUT         => $lut,
```

Using the CONVERTER hint you can also build a pipe and perform several netpbm operations to get the special result you like. Using it this way the first converter/filecommand in the pipe should be specified with the CONVERTER hint and subsequent converters + flags in the FLAGS hint. This is because wpic tries to figure out the required format to be written by wpnm based on the first converter. Be careful when using the PBMBIN var as it will only be prepended to the converter. If more converters are in the FLAGS part specify the full path unless they are in your PATH anyway.

Example:

```
$im->wpic('test.ps',{CONVERTER  => 'pgmtopbm',
                     FLAGS => "-dither8 | pnmtops" })
```

Some of the options may appear silly at the moment and probably are. The situation will hopefully improve as people use the code and the need for different/modified options becomes clear. The general idea is to make the function perl compliant: easy things should be easy, complicated tasks possible.

rim

```
Usage: $x = rim($file);
or        rim($x,$file);
```

Read images in most formats, with improved RGB handling.

You specify a filename and get back a PDL with the image data in it. Any PNM handled format or FITS will work. In the second form, $x is an existing PDL that gets loaded with the image data.

If the image is in one of the standard RGB formats, then you get back data in (,,) format – that is to say, the third dim contains the color information. That allows you to do simple indexing into the image without knowing whether it is color or not – if present, the RGB information is silently broadcasted over. (Contrast "rpic", which munges the information by putting the RGB index in the 0th dim, screwing up subsequent broadcasting operations).

If the image is in FITS format, then you get the data back in exactly the same order as in the file itself.

Images with a ".Z" or ".gz" extension are assumed to be compressed with UNIX "compress" or "gzip", respectively, and are automatically uncompressed before reading.

OPTIONS

The same as "rpic", which is used as an engine:

- FORMAT

  If you don't specify this then formats are autodetected. If you do specify it then only the specified interpreter is tried. For example,

```
$x = rim("foo.gif",{FORMAT=>"JPEG"})
```

  forces JPEG interpretation.

- XTRAFLAGS

  Contains extra command line flags for the pnm interpreter. For example,

```
$x = rim("foo.jpg",{XTRAFLAGS=>"-nolut"})
```

  prevents use of a lookup table in JPEG images.

wim

Write a pdl to an image file with selected type (or using filename extensions)

```
wim $pdl,$file;
$pdl->wim("foo.gif",{LUT=>$lut});
```

Write out an image file. You can specify the format explicitly as an option, or the function will try to guess the correct image format from the filename extension, e.g.

```
$pdl->wim("image.gif");
$pdl->wim("image.fits");
```

will write a gif and a FITS file. The data written out will be scaled to byte if the input if of type float/double. Input data that is of a signed integer type and contains negative numbers will be rejected.

If you append `.gz` or `.Z` to the end of the file name, the final file will be automatically compressed with "gzip" | "compress", respectively.

OPTIONS

You can pass in a hash ref whose keys are options. The code uses the PDL::Options module so unique abbreviations are accepted. Accepted keys are the same as for "wpic", which is used as an engine:

- CONVERTER

  Names the converter program to be used by pbmplus (e.g. "ppmtogif" to output a gif file)

- FLAGS

  Flags that should be passed to the converter (replacing any default flag list) e.g. "-interlaced" to make an interlaced GIF

- IFORM

  Explicitly specifies the intermediate format (e.g. PGM, PPM, or PNM).

- XTRAFLAGS

  Flags that should be passed to the converter (in addition to any default flag list).

- FORMAT

  Explicitly specifies the output image format (allowing pbmplus to pick an output converter)

- COLOR

  Specifies color conversion (e.g. 'bw' converts to black-and-white; see pbmplus for details).

- LUT

  Use color-table information

rmpeg

Read an image sequence (a (3,x,y,n) byte pdl) from an animation.

```
$ndarray = rmpeg('movie.mpg'); # $ndarray is (3,x,y,nframes) byte
```

Reads a stack of RGB images from a movie. While the format generated is nominally MPEG, the file extension is used to determine the video encoder type. It uses the program `ffmpeg`, and throws an exception if not found.

wmpeg

Write an image sequence (a (3,x,y,n) byte pdl) as an animation.

```
$ndarray->wmpeg('movie.mpg'); # $ndarray is (3,x,y,nframes) byte
```

Writes a stack of RGB images as a movie. While the format generated is nominally MPEG, the file extension is used to determine the video encoder type. E.g. `.mpg` for MPEG-1 encoding, `.mp4` for MPEG-4 encoding, `.gif` for GIF animation

`wmpeg` requires a 4-D pdl of type **byte** as input. The first dim **has** to be of size 3 since it will be interpreted as RGB pixel data. `wmpeg` returns 1 on success and undef on failure.

```
use strict; use warnings;
use PDL;
use PDL::IO::Pic;
my ($width, $height, $framecount, $xvel, $maxheight, $ballsize) =
 ↪(320, 80, 100, 15, 60, 8);
my $frames = zeros byte, $width, $height, $framecount;
my $coords = yvals(3, $framecount); # coords for drawing ball, all
 ↪val=frameno
my ($xcoords, $ycoords) = map $coords->slice($_), 0, 1;
$xcoords *= $xvel; # moves $xvel pixels/frame
$xcoords .= $width - abs(($xcoords % (2*$width)) - $width); # back
 ↪and forth
my $sqrtmaxht = sqrt $maxheight;
$ycoords .= indx($maxheight - (($ycoords % (2*$sqrtmaxht)) -
```

(continues on next page)

(continued from previous page)

```
 ↪$sqrtmaxht)**2));
my $val = pdl(byte,250);  # start with white
$frames->range($coords, [$ballsize,$ballsize,1], 't') .= $val;
$frames = $frames->dummy(0, 3)->copy; # now make the movie
$frames->wmpeg('bounce.gif');  # or bounce.mp4, ffmpeg deals OK

# iterate running this with:
rm bounce.gif; perl scriptname.pl && animate bounce.gif
```

Some of the input data restrictions will have to be relaxed in the future but routine serves as a proof of principle at the moment. It uses the program ffmpeg to encode the frames into video. Currently, wmpeg doesn't allow modification of the parameters written through its calling interface. This will change in the future as needed.

In the future it might be much nicer to implement a movie perl object that supplies methods for manipulating the image stack (insert, cut, append commands) and a final movie->make() call would invoke ffmpeg on the picture stack (which will only be held on disk). This should get around the problem of having to hold a huge amount of data in memory to be passed into wmpeg (when you are, e.g. writing a large animation from PDL3D rendered fly-throughs).

imageformat

Figure out the format of an image file from its magic numbers, or else, from its extension.

Currently recognized image formats are: PNM, GIF, TIFF, JPEG, SGI, RAST, IFF, PCX, PS, FITS, PNG, XBM. If the format can not be determined, the string 'UNKNOWN' is returned.

```
$format=imageformat($path); # find out image format of certain file
print "Unknown image format" if $format eq 'UNKNOWN';
$canread=rpiccan($format); # check if this format is readable in␣
 ↪this system
if($canread){
    $pdl=rpic($path) ; # attempt to read image ONLY if we can
} else {
    print "Image can't be read\n"; # skip unreadable file
}
```

BUGS

Currently only a random selection of converters/formats provided by pbmplus/netpbm is supported. It is hoped that the more important formats are covered. Other formats can be added as needed. Please send patches to the author.

PDL::IO::Pnm

Reading and writing images in the PNM formats: PBM, PGM and PPM.

```
use PDL;
use PDL::IO::Pnm;
use File::Temp qw(tempdir);
my $file = tempdir(CLEANUP => 1) . "/img.pgm";
wpnm(byte([[0, 128], [255, 64]]), $file, 'PGM', 1);
my $im = rpnm($file);
print $im->flat, " ", $im->type, "\n";            # [0 128 255 64]␣
 ↪byte
```

`rpnm($file)` reads a PBM, PGM or PPM file, raw or ASCII, into an ndarray - 2-D for grey levels, `(3, width, height)` for colour - and `wpnm($im, $file, $format, $raw)` writes one. `pnminraw`, `pnminascii` and `pnmout` are the kernels underneath, reading and writing through a Perl filehandle.

This is PDL::IO::Pnm of PDL 2.106: upstream's Perl, unchanged, over PDL's own kernels run by pperl's engine. PDL::IO::Pic uses it, so `use PDL` loads it.

PDL::IO::Storable

helper functions to make PDL usable with serialisation packages

SYNOPSIS

```
use Storable;
use PDL::IO::Storable;
$hash = {
          'foo' => 42,
          'bar' => zeroes(23,45),
        };
store $hash, 'perlhash.dat';

use JSON::MaybeXS;
$encoder = JSON::MaybeXS->new(allow_tags => 1);
my $ndarray = xvals (5,2);
my $encoded_json = $encoder->encode ($ndarray);
my $decoded_ndarray = $encoder->decode ($encoded_json);
```

DESCRIPTION

Serialisation packages such as `Storable`, `Sereal`, `JSON::MaybeXS` and `CBOR::XS` implement object persistence for Perl data structures that can contain arbitrary Perl objects. This module implements the relevant methods to be able to store and retrieve ndarrays via `Storable` as well as packages that support the *Types::Serialiser* protocol (currently Sereal, CBOR::XS and JSON packages).

Note that packages supporting the `Types::Serialiser` protocol need to have their respective flags enabled so that the FREEZE and THAW callbacks are used.

Note also that while JSON::MaybeXS is supported, if it has to fall back to *JSON::PP*, it will fail. *JSON::XS* treats the data it gets back from `FREEZE` as items to encode, while *JSON::PP* treats the list it gets as strings already encoded. They are fundamentally incompatible, so this module supports the JSON::XS option.

Finally, data flow is not preserved. If a data structure containing ndarrays connected by data flow is serialised then this will need to be explicitly reinstated on deserialisation.

FUNCTIONS

store

store an ndarray using *Storable*

```
$x = random 12,10;
$x->store('myfile');
```

freeze

freeze an ndarray using *Storable*

```
$x = random 12,10;
$frozen = $x->freeze;
```

PDL::Image2D

Two-dimensional image processing: median filters, polygon filling, connected components, rotation and warping.

```
use PDL;
use PDL::Image2D;
my $im = zeroes(long, 5, 5);
polyfill($im, float([[1, 1], [3, 1], [3, 3], [1, 3]]), 7);
print $im->sum, " ", sequence(5, 4)->med2d(ones(3, 3))->at(2, 2), "\
 ↪n";   # 63 12
```

`med2d` and `med2df` are median filters (by a kernel, or by a box); `polyfill`, `polyfillv`, `pnpoly` fill or select the inside of a polygon; `cc8compt`, `cc4compt` and `ccNcompt` label connected components; `max2d_ind` and `centroid2d` locate features; `rot2d` and `rotnewsz` rotate a byte image; `fitwarp2d`, `applywarp2d`, `warp2d` and `warp2d_kernel` fit and apply a polynomial distortion; `conv2d` convolves with a kernel (`{ Boundary`

`=> 'Reflect' }` and the like choose the edge treatment), `box2d` is a box-mean filter, `patch2d` and `patchbad2d` replace marked or bad pixels by the mean of their neighbours, `bilin2d` and `rescale2d` resample into an ndarray of another size, and `crop` gives the bounding box of the non-zero pixels.

`polyfill_pp`, `pnpoly_pp` and `pnpolyfill_pp` are the kernels under `polyfill`, `pnpoly` and `polyfillv`.

This is PDL::Image2D of PDL 2.106: upstream's Perl, unchanged, over PDL's own kernels and support C run by pperl's engine.

Functions

Other Functions

`rotnewsz`

`($cols, $rows) = rotnewsz($m, $n, $angle)` - the size of an `$m` by `$n` image once `rot2d` has turned it by `$angle` degrees.

PDL::ImageND

Image processing in any number of dimensions: convolution, rebinning, interpolation, circular masks, contours and graph layout forces.

```
use PDL;
use PDL::ImageND;
print convolveND(sequence(5), pdl(1, 1, 1)), "\n";        # [1 3 6 9
 ↪7]
print rebin(sequence(4), 2), " ", kernctr(sequence(4), pdl(1, 2,
 ↪1))->flat, "\n";
# [0.5 2.5] [2 1 0 1]
```

`convolveND($a, $kernel, { boundary => 'periodic' })` convolves in as many dimensions as the kernel has, with a choice of boundary conditions and of the direct or the FFT method; `convolve` is the older form, wrapping around. `rebin($a, @dims)` changes the size by averaging or replicating (`{ Norm => 1 }` keeps the sum), `ninterpol($point, $data, $n)` interpolates linearly in the first `$n` dimensions, `kernctr($image, $kernel)` pads a kernel to the size of an image for the FFT, and `circ_mean` and `circ_mean_p` average around rings. `contour_segments` and `contour_polylines` trace a contour level through a 2-D field, `path_join` and `path_segs` turn edges into paths, `combcoords` packs three coordinates into one ndarray, and `attract` and `repulse` compute the spring and the repulsive forces of a graph layout.

This is PDL::ImageND of PDL 2.106: upstream's Perl, unchanged, over PDL's own kernels run by pperl's engine.

PDL::ImageRGB

Utility functions for RGB image data: palette quantisation, palette lookup, conversion to grey, and scaling to bytes.

```
use PDL;
use PDL::ImageRGB;
print rgbtogr(byte([[10, 20, 30]])), " ", bytescl(pdl(0, 500, 1000),
 ↪100), "\n";   # [18] [0 50 100]
my $lut = byte([[0, 0, 0], [255, 255, 255]]);
print interlrgb(byte(1, 0), $lut)->flat, "\n";        # [255 255 255
 ↪0 0 0]
```

An RGB image here is `(3, width, height)`. `cquant($image, $ncolours)` reduces an RGB byte image to a palette image and its colour table; `interlrgb($palette_image, $lut)` turns one back into RGB; `rgbtogr` converts RGB to grey levels; `bytescl` scales an ndarray into 0..255 (or another top) as bytes.

This is PDL::ImageRGB of PDL 2.106: upstream's Perl, unchanged, over PDL's own `cquant_c` kernel (ppm_quant) run by pperl's engine.

PDL::Lite

PDL with methods only: the core modules loaded, four names imported.

```
use PDL::Lite;
my $x = pdl(1, 2, 3);
print $x->sum, " ", PDL->zeroes(2), " ", defined &main::zeroes ?
 ↪"imported" : "methods only", "\n";   # 6 [0 0] methods only
```

`use PDL::Lite` loads PDL::Core, PDL::Ops, PDL::Primitive, PDL::Ufunc, PDL::Basic, PDL::Slices and PDL::Bad, and imports only `pdl`, `piddle`, `null` and `barf`: everything else is called as a method, or fully qualified. For the same modules with their functions imported, use PDL::LiteF; for the whole of PDL, `use PDL`.

This is PDL::Lite of PDL 2.106: upstream's Perl, unchanged.

PDL::LiteF

The core PDL modules, with their functions imported.

```
use PDL::LiteF;
print sum(pdl(1, 2, 3)), " ", zeroes(2), " ", defined &main::det ?
 ↪"MatrixOps" : "no MatrixOps", "\n";   # 6 [0 0] no MatrixOps
```

`use PDL::LiteF` loads the modules PDL::Lite does - PDL::Core, PDL::Ops, PDL::Primitive, PDL::Ufunc, PDL::Basic, PDL::Slices and PDL::Bad - and imports each one's functions, as `use PDL` does. Unlike `use PDL` it leaves out PDL::Math, PDL::MatrixOps and the IO modules.

This is PDL::LiteF of PDL 2.106: upstream's Perl, unchanged.

PDL::Math

PDL's mathematical functions: trigonometric and hyperbolic, rounding, error and Bessel functions, log gamma, complex square roots, logarithms and inverses, and polynomials.

```
use PDL;
print floor(pdl(1.5, -1.5)), " ", ceil(pdl(1.5, -1.5)), " ",␣
↪rint(pdl(0.5, 1.5, 2.5)), "\n";   # [1 -2] [2 -1] [0 2 2]
printf "%.4f %.4f %.4f\n", asin(pdl(1)), tanh(pdl(1)), erf(pdl(1));␣
↪                  # 1.5708 0.7616 0.8427
print isfinite(pdl(1, 9**9**9, -9**9**9)), "\n";                    ␣
↪              # [1 0 0]
my ($lg, $sign) = lgamma(pdl(5));
print "$lg $sign ", pow(byte(2), 3), "\n";                          ␣
↪               # 3.17805383034795 1 8
print clog(czip(0, 1)), "\n";                                       ␣
↪              # 1.57079637050629i
```

Each function works element by element and broadcasts; most work in place (`$x->inplace->floor`). `sin`, `cos`, `exp`, `log` and `sqrt` are PDL::Ops's, as upstream has them. The `c...` functions take real input as complex, so `csqrt(-4)` is `2i` where `sqrt(-4)` is NaN.

This is PDL::Math of PDL 2.106. The kernels are PDL's own, through pperl's engine; `polyroots` (the roots of a polynomial), `polyfromroots` (its coefficients from the roots) and `polyval` (its value at a point), all with coefficients in decreasing powers, are upstream's Perl unchanged.

PDL::MatrixOps

Linear algebra on PDL's ndarrays: determinants, inverses, LU, singular value and eigen decompositions, linear systems, triangular storage.

```
use PDL;
use PDL::MatrixOps;
my $m = pdl([4, 7], [2, 6]);
print det($m), " ", inv($m)->flat, "\n";                    # 10 [0.6␣
↪-0.7 -0.2 0.4]
print identity(2)->flat, " ", ($m x inv($m))->flat, "\n";  # [1 0 0␣
↪1] [1 0 0 1]
my ($u, $s, $v) = svd(pdl([3, 0], [0, 4]));
print "$s\n";                                               # [4 3]
my ($ev, $e) = eigens_sym(pdl([2, 1], [1, 2]));
print qsort($e), "\n";                                      # [1 3]
```

A matrix is a 2-D ndarray indexed `(column, row)`, and every function broadcasts over further dimensions, so a stack of matrices is one call. `x` is matrix multiplication (PDL::Primitive's `matmult`).

This is PDL::MatrixOps of PDL 2.106. The kernels are PDL's own, through pperl's engine; upstream's Perl is used unchanged for `identity`, `stretcher`, `inv`, `det`, `determinant`, `lu_decomp`, `lu_decomp2`, `lu_backsub`, `eigens`, `eigens_sym`, `gurney` and `tritosym`.

PDL::Ops

PDL's operators: arithmetic, comparison, bitwise and the unary functions, element by element, as the functions behind Perl's operators on ndarrays.

```
use PDL;
my ($a, $b) = (pdl(1, 2, 3), pdl(4, 5, 6));
print $a + $b, " ", $a * $b, " ", $b ** 2, " ", $b % 4, "\n";   # [5␣
↪7 9] [4 10 18] [16 25 36] [0 1 2]
print $a > 1, " ", $a <=> 2, " ", -$a, "\n";                    # [0 1␣
↪1] [-1 0 1] [-1 -2 -3]
print sqrt(pdl(4, 9)), " ", abs(pdl(-2, 3)), " ", log10(pdl(10,␣
↪100)), "\n";   # [2 3] [2 3] [1 2]
print pdl(6) & 3, " ", byte(250) + 10, "\n";                 # 2 4
my $z = czip(3, 4);
print $z, " ", abs($z), " ", $z->re, " ", conj($z), "\n";    # 3+4i␣
↪5 3 3-4i
my $x = $a;
$x += 10;
print "$a\n";                                                # [11 12␣
↪13]
```

Every operation broadcasts: operands of different shapes are matched dimension by dimension, a dimension of size 1 (or a Perl number) repeated to fit. The result has the larger operand type - `byte(250) + 10` stays a byte and wraps. A binary operation takes an output and a swap flag: `minus($a, $b, $c, 1)` writes `$b - $a` into `$c`. With three arguments the third is the swap flag, as perl's overloading passes it - `minus($a, $b, 1)` returns `$b - $a`. With `$a->inplace` the result is written into `$a`.

The operators are overloaded with these functions: `+ - * / ** %`, `== != < > <= >= <=>`, `& | ^ << >> ~ !`, `atan2 sqrt abs sin cos exp log`, every assignment form (`+=` and the rest rewrite the left ndarray, so `$x += 1` reaches every name of it), `++`, `--` and `.=` (assignment into an ndarray or a view of one: `assgn`). Unary minus is perl's `0 - $x`. `eq` compares element-wise and warns when the other operand is neither a number nor an ndarray; the other string operators are not overloaded and die.

This is PDL::Ops of PDL 2.106. The kernels are PDL's own, through pperl's engine. The overload handlers are upstream's Perl (`PDL::overload_plus` and the rest), each with a native fast path in its place that hands anything unusual back to it; `abs` (`_rabs` for real types, `_cabs` for complex), `log10`, `r2C` and `i2C` are upstream's Perl unchanged.

PDL::Options

simplifies option passing by hash in PerlDL

SYNOPSIS

```
use PDL::Options;

%hash = parse( \%defaults, \%user_options);

```

(continues on next page)

(continued from previous page)

```
use PDL::Options ();

$opt = PDL::Options->new;
$opt = PDL::Options->new( \%defaults );

$opt->defaults ( \%defaults );
$opt->synonyms ( { 'COLOR' => 'COLOUR' } );

$hashref = $opt->defaults;

$opt->options ( \%user_options );

$hashref = $opt->options;

$opt->incremental(1);
$opt->full_options(0);
```

DESCRIPTION

Object to simplify option passing for PerlDL subroutines. Allows you to merge a user defined options with defaults. A simplified (non-OO) interface is provided.

Utility functions

ifhref

```
parse({Ext => 'TIF', ifhref($opt)});
```

just return the argument if it is a hashref otherwise return an empty hashref. Useful in conjunction with parse to return just the default values if argument is not a hash ref

NON-OO INTERFACE

A simplified non-object oriented interface is provided. These routines are exported into the callers namespace by default.

- parse(\%defaults, \%user_options)

  This will parse user options by using the defaults. The following settings are used for parsing: The options are case-sensitive, a default synonym table is consulted (see “Default Synonyms”), minimum-matching is turned on, and translation of values is not performed.

  A hash (not hash reference) containing the processed options is returned.

  ```
  %options = parse( { LINE => 1, COLOUR => 'red'}, { COLOR =>
  ↪'blue'});
  ```

- iparse(\%defaults, \%user_options)

  Same as `parse` but matching is case insensitive

Default Synonyms

The following default synonyms are available in the non-OO interface:

```
COLOR  => COLOUR
COLOUR => COLOR
CENTER => CENTRE
CENTRE => CENTER
```

METHODS

The following methods are available to PDL::Options objects.

- new()

  Constructor. Creates the object. With an optional argument can also set the default options.

- extend (\%options)

  This will copy the existing options object and extend it with the requested extra options.

- defaults(\%defaults)

  Method to set or return the current defaults. The argument should be a reference to a hash. The hash reference is returned if no arguments are supplied.

  The current values are reset whenever the defaults are changed.

- add_synonym (\%synonyms)

  Method to add another synonym to an option set The argument should be a reference to a hash.

- add_translation (\%translation)

  Method to add another translation rule to an option set. The argument should be a reference to a hash.

- synonyms(\%synonyms)

  Method to set or return the current synonyms. The argument should be a reference to a hash. The hash reference is returned if no arguments are supplied.

  This allows you to provide alternate keywords (such as allowing 'COLOR' as an option when your defaults uses 'COLOUR').

- current

  Returns the current state of the options. This is returned as a hash reference (although it is not a reference to the actual hash stored in the object). If full_options() is true the full options hash is returned, if full_options() is false only the modified options are returned (as set by the last call to options()).

- clear_current

  This routine clears the 'state' of the `PDL::Options` object so that the next call to current will return an empty list

- translation

  Provide translation of options to more specific values that are recognised by the program. This allows, for example, the automatic translation of the string 'red' to '#ff0000'.

  This method can be used to setup the dictionary and is hash reference with the following structure:

```
OPTIONA => {
            'string1' => decode1,
            'string2' => decode2
            },
OPTIONB => {
            's4' => decodeb1,
           }
etc....
```

  Where OPTION? corresponds to the top level option name as stored in the defaults array (eg LINECOLOR) and the anonymous hashes provide the translation from string1 ('red') to decode1 ('#ff0000').

  An options string will be translated automatically during the main options() processing if autotrans() is set to true. Else translation can be initiated by the user using the translate() method.

- incremental

  Specifies whether the user defined options will be treated as additions to the current state of the object (1) or modifications to the default values only (0).

  Can be used to set or return this value. Default is false.

- full_options

  Governs whether a complete set of options is returned (ie defaults + expanded user options), true, or if just the expanded user options are returned, false (ie the values specified by the user).

  This can be useful when you are only interested in the changes to the options rather than knowing the full state. (For example, if defaults contains keys for COLOUR and LINESTYLE and the user supplied a key of COL, you may simply be interested in the modification to COLOUR rather than the state of LINESTYLE and COLOUR.)

  Default is true.

- casesens

  Specifies whether the user defined options will be processed independent of case (0) or not (1). Default is to be case insensitive.

  Can be used to set or return this value.

- minmatch

  Specifies whether the user defined options will be minimum matched with the defaults (1) or whether the user defined options should match the default keys exactly. Defaults is true (1).

If a particular key matches exactly (within the constraints imposed bby case sensitivity) this key will always be taken as correct even if others are similar. For example COL would match COL and COLOUR but this implementation will always return COL in this case (note that for CO it will return both COL and COLOUR and pick one at random.

Can be used to set or return this value.

- autotrans

  Specifies whether the user defined options will be processed via the translate() method immediately following the main options parsing. Default is to autotranslate (1).

  Can be used to set or return this value.

- casesenstrans

  Specifies whether the keys in the options hash will be matched insensitive of case (0) during translation() or not (1). Default is to be case insensitive.

  Can be used to set or return this value.

- minmatchtrans

  Specifies whether the keys in the options hash will be minimum matched during translation(). Default is false (0).

  If a particular key matches exactly (within the constraints imposed bby case sensitivity) this key will always be taken as correct even if others are similar. For example COL would match COL and COLOUR but this implementation will always return COL in this case (note that for CO it will return both COL and COLOUR and pick one at random.

  Can be used to set or return this value.

- warnonmissing

  Turn on or off the warning message printed when an options is not in the options hash. This can be convenient when a user passes a set of options that has to be parsed by several different option objects down the line.

- debug

  Turn on or off debug messages. Default is off (0). Can be used to set or return this value.

- options

  Takes a set of user-defined options (as a reference to a hash) and merges them with the current state (or the defaults; depends on the state of incremental()).

  The user-supplied keys will be compared with the defaults. Case sensitivity and minimum matching can be configured using the mimatch() and casesens() methods.

  A warning is raised if keys present in the user options are not present in the defaults unless warnonmissing is set.

  A reference to a hash containing the merged options is returned.

```
$merged = $opt->options( { COL => 'red', Width => 1});
```

The state of the object can be retrieved after this by using the current() method or by using the options() method with no arguments. If full_options() is true, all options are returned (options plus overrides), if full_options() is false then only the modified options are returned.

Synonyms are supported if they have been configured via the synonyms() method.

- translate

  Translate the current option values (eg those set via the options() method) using the provided translation().

  This method updates the current state of the object and returns the updated options hash as a reference.

```
$ref = $opt->translate;
```

EXAMPLE

Two examples are shown. The first uses the simplified interface and the second uses the object-oriented interface.

Non-OO

```
use PDL::Options (':Func');

%options = parse( {
                LINE => 1,
                COLOUR => 'red',
               },
               {
                COLOR => 'blue'
               }
             );
```

This will return a hash containing

```
%options = (
             LINE => 1,
             COLOUR => 'blue'
           )
```

Object oriented

The following example will try to show the main points:

```
use PDL::Options ();

# Create new object and supply defaults
```

(continues on next page)

(continued from previous page)

```
$opt = PDL::Options->new(    { Colour => 'red',
                               LineStyle => 'dashed',
                               LineWidth => 1
                             }
                         );

# Create synonyms
$opt->synonyms( { Color => 'Colour' } );

# Create translation dictionary
$opt->translation( { Colour => {
                        'blue' => '#0000ff',
                        'red'  => '#ff0000',
                        'green'=> '#00ff00'
                               },
                     LineStyle => {
                      'solid' => 1,
                      'dashed' => 2,
                      'dotted' => 3
                      }
                   }
                 );

# Generate and parse test hash
$options = $opt->options( { Color => 'green',
                            lines => 'solid',
                          }
                        );
```

When this code is run, $options will be the reference to a hash containing the following:

```
Colour => '#00ff00',
LineStyle => 1,
LineWidth => 1
```

If full_options() was set to false (0), $options would be a reference to a hash containing:

```
Colour => '#00ff00',
LineStyle => 1
```

Minimum matching and case insensitivity can be configured for both the initial parsing and for the subsequent translating. The translation can be turned off if not desired.

Currently synonyms are not available for the translation although this could be added quite simply.

PDL::Primitive

PDL's primitives: products, selecting by a mask, clipping, searching sorted data, interpolation, set operations on vectors, statistics.

```
use PDL;
my ($a, $b) = (pdl(1, 2, 3), pdl(4, 5, 6));
print inner($a, $b), " ", crossp($a, $b), " ", norm(pdl(3, 4)), "\n
↪";   # 32 [-3 6 -3] [0.6 0.8]
print $a->clip(1.5, 2.5), " ", which($a > 1), " ", $a->where($a >␣
↪1), "\n";   # [1.5 2 2.5] [1 2] [2 3]
print uniq(pdl(3, 1, 3)), " ", append($a, 9), " ", vsearch(2.5, $a),␣
↪"\n";   # [1 3] [1 2 3 9] 2
print +(pdl([1, 2], [3, 4]) x pdl([1], [1]))->flat, "\n";       # [3␣
↪7]
my ($mean, $prms) = stats($b);
```

(continues on next page)

(continued from previous page)

```
print "$mean $prms ", interpol(1.5, $a, $b), "\n";                # 5
 ↪1 4.5
```

`where` returns a view: `$x->where($x < 0) .= 0` zeroes the negative elements of `$x`. `x` is matrix multiplication (`matmult`).

This is PDL::Primitive of PDL 2.106. The kernels are PDL's own, through pperl's engine; upstream's Perl is used unchanged for `matmult`, `append`, `glue`, `clip`, `hclip`, `lclip`, `stats`, `statsover`, `fibonacci`, `one2nd`, `uniq`, `uniqind`, `uniqvec`, `vsearch`, `interpND`, `whichND`, `whichND_both`, `whereND`, `whereND_both`, `where_both`, `setops`, `intersect`, the `...vec` and `..._sorted` set operations (`unionvec`, `intersectvec`, `setdiffvec`, `union_sorted`, `intersect_sorted`, `setdiff_sorted`), `conv1d`, and the random numbers: `random` (uniform in [0, 1)), `randsym` (uniform in (0, 1)), `grandom` (normal, mean 0 and standard deviation 1) and `srandom` (seeds them).

PDL::Slices

Take pieces of an ndarray, and rearrange the pieces you take.

```
use PDL;
my $m = sequence(4, 3);
print $m->slice("1:2,(0)"), " ", $m->slice(":,(-1)"), "\n";       #
 ↪[1 2] [8 9 10 11]
print $m->dice([0, 3], [2])->flat, " ", $m->xchg(0, 1)->dims, "\n";
 ↪ # [8 11] 34
print sequence(5)->index(pdl(4, 0)), " ", sequence(5)->rotate(1), "\
 ↪n";   # [4 0] [4 0 1 2 3]
my $row = $m->slice(":,1");
$row .= 0;
print $m->sum, " ", $m->clump(-1)->dims, "\n";                     #
 ↪44 12
my ($len, $val) = rle(pdl(5, 5, 7));
print "$len $val ", rld($len, $val), "\n";                        # [2
 ↪1] [5 7] [5 5 7]
```

Most of these return a view, not a copy: the result shares storage with the ndarray it came from, so writing into the view writes into the original - `$row .= 0` above zeroes a row of `$m`. Call `sever` or `copy` when the two should part company.

`slice` takes, per dimension, a range `"start:end:step"`, a single index in parentheses `"(i)"` (which drops the dimension) or nothing for all; negative indices count from the end. `dice` and `dice_axis` pick elements by number, `index`, `index1d` and `index2d` by an index ndarray, `range` gathers neighbourhoods around coordinates (and `indexND`, one element at each), `diagonal` takes a diagonal. The rest rearrange without changing values: `xchg`, `mv`, `reorder`, `flat`, `clump`, `splitdim`, `rotate`, `lags`, and `broadcast`/`unbroadcast` for broadcasting control. `rle`/`rld` and their `vec`, `seq` and `ND` forms encode and decode runs.

This is PDL::Slices of PDL 2.106. The kernels are PDL's own, through pperl's engine; upstream's Perl is used unchanged for `slice`, `dice`, `dice_axis`, `diagonal`, `reorder`, `meshgrid`, `using`, `rle`, `rld`, `rleND`, `rldND`, `rldvec`, `rldseq`, `indexND` and `indexNDb`.

PDL::Trans

Modules

- `PDL::Trans::VTable`

Functions

Dataflow and views

parents

`$trans->parents` - the ndarrays the transformation reads.

children

`$trans->children` - the ndarrays the transformation produces.

address

`$trans->address` - the memory address of the transformation, the number its reference holds. For debugging.

bvalflag

`$trans->bvalflag` - whether the transformation handles bad values.

flags

`$trans->flags` - the names of the flags set on the transformation, such as `PDL_ITRANS_ISAFFINE`.

vtable

`$trans->vtable` - the description of the operation behind the transformation, a `PDL::Trans::VTable` object.

affine

`$trans->affine` - 1 when the transformation is a view expressed as an offset and a step per dimension, 0 otherwise.

offs

`$trans->offs` - the offset of an affine view into its parent's data.

incs

`$trans->incs` - the step per dimension of an affine view. Dies for a transformation that is not affine.

trans_children_indices

`$trans->trans_children_indices` - for each parent, the slot the transformation occupies in that parent's list of children.

ind_sizes

`$trans->ind_sizes` - the size of each named dimension of the operation's signature.

inc_sizes

`$trans->inc_sizes` - the step in elements for each dimension of each parameter of the operation.

PDL::Trans::VTable

Functions

Dataflow and views

name

`$vtable->name` - the name of the operation, such as `PDL::Ops::plus`.

flags

`$vtable->flags` - the names of the flags of the operation, such as `PDL_TRANS_DO_BROADCAST`.

par_names

`$vtable->par_names` - two array references: the names of the operation's input parameters, and of its outputs.

dump

`$vtable->dump` - print the description of an operation to standard output.

PDL::Transform

Coordinate transformations as objects, and the resampling of images through them.

```
use PDL;
use PDL::Transform;
my $t = t_linear(scale => 2, pre => pdl(1, 0));
```

(continues on next page)

(continued from previous page)

```
print $t->apply(pdl(1, 1)), " ", $t->invert(pdl(4, 2)), "\n";     #␣
↪[4 2] [1 1]
print sequence(3, 3)->map(t_linear(rot => 90), { method => 'sample'␣
↪})->slice(':,(0)'), "\n";
# [2 5 8]
```

A transformation is made by a constructor - `t_linear` (scale, rotation, offset, matrix), `t_scale`, `t_offset`, `t_rot`, `t_identity`, `t_lookup` (a table), `t_fits` (the world coordinates of a FITS header), `t_code` (your own subs), `t_cylindrical`, `t_radial`, `t_spherical`, `t_quadratic`, `t_cubic`, `t_quartic`, `t_projective` - and combined: `$a x $b` or `t_compose` applies `$b` first, `!$t` or `t_inverse` reverses, `$t ** $n` repeats, `t_wrap` conjugates. `$t->apply($coords)` and `$t->invert($coords)` transform coordinates (the first dimension runs over the axes). `$image->map($t, ...)` resamples an image through a transformation and unmap through its inverse, with the interpolation `method` (`sample`, `linear`, `cubic`, `fft`, the anti-aliasing `jacobian`, `hanning`, `gaussian`) and the boundary condition among their options.

This is PDL::Transform of PDL 2.106: upstream's Perl, unchanged, over PDL's own kernels run by pperl's engine.

Modules

- `PDL::Transform::Cartography` - Useful cartographic projections

PDL::Transform::Cartography

Useful cartographic projections

> **Note**
>
> The plotting lines in the examples (`pgswin()` and `plot`) come from PDL::Graphics::Simple, which is not bundled with pperl. The projections and the data functions (`graticule`, `earth_coast`, `earth_image`, `earth_shape`, `clean_lines`) work without it.

SYNOPSIS

```
# make a Mercator map of Earth
use PDL::Transform::Cartography;
use PDL::Graphics::Simple;
$x = earth_coast();
$x = graticule(10,2)->glue(1,$x);
$t = t_mercator;
$w = pgswin();
$w->plot(with=>'polylines', $t->apply($x)->clean_lines);
```

DESCRIPTION

PDL::Transform::Cartography includes a variety of useful cartographic and observing projections (mappings of the surface of a sphere), including reprojected observer coordinates. See *PDL::Transform* for more information about image transforms in general.

Cartographic transformations are used for projecting not just terrestrial maps, but also any nearly spherical surface including the Sun, the Celestial sphere, various moons and planets, distant stars, etc. They also are useful for interpreting scientific images, which are themselves generally projections of a sphere onto a flat focal plane (e.g. the "t_gnomonic" projection).

Unless otherwise noted, all the transformations in this file convert from (theta,phi) coordinates on the unit sphere (e.g. (lon,lat) on a planet or (RA,dec) on the celestial sphere) into some sort of projected coordinates, and have inverse transformations that convert back to (theta,phi). This is equivalent to working from the equidistant cylindrical (or "plate carree") projection, if you are a cartography wonk.

The projected coordinates are generally in units of body radii (radians), so that multiplying the output by the scale of the map yields physical units that are correct wherever the scale is correct for that projection. For example, areas should be correct everywhere in the authalic projections; and linear scales are correct along meridians in the equidistant projections and along the standard parallels in all the projections.

The transformations that are authalic (equal-area), conformal (equal-angle), azimuthal (circularly symmetric), or perspective (true perspective on a focal plane from some viewpoint) are marked. The first two categories are mutually exclusive for all but the "unit sphere" 3-D projection.

Extra dimensions tacked on to each point to be transformed are, in general, ignored. That is so that you can add on an extra index to keep track of pen color. For example, "earth_coast" returns a 3x<n> ndarray containing (lon, lat, pen) at each list location. Transforming the vector list retains the pen value as the first index after the dimensional directions.

GENERAL NOTES ON CARTOGRAPHY

Unless otherwise noted, the transformations and miscellaneous information in this section are taken from Snyder & Voxland 1989: "An Album of Map Projections", US Geological Survey Professional Paper 1453, US Printing Office (Denver); and from Snyder 1987: "Map Projections - A Working Manual", US Geological Survey Professional Paper 1395, US Printing Office (Denver, USA). You can obtain your own copy of both by contacting the U.S. Geological Survey, Federal Center, Box 25425, Denver, CO 80225 USA.

The mathematics of cartography have a long history, and the details are far trickier than the broad overview. For terrestrial (and, in general, planetary) cartography, the best reference datum is not a sphere but an oblate ellipsoid due to centrifugal force from the planet's rotation. Furthermore, because all rocky planets, including Earth, have randomly placed mass concentrations that affect the gravitational field, the reference gravitational isosurface (sea level on Earth) is even more complex than an ellipsoid and, in general, different ellipsoids have been used for different locations at the same time and for the same location at different times.

The transformations in this package use a spherical datum and hence include global distortion at about the 0.5% level for terrestrial maps (Earth's oblateness is ~1/300). This

is roughly equal to the dimensional precision of physical maps printed on paper (due to stretching and warping of the paper) but is significant at larger scales (e.g. for regional maps). If you need more precision than that, you will want to implement and use the ellipsoidal transformations from Snyder 1987 or another reference work on geodesy. A good name for that package would be `...::Cartography::Geodetic`.

GENERAL NOTES ON PERSPECTIVE AND SCIENTIFIC IMAGES

Cartographic transformations are useful for interpretation of scientific images, as all cameras produce projections of the celestial sphere onto the focal plane of the camera. A simple (single-element) optical system with a planar focal plane generates gnomonic images – that is to say, gnomonic projections of a portion of the celestial sphere near the paraxial direction. This is the projection that most consumer grade cameras produce.

Magnification in an optical system changes the angle of incidence of the rays on the focal plane for a given angle of incidence at the aperture. For example, a 10x telescope with a 2 degree field of view exhibits the same gnomonic distortion as a simple optical system with a 20 degree field of view. Wide-angle optics typically have magnification less than 1 ('fisheye lenses'), reducing the gnomonic distortion considerably but introducing "equidistant azimuthal" distortion – there's no such thing as a free lunch!

Because many solar-system objects are spherical, PDL::Transform::Cartography includes perspective projections for producing maps of spherical bodies from perspective views. Those projections are "t_vertical" and "t_perspective". They map between (lat,lon) on the spherical body and planar projected coordinates at the viewpoint. "t_vertical" is the vertical perspective projection given by Snyder, but "t_perspective" is a fully general perspective projection that also handles magnification correction.

TRANSVERSE & OBLIQUE PROJECTIONS; STANDARD OPTIONS

Oblique projections rotate the sphere (and graticule) to an arbitrary angle before generating the projection; transverse projections rotate the sphere exactly 90 degrees before generating the projection.

Most of the projections accept the following standard options, useful for making transverse and oblique projection maps.

- o, origin, Origin [default (0,0,0)]

  The origin of the oblique map coordinate system, in (old-theta, old-phi) coordinates.

- r, roll, Roll [default 0.0]

  The roll angle of the sphere about the origin, measured CW from (N = up) for reasonable values of phi and CW from (S = up) for unreasonable values of phi. This is equivalent to observer roll angle CCW from the same direction.

- u, unit, Unit [default 'degree']

  This is the name of the angular unit to use in the lon/lat coordinate system.

- b, B

  The "B" angle of the body – used for extraterrestrial maps. Setting this parameter is exactly equivalent to setting the phi component of the origin, and in fact overrides

it.

- l,L

  The longitude of the central meridian as observed – used for extraterrestrial maps. Setting this parameter is exactly equivalent to setting the theta component of the origin, and in fact overrides it.

- p,P

  The "P" (or position) angle of the body – used for extraterrestrial maps. This parameter is a synonym for the roll angle, above.

- bad, Bad, missing, Missing [default nan]

  This is the value that missing points get. Mainly useful for the inverse transforms. (This should work fine if set to BAD).

EXAMPLES

Draw a Mercator map of the world on-screen:

```
$w = pgswin();
$w->plot(with=>'polylines', earth_coast->apply(t_mercator)->clean_
 ↪lines);
```

Here, `earth_coast()` returns a 3xn ndarray containing (lon, lat, pen) values for the included world coastal outline; `t_mercator` converts the values to projected Mercator coordinates, and `clean_lines` breaks lines that cross the 180th meridian.

Draw a Mercator map of the world, with lon/lat at 10 degree intervals:

```
$w = pgswin();
$x = earth_coast()->glue(1,graticule(10,1));
$w->plot(with=>'polylines', $x->apply(t_mercator)->clean_lines);
```

This works just the same as the first example, except that a map graticule has been applied with interline spacing of 10 degrees lon/lat and inter-vertex spacing of 1 degree (so that each meridian contains 181 points, and each parallel contains 361 points).

NOTES

Currently angular conversions are rather simpleminded. A list of common conversions is present in the main constructor, which inserts a conversion constant to radians into the {params} field of the new transform. Something like Math::Convert::Units should be used instead to generate the conversion constant.

A cleaner higher-level interface is probably needed (see the examples); for example, earth_coast could return a graticule if asked, instead of needing one to be glued on.

The class structure is somewhat messy because of the varying needs of the different transformations. PDL::Transform::Cartography is a base class that interprets the origin options and sets up the basic machinery of the Transform. The conic projections have their own subclass, PDL::Transform::Conic, that interprets the standard parallels. Since the cylindrical and azimuthal projections are pretty simple, they are not subclassed.

AUTHOR

Copyright 2002, Craig DeForest (deforest@boulder.swri.edu). This module may be modified and distributed under the same terms as PDL itself. The module comes with NO WARRANTY.

The included digital world map is derived from the 1987 CIA World Map, translated to ASCII in 1988 by Joe Dellinger (geojoe@freeusp.org) and simplified in 1995 by Kirk Johnson (tuna@indra.com) for the program XEarth. The map comes with NO WARRANTY. An ASCII version of the map, and a sample PDL function to read it, may be found in the `examples` subdirectory of the PDL source distribution.

FUNCTIONS

The module exports both transform constructors ('t_<foo>') and some auxiliary functions (no leading 't_').

graticule

```
$lonlatp     = graticule(<grid-spacing>,<line-segment-size>);
$lonlatp     = graticule(<grid-spacing>,<line-segment-size>,1);
```

(Cartography) PDL constructor - generate a lat/lon grid.

Returns a grid of meridians and parallels as a list of vectors suitable for sending to PDL::Graphics::Simple for plotting. The grid is in degrees in (theta, phi) coordinates – this is (E lon, N lat) for terrestrial grids or (RA, dec) for celestial ones. You must then transform the graticule in the same way that you transform the map.

You can attach the graticule to a vector map using the syntax:

```
$out = graticule(10,2)->glue(1,$map);
```

In array context you get back a 2-element list containing an ndarray of the (theta,phi) pairs and an ndarray of the pen values (1 or 0) suitable for calling PDL::Graphics::Simple. In scalar context the two elements are combined into a single ndarray.

The pen values associated with the graticule are negative, which will cause PDL::Graphics::Simple to plot them as hairlines.

If a third argument is given, it is a hash of options, which can be:

- nan - if true, use two columns instead of three, and separate lines with a 'nan' break
- lonpos - if true, all reported longitudes are positive (0 to 360) instead of (-180 to 180).
- dup - if true, the meridian at the far boundary is duplicated.

earth_coast

```
$x = earth_coast()
```

(Cartography) PDL constructor - coastline map of Earth

Returns a vector coastline map based on the 1987 CIA World Coastline database (see author information). The vector coastline data are in plate carree format so they can be converted to other projections via the *apply* method and cartographic transforms, and are suitable for plotting with the polylines plot type in the PDL::Graphics::Simple output library: the first dimension is (X,Y,pen) with breaks having a pen value of 0 and hairlines having negative pen values. The second dimension broadcasts over all the points in the data set.

The vector map includes lines that pass through the antipodean meridian, so if you want to plot it without reprojecting, you should run it through "clean_lines" first:

```
$w = pgswin();
$w->plot(with=>'polylines',
  earth_coast->clean_lines);     # plot plate carree map of world
$w->plot(with=>'polylines',
  earth_coast->apply(t_gnomonic)->clean_lines)# plot gnomonic map of␣
↪world
```

`earth_coast` is just a quick-and-dirty way of loading the file "earth_coast.vec.fits" that is part of the normal installation tree.

earth_image

```
$rgb = earth_image()
```

(Cartography) PDL constructor - RGB pixel map of Earth

Returns an RGB image of Earth based on data from the MODIS instrument on the NASA EOS/Terra satellite. (You can get a full-resolution image from http://earthobservatory.nasa.gov/Newsroom/BlueMarble/). The image is a plate carree map, so you can convert it to other projections via the *map* method and cartographic transforms.

This is just a quick-and-dirty way of loading the earth-image files that are distributed along with PDL.

earth_shape

```
$fits_shape = earth_shape()
```

(Cartography) PDL constructor - height map of Earth

Returns a height map of Earth based on data from the General Bathymetric Chart of the Oceans (GEBCO) produced by the British Oceanographic Data Centre. (You can get a full-resolution image from http://visibleearth.nasa.gov/view.php?id=73934). The image is a plate carree map, so you can convert it to other projections via the *map* method and cartographic transforms. The data is from 8-bit grayscale (so only 256 levels), but is returned as float, values in Earth radii, in dimensions (2048,1024), like "earth_image". The range represents a span of 6400m, so Everest and the Marianas Trench are not accurately represented.

```
Value       Hex value   Float    From centre in km   Float as radius
Base        00          0.0      6370.69873km        0.99995
```

(continues on next page)

(continued from previous page)

```
Sea level   0C          0.04705  6371km              1.0
Highest     FF          1.0      6377.09863km        1.00096
```

Code:

```
$shape = earth_shape();
```

raster2fits

```
$pdl_fits = raster2fits($pdl, \@axislabels, \@axisunits, \
 ↪@axisranges);
$pdl_fits = raster2fits($pdl, @PDL::Transform::Cartography::PLATE_
 ↪CARREE);
```

Convert a raster ([3,]x,y) to FITS (x,y[,3]), with a suitable header for the given parameters.

clean_lines

```
$x = clean_lines(t_mercator->apply(scalar(earth_coast())));
$x = $lines->clean_lines; # same as above, both "first (scalar) form
 ↪"
$x = clean_lines($line_pen[,threshold][,opt]); # also same but␣
 ↪threshold given
$x = clean_lines($line,$pen[,threshold][,opt]); # "second (list)␣
 ↪form"
```

(Cartography) PDL method - remove projection irregularities

`clean_lines` massages vector data to remove jumps due to singularities in the transform.

In the first (scalar) form, `$line_pen` contains both (X,Y) points and pen values in the 3rd column suitable to be fed to the polylines plot type in the PDL::Graphics::Simple.

In the second (list) form, `$lines` contains the (X,Y) points and `$pen` contains the pen values, in one less dimension than the `$lines`.

`clean_lines` assumes that all the outline polylines are local – that is to say, there are no large jumps. Any jumps larger than a threshold size are broken by setting the appropriate pen values to 0.

The `threshold` parameter sets the relative size of the largest jump, relative to the map range (as determined by a min/max operation). The default size is 0.1. If `threshold` is greater than or equal to 1, lines will not be broken based on point separation.

The following options are interpreted:

- or, orange, output_range, Output_Range

  ```
  $lp = $lp->clean_lines(1.1,{or=>[[178.9,179.7], [62.8,64.5]]})
  ```

This sets the window of output space, similar to that in *"map" in PDL::Transform*. As there, it specifies a quadrilateral in output space. Any points not in that will be removed from the output, and line breaks (0 pen values) will be inserted before.

Because this returns a selection of the inputs, it will not broadcast.

- fn, filter_nan

  Defaults to true. Will break before any points with bad/NaN/Inf coordinates, and remove those points from the output.

  Because this returns a selection of the inputs, it will not broadcast.

NOTES

This almost never catches stuff near the apex of cylindrical maps, because the anomalous vectors get arbitrarily small. This could be improved somewhat by looking at individual runs of the pen and using a relative length scale that is calibrated to the rest of each run. it is probably not worth the computational overhead.

t_unit_sphere

```
$t = t_unit_sphere(<options>);
```

(Cartography) 3-D globe projection (conformal; authalic)

This is similar to the inverse of *t_spherical*, but the inverse transform projects 3-D coordinates onto the unit sphere, yielding only a 2-D (lon/lat) output. Similarly, the forward transform deprojects 2-D (lon/lat) coordinates onto the surface of a unit sphere.

The cartesian system has its Z axis pointing through the pole of the (lon,lat) system, and its X axis pointing through the equator at the prime meridian.

Unit sphere mapping is unusual in that it is both conformal and authalic. That is possible because it properly embeds the sphere in 3-space, as a notional globe.

This is handy as an intermediate step in lots of transforms, as Cartesian 3-space is cleaner to work with than spherical 2-space.

Higher dimensional indices are preserved, so that "rider" indices (such as pen value) are propagated.

There is no oblique transform for t_unit_sphere, largely because it's so easy to rotate the output using t_linear once it's out into Cartesian space. In fact, the other projections implement oblique transforms by *wrapping t_linear* with "t_unit_sphere".

OPTIONS:

- radius, Radius (default 1.0)

  The radius of the sphere, for the inverse transform. (Radius is ignored in the forward transform). Defaults to 1.0 so that the resulting Cartesian coordinates are in units of "body radii".

t_rot_sphere

```
$t = t_rot_sphere({origin=>[<theta>,<phi>],roll=>[<roll>]});
```

(Cartography) Generate oblique projections

You feed in the origin in (theta,phi) and a roll angle, and you get back out (theta', phi') coordinates. This is useful for making oblique or transverse projections: just compose t_rot_sphere with your favorite projection and you get an oblique one.

Most of the projections automagically compose themselves with t_rot_sphere if you feed in an origin or roll angle.

t_rot_sphere converts the base plate carree projection (straight lon, straight lat) to a Cassini projection.

OPTIONS

- STANDARD POSITIONAL OPTIONS

t_orthographic

```
$t = t_orthographic(<options>);
```

(Cartography) Ortho. projection (azimuthal; perspective)

This is a perspective view as seen from infinite distance. You can specify the sub-viewer point in (lon,lat) coordinates, and a rotation angle of the map CW from (north=up). This is equivalent to specify viewer roll angle CCW from (north=up).

t_orthographic is a convenience interface to t_unit_sphere – it is implemented as a composition of a t_unit_sphere call, a rotation, and a slice.

[*] In the default case where the near hemisphere is mapped, the inverse exists. There is no single inverse for the whole-sphere case, so the inverse transform superimposes everything on a single hemisphere. If you want an invertible 3-D transform, you want "t_unit_sphere".

OPTIONS

- STANDARD POSITIONAL OPTIONS
- m, mask, Mask, h, hemisphere, Hemisphere [default 'near']

  The hemisphere to keep in the projection (see *PDL::Transform::Cartography*).

NOTES

Alone of the various projections, this one does not use "t_rot_sphere" to handle the standard options, because the cartesian coordinates of the rotated sphere are already correctly projected – t_rot_sphere would put them back into (theta', phi') coordinates.

t_carree

```
$t = t_carree(<options>);
```

(Cartography) Plate Carree projection (cylindrical; equidistant)

This is the simple Plate Carree projection – also called a "lat/lon plot". The horizontal axis is theta; the vertical axis is phi. This is a no-op if the angular unit is radians; it is a simple scale otherwise.

OPTIONS

- STANDARD POSITIONAL OPTIONS
- s, std, standard, Standard (default 0)

  The standard parallel where the transformation is conformal. Conformality is achieved by shrinking of the horizontal scale to match the vertical scale (which is correct everywhere).

t_mercator

```
$t = t_mercator(<options>);
```

(Cartography) Mercator projection (cylindrical; conformal)

This is perhaps the most famous of all map projections: meridians are mapped to parallel vertical lines and parallels are unevenly spaced horizontal lines. The poles are shifted to +/- infinity. The output values are in units of globe-radii for easy conversion to kilometers; hence the horizontal extent is -pi to pi.

You can get oblique Mercator projections by specifying the `origin` or `roll` options; this is implemented via "t_rot_sphere".

OPTIONS

- STANDARD POSITIONAL OPTIONS
- c, clip, Clip (default 75 [degrees])

  The north/south clipping boundary of the transformation. Because the poles are displaced to infinity, many applications require a clipping boundary. The value is in whatever angular unit you set with the standard 'units' option. The default roughly matches interesting landforms on Earth. For no clipping at all, set c=>0. For asymmetric clipping, use a 2-element list ref or ndarray.

- s, std, Standard (default 0)

  This is the parallel at which the map has correct scale. The scale is also correct at the parallel of opposite sign.

t_utm

```
$t = t_utm(<zone>,<options>);
```

(Cartography) Universal Transverse Mercator projection (cylindrical)

This is the internationally used UTM projection, with 2 subzones (North/South). The UTM zones are parametrized individually, so if you want a Zone 30 map you should use `t_utm(30)`. By default you get the northern subzone, so that locations in the southern

hemisphere get negative Y coordinates. If you select the southern subzone (with the "subzone=>-1" option), you get offset southern UTM coordinates.

The 20-subzone military system is not yet supported. If/when it is implemented, you will be able to enter "subzone=>[a-t]" to select a N/S subzone.

Note that UTM is really a family of transverse Mercator projections with different central meridia. Each zone properly extends for three degrees of longitude on either side of its appropriate central meridian, with Zone 1 being centered at -177 degrees longitude (177 west). Properly speaking, the zones only extend from 80 degrees south to 84 degrees north; but this implementation lets you go all the way to 90 degrees. The default UTM coordinates are meters. The origin for each zone is on the equator, at an easting of -500,000 meters.

The default output units are meters, assuming that you are wanting a map of the Earth. This will break for bodies other than Earth (which have different radii and hence different conversions between lat/lon angle and meters).

The standard UTM projection has a slight reduction in scale at the prime meridian of each zone: the transverse Mercator projection's standard "parallels" are 180km e/w of the central meridian. However, many Europeans prefer the "Gauss-Kruger" system, which is virtually identical to UTM but with a normal tangent Mercator (standard parallel on the prime meridian). To get this behavior, set "gk=>1".

Like the rest of the PDL::Transform::Cartography package, t_utm uses a spherical datum rather than the "official" ellipsoidal datums for the UTM system.

This implementation was derived from the rather nice description by Denis J. Dean, located on the web at: http://www.cnr.colostate.edu/class_info/nr502/lg3/datums_coordinates/utm.html

OPTIONS

- STANDARD OPTIONS

  (No positional options – Origin and Roll are ignored)

- ou, ounit, OutputUnit (default 'meters')

  (This is likely to become a standard option in a future release) The unit of the output map. By default, this is 'meters' for UTM, but you may specify 'deg' or 'km' or even (heaven help us) 'miles' if you prefer.

- sz, subzone, SubZone (default 1)

  Set this to -1 for the southern hemisphere subzone. Ultimately you should be able to set it to a letter to get the corresponding military subzone, but that's too much effort for now.

- gk, gausskruger (default 0)

  Set this to 1 to get the (European-style) tangent-plane Mercator with standard parallel on the prime meridian. The default of 0 places the standard parallels 180km east/west of the prime meridian, yielding better average scale across the zone. Setting gk=>1 makes the scale exactly 1.0 at the central meridian, and >1.0 everywhere else on the projection. The difference in scale is about 0.3%.

t_sin_lat

```
$t = t_sin_lat(<options>);
```

(Cartography) Cyl. equal-area projection (cyl.; authalic)

This projection is commonly used in solar Carrington plots; but not much for terrestrial mapping.

OPTIONS

- STANDARD POSITIONAL OPTIONS
- s,std, Standard (default 0)

  This is the parallel at which the map is conformal. It is also conformal at the parallel of opposite sign. The conformality is achieved by matched vertical stretching and horizontal squishing (to achieve constant area).

t_sinusoidal

```
$t = t_sinusoidal(<options>);
```

(Cartography) Sinusoidal projection (authalic)

Sinusoidal projection preserves the latitude scale but scales longitude according to cos(lat); in this respect it is the companion to "t_sin_lat", which is also authalic but preserves the longitude scale instead.

OPTIONS

- STANDARD POSITIONAL OPTIONS

t_conic

```
$t = t_conic(<options>)
```

(Cartography) Simple conic projection (conic; equidistant)

This is the simplest conic projection, with parallels mapped to equidistant concentric circles. It is neither authalic nor conformal. This transformation is also referred to as the "Modified Transverse Mercator" projection in several maps of Alaska published by the USGS; and the American State of New Mexico re-invented the projection in 1936 for an official map of that State.

OPTIONS

- STANDARD POSITIONAL OPTIONS
- s, std, Standard (default 29.5, 45.5)

  The locations of the standard parallel(s) (where the cone intersects the surface of the sphere). If you specify only one then the other is taken to be the nearest pole. If you specify both of them to be one pole then you get an equidistant azimuthal map. If you specify both of them to be opposite and equidistant from the equator you get a Plate Carree projection.

t_albers

```
$t = t_albers(<options>)
```

(Cartography) Albers conic projection (conic; authalic)

This is the standard projection used by the US Geological Survey for sectionals of the 48 contiguous United States of America.

The projection reduces to the Lambert equal-area conic (infrequently used and not to be confused with the Lambert conformal conic, "t_lambert"!) if the pole is used as one of the two standard parallels.

Notionally, this is a conic projection onto a cone that intersects the sphere at the two standard parallels; it works best when the two parallels straddle the region of interest.

OPTIONS

- STANDARD POSITIONAL OPTIONS
- s, std, standard, Standard (default (29.5,45.5))

  The locations of the standard parallel(s). If you specify only one then the other is taken to be the nearest pole and a Lambert Equal-Area Conic map results. If you specify both standard parallels to be the same pole, then the projection reduces to the Lambert Azimuthal Equal-Area map as a special case. (Note that "t_lambert" is Lambert's Conformal Conic, the most commonly used of Lambert's projections.)

  The default values for the standard parallels are those chosen by Adams for maps of the lower 48 US states: (29.5,45.5). The USGS recommends (55,65) for maps of Alaska and (8,18) for maps of Hawaii – these latter are chosen to also include the Canal Zone and Philippine Islands farther south, which is why both of those parallels are south of the Hawaiian islands.

  The transformation reduces to the cylindrical equal-area (sin-lat) transformation in the case where the standard parallels are opposite and equidistant from the equator, and in fact this is implemented by a call to t_sin_lat.

t_lambert

```
$t = t_lambert(<options>);
```

(Cartography) Lambert conic projection (conic; conformal)

Lambert conformal conic projection is widely used in aeronautical charts and state base maps published by the USA's FAA and USGS. It's especially useful for mid-latitude charts. In particular, straight lines approximate (but are not exactly) great circle routes of up to ~2 radians.

The default standard parallels are 33 and 45 to match the USGS state 1:500,000 base maps of the United States. At scales of 1:500,000 and larger, discrepancies between the spherical and ellipsoidal projections become important; use care with this projection on spheres.

OPTIONS

- STANDARD POSITIONAL OPTIONS

- s, std, standard, Standard (default (33,45))

  The locations of the standard parallel(s) for the conic projection. The transform reduces to the Mercator projection in the case where the standard parallels are opposite and equidistant from the equator, and in fact this is implemented by a call to t_mercator.

- c, clip, Clip (default [-75,75])

  Because the transform is conformal, the distant pole is displaced to infinity. Many applications require a clipping boundary. The value is in whatever angular unit you set with the standard 'unit' option. For consistency with "t_mercator", clipping works the same way even though in most cases only one pole needs it. Set this to 0 for no clipping at all.

t_stereographic

```
$t = t_stereographic(<options>);
```

(Cartography) Stereographic projection (az.; conf.; persp.)

The stereographic projection is a true perspective (planar) projection from a point on the spherical surface opposite the origin of the map.

OPTIONS

- STANDARD POSITIONAL OPTIONS
- c, clip, Clip (default 120)

  This is the angular distance from the center to the edge of the projected map. The default 120 degrees gives you most of the opposite hemisphere but avoids the hugely distorted part near the antipodes.

t_gnomonic

```
$t = t_gnomonic(<options>);
```

(Cartography) Gnomonic (focal-plane) projection (az.; persp.)

The gnomonic projection projects a hemisphere onto a tangent plane. It is useful in cartography for the property that straight lines are great circles; and it is useful in scientific imaging because it is the projection generated by a simple optical system with a flat focal plane.

OPTIONS

- STANDARD POSITIONAL OPTIONS
- c, clip, Clip (default 75)

  This is the angular distance from the center to the edge of the projected map. The default 75 degrees gives you most of the hemisphere but avoids the hugely distorted part near the horizon.

t_az_eqd

```
$t = t_az_eqd(<options>);
```

(Cartography) Azimuthal equidistant projection (az.; equi.)

Basic azimuthal projection preserving length along radial lines from the origin (meridians, in the original polar aspect). Hence, both azimuth and distance are correct for journeys beginning at the origin.

Applied to the celestial sphere, this is the projection made by fisheye lenses; it is also the projection into which `t_vertical` puts perspective views.

The projected plane scale is normally taken to be planetary radii; this is useful for cartographers but not so useful for scientific observers. Setting the 't=>1' option causes the output scale to shift to camera angular coordinates (the angular unit is determined by the standard 'Units' option; default is degrees).

OPTIONS

- STANDARD POSITIONAL OPTIONS
- c, clip, Clip (default 180 degrees)

  The largest angle relative to the origin. Default is the whole sphere.

t_az_eqa

```
$t = t_az_eqa(<options>);
```

(Cartography) Azimuthal equal-area projection (az.; auth.)

OPTIONS

- STANDARD POSITIONAL OPTIONS
- c, clip, Clip (default 180 degrees)

  The largest angle relative to the origin. Default is the whole sphere.

t_hammer, t_aitoff

(Cartography) Hammer/Aitoff elliptical projection (az.; auth.)

The Hammer/Aitoff projection is often used to display the Celestial sphere. It is mathematically related to the Lambert Azimuthal Equal-Area projection ("t_az_eqa"), and maps the sphere to a 2:1 ellipse, with vertical radius sqrt(2) and horizontal radius of 2 sqrt(2).

OPTIONS

- STANDARD POSITIONAL OPTIONS

t_vertical, t_zenithal

```
$t = t_vertical(<options>);
```

(Cartography) Vertical perspective projection (az.; persp.)

Vertical (also called "zenithal") perspective projection is a generalization of gnomonic and stereographic projection, and a special case of perspective projection. It is a projection from the sphere onto a tangent plane from a point at the camera location.

OPTIONS

- STANDARD POSITIONAL OPTIONS
- m, mask, Mask, h, hemisphere, Hemisphere [default 'near']

  The hemisphere to keep in the projection (see *PDL::Transform::Cartography*).
- r0, R0, radius, d, dist, distance [default 2.0]

  The altitude of the focal plane above the center of the sphere. The default places the point of view one radius above the surface.
- t, telescope, Telescope, cam, Camera (default '')

  If this is set, then the central scale is in telescope or camera angular units rather than in planetary radii. The angular units are parsed as with the normal 'u' option for the lon/lat specification. If you specify a non-string value (such as 1) then you get telescope-frame radians, suitable for working on with other transformations.
- f, fish, fisheye (default '')

  If this is set then the output is in azimuthal equidistant coordinates instead of in tangent-plane coordinates. This is a convenience function for '(t_az_eqd) x !(t_gnomonic) x (t_vertical)'.

t_perspective

```
$t = t_perspective(<options>);
```

(Cartography) Arbitrary perspective projection

Perspective projection onto a focal plane from an arbitrary location within or without the sphere, with an arbitrary central look direction, and with correction for magnification within the optical system.

In the forward direction, t_perspective generates perspective views of a sphere given (lon/lat) mapping or vector information. In the reverse direction, t_perspective produces (lon/lat) maps from aerial or distant photographs of spherical objects.

Viewpoints outside the sphere treat the sphere as opaque by default, though you can use the 'm' option to specify either the near or far surface (relative to the origin). Viewpoints below the surface treat the sphere as transparent and undergo a mirror reversal for consistency with projections that are special cases of the perspective projection (e.g. t_gnomonic for r0=0 or t_stereographic for r0=-1).

Magnification correction handles the extra edge distortion due to higher angles between the focal plane and focused rays within the optical system of your camera. If you do not

happen to know the magnification of your camera, a simple rule of thumb is that the magnification of a reflective telescope is roughly its focal length (plate scale) divided by its physical length; and the magnification of a compound refractive telescope is roughly twice its physical length divided by its focal length. Simple optical systems with a single optic have magnification = 1. Fisheye lenses have magnification < 1.

This transformation was derived by direct geometrical calculation rather than being translated from Voxland & Snyder.

OPTIONS

- STANDARD POSITIONAL OPTIONS

  As always, the 'origin' field specifies the sub-camera point on the sphere.

  The 'roll' option is the roll angle about the sub-camera point, for consistency with the other projections.

- p, ptg, pointing, Pointing (default (0,0,0))

  The pointing direction, in (horiz. offset, vert. offset, roll) of the camera relative to the center of the sphere. This is a spherical coordinate system with the origin pointing directly at the sphere and the pole pointing north in the pre-rolled coordinate system set by the standard origin. It's most useful for space-based images taken some distance from the body in question (e.g. images of other planets or the Sun).

  Be careful not to confuse 'p' (pointing) with 'P' (P angle, a standard synonym for roll).

- c, cam, camera, Camera (default undef)

  Alternate way of specifying the camera pointing, using a spherical coordinate system with poles at the zenith (positive) and nadir (negative) – this is useful for aerial photographs and such, where the point of view is near the surface of the sphere. You specify (azimuth from N, altitude from horizontal, roll from vertical=up). If you specify pointing by this method, it overrides the 'pointing' option, above. This coordinate system is most useful for aerial photography or low-orbit work, where the nadir is not necessarily the most interesting part of the scene.

- r0, R0, radius, d, dist, distance [default 2.0]

  The altitude of the point of view above the center of the sphere. The default places the point of view 1 radius above the surface. Do not confuse this with 'r', the standard origin roll angle! Setting r0 < 1 gives a viewpoint inside the sphere. In that case, the images are mirror-reversed to preserve the chirality of the perspective. Setting r0=0 gives gnomonic projections; setting r0=-1 gives stereographic projections. Setting r0 < -1 gives strange results.

- iu, im_unit, image_unit, Image_Unit (default 'degrees')

  This is the angular units in which the viewing camera is calibrated at the center of the image.

- mag, magnification, Magnification (default 1.0)

  This is the magnification factor applied to the optics – it affects the amount of tangent-plane distortion within the telescope. 1.0 yields the view from a simple optical system; higher values are telescopic, while lower values are wide-angle

(fisheye). Higher magnification leads to higher angles within the optical system, and more tangent-plane distortion at the edges of the image. The magnification is applied to the incident angles themselves, rather than to their tangents (simple two-element telescopes magnify tan(theta) rather than theta itself); this is appropriate because wide-field optics more often conform to the equidistant azimuthal approximation than to the tangent plane approximation. If you need more detailed control of the relationship between incident angle and focal-plane position, use mag=1.0 and compose the transform with something else to tweak the angles.

- m, mask, Mask, h, hemisphere, Hemisphere [default 'near']

  'hemisphere' is by analogy to other cartography methods although the two regions to be selected are not really hemispheres.

- f, fov, field_of_view, Field_Of_View [default 60 degrees]

  The field of view of the telescope – sets the crop radius on the focal plane. If you pass in a scalar, you get a circular crop. If you pass in a 2-element list ref, you get a rectilinear crop, with the horizontal 'radius' and vertical 'radius' set separately.

EXAMPLES

Model a camera looking at the Sun through a 10x telescope from Earth (~230 solar radii from the Sun), with an 0.5 degree field of view and a solar P (roll) angle of 30 degrees, in February (sub-Earth solar latitude is 7 degrees south). Convert a solar FITS image taken with that camera to a FITS lon/lat map of the Sun with 20 pixels/degree latitude:

```
# Define map output header (no need if you don't want a FITS output␣
 ↪map)
$maphdr = {NAXIS1=>7200,NAXIS2=>3600,              # Size of image
           CTYPE1=>longitude,CTYPE2=>latitude,    # Type of axes
           CUNIT1=>deg,CUNIT2=>deg,               # Unit of axes
           CDELT1=>0.05,CDELT2=>0.05,             # Scale of axes
           CRPIX1=>3601,CRPIX2=>1801,             # Center of map
           CRVAL1=>0,CRVAL2=>0                    # (lon,lat) of␣
 ↪center
           };

# Set up the perspective transformation, and apply it.
$t = t_perspective(r0=>229,fov=>0.5,mag=>10,P=>30,B=>-7);
$map = $im->map( $t , $maphdr );
```

Draw an aerial-view map of the Chesapeake Bay, as seen from a sounding rocket at an altitude of 100km, looking NNE from ~200km south of Washington (the radius of Earth is 6378 km; Washington D.C. is at roughly 77W,38N). Superimpose a linear coastline map on a photographic map.

```
$x = graticule(1,0.1)->glue(1,earth_coast());
$t = t_perspective(r0=>6478/6378.0,fov=>60,cam=>[22.5,-20],o=>[-77,
 ↪36])
$w = pgswin(size=>[10,6],J=>1);
$w->plot(with=>'fits', earth_image()->map($t,[800,500],{m=>linear}),
  with=>'polylines', $x->apply($t)->clean_lines);
```

Model a 5x telescope looking at Betelgeuse with a 10 degree field of view (since

the telescope is looking at the Celestial sphere, r is 0 and this is just an expensive modified-gnomonic projection).

```
$t = t_perspective(r0=>0,fov=>10,mag=>5,o=>[88.79,7.41])
```

PDL::Types

define fundamental PDL Datatypes

SYNOPSIS

```
use PDL::Types;

$pdl = ushort( 2.0, 3.0 );
print "The actual c type used to store ushort's is '" .
   $pdl->type->realctype() . "'\n";
The actual c type used to store ushort's is 'unsigned short'
```

DESCRIPTION

Internal module - holds all the PDL Type info. The type info can be accessed easily using the PDL::Type object returned by the *type* method as shown in the synopsis.

Skip to the end of this document to find out how to change the set of types supported by PDL.

FUNCTIONS

A number of functions are available for module writers to get/process type information. These are used in various places (e.g. PDL::PP, PDL::Core) to generate the appropriate type loops, etc.

typesrtkeys

Returns an array of keys of typehash sorted in order of type complexity

```
pdl> @typelist = PDL::Types::typesrtkeys;
pdl> print @typelist;
PDL_SB PDL_B PDL_S PDL_US PDL_L PDL_UL PDL_IND PDL_ULL PDL_LL PDL_F␣
 ↪PDL_D PDL_LD PDL_CF PDL_CD PDL_CLD
```

ppdefs

Returns an array of pp symbols for all real types. This informs the default GenericTypes for pp_def functions, making support for complex types require an “opt-in”.

```
pdl> print PDL::Types::ppdefs
A B S U L K N P Q F D E
```

ppdefs_complex

Returns an array of pp symbols for all complex types.

```
pdl> print PDL::Types::ppdefs_complex
G C H
```

ppdefs_all

Returns an array of pp symbols for all types including complex.

```
pdl> print PDL::Types::ppdefs_all
A B S U L K N P Q F D E G C H
```

typesynonyms

return type related synonym definitions to be included in pdl.h . This routine must be updated to include new types as required. Mostly the automatic updating should take care of the vital things.

PDL TYPES OVERVIEW

As of 2.065, PDL supports these types:

- SByte

  Signed 8-bit value.

- Byte

  Unsigned 8-bit value.

- Short

  Signed 16-bit value.

- UShort

  Unsigned 16-bit value.

- Long

  Signed 32-bit value.

- ULong

  Unsigned 32-bit value.

- Indx

  Signed value, same size as a pointer on the system in use.

- ULongLong

  Unsigned 64-bit value.

- LongLong

  Signed 64-bit value.

- Float

  IEEE 754 single-precision real floating-point value.

- Double

  IEEE 754 double-precision real value.

- LDouble

  A C99 “long double”, defined as “at least as precise as a double”, but often more precise.

- CFloat

  A C99 complex single-precision floating-point value.

- CDouble

  A C99 complex double-precision floating-point value.

- CLDouble

  A C99 complex “long double” - see above for description.

As of 2.099, documentation for PDL::Type is separate. See there for more.

DEVELOPER NOTES ON ADDING/REMOVING TYPES

You can change the types that PDL knows about by editing entries in the definition of the variable `@types` that appears close to the top of the file `lib/PDL/Types.pm`.

Format of a type entry

Each entry in the `@HASHES` array is a hash reference. Here is an example taken from the actual code that defines the `ushort` type:

```
{
  identifier => 'US',
  onecharident => 'U',   # only needed if different from identifier
  ctype => 'PDL_Ushort',
  realctype => 'unsigned short',
  ppforcetype => 'ushort',
  usenan => 0,
  packtype => 'S*',
  defbval => 'USHRT_MAX',
  real=>1,
  integer=>1,
  unsigned=>1,
},
```

Before we start to explain the fields please take this important message on board: *entries must be listed in order of increasing complexity*. This is critical to ensure that PDL’s type conversion works correctly. Basically, a less complex type will be converted to a more complex type as required.

Fields in a type entry

Each type entry has a number of required and optional entry.

A list of all the entries:

- identifier

  Required. A short sequence of uppercase letters that identifies this type uniquely. More than three characters is probably overkill.

- onecharident

  Optional. Only required if the `identifier` has more than one character. This should be a unique uppercase character that will be used to reference this type in PP macro expressions of the `TBSULFD` type - see *"$T" in PDL::PP*.

- ctype

  Required. The `typedefed` name that will be used to access this type from C code.

- realctype

  Required. The C compiler type that is used to implement this type. For portability reasons this one might be platform dependent.

- ppforcetype

  Required. The type name used in PP signatures to refer to this type.

- usenan

  Required. Flag that signals if this type has to deal with NaN issues. Generally only required for floating point types.

- packtype

  Required. The Perl pack type used to pack Perl values into the machine representation for this type. For details see `perldoc -f pack`.

- integer

  Required. Boolean - is this an integer type?

- unsigned

  Required. Boolean - is this an unsigned type?

- real

  Required. Boolean - is this a real (not complex) type?

- realversion

  String - the real version of this type (e.g. cdouble -> 'D').

- complexversion

  String - the complex version of this type (e.g. double -> 'C').

Also have a look at the entries at the top of `lib/PDL/Types.pm`.

Other things you need to do

You need to check modules that do I/O (generally in the IO part of the directory tree). In the future we might add fields to type entries to automate this. This requires changes to those IO modules first though.

You may also need to update any type macros in PP files (i.e. `$TBSULFD...`) to reflect the new type - PP will throw an error if you have a `$T...` macro which misses types supported by the operation.

PDL::Ufunc

Reductions of PDL's ndarrays: sums, products, means, extrema, medians, percentiles, logical and bitwise folds, running sums and products, and sorting.

```
use PDL;
my $m = pdl([3, 1, 2], [9, 7, 8]);
print $m->sum, " ", $m->avg, " ", $m->max, "\n";         # 30 5 9
print sumover($m), " ", minimum($m), "\n";               # [6 24] [1␣
 ↪7]
print $m->transpose->sumover, "\n";                      # [12 8 10]
print qsort(pdl(3, 1, 2)), " ", qsorti(pdl(3, 1, 2)), "\n";   # [1 2␣
 ↪3] [1 2 0]
my ($min, $max) = $m->minmax;
print "$min $max ", cumusumover(pdl(1, 2, 3)), "\n";     # 1 9 [1 3␣
 ↪6]
print pct(pdl(1 .. 9), 0.5), " ", medover(pdl(1, 2, 3, 4)), "\n";
 ↪# 5 2.5
```

The functions come in two shapes. The `...over` functions reduce the FIRST dimension and broadcast over the others: a 3x2 matrix gives 2 sums. To reduce another dimension, move it first (`transpose`, `mv`, `xchg`). The whole-array functions (`sum`, `avg`, `min`, `median`, `and`, ...) reduce every value to one, a 0-dim ndarray. Bad values are skipped throughout.

This is PDL::Ufunc of PDL 2.106. The kernels are PDL's own, through pperl's engine; upstream's Perl is used unchanged for `minmax`, `minimum_n_ind`/`maximum_n_ind` (the n smallest or largest) and the synonyms `minover`, `maxover`, `minover_ind`, `maxover_ind`, `minover_n_ind`, `maxover_n_ind`, `minmaxover`, `avgover`, `davgover`, `any` and `all`.

inner

`inner($a, $b)` – inner (dot) product along the first dimension.

Given two ndarrays with matching first-axis length n, computes `c = sum_i a_i * b_i`. For 1-D inputs this is the standard dot product, a 0-dimensional result; for higher-rank inputs the contraction is over axis 0 and the remaining axes broadcast.

Signature

```
$c = inner($a, $b);        # function form
$c = $a->inner($b);        # method form
inner($a, $b, $c);         # writes into $c, returns nothing
```

Bad values

If any element of `$a` or `$b` along the first dimension is bad, that result is bad.

Examples

```
use PDL;
my $a = pdl([1, 2, 3]);
my $b = pdl([4, 5, 6]);
print inner($a, $b);            # 32   (1*4 + 2*5 + 3*6)
print $a->inner($b);            # 32   (method form)

# Scalar-on-vector also works (scalar broadcasts to each element)
print inner(pdl([1, 2, 3]), 2); # 12   (1*2 + 2*2 + 3*2)
```

Errors

Croaks when the dimensions do not match, or with the usage when given fewer than two or more than three arguments.

zeroes

Core.xs `new_from_specification(invoc, ...)`, `ALIAS: PDL::zeroes = 1`.

Also available as `PDL::new_from_specification`.

`ST(0)` is ALWAYS the invocant - that is the whole character of this sub and the reason upstream keeps a second, lenient one in Core.pm. `PDL::zeroes(4,4)` therefore means "the class 4, one dimension of 4", and upstream reaches `Can't locate object method "initialize" via package "4"`. It is not a synonym for `zeroes(4,4)`, and treating it as one - which we did, by skipping the invocant only when it was the literal string "PDL" - silently accepted a call perl5 refuses.

get_dataref

Return a reference to the scalar holding the ndarray's raw bytes.

my $ref = $pdl->get_dataref; # SCALAR ref

The scalar holds the ndarray's data in machine format - the same bytes you would find in a file written by `PDL::IO::FastRaw`. For all but the smallest ndarrays (up to 32 bytes of data) it IS the data: writing into `$$ref` writes the ndarray. Call `$pdl->upd_data` afterwards in either case; it tells views of `$pdl` about the change, and copies the bytes back for a small ndarray, whose scalar is a copy.

The ndarray is made physical first, so a slice or other view yields the bytes of its own elements rather than its parent's.

upd_data

Tell the ndarray that the scalar `get_dataref` returned was changed.

$pdl->upd_data; # after writing into the scalar $pdl->upd_data(1); # after replacing the scalar's buffer

Any views derived from `$pdl` are told their parent changed, so they see the new data. For a small ndarray, whose scalar is a copy, the bytes are copied back and the scalar is released; a true argument keeps the scalar and makes it the ndarray's data instead.

For an ndarray whose data is the scalar, the ndarray is pointed at the scalar's buffer again - which is what makes a buffer that moved, such as one a file was mapped into, take effect.

Croaks with `Trying to touch dataref of magical (mmaped?) pdl` for an ndarray whose data is owned elsewhere, and with `Trying to upd_data but datasv now length N instead of M` if a small ndarray's scalar was resized.

at

Return a single element of an ndarray as a plain Perl scalar.

`@pos` is a coordinate list whose length matches the number of dimensions of `$pdl`. Indices may be negative (counted from the far end, so `-1` is the last element along that axis). Missing trailing indices default to 0; extra trailing indices past `$pdl->ndims` are ignored.

The value you get back is current even if `$pdl` is a view onto another ndarray that has since been written to. Integer-typed ndarrays give you an integer, float-typed ones a float.

Signature

```
$z = at($pdl, @pos);        # function form
$z = $pdl->at(@pos);        # method form
```

Broadcasting

`at` does not broadcast. It is a scalar-valued accessor: supply exactly one coordinate tuple.

Bad values

If `$pdl` has its bad-value flag set and the element fetched is the bad value, `at` returns the string `"BAD"`. With the flag clear the raw number is returned regardless of what it happens to be.

Examples

```
use PDL;
my $x = sequence(3, 4);      # 3x4, values 0..11
print $x->at(1, 2);          # 7
print $x->at(-1, -1);        # 11 (last element via negative
 ↪indexing)

# BAD value propagation
my $b = pdl([1, 2, 3]);
$b->badflag(1);
$b->inplace->setbadat(1);
print $b->at(1);             # "BAD"
```

Errors

Croaks with `"Position out of range"` when:

- `$pdl` is a null ndarray, fresh from `PDL->null` and not yet given dimensions;
- `$pdl` has zero elements, as `pdl([])` does;
- any supplied index, after negative indices are resolved, falls outside `[0, dim_size)` for its axis.

set_autopthread_targ

`set_autopthread_targ($n)` - the number of threads an operation is split across, at most; 0 turns the splitting off. Returns `$n`.

An operation is split along one of its broadcast dimensions, the one that divides most evenly, when its largest ndarray has at least `get_autopthread_size` Mi elements. The threads are pperl's own pool, so `--no-parallel` keeps every operation on one thread whatever this says. `PDL_AUTOPTHREAD_TARG` in the environment sets it when PDL loads; the default is `online_cpus`.

flowing

Turn on dataflow, so ndarrays derived from this one track its changes.

my $b = $a->flowing->slice('0:4'); $a->set(2, 99); print $b->at(2); # 99 - $b followed the change

Returns the ndarray, so it chains. Without `flowing`, a derived ndarray keeps whatever values it had when it was made.

Views built by slicing and other index arithmetic follow their parent. Results of computed expressions such as `$a + $a` do not yet: the expression is evaluated once and the link is not retained, so a later write to `$a` will not refresh them.

sever

Detach a view from its parent, keeping the values it has right now.

my $view = $big->slice('0:9'); $view->sever; # now an ndarray in its own right

Returns the ndarray. A slice or other view normally shares its parent's data; after `sever` it owns a copy of the elements it was showing, and neither side sees the other's writes. Useful when you want to keep a small window and let a large parent be freed.

Severing an ndarray that has no parent does nothing.

set_datatype

Change the element type of an ndarray in place.

$pdl->set_datatype($typecode);

`$typecode` is the integer type code, as `get_datatype` and a type's `enum` return; it must be in range or the call croaks with `set_datatype: datatype out of range`.

A null ndarray that has no data yet simply takes on the new type. Otherwise the existing values are converted, exactly as `convert` would, but the ndarray itself is modified rather than a new one returned. `PDL::IO::Storable` uses this when reconstituting an ndarray it has read back.

set_donttouchdata

Declare that the ndarray's storage belongs to someone else.

$pdl->set_donttouchdata; $pdl->set_donttouchdata($nbytes);

After this the ndarray will not free its own data when it goes away - the caller who supplied that memory is responsible for it. With a size argument, the ndarray also records that many bytes as its extent. Returns 1.

This is how a memory-mapped ndarray is set up, by `set_data_by_file_map` and hence by `PDL::IO::FastRaw::mapfraw`. Setting it on an ndarray whose data PDL did allocate leaks that data.

setdims

Give an ndarray a new shape, in place.

$pdl->setdims([3, 4]);

The argument is an arrayref of dimension sizes; anything else means no dimensions. The ndarray is modified rather than a new one returned, and storage is allocated to match the new shape.

This does not rearrange existing values into the new shape - use `reshape` for that.

set_sv_to_null_pdl

Turn an existing scalar into a null ndarray.

PDL::set_sv_to_null_pdl($sv);

The scalar is made to refer to a freshly created ndarray with no dimensions and no data, as `PDL->null` returns; whatever it held before is replaced.

Deserialisation is what this exists for. `PDL::IO::Storable` gets an empty blessed stub back from `Storable` and needs to make a real ndarray out of it before filling in the dimensions and data.

hdrcpy

Get or set whether the header travels with derived ndarrays.

$pdl->hdrcpy(1); my $on = $pdl->hdrcpy;

With the flag on, ndarrays made from `$pdl` by an operation get a deep copy of its header, and the flag; with it off - the default - they start without a header. It returns the setting, after any change.

5.2.76 POSIX

The POSIX (IEEE Std 1003.1) C standard library, exposed to Perl.

Reach for `POSIX` when you need something the Perl core does not give you directly: a `strftime` format, `setlocale` to switch numeric conventions, `sigaction` for signal handling, wait-status macros like `WIFEXITED` / `WEXITSTATUS`, `mkfifo`, or any of the hundreds of `E*` / `O_*` / `F_*` / `S_*` constants from `<errno.h>`, `<fcntl.h>`, and friends.

```
use POSIX qw(strftime floor ceil fmod :sys_wait_h);
use POSIX qw(:math_h_c99);

print strftime("%Y-%m-%d %H:%M:%S", gmtime 86400 * 365), "\n";   #␣
↪1971-01-01 00:00:00
printf "%s %s %s %s\n", floor(-1.5), ceil(-1.5), fmod(7, -3),␣
↪round(2.5);   # -2 -1 1 3

system $^X, '-e', 'exit 3';
print "exited ", WEXITSTATUS($?), "\n" if WIFEXITED($?);          #␣
↪exited 3

printf "EINTR is %d, PATH_MAX %d\n", POSIX::EINTR, POSIX::PATH_MAX; ␣
↪ # 4, 4096
```

The functions below are the C library's, called directly, so they behave as the host's C library does (glibc or musl on Linux). This is a native implementation of the XS half of POSIX 2.26; its `POSIX.pm` is used unchanged. That `.pm` also provides the many POSIX names that are perl built-ins under another name (`POSIX::printf` is `printf`, `POSIX::exit` is `exit`, `POSIX::getpid` is `$$` ...), the classes `POSIX::SigSet`, `POSIX::SigAction` and `POSIX::Termios`, and a helpful `die` for the C functions that make no sense in Perl (`POSIX::malloc`, `POSIX::strcpy` ...).

`use POSIX` with no list exports 587 names - most of the C89 library and its constants. Ask for less: a list of names, or one of the tags named after the C header it comes from (`:sys_wait_h`, `:fcntl_h`, `:math_h`, `:math_h_c99` for the C99 math functions, `:termios_h`, `:signal_h`, ...). The C99 functions are never exported by default.

Every macro the platform defines is a constant sub. Any other name dies when called: one POSIX knows but the platform lacks with "Your vendor has not defined POSIX macro OPEN_MAX, used at FILE line N", one that is no POSIX macro with "tcgetattr is not a valid POSIX macro at FILE line N" - the location being the caller's.

Differences from upstream

One, where perl 5.44 with POSIX.xs fails: a NaN payload of 2**64 or more (`nan(1e20)`, `setpayload($x, 1e20)`) gives the largest payload and warns "payload lost bits". POSIX.xs's conversion of such a number is undefined C: on x86-64 it gives payload 0 and no warning, losing every bit silently (t/81-xs-native/POSIX/380-or-better.t).

Modules

- `POSIX::SigSet`
- `POSIX::Termios`

Functions

Math

acos

`acos($x)`: the arc cosine of `$x`, in radians; NaN outside -1..1. Exported by default.

acosh

`acosh($x)`: the inverse hyperbolic cosine; NaN below 1.

asin

`asin($x)`: the arc sine of `$x`, in radians; NaN outside -1..1. Exported by default.

asinh

`asinh($x)`: the inverse hyperbolic sine.

atan

`atan($x)`: the arc tangent of `$x`, in radians, between -pi/2 and pi/2. Perl's own `atan2($y, $x)` covers the full circle. Exported by default.

atanh

`atanh($x)`: the inverse hyperbolic tangent; infinite at -1 and 1, NaN outside them.

cbrt

`cbrt($x)`: the cube root, negative for negative `$x`: `cbrt(-27)` is -3.

ceil

`ceil($x)`: the smallest integral value not below `$x`, as a floating-point number: `ceil(-1.5)` is -1. Exported by default.

cosh

`cosh($x)`: the hyperbolic cosine. Exported by default.

erf

`erf($x)`: the error function.

erfc

`erfc($x)`: the complementary error function, `1 - erf($x)`, computed without the loss of precision for large `$x`.

exp2

`exp2($x)`: 2 to the power `$x`.

expm1

`expm1($x)`: `exp($x) - 1`, accurate for `$x` near 0.

floor

`floor($x)`: the largest integral value not above `$x`, as a floating-point number: `floor(-1.5)` is -2. Exported by default.

j0

`j0($x)`: the Bessel function of the first kind of order 0; `j1` is order 1, `jn` any order.

j1

`j1($x)`: the Bessel function of the first kind of order 1.

lgamma

`lgamma($x)`: the natural logarithm of the absolute value of the gamma function: `lgamma(5)` is log(24).

log10

`log10($x)`: the base-10 logarithm. Exported by default.

log1p

`log1p($x)`: `log(1 + $x)`, accurate for `$x` near 0.

log2

`log2($x)`: the base-2 logarithm.

logb

`logb($x)`: the binary exponent of `$x`, as a floating-point number: `logb(8)` is 3. `ilogb` returns it as an integer.

nearbyint

`nearbyint($x)`: `$x` rounded to an integral value in the current rounding mode (see `fesetround`), without raising the inexact floating-point exception.

rint

`rint($x)`: `$x` rounded to an integral value in the current rounding mode; in the default mode halves go to the even neighbour: `rint(2.5)` is 2.

round

`round($x)`: `$x` rounded to the nearest integral value, halves away from zero: `round(2.5)` is 3, `round(-2.5)` is -3.

sinh

`sinh($x)`: the hyperbolic sine. Exported by default.

tan

`tan($x)`: the tangent of `$x` radians. Exported by default.

tanh

`tanh($x)`: the hyperbolic tangent. Exported by default.

tgamma

`tgamma($x)`: the gamma function: `tgamma(5)` is 24.

trunc

`trunc($x)`: `$x` with its fraction dropped, towards zero: `trunc(-2.7)` is -2.

y0

`y0($x)`: the Bessel function of the second kind of order 0; `y1` is order 1, `yn` any order.

y1

`y1($x)`: the Bessel function of the second kind of order 1.

copysign

`copysign($x, $y)`: the magnitude of `$x` with the sign of `$y`, negative zero included: `copysign(3, -0.0)` is -3.

fdim

`fdim($x, $y)`: `$x - $y` when that is positive, else 0.

fmax

`fmax($x, $y)`: the larger of the two; a NaN argument is ignored: `fmax(1, "nan")` is 1.

fmin

`fmin($x, $y)`: the smaller of the two; a NaN argument is ignored.

fmod

`fmod($x, $y)`: the floating-point remainder of `$x / $y`, with the sign of `$x`: `fmod(7, -3)` is 1. Unlike %, it does not truncate its operands to integers. Exported by default.

hypot

`hypot($x, $y)`: `sqrt($x**2 + $y**2)`, without overflow or underflow in the squares: `hypot(3, 4)` is 5.

nextafter

`nextafter($x, $y)`: the next representable floating-point number after `$x` in the direction of `$y`.

nexttoward

`nexttoward($x, $y)`: as `nextafter`; C's version takes `$y` as a `long double`, which for a Perl number makes no difference.

remainder

`remainder($x, $y)`: `$x - $n * $y` with `$n` the integer nearest to `$x / $y` (halves to even), so the result can be negative: `remainder(7, 3)` is 1, `remainder(8, 3)` is -1.

frexp

Split a floating-point number into mantissa and exponent.

modf

Split a number into integer and fractional parts, both as doubles.

ldexp

Compute `$x * 2**$exp` with a single rounding step.

Synopsis

```
my $y = POSIX::ldexp(1.5, 10);   # 1536
```

Differences from upstream

Fully compatible with upstream POSIX.

scalbn

Compute `$x * FLT_RADIX**$n` efficiently. On IEEE-754 systems `scalbn` is equivalent to `ldexp`.

Differences from upstream

Fully compatible with upstream POSIX.

fma

Fused multiply-add: `$x * $y + $z` with a single rounding.

nan

Build a NaN, optionally carrying a payload.

remquo

Floating-point remainder with partial quotient.

jn

Bessel function of the first kind, integer order `$n`.

yn

Bessel function of the second kind, integer order `$n`.

Float classification

getpayload

`getpayload($nv)` - the payload carried by the NaN `$nv`, as a number.

setpayload

`setpayload($nv, $payload)` - make `$nv` a quiet NaN carrying `$payload`.

setpayloadsig

`setpayloadsig($nv, $payload)` - make `$nv` a SIGNALING NaN carrying `$payload`, writing the result back into the first argument exactly as `setpayload` does.

issignaling

`issignaling($nv)` - true when `$nv` is a signaling NaN.

fpclassify

Classify a floating-point number.

ilogb

Exponent of `$x` as an integer, `trunc(log2(|$x|))`.

Edge cases

- `ilogb(0)` returns `FP_ILOGB0` (typically `INT_MIN`).
- `ilogb(NaN)` returns `FP_ILOGBNAN`.
- `ilogb(inf)` returns `INT_MAX`.

Differences from upstream

Fully compatible with upstream POSIX.

isfinite

`isfinite($x)`: 1 when `$x` is neither infinite nor NaN, else 0.

isinf

`isinf($x)`: 1 when `$x` is infinite, of either sign, else 0.

isnan

`isnan($x)`: 1 when `$x` is NaN, else 0.

isnormal

`isnormal($x)`: 1 when `$x` is a normal number - not zero, subnormal, infinite or NaN: `isnormal(1e-310)` is 0.

signbit

`signbit($x)`: 1 when the sign bit of `$x` is set, which includes negative zero: `signbit(-0.0)` is 1.

lrint

Round `$x` to the nearest integer, respecting the current rounding mode, and return it as an integer.

Differences from upstream

Fully compatible with upstream POSIX.

See also

- `lround` - always rounds half-away-from-zero regardless of mode.
- `fegetround` / `fesetround` - query or change the rounding mode.

lround

Round `$x` half-away-from-zero to the nearest integer.

Differences from upstream

Fully compatible with upstream POSIX.

See also

- `lrint` - rounds according to the current FP rounding mode.

isgreater

`isgreater($x, $y)`: 1 when `$x > $y`, else 0 - and 0 when either is NaN, as for `isgreaterequal`, `isless`, `islessequal` and `islessgreater`; `isunordered` tells that case apart.

isgreaterequal

`isgreaterequal($x, $y)`: 1 when `$x >= $y`, else 0.

isless

`isless($x, $y)`: 1 when `$x < $y`, else 0.

islessequal

`islessequal($x, $y)`: 1 when `$x <= $y`, else 0.

islessgreater

`islessgreater($x, $y)`: 1 when `$x` is less or greater than `$y`, 0 when they are equal or either is NaN.

isunordered

`isunordered($x, $y)`: 1 when either is NaN, so that they cannot be compared, else 0.

fegetround

Current floating-point rounding direction.

What you get back

An integer matching one of the `FE_TONEAREST`, `FE_DOWNWARD`, `FE_UPWARD`, `FE_TOWARDZERO` constants.

Differences from upstream

Fully compatible with upstream POSIX.

See also

- `fesetround` - change the mode.

FLT_ROUNDS

The current rounding direction as C's `FLT_ROUNDS` reports it.

fesetround

Change the floating-point rounding direction.

Wait status

WEXITSTATUS

Exit code of a child that terminated normally.

WIFEXITED

True if the child terminated normally (via `exit` or `return` from `main`).

Differences from upstream

Fully compatible with upstream POSIX.

WIFSIGNALED

True if the child was killed by a signal.

Differences from upstream

Fully compatible with upstream POSIX.

See also

- `WTERMSIG` - the signal number, when this is true.

WIFSTOPPED

True if the child is stopped (usable with `waitpid(..., WUNTRACED)`).

Differences from upstream

Fully compatible with upstream POSIX.

WSTOPSIG

Signal number that stopped the child, meaningful only when `WIFSTOPPED($status)` is true.

Differences from upstream

Fully compatible with upstream POSIX.

WTERMSIG

Signal number that killed the child, meaningful only when `WIFSIGNALED($status)` is true.

Differences from upstream

Fully compatible with upstream POSIX.

Strings and printing

mblen

`mblen($s, $n = ~0)` - the number of bytes in the first multibyte character of `$s`, examining at most `$n` bytes.

mbtowc

`mbtowc($pwc, $s, $n = ~0)` - decode the first multibyte character of `$s` into `$pwc` and return how many bytes it occupied.

wctomb

`wctomb($s, $wchar)` - encode the wide character `$wchar` into `$s` and return the number of bytes written.

strtold

`strtold($str)` - parse a floating-point number off the front of `$str`.

strtod

Parse a double from the start of a string, locale-aware.

strtol

Parse a signed integer from the start of a string, in a given base.

strtoul

Parse an unsigned integer from the start of a string, in a given base.

strcoll

Compare two strings using the current `LC_COLLATE` ordering.

What you get back

A negative, zero, or positive integer, suitable for use as a `cmp`-like sort return. The ordering depends on the locale set via `setlocale(LC_COLLATE, ...)`.

Differences from upstream

Fully compatible with upstream POSIX.

strxfrm

Locale-transformed form of a string, for repeated collation.

System and process

`cuserid`

`cuserid($s = 0)` - the login name associated with the process's effective user ID, or `undef` when it cannot be determined.

`setuid`

Change the real user ID of the current process.

What you get back

1 on success, `0` on failure (and `$!` is set). Permission is required; only privileged processes can switch to arbitrary UIDs.

Differences from upstream

Fully compatible with upstream POSIX.

`setgid`

Change the real group ID of the current process.

What you get back

1 on success, `0` on failure.

Differences from upstream

Fully compatible with upstream POSIX.

`setpgid`

Put process `$pid` into process group `$pgid`.

`setsid`

Create a new session and become its leader.

What you get back

The new session ID on success, `-1` on failure. The caller must not already be a process group leader.

Differences from upstream

Fully compatible with upstream POSIX.

`uname`

Kernel and machine identification as a five-element list.

sysconf

Runtime system configuration value for the given `_SC_*` name.

_exit

Terminate the process immediately with the given status, skipping `END` blocks, destructors, and stdio flushing.

abort

Abort the process abnormally (typically producing a core dump).

Differences from upstream

Fully compatible with upstream POSIX.

nice

Adjust the current process's scheduling niceness by `$incr`.

pause

Suspend the process until any signal is delivered.

What you get back

Always `-1` (with `$!` set to `EINTR`) once a signal handler returns - `pause` has no "success" exit path.

Differences from upstream

Fully compatible with upstream POSIX.

sleep

Suspend the process for `$secs` seconds, or until a signal arrives.

What you get back

The number of seconds left unslept - `0` for a full sleep, or a positive remainder when a signal cut the sleep short.

Differences from upstream

Fully compatible with upstream POSIX.

File and I/O

ttyname

Device path of the terminal attached to `$fd`, or `undef` if none.

Differences from upstream

Fully compatible with upstream POSIX.

ctermid

Path of the controlling terminal.

What you get back

On most systems, the string `"/dev/tty"`.

Differences from upstream

Fully compatible with upstream POSIX.

getcwd

Current working directory as an absolute path.

What you get back

The path as a byte string, or `undef` if the call fails (for example, if the process has no read permission on some ancestor directory).

Differences from upstream

Fully compatible with upstream POSIX.

See also

- `Cwd::getcwd` - the recommended Perl-level interface.

access

Check the caller's permissions on a path.

lchown

Change the owner/group of a symlink itself (without following it).

Synopsis

```
POSIX::lchown($uid, $gid, $path);
```

What you get back

1 on success, `0` on failure.

Differences from upstream

Fully compatible with upstream POSIX.

mkfifo

Create a FIFO (named pipe) at `$path` with permission bits `$mode`.

What you get back

1 on success, `0` on failure.

Differences from upstream

Fully compatible with upstream POSIX.

open

Open a file by path, returning a raw file descriptor.

close

Close a raw file descriptor.

What you get back

`"0 but true"` on success, `undef` on failure. A negative `$fd` is rejected with `$!` set to `EBADF`.

Differences from upstream

Fully compatible with upstream POSIX.

See also

- open, dup, dup2 - where fds come from.

dup

Duplicate a file descriptor, returning the lowest-numbered unused fd.

What you get back

The new fd as an integer on success, `undef` on failure. A negative `$fd` is rejected with `$!` set to `EBADF`.

Differences from upstream

Fully compatible with upstream POSIX.

dup2

Duplicate `$fd1` onto `$fd2`, closing `$fd2` first if necessary.

lseek

Reposition the read/write offset of an open fd.

pipe

Create an anonymous pipe and return its two fds.

read

Read up to `$nbytes` bytes from `$fd` into `$buffer`.

write

Write bytes from `$buffer` to `$fd`.

Time

strftime

Format a broken-down time as a string using a format template.

mktime

Convert a broken-down local time into epoch seconds.

difftime

Difference between two epoch times, `$t1 - $t2`, as a double.

Differences from upstream

Fully compatible with upstream POSIX.

tzset

Refresh the process's timezone information from the `TZ` environment variable.

Differences from upstream

Fully compatible with upstream POSIX.

tzname

Short names of the current standard and daylight timezones.

clock

Approximate processor time used by the program, in `CLOCKS_PER_SEC` units.

What you get back

An integer count of clock ticks. Divide by `POSIX::CLOCKS_PER_SEC` for seconds. On Linux this counts user+system CPU time of the whole process.

Differences from upstream

Fully compatible with upstream POSIX.

times

Raw wall + CPU times of the process and its children, as a five-element list.

asctime

Canonical English timestamp string from a broken-down time.

`ctime`

Canonical English timestamp string for an epoch time, in local time.

Locale

`setlocale`

Query or change the program's locale setting.

`localeconv`

Numeric and monetary formatting rules for the active locale.

Errno and path limits

`fpathconf`

Runtime limit for a configuration variable on an open fd.

`pathconf`

Runtime limit for a configuration variable on a pathname.

What you get back

The limit value, or `-1` if unsupported/unlimited.

Differences from upstream

Fully compatible with upstream POSIX.

See also

- `fpathconf` - same query on an already-open fd.

Terminal control

`tcdrain`

Block until all queued output on `$fd` has been transmitted.

What you get back

`"0 but true"` on success, `undef` on failure. A negative `$fd` sets `$!` to `EBADF`.

Differences from upstream

Fully compatible with upstream POSIX.

`tcflow`

Suspend or resume transmission or reception on terminal `$fd`.

`tcflush`

Discard buffered input, output, or both on terminal `$fd`.

`tcsendbreak`

Send a continuous break condition on terminal `$fd` for roughly `$duration` tenths of a second (0 means the implementation default).

What you get back

`"0 but true"` on success, `undef` on failure. Negative `$duration` sets `$!` to `EINVAL`.

Differences from upstream

Fully compatible with upstream POSIX.

`tcgetpgrp`

Process group ID of the foreground process group for terminal `$fd`.

What you get back

The pgid as an integer, or `-1` on error (with `$!` set).

Differences from upstream

Fully compatible with upstream POSIX.

`tcsetpgrp`

Make `$pgrp` the foreground process group of terminal `$fd`.

What you get back

`"0 but true"` on success, `undef` on failure.

Differences from upstream

Fully compatible with upstream POSIX.

Signals

`sigprocmask`

Change, query, or both the set of signals blocked for this process.

`sigpending`

Fill `$sigset` with the signals currently pending for delivery.

What you get back

`"0 but true"` on success, `undef` on failure.

Differences from upstream

Fully compatible with upstream POSIX.

sigsuspend

Temporarily replace the signal mask with `$sigset` and suspend the process until any non-blocked signal arrives.

What you get back

Always `undef` (with `$!` set to `EINTR`) once a signal handler has run - there is no success exit path.

Differences from upstream

Fully compatible with upstream POSIX.

sigaction

Install or inspect a signal handler for signal `$sig`.

POSIX::SigSet

Functions

Signals

new

Create a `POSIX::SigSet` object, optionally pre-populated with the given signal numbers.

addset

Add signal `$sig` to the set.

What you get back

`"0 but true"` on success, `undef` on failure.

Differences from upstream

Fully compatible with upstream POSIX.

delset

Remove signal `$sig` from the set.

What you get back

`"0 but true"` on success, `undef` on failure.

Differences from upstream

Fully compatible with upstream POSIX.

emptyset

Remove every signal from the set.

Differences from upstream

Fully compatible with upstream POSIX.

fillset

Add every signal to the set.

Differences from upstream

Fully compatible with upstream POSIX.

ismember

Test whether signal `$sig` is in the set.

What you get back

1 if the signal is a member, `0` if it is not, `-1` on error.

Differences from upstream

Fully compatible with upstream POSIX.

new

Create a `POSIX::SigSet` object, optionally pre-populated with the given signal numbers.

Synopsis

```
use POSIX qw(SIGINT SIGTERM);
my $set = POSIX::SigSet->new(SIGINT, SIGTERM);
```

What you get back

A blessed `POSIX::SigSet` reference, with `sigemptyset` applied first and then each argument added via `sigaddset`.

Differences from upstream

Fully compatible with upstream POSIX.

See also

- `addset`, `delset`, `emptyset`, `fillset`, `ismember` - mutate or query the set.
- `sigprocmask` - install a `SigSet` as the process mask.

POSIX::Termios

Functions

Terminal control

new

Create a fresh `POSIX::Termios` object, all fields zeroed.

getattr

Fill the `POSIX::Termios` object with the current settings of `$fd`.

setattr

Apply the `POSIX::Termios` settings to `$fd`.

getispeed

Input baud rate encoded in the termios structure.

What you get back

The encoded speed as an integer (compare against `B9600`, `B115200`, etc., which this module also exports).

Differences from upstream

Fully compatible with upstream POSIX.

getospeed

Output baud rate encoded in the termios structure.

Differences from upstream

Fully compatible with upstream POSIX.

setispeed

Encode an input baud rate into the termios structure.

What you get back

`"0 but true"` on success, `undef` on failure. The change is not applied to the terminal until you call `setattr`.

Differences from upstream

Fully compatible with upstream POSIX.

`setospeed`

Encode an output baud rate into the termios structure.

Differences from upstream

Fully compatible with upstream POSIX.

`getcc`

Value of a special control character in the termios structure.

`setcc`

Set a special control character in the termios structure.

Edge cases

- Indices beyond `NCCS` croak with `Bad setcc subscript`.
- The change is not applied until you call `setattr`.

Differences from upstream

Fully compatible with upstream POSIX.

`new`

Create a fresh `POSIX::Termios` object, all fields zeroed.

Synopsis

```
use POSIX;
my $t = POSIX::Termios->new;
$t->getattr(fileno(STDIN));
```

What you get back

A blessed `POSIX::Termios` reference. To fill it with the current terminal settings, follow up with `$t->getattr($fd)`.

Differences from upstream

Fully compatible with upstream POSIX.

See also

- `getattr`, `setattr` - populate and apply terminal settings.

getattr

Fill the `POSIX::Termios` object with the current settings of `$fd`.

Synopsis

```
$t->getattr(fileno(STDIN));
```

What you get back

`"0 but true"` on success, `undef` on failure. `$fd` defaults to `0` (stdin).

Differences from upstream

Fully compatible with upstream POSIX.

setattr

Apply the `POSIX::Termios` settings to `$fd`.

Synopsis

```
use POSIX qw(TCSANOW TCSADRAIN);
$t->setattr(fileno(STDIN), TCSANOW);
```

What you get back

`"0 but true"` on success, `undef` on failure. `$fd` defaults to `0`, `$optional_actions` defaults to `TCSANOW` (apply immediately).

Edge cases

- Negative `$optional_actions` sets `$!` to `EINVAL`.

Differences from upstream

Fully compatible with upstream POSIX.

getcc

Value of a special control character in the termios structure.

Synopsis

```
use POSIX qw(VINTR VEOF);
my $intr = $t->getcc(VINTR);   # Ctrl-C byte
```

Edge cases

- Indices beyond the `NCCS` bound croak with `Bad getcc subscript`.

Differences from upstream

Fully compatible with upstream POSIX.

frexp

Split a floating-point number into mantissa and exponent.

Synopsis

```
my ($frac, $exp) = POSIX::frexp($x);
# $x == $frac * 2**$exp, with 0.5 <= |$frac| < 1 (or $frac == 0).
```

What you get back

A two-element list: the fractional part as a double and the exponent as an integer.

Differences from upstream

Fully compatible with upstream POSIX.

See also

- `ldexp` - the inverse operation: reassemble `$x` from `$frac` and `$exp`.
- `modf` - split into integer and fractional parts instead.

modf

Split a number into integer and fractional parts, both as doubles.

Synopsis

```
my ($frac, $int) = POSIX::modf(3.75);   # (0.75, 3.0)
```

What you get back

A two-element list `($frac, $int)`. Both parts carry the sign of the input.

Differences from upstream

Fully compatible with upstream POSIX.

See also

- `frexp` - split into mantissa and exponent instead.

fma

Fused multiply-add: `$x * $y + $z` with a single rounding.

Synopsis

```
my $r = POSIX::fma($x, $y, $z);
```

What you get back

A double. Because there is only one rounding step, the result can be more accurate than the naive two-step expression, especially for catastrophic-cancellation patterns like `$a * $b - $c * $d` rewritten as `fma($a, $b, -($c * $d))`.

Differences from upstream

Fully compatible with upstream POSIX.

nan

Build a NaN, optionally carrying a payload.

Synopsis

```
my $q = POSIX::nan();     # the platform's default NaN
my $p = POSIX::nan(42);   # NaN carrying payload 42
```

What you get back

A NaN whose low mantissa bits hold the payload, readable again with `POSIX::getpayload`. The payload is truncated to the 51 bits an IEEE double has room for.

Edge cases

- No argument yields the default NaN, which is not necessarily the zero payload on every platform.
- The argument is a NUMBER, not a string of digits: `nan("0x2a")` numifies to 0, and `nan("42abc")` to 42, exactly as any other numeric context would.
- A negative payload wraps rather than clamping, so `nan(-1)` gives the all-ones payload.

Differences from upstream

Payloads at or above 2**64 only: see `nv_to_uv_c`. Every payload an IEEE double can actually represent matches upstream exactly.

remquo

Floating-point remainder with partial quotient.

Synopsis

```
my ($rem, $quo) = POSIX::remquo($x, $y);
```

What you get back

A two-element list: the IEEE remainder and the low bits of the quotient as an integer (typically at least three bits, enough for argument reduction of trigonometric functions).

Differences from upstream

Fully compatible with upstream POSIX.

jn

Bessel function of the first kind, integer order `$n`.

Synopsis

```
my $y = POSIX::jn($n, $x);
```

Differences from upstream

Fully compatible with upstream POSIX.

See also

- `j0`, `j1` - fixed-order variants for `$n == 0` and `$n == 1`.
- yn - Bessel function of the second kind.

yn

Bessel function of the second kind, integer order `$n`.

Synopsis

```
my $y = POSIX::yn($n, $x);
```

Edge cases

- `yn($n, 0)` returns negative infinity (the function has a singularity at zero).

Differences from upstream

Fully compatible with upstream POSIX.

See also

- `y0`, `y1` - fixed-order variants.
- `jn` - Bessel function of the first kind.

fpclassify

Classify a floating-point number.

Synopsis

```
use POSIX qw(fpclassify FP_NAN FP_INFINITE FP_ZERO FP_SUBNORMAL FP_
 ↪NORMAL);
my $k = fpclassify($x);
```

What you get back

An integer matching one of the `FP_*` constants. Compare against the symbolic names, not a hardcoded number - the values are libc implementation details.

Differences from upstream

Fully compatible with upstream POSIX.

See also

- `isnan`, `isinf`, `isfinite`, `isnormal` - narrower single-class tests.

FLT_ROUNDS

The current rounding direction as C's `FLT_ROUNDS` reports it.

What you get back

1 for round-to-nearest, which is the default. The other values are `0` toward zero, `2` toward +infinity, `3` toward -infinity.

Differences from upstream

None. `FLT_ROUNDS` is a FUNCTION here, not a constant, because it is one upstream too: it takes no arguments and raises a usage error if given any, and its value tracks `fesetround` instead of being fixed once and for all.

fesetround

Change the floating-point rounding direction.

Synopsis

```
use POSIX qw(fesetround FE_DOWNWARD);
fesetround(FE_DOWNWARD);
```

What you get back

`0` on success, non-zero if the requested mode is not supported.

Differences from upstream

Fully compatible with upstream POSIX.

WEXITSTATUS

Exit code of a child that terminated normally.

Synopsis

```
system($cmd);
my $code = POSIX::WEXITSTATUS($?);
```

What you get back

The low 8 bits of the child's `exit()` argument. Only meaningful when `WIFEXITED($status)` is true.

Differences from upstream

Fully compatible with upstream POSIX.

strtod

Parse a double from the start of a string, locale-aware.

Synopsis

```
use POSIX qw(strtod);
my ($num, $unparsed) = strtod("3.14abc");   # (3.14, 3)
```

What you get back

A two-element list: the parsed value and the number of bytes that did not form part of the number. When `$unparsed == 0`, the whole string was consumed.

Edge cases

- Input that doesn't start with a number: returns `(0, length)`.
- Overflow: returns `HUGE_VAL` and sets `$!` to `ERANGE`.

Differences from upstream

Fully compatible with upstream POSIX.

See also

- `strtol`, `strtoul` - integer variants.

strtol

Parse a signed integer from the start of a string, in a given base.

Synopsis

```
use POSIX qw(strtol);
my ($n, $unparsed) = strtol("0x2a rest", 0);   # (42, 5)
```

What you get back

A two-element list: the parsed integer and the number of bytes that were not consumed. Base `0` auto-detects from prefix (`0x`, `0b`, leading `0`); otherwise `$base` must be 2-36.

Edge cases

- Invalid base: returns `(undef, undef)` and sets `$!` to `EINVAL`.
- Overflow: returns `LONG_MIN` / `LONG_MAX` and sets `$!` to `ERANGE`.

Differences from upstream

Fully compatible with upstream POSIX.

See also

- `strtoul` - unsigned variant.
- `strtod` - floating-point variant.

strtoul

Parse an unsigned integer from the start of a string, in a given base.

Synopsis

```
use POSIX qw(strtoul);
my ($n, $unparsed) = strtoul("255 end", 10);
```

Edge cases

- Invalid base: returns `(undef, undef)` and sets `$!` to `EINVAL`.
- Negative input: parsed and two's-complement-cast to unsigned, matching C `strtoul`.

Differences from upstream

Fully compatible with upstream POSIX.

See also

- `strtol` - signed variant.

strxfrm

Locale-transformed form of a string, for repeated collation.

Synopsis

```
use POSIX qw(strxfrm);
my @sorted = map { $_->[1] }
             sort { $a->[0] cmp $b->[0] }
             map { [ strxfrm($_), $_ ] } @words;
```

What you get back

A byte string whose plain `cmp` ordering equals `strcoll`'s ordering of the originals under the current `LC_COLLATE` locale. Worth it when the same string is compared many times, as in a sort.

Differences from upstream

Fully compatible with upstream POSIX.

setpgid

Put process `$pid` into process group `$pgid`.

Synopsis

```
POSIX::setpgid($pid, $pgid);
```

What you get back

1 on success, `0` on failure. A `$pid` of `0` means the calling process; a `$pgid` of `0` means use `$pid` as the new group ID.

Differences from upstream

Fully compatible with upstream POSIX.

uname

Kernel and machine identification as a five-element list.

Synopsis

```
use POSIX qw(uname);
my ($sysname, $nodename, $release, $version, $machine) = uname();
```

What you get back

Five strings in order: sysname (e.g. `"Linux"`), nodename (hostname), release (kernel release), version (kernel version string), and machine (architecture, e.g. `"x86_64"`).

Edge cases

- On `uname` failure, returns an empty list.

Differences from upstream

Fully compatible with upstream POSIX.

sysconf

Runtime system configuration value for the given _SC_* name.

Synopsis

```
use POSIX qw(sysconf _SC_OPEN_MAX _SC_PAGESIZE);
my $max_fd = sysconf(_SC_OPEN_MAX);
```

What you get back

The configured value, or -1 if the option is not supported (in which case $! may or may not be set - distinguish by checking $! before and after).

Differences from upstream

Fully compatible with upstream POSIX.

access

Check the caller's permissions on a path.

Synopsis

```
use POSIX qw(access R_OK W_OK);
print "readable\n" if access($path, R_OK);
```

What you get back

The string "0 but true" when the access check succeeds, or undef when it fails (with $! set). The "0 but true" return matches core Perl's convention for system calls whose success value is 0.

Edge cases

- Check uses real (not effective) UID/GID, so is vulnerable to TOCTOU races; prefer trying the operation and handling failure.

Differences from upstream

Fully compatible with upstream POSIX.

open

Open a file by path, returning a raw file descriptor.

Synopsis

```
use POSIX qw(open O_RDONLY O_CREAT O_WRONLY);
my $fd = open($path, O_RDONLY)
    or die "open: $!";
```

What you get back

A non-negative integer fd on success, `undef` on failure (with `$!` set). This is the raw system fd, not a Perl filehandle - pair it with `POSIX::close` or convert via `IO::Handle::fdopen`.

Differences from upstream

Fully compatible with upstream POSIX. Third argument `$mode` defaults to `0666` when opening with `O_CREAT` and no mode given.

See also

- `close`, dup, `lseek`, `read`, `write` - the rest of the raw fd API.
- Core open - the Perl-native filehandle interface.

dup2

Duplicate `$fd1` onto `$fd2`, closing `$fd2` first if necessary.

Synopsis

```
POSIX::dup2($fd, 1);   # redirect stdout to $fd
```

What you get back

The target fd on success, `undef` on failure. Either argument being negative is rejected with `$!` set to EBADF.

Differences from upstream

Fully compatible with upstream POSIX.

lseek

Reposition the read/write offset of an open fd.

Synopsis

```
use POSIX qw(lseek SEEK_SET SEEK_CUR SEEK_END);
my $pos = lseek($fd, 0, SEEK_CUR);    # current offset
```

What you get back

The new absolute offset on success, `-1` on failure (with `$!` set).

Differences from upstream

Fully compatible with upstream POSIX.

pipe

Create an anonymous pipe and return its two fds.

Synopsis

```
use POSIX qw(pipe);
my ($rd, $wr) = pipe();
```

What you get back

A two-element list `($read_fd, $write_fd)` on success. On failure, a single `undef` is returned and `$!` is set.

Differences from upstream

Fully compatible with upstream POSIX.

read

Read up to `$nbytes` bytes from `$fd` into `$buffer`.

Synopsis

```
use POSIX qw(read);
my $buf = "";
my $n = read($fd, $buf, 4096);
```

What you get back

On success, the number of bytes read (or `"0 but true"` for EOF); on failure, `undef` (with `$!` set). The data is written into `$buffer` in place - truncated or grown to match the actual read length.

Edge cases

- Partial reads are normal on pipes, sockets, and terminals; always check the return length.

Differences from upstream

Fully compatible with upstream POSIX.

write

Write bytes from `$buffer` to `$fd`.

Synopsis

```
POSIX::write($fd, $data, length($data));
```

What you get back

The number of bytes actually written. A value less than `$nbytes` is not an error - common for pipes and sockets - and the caller must loop to write the rest.

Differences from upstream

Fully compatible with upstream POSIX.

strftime

Format a broken-down time as a string using a format template.

Synopsis

```
use POSIX qw(strftime);
my @tm = localtime;
my $str = strftime("%Y-%m-%d %H:%M:%S", @tm);
```

What you get back

A byte string formatted according to the template. Argument order matches `localtime` / `gmtime`: second, minute, hour, mday, mon (0-11), year (years since 1900), wday, yday, isdst - the last three optional and defaulting to `-1`.

Edge cases

- Fewer than seven arguments (format plus the first six tm fields): returns the empty string.
- Output truncated at 1024 bytes.

- Month is 0-11 and year is years-since-1900, the `struct tm` convention, *not* the 1-12 / 4-digit-year human convention.
- `$wday` and `$yday` are accepted and IGNORED, as upstream ignores them. Both are derived from the date, so passing a wrong weekday cannot produce a wrong `%A`; passing none is the normal call.
- Out-of-range fields normalise rather than being echoed back: month 12 is January of the following year.

Differences from upstream

Fully compatible with upstream POSIX.

See also

- `mktime` - go the other way: broken-down time to epoch seconds.
- `asctime`, `ctime` - simpler canned-format alternatives.

mktime

Convert a broken-down local time into epoch seconds.

Synopsis

```
use POSIX qw(mktime);
my $t = mktime($sec, $min, $hour, $mday, $mon, $year - 1900);
```

What you get back

The epoch seconds as an integer on success. The sentinel value `"0 but true"` is returned when the epoch genuinely is `0` (so you can distinguish it from failure). `undef` is returned on failure (when the input cannot be represented).

Edge cases

- The `tm` fields are normalised in place by libc, so values outside the usual ranges (e.g. `mon = 13`) are accepted and carry into adjacent fields.
- `wday` and `yday` are ignored on input; `isdst` defaults to `-1` (let libc figure it out) when omitted.

Differences from upstream

Fully compatible with upstream POSIX.

tzname

Short names of the current standard and daylight timezones.

Synopsis

```
use POSIX qw(tzname);
my ($std, $dst) = tzname();
```

What you get back

A two-element list. Both strings are derived from `TZ` - the call also implicitly refreshes the timezone cache.

Differences from upstream

Fully compatible with upstream POSIX.

times

Raw wall + CPU times of the process and its children, as a five-element list.

Synopsis

```
my ($real, $user, $sys, $cuser, $csys) = POSIX::times();
```

What you get back

Five integer tick counts, in `sysconf(_SC_CLK_TCK)` units - raw, not divided by the ticks-per-second constant. Divide if you want seconds.

Differences from upstream

Fully compatible with upstream POSIX.

asctime

Canonical English timestamp string from a broken-down time.

Synopsis

```
use POSIX qw(asctime);
my @tm = localtime;
print asctime(@tm);   # "Wed Apr 22 14:30:00 2026\n"
```

What you get back

A 25-byte string **including the trailing newline**, or `undef` if nine arguments are not supplied.

Differences from upstream

Fully compatible with upstream POSIX. The trailing newline is preserved as-is; do not assume this function trims it.

ctime

Canonical English timestamp string for an epoch time, in local time.

Synopsis

```
use POSIX qw(ctime);
print ctime(time);   # "Wed Apr 22 14:30:00 2026\n"
```

What you get back

A 25-byte string including the trailing newline, or `undef` on conversion failure.

Differences from upstream

Fully compatible with upstream POSIX. The trailing newline is preserved.

See also

- `asctime` - same formatting, but from a broken-down time list.

_exit

Terminate the process immediately with the given status, skipping `END` blocks, destructors, and stdio flushing.

Synopsis

```
POSIX::_exit(0);
```

`POSIX::exit` is a different function: perl's own `exit`, which does run `END` blocks and destructors.

Differences from upstream

Fully compatible with upstream POSIX.

nice

Adjust the current process's scheduling niceness by `$incr`.

Synopsis

```
POSIX::nice(5);   # lower priority
```

What you get back

The new niceness value. When the new value genuinely is `0`, returns the string `"0 but true"` to distinguish it from error. On error, returns `undef` and sets `$!`.

Edge cases

- Positive increments lower priority; only root can pass negative values to raise priority.

Differences from upstream

Fully compatible with upstream POSIX.

setlocale

Query or change the program's locale setting.

Synopsis

```
use POSIX qw(setlocale LC_ALL LC_NUMERIC);
setlocale(LC_ALL, "");              # honour environment
my $cur = setlocale(LC_NUMERIC);    # query current
```

What you get back

The resulting locale name as a string, or `undef` if the category/locale combination is invalid. Calling with one argument queries; calling with two sets. Passing `""` as the new locale asks libc to pick from `LC_*` / `LANG` environment variables.

Edge cases

- Changing a category can affect formatting of numbers, collation, date strings, and error messages throughout the process.

Differences from upstream

Fully compatible with upstream POSIX.

See also

- `localeconv` - inspect the active locale's numeric and monetary conventions.

localeconv

Numeric and monetary formatting rules for the active locale.

Synopsis

```
use POSIX qw(localeconv);
my $lc = localeconv();
print "Decimal: $lc->{decimal_point}\n";
```

What you get back

A hashref whose keys are the `struct lconv` field names - `decimal_point`, `thousands_sep`, `grouping`, `int_curr_symbol`, `currency_symbol`, `mon_decimal_point`, `mon_thousands_sep`, `mon_grouping`, `positive_sign`, `negative_sign`, and the monetary char fields (`int_frac_digits`, `frac_digits`, `p_cs_precedes`, `p_sep_by_space`, `n_cs_precedes`, `n_sep_by_space`, `p_sign_posn`, `n_sign_posn`).

Edge cases

- Char fields equal to `CHAR_MAX` mean "not available in this locale"; all numeric char fields are returned unconditionally.
- Returns `undef` if libc `localeconv()` fails (rare).

Differences from upstream

Fully compatible with upstream POSIX.

See also

- `setlocale` - pick which locale those rules come from.

fpathconf

Runtime limit for a configuration variable on an open fd.

Synopsis

```
use POSIX qw(fpathconf _PC_NAME_MAX);
my $max = fpathconf($fd, _PC_NAME_MAX);
```

What you get back

The limit value, or `-1` if the variable is unsupported or unlimited (check `$!` to distinguish).

Differences from upstream

Fully compatible with upstream POSIX.

tcflow

Suspend or resume transmission or reception on terminal `$fd`.

Synopsis

```
use POSIX qw(tcflow TCOOFF TCOON);
tcflow($fd, TCOOFF);   # pause output
```

What you get back

`"0 but true"` on success, `undef` on failure. Negative `$action` sets `$!` to `EINVAL`.

Differences from upstream

Fully compatible with upstream POSIX.

tcflush

Discard buffered input, output, or both on terminal `$fd`.

Synopsis

```
use POSIX qw(tcflush TCIFLUSH TCOFLUSH TCIOFLUSH);
tcflush($fd, TCIOFLUSH);   # drop pending input and output
```

What you get back

`"0 but true"` on success, `undef` on failure. Negative `$queue_selector` sets `$!` to `EINVAL`.

Differences from upstream

Fully compatible with upstream POSIX.

sigprocmask

Change, query, or both the set of signals blocked for this process.

Synopsis

```
use POSIX qw(sigprocmask SIG_BLOCK SIG_UNBLOCK SIG_SETMASK);
my $mask = POSIX::SigSet->new(SIGINT);
sigprocmask(SIG_BLOCK, $mask);
```

What you get back

`"0 but true"` on success, `undef` on failure. When `$oldsigset` is supplied, it is filled with the mask in effect before the call.

Edge cases

- Passing a non-`POSIX::SigSet` reference for either set croaks with `sigset is not of type POSIX::SigSet` / `oldsigset is not of type POSIX::SigSet`.

Differences from upstream

Fully compatible with upstream POSIX.

See also

- `sigpending`, `sigsuspend`, `sigaction` - the rest of the POSIX signal API.

sigaction

Install or inspect a signal handler for signal `$sig`.

Synopsis

```
use POSIX qw(sigaction SIGINT);
my $action = POSIX::SigAction->new("IGNORE");
my $old = POSIX::SigAction->new;
sigaction(SIGINT, $action, $old);
```

What you get back

`"0 but true"` on success, `undef` on failure. When `$oldaction` is supplied, it is populated with the previous `HANDLER`, `MASK`, `FLAGS`, and `SAFE` fields.

Edge cases

- Negative `$sig` croaks with `Negative signals are not allowed`.
- An action hash without a `HANDLER` key croaks with `Can't supply an action without a HANDLER`.

See also

- `sigprocmask` - change the blocked-signal mask.
- `POSIX::SigSet` - build the `MASK` field of an action.

5.2.77 Package

Namespace containing the following modules:

- `Package::Stash`

Package::Stash

Namespace containing the following modules:

- `Package::Stash::XS` - The compiled implementation of Package::Stash: reading and changing a package's symbol table - its scalars, arrays, hashes, subs and IO handles - by name.

Package::Stash::XS

The compiled implementation of Package::Stash: reading and changing a package's symbol table - its scalars, arrays, hashes, subs and IO handles - by name.

A variable is named with its sigil (`'$foo'`, `'@ISA'`, `'%h'`, `'&f'`; no sigil means the IO handle) or given as `{ name => 'foo', type => 'SCALAR' }`. `add_symbol` installs a value, `get_symbol` returns a reference to it, `get_or_add_symbol` vivifies it first, `has_symbol` and `remove_symbol` test and remove one slot, `remove_glob` the whole glob, and `list_all_symbols` / `get_all_symbols` list them, optionally of one type. The object may also wrap an anonymous stash (a hash ref).

This is a native implementation of Package::Stash::XS 0.32's `XS.xs`; its `Package/Stash/XS.pm` is used unchanged, and Package::Stash, which picks it as its implementation, comes from CPAN.

Synopsis

```
use Package::Stash;                    # uses this one when it can

my $stash = Package::Stash->new('Foo');
$stash->add_symbol('%foo', { bar => 1 });
$stash->add_symbol('&hello', sub { "Hello" });
print ${ $stash->get_symbol('%foo') }{bar}, "\n";
print join(' ', sort $stash->list_all_symbols('CODE')), "\n";
$stash->remove_symbol('&hello');
```

Differences from upstream

None.

Functions

Symbol tables

new

A stash object for the package named `$package`, or for the anonymous stash `\%stash`.

name

The package's name.

Edge cases

- Called on the class dies "Can't call name as a class method".
- An anonymous stash has none: dies "Can't get the name of an anonymous package".

namespace

A reference to the stash itself: `\%Foo::Bar::`, created when there is none yet. The object keeps it as a weak reference.

Edge cases

- Called on the class dies "Can't call namespace as a class method".

add_symbol

Install `$initial` in a slot: a reference installs its referent, a plain value a copy of it, nothing an empty value. Under the debugger (`$^P & 0x10`) a sub also gets its `%DB::sub` entry, from `filename`, `first_line_num` and `last_line_num` options.

remove_glob

Delete the whole glob `$name` (no sigil) from the stash.

has_symbol

Whether the slot holds something: 1 or 0, undef when the stash has no such entry at all.

Edge cases

- An entry that is not yet a glob (a sub stub or constant) counts as a sub and as nothing else.

get_symbol

A reference to the slot's value, or undef when it has none.

get_or_add_symbol

A reference to the slot's value, created empty when there is none.

Edge cases

- &name dies "Don't know how to vivify CODE variables" whenever the entry exists.

remove_symbol

Empty one slot of the glob; for an entry that is not yet a glob, & deletes it.

list_all_symbols

The names in the stash, or with a type the names whose slot of that type holds something.

Synopsis

```
my @all  = $stash->list_all_symbols;
my @subs = $stash->list_all_symbols('CODE');
```

Edge cases

- A type that is not a string dies "vartype must be a string".

get_all_symbols

A hash of the stash: name => glob, or with a type name => a reference to that slot's value, for the names whose slot holds something. Entries that are not yet globs are made globs first.

Synopsis

```
my $subs = $stash->get_all_symbols('CODE');   # { name => \&code }
```

new

A stash object for the package named $package, or for the anonymous stash \%stash.

Synopsis

```
my $s = Package::Stash::XS->new('Foo::Bar');
my $a = Package::Stash::XS->new({});          # an anonymous stash
```

Edge cases

- A name that is not a module name dies “NAME is not a module name”.
- Anything but a string or a hash ref dies “Package::Stash->new must be passed the name of the package to access”.

add_symbol

Install `$initial` in a slot: a reference installs its referent, a plain value a copy of it, nothing an empty value. Under the debugger (`$^P & 0x10`) a sub also gets its `%DB::sub` entry, from `filename`, `first_line_num` and `last_line_num` options.

Synopsis

```
$stash->add_symbol('$x', \1);
$stash->add_symbol('@ISA', ['Base']);
$stash->add_symbol('&f', sub { 42 }, filename => 'gen.pl', first_
↪line_num => 1);
```

Edge cases

- A value of the wrong kind dies “VALUE is not of type TYPE”.
- `&name` with no value dies “Don’t know how to vivify CODE variables”.
- A name containing `::` dies “Variable names may not contain ::”.

5.2.78 PadWalker

Reach into another subroutine’s `my` and `our` variables - read them, change them, find out their names - from anywhere on the call stack.

`PadWalker` is the tool of choice for debuggers, introspection utilities, and any code that needs to look at variables it did not declare. It is what Perl’s own built-in debugger uses, and it is the modern replacement for `Devel::LexAlias` when you want to alias or substitute a lexical in a caller’s pad.

Every function that walks the stack takes a `$level` argument interpreted just like the argument to `caller`:

- `0` - the current scope.
- `1` - the scope of whoever called the current sub.
- `2` - two frames up, and so on.

File scope is a valid destination: asking for a `$level` deeper than the call stack supports raises `Not nested deeply enough`.

Returned hashes key on the variable name *including* its sigil - so `$x` appears under the key `'$x'`, `@items` under `'@items'`. Values are always references to the live variable, so assigning through the reference updates the original.

```
use PadWalker qw(peek_my closed_over var_name set_closed_over);

sub inner {
    my $vars = peek_my(1);                          # the caller's␣
↪lexicals
    ${ $vars->{'$count'} }++;                       # change the caller
↪'s $count
    return join ",", sort keys %$vars;
}
sub outer {
    my $count = 41;
    my @items = (1, 2);
    my $names = inner();
    print "$names; count is now $count\n";      # $count,@items;␣
↪count is now 42
}
outer();

my $x = 10;
my $add = sub { $_[0] + $x };
print join(",", keys %{ closed_over($add) }), " | ", var_name(0, \
↪$x), "\n";   # $x | $x
set_closed_over($add, { '$x' => \100 });
print $add->(1), "\n";                              # 101
```

The functions are peek_my, peek_our, peek_sub (the lexicals a sub declares), closed_over and set_closed_over (the variables a closure captured), and var_name (the name of a variable, given a reference to it). This is a native implementation of PadWalker 2.5; its PadWalker.pm is used unchanged, and nothing is exported by default.

Differences from upstream

None.

Functions

Lexical inspection

peek_my

Return every my variable in scope at a given call-stack depth as a hash of name-to-reference pairs.

peek_our

Return every our variable in scope at a given call-stack depth as a hash of name-to-reference pairs.

peek_sub

Return the `my` variables declared inside a given subroutine, whether or not the sub is currently on the call stack.

closed_over

Return the lexicals that a subroutine closes over - the variables it references but did not itself declare.

var_name

Given a reference to a variable, return the name that variable has in a specified subroutine's pad - or `undef` if it is not there.

Lexical modification

set_closed_over

Replace the lexicals that a subroutine closes over with a new set of references.

peek_my

Return every `my` variable in scope at a given call-stack depth as a hash of name-to-reference pairs.

Synopsis

```
use PadWalker qw(peek_my);
my $h = peek_my($level);
```

What you get back

A hash reference. Each key is a variable name *with* its sigil - `'$x'`, `'@list'`, `'%env'`. Each value is a reference to the live variable, so dereferencing and assigning through it changes the original. `our` variables are not included; use `peek_our` for those.

Examples

Read a `my` variable in the current scope:

```
my $x = 12;
my $h = peek_my(0);
print ${ $h->{'$x'} };      # 12
```

Modify the caller's `my` variable:

```
sub bump_x {
    my $h = peek_my(1);
```

(continues on next page)

(continued from previous page)

```
    ${ $h->{'$x'} }++;
}
my $x = 5;
bump_x();
print $x;                   # 6
```

A `my` declared deeper than the target frame is not in the returned hash - only variables visible at the call site come back.

Edge cases

- Called with other than one argument: croaks with `Usage: PadWalker::peek_my(uplevel)`.
- `$level` deeper than the call stack croaks with `Not nested deeply enough`.
- Negative `$level` is not supported and croaks.
- Variables declared inside an `eval BLOCK` between the target frame and the call site are folded in at the sequence number of the call - they become visible alongside the target's own lexicals.

Differences from upstream

Fully compatible with upstream PadWalker 2.5.

See also

- `peek_our` - same idea for `our` variables.
- `peek_sub` - inspect a CV's pad directly, without walking frames.
- `var_name` - given a reference, find the name it had in a pad.

peek_our

Return every `our` variable in scope at a given call-stack depth as a hash of name-to-reference pairs.

Synopsis

```
use PadWalker qw(peek_our);
my $h = peek_our($level);
```

What you get back

A hash reference keyed on sigiled variable names, with values that are references to the package variables those `our` declarations alias. Dereferencing reads from the package slot; assigning through the reference writes back to it.

Examples

```
package Main;
our $config = 'ok';
my $h = peek_our(0);
print ${ $h->{'$config'} };  # ok
```

Inspect a caller's our variables:

```
sub show_our {
    my $h = peek_our(1);
    print join ",", sort keys %$h;
}
```

Edge cases

- `$level` works exactly as in `peek_my` - `0` for the current scope, `1` for the caller, and so on.
- `our` declarations are resolved through the package stash in effect at the declaration site, not the calling site.
- A package with an `our` name but no value yet appears in the hash with a reference to `undef`.

Differences from upstream

Fully compatible with upstream PadWalker 2.5.

See also

- `peek_my` - the sibling for `my` variables.
- `var_name` - resolve a reference back to its declared name.

peek_sub

Return the `my` variables declared inside a given subroutine, whether or not the sub is currently on the call stack.

Synopsis

```
use PadWalker qw(peek_sub);
my $h = peek_sub(\&some_sub);
```

What you get back

A hash reference keyed on sigiled variable names. The references point at whatever values the pad currently holds. If the sub is not active, those values will typically be `undef` for scalars or empty for aggregates - the sub has not yet run to populate them. If the sub *is* active, the references point at the live values of the most recent invocation.

Examples

```
my $x = "Hello!";
my $r = peek_sub(sub { $x })->{'$x'};
print $$r;                    # Hello!
```

Inspect the pad of a named sub:

```
sub counter { my $n = 0; sub { $n++ } }
my $h = peek_sub(\&counter);
print join ",", sort keys %$h;   # $n
```

Edge cases

- If the sub declares several `my` variables with the same name, only the last one is returned. There is no way to distinguish shadowed entries; this is a known upstream limitation.
- A sub with no pad of its own - one implemented natively rather than written in Perl - croaks with `PadWalker: cv has no padlist`.
- A sub name (a string) is looked up as `\&{"name"}` would be; anything else that is not code croaks with `PadWalker::peek_sub: cv is not a CODE reference`.

Differences from upstream

Fully compatible with upstream PadWalker 2.5.

See also

- `closed_over` - the strict subset of `peek_sub` covering only variables the sub closes over.
- `peek_my` - walk the live call stack instead of a named sub.
- `var_name` - name-from-reference lookup against the same pad.

closed_over

Return the lexicals that a subroutine closes over - the variables it references but did not itself declare.

Synopsis

```
use PadWalker qw(closed_over);
my $h = closed_over(\&some_sub);
my ($h, $slots) = closed_over(\&some_sub);
```

What you get back

In scalar context, a hash reference keyed on sigiled variable names with references to the enclosing variables as values. In list context, that hash reference plus a second hash reference keyed on the sub's pad slot indices (as numbers) - useful for tools that need to match up pad positions with values.

Only captured lexicals appear; `my` variables declared inside the sub itself and `our` variables are both excluded.

Examples

Classic closure:

```
my $n = 41;
my $adder = sub { $n + $_[0] };
my $h = closed_over($adder);
${ $h->{'$n'} } = 100;
print $adder->(1);            # 101
```

List form for serialisers that need pad indices:

```
my ($names, $slots) = closed_over($sub);
for my $idx (sort { $a <=> $b } keys %$slots) {
    print "slot $idx -> ", ${ $slots->{$idx} }, "\n";
}
```

Edge cases

- A sub that captures nothing returns an empty hash reference.
- A sub with no pad of its own - one implemented natively rather than written in Perl - returns empty hashes rather than croaking.
- A sub name (a string) is looked up as `\&{"name"}` would be; anything else that is not code croaks with `PadWalker::closed_over: cv is not a CODE reference`.

Differences from upstream

Fully compatible with upstream PadWalker 2.5.

See also

- `set_closed_over` - substitute the captured variables wholesale.
- `peek_sub` - full pad, not just the captures.
- `var_name` - given one of the returned references, find its name.

set_closed_over

Replace the lexicals that a subroutine closes over with a new set of references.

Synopsis

```
use PadWalker qw(set_closed_over);
set_closed_over(\&some_sub, \%replacements);
```

What you get back

Nothing useful - the function is called for its side effect. For every name in `%replacements` that matches one of the sub's captured pad slots, the corresponding slot is replaced by the referent of `$replacements{$name}`.

Examples

Swap a closure's captured variable for a different scalar:

```
my $n = 1;
my $say = sub { print "$n\n" };
my $other = 42;
set_closed_over($say, { '$n' => \$other });
$say->();                    # 42
```

Round-trip through `closed_over` is the idiomatic pattern:

```
my $refs = closed_over($sub);
$refs->{'$x'} = \my $fresh;
set_closed_over($sub, $refs);
```

Edge cases

- Names in `%replacements` that the sub does not close over are silently ignored.
- The reftype of each replacement must match the original - scalar for scalar, array for array, and so on. A mismatch croaks with `Incorrect reftype for variable NAME (got X expected Y)`.
- A non-reference value in `%replacements` croaks with `The variable for NAME is not a reference`.
- A second argument that is not a hash reference croaks with `PadWalker::set_closed_over: pad is not a HASH reference`.

Differences from upstream

Upstream PadWalker 2.5 crashes when the first argument is not a code reference, or is a sub with no pad of its own (one implemented natively rather than written in Perl); here both are a no-op.

See also

- `closed_over` - read the captures this function writes.
- `peek_sub` - broader inspection, read-only.

var_name

Given a reference to a variable, return the name that variable has in a specified subroutine's pad - or `undef` if it is not there.

Synopsis

```
use PadWalker qw(var_name);
my $name = var_name($level, \$var);
my $name = var_name(\&sub,  \$var);
```

What you get back

A string - the sigiled pad name, e.g. `'$foo'` or `'@items'`. If the reference does not correspond to any pad slot in the target sub, returns `undef`.

The first argument selects the sub to search: a non-negative integer is interpreted the same as the argument to `peek_my` (walk the call stack), a code reference is searched directly.

Examples

Look up the name of a local variable by reference:

```
my $foo;
print var_name(0, \$foo);        # $foo
```

Wrap it for use from helper subs:

```
sub my_name {
    return var_name(1, shift);
}
my $bar;
print my_name(\$bar);            # $bar
```

Edge cases

- References to globals, package variables, or anonymous SVs return `undef` - only pad entries are searched.
- If several pad slots point at the same SV, the last one wins (same caveat as `peek_sub`).
- The second argument must be a reference; passing a plain value croaks with `Usage: PadWalker::var_name(sub, var_ref)`.

Differences from upstream

Fully compatible with upstream PadWalker 2.5.

See also

- peek_my - the inverse direction, names to references.
- peek_sub - all names in a sub's pad regardless of value.
- closed_over - captured lexicals only.

5.2.79 Params

Namespace containing the following modules:

- Params::Check - A generic input parsing/checking mechanism.
- Params::Util - Check parameters: each function returns its argument if it is a value of the kind the name says, and undef if not.

Params::Check

A generic input parsing/checking mechanism.

SYNOPSIS

```
use Params::Check qw[check allow last_error];

sub fill_personal_info {
    my %hash = @_;
    my $x;

    my $tmpl = {
        firstname   => { required   => 1, defined => 1 },
        lastname    => { required   => 1, store => \$x },
        gender      => { required   => 1,
                         allow      => [qr/M/i, qr/F/i],
                       },
        married     => { allow      => [0,1] },
        age         => { default    => 21,
                         allow      => qr/^\d+$/,
                       },

        phone       => { allow => [ sub { return 1 if /$valid_re/ },
                                    '1-800-PERL' ]
                       },
        id_list     => { default        => [],
                         strict_type    => 1
                       },
        employer    => { default => 'NSA', no_override => 1 },
    };
```

(continues on next page)

(continued from previous page)

```
    ### check() returns a hashref of parsed args on success ###
    my $parsed_args = check( $tmpl, \%hash, $VERBOSE )
                        or die qw[Could not parse arguments!];

    ... other code here ...
}

my $ok = allow( $colour, [qw|blue green yellow|] );

my $error = Params::Check::last_error();
```

DESCRIPTION

Params::Check is a generic input parsing/checking mechanism.

It allows you to validate input via a template. The only requirement is that the arguments must be named.

Params::Check can do the following things for you:

- Convert all keys to lowercase
- Check if all required arguments have been provided
- Set arguments that have not been provided to the default
- Weed out arguments that are not supported and warn about them to the user
- Validate the arguments given by the user based on strings, regexes, lists or even subroutines
- Enforce type integrity if required

Most of Params::Check's power comes from its template, which we'll discuss below:

Template

As you can see in the synopsis, based on your template, the arguments provided will be validated.

The template can take a different set of rules per key that is used.

The following rules are available:

- default

  This is the default value if none was provided by the user. This is also the type `strict_type` will look at when checking type integrity (see below).

- required

  A boolean flag that indicates if this argument was a required argument. If marked as required and not provided, check() will fail.

- strict_type

This does a `ref()` check on the argument provided. The `ref` of the argument must be the same as the `ref` of the default value for this check to pass.

This is very useful if you insist on taking an array reference as argument for example.

- defined

  If this template key is true, enforces that if this key is provided by user input, its value is `defined`. This just means that the user is not allowed to pass `undef` as a value for this key and is equivalent to: allow => sub { defined $_[0] && OTHER TESTS }

- no_override

  This allows you to specify `constants` in your template. ie, they keys that are not allowed to be altered by the user. It pretty much allows you to keep all your `configurable` data in one place; the `Params::Check` template.

- store

  This allows you to pass a reference to a scalar, in which the data will be stored:

```
my $x;
my $args = check(foo => { default => 1, store => \$x }, $input);
```

  This is basically shorthand for saying:

```
my $args = check( { foo => { default => 1 }, $input );
my $x    = $args->{foo};
```

  You can alter the global variable $Params::Check::NO_DUPLICATES to control whether the `store`'d key will still be present in your result set. See the "Global Variables" section below.

- allow

  A set of criteria used to validate a particular piece of data if it has to adhere to particular rules.

  See the `allow()` function for details.

Functions

check(\%tmpl, \%args, [$verbose]);

This function is not exported by default, so you'll have to ask for it via:

```
use Params::Check qw[check];
```

or use its fully qualified name instead.

`check` takes a list of arguments, as follows:

- Template

  This is a hash reference which contains a template as explained in the `SYNOPSIS` and `Template` section.

- Arguments

  This is a reference to a hash of named arguments which need checking.

- Verbose

  A boolean to indicate whether `check` should be verbose and warn about what went wrong in a check or not.

  You can enable this program wide by setting the package variable `$Params::Check::VERBOSE` to a true value. For details, see the section on `Global Variables` below.

`check` will return when it fails, or a hashref with lowercase keys of parsed arguments when it succeeds.

So a typical call to check would look like this:

```
my $parsed = check( \%template, \%arguments, $VERBOSE )
                or warn q[Arguments could not be parsed!];
```

A lot of the behaviour of `check()` can be altered by setting package variables. See the section on `Global Variables` for details on this.

allow($test_me, \@criteria);

The function that handles the `allow` key in the template is also available for independent use.

The function takes as first argument a key to test against, and as second argument any form of criteria that are also allowed by the `allow` key in the template.

You can use the following types of values for allow:

- string

  The provided argument MUST be equal to the string for the validation to pass.

- regexp

  The provided argument MUST match the regular expression for the validation to pass.

- subroutine

  The provided subroutine MUST return true in order for the validation to pass and the argument accepted.

  (This is particularly useful for more complicated data).

- array ref

  The provided argument MUST equal one of the elements of the array ref for the validation to pass. An array ref can hold all the above values.

It returns true if the key matched the criteria, or false otherwise.

last_error()

Returns a string containing all warnings and errors reported during the last time `check` was called.

This is useful if you want to report then some other way than `carp`'ing when the verbose flag is on.

It is exported upon request.

Global Variables

The behaviour of Params::Check can be altered by changing the following global variables:

$Params::Check::VERBOSE

This controls whether Params::Check will issue warnings and explanations as to why certain things may have failed. If you set it to 0, Params::Check will not output any warnings.

The default is 1 when *warnings* are enabled, 0 otherwise;

$Params::Check::STRICT_TYPE

This works like the `strict_type` option you can pass to `check`, which will turn on `strict_type` globally for all calls to `check`.

The default is 0;

$Params::Check::ALLOW_UNKNOWN

If you set this flag, unknown options will still be present in the return value, rather than filtered out. This is useful if your subroutine is only interested in a few arguments, and wants to pass the rest on blindly to perhaps another subroutine.

The default is 0;

$Params::Check::STRIP_LEADING_DASHES

If you set this flag, all keys passed in the following manner:

```
function( -key => 'val' );
```

will have their leading dashes stripped.

$Params::Check::NO_DUPLICATES

If set to true, all keys in the template that are marked as to be stored in a scalar, will also be removed from the result set.

Default is false, meaning that when you use `store` as a template key, `check` will put it both in the scalar you supplied, as well as in the hashref it returns.

$Params::Check::PRESERVE_CASE

If set to true, *Params::Check* will no longer convert all keys from the user input to lowercase, but instead expect them to be in the case the template provided. This is useful when you want to use similar keys with different casing in your templates.

Understand that this removes the case-insensitivity feature of this module.

Default is 0;

$Params::Check::ONLY_ALLOW_DEFINED

If set to true, *Params::Check* will require all values passed to be `defined`. If you wish to enable this on a 'per key' basis, use the template option `defined` instead.

Default is 0;

$Params::Check::SANITY_CHECK_TEMPLATE

If set to true, *Params::Check* will sanity check templates, validating for errors and unknown keys. Although very useful for debugging, this can be somewhat slow in hot-code and large loops.

To disable this check, set this variable to `false`.

Default is 1;

$Params::Check::WARNINGS_FATAL

If set to true, *Params::Check* will `croak` when an error during template validation occurs, rather than return `false`.

Default is 0;

$Params::Check::CALLER_DEPTH

This global modifies the argument given to `caller()` by `Params::Check::check()` and is useful if you have a custom wrapper function around `Params::Check::check()`. The value must be an integer, indicating the number of wrapper functions inserted between the real function call and `Params::Check::check()`.

Example wrapper function, using a custom stacktrace:

```
sub check {
    my ($template, $args_in) = @_;

    local $Params::Check::WARNINGS_FATAL = 1;
    local $Params::Check::CALLER_DEPTH = $Params::Check::CALLER_
↪DEPTH + 1;
    my $args_out = Params::Check::check($template, $args_in);

    my_stacktrace(Params::Check::last_error) unless $args_out;
```

(continues on next page)

(continued from previous page)

```
    return $args_out;
}
```

Default is 0;

Params::Util

Check parameters: each function returns its argument if it is a value of the kind the name says, and `undef` if not.

`_STRING` is a defined, non-empty, non-reference value; `_NUMBER` one that is or looks like a number. `_SCALAR`, `_ARRAY`, `_HASH` and `_CODE` are unblessed references to such a thing, the plain names non-empty, the `0` forms (`_SCALAR0`, `_ARRAY0`, `_HASH0`) empty too. `_ARRAYLIKE`, `_HASHLIKE` and `_CODELIKE` also accept objects that overload `@{}`, `%{}` or `&{}`. `_REGEX` is a compiled regex, `_INSTANCE($obj, $class)` an object that `isa $class`.

These are the compiled functions of Params::Util 1.102; its `Params/Util.pm` and `Params/Util/PP.pm` are used unchanged, and the functions it has no compiled form of (`_IDENTIFIER`, `_CLASS`, `_POSINT`, `_SET`, `_HANDLE`, ...) come from `Params::Util::PP`.

Synopsis

```
use Params::Util qw(_STRING _HASH _INSTANCE);

sub new {
    my $class = shift;
    my $name  = _STRING(shift)         or die "no name";
    my $opts  = _HASH(shift) // {};
    my $log   = _INSTANCE(shift, 'Log') or die "no logger";
    ...
}
```

Differences from upstream

None.

Modules

- `Params::Util::PP` - PurePerl Params::Util routines

Functions

Value checks

_STRING

The value itself if it is a defined, non-reference string of at least one character (a number counts, in its string form), else undef.

Synopsis

```
my $name = _STRING($in) or die "need a name";
```

_NUMBER

The value itself if it is a number, or a non-empty string that looks like one (looks_like_number), else undef.

Synopsis

```
my $n = _NUMBER($in) // die "not a number";
```

Reference checks

_SCALAR0

An unblessed reference to a scalar, whatever it holds, else undef.

_SCALAR

An unblessed reference to a scalar holding a non-empty string, else undef.

Synopsis

```
my $text = _SCALAR($ref) or die "need a reference to some text";
```

_REGEX

A compiled regex (qr//), else undef.

_ARRAY0

An unblessed array reference, empty or not, else undef.

_ARRAY

An array reference with at least one element, else undef.

Synopsis

```
my $list = _ARRAY($in) or die "need a non-empty list";
```

_ARRAYLIKE

An array reference, or an object that overloads @{}, else undef.

_HASH0

A hash reference, empty or not, else undef.

_HASH

A hash reference with at least one key, else undef.

Synopsis

```
my $opts = _HASH($in) || {};
```

_HASHLIKE

A hash reference, or an object that overloads %{}, else undef.

_CODE

A code reference, else undef.

_CODELIKE

A code reference, or an object that overloads &{}, else undef.

_INSTANCE

An object that isa the class given (its own isa method decides), else undef; an empty class name is never matched.

Synopsis

```
my $dbh = _INSTANCE($in, 'DBI::db') or die "need a database handle";
```

5.2.80 Parse

Namespace containing the following modules:

- `Parse::CPAN`

Parse::CPAN

Namespace containing the following modules:

- `Parse::CPAN::Meta` - Parse META.yml and META.json CPAN metadata files

Parse::CPAN::Meta

Parse META.yml and META.json CPAN metadata files

VERSION

version 2.150013

SYNOPSIS

```
################################################
# In your file

---
name: My-Distribution
version: 1.23
resources:
  homepage: "http://example.com/dist/My-Distribution"

################################################
# In your program

use Parse::CPAN::Meta;

my $distmeta = Parse::CPAN::Meta->load_file('META.yml');

# Reading properties
my $name     = $distmeta->{name};
my $version  = $distmeta->{version};
my $homepage = $distmeta->{resources}{homepage};
```

DESCRIPTION

Parse::CPAN::Meta is a parser for `META.json` and `META.yml` files, using *JSON::PP* and/or *CPAN::Meta::YAML*.

Parse::CPAN::Meta provides three methods: `load_file`, `load_json_string`, and `load_yaml_string`. These will read and deserialize CPAN metafiles, and are described below in detail.

Parse::CPAN::Meta provides a legacy API of only two functions, based on the YAML functions of the same name. Wherever possible, identical calling semantics are used. These may only be used with YAML sources.

All error reporting is done with exceptions (die'ing).

Note that META files are expected to be in UTF-8 encoding, only. When converted string data, it must first be decoded from UTF-8.

METHODS

load_file

```
my $metadata_structure = Parse::CPAN::Meta->load_file('META.json');

my $metadata_structure = Parse::CPAN::Meta->load_file('META.yml');
```

This method will read the named file and deserialize it to a data structure, determining whether it should be JSON or YAML based on the filename. The file will be read using the ":utf8" IO layer.

load_yaml_string

```
my $metadata_structure = Parse::CPAN::Meta->load_yaml_string($yaml_
↪string);
```

This method deserializes the given string of YAML and returns the first document in it. (CPAN metadata files should always have only one document.) If the source was UTF-8 encoded, the string must be decoded before calling `load_yaml_string`.

load_json_string

```
my $metadata_structure = Parse::CPAN::Meta->load_json_string($json_
↪string);
```

This method deserializes the given string of JSON and the result. If the source was UTF-8 encoded, the string must be decoded before calling `load_json_string`.

load_string

```
my $metadata_structure = Parse::CPAN::Meta->load_string($some_
↪string);
```

If you don't know whether a string contains YAML or JSON data, this method will use some heuristics and guess. If it can't tell, it assumes YAML.

yaml_backend

```
my $backend = Parse::CPAN::Meta->yaml_backend;
```

Returns the module name of the YAML serializer. See "ENVIRONMENT" for details.

json_backend

```
my $backend = Parse::CPAN::Meta->json_backend;
```

Returns the module name of the JSON serializer. If `CPAN_META_JSON_BACKEND` is set, this will be whatever that's set to. If not, this will either be *JSON::PP* or *JSON*. If `PERL_JSON_BACKEND` is set, this will return *JSON* as further delegation is handled by the *JSON* module. See "ENVIRONMENT" for details.

json_decoder

```
my $decoder = Parse::CPAN::Meta->json_decoder;
```

Returns the module name of the JSON decoder. Unlike "json_backend", this is not necessarily a full *JSON*-style module, but only something that will provide a `decode_json` subroutine. If `CPAN_META_JSON_DECODER` is set, this will be whatever that's set to. If not, this will be whatever has been selected as "json_backend". See "ENVIRONMENT" for more notes.

FUNCTIONS

For maintenance clarity, no functions are exported by default. These functions are available for backwards compatibility only and are best avoided in favor of `load_file`.

Load

```
my @yaml = Parse::CPAN::Meta::Load( $string );
```

Parses a string containing a valid YAML stream into a list of Perl data structures.

LoadFile

```
my @yaml = Parse::CPAN::Meta::LoadFile( 'META.yml' );
```

Reads the YAML stream from a file instead of a string.

ENVIRONMENT

CPAN_META_JSON_DECODER

By default, *JSON::PP* will be used for deserializing JSON data. If the `CPAN_META_JSON_DECODER` environment variable exists, this is expected to be the name of a loadable module that provides a `decode_json` subroutine, which will then be used for deserialization. Relying only on the existence of said subroutine allows for maximum compatibility, since this API is provided by all of *JSON::PP*, *JSON::XS*, Cpanel::JSON::XS, JSON::MaybeXS, JSON::Tiny, and Mojo::JSON.

CPAN_META_JSON_BACKEND

By default, *JSON::PP* will be used for deserializing JSON data. If the `CPAN_META_JSON_BACKEND` environment variable exists, this is expected to be the name of a loadable module that provides the *JSON* API, since downstream code expects to be able to call `new` on this class. As such, while *JSON::PP*, *JSON::XS*, Cpanel::JSON::XS and JSON::MaybeXS will work for this, to use Mojo::JSON or JSON::Tiny for decoding requires setting "CPAN_META_JSON_DECODER".

PERL_JSON_BACKEND

If the `CPAN_META_JSON_BACKEND` environment variable does not exist, and if `PERL_JSON_BACKEND` environment variable exists, is true and is not "JSON::PP", then the *JSON* module (version 2.5 or greater) will be loaded and used to interpret `PERL_JSON_BACKEND`. If *JSON* is not installed or is too old, an exception will be thrown. Note that at the time of writing, the only useful values are 1, which will tell *JSON* to guess, or *JSON::XS* - if you want to use a newer JSON module, see "CPAN_META_JSON_BACKEND".

PERL_YAML_BACKEND

By default, *CPAN::Meta::YAML* will be used for deserializing YAML data. If the `PERL_YAML_BACKEND` environment variable is defined, then it is interpreted as a module to use for deserialization. The given module must be installed, must load correctly and must implement the `Load()` function or an exception will be thrown.

5.2.81 Perl

Namespace containing the following modules:

- `Perl::OSType` - Map Perl operating system names to generic types

Perl::OSType

Map Perl operating system names to generic types

VERSION

version 1.010

SYNOPSIS

```
use Perl::OSType ':all';

$current_type = os_type();
$other_type = os_type('dragonfly'); # gives 'Unix'
```

DESCRIPTION

Modules that provide OS-specific behaviors often need to know if the current operating system matches a more generic type of operating systems. For example, 'linux' is a type of 'Unix' operating system and so is 'freebsd'.

This module provides a mapping between an operating system name as given by $^0 and a more generic type. The initial version is based on the OS type mappings provided in Module::Build and *ExtUtils::CBuilder*. (Thus, Microsoft operating systems are given the type 'Windows' rather than 'Win32'.)

USAGE

No functions are exported by default. The export tag ":all" will export all functions listed below.

os_type()

```
$os_type = os_type();
$os_type = os_type('MSWin32');
```

Returns a single, generic OS type for a given operating system name. With no arguments, returns the OS type for the current value of $^0. If the operating system is not recognized, the function will return the empty string.

is_os_type()

```
$is_windows = is_os_type('Windows');
$is_unix    = is_os_type('Unix', 'dragonfly');
```

Given an OS type and OS name, returns true or false if the OS name is of the given type. As with `os_type`, it will use the current operating system as a default if no OS name is provided.

5.2.82 PerlIO

On demand loader for PerlIO layers and root of PerlIO::* name space

SYNOPSIS

```
# support platform-native and CRLF text files
open(my $fh, "<:crlf", "my.txt") or die "open failed: $!";

# append UTF-8 encoded text
open(my $fh, ">>:encoding(UTF-8)", "some.log")
  or die "open failed: $!";

# portably open a binary file for reading
open(my $fh, "<", "his.jpg") or die "open failed: $!";
binmode($fh) or die "binmode failed: $!";

Shell:
  PERLIO=:perlio perl ....
```

DESCRIPTION

When an undefined layer 'foo' is encountered in an `open` or `binmode` layer specification then C code performs the equivalent of:

```
use PerlIO 'foo';
```

The Perl code in PerlIO.pm then attempts to locate a layer by doing

```
require PerlIO::foo;
```

Otherwise the `PerlIO` package is a place holder for additional PerlIO related functions.

Layers

Generally speaking, PerlIO layers (previously sometimes referred to as "disciplines") are an ordered stack applied to a filehandle (specified as a space- or colon-separated list, conventionally written with a leading colon). Each layer performs some operation on any input or output, except when bypassed such as with `sysread` or `syswrite`. Read operations go through the stack in the order they are set (left to right), and write operations in the reverse order.

There are also layers which actually just set flags on lower layers, or layers that modify the current stack but don't persist on the stack themselves; these are referred to as pseudo-layers.

When opening a handle, it will be opened with any layers specified explicitly in the open() call (or the platform defaults, if specified as a colon with no following layers).

If layers are not explicitly specified, the handle will be opened with the layers specified by the *${^OPEN}* variable (usually set by using the *open* pragma for a lexical scope, or the `-C` command-line switch or `PERL_UNICODE` environment variable for the main program scope).

If layers are not specified in the open() call or `${^OPEN}` variable, the handle will be opened with the default layer stack configured for that architecture; see "Defaults and how to override them".

Some layers will automatically insert required lower level layers if not present; for example `:perlio` will insert `:unix` below itself for low level IO, and `:encoding` will insert the platform defaults for buffered IO.

The `binmode` function can be called on an opened handle to push additional layers onto the stack, which may also modify the existing layers. `binmode` called with no layers will remove or unset any existing layers which transform the byte stream, making the handle suitable for binary data.

The following layers are currently defined:

- :unix

  Lowest level layer which provides basic PerlIO operations in terms of UNIX/POSIX numeric file descriptor calls (open(), read(), write(), lseek(), close()). It is used even on non-Unix architectures, and most other layers operate on top of it.

- :stdio

  Layer which calls `fread`, `fwrite` and `fseek`/`ftell` etc. Note that as this is "real" stdio it will ignore any layers beneath it and go straight to the operating system via the C library as usual. This layer implements both low level IO and buffering, but is rarely used on modern architectures.

- :perlio

  A from scratch implementation of buffering for PerlIO. Provides fast access to the buffer for `sv_gets` which implements Perl's readline/<> and in general attempts to minimize data copying.

  `:perlio` will insert a `:unix` layer below itself to do low level IO.

- :crlf

  A layer that implements DOS/Windows like CRLF line endings. On read converts pairs of CR,LF to a single "\n" newline character. On write converts each "\n" to a CR,LF pair. Note that this layer will silently refuse to be pushed on top of itself.

  It currently does *not* mimic MS-DOS as far as treating of Control-Z as being an end-of-file marker.

  On DOS/Windows like architectures where this layer is part of the defaults, it also acts like the `:perlio` layer, and removing the CRLF translation (such as with `:raw`) will only unset the CRLF translation flag. Since Perl 5.14, you can also apply another `:crlf` layer later, such as when the CRLF translation must occur after an encoding layer. On other architectures, it is a mundane CRLF translation layer and can be added and removed normally.

```
# translate CRLF after encoding on Perl 5.14 or newer
binmode $fh, ":raw:encoding(UTF-16LE):crlf"
  or die "binmode failed: $!";
```

- :utf8

  Pseudo-layer that declares that the stream accepts Perl's *internal* upgraded encoding of characters, which is approximately UTF-8 on ASCII machines, but UTF-EBCDIC on EBCDIC machines. This allows any character Perl can represent to be read from or written to the stream.

  This layer (which actually sets a flag on the preceding layer, and is implicitly set by any `:encoding` layer) does not translate or validate byte sequences.

  CAUTION: Do not use this layer to translate from UTF-8 bytes, as invalid UTF-8 or binary data will result in malformed Perl strings. It is unlikely to produce invalid UTF-8 when used for output, though it will instead produce UTF-EBCDIC on EBCDIC systems. The `:encoding(UTF-8)` layer (hyphen is significant) is preferred as it will ensure translation between valid UTF-8 bytes and valid Unicode characters.

- :bytes

  This is the inverse of the `:utf8` pseudo-layer. It turns off the flag on the layer below so that data read from it is considered to be Perl's internal downgraded encoding, thus interpreted as the native single-byte encoding of Latin-1 or EBCDIC. Likewise on output Perl will warn if a "wide" character (a codepoint not in the range 0..255) is written to a such a stream.

  This is very dangerous to push on a handle using an `:encoding` layer, as such a layer assumes to be working with Perl's internal upgraded encoding, so you will likely get a mangled result. Instead use `:raw` or `:pop` to remove encoding layers.

- :raw

  The `:raw` pseudo-layer is *defined* as being identical to calling `binmode($fh)` - the stream is made suitable for passing binary data, i.e. each byte is passed as-is. The stream will still be buffered (but this was not always true before Perl 5.14).

  In Perl 5.6 and some books the `:raw` layer is documented as the inverse of the `:crlf` layer. That is no longer the case - other layers which would alter the binary nature of the stream are also disabled. If you want UNIX line endings on a platform that normally does CRLF translation, but still want UTF-8 or encoding defaults, the appropriate thing to do is to add `:perlio` to the PERLIO environment variable, or open the handle explicitly with that layer, to replace the platform default of `:crlf`.

  The implementation of `:raw` is as a pseudo-layer which when "pushed" pops itself and then any layers which would modify the binary data stream. (Undoing `:utf8` and `:crlf` may be implemented by clearing flags rather than popping layers but that is an implementation detail.)

  As a consequence of the fact that `:raw` normally pops layers, it usually only makes sense to have it as the only or first element in a layer specification. When used as the first element it provides a known base on which to build e.g.

```
open(my $fh,">:raw:encoding(UTF-8)",...)
  or die "open failed: $!";
```

will construct a "binary" stream regardless of the platform defaults, but then enable UTF-8 translation.

- :pop

  A pseudo-layer that removes the top-most layer. Gives Perl code a way to manipulate the layer stack. Note that :pop only works on real layers and will not undo the effects of pseudo-layers or flags like :utf8. An example of a possible use might be:

```
open(my $fh,...) or die "open failed: $!";
...
binmode($fh,":encoding(...)") or die "binmode failed: $!";
# next chunk is encoded
...
binmode($fh,":pop") or die "binmode failed: $!";
# back to un-encoded
```

  A more elegant (and safer) interface is needed.

Custom Layers

Some custom layers come with the Perl distribution.

- :encoding

  Use :encoding(ENCODING) to transparently do character set and encoding transformations, for example from Shift-JIS to Unicode. Note that an :encoding also enables :utf8. See *PerlIO::encoding* for more information.

- :mmap

  A layer which implements "reading" of files by using mmap() to make a (whole) file appear in the process's address space, and then using that as PerlIO's "buffer". This *may* be faster in certain circumstances for large files, and may result in less physical memory use when multiple processes are reading the same file.

  Files which are not mmap()-able revert to behaving like the :perlio layer. Writes also behave like the :perlio layer, as mmap() for write needs extra house-keeping (to extend the file) which negates any advantage.

  The :mmap layer will not exist if the platform does not support mmap(). See *PerlIO::mmap* for more information.

- :via

  :via(MODULE) allows a transformation to be applied by an arbitrary Perl module, for example compression / decompression, encryption / decryption. See *PerlIO::via* for more information.

- :scalar

  A layer implementing "in memory" files using scalar variables, automatically used in place of the platform defaults for IO when opening such a handle. As such, the scalar is expected to act like a file, only containing or storing bytes. See *PerlIO::scalar* for more information.

Alternatives to raw

To get a binary stream an alternate method is to use:

```
open(my $fh,"<","whatever") or die "open failed: $!";
binmode($fh) or die "binmode failed: $!";
```

This has the advantage of being backward compatible with older versions of Perl that did not use PerlIO or where `:raw` was buggy (as it was before Perl 5.14).

To get an unbuffered stream specify an unbuffered layer (e.g. `:unix`) in the open call:

```
open(my $fh,"<:unix",$path) or die "open failed: $!";
```

Defaults and how to override them

If the platform is MS-DOS like and normally does CRLF to "\n" translation for text files then the default layers are:

```
:unix:crlf
```

Otherwise if `Configure` found out how to do "fast" IO using the system's stdio (not common on modern architectures), then the default layers are:

```
:stdio
```

Otherwise the default layers are

```
:unix:perlio
```

Note that the "default stack" depends on the operating system and on the Perl version, and both the compile-time and runtime configurations of Perl. The default can be overridden by setting the environment variable PERLIO to a space or colon separated list of layers, however this cannot be used to set layers that require loading modules like `:encoding`.

This can be used to see the effect of/bugs in the various layers e.g.

```
cd .../perl/t
PERLIO=:stdio  ./perl harness
PERLIO=:perlio ./perl harness
```

For the various values of PERLIO see "PERLIO" in perlrun.

The following table summarizes the default layers on UNIX-like and DOS-like platforms and depending on the setting of `$ENV{PERLIO}`:

```
PERLIO     UNIX-like                   DOS-like
------     ---------                   --------
unset / "" :unix:perlio / :stdio [1]   :unix:crlf
:stdio     :stdio                      :stdio
:perlio    :unix:perlio                :unix:perlio
```

(continues on next page)

(continued from previous page)

```
# [1] ":stdio" if Configure found out how to do "fast stdio"␣
 ↪(depends
# on the stdio implementation) and in Perl 5.8, else ":unix:perlio"
```

Querying the layers of filehandles

The following returns the **names** of the PerlIO layers on a filehandle.

```
my @layers = PerlIO::get_layers($fh); # Or FH, *FH, "FH".
```

The layers are returned in the order an open() or binmode() call would use them, and without colons.

By default the layers from the input side of the filehandle are returned; to get the output side, use the optional `output` argument:

```
my @layers = PerlIO::get_layers($fh, output => 1);
```

(Usually the layers are identical on either side of a filehandle but for example with sockets there may be differences.)

There is no set_layers(), nor does get_layers() return a tied array mirroring the stack, or anything fancy like that. This is not accidental or unintentional. The PerlIO layer stack is a bit more complicated than just a stack (see for example the behaviour of `:raw`). You are supposed to use open() and binmode() to manipulate the stack.

Implementation details follow, please close your eyes.

The arguments to layers are by default returned in parentheses after the name of the layer, and certain layers (like `:utf8`) are not real layers but instead flags on real layers; to get all of these returned separately, use the optional `details` argument:

```
my @layer_and_args_and_flags = PerlIO::get_layers($fh, details =>␣
 ↪1);
```

The result will be up to be three times the number of layers: the first element will be a name, the second element the arguments (unspecified arguments will be `undef`), the third element the flags, the fourth element a name again, and so forth.

You may open your eyes now.

Modules

- `PerlIO::encoding` - Open a filehandle with a transparent character-set encoding filter.
- `PerlIO::mmap` - The `:mmap` PerlIO layer: read a file through a memory mapping instead of `read(2)` calls.
- `PerlIO::scalar` - in-memory IO, scalar IO
- `PerlIO::utf8_strict` - A UTF-8 I/O layer that refuses malformed input.
- `PerlIO::via` - Write a PerlIO layer in Perl: open with `:via(MyClass)` and I/O dispatches to your class.

PerlIO::encoding

Open a filehandle with a transparent character-set encoding filter.

`PerlIO::encoding` provides the `:encoding(NAME)` layer that open and binmode accept. Bytes read through the layer are decoded from NAME into Perl character strings; character strings written through it are encoded back into NAME before reaching the layer below. Both directions go through `Encode`, so every encoding `Encode` knows is available:

```
open my $fh, '<:encoding(UTF-8)', $file or die $!;
binmode STDOUT, ':encoding(iso-8859-1)';
```

The encoding name is resolved with `Encode::find_encoding`. A name it does not know warns `Cannot find encoding "NAME"` and the layer fails to be pushed, with `$!` set to `EINVAL`.

`$PerlIO::encoding::fallback` holds the CHECK value handed to `Encode`'s `encode` and `decode` for every conversion the layer makes. It defaults to `Encode::PERLQQ | Encode::WARN_ON_ERR | Encode::ONLY_PRAGMA_WARNINGS`, so malformed data is substituted and warned about rather than being fatal. Each handle captures the value in effect when its layer is pushed, so changing it afterwards does not affect handles that are already open. It must be an integer: a reference croaks with `PerlIO::encoding::fallback must be an integer`. Whatever it is set to, the layer always adds `Encode::STOP_AT_PARTIAL` and always clears `Encode::LEAVE_SRC`.

A partial character stranded in the buffer is an error wherever it cannot be represented: closing such a handle croaks with `Close with partial character`, and `tell` on one croaks with `Cannot tell at partial character`.

Encodings that report `needs_lines` - the stateful ones that have to see whole lines - make the layer split writes at newlines and flush each line on its own.

This is a native implementation of PerlIO::encoding 0.31; its `PerlIO/encoding.pm` is used unchanged, and the layer loads itself (and `Encode`) the first time `:encoding(...)` is named.

Differences from upstream

None.

PerlIO::mmap

The `:mmap` PerlIO layer: read a file through a memory mapping instead of `read(2)` calls.

```
open my $fh, '<:mmap', $file or die "open: $!";
my @lines = <$fh>;
print join(",", PerlIO::get_layers($fh)), "\n";   # unix,perlio,mmap
```

On the first read the layer maps the rest of the file, from the current position to its end, and reads come straight out of the mapping instead of being copied into a buffer. Only a regular file is mapped; anything else (a pipe, a terminal) reads as an ordinary buffered handle, and writing always goes through an ordinary buffer. Nothing needs to be loaded: naming the layer in open or `binmode` loads it.

This is a native implementation of PerlIO::mmap 0.017.

Differences from upstream

None.

PerlIO::scalar

in-memory IO, scalar IO

SYNOPSIS

```
my $scalar = '';
...
open my $fh, "<",  \$scalar or die;
open my $fh, ">",  \$scalar or die;
open my $fh, ">>", \$scalar or die;
```

or

```
my $scalar = '';
...
open my $fh, "<:scalar",  \$scalar or die;
open my $fh, ">:scalar",  \$scalar or die;
open my $fh, ">>:scalar", \$scalar or die;
```

DESCRIPTION

A filehandle is opened but the file operations are performed "in-memory" on a scalar variable. All the normal file operations can be performed on the handle. The scalar is considered a stream of bytes. Currently fileno($fh) returns -1.

Attempting to open a read-only scalar for writing will fail, and if warnings are enabled, produce a warning.

IMPLEMENTATION NOTE

`PerlIO::scalar` only exists as a stub. One does not need to explicitly `use PerlIO::scalar`.

PerlIO::utf8_strict

A UTF-8 I/O layer that refuses malformed input.

`:utf8_strict` decodes UTF-8 like `:encoding(UTF-8)`, much faster, and like it unlike `:utf8` it validates: a read that meets an ill-formed sequence, a surrogate, a non-shortest form, a code point beyond U+10FFFF or a noncharacter dies. Writing through it encodes as `:utf8` does.

Synopsis

```
open my $fh, '<:utf8_strict', $file or die $!;
my $line = <$fh>;            # dies on malformed UTF-8

open my $lax, '<:utf8_strict(allow_noncharacters)', $file or die $!;
binmode STDOUT, ':utf8_strict';
```

Options

A comma-separated list in parentheses relaxes the check: `allow_surrogates`, `allow_noncharacters`, `allow_nonshortest`, or `loose` for all three; `strict`, the default, for none. An unknown word dies with `Unknown argument to :utf8_strict`.

The errors are `Can't decode ill-formed UTF-8 octet sequence <..>`, with the bytes in hex and `at end of file` when the input ends inside a sequence, and `Can't interchange noncharacter code point U+...`. The handle's error flag is set as well.

This is a native implementation of PerlIO::utf8_strict 0.010's `utf8_strict.xs`; its `PerlIO/utf8_strict.pm` is used unchanged, and perl loads it by itself the first time `:utf8_strict` is named.

Differences from upstream

None.

PerlIO::via

Write a PerlIO layer in Perl: open with `:via(MyClass)` and I/O dispatches to your class.

`PerlIO::via` provides the `:via(CLASS)` layer. A handle opened or binmoded with it routes every I/O operation to a method call on CLASS, so the whole behaviour of a layer - buffering, filtering, transcoding - is defined by an ordinary Perl class:

```
package PerlIO::via::UpperCase;
sub PUSHED { my ($class, $mode, $fh) = @_; bless {}, $class }
sub WRITE  { my ($self, $buf, $fh) = @_; print $fh uc $buf; length
```

(continues on next page)

(continued from previous page)

```
 ↪$buf }
sub FILL   { my ($self, $fh) = @_; scalar <$fh> }

package main;
open my $out, '>:via(UpperCase)', $file or die $!;
print $out "hello\n";                 # the file gets HELLO
```

CLASS is looked up as `PerlIO::via::CLASS` first and as CLASS itself second, so both spellings of the layer name work. If neither package exists the layer warns `Cannot find package 'CLASS'` and fails to be pushed; `:via()` with no name at all warns `No package specified`.

`PUSHED` is the only method a class must supply. It is called with the class name and the open mode. If it returns an object, that object becomes the invocant for every later call; a true non-object return is taken as a failure code and aborts the push. Every other method is optional - when one is missing, the layer falls back to the default behaviour for that operation. The full set is `PUSHED`, `POPPED`, `OPEN`, `FDOPEN`, `SYSOPEN`, `GETARG`, `FILENO`, `READ`, `WRITE`, `FILL`, `CLOSE`, `SEEK`, `TELL`, `UNREAD`, `FLUSH`, `SETLINEBUF`, `CLEARERR`, `ERROR`, `EOF`, `BINMODE` and `UTF8`.

Each method receives the object, then its own arguments, then - when there is a layer below - a filehandle onto that layer. That handle is how a class reads and writes the data passing through it.

Reading goes through `FILL` when the class defines one: the layer buffers what `FILL` returns and hands it upwards a piece at a time. With no `FILL`, `READ` is called instead and must return how many bytes it put in the buffer; a count outside the requested range warns `Invalid return from CLASS::READ = N, expected undef or 0 to M` and fails with `EINVAL`.

`UTF8` is called with a true value when the layer below already delivers characters; returning true marks this layer's data as characters too. `BINMODE` returning `undef`, or not being defined at all, pops the layer.

This is a native implementation of PerlIO::via 0.21; its `PerlIO/via.pm` is used unchanged.

Differences from upstream

None.

Modules

- `PerlIO::via::QuotedPrint` - PerlIO layer for quoted-printable strings

PerlIO::via::QuotedPrint

PerlIO layer for quoted-printable strings

SYNOPSIS

```
use PerlIO::via::QuotedPrint;

open(my $in, '<:via(QuotedPrint)', 'file.qp') or
    die "Can't open file.qp for reading: $!\n";

open(my $out, '>:via(QuotedPrint)', 'file.qp') or
    die "Can't open file.qp for writing: $!\n";
```

DESCRIPTION

This module implements a PerlIO layer that works on files encoded in the quoted-printable format. It will decode from quoted-printable while reading from a handle, and it will encode as quoted-printable while writing to a handle.

HISTORY

See the Changes file.

5.2.83 Peta

Namespace containing the following modules:

- `Peta::Dict` - a fast dictionary bound to a Perl hash with `tie`
- `Peta::FFI` - Call C library functions from Perl with no build step and no binding crate.
- `Peta::ReadLine` - Interactive line editing, command history, and configurable key bindings, with the Term::ReadLine::Gnu interface.
- `Peta::Shell` - ipps, the interactive mode of pperl
- `Peta::WebGPU` - compute and draw on the graphics card
- `Peta::XS` - the interpreter's capability layer for pure Perl

Peta::Dict

Peta::Dict - a fast dictionary bound to a Perl hash with `tie`.

```
use Peta::Dict;

tie my %count, 'Peta::Dict';
$count{$_}++ for qw(a b a c a);
print join(", ", map { "$_=$count{$_}" } sort keys %count), "\n";
 ↪# a=3, b=1, c=1
delete $count{b};
print exists $count{b} ? "b still there\n" : "b gone\n";
 ↪# b gone
```

It behaves as a plain hash does - the same keys, values, `exists`, `delete`, `each` and `keys` - with its storage built for speed: under the JIT an element access compiles to a direct table probe. Iteration order is the table's own. Peta::Dict is pperl's own module, version 0.2.0.

%h itself stays a faithful perl5 hash; what `tie` binds it to is a separate stratum: an open-addressed table (node's `Map` class, ~one cache line per access) whose element accesses the JIT compiles to an in-register probe. That is the same "native store + JIT probe" shape that carries Memoize, applied to a general container - a dictionary is a language facility every pole ships, and this one is stratified beside %h rather than changing it.

The tie protocol is perl5's, untouched (`pp_sys.c pp_tie`, the `PERL_MAGIC_tied` node, the per-access `PERL_MAGIC_tiedelem` proxy, `mg.c Perl_magic_methcall`); the class merely implements the methods natively, so even the interpreted path never runs Perl code:

- `FETCH(obj, key)` returns a copy of the stored value, as the pure-Perl class does - so a direct `tied(%h)->FETCH($k)` cannot change the entry through its result. A missing key returns undef, unconditionally (perl calls FETCH for every rvalue read; there is no existence pre-check to skip).

- `STORE(obj, key, val)` copies `val` in (a `sv_setsv` without get-magic and without stealing: `val` is the throwaway proxy, or the already-copied RHS of `%h = (...)`, and `$x = $h{$k} = 5` reads the proxy again after the STORE). `$h{$k}++` is exactly one FETCH and one STORE on one proxy (`pp_preinc` -> `sv_inc` -> `SvSETMAGIC`).
- `EXISTS/DELETE/CLEAR/FIRSTKEY/NEXTKEY/SCALAR` are each exactly one synchronous call from the responsible C function (`magic_existspack`, `magic_clearpack`, `magic_wipepack`, `magic_nextpack`, `magic_scalarpack`). `delete` returns the value. Iteration order is whatever this class produces (perl imposes none on a tied hash); `keys %h` never FETCHes.

KEYS. A key is the integer or the string perl would stringify it to, so an integer key and its decimal string name the same entry, exactly as in a plain hash (`$h{5}` is `$h{"5"}`; `"05"` is another key). An IOK-only key is taken as its integer; anything else is stringified by perl's own `sv_2pv_flags` (which warns for undef as perl does) and an exact canonical decimal (no sign on zero, no leading zero, in IV range) is folded back to an integer. Integer keys live in the open-addressed table the JIT probes; string keys live in a side map that is correct and native but not JIT-probed. Iteration returns integer keys as IVs, whose string form is that same decimal. A string key is held as a hash holds it: a UTF-8 key that fits in Latin-1 is the same entry as its byte string, and one that does not keeps its UTF-8 flag through `keys`.

The pure-Perl `assets/modules/user/Peta/Dict.pm` is the fallback perl5 (the t/TEST oracle) loads: a plain hash behind the same protocol, identical output, merely not fast. It is not embedded: pperl's registry answers the `require` first, and a build without this class stops there with the capability hint.

The JIT seam: `[DictTable]` is `#[repr(C)]` with the probed fields first (`slots/state/mask/shift`), so compiled code reaches an entry with offset arithmetic from the table pointer. A HIT (an existing integer key) is served in-register; a MISS (an insert, which may grow the table) goes through the same Rust functions the methods use, after which the probe reloads the arrays from the struct.

Peta::FFI

Call C library functions from Perl with no build step and no binding crate.

`Peta::FFI` is the dynamic FFI layer pperl ships for reaching into shared libraries at runtime. You open a library with `dlopen`, call any of its exported functions through `call` by giving a type signature string, and release the handle with `dlclose`. `scan` finds the libraries in a list of directories, which is useful for finding the right file before you open it.

This is how Perl code here reaches a C library: pperl loads no compiled extension modules, so anything living in a `.so` is called either through this module or through one of the bindings built on it. pperl's *FFI::Platypus* is one of them: its calls, types, records and closures are this module's, so whatever FFI::Platypus can express, Peta::FFI can, in its own signature language.

Reach for it when:

- The function you need lives in a system library (`libm`, `libc`, `libuuid`, `libcrypto`).
- You already know the C prototype and want a one-liner, not a build step.

- You are calling into a third-party `.so` that no pre-baked wrapper covers.

C calling back into Perl is supported: `closure` wraps a coderef as a function pointer you can hand to any C API that wants one (see the Callbacks category). C structs are records: `record` declares one as a Perl class, and a signature passes and returns it by value or by pointer (see the Records category). A library's global variables are reached with `symbol`, `fetch`/`store` and `variable`.

What it does not do is **derive types from a header**: you read the C prototype and write the matching signature by hand, and for a struct its members in order, since a signature that disagrees with the real prototype is undefined behaviour rather than an error.

The two sibling modules `Peta::FFI::Libc` and `Peta::FFI::UUID` are pre-baked convenience wrappers built on top of this layer - they handle the `dlopen` / `call` / `dlclose` dance for you for a fixed set of functions. If your need is covered by one of them, prefer it over hand-rolled FFI.

A call that can block for good - `statfs` on a dead NFS mount - runs on a *Peta::FFI::Pool* thread instead, with a deadline, and reports how it went as an event. A library that calls back on threads of its own gets a queued closure, whose calls wait in a *Peta::FFI::Queue* for Perl's event loop.

Signature strings

Every `call`, `function` and `closure` takes a signature string of the form `(args)ret`, where each position is one type:

Type	C type	Perl side
v	void	return only; 1 is returned
i	int	integer
l	long	integer
L	unsigned long / size_t	unsigned integer
i8 i16 i32 i64	int8_t … int64_t	integer
u8 u16 u32 u64	uint8_t … uint64_t	unsigned integer
b	bool	perl's true or false
d	double	float
f	float	float
D	long double	float (rounded to a double)
cf cd	float / double complex	[re, im]; a number is [n, 0]
p	const char *	input string; a returned string is copied
s	char * the caller frees	a result, copied, then freed; *s an out argument
P	mutable buffer	output buffer; \$buf is written
o	opaque pointer	raw address as integer
<Class>	a C object's pointer	an object of a declared handle type
{Class}	struct by value	an object of a declared record class
*{Class}	struct *	the same object, by pointer
*T	T *	\$scalar in and out; undef is NULL
*<Class>	T ** C stores a handle in	\$scalar that gets the object
T[N] T[]	T * to an array	\@array in and out
T[0]	T *[] ended by NULL	\@array of o, p or handles
*T[r] *T[#k] *T[0]	T ** to an array C allocates	\$scalar or \@array it fills
*P[r] *P[#k]	char ** to bytes C allocates	\$scalar that gets the bytes
&T[r] &T[#k] &T[0]	const T ** to an array C keeps	the same, copied, never freed
&P[r] &P[#k]	const char ** to bytes C keeps	\$scalar that gets a copy
result &T[#k] &T[0]	const T * to an array C keeps	an array reference of copies
result &P[#k]	const char * to bytes C keeps	a copy of the bytes

A signature with no arguments is written ()ret, e.g. ()i for an int-returning no-arg function. Types may be separated by blanks: (u64 <My::Pool>)b. A variadic function lists its named parameters, a ;, and the types this call passes through its ...: (iL;o)i is ioctl(int, unsigned long, ...) passing one pointer.

An unsigned type reads its argument as an unsigned integer, so 2**64-1 passes as itself, not as -1, and returns above 2**63 come back unsigned. s is for C functions whose returned string the caller owns; function names the free function that releases it. <Class> is a typed handle declared with handle_type, {Class} a record declared with record. An argument is read once, as an XS function reads it, so a regex capture or a tied scalar passes its value.

`*T` and `T[N]` take the numbers, `o`, `p` (an array of C strings, `char **`) and `b`: `(d*i)d` is `frexp(double, int *)`, called with `\my $exp`, and `(i32[]LLo)v` is `qsort` sorting `\@numbers` in place. `T[N]` also takes handles and records, and C's changes to the records are written back: `({My::Point}[]LLo)v` sorts `\@points`. `T[0]` is an array of `o`, `p` or handles that C reads up to a NULL the call appends, as `execv`'s `argv` or a NULL-terminated list of handles.

Some C functions hand over what they allocate through a pointer the caller passes. `*<Class>` is a handle stored there, as `sqlite3_open` stores its `sqlite3 *`: called with `\my $db`, `$db` becomes the object, owned by the caller and destroyed with it; a handle already in `$db` goes in, and stays the same object if C leaves it. `*s` is a string stored there, copied into the scalar and freed.

`*T[r]`, `*T[#k]` and `*T[0]` are an array of `T` the callee allocates and stores there: as long as the function's integer result (`[r]`), as argument `k` (`[#k]`, an integer or an `*` integer, counted from 1), or up to a NULL element (`[0]`, for `o`, `p`, `s` and handles). `(<My::Conn>*<My::Item>[r]u32)i` lists a connection's items: called with `\my $items`, `$items` becomes an array reference of objects, each the caller's; a reference to an array is filled instead. Strings (`*s[...]`) are copied and each freed, numbers and `o` read, records copied. A negative length is the callee's error and leaves `undef`. The array itself is freed with `function`'s `free` - or, for records, with its `release`, `(array, count)`, the library's function that also frees what the records point to. Records keep the array until the last of them is gone, so a record's `p` member reads its string for as long as the record lives; a bare copy of its bytes does not keep it.

`*P[r]` and `*P[#k]` are bytes the callee allocates and stores there, with the length as for an array: one byte string, NULs included, where `*u8[#k]` would give an array of numbers. librados's `rados_mon_command` hands over its reply this way, as a `char **` and a `size_t *` freed with `rados_buffer_free`: `(op[]LPL*P[#7]*L*P[#9]*L)i` with `free => "rados_buffer_free"`, the input buffer passed as `\$inbuf` and the reply taken with `\my $out, \my $outlen, \my $status, \my $statuslen`. A NULL leaves `undef`, and so does a negative length; the buffer is freed with `function`'s `free`. A buffer ended by a NUL is an `*s`. Bytes the callee only lends are `&P[r]` and `&P[#k]`, and `&P[#k]` is also a result: copied, never freed, as the lent arrays below.

`&T[r]`, `&T[#k]` and `&T[0]` are the same for an array the callee only lends - a pointer into memory it keeps, as libxkbcommon's `xkb_keymap_key_get_syms_by_level` hands out a keymap's keysyms: `(<Keymap>u32u32u32&u32[r])i`. The elements are copied and the array is never freed. They are numbers, `o`, `p`, `b` or records; an `s`, which the caller frees, and a handle, whose object owns its pointer, cannot be lent.

`&T[#k]` and `&T[0]` are also a result: the array C returns, as libxkbcommon's `xkb_compose_table_entry_sequence` returns an entry's keysyms and stores their count through a `size_t *`: `(o*L)&u32[#2]`, called as `$f->($entry, \my $n)`. The call returns an array reference of the copies, or `undef` for a negative length or a NULL with elements. The length is read after the call, from an integer or an `*` integer argument; `[r]` is no form here, since the result is the array itself.

`P` passes the bytes of the scalar it references, which hold what the callee wrote afterwards: `my $buf = "\0" x 64; call(..., \$buf)`. Given a string or a number instead, it passes a zeroed buffer of that length or that many bytes (at least 16) that nobody reads back.

`o` is the handle type for C APIs built on opaque structs (`PGconn*`, `sqlite3*`, `MYSQL*`): the raw address travels as a Perl integer, is never dereferenced by the runtime, and `undef`/`0`

passes NULL. Never use p for such pointers - p returns copy-until-NUL string semantics, which is wrong and unsafe for non-string data.

Memory primitives

For C APIs that traffic in caller-owned memory (out-parameters, pointer arrays, length-counted buffers) the module provides the pointer toolbox: alloc/free, peek/peek_cstr, poke, and pack_ptr/unpack_ptr for bytes, fetch/store for a value of any type at an address, and sizeof/alignof. Addresses are ordinary Perl integers as with o. A pointer array (e.g. char *argv[]) is built portably as join "", map pack_ptr($_), @addrs poked into an alloced block, or passed as a p[] array.

Synopsis

```
use Peta::FFI;

my $libm = Peta::FFI::dlopen("libm.so.6");
my $root = Peta::FFI::call($libm, "sqrt", "(d)d", 2.0);
Peta::FFI::dlclose($libm);
print $root, "\n";       # 1.4142135623731

Peta::FFI::record("Div", quot => "i", rem => "i");      # div_t
my $d = Peta::FFI::call(undef, "div", "(ii){Div}", 17, 5);
print $d->quot, " r ", $d->rem, "\n";                   # 3 r 2
```

Modules

- Peta::FFI::EventSource - events from a C library's own threads, drained on Perl's
- Peta::FFI::LMDB - Lightning memory-mapped databases: transactional key-value stores in a file, over the system's liblmdb.
- Peta::FFI::Libc - Call common libc functions from Perl without writing a single line of FFI glue.
- Peta::FFI::PCRE2 - Compile and run PCRE2 regular expressions via the system's libpcre2-8 library.
- Peta::FFI::Pool - Run C functions on worker threads, so that a call which hangs cannot hang the program.
- Peta::FFI::Queue - Callbacks a C library makes from threads of its own, queued for Perl's event loop.
- Peta::FFI::UUID - Generate and parse RFC 4122 UUIDs via the system's libuuid library.

Functions

Library loading

dlopen

Open a shared library and return a handle suitable for passing to `call`.

dlclose

Release a library handle previously returned by `dlopen`.

Function calls

call

Invoke a C function from an opened library and return its result.

function

Prepare a C function once and return it as a code reference.

attach

Prepare a C function once and install it as a named Perl sub.

errno

errno as the last C call through Peta::FFI left it.

Symbol introspection

symbol

The address of a symbol - a function or a variable - in a library.

variable

A library's global variable as a Perl scalar.

scan

Find the shared libraries in a list of directories.

Handles

handle_type

Declare a Perl class for a C object type, with its destructor.

`release`

Destroy a handle's C object now, ahead of its last reference.

Records

`record`

Declare a record class: a C struct, passed by value or by pointer.

`union`

Declare a union class: a C union, reached by pointer and in memory.

`sizeof`

The size of a type in bytes, as C's `sizeof`.

`alignof`

The alignment of a type in bytes, as C's `_Alignof`.

Callbacks

`closure`

Wrap a Perl coderef as a C-callable function pointer.

`closure_free`

Release a closure created by `closure`.

Memory

`fetch`

Read the value of a type at an address.

`store`

Write a value of a type at an address.

`peek`

Read `$len` raw bytes at address `$ptr` into a Perl byte string.

peek_cstr

Read the NUL-terminated C string at address `$ptr`.

poke

Copy a Perl byte string into memory at address `$ptr`.

alloc

Allocate `$len` zeroed bytes of C memory; returns the address.

free

Release memory obtained from `alloc`.

pack_ptr

Pack an address into a native pointer-sized byte string.

unpack_ptr

Unpack a native pointer-sized byte string into an address.

Peta::FFI::EventSource

events from a C library's own threads, drained on Perl's

SYNOPSIS

```
use Peta::FFI;
use Peta::FFI::EventSource;

my $lib = Peta::FFI::dlopen('/opt/example/lib/libexample.so');
Peta::FFI::handle_type('Example::Monitor', $lib, 'example_monitor_
↪free');
my $open = Peta::FFI::function($lib, 'example_monitor_open', '(p)
↪<Example::Monitor>');
my $fd   = Peta::FFI::function($lib, 'example_monitor_fd',   '(
↪<Example::Monitor>)i32');
my $next = Peta::FFI::function($lib, 'example_monitor_next', '(
↪<Example::Monitor>)s',
                               free => 'example_string_free');

my $source = Peta::FFI::EventSource->new($open->('block'), fd =>
↪$fd, next => $next);

# With AnyEvent (and so with EV underneath):
my $guard = $source->watch(sub { handle_event($_) for @_ });
```

(continues on next page)

(continued from previous page)

```
AnyEvent->condvar->recv;

# With Mojo::IOLoop, which takes filehandles:
Mojo::IOLoop->singleton->reactor->io($source->fh, sub { handle_
↪event($_) for $source->drain })
    ->watch($source->fh, 1, 0);

# With a loop of your own:
vec(my $rin = '', $source->fd, 1) = 1;
while (select(my $rout = $rin, undef, undef, undef)) {
    handle_event($_) for $source->drain;
}
```

DESCRIPTION

A library that produces events on threads of its own - a device monitor, a netlink listener - must not call into Perl from those threads: Perl runs on the interpreter's thread only, and a *Peta::FFI* closure called from anywhere else stops the program. The library queues the events instead, and signals that there are some through a file descriptor. This module watches the descriptor and, when it reads ready, takes the events one by one until the queue is empty.

One source is one handle of the library's: a library with several independent event streams opens a handle for each, and each becomes a source of its own.

A *Peta::FFI::Pool*, which runs C functions on threads of its own, is such a source too, with its own `fd` and `next`, and so is a *Peta::FFI::Queue*, where the calls of queued closures wait; their events are hash references:

```
my $source = Peta::FFI::EventSource->new($pool,
    fd => \&Peta::FFI::Pool::fd, next => \&Peta::FFI::Pool::next);
```

The library's half

The library provides, for its source handle type:

- a file descriptor function, `int fd(source *)`

  returning a descriptor that reads ready while events are queued - an eventfd or the read end of a pipe. Peta::FFI calls it once, in `new`.

- a next-event function, `char *next(source *)`

  returning the oldest queued event as a string the caller frees, or NULL when the queue is empty. Declared with the `s` result type and the library's `free` function, so Perl receives a copy and the library's string is released at once.

- a destructor

  declared with `handle_type`, which stops the library's thread and closes the descriptor. It runs once, when the last reference to the handle goes; the source holds one.

Clearing the descriptor is the library's job: when `next` returns NULL, the library resets its eventfd or empties its pipe. Peta::FFI only waits for readability, level-triggered, and drains until NULL, so it never needs to know which kind of descriptor it is. A full queue is the library's to report, typically as an event of its own saying how many were lost; such an event passes through like any other.

METHODS

- new($handle, fd => $fd_function, next => $next_function)

  The source for `$handle`. Both functions are code references from `Peta::FFI::function` taking the handle; `$fd_function` is called once, here. Croaks when the library returns no descriptor.

- fd

  The library's descriptor, for an event loop that takes descriptor numbers (*EV*, `select`). Never close it: it is the library's.

- fh

  A read filehandle on a duplicate of the descriptor, for an event loop that takes filehandles (Mojo::IOLoop, *IO::Select*). It becomes readable exactly when the descriptor does, and closing it - or letting it go - closes only the duplicate, so it may outlive the source. The same filehandle is returned on every call.

- drain

  The queued events, oldest first, each as `next` returned it - the string a library returned, a pool's hash reference; the empty list when there are none.

- watch($callback)

  Watches the descriptor with *AnyEvent* (loaded on first use) and calls `$callback` with the drained events whenever there are some. Returns the watcher: the watch lasts as long as it is referenced.

- handle

  The library handle the source was made for.

SEE ALSO

Peta::FFI - `function`, `handle_type` and the `s` result type.

Peta::FFI::Pool - C functions run on worker threads, their calls reported as events.

Peta::FFI::Queue - closures a library calls on its own threads, their calls queued for the event loop.

Peta::FFI::LMDB

Lightning memory-mapped databases: transactional key-value stores in a file, over the system's liblmdb.

An environment (`Peta::FFI::LMDB::Env`) is a file, or a directory, holding one unnamed database and, with `maxdbs`, named ones. Everything happens in a transaction (`Peta::FFI::LMDB::Txn`): read transactions see a snapshot and never block; one write

transaction at a time commits atomically, and nothing it wrote survives an abort or a crash before the commit. A database handle (`Peta::FFI::LMDB::DB`) names one database; a cursor (`Peta::FFI::LMDB::Cursor`) walks one in key order.

liblmdb is the system's library, loaded when first needed; a call without it croaks naming the library it looked for.

Synopsis

```
use Peta::FFI::LMDB qw(:flags);
my $env = Peta::FFI::LMDB::Env->new('data.lmdb', flags => MDB_
 ↪NOSUBDIR,
                                    mapsize => 1 << 30, maxdbs => 4);
my $txn = $env->begin;
my $db  = $txn->open_db('users', MDB_CREATE);
$txn->put($db, alice => 'admin');
$txn->commit;

my $r = $env->begin(MDB_RDONLY);
print $r->get($db, 'alice'), "\n";
my $c = $r->cursor($db);
while (my ($k, $v) = $c->next) { print "$k=$v\n" }
```

Keys and values

Keys and values are byte strings; a string with characters over 255 croaks `Wide character`. In an `MDB_INTEGERKEY` database the keys are unsigned integers, and in an `MDB_DUPSORT|MDB_INTEGERDUP` one the values. A key may be at most `$env->maxkeysize` bytes, 511 with the usual liblmdb. A missing key is undef, not an error. `$txn->get_view($db, $key, $var)` makes `$var` the value without copying it: a read-only scalar that becomes undef when its transaction ends or, in a write transaction, at the next write.

Errors

LMDB's errors croak with a `Peta::FFI::LMDB::Error` object: `$@->code` is LMDB's code, to compare with the `MDB_*` constants of the `:errors` tag, `$@->message` its text, which the object also stringifies to.

```
eval { $txn->put($db, $key, $value) };
if (ref $@ && $@->code == MDB_MAP_FULL) { ... }
```

Misuse croaks with a plain message naming the problem: using a transaction that has ended, a closed environment or cursor, a database of another environment, an option `new` does not know.

Ordering

A database keeps its keys in byte order (integer order with `MDB_INTEGERKEY`) unless `$db->set_compare` gives it a sort sub; an `MDB_DUPSORT` database orders a key's values the same way, or by `$db->set_dupsort`'s sub. The sub is called as a `sort` block is, with the two items in `$a` and `$b` of its package. The file does not remember it: set it every time the environment is opened.

Constants

`use Peta::FFI::LMDB qw(:flags)` imports the flags of `new`, `begin`, `open_db`, `put`, `del` and `copy` (`MDB_NOSUBDIR`, `MDB_RDONLY`, `MDB_CREATE`, `MDB_DUPSORT`, `MDB_NOOVERWRITE`, `MDB_CP_COMPACT` and the rest); `:errors` the error codes (`MDB_NOTFOUND`, `MDB_MAP_FULL` ...); `:cursor_ops` the operations of `$cursor->get` (`MDB_FIRST`, `MDB_SET_RANGE` ...); `:all` all of them. They are also callable as `Peta::FFI::LMDB::MDB_CREATE` without importing.

The DBM modules' write policy

NDBM_File, ODBM_File, GDBM_File and DB_File (its Hash and Btree databases) keep their files with LMDB too, without transactions of their own. `$Peta::FFI::LMDB::DBM_WRITE`, read when a file is tied, says when their writes reach the file:

- `'back'` (the default): the writes of a tie collect in one LMDB transaction, committed at `sync` and when the hash is untied. Fast, as gdbm is; other processes see the writes after the commit, and a crash loses what was not committed. Like a gdbm writer, the tie holds the file's one writer slot until then: another process that writes the file waits. Readers never wait.
- `'through'`: every write is committed and synced at once - visible to other processes immediately, and a disk sync per write. Use it for files that several processes write.

GDBM_File's own sync request, `GDBM_SYNC` or `sync_mode(1)`, makes its tie write-through.

The DBM modules' files

A DBM module's file is an LMDB environment of its own (one file, `MDB_NOSUBDIR`, with LMDB's lock file `NAME-lock` beside it), which Peta::FFI::LMDB can open, with `maxdbs => 1` or more, when the module has it closed. Its main database holds two records: the named database `data`, with the keys and values, and `pperl-store`, whose value says what they are - `version=1 dups=0`, or `dups=1` when a key may hold several values (DB_File's `R_DUP`). Such a key is stored as the key followed by an 8-byte big-endian sequence number, the order its values were stored in. A key that is empty or starts with a NUL byte is stored behind one more NUL byte. The modules refuse an LMDB file without the `pperl-store` record.

Modules

- `Peta::FFI::LMDB::Cursor` - A cursor: a position in a database that walks its keys in order, finds the first key at or after a given one, and writes or deletes where it stands.
- `Peta::FFI::LMDB::DB` - A database handle: one database of an LMDB environment, as `$txn->open_db` returns it, to pass to the transaction's and cursor's methods.
- `Peta::FFI::LMDB::Env` - An LMDB environment: the file (or directory) a set of databases lives in, and what every transaction starts from.
- `Peta::FFI::LMDB::Txn` - A transaction: everything read from or written to an LMDB environment happens in one.

Functions

Errors

`strerror`

LMDB's message for an error code: `Peta::FFI::LMDB::strerror(MDB_MAP_FULL)` is `MDB_MAP_FULL: Environment mapsize limit reached`. A positive code is a system error, and gives the system's message.

Library

`version`

The version of the system's liblmdb: `Peta::FFI::LMDB::version()` gives its version string, such as `LMDB 0.9.33: (May 21, 2024)`; in list context the string and its major, minor and patch numbers.

Peta::FFI::LMDB::Cursor

A cursor: a position in a database that walks its keys in order, finds the first key at or after a given one, and writes or deletes where it stands.

`$txn->cursor($db)` opens one. Every move returns the key and value it lands on as a two-element list, or an empty list when there is nothing there, so a loop reads naturally:

```
my $c = $txn->cursor($db);
while (my ($k, $v) = $c->next) { print "$k=$v\n" }
```

A new cursor stands nowhere: `next` starts at the first key, `prev` at the last. In an `MDB_DUPSORT` database the cursor visits every value of a key; the _dup moves stay within the current key and the _nodup moves skip to the next key.

A cursor ends with its transaction. A read transaction's cursor can move on to another read transaction with `renew`.

Functions

Moving

get

Move the cursor by any of LMDB's cursor operations: `$c->get($op)`, `$c->get($op, $key)`, `$c->get($op, $key, $value)`, with `$op` an `MDB_*` constant of the `:cursor_ops` tag (`MDB_SET_RANGE` and the like). The key and value it lands on, or an empty list. The named moves below do the same more readably.

first

To the first key (and its first value): `($k, $v) = $c->first`.

last

To the last key (and its last value).

next

To the next item - the next value of the key in an `MDB_DUPSORT` database, else the next key; from a new cursor, the first. An empty list after the last.

prev

To the previous item; from a new cursor, the last. An empty list before the first.

first_dup

To the current key's first value (`MDB_DUPSORT` databases).

last_dup

To the current key's last value (`MDB_DUPSORT` databases).

next_dup

To the current key's next value; an empty list after its last (`MDB_DUPSORT` databases).

prev_dup

To the current key's previous value; an empty list before its first (`MDB_DUPSORT` databases).

next_nodup

To the first value of the next key, skipping the current key's other values.

prev_nodup

To the last value of the previous key.

current

The key and value the cursor stands on, without moving.

set

To the key itself: `($k, $v) = $c->set($key)`. An empty list when the key is not stored.

set_range

To the first key at or after the one given, in the database's order: `($k, $v) = $c->set_range('ab')` finds ab, or the first key after it - the start of a range or prefix walk. An empty list when no key follows.

get_both

To a key holding a given value: `$c->get_both($key, $value)` (MDB_DUPSORT databases). An empty list when the key does not hold it.

get_both_range

To a key's first value at or after the one given: `$c->get_both_range($key, $value)` (MDB_DUPSORT databases).

count

How many values the current key holds (MDB_DUPSORT databases).

Writing

put

Store a key and value and leave the cursor on them: `$c->put($key, $value)`. `$c->put($key, $value, MDB_CURRENT)` replaces the value the cursor stands on (the key must be the cursor's). The flags MDB_NOOVERWRITE, MDB_NODUPDATA, MDB_APPEND and MDB_APPENDDUP work as for `$txn->put`. True when stored, false when MDB_NOOVERWRITE or MDB_NODUPDATA refused. MDB_RESERVE and MDB_MULTIPLE croak.

del

Delete the item the cursor stands on: `$c->del`. In an MDB_DUPSORT database, `$c->del(MDB_NODUPDATA)` deletes all the key's values. The next `next` returns the item after the deleted one.

Ending

renew

Move a read transaction's cursor to another read transaction: `$c->renew($txn)`, cheaper than opening a new cursor. It then stands nowhere. A write transaction croaks `renew needs a read transaction`.

close

Close the cursor now, rather than when it goes out of scope or its transaction ends. Using it afterwards croaks `the cursor is closed or its transaction has ended`.

Peta::FFI::LMDB::DB

A database handle: one database of an LMDB environment, as `$txn->open_db` returns it, to pass to the transaction's and cursor's methods.

A handle belongs to its environment, not to the transaction that opened it: once that transaction has committed, every later transaction of the environment can use it. Handles of one environment cannot be used with another's transactions: that croaks `Peta::FFI::LMDB: the database belongs to another environment`.

A database keeps its keys in LMDB's byte order (or integer order, with `MDB_INTEGERKEY`) unless given a sort sub with `set_compare`; an `MDB_DUPSORT` database orders a key's values the same way, or by `set_dupsort`'s sub.

Functions

Ordering

set_compare

Order the database's keys by a sort sub of your own.

set_dupsort

Order the values of each key of an `MDB_DUPSORT` database by a sort sub, called as `set_compare`'s is: `$db->set_dupsort(sub { $a <=> $b })`. Set it every time the environment is opened, before the first read or write.

Information

dbi

LMDB's number for the database within its environment.

set_compare

Order the database's keys by a sort sub of your own.

Synopsis

```
$db->set_compare(sub { lc $a cmp lc $b });
```

What you get back

Nothing. From then on every transaction uses the sub to place and find keys in this database.

Edge cases

- The sub sees the two keys in `$a` and `$b` of its own package, as a `sort` block does, and returns less than, equal to or greater than zero.
- The database does not remember the sub: set the same one every time the environment is opened, before the first read or write. Data stored under one order and read under another is not found.
- A sub that dies makes the operation that called it croak with the sub's error, after LMDB has finished it.
- A plain value instead of a code reference croaks `Peta::FFI::LMDB: set_compare needs a code reference`.

See also

- `set_dupsort` - the order of a key's values
- `cmp` (a `Peta::FFI::LMDB::Txn` method) - compares two keys this way

Peta::FFI::LMDB::Env

An LMDB environment: the file (or directory) a set of databases lives in, and what every transaction starts from.

`Peta::FFI::LMDB::Env->new` opens one; `begin` starts a transaction in it. An environment holds an unnamed database and, when opened with `maxdbs`, that many named ones. Its memory map has a fixed size, `mapsize`: a write that would grow the data past it fails with `MDB_MAP_FULL`, so open with room to spare - the size reserves address space, not disk or memory.

A file can be open in one environment per process: a second `Peta::FFI::LMDB::Env->new` of the same file croaks while the first is open. The environment closes when its last reference goes, or at `close`.

Synopsis

```
use Peta::FFI::LMDB qw(:flags);

my $env = Peta::FFI::LMDB::Env->new('data.lmdb', flags => MDB_
↪NOSUBDIR,
                                    mapsize => 1 << 30, maxdbs => 4);
```

(continues on next page)

(continued from previous page)

```
my $txn = $env->begin;
# ...
$txn->commit;
print $env->stat->{entries}, "\n";
```

Functions

Environments

new

Open an environment: the file or directory `$path`, with options.

begin

Start a transaction: `$env->begin` for a write transaction, `$env->begin(MDB_RDONLY)` for a read one.

stat

The unnamed database's statistics, as a hash reference: `entries` (the number of keys), `depth` of its tree, `branch_pages`, `leaf_pages`, `overflow_pages`, and the page size `psize`. A named database's are `$txn->stat($db)`.

info

The environment's state, as a hash reference: `mapsize`, the map's address `mapaddr`, the last page used `last_pgno`, the last committed transaction's ID `last_txnid`, and the readers allowed and live, `maxreaders` and `numreaders`.

sync

Flush committed data to disk: needed only when the environment was opened with `MDB_NOSYNC` or `MDB_MAPASYNC`, as commits otherwise sync themselves. `$env->sync(1)` forces the flush even then.

copy

Copy the environment to `$path` while it is in use - a consistent backup of the last commit. `$path` is a directory, or with `MDB_NOSUBDIR` the copy's file name, which must not exist. `$env->copy($path, MDB_CP_COMPACT)` leaves the free pages out, making a smaller copy.

path

The path the environment was opened with.

flags

The environment's MDB_* flags, as a number to test with &.

set_flags

$env->set_flags($flags, $on): switch flags on (true $on) or off while open. Only MDB_NOSYNC, MDB_NOMETASYNC, MDB_MAPASYNC and MDB_NOMEMINIT can change; others croak Invalid argument.

maxkeysize

The longest key the environment takes, in bytes (511 with the usual liblmdb), which is also the longest value of an MDB_DUPSORT database. A longer one croaks MDB_BAD_VALSIZE.

reader_check

Free the reader slots of processes that died with a read transaction open; returns how many it freed. Such slots keep pages from being reused until cleared.

close

Close the environment now, rather than when its last reference goes. No transaction may be live: that croaks Peta::FFI::LMDB: the environment has live transactions. Using the environment afterwards croaks the environment is closed.

new

Open an environment: the file or directory $path, with options.

Synopsis

```
my $env = Peta::FFI::LMDB::Env->new($path, %options);
```

Options

- flags - MDB_* environment flags OR'd together, chiefly MDB_NOSUBDIR ($path is the data file itself, with the lock file $path-lock beside it; without it $path is a directory holding data.mdb and lock.mdb), MDB_RDONLY (read only), MDB_NOSYNC, MDB_NOMETASYNC, MDB_MAPASYNC (sync less, risking the last commits on a crash), MDB_NOTLS, MDB_NORDAHEAD, MDB_NOMEMINIT, MDB_WRITEMAP.
- mode - the permission of files it creates (default 0644).
- mapsize - the memory map's size in bytes, the most data the environment can hold (LMDB's default is 1 MiB).
- maxdbs - how many named databases open_db may open.
- maxreaders - how many read transactions may be live at once (default 126).

What you get back

A `Peta::FFI::LMDB::Env` object. Failures croak: an LMDB error with a `Peta::FFI::LMDB::Error`, an unknown option with `Peta::FFI::LMDB::Env->new: unknown option 'NAME'`, a file already open in the process with `... is already open in this process`.

Examples

```
my $env = Peta::FFI::LMDB::Env->new('cache.lmdb', flags => MDB_
↪NOSUBDIR);
```

A directory environment with named databases:

```
mkdir 'app.db';
my $env = Peta::FFI::LMDB::Env->new('app.db', maxdbs => 8, mapsize␣
↪=> 1 << 32);
```

Edge cases

- The directory form needs the directory to exist; a file it creates.
- A second environment on a file already open in the process croaks rather than open it: LMDB's locks would break under two.

See also

- `begin` - starts a transaction
- `close` - closes the environment now

begin

Start a transaction: `$env->begin` for a write transaction, `$env->begin(MDB_RDONLY)` for a read one.

Synopsis

```
my $txn = $env->begin;
my $r   = $env->begin(MDB_RDONLY);
```

What you get back

A `Peta::FFI::LMDB::Txn`. A read transaction sees the data as it was when it began, however long it lives, and never waits. A write transaction waits while another one - in this process or another - is live, as there is one writer at a time.

Edge cases

- A transaction that goes out of scope without `commit` is aborted: its writes are discarded.
- A long-lived read transaction keeps the pages it sees from being reused, so the file grows while writers work; end read transactions (or `reset` them) when done.

See also

- `Peta::FFI::LMDB::Txn` - what a transaction does
- `stat` - the size of the unnamed database

Peta::FFI::LMDB::Txn

A transaction: everything read from or written to an LMDB environment happens in one.

`$env->begin` starts a write transaction, `$env->begin(MDB_RDONLY)` a read one. A read transaction sees the data as it was when it began, never waits and never blocks a writer. A write transaction sees its own writes; nothing it writes is visible elsewhere until `commit` makes all of it durable at once, and `abort` - or the transaction going out of scope - discards all of it. There is one write transaction at a time across all processes using the file.

Keys and values are byte strings: a string with characters over 255 croaks `Wide character`. In a database opened with `MDB_INTEGERKEY` the keys are unsigned integers, and with `MDB_DUPSORT|MDB_INTEGERDUP` the values.

Synopsis

```
my $txn = $env->begin;
my $db  = $txn->open_db('users', MDB_CREATE);
$txn->put($db, alice => 'admin');
print $txn->get($db, 'alice'), "\n";    # admin
$txn->commit;
```

Edge cases

- After `commit` or `abort` the transaction is over: using it croaks `Peta::FFI::LMDB: the transaction has ended`.
- While a child transaction (`begin` on a transaction) is live, using its parent croaks `the transaction has a live child transaction`.

Functions

Reading and writing

get

Look up a key; the value, or undef when the key is not stored.

get_view

Look up a key and make a variable the value itself, without copying it: for large values read once.

put

Store a value under a key.

del

Delete a key - in an `MDB_DUPSORT` database all its values - or, with a value, just that one value: `$txn->del($db, $key)`, `$txn->del($db, $key, $value)`. True when something was deleted, false when there was nothing to delete.

cursor

Open a cursor on a database: `$txn->cursor($db)`, a `Peta::FFI::LMDB::Cursor` that walks the keys in order. It ends with the transaction; a read transaction's cursor can be moved to another read transaction with `renew`.

Databases

open_db

Open a database of the environment, for this and later transactions.

stat

A database's statistics, as a hash reference: `entries` (the number of items), `depth`, `branch_pages`, `leaf_pages`, `overflow_pages`, `psize`.

drop

Empty a database: `$txn->drop($db)`. `$txn->drop($db, 1)` deletes the database itself, after which its handle is no longer valid.

db_flags

The `MDB_*` flags a database was created with, as a number to test with &.

cmp

Compare two keys as the database orders them - by its `set_compare` sub, or LMDB's order for its flags: `-1`, `0` or `1`, as `cmp` returns.

dcmp

Compare two values as an `MDB_DUPSORT` database orders a key's values - by its `set_dupsort` sub, or LMDB's order: `-1`, `0` or `1`.

Ending a transaction

commit

Make the transaction's writes durable and visible, and end it. A failure croaks; the transaction is over either way. Committing a read transaction ends it, keeping the databases it opened.

abort

Discard the transaction's writes and end it. Ending a transaction that has already ended does nothing. A transaction that goes out of scope is aborted.

reset

Let a read transaction's snapshot go, keeping the transaction for `renew`: cheaper than ending and beginning, for a reader that pauses. A write transaction croaks `reset needs a read transaction`.

renew

Give a `reset` read transaction a fresh snapshot of the data as it is now.

Nesting

begin

Start a child transaction inside a write transaction: `$txn->begin`. Its writes join the parent's at its `commit`, or vanish at its `abort`, while the parent's other writes stand. The parent cannot be used until the child ends. A read transaction cannot have children.

Information

id

The transaction's ID: for a write transaction its own, for a read one the ID of the commit its snapshot shows.

env

The transaction's environment, a `Peta::FFI::LMDB::Env`.

get

Look up a key; the value, or undef when the key is not stored.

Synopsis

```
my $value = $txn->get($db, $key);
```

What you get back

A copy of the value as a string (an integer in an `MDB_INTEGERDUP` database), or undef. In an `MDB_DUPSORT` database, the key's first value.

Edge cases

- A key too long for the environment croaks with `MDB_BAD_VALSIZE`; `maxkeysize` gives the limit.
- In a write transaction, it sees the transaction's own writes.

See also

- `get_view` - the same without copying the value
- `Peta::FFI::LMDB::Cursor` - walk keys in order, find a range

get_view

Look up a key and make a variable the value itself, without copying it: for large values read once.

Synopsis

```
my $view;
if ($txn->get_view($db, $key, $view)) { print length $view }
```

What you get back

True when the key is stored, with `$view` a read-only string over the value in the database's memory map; false when not, with `$view` undef.

Edge cases

- `$view` becomes undef when the transaction ends, and in a write transaction at its next write: copy what must outlive that (`my $copy = $view`).
- Assigning to `$view` croaks `Modification of a read-only value attempted`; a later `get_view` into the same variable replaces it.
- The view must be a plain scalar variable, given as the argument: a returned value would be copied by the assignment.

See also

- `get` - a copy of the value

put

Store a value under a key.

Synopsis

```
$txn->put($db, $key, $value);
my $added = $txn->put($db, $key, $value, MDB_NOOVERWRITE);
```

Flags

- none - store, replacing the key's value; in an `MDB_DUPSORT` database, add the value to the key's values.
- `MDB_NOOVERWRITE` - store only a key not yet there.
- `MDB_NODUPDATA` - in an `MDB_DUPSORT` database, store only a value the key does not hold yet.
- `MDB_APPEND`, `MDB_APPENDDUP` - the key (value) goes after all the others: a fast load of sorted data; out of order it croaks `MDB_KEYEXIST`.

What you get back

True when stored, false when `MDB_NOOVERWRITE` or `MDB_NODUPDATA` found the key (value) already there.

Edge cases

- In a read transaction it croaks with LMDB's `Permission denied`.
- `MDB_RESERVE` is refused with a croak.
- When the data outgrows the environment's `mapsize` it croaks `MDB_MAP_FULL`, and the transaction can only be aborted.

See also

- `del` - removes a key or one value
- `Peta::FFI::LMDB::Cursor` - `put` at a cursor

open_db

Open a database of the environment, for this and later transactions.

Synopsis

```
my $main  = $txn->open_db;                          # the unnamed␣
↪database
my $users = $txn->open_db('users', MDB_CREATE);
```

What you get back

A `Peta::FFI::LMDB::DB` handle. It belongs to the environment: once the transaction that opened it commits (a read one, too), every later transaction can use it.

Flags

- `MDB_CREATE` - create a named database that does not exist (in a write transaction).
- `MDB_DUPSORT` - keys may hold several values, kept sorted; `MDB_DUPFIXED`, `MDB_INTEGERDUP`, `MDB_REVERSEDUP` refine it.
- `MDB_INTEGERKEY` - keys are unsigned integers; `MDB_REVERSEKEY` - keys compare from their last byte.

Edge cases

- A named database needs the environment opened with `maxdbs`; one more than that croaks `MDB_DBS_FULL`.
- A name that does not exist, without `MDB_CREATE`, croaks `MDB_NOTFOUND`.
- A handle opened in a transaction that aborts is gone with it.

See also

- `drop` - empties or deletes a database
- `Peta::FFI::LMDB::DB` - a database's own order

Peta::FFI::Libc

Call common libc functions from Perl without writing a single line of FFI glue.

Pre-baked libc bindings: each function here calls the C library directly, so there is no handle to open and no signature string to write. Reach for `Peta::FFI` when you need a function this module does not cover.

```
use Peta::FFI::Libc qw(getpid strlen strerror gethostname uname␣
↪access R_OK);

print getpid() == $$ ? "getpid is \$\$\n" : "?\n";
print strlen("hello"), " ", strerror(2), "\n";   # 5 No such file or␣
↪directory
my ($sys, $node) = uname();
print "$sys on $node\n" if gethostname() eq $node;
```

(continues on next page)

(continued from previous page)

```
print access("/etc/passwd", R_OK) == 0 ? "readable\n" : "not␣
↪readable: $!\n";
```

The functions keep C's conventions: the ones that report success return 0 for it and -1 for failure, with `$!` set to the C `errno`. Nothing is exported by default; name what you want.

Function	Returns
`getpid`, `getppid`	the process id, the parent's
`getuid`, `getgid`	the real user and group id
`geteuid`, `getegid`	the effective user and group id
`strlen($s)`	the length of `$s`; a NUL byte in it dies
`strerror($errno)`	the system's message for an error number
`getenv($name)`	the value, or undef when unset
`setenv($name, $value, $over)`	0 / -1; `$over` false keeps an existing value
`unsetenv($name)`	0 / -1
`abs($n)`, `labs($n)`	the absolute value, as an int / a long
`sleep($s)`, `usleep($us)`	seconds left unslept / 0 or -1
`gethostname()`	the host name
`uname()`	(sysname, nodename, release, version, machine)
`access($path, $mode)`	0 / -1, `$mode` an OR of `F_OK`, `R_OK`, `W_OK`, `X_OK`
`unlink`, `rmdir($path)`	0 / -1
`mkdir($path, $mode)`	0 / -1
`chmod($path, $mode)`	0 / -1
`chown($path, $uid, $gid)`	0 / -1
`time()`	seconds since the epoch
`clock()`	processor time used, in `CLOCKS_PER_SEC` units

Peta::FFI::Libc is pperl's own module, version 0.2.0.

Peta::FFI::PCRE2

Compile and run PCRE2 regular expressions via the system's libpcre2-8 library.

The library is located at run time, so pperl needs no build-time dependency on it. If `libpcre2-8.so` is not installed, `use Peta::FFI::PCRE2` still succeeds, the `PCRE2_*` constants still work, and every other call croaks with an instruction telling you which package to install.

`Peta::FFI::PCRE2` is an explicit binding, not a regex-engine plugin: a compiled pattern is a blessed object and matching is a method call. Perl's own `m//` is untouched. Reach for it when you want PCRE2's JIT specifically - each method is one native call, and the scan loop behind `count` runs entirely on the C side.

A pattern whose scalar carries the UTF8 flag is compiled with `PCRE2_UTF`. A subject is matched in the pattern's encoding: against a UTF pattern a byte string is matched as its UTF-8 upgrade, and against a byte pattern a UTF-8 string that fits in Latin-1 is matched as its bytes - so `"\xe9"` matches `"\xe9"` whichever way either is stored. Every

reported offset is a byte offset into the subject in that encoding. A start offset inside a UTF-8 character croaks. A subject with characters above 0xFF against a byte pattern is matched as its UTF-8 bytes. `substitute`'s result is UTF-8 exactly when the subject it matched was.

Synopsis

```
use Peta::FFI::PCRE2 qw(PCRE2_CASELESS);

my $re = Peta::FFI::PCRE2->new("ab+c", PCRE2_CASELESS);
my ($start, $end) = $re->match("xxABBBCxx");   # byte offsets, () on
↪no match
my $n   = $re->count($genome);                  # non-overlapping
↪match count
my $out = $re->substitute($seq, "<2>");         # global replace,
↪new string
```

Compile constants

Pass these to `new`, OR'd together. All are exportable on request; none are exported by default.

- `PCRE2_CASELESS` - case-insensitive matching, like `/i`.
- `PCRE2_MULTILINE` - `^` and `$` match at internal newlines, like `/m`.
- `PCRE2_DOTALL` - `.` matches newline too, like `/s`.
- `PCRE2_EXTENDED` - ignore unescaped whitespace and `#` comments in the pattern, like `/x`. `PCRE2_EXTENDED_MORE` additionally ignores spaces and tabs inside character classes, like `/xx`.
- `PCRE2_UNGREEDY` - invert greediness: quantifiers are lazy unless followed by `?`.
- `PCRE2_LITERAL` - treat the whole pattern as a literal string, with no metacharacters at all.
- `PCRE2_DUPNAMES` - permit several capture groups to share one name.
- `PCRE2_ANCHORED` - match only at the start offset.
- `PCRE2_UTF` - interpret pattern and subject as UTF-8. Set automatically when the pattern scalar is UTF8-flagged, so you rarely need it by hand.

Substitution constants

Pass these to `substitute`, whose default is `PCRE2_SUBSTITUTE_GLOBAL` alone.

- `PCRE2_SUBSTITUTE_GLOBAL` - replace every match, not just the first.
- `PCRE2_SUBSTITUTE_EXTENDED` - enable backslash escapes and conditional forms such as `${1:-default}` in the replacement.

Differences from upstream

There is no CPAN module this mirrors. The closest, `re::engine::PCRE2`, is a different design: it replaces perl's regex engine inside a lexical scope so that ordinary `m//` runs under PCRE2, and it offers no substitution entry point. This module never touches perl's engine and exposes PCRE2 directly instead, which is why matching is a method call rather than an operator.

Functions

Construction

new

Compile a pattern into a `Peta::FFI::PCRE2` object.

Matching

match

Match the pattern against a subject string once.

count

Count non-overlapping matches of the pattern in a subject string.

Substitution

substitute

Replace matches of the pattern in a subject, returning a new string.

Introspection

capture_count

Number of capturing groups in the compiled pattern.

Synopsis

```
Peta::FFI::PCRE2->new("(a)(b(c))?")->capture_count;   # 3
```

jit

Whether this pattern was successfully JIT-compiled.

jit_available

Whether the loaded libpcre2-8 was built with JIT support.

version

Version string of the loaded libpcre2-8 (e.g. `"10.47 2025-06-30"`).

new

Compile a pattern into a `Peta::FFI::PCRE2` object.

`$options` is a bitwise OR of the `PCRE2_*` compile constants (default 0). A UTF8-flagged pattern automatically adds `PCRE2_UTF|PCRE2_NO_UTF_CHECK`. The pattern is JIT-compiled when the library supports it; `jit` reports whether that succeeded. Croaks with PCRE2's message and the byte offset on a bad pattern.

Synopsis

```
my $re = Peta::FFI::PCRE2->new("a[act]ggtaaa|tttacc[agt]t");
my $ci = Peta::FFI::PCRE2->new("hello", PCRE2_CASELESS);
```

match

Match the pattern against a subject string once.

Returns a list of byte-offset pairs: `(start, end)` of the whole match followed by one pair per capture group (`undef, undef` for groups that did not participate), or the empty list on no match. An optional `$startoffset` (byte offset, default 0) begins the match part-way into the subject; an offset past the end of the subject returns the empty list.

Call it in list context. In scalar context you get the last value pushed, which is the end offset of the final pair, not a count and not a boolean.

Synopsis

```
my ($s, $e, @captures) = $re->match($subject);
while (my ($s, $e) = $re->match($subject, $pos)) {
    $pos = $e;
}
```

count

Count non-overlapping matches of the pattern in a subject string.

The whole scan loop runs natively: one method call per subject, not one per match. Empty matches are counted the way a global match ought to: after an empty match the scan retries at the same offset with `PCRE2_NOTEMPTY_ATSTART|PCRE2_ANCHORED` and then advances one character (the pcre2demo.c idiom), stepping over a whole UTF-8 character or CRLF pair where applicable.

Synopsis

```
my $n = Peta::FFI::PCRE2->new("agggtaaa|tttaccct", PCRE2_CASELESS)
                    ->count($genome);
```

substitute

Replace matches of the pattern in a subject, returning a new string.

Global by default (PCRE2_SUBSTITUTE_GLOBAL); pass an explicit $options value to override; it replaces the default rather than adding to it, so include PCRE2_SUBSTITUTE_GLOBAL yourself if you still want all occurrences. The replacement uses PCRE2 substitution syntax ($1, ${name}; \ escapes with PCRE2_SUBSTITUTE_EXTENDED). The subject is not modified, and a UTF8-flagged subject yields a UTF8-flagged result.

Synopsis

```
my $clean = Peta::FFI::PCRE2->new(">.*\\n|\\n")->substitute($fasta,
 ↪"");
```

Peta::FFI::Pool

Run C functions on worker threads, so that a call which hangs cannot hang the program.

Some C calls can block inside the kernel for as long as it likes: `statfs`, `stat` or open on an NFS, CIFS or CephFS mount whose server is gone waits uninterruptibly, and no signal or alarm gets the thread back. perl5 programs fork a child with a timeout for every such probe. A pool runs the call on a thread of its own instead, and reports how it went as an event: the event loop stays free, and a hung mount costs one parked thread, not a process per probe.

`Peta::FFI::Pool->new(threads => 4)` makes a pool of at most four threads. `$pool->call($function, $deadline, @args)` runs a function prepared with *Peta::FFI*'s `function` or `attach` with `@args`, and returns the call's id at once. When the call returns, an event `{ id => $id, state => 'done', result => ..., errno => ... }` is queued, and what the function wrote through its arguments (a P buffer, an `*{Class}` record, an `*i`) has been written into the caller's scalars by the time the event is taken. When `$deadline` seconds pass first, the event is `{ id => $id, state => 'timeout' }` instead. The thread stays with the call until it returns, since nothing can cancel it, and what the call then produces is thrown away: the caller's scalars are left alone.

A pool never queues a call. When all its threads are taken, by calls running or by calls hung past their deadline, the call's event is `{ id => $id, state => 'busy' }`, at once.

The events are taken with `next`, oldest first, and `fd` reads ready while there are some, so the pool is a *Peta::FFI::EventSource* for any event loop.

Synopsis

```
use Peta::FFI;
use Peta::FFI::Pool;
use Peta::FFI::EventSource;

my $libc   = Peta::FFI::dlopen("libc.so.6");
my $statfs = Peta::FFI::function($libc, "statfs", "(pP)i");

my $pool   = Peta::FFI::Pool->new(threads => 4);
my $source = Peta::FFI::EventSource->new($pool,
    fd => \&Peta::FFI::Pool::fd, next => \&Peta::FFI::Pool::next);

my $st = "\0" x 120;                    # struct statfs, x86-64
my $probe = $pool->call($statfs, 2, "/mnt/share", \$st);
my $guard = $source->watch(sub {
    for my $event (@_) {
        next unless $event->{id} == $probe;
        if ($event->{state} eq 'done') {
            print $event->{result} == 0 ? "mounted\n" : "error
 ↪$event->{errno}\n";
        }
        else {
            print "/mnt/share does not answer\n";    # timeout, or␣
 ↪busy
        }
    }
});
```

What a call takes

A call's arguments are read and copied before `call` returns, so the thread never reads a Perl value, and changing them meanwhile changes nothing. A function can take numbers, `b`, `o`, `p`, `P`, `*T` of a number or `o`, handles and records (`{Class}` and `*{Class}`). It can return `v`, a number other than a long double or a complex one, `b`, `o`, `p`, `s`, a handle or a record. Arrays, the out pointers and arrays of `*T[...]`, `*<Class>`, `*s` and `*P[...]`, and closures are refused: a call that needs them runs on Perl's own thread, with `$function->(@args)`. A closure passed as an `o` still cannot be called on a pool's thread, which stops the program as any thread of a library's own does.

A handle passed to a call is kept alive until the call returns, even past its deadline, so its destructor cannot free what the thread is still using. A handle a late call returns is destroyed, and a string it returns freed; a plain number is lost, so a file descriptor a late open returns stays open.

Threads, signals and fork

A pool's threads start when a call needs one, up to `threads`, and block every signal, which Perl's thread handles. They belong to the process that made the pool: after `fork`, the child makes a pool of its own, and `call` croaks on the parent's.

Functions

Pools

new

`Peta::FFI::Pool->new(threads => $n)`: a pool of at most `$n` threads (4 when not given), none started yet.

call

`$pool->call($function, $deadline, @args)`: run `$function`, a code reference from *Peta::FFI*'s `function` or `attach`, with `@args` on one of the pool's threads, and return the call's id. Its event is done when it returns, `timeout` when `$deadline` seconds (a fraction is fine; `undef` is no deadline) pass first, and `busy` at once when every thread is taken.

Events

fd

`$pool->fd`: a descriptor that reads ready while events are queued, for an event loop. Never close it: it is the pool's.

next

`$pool->next`: the oldest event, a hash reference, or undef when there is none. `id` is the call's, `state` is done, `timeout` or `busy`, and a done event has the function's `result` and the `errno` the call left; what the function wrote through its arguments is in the caller's scalars when it is returned.

Peta::FFI::Queue

Callbacks a C library makes from threads of its own, queued for Perl's event loop.

Some libraries call back on a thread of theirs: librados calls its monitor log callback and its watch and notify callbacks that way. Perl cannot run there, so a *Peta::FFI* closure called from such a thread stops the program. A queued closure runs no Perl when it is called: it copies its arguments, as its signature reads them, into a queue and returns at once, and Perl runs its sub later, when the event loop takes the queue's events.

`Peta::FFI::Queue->new` makes a queue, and `Peta::FFI::closure($sig, $sub, queue => $queue)` a closure that queues into it. Every call of the closure, from any thread - Perl's own included - becomes one event, `{ handler => $sub, args => [...], closure => $address }`; `dispatch` runs each queued event's handler with its arguments, oldest first. The queue reads ready on `fd` while it holds events, so it is a *Peta::FFI::EventSource* for any event loop.

A queued closure returns `v`, or a number, `b` or `o` given once as `returns => $value` (0 when not given), since nothing can compute a value at the time of the call. Its arguments are what any closure takes: numbers, `b`, `o`, `p` (copied up to its NUL) and records, copied, and bytes or an array of numbers C passes with their length in another argument, `&P[#k]` and `&T[#k]`. A `P` argument, an address valid only during the call, is not.

Synopsis

```
use Peta::FFI;
use Peta::FFI::Queue;
use Peta::FFI::EventSource;

my $queue = Peta::FFI::Queue->new;

# librados's rados_log_callback2_t
my $log = Peta::FFI::closure('(opppp u64u64u64 pp)v', sub {
    my (undef, $line, $channel, $who, $name, $sec, $nsec, $seq,
 ↪$level, $msg) = @_;
    print "$level $who: $msg\n";
}, queue => $queue);
$monitor_log2->($cluster, "info", $log, undef);

# rados_watchcb2_t: the notify's payload, data_len bytes
my $watch = Peta::FFI::closure('(ou64u64u64&P[#6]L)v', sub {
    my (undef, $notify_id, $cookie, $notifier, $payload) = @_;
    ...
}, queue => $queue);

my $source = Peta::FFI::EventSource->new($queue,
    fd => \&Peta::FFI::Queue::fd, next => \&Peta::FFI::Queue::next);
my $guard = $source->watch(sub { $_->{handler}->(@{ $_->{args} })
 ↪for @_ });

# or, with a loop of your own
vec(my $rin = '', $queue->fd, 1) = 1;
$queue->dispatch while select(my $rout = $rin, undef, undef, undef);
```

Bounds and lifetimes

A queue holds at most `limit` events (`Peta::FFI::Queue->new(limit => $n)`, 65536 when not given), so a library calling faster than Perl takes them cannot fill the memory: a call that finds the queue full is dropped, and `lost` counts it. An event whose closure was freed with `closure_free` before Perl took it is dropped too. A queued closure keeps its queue's memory alive, so a library may call it after the queue object is gone; those calls are dropped. As for any closure, `closure_free` comes only after the library has been told to stop calling.

Functions

Queues

new

`Peta::FFI::Queue->new(limit => $n)`: a queue of at most `$n` events, 65536 when not given.

dispatch

`$queue->dispatch`: run the handler of every queued call with its arguments, oldest first, and return how many ran. A handler that dies stops it there, with the error; the calls after it stay queued.

lost

`$queue->lost`: how many calls were dropped because the queue was full.

Events

fd

`$queue->fd`: a descriptor that reads ready while events are queued, for an event loop. Never close it: it is the queue's.

next

`$queue->next`: the oldest queued call as a hash reference - its closure's sub as `handler`, the arguments as the sub would have got them as `args`, the closure's address as `closure` - or undef when there is none.

Peta::FFI::UUID

Generate and parse RFC 4122 UUIDs via the system's libuuid library.

The library is located at run time, so pperl needs no build-time dependency on it. If `libuuid.so` is not installed, `use Peta::FFI::UUID` still succeeds and every call croaks with an instruction telling you which package to install.

```
use Peta::FFI::UUID qw(uuid_generate_random uuid_parse uuid_unparse␣
↪uuid_is_null);

my $text  = uuid_generate_random();     # "2d6c8b1e-0f4a-4c3e-9b7d-
↪5a1e2f3c4d5e"
my $bytes = uuid_parse($text);          # the same UUID as 16 raw␣
↪bytes
print uuid_unparse($bytes) eq $text ? "round trip\n" : "differs\n";
print uuid_is_null("\0" x 16) ? "nil UUID\n" : "not nil\n";
```

The generators return the text form; `uuid_parse` and `uuid_unparse` convert between it and the binary form. Nothing is exported by default. Peta::FFI::UUID is pperl's own module, version 0.2.0.

Functions

Other Functions

uuid_generate

`uuid_generate()`: a new UUID as its 36-character text form - random (version 4) when the system has a good random source, else time-based (version 1).

uuid_generate_random

`uuid_generate_random()`: a new random (version 4) UUID, as text: `"2d6c8b1e-0f4a-4c3e-9b7d-5a1e2f3c4d5e"`.

uuid_generate_time

`uuid_generate_time()`: a new time-based (version 1) UUID, as text. It carries the generation time and a node identifier, so it reveals when and where it was made.

uuid_parse

`uuid_parse($text)`: the 16-byte binary form of a UUID's text form, or undef when `$text` is not one.

uuid_is_null

`uuid_is_null($bytes)`: 1 when the 16-byte binary UUID is all zeros (the nil UUID), else 0. Anything but 16 bytes dies "requires a 16-byte UUID".

uuid_unparse

`uuid_unparse($bytes)`: the 36-character text form of a 16-byte binary UUID, in lower case. Anything but 16 bytes dies "requires a 16-byte UUID".

closure

Wrap a Perl coderef as a C-callable function pointer.

Synopsis

```
# int (*)(void*) - a progress handler
my $ptr = Peta::FFI::closure('(o)i', sub { my ($ud) = @_; 0 });
Peta::FFI::call($lib, 'sqlite3_progress_handler', '(oioo)v',
                $db, 100, $ptr, undef);
...
Peta::FFI::closure_free($ptr);
```

The signature grammar is `call`'s. A closure takes and returns the numbers, `o`, `p`, `P`, `b` and records - `{Class}` by value, and as an argument `*{Class}` by pointer, which the callback gets as a read-only copy. As an argument it also takes what C lends with its length in another argument: `&P[#k]` bytes, as a string, and `&T[#k]` numbers or `o`, as an array reference - `(o&P[#3]L)v` is a callback handed `void *data, size_t len`. There is no `;`, `s`, handle type, other array, pointer to a number, long double or complex number: C calls the closure through a fixed prototype and owns nothing it hands over.

The returned value is the raw address of the trampoline, to be passed wherever C wants the function pointer.

Options

- `queue => $queue` - a queued closure, which C may call on any thread: each call copies its arguments into the *Peta::FFI::Queue* `$queue` and returns at once, and the sub runs when Perl takes the queue's events. It takes no `P`, an address valid only during the call, and returns `v`, a number, `b` or `o`.
- `returns => $value` - what a queued closure returns to C, read once, here; 0 when not given.

Threads

A closure may be called only on the interpreter's own thread, during a C call Perl made - a progress handler, a comparator, a visitor. A library that calls it from a thread of its own stops the process with a message saying so, since Perl cannot run there. A library that calls back on its own threads takes a queued closure instead, and events a library queues itself reach Perl through a file descriptor the event loop watches, as a *Peta::FFI::EventSource*.

Lifetime

The closure stays alive until `closure_free` is called with the address this returned. Freeing it while C still holds the pointer leaves that library calling into released memory, so free it only after the C side has been told to stop - for a driver, that means tying it to the handle and releasing it at disconnect.

Errors in the callback

A callback that dies does NOT propagate: the error would have to unwind through the C caller's stack frame. `$@` is set and the closure returns a zero of its declared return type; check `$@` after the C call that triggered it.

dlopen

Open a shared library and return a handle suitable for passing to `call`.

Synopsis

```
my $lib = Peta::FFI::dlopen("libm.so.6");
my $lib = Peta::FFI::dlopen("/usr/lib/libuuid.so.1");   # absolute␣
↪path
```

What you get back

An opaque integer handle. Treat it as a token: pass it to `call` and later to `dlclose`, but do not do arithmetic on it. Store it in a lexical and keep it alive as long as you want to call into the library.

The argument is either a bare soname (e.g. `"libm.so.6"`) that the dynamic linker resolves through the usual `LD_LIBRARY_PATH` / `ld.so.cache` machinery, or an absolute path to an `.so` file. Both `RTLD_NOW` and `RTLD_GLOBAL` are set - symbols are resolved eagerly and become visible to subsequently loaded libraries.

Edge cases

- **Library not found** - croaks with the message reported by `dlerror`, e.g. `Peta::FFI::dlopen: libnope.so: cannot open shared object file: No such file or directory`.
- **Name contains a null byte** - croaks with `Peta::FFI::dlopen: invalid library name (contains null byte)`.
- **No argument** - croaks with `Peta::FFI::dlopen: requires library name`.
- **Calling dlopen repeatedly with the same name** - returns the same (reference-counted) handle each time. Pair every successful `dlopen` with a matching `dlclose` if you want the library to eventually unload.

call

Invoke a C function from an opened library and return its result.

Synopsis

```
my $n = Peta::FFI::call($lib, "strlen",   "(p)L", "hello");      # 5
my $r = Peta::FFI::call($lib, "sqrt",     "(d)d", 2.0);          #␣
↪1.4142...
my $s = Peta::FFI::call($lib, "getenv",   "(p)p", "PATH");       # /
↪usr/bin:...
Peta::FFI::call($lib, "srand", "(i)v", 42);                      #␣
↪void return
```

Arguments

- `$lib` - handle returned by `dlopen`.
- `$func` - symbol name to look up in the library, or the address of a function: a pointer C handed out, such as an entry of a table of callbacks, which has no name to look up.
- `$sig` - signature string `(args)ret`; see the module-level type-code table.
- the remaining arguments - one value per type code in `args`, coerced to the matching C type before the call.

What you get back

A single scalar whose shape depends on the return type:

- the integer types, `b` - an integer; perl's true or false.
- `d` / `f` / `D` - a float (a long double rounded to one).
- `cf` / `cd` - `[re, im]`.
- `p` - the returned `const char *` copied into a Perl string; `undef` if the C function returned `NULL`.
- `o` - the address; `0` for `NULL`.
- `v` - 1, so the call chains naturally in boolean contexts.
- `P` - pointer returned as a string (same rules as `p`).
- `*T` - a reference to the value it points to; `T[N]` - a reference to an array of the `N` values; `undef` for `NULL`.
- `{Class}` - a new record object; `*{Class}` - a copy of the record it points to, `undef` for `NULL`.

Output buffers (P)

A `P` argument that is a reference to a scalar passes that scalar's own bytes, and after the call the scalar holds what the callee wrote there - as many bytes as it had: `my $buf = "\0" x 64; call(..., \$buf)`. Any other `P` argument is a zeroed buffer the callee may write and nobody reads, as long as the string passed (minimum 16 bytes) or as many bytes as the number says.

Pointers and arrays

A `*T` argument is a reference to a scalar, which the callee reads and writes - an out-parameter, `\my $n` - or `undef` for `NULL`; a reference to an array passes its elements. A `T[N]` argument is a reference to an array of `N` values, and `T[]` one of any length; after the call the array holds what the callee left there.

Edge cases

- **Wrong argument count** - croaks with `Peta::FFI::call FNAME: expected N args, got M`.
- **Bad signature string** - croaks with `FFI signature error: ...` describing the offending character or missing `)`.
- **Symbol not found** - croaks with `Peta::FFI::call: symbol not found: FNAME` or the message reported by `dlerror`.
- **Incorrect type codes** - calling a function with a signature that does not match its real prototype is undefined behaviour. Check the C header before writing the signature.
- **String argument contains a null byte** - croaks with `Peta::FFI::call FNAME: CString error: ...`.

- **A handle of the wrong class, or a released one** - croaks before the call.

`call` parses the signature, looks the symbol up and prepares the call interface every time; a function called more than a few times is better prepared once with `function` or `attach`.

function

Prepare a C function once and return it as a code reference.

Synopsis

```
my $move_to = Peta::FFI::function($cairo, "cairo_move_to", "(odd)v
 ↪");
$move_to->($cr, 10, 20);

my $validate = Peta::FFI::function($lib, "schema_validate", "(
 ↪<My::Schema>p)s",
                                   free => "string_free");
my $errors = $validate->($schema, $json);
```

Arguments

- `$lib`, `$name`, `$signature` - as for `call`.
- `free => $function` - the library function that frees what the callee hands over: an `s` result, an `*s` argument, an array the callee allocates (`*T[r]`, `*T[#k]`, `*T[0]`) and the strings in one, and bytes it allocates (`*P[r]`, `*P[#k]`). By name (looked up in `$lib`) or by address. Without it these are freed with the C library's `free()`, which is right for C code that allocates with `malloc`, and wrong for anything else - a Rust library must name its own.
- `release => $function` - for an array of records the callee allocates: the library function `(array, count)` that frees it and whatever its records point to (libvirt's `virTypedParamsFree`). It runs when the last record taken from the array is gone.

What you get back

A code reference. Calling it with the arguments the signature lists returns what `call` would. The signature is parsed, the symbol resolved and the call interface prepared once, here, so each call costs only its argument and result conversion. A function whose arguments and result are integers, `f`, `d` or `o` - at most eight arguments, six of them integers or `o`, and not variadic - is also compiled into machine code of its own that calls it directly, once it has been called 8192 times, when the compile has paid for itself. `PPERL_FFI_STUBS=N` compiles after N calls instead, and `PPERL_FFI_STUBS=0` sends every call through the general path.

The function keeps its library loaded for as long as the code reference lives, whatever `dlclose` is called on.

Edge cases

- **Symbol not found**, **bad signature** - croak here, as `call` would on its first use.
- **Wrong argument count** - croaks with `NAME: expected N args, got M`, NAME being the C function's.
- **`free` on a function that hands nothing over**, **`release` on one without an allocated array of records** - croak.

attach

Prepare a C function once and install it as a named Perl sub.

Synopsis

```
package My::Zlib;
my $z = Peta::FFI::dlopen("libz.so.1");
Peta::FFI::attach($z, "zlibVersion", "()p");          #␣
↪My::Zlib::zlibVersion
Peta::FFI::attach($z, "crc32", "(Lpu32)L", as => "crc");
print zlibVersion(), "\n";
```

Arguments

As `function`, plus `as => $sub_name`: the Perl name to install, qualified with the calling package unless it contains `::`. Without it the C function's own name is used.

What you get back

A reference to the installed sub. Redefining the sub (another `attach` of the same name) releases the function it replaced.

errno

errno as the last C call through Peta::FFI left it.

Synopsis

```
my $fd = Peta::FFI::call($libc, "open", "(pi;u32)i", $path, 0x40,␣
↪0644);
if ($fd < 0) {
    local $! = Peta::FFI::errno();
    die "open $path: $!";
}
```

What you get back

An integer: the value errno had the moment the C function returned, read before Perl could change it. As in C, it means something only when the function reported a failure. Assigning it to `$!` gives its message.

handle_type

Declare a Perl class for a C object type, with its destructor.

Synopsis

```
Peta::FFI::handle_type("My::Schema", $lib, "schema_free");
my $compile = Peta::FFI::function($lib, "schema_compile", "(p)
 ↪<My::Schema>");

my $schema = $compile->($schema_json) or die "invalid schema";
...                                    # schema_free runs when
 ↪$schema goes
```

What it does

After this, a signature may name the type as `<My::Schema>`:

- **As a result**, the returned pointer becomes an object of class `My::Schema`; a NULL pointer becomes `undef`.
- **As an argument**, a `My::Schema` object passes its pointer, and `undef` passes NULL. Anything else - another class's handle, a plain number, a released handle - croaks rather than reaching C.
- When the last reference to an object goes, the destructor is called with its pointer, exactly once. No `DESTROY` method is involved, so the class is free for the program's own methods and subclasses.

`$destructor` is a function name in `$lib`, or an address. The library stays loaded for as long as the program runs, since objects may outlive every `dlclose`.

Edge cases

- **Declared again with the same destructor** - no effect.
- **Declared again with another destructor** - croaks.

release

Destroy a handle's C object now, ahead of its last reference.

Synopsis

```
Peta::FFI::release($schema);    # schema_free runs here
```

What you get back

True when the object was destroyed; false when `$handle` is no handle or was released already. A released handle stays an object of its class, and passing it to C croaks.

record

Declare a record class: a C struct, passed by value or by pointer.

Synopsis

```
Peta::FFI::record("My::Point", x => "d", y => "d");
Peta::FFI::record("My::Rect",  origin => "{My::Point}", size => "
 ↪{My::Point}");

my $p = My::Point->new(x => 1.5, y => -2);
print $p->x, "\n";                                  # 1.5
$p->y(4);                                           # set

# struct Point point_add(struct Point, struct Point);
my $sum = Peta::FFI::call($lib, "point_add", "({My::Point}
 ↪{My::Point}){My::Point}", $p, $p);
# void point_scale(struct Point *, double);
Peta::FFI::call($lib, "point_scale", "(*{My::Point}d)v", $p, 2);
```

Members

Each member is a name and its type, in the order of the C struct: the integer types, `f`, d, b, o, p (a `const char *`), a fixed array of numbers or o such as `u8[16]`, and another record by value, `{Class}`. The layout - each member's offset and the size and alignment of the whole - is the C compiler's for the platform, as libffi computes it.

The class

`Class->new(member => value, ...)` makes a zeroed record and sets the members given. Each member has an accessor: `$r->name` reads it, `$r->name($value)` sets it; an array member also takes `($index)`, `($index, $value)` and an array reference; a record member reads as a copy, an object of its class, and is set from one. A record is a reference to a string of the struct's bytes, so `$$r` is them and a record can be built from bytes C produced: `bless \$bytes, "My::Point"`.

A `p` member reads the string it points to, `undef` for `NULL`. Set from Perl, it points to the record's own copy of the string, which lives as long as the record does or until the member is set again; `undef` sets `NULL`. A string C stored in the member is C's: the record never frees it. Where C moves the strings between records - an array of them it sorts, written back - each goes with the record that points to it, and a record stored into another

as its member gives it copies of its own. A bare copy of the record's bytes points to the same strings but does not keep them.

In a signature `{Class}` passes and returns the struct by value and `*{Class}` a pointer to it - the record's own bytes, which the callee may change in place; `undef` is `NULL`.

Edge cases

- **A class declared twice** - croaks.
- **A member type a struct cannot hold here** (`s`, `P`, a handle, a pointer type, a long double or complex member) - croaks naming it.

union

Declare a union class: a C union, reached by pointer and in memory.

Synopsis

```
Peta::FFI::record("Keysym", scancode => "i32", sym => "i32", mod =>
 ↪"u16", unused => "u32");
Peta::FFI::record("KeyEvent", type => "u32", timestamp => "u32",␣
 ↪windowID => "u32",
                  state => "u8", repeat => "u8", pad => "u8[2]",␣
 ↪keysym => "{Keysym}");
Peta::FFI::union("Event", type => "u32", key => "{KeyEvent}",␣
 ↪padding => "u8[56]");

my $ev = Event->new;                          # SDL_Event
while (Peta::FFI::call($sdl, "SDL_PollEvent", "(*{Event})i", $ev)) {
    print $ev->key->keysym->sym, "\n" if $ev->type == 0x300;   #␣
 ↪SDL_KEYDOWN
}
```

As `record`, with every member at offset 0: the union is as large as its largest member, rounded to its strictest alignment. A member that is a record - in a union or a struct - reads as a copy, an object of its class, and is set from one.

A union passes by pointer, `*{Class}`, and is read and written whole by `fetch`, `store` and as a member of a record. Passing it by value

- as `{Class}`, or inside a struct passed by value - croaks: libffi has no union type, and a struct of the same size passes differently on some ABIs, which would be a wrong call rather than an error.

sizeof

The size of a type in bytes, as C's `sizeof`.

Synopsis

```
my $n = Peta::FFI::sizeof("{My::Point}");   # 16
my $buf = Peta::FFI::alloc(Peta::FFI::sizeof("u32[8]"));
```

Any one type of the signature language: a number type, o, p (a pointer), `T[N]`, `*T` and a record. `T[]` is 0.

symbol

The address of a symbol - a function or a variable - in a library.

Synopsis

```
my $environ = Peta::FFI::symbol($libc, "environ");   # char ***
my $first = Peta::FFI::peek_cstr(Peta::FFI::fetch(Peta::FFI::fetch(
 ↪$environ, "o"), "o"));
```

`$lib` is a dlopen handle, or `undef` for everything loaded. Croaks when the library has no such symbol.

fetch

Read the value of a type at an address.

Synopsis

```
my $n  = Peta::FFI::fetch($ptr, "i32");
my $xy = Peta::FFI::fetch($ptr, "d[2]");           # [1.5, -2]
my $pt = Peta::FFI::fetch($ptr, "{My::Point}");    # a My::Point␣
 ↪copy
```

What `call` would return for that type, read from the memory at `$addr`: the numbers, b, o (`0` for `NULL`), D as a float, `cf`/`cd` as `[re, im]`, p - the C string the `char *` there points to, `T[N]` as an array reference and `{Class}` as a record. Reading memory the process does not own is undefined behaviour.

store

Write a value of a type at an address.

Synopsis

```
Peta::FFI::store($ptr, "i32", 42);
Peta::FFI::store($ptr, "{My::Point}", My::Point->new(x => 1));
```

The numbers, b, o, D, `cf`/`cd` (`[re, im]`), `T[N]` from an array reference and `{Class}` from a record of that class. A string is not stored: memory C keeps would point into a Perl value that moves - `alloc` and poke its bytes, and store the address as o.

variable

A library's global variable as a Perl scalar.

Synopsis

```
my $optind = Peta::FFI::variable($libc, "optind", "i");
print $$optind, "\n";        # reads the C variable
$$optind = 1;                # writes it
```

A reference to a scalar bound to the variable: reading `$$var` reads the C variable at that moment, assigning to it writes the variable, for any type `store` can write; a `p` variable is read-only. The library stays loaded while the scalar lives. Croaks when the library has no such symbol.

dlclose

Release a library handle previously returned by `dlopen`.

Synopsis

```
Peta::FFI::dlclose($lib);
```

What you get back

Always 1. The return value exists so the call composes cleanly in expressions; inspecting it tells you nothing about success.

Edge cases

- **No argument** - croaks with `Peta::FFI::dlclose: requires library handle`.
- **Zero or null handle** - silently ignored. Passing `0` is safe and commonly used as an "already closed" sentinel.
- **Double close** - passing a handle that has already been released is undefined behaviour at the `dlclose` level; keep a single owner per handle or null out your copy after closing.
- **Outstanding calls** - closing a library while a pointer or string it returned is still in use is undefined behaviour. Copy everything you need out of the library first.

scan

Find the shared libraries in a list of directories.

Synopsis

```
my $libs = Peta::FFI::scan;
print $libs->{"libm.so.6"}, "\n";          # /usr/lib/libm.so.6
my @names = grep { /^libssl/ } keys %$libs;

my $ours = Peta::FFI::scan("/opt/PetaTech/lib");
my $core = Peta::FFI::dlopen($ours->{"libpeta_core.so"});
```

What you get back

A hashref mapping each library's file name to its path: every `lib*.so` and `lib*.so.*` file in the directories searched that this process can load - an ELF file of its own architecture. A linker script (`/usr/lib/libc.so` is one), a 32-bit library on a 64-bit system and any other file are left out. A name found in more than one directory maps to the first one's file.

Where it looks

- **`scan(@dirs)`** - those directories, in that order, and no others.
- **`scan()`** - the directories in `PETA_FFI_PATH` (colon-separated, like `PATH`), then where the dynamic linker looks for a bare name: `LD_LIBRARY_PATH`, the directories `/etc/ld.so.conf` configures and the system's own (`/lib`, `/usr/lib` and their 64-bit forms).

The search happens only here. `dlopen` with a bare name asks the dynamic linker, which never reads `PETA_FFI_PATH`; a library installed in a directory of its own is found by `scan` and opened by the path it returns.

Edge cases

- **A directory that does not exist or cannot be read** - skipped.
- **One directory reached twice** (`/lib64` is often a link to `/usr/lib`) - searched once. A library in a system directory is reported under the directory's real path; one in a directory you named, under the name you gave.

peek

Read `$len` raw bytes at address `$ptr` into a Perl byte string.

Synopsis

```
my $bytes = Peta::FFI::peek($ptr, 16);
```

What you get back

A byte string of exactly `$len` bytes copied from `$ptr`; `undef` when `$ptr` is `0`/`undef`. `$len` of `0` returns the empty string.

Edge cases

- **Fewer than 2 arguments** - croaks.
- **Address or length wrong** - reading memory the process does not own is undefined behaviour; the length must come from the same C API that produced the pointer (e.g. `PQgetlength`).

peek_cstr

Read the NUL-terminated C string at address `$ptr`.

Synopsis

```
my $str = Peta::FFI::peek_cstr($ptr);
```

What you get back

The bytes at `$ptr` up to (excluding) the first NUL; `undef` when `$ptr` is `0`/`undef`. This is the reader for `o`-typed returns that point at C strings (`PQgetvalue`, `mysql_error`, ...).

poke

Copy a Perl byte string into memory at address `$ptr`.

Synopsis

```
my $buf = Peta::FFI::alloc(8);
Peta::FFI::poke($buf, pack("l", 42));
```

What you get back

The number of bytes written (the string's byte length).

Edge cases

- **Fewer than 2 arguments or NULL pointer** - croaks; poking through NULL is never meaningful.
- **Buffer too small** - writing past an allocation is undefined behaviour; the destination must be at least as large as the string, which the caller controls via `alloc`.

alloc

Allocate `$len` zeroed bytes of C memory; returns the address.

Synopsis

```
my $out = Peta::FFI::alloc(8);       # e.g. a sqlite3** out-param
↪cell
Peta::FFI::call($lib, "sqlite3_open", "(po)i", ":memory:", $out);
my $db = Peta::FFI::unpack_ptr(Peta::FFI::peek($out, 8));
Peta::FFI::free($out);
```

What you get back

The address of a zeroed `calloc` block, as an integer for `o` arguments. The caller owns it: every `alloc` needs a matching `free`. A `$len` of `0` still returns a valid 1-byte allocation.

free

Release memory obtained from `alloc`.

Synopsis

```
Peta::FFI::free($ptr);
```

What you get back

Always 1.

Edge cases

- **Zero or undef pointer** - silently ignored, like `free(NULL)`.
- **Double free / foreign pointers** - undefined behaviour; only pass addresses obtained from `alloc`, exactly once. Memory a C library allocated is released by that library's own function (`PQclear`, `mysql_free_result`, ...), never by `free`.

pack_ptr

Pack an address into a native pointer-sized byte string.

Synopsis

```
# Build a char*[] for PQexecParams-style APIs:
my $vec = join "", map { Peta::FFI::pack_ptr($_) } @addrs;
```

What you get back

The address as native-endian bytes, sized to the platform pointer width - the in-memory representation a C pointer slot holds.

unpack_ptr

Unpack a native pointer-sized byte string into an address.

Synopsis

```
my $db = Peta::FFI::unpack_ptr(Peta::FFI::peek($out, 8));
```

What you get back

The address stored in the string's first pointer-sized bytes, as an integer for o arguments. Croaks when the string is shorter than the platform pointer width.

Peta::ReadLine

Interactive line editing, command history, and configurable key bindings, with the Term::ReadLine::Gnu interface.

Install a readline instance, hand it a prompt, and you get the usual bash-style editing: cursor motion, word-wise kill and yank, incremental history search, filename completion, and an inputrc-controlled key map. The module has Term::ReadLine::Gnu's whole surface - nearly one hundred entry points expose readline's C-level interface directly, organised here by the same section names the GNU Readline manual uses - and `Term::ReadLine::Gnu` is this module under its old name.

A typical script calls `new` to obtain the readline object, then `readline` in a loop with `add_history` after each accepted line. Scripts that customise behaviour reach for `rl_parse_and_bind` and `rl_variable_bind` for inputrc-style configuration, or install completion by binding `rl_completion_entry_function` via the `Attribs` tied hash.

```
use Term::ReadLine;

my $term = Term::ReadLine->new('demo', \*STDIN, \*STDOUT);
print $term->ReadLine, "\n";                    # Term::ReadLine::Gnu
$term->add_history($_) for 'ls -l', 'make test', 'git status';
my @h = $term->GetHistory;
print scalar(@h), " in history, last '$h[-1]'\n";   # 3 in history,␣
↪last 'git status'

my $attribs = $term->Attribs;                   # readline's␣
↪variables, as a hash
$attribs->{completion_entry_function} = $attribs->{list_completion_
↪function};
$attribs->{completion_word} = [qw(alpha beta gamma)];   # Tab␣
↪completes these
```

(continues on next page)

(continued from previous page)

```
my $line = $term->readline('> ');              # one line, with␣
↪editing and history
```

Programs normally `use Term::ReadLine`, which picks `Term::ReadLine::Gnu` when it is available, as it is here, and gets this module; a program that names `Term::ReadLine::Gnu` gets it under that name, and `ReadLine` answers with the name it was asked by. The library behind the interface is pperl's own line editor, built in: no readline or curses library is loaded, and the terminal is described from the terminfo database. It behaves as GNU Readline 8.3 does - the same commands, key bindings, init file, history and completion, and the same screen after every key - and says what it is: `$attribs->{library_version}` is `8.3 (Peta::ReadLine 0.2.0)`, the interface level first, where programs look for a number, and `$attribs->{gnu_readline_p}` is 0.

A few methods are Perl in `ReadLine/XS.pm` over private XSUBs, and so are not among the entries below: `$term->rl_message($fmt, @args)` shows `sprintf($fmt, @args)` in place of the prompt until `rl_clear_message`; `$term->rl_discard_keymap($map)` frees the bindings of a keymap (by name or handle) and returns it, still usable; `$term->get_history_event($string, $cindex [, $qchar])` expands the history event at `$cindex` and returns `($text, $cindex)`, the index where scanning stopped, so a string of several `!`-events can be walked one at a time.

This is a native implementation of the XS half of Term::ReadLine::Gnu 1.47; `ReadLine.pm` and `ReadLine/XS.pm` are its `Gnu.pm` and `Gnu/XS.pm` under this module's name.

Differences from upstream

The module is `Peta::ReadLine`; `Term::ReadLine::Gnu` is an alias of it, so a program written for Term::ReadLine::Gnu runs unchanged and sees that name, while `Peta::ReadLine->new` reports `Peta::ReadLine`.

Modules

- `Peta::ReadLine::XS`

Peta::ReadLine::XS

Functions

Parse and configuration

`rl_get_function_name`

Return the name under which a readline command function is registered, or `undef` if it has none.

rl_get_all_function_names

Return the name of every readline command currently known, including any added with `rl_add_defun`.

rl_parse_and_bind

Apply a single line of inputrc syntax (`"\\C-x\\C-r": re-read-init-file`, `set editing-mode vi`, ...).

rl_read_init_file

Load and apply an inputrc file. Defaults to `$ENV{INPUTRC}` or `~/.inputrc`.

rl_variable_bind

Set inputrc variable `$name` to the string `$value` (e.g. `completion-ignore-case`, `On`).

rl_variable_value

Return the current value of inputrc variable `$variable` as a string, or `undef` if it is unknown.

rl_variable_dumper

Print every inputrc variable and its current value to `rl_outstream`. Pass truthy `$readable` for inputrc syntax.

rl_function_dumper

Print every named readline command and the keys bound to it. Pass truthy `$readable` for inputrc-style output.

rl_macro_dumper

Print every key macro bound in the current keymap. Pass truthy `$readable` for inputrc-style output.

rl_get_termcap

Look up the termcap capability named `$cap` and return its string value, or `undef` if not defined.

Input

rl_clear_timeout

Cancel any timeout previously set with `rl_set_timeout`, so reads wait indefinitely again.

rl_timeout_remaining

Report how much of the timeout set by `rl_set_timeout` is still left.

rl_read_key

Block until one key is available on `rl_instream` and return its byte value.

rl_getc

Read one byte from `$stream` (defaulting to `rl_instream`), bypassing readline's macro and timeout logic.

rl_stuff_char

Inject one byte onto readline's pending-input queue, as if the user had just pressed it.

rl_execute_next

Arrange for the next call to `rl_read_key` to return `$c` without doing any terminal I/O.

rl_clear_pending_input

Discard any input queued with `rl_stuff_char` or `rl_execute_next`.

rl_set_keyboard_input_timeout

Set the multi-byte escape-sequence timeout in microseconds. Returns the previous value.

Terminal

tgetstr

Return the terminal's escape sequence for termcap capability `$id`, or `undef` if it has none.

rl_prep_terminal

Put the terminal into raw mode for line editing. Pass a truthy `$meta_flag` to enable 8-bit input.

rl_deprep_terminal

Undo `rl_prep_terminal` and restore the terminal to cooked mode.

rl_reset_terminal

Re-query termcap for `$terminal_name` (default `$ENV{TERM}`), refreshing readline's idea of the terminal.

rl_set_screen_size

Override readline's idea of the window size with `$rows` and `$cols`.

rl_get_screen_size

Return the terminal size readline is currently assuming as `($rows, $cols)`.

rl_resize_terminal

Re-read the terminal size from the OS - typically called from a `SIGWINCH` handler.

rl_reset_screen_size

Force readline to re-query `TIOCGWINSZ` and reset `screenheight`/`screenwidth` from scratch.

Line editing

rl_completion_matches

Build the list of completions for `$text` by calling a generator repeatedly. Returns the matches.

rl_insert_text

Insert `$text` into the line buffer at point, advancing the cursor past the inserted characters.

rl_delete_text

Delete the characters of the current line in the half-open range `[$start, $end)`. Returns the number removed.

rl_copy_text

Return a copy of the line buffer in the half-open range `[$start, $end)` without modifying the buffer.

rl_kill_text

Delete text in `[$start, $end)` and push it onto the kill ring so it becomes yankable with `C-y`.

rl_replace_line

Replace the entire line buffer with `$text`. Passing a truthy `$clear_undo` also drops the undo list.

rl_push_macro_input

Queue `$macro` as pending input so readline re-reads it character-by-character on the next key request.

Display

rl_display_match_list

Display an array reference of completion matches in columns, the way readline lists them itself.

rl_redisplay

Repaint the current line from readline's in-memory buffer. Call this after you edit the buffer programmatically.

rl_forced_update_display

Force a full repaint even if readline thinks nothing changed. Useful after background output corrupts the screen.

rl_on_new_line

Tell readline that the cursor is now on a fresh line, so the next redisplay reprints the prompt.

rl_on_new_line_with_prompt

Like `rl_on_new_line`, but asserts the prompt is already physically on screen - skip the reprint.

rl_reset_line_state

Reset the display state so the next `rl_redisplay` assumes a clean line (no partial output pending).

rl_clear_message

Remove the status message installed by `rl_message` and restore the original prompt.

`rl_crlf`

Emit a newline (CRLF) on the output stream, moving readline's cursor tracking with it.

`rl_ding`

Ring the terminal bell (or flash, depending on the `bell-style` inputrc setting).

`rl_show_char`

Display character `$c` using readline's usual control-character rendering (e.g. `^A` for byte 1).

`rl_save_prompt`

Save the current prompt and line state so it can be restored after a temporary message or sub-prompt.

`rl_restore_prompt`

Restore the prompt and line state previously stashed by `rl_save_prompt`.

`rl_set_prompt`

Change the prompt to `$prompt` for the next redisplay. Accepts `\[...\]` escapes to mark invisible regions.

`rl_expand_prompt`

Parse a prompt string for invisible-character escapes and return its visible length.

Basic readline

`rl_readline`

Display a prompt, read one line with full editing, and return the entered string (or `undef` on EOF).

`rl_initialize`

Initialise (or re-initialise) readline's internal state and re-read the inputrc. Returns `0` on success.

History

`add_history`

Append `$line` to the end of the history list so it shows up in later Up-arrow recalls and searches.

clear_history

Delete every entry from the in-memory history list.

using_history

Reset the history offset pointer back to the end of the list so `previous_history` starts from the newest entry.

where_history

Return the current offset into the history list (the index a subsequent `current_history` would read).

history_set_pos

Move the history cursor to `$pos`. Returns `1` on success, `0` if the position is out of range.

current_history

Return the line at the current history cursor, or `undef` if the cursor is past the end.

history_get

Return the history line at absolute `$offset`, or `undef` if no such entry exists.

previous_history

Move the history cursor one step back and return that entry, or `undef` if already at the oldest line.

next_history

Move the history cursor one step forward and return that entry, or `undef` if already past the newest line.

remove_history

Delete the history entry at `$which` and return its text.

replace_history_entry

Replace the history entry at `$which` with `$line` and return the previous text, or `undef` if out of range.

stifle_history

Cap the history list at `$max` entries, or lift the cap when `$max` is `undef`. Returns the effective cap.

unstifle_history

Remove any stifling cap on the history list and return the previous cap (or a negative value if none was set).

history_is_stifled

Return non-zero if the history list is currently stifled (length-capped), zero otherwise.

history_total_bytes

Return the total number of bytes occupied by all history lines in memory.

read_history_range

Load lines from a history file into memory. Reads the whole file by default, or lines `$from..$to` when given.

write_history

Write every entry in the current history list to `$filename`, overwriting the file. Returns `0` on success.

append_history

Append the last `$nelements` entries of the in-memory history to `$filename`, preserving existing contents.

history_truncate_file

Truncate `$filename` to at most `$nlines` of history, keeping the newest lines. Returns `0` on success.

history_expand

Apply csh-style history expansion (`!!`, `!$`, `^old^new^`) to `$line`. Returns `(code, expanded)`.

Synopsis

```
my ($code, $expanded) = $term->history_expand($input);
# $code: 0 no change, 1 expanded, -1 error, 2 print-only
```

history_search

Search the history for an entry that contains `$string`, moving the cursor to the match. Returns the match offset or `-1`.

history_search_prefix

Same as `history_search`, but matches only when the history entry *starts* with `$string`.

history_search_pos

Search the history starting at absolute `$pos` (default: current cursor). Returns match offset or `-1`.

history_tokenize

Split `$text` into tokens the way Bash history expansion does (word-splitting, quote awareness). Returns a list.

Character classification

rl_alphabetic

Return non-zero if byte `$c` is a word-constituent character under readline's locale-aware rules.

Undo

rl_begin_undo_group

Open a new undo group so a sequence of edits collapses into one user-visible undo step.

rl_end_undo_group

Close the undo group opened by `rl_begin_undo_group`.

rl_do_undo

Perform one undo step. Returns `0` when no further undo is available.

rl_free_undo_list

Drop the entire undo history for the current line.

rl_modifying

Record the range `[$start, $end)` of the line buffer on the undo stack before you modify it by hand.

Signal handling

`rl_cleanup_after_signal`

Restore the terminal to cooked mode and reset signal handlers - call this from your own signal handler.

`rl_free_line_state`

Free the partially-edited line buffer so a signal-handling exit leaves readline in a clean state.

`rl_reset_after_signal`

Re-prepare the terminal and reinstall readline's signal handlers after a `SIGCONT` or similar resumption.

`rl_check_signals`

Give readline a chance to run any deferred signal handlers.

`rl_echo_signal_char`

Echo the tty-configured character for signal `$sig` (e.g. `^C` for `SIGINT`).

`rl_pending_signal`

Return the number of a signal readline has observed but not yet dispatched, or `0` if none is pending.

`rl_set_signals`

Install readline's default signal handlers (for `SIGINT`, `SIGTERM`, `SIGQUIT`, `SIGWINCH`, `SIGHUP`, ...).

`rl_clear_signals`

Remove the signal handlers installed by `rl_set_signals`.

State save and restore

`rl_save_state`

Snapshot readline's internal state and return an opaque handle you can later pass to `rl_restore_state`.

rl_restore_state

Reinstall the state previously captured by `rl_save_state`.

rl_completion_matches

Build the list of completions for `$text` by calling a generator repeatedly. Returns the matches.

The generator is called as `$fn->($text, $state)`, with `$state` zero on the first call and non-zero on every call after it, and returns one match each time or `undef` once it is exhausted. Omitting `$fn` uses whatever `$attribs{completion_entry_function}` currently holds.

A generator passed here is in force for the duration of this call only: whatever completion function `$attribs` held is put back afterwards, so a one-off generator cannot disturb it.

rl_readline

Display a prompt, read one line with full editing, and return the entered string (or `undef` on EOF).

Synopsis

```
while (defined (my $line = $term->readline('prompt> '))) {
    $term->addhistory($line) if $line =~ /\S/;
    last if $line eq 'quit';
}
```

The call blocks until the user presses Return. A bare Ctrl-D on an empty line returns `undef`. The returned string has its trailing newline already stripped, matching the underlying `readline(3)` C function. The prompt argument is optional; pass `undef` for none.

add_history

Append `$line` to the end of the history list so it shows up in later Up-arrow recalls and searches.

Synopsis

```
$term->add_history($line) if $line =~ /\S/;
```

Readline does not deduplicate for you. Wrap the call in an `if` if you want to skip blank or repeated lines. Use `write_history` to persist the collected lines to disk.

read_history_range

Load lines from a history file into memory. Reads the whole file by default, or lines `$from..$to` when given.

Synopsis

```
$term->ReadHistory;                          # default file, full
↪range
$term->ReadHistory('~/.myhist', 100, -1);  # last hundred-odd lines
```

Passing `undef` for `$filename` reads from `~/.history`. `$to = -1` means "to the end". Returns `0` on success, a non-zero errno on failure.

rl_parse_and_bind

Apply a single line of inputrc syntax (`"\\C-x\\C-r": re-read-init-file`, `set editing-mode vi`, ...).

Synopsis

```
$term->parse_and_bind('set editing-mode vi');
$term->parse_and_bind('"\\C-l": clear-screen');
```

This is the programmatic door into the same grammar that `~/.inputrc` uses. Returns `0` on a successful parse.

Peta::Shell

ipps, the interactive mode of pperl

SYNOPSIS

```
$ pperl --shell
ipps> my @list = (1, 2, 3)
(1, 2, 3)
ipps> push @list, 4; scalar @list
4
ipps> for my $n (@list) {
 ...>     print $n * 2, " ";
 ...> }
2 4 6 8
ipps> ^D
```

From Perl:

```
use Peta::Shell;
exit Peta::Shell->run(@ARGV);
```

DESCRIPTION

ipps reads Perl, runs it, and prints the value of the last statement. Everything a line declares is still there for the next line: `my` variables, subs, loaded modules, pragmas, the current package. See *Peta::Shell::Session* for exactly what carries over and how.

At the prompt

- A line whose last statement ends in `;` prints nothing. Without the `;` its value is printed as *Peta::Shell::Printer* shows it: a number bare, a string in quotes, a list in parentheses, a reference as its structure, nothing for an empty list. A loop or a conditional typed by itself prints nothing either, and neither does a last statement that is a `print`, `printf` or `say`: its value is only whether the output succeeded.
- When what your code printed does not end in a newline, the prompt starts on the next line and a `%` in reverse video marks where the output stopped.
- The value last printed is in `$ans`, and all of them, when there were several, in `@ans`:

```
ipps> 6 * 7
42
ipps> $ans + 1
43
```

- Input that is not finished (an open bracket, an open quote, a here-document without its end) gets a second prompt, `...>`, until it is. Blank lines inside it are kept, so pasted code works.
- Tab completes the word in front of the cursor: a variable of the session, a key of one of its hashes, a method of an object or class, a sub, a module after `use`, a file name inside a string, a command. With several candidates it completes as far as they agree, and a second Tab lists them. *Peta::Shell::Complete* says exactly what is offered where. When none of that fits, Tab completes a file name.
- Ctrl-C at a prompt drops the input typed so far. Ctrl-C while a line runs stops that line; the session goes on.
- Ctrl-D on an empty prompt ends the session, and so does `exit`.
- An error is printed and the session goes on with everything it had.

Commands

A line that starts with a colon and a word is a command of ipps, not Perl. A command may be shortened while it stays unique: `:q`, `:v`.

- :help

  The list of commands, yours and the macros included.

- :vars

  The variables of the session: name, kind and value, shortened.

```
ipps> my @list = (1, 2, 3); my $name = "ada";
ipps> :vars
```

(continues on next page)

(continued from previous page)

```
@ans   array of 0  ()
$ans   undef       undef
@list  array of 3  (1, 2, 3)
$name  string      'ada'
```

- :scalar EXPR

  The value of EXPR in scalar context; a line is otherwise evaluated in list context. `:scalar @list` is the number of elements. The word `scalar` is put in front and nothing more, so `:scalar 1, 2` is the list `scalar(1), 2`, as in Perl.

- :dump EXPR

  The value whole: every element, every level, every character, whatever the settings say and whether or not the line ends in `;`.

- :time LINE

  Runs the line and then shows the wall-clock and the processor time it took, compiling included.

- :jit LINE

  Runs the line and then shows what the JIT did while it ran: how many loops it compiled to machine code, how many loops the line brought that it had not seen before, and compiled of seen for everything since ipps started, its own code included.

```
ipps> :jit my $t = 0; for my $i (1 .. 300_000) { $t += $i } $t
45000150000
jit: 1 loop compiled, 1 new loop seen (1 of 68 since the start)
```

  A loop is compiled once it has run often enough, and that may be in a later line than the one that wrote it: the loop of a sub is seen where the sub is defined and compiled where a call makes it hot. The counts say that a loop was compiled, not why another was not.

- :source SUB

  The code of a sub, by name or by an expression that gives a code reference, as *B::Deparse* writes it.

- :which MODULE

  The file pperl loads the module from, or `built into pperl`, and whether it is loaded. A file name works too: `:which ExtUtils/typemap`.

- :install MODULE ...

  Installs modules from CPAN with pperl's own client, as `pperl --cpan` does. They can be used at once.

- **programs,**
  programs NAME ...

  Makes each NAME a sub of `main` that runs the program of that name, as the `autorun` setting does for every unknown sub; see "Programs as functions". A sub so declared needs no parentheses. Without names it lists them.

- :load FILE

  Runs a file in the session: what it declares is there afterwards. The value of its last statement is not shown.

- :save FILE

  Writes every line that ran without an error, in order, as a script. Commands are not written, the lines they ran are.

- **set,**
  set NAME, :set NAME VALUE

  Shows all settings, shows one, changes one:

```
max_items   elements shown of an array or hash (24); 0: all
max_depth   levels shown of a nested structure (6); 0: all
max_string  characters shown of a string (240); 0: all
width       columns for a printed value; 0: the terminal's
time        on: show the times of every line
prompt      the prompt; quotes keep a space: :set prompt "> "
prompt2     the prompt for unfinished input
shell       what "! command" runs the command with
autorun     on: an unknown sub of main runs the program of its name
```

  To keep a setting, put it in `rc.pl`: see “set”.

- **history,**
  history N

  The last 20, or N, lines entered. On a terminal these include earlier sessions.

- :reset

  Starts the session afresh: no `my` variables, the first pragmas, the package `main`, no macros, and `rc.pl` run again. Subs and package variables are not the session's and stay.

- :quit

  Leaves, as Ctrl-D does.

`::name(...)` is Perl, a call into `main`, and stays Perl.

Commands of your shell

A line that starts with `!` and a space is handed to your shell as it stands and runs on the terminal:

```
ipps> ! ls -l *.pl
ipps> ! git status
```

Nothing of such a line is Perl, and its output is not kept. An exit status other than 0 is reported. To have a command's output in a variable, use Perl's backticks, which is Perl and works as always:

```
ipps> my @files = `ls *.pl`
```

The space matters: `!$done` and `!defined $x` are Perl's negation.

The command runs under `$SHELL -c`, or `/bin/sh -c` without `$SHELL`. Such a shell does not read the start file of an interactive one, so its aliases are unknown to it. The `shell` setting changes that; for bash's aliases:

```
ipps> :set shell bash -ic
```

Programs as functions

With `:set autorun on`, a call of a sub that `main` does not have runs the program of that name instead. The arguments are joined with spaces into a command line for `/bin/sh`; the result is the program's output, a list of lines in list context and one string otherwise. Its errors reach the terminal and its exit status is in `$?`:

```
ipps> :set autorun on
ipps> whoami()
"rj\n"
ipps> my @lines = uname('-a');
```

Perl's rules for calling a sub still decide what parses. Without parentheses a name must be declared, which `:programs` does: `:programs ls` and then `ls '-l'`. Each argument is Perl, a quoted string: `ls -l` is `ls(-l $_)`, a file test. The shell still expands `*` in them. Real shell syntax is what `! command` is for.

A program that cannot be run is an error, and so a typing error in the name of a sub is reported differently: `pritn("x")` says `Can't exec "pritn": No such file or directory`.

autorun is `main`'s `AUTOLOAD`, so it cannot be switched on while `main` has an `AUTOLOAD` of your own, and switching it off leaves yours alone. It works in package `main` only.

Macros and commands of your own

`rc.pl` is the place for them:

```
Peta::Shell->macro(p => 'print');
Peta::Shell->command(pwd => sub { require Cwd; print Cwd::getcwd(),
 ↪"\n" });
```

After that `p "hello\n"` at the prompt runs `print "hello\n"`, and `:pwd` prints the directory. See "macro" and "command".

Without a terminal

When standard input is not a terminal, ipps reads it line by line without prompt or editing and prints values and errors the same way:

```
$ echo 'my $x = 6; $x * 7' | pperl --shell
42
```

Files

Both live under `$PPERL_HOME/ipps`, by default `~/.pperl/ipps`.

- rc.pl

  Perl run in the session before the first prompt. What it declares is there at the prompt. Not read with `--norc`.

- history

  The lines typed at the prompt, read at start and written at the end.

OPTIONS

- –norc

  Do not run `rc.pl`.

METHODS

run

```
my $status = Peta::Shell->run(@arguments);
```

Runs a session to its end and returns the exit status: 0, or 2 for arguments it does not understand.

new

```
my $shell = Peta::Shell->new(%options);
```

Options: `rc` (run `rc.pl`, default true), `home` (the directory of `rc.pl` and `history`), `in`, `out`, `err` (file handles, default the standard three), `prompt` and `prompt2`.

loop

Reads and evaluates until the input ends. Returns the exit status.

session

The *Peta::Shell::Session* of this shell.

current

```
my $shell = Peta::Shell->current;
```

The shell that is running, or undef. This is how rc.pl and the lines typed at the prompt reach it.

macro

```
Peta::Shell->macro(p  => 'print');
Peta::Shell->macro(ls => sub { my ($rest) = @_; "print map { \"\$_\\
↪n\" } glob('$rest*')" });
```

Defines a macro: a word that, typed as the first word of a line and followed by a space or the end of the line, is replaced before the line is compiled. A string replaces the word and the rest of the line stays; a code reference gets the rest of the line and returns the Perl to run instead. undef removes the macro. Called on the class, it means the running shell.

command

```
Peta::Shell->command(pwd => sub { my ($shell, $rest) = @_; require␣
↪Cwd; print Cwd::getcwd(), "\n" });
```

Defines a command of your own, typed as :pwd. It gets the shell and the rest of the line. undef removes it. The names of the built-in commands are taken.

set

```
Peta::Shell->set(max_items => 100);
```

Changes a setting, as :set does at the prompt.

Modules

- Peta::Shell::Complete - what Tab offers in ipps
- Peta::Shell::Printer - show a Perl value as bounded, readable text
- Peta::Shell::Session - evaluate Perl line by line and keep the state

Peta::Shell::Complete

what Tab offers in ipps

SYNOPSIS

```
use Peta::Shell::Complete;
```

(continues on next page)

(continued from previous page)

```
my $complete = Peta::Shell::Complete->new(session => $session);

my ($from, @words) = $complete->complete('my $n = $cou', 12);
# $from is 8, @words is ('$count', '$country'):
# each word replaces the line's text from offset 8 to the cursor
```

DESCRIPTION

Given a line and the position of the cursor in it, this module says what the word in front of the cursor can become. It looks only at what exists: the variables of a *Peta::Shell::Session*, the packages and subs of the interpreter, the modules on the search path, the files on disk. It runs no code of the line, so it cannot complete through the result of a call.

What is offered depends on what stands in front of the cursor:

- `$na`, `@na`, `%na`

  The variables of the session and of the current package. After `$` an array is offered as `$name[` and a hash as `$name{`; after `@` a hash is offered as `@name{`, the slice. `$Some::Package::na` offers the variables of that package.

- `$hash{ke`, `$ref->{ke`, `$data{list}[0]{ke`

  The keys of that hash, with the closing brace. Only keys that can be written without quotes are offered.

- `$object->me`, `Class->me`

  The methods of the object's or the named class, inherited ones included. Those that start with an underscore are offered only after an underscore.

- `use Mo`, `no Mo`, `require Mo`

  The modules that are built into pperl or on the search path, one level at a time: `File::Te` offers `File::Temp`, and a namespace that has modules below it as `File::Spec::`.

- `"dir/fi` (inside a string)

  The files of that directory. A directory gets its `/`.

- `! command fi`

  The files of that directory, for the last word of a line that is handed to the shell.

- `na` (a plain word)

  The subs of the current package, Perl's functions and keywords, the loaded packages, and at the start of a line the macros. `Some::Package::na` offers the subs and packages below it.

- `:co`

  The commands of ipps, and after some of them what they take: a setting after `:set`, a file after `:load` and `:save`, a module after `:which` and `:install`, a sub after `:source`.

METHODS

new

```
my $complete = Peta::Shell::Complete->new(%options);
```

Options:

- session

  The *Peta::Shell::Session* whose variables and current package are offered. Without one, only what does not need it is offered, in the package `main`.

- commands

  A code reference that returns the names of the commands, without the colon.

- command

  A code reference that gets a command as typed, maybe shortened, and returns its full name or nothing.

- settings

  A code reference that returns the names of the settings.

- macros

  A code reference that returns the names of the macros.

complete

```
my ($from, @words) = $complete->complete($line, $cursor);
```

Returns the offset in `$line` from which the text up to `$cursor` is replaced, and the words it can be replaced with, sorted, each once. Returns the empty list when there is nothing to offer. `$cursor` defaults to the end of the line.

Peta::Shell::Printer

show a Perl value as bounded, readable text

SYNOPSIS

```
use Peta::Shell::Printer;

my $printer = Peta::Shell::Printer->new(width => 72);

print $printer->format(42), "\n";                  # 42
print $printer->format('$5 each'), "\n";           # '$5 each'
print $printer->format("a\tb"), "\n";              # "a\tb"
print $printer->format(1, 2, 3), "\n";             # (1, 2, 3)
print $printer->format({ b => [1, 2], a => undef }), "\n";
                                                   # { a => undef, b
 ↪=> [1, 2] }
```

DESCRIPTION

`format` turns values into text.

- A number is shown bare, a string quoted, `undef` as `undef`, a boolean as `true` or `false`. Whether a scalar is a number or a string is what it was created as: `42` and `'42'` look different. A float is shown with as many digits as it takes to read it back as the same number: `0.1 + 0.2` is `0.30000000000000004`.
- A string is quoted so that it needs as few escapes as it allows; what is shown is Perl that evaluates to the string.

```
text                 'text'
$x and @y            '$x and @y'
say "hi"             'say "hi"'
it's "quoted"        q{it's "quoted"}
C:\dir\file          'C:\dir\file'
a tab inside         "a\tb"
a tab and a "        qq{a\t"b"}
```

  When nothing in it has to be written as an escape sequence it is in a literal form, where `$`, `@` and `"` are characters like any other: `'...'`, or `q{...}` when it has a single quote, with the first of `{}`, `()`, `[]`, `<>` that does not occur in it. When it has a character that cannot be shown as itself it is in an interpolating form, `"..."` or `qq{...}` by the same choice. Shown as a number, never as themselves, are control characters, the bytes above 127 of a byte string, and in a character string whatever has no shape of its own or changes how its neighbours are laid out: a zero-width space, a direction override, a no-break space.
- An array is `[1, 2, 3]`, a hash `{ key => value }` with its keys sorted. Both stay on one line when they fit the width and are laid out one element per line when they do not.
- An object is its class in front of its contents, `Point { x => 1 }`, or its class and its string when it overloads stringification: `URI("http://example.com/")`.
- A code reference is `\&main::name` when the sub has a name and `sub { ... }` when it has none. A compiled pattern is `qr/.../`, a glob `\*main::STDOUT`, a reference to a scalar `\"text"`.
- Several values are a list in parentheses. No value at all is the empty string.

Everything is bounded: a container shows its first `max_items` elements and says how many more there are, nesting stops at `max_depth`, a string is cut at `max_string` characters with its full length noted. A structure that contains itself is shown once and marked where it repeats.

METHODS

new

```
my $printer = Peta::Shell::Printer->new(%options);
```

- width

  Columns available; a container that fits is printed on one line. Default 80.

- max_items

  Elements of one array or hash to show. Default 24. 0 means all.

- max_depth

  Levels of nesting to show. Default 6. 0 means all.

- max_string

  Characters of one string to show. Default 240. 0 means all.

- indent

  Spaces per level in the multi-line layout. Default 2.

format

```
my $text = $printer->format(@values);
```

The values as text, without a trailing newline.

Peta::Shell::Session

evaluate Perl line by line and keep the state

SYNOPSIS

```
use Peta::Shell::Session;

my $session = Peta::Shell::Session->new;

my $r = $session->eval('my @list = (1, 2, 3); scalar @list');
print "$r->{status}: @{ $r->{values} }\n";      # ok: 3

$r = $session->eval('push @list, 4; "@list"');  # @list is still
↪there
print "@{ $r->{values} }\n";                    # 1 2 3 4

$r = $session->eval('for my $i (@list) {');
print $r->{status}, "\n";                       # incomplete
```

DESCRIPTION

A session evaluates pieces of Perl one after another as if they were consecutive lines of one program. What a line leaves behind is there for every later line:

- its `my`, `state` and `our` variables, when declared at the line's top level;
- its pragmas: `use strict`, `use warnings`, `use feature`, `use v5.36` and any other lexical pragma;
- the current package;
- subs, packages and loaded modules, as in any program.

A variable declared inside a block of the line (`for my $i (...)`, `if (...) { my $t }`) belongs to that block and is gone with it, as in a program.

Each line is compiled once and run at once. A line that does not compile changes nothing. A line that dies keeps what it had declared and assigned before it died.

How a `my` variable survives

The variable itself is kept, not a copy: after the line that declares it, later lines reach it under its name as a package variable of a hidden package, bound with `our` when the line is compiled. So a closure and a named sub see every later assignment, `\$x` is the same reference in every line, and a second `my $x` in a later line makes a new variable while subs compiled before keep the old one.

Two things follow from "package variable". `local $x` works on it in a later line, which a true lexical refuses. And the name is resolved when a line is compiled, so text compiled later at run time (a string `eval`) sees the variable, but a symbolic reference by its plain name does not.

METHODS

new

```
my $session = Peta::Shell::Session->new(%options);
```

Options:

- name

  The name lines are reported under. Line 12 of a session named `ipps` is the file `(ipps:12)` in messages. Default `ipps`.

- package

  The package the first line is compiled in. Default `main`.

- preamble

  Perl evaluated before the first line; it sets the pragmas the session starts with and is not counted as a line. Default `use strict qw(refs subs); use warnings;`. Pass an empty string for none.

Dies if the preamble does not compile or dies.

eval

```
my $result = $session->eval($text);
```

Passes `$text` through the preprocessors, compiles it and runs it in list context. `$text` may hold several lines. Returns a hash reference:

- status

  ok, `error`, `incomplete` or `empty`.

`incomplete` means the text ends inside a construct: an open bracket, a string or here-document without its end, an expression that expects more. Nothing was run. The caller reads more input and calls `eval` again with the whole text.

`empty` means there was nothing but blank space, before or after the preprocessors.

- values

  Array reference: what the last statement returned, in list context. Empty unless the status is `ok`.

- error

  For `error`: the exception, as it was thrown (a string or an object).

- phase

  For `error`: `preprocess`, `compile` or `run`.

- warnings

  Array reference of the warnings the line raised, compiling or running, unless a line has installed its own `$SIG{__WARN__}`, which then gets them.

- line

  The line number this text got. Only `ok` and `error` texts are numbered.

- text

  The text after the preprocessors.

- wall, cpu

  Seconds of wall-clock and of processor time, compiling and running.

variables

```
my @names = $session->variables;
```

The names of the session's variables with their sigils, sorted.

variable

```
my $ref = $session->variable('@list');
```

A reference to the variable itself, or `undef` when the session has none of that name.

bind

```
$session->bind('$ans', \$value);
```

Makes the referenced variable the session's variable of that name, as if a line had declared it. The name is a sigil ($, @ or %) and an identifier; the reference must be of the matching kind.

package

The package the next line is compiled in.

line

The number of the last numbered line; 0 before the first.

name

The session's name.

add_preprocessor

```
$session->add_preprocessor(sub { my ($text, $session) = @_; ...;
↪$text });
```

Appends a preprocessor. Before a text is compiled it passes through the preprocessors in the order they were added; each gets the text and the session and returns the text to go on with. Returning an empty string ends the line there (status `empty`). An exception makes the line an `error` of phase `preprocess`.

This is where macros, aliases and commands of the shell live: they turn what was typed into Perl.

remove_preprocessor

```
$session->remove_preprocessor($code);
```

Removes that preprocessor. Returns true if it was there.

preprocessors

The list of preprocessors, in order.

LIMITS

- Text that turns out to be incomplete has still been compiled as far as it went, so a `use` or `BEGIN` block in it has already run and runs again when the completed text is compiled.
- `local` at a line's top level lasts to the end of that line.
- The match variables (`$1`, `$&`) are scoped to the line.
- A lexical sub (`my sub name`) is not kept.

Peta::WebGPU

`Peta::WebGPU` - compute and draw on the graphics card.

WebGPU is the modern successor to OpenGL: a portable API that reaches Vulkan, Metal and Direct3D 12 underneath, so the same program runs on whichever of those the machine has. `Peta::WebGPU` is pperl's binding to it, built on the wgpu implementation.

```
use Peta::WebGPU;

my $gpu = Peta::WebGPU::Device->new;
printf "%s on %s\n", $gpu->info->{name}, $gpu->info->{backend};

my $shader = $gpu->shader(<<'WGSL');
@group(0) @binding(0) var<storage, read_write> data: array<u32>;
@compute @workgroup_size(1)
fn main(@builtin(global_invocation_id) id: vec3<u32>) {
    data[id.x] = data[id.x] * 2u;
}
WGSL

my $buf = $gpu->storage_buffer(pack 'L*', 1 .. 8);
$gpu->compute($shader, 'main', [$buf], 8);
print join(',', unpack 'L*', $buf->read), "\n";   # 2,4,6,8,10,12,
 ↪14,16
```

This build may not have it

The GPU backend is large, so it is a build option that is off by default. `Peta::WebGPU::have_gpu()` answers whether this pperl has it AND found a usable adapter, without dying, so a program can fall back to doing the work on the CPU:

```
if (Peta::WebGPU::have_gpu()) { ... } else { ... }
```

A pperl built without the option tells you so when you load the module, and names the flag to rebuild with.

Shaders are WGSL

The programs that run on the card are written in WGSL, WebGPU's own shading language - not GLSL. `$gpu->shader($source)` compiles one, and a syntax error in it raises a Perl exception with the compiler's message rather than killing the program.

Errors

Everything here reports failure as an exception, carrying the GPU driver's own text, so `eval` is how you trap one. A call that succeeds and has nothing else to give back returns the object it was called on, so `or die` behaves and calls chain:

```
$gpu->compute($shader, 'main', [$buf], 8)->poll;
```

fork

A device, and every buffer, shader, pipeline, surface and texture made from it, belongs to the process that created it. `fork` copies the objects but not the graphics driver's threads, so in the child they cannot be used: any method on one dies with

```
this Peta::WebGPU::Device was created before fork; open a
↪Peta::WebGPU::Device in the child process
```

The child may leave them alone and exit, or open a device of its own and work on that; the parent's objects are unaffected either way. One limit: where the parent has opened the `gl` backend (the default `all` includes it), the child's device comes from the other backends only, and asking for `backend => 'gl'` there fails - OpenGL's display connection is shared with the parent and cannot be opened twice. A worker pool is best served by opening its device inside each worker:

```
my $pid = fork // die "fork: $!";
if (!$pid) {
    my $gpu = Peta::WebGPU::Device->new;    # this process's own
    ...
    exit 0;
}
```

Once a process has asked for an adapter or opened a device, a child forked from it ends, after Perl's own `END` blocks and destructors, without running the exit handlers of the C libraries loaded before the graphics drivers: the drivers' own handlers wait for threads the child does not have. Buffered output is flushed first.

Peta::WebGPU::Device

Opening a device is the first thing any GPU program does. It picks an adapter, opens it, and gives you the one object everything else hangs off:

```
my $gpu = Peta::WebGPU::Device->new;                          # let it
↪choose
my $gpu = Peta::WebGPU::Device->new(power => 'high-performance');
my $gpu = Peta::WebGPU::Device->new(backend => 'vulkan');
```

`power` is `high-performance` (prefer the discrete card) or `low-power` (prefer the integrated one, which saves battery and is often quicker to start). `backend` restricts the choice to one of `vulkan`, `metal`, `dx12`, `gl` or `all`. Opening fails with an exception if the machine has no usable adapter.

On `gl`, what the device can do depends on the OpenGL context the driver hands out. Drawing always works. Compute shaders need OpenGL 4.3 or OpenGL ES 3.1; on an older context (the NVIDIA driver gives 3.3) `compute` and `pipeline` die saying so, and `vulkan` is the backend to use.

- `$gpu->info` - a hash reference describing the adapter actually opened: `name`, `backend`, `device_type`, `driver`, `vendor`, `device`.
- `$gpu->limits` - what this device can do: `max_buffer_size`, `max_compute_workgroups_per_dimension` and the other ceilings you have to stay under.

These are the real hardware limits, not a portable minimum, so a program that runs on one machine can still ask for more than another machine offers.

- `$gpu->shader($wgsl)` - compile a shader.
- `$gpu->storage_buffer($data_or_size)` - a buffer a shader can read and write, and that you can read back.
- `$gpu->uniform_buffer($data_or_size)` - a small read-only buffer of parameters.
- `$gpu->pipeline($shader, $entry)` - prepare a shader entry point to run. Worth keeping when you dispatch the same shader repeatedly.
- `$gpu->compute($shader, $entry, \@buffers, $x, $y, $z)` - build the pipeline, bind and dispatch in one call.
- `$gpu->run($pipeline, \@buffers, $x, $y, $z)` - dispatch a pipeline you already have.
- `$gpu->run($binding, $x, $y, $z)` - dispatch a pipeline whose buffers are already bound (`$pipeline->bind`, below).
- `$gpu->begin`, `$gpu->commit` and `$gpu->batch(sub { ... })` - send several dispatches to the card at once; see "Many dispatches".
- `$gpu->features` - the optional features this device has, as a list of names: `shader-f16` (a shader may say `enable f16;`) and `timestamp-query`. A device has each one its adapter offers. `$gpu->has_feature($name)` is the yes or no for one of them.
- `$gpu->poll` - wait for everything submitted so far to finish.
- `$gpu->memory` - `{ allocated => ..., reserved => ... }`: the bytes this device's buffers and textures occupy, and the bytes it holds from the driver to put them in. `undef` on a backend that keeps no such account (Vulkan and DirectX 12 do).

`Device->new(memory_limit => 90)` makes the device refuse a buffer that would take it past 90 percent of the memory the driver allows this process. The refusal is an `Out of Memory` exception from `storage_buffer`, which a program can catch; without the option the driver decides, and may take the device with it.

The buffers are bound in the order given, as `@binding(0)`, `@binding(1)` and so on within `@group(0)`.

Many dispatches

Each `run` on its own is a round trip to the driver, and binding a list of buffers is work of its own. A program that dispatches the same few shaders over and over - a simulation step, a training step - saves both:

```
my $step = $pipeline->bind([$state, $params]);   # once

$gpu->batch(sub {                                # every step
    $gpu->run($step, $groups);
    $params->write(pack 'f', $rate);
```

(continues on next page)

(continued from previous page)

```
    $gpu->run($step, $groups);
});
```

`$pipeline->bind(\@buffers)` returns a `Peta::WebGPU::Binding`: the pipeline with those buffers bound, which keeps the buffers alive and can be run any number of times.

`$gpu->batch($code)` records every `run` the sub makes and sends them to the card together when it returns. `$gpu->begin` and `$gpu->commit` are the same without a sub. Inside a batch:

- a mistake in a `run` is reported when the batch is sent, by `commit` or `batch`, not by the `run` itself; for a wrong buffer list the message says which run of the batch it was;
- `$buf->write` takes effect in order: dispatches before it see the old contents, dispatches after it the new;
- `$buf->read` sends what is recorded so far, reads, and the batch goes on;
- a sub that dies leaves nothing sent, and its exception reaches the caller of `batch`.

Batches do not nest.

`$gpu->timed($code)` is `batch` with a stopwatch on the card: it returns the nanoseconds the card spent on the batch's dispatches, which is what a shader costs, without the time the program spent getting it there. It waits for the card to finish, and dies on a device without `timestamp-query`.

```
my $ns = $gpu->timed(sub { $gpu->run($step, $groups) });
printf "%.2f ms on the card\n", $ns / 1e6;
```

`Peta::WebGPU::Buffer`

- `$buf->size` - in bytes.
- `$buf->read` - the contents, as a byte string. Unpack it exactly as the shader's type says: `L*` for `array<u32>`, `l*` for `array<i32>`, `f*` for `array<f32>`.
- `$buf->read($offset, $length)` - a part of the contents, both in bytes and both multiples of four; without `$length`, from `$offset` to the end. Reading the one number you need costs the card far less than reading the buffer it is in.
- `$buf->write($bytes, $offset)` - replace part of it. A PDL ndarray of type `float`, `long` or `ulong` in place of `$bytes` is written as it is, so a large buffer can be filled piece by piece.
- `$buf->destroy` - give the buffer's memory back to the card now. A buffer is freed when its last reference goes, but a binding made with it is such a reference; `destroy` does not wait for those. The buffer cannot be used afterwards, and a binding that has it dies when run.

A buffer's size is always rounded up to a multiple of four bytes, because that is the granularity the GPU copies at. Pack `L`, `l` or `f` and it never comes up; pack an odd number of bytes and `size` will be a little larger than what you passed, with the extra bytes zero. A `write` must be aligned the same way.

Reading is not free: it waits for the card to finish and copies the data back across the bus, so read once at the end rather than inside a loop.

Workgroups, not elements

`compute` and `run` take the number of WORKGROUPS to launch, not the number of data elements. A shader declaring `@workgroup_size(64)` processes 64 elements per workgroup, so 1000 elements needs `int(($n + 63) / 64)` workgroups - and the shader must check its own index against the array length, because the last workgroup runs past the end:

```
my $wgsl = <<'WGSL';
@group(0) @binding(0) var<storage, read_write> v: array<f32>;
@compute @workgroup_size(64)
fn scale(@builtin(global_invocation_id) id: vec3<u32>) {
    if (id.x >= arrayLength(&v)) { return; }
    v[id.x] = v[id.x] * 2.0;
}
WGSL
my $buf = $gpu->storage_buffer(pack 'f*', @data);
$gpu->compute($gpu->shader($wgsl), 'scale', [$buf], int((@data + 63)
 ↪/ 64));
```

Drawing

The other half of a graphics card. A program that draws does the same three things every frame: get somewhere to draw, record what to draw there, and hand it over.

```
use SDL2 qw(:all);
use Peta::WebGPU;

my $win  = SDL2::Window->new(title => 'triangle', w => 800, h =>
 ↪600);
my $gpu  = Peta::WebGPU::Device->new(window => $win);
my $surf = $gpu->surface;

my $pipe = $gpu->render_pipeline($gpu->shader($WGSL),
    vertex => 'vs', fragment => 'fs', format => $surf->format,
    vertex_buffers => [ { attributes => ['float32x2', 'float32x3'] }
 ↪],
);
my $verts = $gpu->vertex_buffer(pack 'f*', @triangle);

while (running()) {
    my $frame = $surf->next_frame or next;
    $gpu->render_pass($frame, clear => [0.1, 0.2, 0.3, 1])
        ->pipeline($pipe)->vertices($verts)->draw(3)->end;
    $frame->present;
}
```

Every recording call returns the pass, so a frame reads as one sentence. `end` is what

hands the work to the card; nothing is drawn before it.

Drawing without a window

A render pass does not care whether its target is on screen. Give it a texture instead of a frame and the picture comes back as bytes:

```
my $gpu = Peta::WebGPU::Device->new;           # no window at all
my $img = $gpu->texture(width => 800, height => 600);
$gpu->render_pass($img, clear => [0, 0, 0, 1])
    ->pipeline($pipe)->vertices($verts)->draw(3)->end;
my $rgba = $img->read;                          # 800*600*4 bytes
```

This needs no display, no window manager and no compositor, so it is how a program renders on a server - and how this module's own tests check what was drawn, pixel by pixel.

What a window has to be

`Peta::WebGPU` opens no windows. It asks a window object two questions, and anything that answers them can be drawn on:

- `$win->wm_info` - a hash reference with `driver` (`x11` or `wayland`), `display`, and `window` or `surface`.
- `$win->size` - the list `($width, $height)`.

`SDL2::Window` answers both, which is where a window normally comes from here. A window system this build cannot make a surface on is refused by name rather than failing later.

The window belongs at `Device->new`, not at `surface`, because the adapter has to be one that can actually present to that window - a machine with two cards can otherwise open the one that does not drive the screen.

`Peta::WebGPU::Surface`

`$gpu->surface` - the window's swap chain, configured and ready. `$gpu->surface($other_window)` gives a second window its own.

- `$surf->format` - the pixel format the compositor wants, as a WebGPU name such as `bgra8unorm-srgb`. Pass it to `render_pipeline` so the two agree; they must.
- `$surf->size` - the list `($width, $height)`.
- `$surf->configure($width, $height)` - after the window was resized.
- `$surf->next_frame` - the image to draw this frame into, or **undef** when the window is hidden or the compositor is busy. That is not an error: skip the frame and come back.

`present_mode` chooses how frames reach the screen: `fifo` waits for the display and never tears (the safe default), `immediate` does not wait, `mailbox` keeps only the newest. A mode the window does not offer is refused, with the ones it does offer in the message.

A swap chain lives on the window system's connection. `SDL_Quit`, and `SDL_QuitSubSystem` for video, close that connection, so they take the swap chains of every surface first, with the frames not yet presented. The objects remain: `size` and `format` still answer, while `configure`, `next_frame`, `present` and a render pass on such a frame die saying that the window system was shut down. The device is not affected and goes on working off screen. A window object that is not SDL2's has to outlive its surfaces by itself.

`Peta::WebGPU::Frame`

One image out of the swap chain. It is a render target exactly as a texture is, and `$frame->present` puts it on the screen. A frame that goes out of scope unpresented is discarded, which is the right thing for a frame abandoned half-drawn. Presenting twice is refused.

End the pass before presenting: end is what submits the drawing.

`Peta::WebGPU::Texture`

`$gpu->texture(width => .., height => .., format => ..)` - somewhere to draw that is not the screen. The format defaults to `rgba8unorm`, the same default `render_pipeline` has, so the two agree unless you say otherwise.

- `$tex->size` - the list `($width, $height)`.
- `$tex->format` - its format, by name.
- `$tex->read` - the pixels, tightly packed, top row first. Four bytes per pixel for the 8-bit-per-channel formats, so `unpack 'C*'` gives R, G, B, A in that order.

Reading waits for the card and copies the image back across the bus, exactly as reading a buffer does. It belongs at the end, not in a loop.

`$gpu->depth_buffer($width, $height)` makes the other kind of target: a depth texture, which is what stops a far triangle painting over a near one. Pass it to `render_pass` as `depth => $d` and build the pipeline with `depth => 1`; both halves are needed, and wgpu says so if only one is there.

Render pipelines

`$gpu->render_pipeline($shader, %options)` compiles one shader's vertex and fragment entry points into everything the card needs to draw. It is worth keeping: build it once, use it every frame.

- `vertex` / `fragment` - the entry point names in the WGSL. With one of each in the shader they can be left out.
- `format` - the format of what is being drawn into. Default `rgba8unorm`; for a window it must be `$surf->format`.
- `vertex_buffers` - the shape of the vertex data; see below.
- `topology` - `triangle-list` (the default), `triangle-strip`, `line-list`, `line-strip` or `point-list`.

- `cull` - none (the default), `back` or `front`, and `front_face` (`ccw`, the default, or `cw`), which decide which side of a triangle is its front and whether the other one is drawn at all.
- `depth => 1` - take part in depth testing.
- `blend => 1` - blend with what is already there, by alpha.

Describing the vertices

Each entry of `vertex_buffers` describes one buffer, as a list of `attributes`. The short form is a list of format names, which are laid end to end at `@location(0)`, `@location(1)` and so on:

```
vertex_buffers => [ { attributes => ['float32x3', 'float32x3'] } ],
```

That is the layout of a WGSL function taking consecutive locations, which is what almost every shader has. Anything left out is computed: offsets follow each other, locations count up, and the stride is where the last attribute ends. A hash gives the long form for the cases that need it:

```
vertex_buffers => [ {
    stride     => 32,
    attributes => [ { format => 'float32x3', location => 0, offset
↪=> 0 },
                    { format => 'float32x2', location => 5, offset
↪=> 20 } ],
} ],
```

Formats are WebGPU's own names - `float32`, `float32x2`, `float32x3`, `float32x4`, and the `uint32`, `sint32`, `unorm8x4` and `float16x2` families. A name that is not one of them is refused with the whole list, because a typo here otherwise shows up as geometry that is nearly right.

`Peta::WebGPU::Pass`

`$gpu->render_pass($target, %options)` starts recording. The target is a `Frame` or a `Texture`.

- `clear => [$r, $g, $b, $a]` - the colour to start from, each component 0 to 1. `clear => 0` keeps what is already there, which is how a second pass draws on top of the first. Left out altogether, it clears to black.
- `depth => $depth_texture` - test against depth while drawing.

Then, in order:

- `$pass->pipeline($pipeline)` - what to draw with. First, always: the bind groups take their layout from it.
- `$pass->bind(\@buffers, [$group])` - the uniform and storage buffers of `@group(0)`, in binding order, exactly as `compute` takes them.
- `$pass->vertices($buffer, [$slot])` - the vertex data.

- `$pass->indices($buffer, ['uint16'|'uint32'])` - the index data. 32-bit by default, because a mesh with more than 65536 vertices is ordinary.
- `$pass->draw($vertex_count, [$instances])` or `$pass->draw_indexed($index_count, [$instances])`.
- `$pass->end` - stop recording and hand the work to the card.

Every one of them returns the pass, so they chain. A pass that is dropped without end throws its recording away rather than submitting half a frame.

`$gpu->vertex_buffer($data)` and `$gpu->index_buffer($data)` make the buffers, and take the same arguments `storage_buffer` does - a byte string, a size, or a PDL ndarray of a 32-bit type.

Functions

Availability

have_gpu

True when this pperl can actually reach a graphics card: the build has the GPU option AND an adapter was found.

Adapters

adapters

Every graphics adapter this machine offers, as a list of hash references.

have_gpu

True when this pperl can actually reach a graphics card: the build has the GPU option AND an adapter was found.

It answers rather than dying, so a program can choose a CPU fallback:

```
my $sum = Peta::WebGPU::have_gpu() ? gpu_sum(@data) : cpu_
↪sum(@data);
```

A machine with no GPU driver at all, or a headless container, will say false here even on a build that has the option compiled in.

adapters

Every graphics adapter this machine offers, as a list of hash references.

Each carries `name`, `backend` (`"Vulkan"`, `"Metal"`, `"Dx12"`, `"Gl"`), `device_type` (`"DiscreteGpu"`, `"IntegratedGpu"`, `"Cpu"`, `"Other"`) and `driver`. A machine commonly has more than one - an integrated chip and a discrete card, or the same card through two different backends:

```
for my $a (Peta::WebGPU::adapters()) {
    printf "%-14s %-14s %s\n", $a->{backend}, $a->{device_type}, $a-
↪>{name};
}
```

Which one `Peta::WebGPU::Device->new` picks is decided by its `power` option, not by this list; the list is for reporting and for deciding whether the machine has the card you need.

Peta::XS

Peta::XS - the interpreter's capability layer for pure Perl.

Unlike pperl's other native modules, this is not a CPAN module reimplemented: it is pperl's own versioned, semantic API that lets third-party pure Perl do what internals-XS modules do on perl5.

```
use Peta::XS qw(:facts :magic);

my $x = 1;
print "refcount ", refcount(\$x), "\n";          # 2: $x, and the␣
↪reference passed
my $reads = 0;
my $w = wizard(
    get  => sub { $reads++ },
    set  => sub { my ($ref, $data) = @_; $data->{sets}++ },
    data => sub { return { sets => 0 } },
);
cast(\$x, $w);                                   # attach the hooks␣
↪to $x
my $y = $x + $x;                                 # two reads
$x = 5;                                          # one write
print "reads $reads, sets ", getdata(\$x, $w)->{sets}, "\n";   #␣
↪reads 2, sets 1
print join(",", map { $_->{type} } magic(\$x)), "\n";          # ~
dispell(\$x, $w);                                # detach
```

Capabilities are imported by tag: `:facts` (`refcount`, `value_slots`, `magic`) and `:magic` (`wizard`, `cast`, `dispell`, `getdata`). `use Peta::XS;` alone imports nothing.

CONTRACT (v1.0)

Capabilities: `facts`, `magic`. Evolution is additive within a major version; a capability is never silently redefined.

1. Facts and verbs, never layout. Every exposed datum is defined by observable semantics (never flag bits, offsets, addresses or struct names) and survives any internal refactor.
2. Opaque handles. Anything referring to an interpreter entity (a wizard, a magic attachment) is a runtime-owned opaque value - no arithmetic, no raw pointers as IVs.

3. The boundary speaks Perl. Callbacks are coderefs; data crosses as ordinary Perl values. Consumers are pure Perl and cannot be binary-broken by any pperl release. The loudest possible failure is a compile-time version/capability refusal in `import`.

A variable carrying Peta::XS magic is never JIT-compiled, so its callbacks fire on every access, exactly as the interpreter would fire them. Callbacks run with exactly the timing of perl's tied variables.

Functions

Other Functions

`refcount`

Reference count of the thing `$ref` points at.

`value_slots`

Which value representations the runtime currently considers valid for the scalar `$ref` points at.

`magic`

Inventory of the magic attached to the variable `$ref` points at.

`wizard`

Create a wizard: an opaque bundle of magic callbacks.

`cast`

Attach a wizard to the variable `$ref` points at.

`dispell`

Detach a wizard from the variable `$ref` points at.

`getdata`

Retrieve the private data this wizard's attachment carries.

`refcount`

Reference count of the thing `$ref` points at.

Synopsis

```
use Peta::XS ':facts';
my $x;
my $n = refcount(\$x);   # 2 - see the observer effect below
```

What you get back

An integer: how many references the runtime currently holds to the referent, at call time. Works on any referent - scalars, arrays, hashes, subs, aggregate elements. Croaks if the argument is not a reference; never dies otherwise.

Observer effect

The reference you pass in contributes one count of its own for the duration of the call, exactly as with `Devel::Refcount::refcount`. It is deliberately NOT subtracted: a lexical with no other references reports 2 (its pad slot plus your temporary reference).

Examples

```
my $x = 42;
say refcount(\$x);        # 2: pad slot + the \$x you just made

my $r = \$x;
say refcount($r);         # 2: pad slot + $r (no extra temporary)
my $r2 = \$x;
say refcount($r);         # 3: pad slot + $r + $r2

my @queue = ($r);
say refcount($r);         # 4: the array element counts too

# leak hunting: a cache entry still pinning an object
my $obj = SomeClass->new;
$cache{key} = $obj;
say refcount(\$obj);      # 3 - the cache holds one; forget it and
delete $cache{key};       # the count drops back to 2
```

See also

- `value_slots` - which representations the value holds.
- `magic` - what is attached to the variable.
- `Scalar::Util::refaddr` / `builtin::refaddr` - identity, not count.

value_slots

Which value representations the runtime currently considers valid for the scalar `$ref` points at.

Synopsis

```
use Peta::XS ':facts';
my @slots = value_slots(\42);      # ('int')
my @slots = value_slots(\3.14);    # ('num')
my @slots = value_slots(\'hi');    # ('str')
```

(continues on next page)

(continued from previous page)

```
my @slots = value_slots(\\1);      # ('ref')
my @slots = value_slots(\undef);   # ()
```

What you get back

In list context, a subset of `qw(int num str ref)` - the representations the runtime currently considers valid for this value. In scalar context, how many of them there are. A scalar can hold several at once: after a numeric string is used in numeric context it carries both its string and its numeric form, and a `Scalar::Util::dualvar` carries `int` and `str` by construction.

Contract

This is an observation of optimization state, not of meaning: the same program may legitimately report different slot sets across runtimes and versions. Branch on it for diagnostics and teaching, never for program semantics.

Examples

```
# watch a scalar accumulate representations
my $port = '8080';
say "@{[ value_slots(\$port) ]}";   # str
my $next = $port + 1;               # numeric use caches the number
say "@{[ value_slots(\$port) ]}";   # int str

# dualvars hold two truths at once ($! is the classic case)
use Scalar::Util qw(dualvar);
my $dv = dualvar(5, 'five');
say "@{[ value_slots(\$dv) ]}";     # int str

# a classroom one-liner: show why "10" == 10 costs a conversion
# only the first time
```

See also

- `refcount` - how many references point here.
- `magic` - what is attached to the variable.

magic

Inventory of the magic attached to the variable `$ref` points at.

Synopsis

```
use Peta::XS ':facts';
tie my %h, 'Some::Tie';
```

(continues on next page)

(continued from previous page)

```
for my $m (magic(\%h)) {
    printf "type=%s get=%d set=%d\n", $m->{type}, $m->{get}, $m->
↪{set};
}
```

What you get back

One hashref per attachment, in chain order (most recently attached first, mirroring perl's prepend discipline): `type` is perl's public one-character magic type (the `perlguts` vocabulary - 'P' tied array/hash, 'q' tied scalar, '~' extension magic as used by `cast`), `get`/`set` are booleans saying whether the attachment hooks reads/writes. In scalar context: the number of attachments. An unmagical variable yields an empty list / 0.

Examples

```
my $plain = 1;
say scalar magic(\$plain);          # 0

# is this hash really tied?
tie my %cfg, 'Config::Tied';
my ($m) = magic(\%cfg);
say "tied!" if $m && $m->{type} eq 'P';

# see your own wizards (and their hook shape) from the outside
use Peta::XS ':magic';
my $w = wizard(get => sub { });
my $x = 1;
cast(\$x, $w);
my @mg = magic(\$x);                # ({ type => '~', get => 1, set␣
↪=> 1 })

# debugging aid: why is every read of $slow slow?
printf "%s(get=%d,set=%d)\n", @{$_}{qw(type get set)}
    for magic(\$slow);
```

See also

- `cast` / `dispell` - attach and detach '~' magic.
- `refcount`, `value_slots` - the other facts.
- `perldoc perlguts` - the magic type vocabulary.

wizard

Create a wizard: an opaque bundle of magic callbacks.

Synopsis

```
use Peta::XS ':magic';
my $w = wizard(
    get  => sub { my ($ref, $data) = @_; ... },
    set  => sub { my ($ref, $data) = @_; ... },
    free => sub { my ($ref, $data) = @_; ... },
    data => sub { my ($ref, @args) = @_; return { count => 0 } },
);
```

What you get back

An opaque handle. Hold it, pass it to `cast`, `dispell` and `getdata` - nothing else. One wizard can be cast on any number of variables; each attachment gets its own private data.

Contract

All keys are optional but at least one of `get`/`set`/`free` is required; every value must be a code reference (anything else croaks, as does an unknown key). `get` is called before the variable's value is used, `set` after it changed, `free` while it is being destroyed; each receives `(\$var, $data)` and its return value is ignored (no value substitution in v1). `data` is called once per `cast` to build that attachment's private data. A callback that dies propagates exactly like a dying tied-variable FETCH/STORE. A variable carrying wizard magic is never JIT-compiled, so callbacks fire on every single access, compiled neighbors notwithstanding.

Examples

```
# a watchpoint: who is touching $config?
my $watch = wizard(
    get => sub { warn "read at @{[ join ':', caller ]}\n" },
    set => sub { warn "now: ${$_[0]}\n" },
);

# lazy initialization: get may write the variable before the
# pending read uses it (magic is suspended inside callbacks, so
# this does not recurse)
my $lazy = wizard(get => sub { ${$_[0]} //= expensive() });
my $val;
cast(\$val, $lazy);
say $val;                # expensive() runs here, exactly once
say $val;                # cached now

# per-attachment counters via a data callback
my $counted = wizard(
    data => sub { { reads => 0, writes => 0 } },
    get  => sub { $_[1]{reads}++ },
    set  => sub { $_[1]{writes}++ },
);
```

See also

- `cast` - attach the wizard to a variable.
- `getdata` - read an attachment's private data back.
- `magic` - the facts-side view of an attachment.

cast

Attach a wizard to the variable `$ref` points at.

Synopsis

```
use Peta::XS ':magic';
my $x;
cast(\$x, $w);              # true
cast(\$x, $w);              # false - same wizard twice is a no-op
cast(\$x, $other, 1, 2);    # @args reach $other's data callback
```

What you get back

True when the wizard was attached, false when this wizard was already on the variable (casting twice is a no-op and calls no callbacks). The cast itself fires nothing - the first `get`/`set` comes from the first read/write after it.

Contract

If the wizard has a `data` callback it is called once, here, as `$data_cb->(\$referent, @args)`, and its return value becomes the attachment's private data (see `getdata`). Multiple distinct wizards may be cast on one variable; they fire most recently cast first. Read-only variables can be cast (attaching magic does not write the value - writes still croak before `set` would fire). The attachment lives exactly as long as the variable or until `dispell`ed.

Examples

```
# any scalar works, including aggregate elements
my @row = (1, 2, 3);
cast(\$row[1], $watch);     # watch one array element
my %cfg = (mode => 'dev');
cast(\$cfg{mode}, $watch);  # watch one hash value

# cast args parameterize the attachment via the data callback
my $tagged = wizard(
    data => sub { my ($ref, $tag) = @_; $tag },
    set  => sub { warn "[$_[1]] changed\n" },
);
cast(\my $a, $tagged, 'alpha');
cast(\my $b, $tagged, 'beta');
```

(continues on next page)

(continued from previous page)

```
$a = 1;                     # warns "[alpha] changed"
$b = 2;                     # warns "[beta] changed"
```

See also

- `wizard` - build the handle and its callbacks.
- `dispell` - the inverse operation.
- `getdata` - fetch what the data callback returned.

dispell

Detach a wizard from the variable `$ref` points at.

Synopsis

```
use Peta::XS ':magic';
dispell(\$x, $w);   # true if $w was attached, false otherwise
```

What you get back

True if this wizard's attachment was found and removed, false if it was not attached. Idempotent: a second dispell of the same wizard returns false and changes nothing.

Contract

Removes exactly this wizard's attachment - other wizards on the same variable stay, and so does unrelated magic (a tie, for example). The attachment's private data is released. The `free` callback does NOT run: dispelling is detachment, not destruction; `free` fires only when the variable itself dies.

Examples

```
# scoped watching: attach, observe, detach
cast(\$config, $watch);
run_suspicious_code();
dispell(\$config, $watch);   # $config is an ordinary scalar again

# wizards detach independently
cast(\$x, $w1);
cast(\$x, $w2);
dispell(\$x, $w1);           # $w2 keeps firing
say scalar magic(\$x);       # 1
```

See also

- `cast` - the inverse operation.
- `magic` - check what is (still) attached.

getdata

Retrieve the private data this wizard's attachment carries.

Synopsis

```
use Peta::XS ':magic';
my $data = getdata(\$x, $w);   # whatever $w's data callback
 ↪returned
```

What you get back

The attachment's private data - the value the wizard's `data` callback returned at `cast` time - or undef when this wizard has no attachment on the variable or the wizard has no `data` callback. It is the same value the `get`/`set`/`free` callbacks receive as their second argument: if it is a reference, mutations made inside callbacks are visible here.

Examples

```
# per-variable access statistics, read back after the fact
my $counted = wizard(
    data => sub { { reads => 0, writes => 0 } },
    get  => sub { $_[1]{reads}++ },
    set  => sub { $_[1]{writes}++ },
);
my $x = 1;
cast(\$x, $counted);
my $v = $x; $v = $x;          # two reads
$x = 2;                       # one write
my $stats = getdata(\$x, $counted);
say "$stats->{reads}/$stats->{writes}";   # 2/1

# distinguishing "no attachment" from "no data"
say defined getdata(\$x, $counted) ? 'attached' : 'not here';
```

See also

- `cast` - where the data callback runs.
- `wizard` - declaring the data callback.

5.2.84 Pod

Namespace containing the following modules:

- `Pod::Checker` - check pod documents for syntax errors
- `Pod::Escapes` - for resolving Pod E<...> sequences
- `Pod::Functions` - Group Perl's functions a la perlfunc.pod
- `Pod::Html` - module to convert pod files to HTML
- `Pod::Man` - Convert POD data to formatted *roff input
- `Pod::ParseLink` - Parse an L<> formatting code in POD text
- `Pod::Perldoc` - Look up Perl documentation in Pod format.
- `Pod::Simple` - framework for parsing Pod
- `Pod::Text` - Convert POD data to formatted text
- `Pod::Usage` - extracts POD documentation and shows usage information

Pod::Checker

check pod documents for syntax errors

SYNOPSIS

```
use Pod::Checker;

$syntax_okay = podchecker($filepath, $outputpath, %options);

my $checker = Pod::Checker->new(%options);
$checker->parse_from_file($filepath, \*STDERR);
```

OPTIONS/ARGUMENTS

`$filepath` is the input POD to read and `$outputpath` is where to write POD syntax error messages. Either argument may be a scalar indicating a file-path, or else a reference to an open filehandle. If unspecified, the input-file it defaults to `\*STDIN`, and the output-file defaults to `\*STDERR`.

podchecker()

This function can take a hash of options:

- **-warnings** => *val*

  Turn warnings on/off. *val* is usually 1 for on, but higher values trigger additional warnings. See "Warnings".

- **-quiet** => *val*

  If `val` is true, do not print any errors/warnings.

DESCRIPTION

podchecker will perform syntax checking of Perl5 POD format documentation.

Curious/ambitious users are welcome to propose additional features they wish to see in **Pod::Checker** and **podchecker** and verify that the checks are consistent with perlpod.

The following checks are currently performed:

- Unknown '=xxxx' commands, unknown 'X<...>' interior-sequences, and unterminated interior sequences.
- Check for proper balancing of `=begin` and `=end`. The contents of such a block are generally ignored, i.e. no syntax checks are performed.
- Check for proper nesting and balancing of `=over`, `=item` and `=back`.
- Check for same nested interior-sequences (e.g. `L<...L<...>...>`).
- Check for malformed or non-existing entities `E<...>`.
- Check for correct syntax of hyperlinks `L<...>`. See perlpod for details.
- Check for unresolved document-internal links. This check may also reveal misspelled links that seem to be internal links but should be links to something else.

DIAGNOSTICS

Errors

- empty =headn

  A heading (`=head1` or `=head2`) without any text? That ain't no heading!

- =over on line *N* without closing =back
- You forgot a '=back' before '=head_N_'
- =over is the last thing in the document?!

  The `=over` command does not have a corresponding `=back` before the next heading (`=head1` or `=head2`) or the end of the file.

- '=item' outside of any '=over'
- =back without =over

  An `=item` or `=back` command has been found outside a `=over`/`=back` block.

- Can't have a 0 in =over *N*

  You need to indent a strictly positive number of spaces, not 0.

- =over should be: '=over' or '=over positive_number'

  Either have an argumentless =over, or have its argument a strictly positive number.

- =begin *TARGET* without matching =end *TARGET*

  A `=begin` command was found that has no matching =end command.

- =begin without a target?

  A `=begin` command was found that is not followed by the formatter specification.

- =end *TARGET* without matching =begin.

  A standalone =end command was found.

- '=end' without a target?

  '=end' directives need to have a target, just like =begin directives.

- '=end *TARGET*' is invalid.

  TARGET needs to be one word

- =end *CONTENT* doesn't match =begin *TARGET*

  CONTENT needs to match =begin's *TARGET*.

- =for without a target?

  There is no specification of the formatter after the `=for` command.

- unresolved internal link *NAME*

  The given link to *NAME* does not have a matching node in the current POD. This also happened when a single word node name is not enclosed in `""`.

- Unknown directive: *CMD*

  An invalid POD command has been found. Valid are `=head1`, `=head2`, `=head3`, `=head4`, `=over`, `=item`, `=back`, `=begin`, `=end`, `=for`, `=pod`, `=cut`

- Deleting unknown formatting code *SEQ*

  An invalid markup command has been encountered. Valid are: `B<>`, `C<>`, `E<>`, `F<>`, `I<>`, `L<>`, `S<>`, `X<>`, `Z<>`

- Unterminated *SEQ*<> sequence

  An unclosed formatting code

- An E<...> surrounding strange content

  The *STRING* found cannot be interpreted as a character entity.

- An empty E<>

- An empty `L<>`

- An empty X<>

  There needs to be content inside E, L, and X formatting codes.

- Spurious text after =pod / =cut

  The commands =pod and `=cut` do not take any arguments.

- =back doesn't take any parameters, but you said =back *ARGUMENT*

  The `=back` command does not take any arguments.

- =pod directives shouldn't be over one line long! Ignoring all *N* lines of content

  Self explanatory

- =cut found outside a pod block.

  A '=cut' directive found in the middle of non-POD

- Invalid =encoding syntax: *CONTENT*

  Syntax error in =encoding directive

Warnings

These may not necessarily cause trouble, but indicate mediocre style.

- nested commands *CMD*<...*CMD*<...>...>

  Two nested identical markup commands have been found. Generally this does not make sense.

- multiple occurrences (*N*) of link target *name*

  The POD file has some `=item` and/or `=head` commands that have the same text. Potential hyperlinks to such a text cannot be unique then. This warning is printed only with warning level greater than one.

- line containing nothing but whitespace in paragraph

  There is some whitespace on a seemingly empty line. POD is very sensitive to such things, so this is flagged. **vi** users switch on the **list** option to avoid this problem.

- =item has no contents

  There is a list `=item` that has no text contents. You probably want to delete empty items.

- You can't have =items (as at line *N*) unless the first thing after the =over is an =item

  A list introduced by `=over` starts with a text or verbatim paragraph, but continues with `=items`. Move the non-item paragraph out of the `=over`/`=back` block.

- Expected '=item *EXPECTED VALUE*'

- Expected '=item *'

- Possible =item type mismatch: '*x*' found leading a supposed definition =item

  A list started with e.g. a bullet-like `=item` and continued with a numbered one. This is obviously inconsistent. For most translators the type of the *first* `=item` determines the type of the list.

- You have '=item x' instead of the expected '=item *N*'

  Erroneous numbering of =item numbers; they need to ascend consecutively.

- Unknown E content in E<*CONTENT*>

  A character entity was found that does not belong to the standard ISO set or the POD specials `verbar` and `sol`. *Currently, this warning only appears if a character entity was found that does not have a Unicode character. This should be fixed to adhere to the original warning.*

- empty =over/=back block

  The list opened with `=over` does not contain anything.

- empty section in previous paragraph

The previous section (introduced by a =head command) does not contain any valid content. This usually indicates that something is missing. Note: A =head1 followed immediately by =head2 does not trigger this warning.

- Verbatim paragraph in NAME section

  The NAME section (=head1 NAME) should consist of a single paragraph with the script/module name, followed by a dash `-' and a very short description of what the thing is good for.

- =head_n_ without preceding higher level

  For example if there is a =head2 in the POD file prior to a =head1.

- A non-empty Z<>

  The Z<> sequence is supposed to be empty. Caveat: this issue is detected in *Pod::Simple* and will be flagged as an *ERROR* by any client code; any contents of Z<...> will be disregarded, anyway.

Hyperlinks

There are some warnings with respect to malformed hyperlinks:

- ignoring leading/trailing whitespace in link

  There is whitespace at the beginning or the end of the contents of L<...>.

- alternative text/node '%s' contains non-escaped | or /

  The characters | and / are special in the L<...> context. Although the hyperlink parser does its best to determine which "/" is text and which is a delimiter in case of doubt, one ought to escape these literal characters like this:

```
/     E<sol>
|     E<verbar>
```

Note that the line number of the error/warning may refer to the line number of the start of the paragraph in which the error/warning exists, not the line number that the error/warning is on. This bug is present in errors/warnings related to formatting codes. *This should be fixed.*

RETURN VALUE

podchecker returns the number of POD syntax errors found or -1 if there were no POD commands at all found in the file.

EXAMPLES

See "SYNOPSIS"

SCRIPTS

The **podchecker** script that comes with this distribution is a lean wrapper around this module. See the online manual with

```
podchecker -help
podchecker -man
```

INTERFACE

While checking, this module collects document properties, e.g. the nodes for hyperlinks (`=headX`, `=item`) and index entries (`X<>`). POD translators can use this feature to syntax-check and get the nodes in a first pass before actually starting to convert. This is expensive in terms of execution time, but allows for very robust conversions.

Since v1.24 the **Pod::Checker** module uses only the **poderror** method to print errors and warnings. The summary output (e.g. "Pod syntax OK") has been dropped from the module and has been included in **podchecker** (the script). This allows users of **Pod::Checker** to control completely the output behavior. Users of **podchecker** (the script) get the well-known behavior.

v1.45 inherits from *Pod::Simple* as opposed to all previous versions inheriting from Pod::Parser. Do **not** use Pod::Simple's interface when using Pod::Checker unless it is documented somewhere on this page. I repeat, DO **NOT** USE POD::SIMPLE'S INTERFACE.

The following list documents the overrides to Pod::Simple, primarily to make Pod::Coverage happy:

- end_B
- end_C
- end_Document
- end_F
- end_I
- end_L
- end_Para
- end_S
- end_X
- end_fcode
- end_for
- end_head
- end_head1
- end_head2
- end_head3
- end_head4
- end_item

- end_item_bullet
- end_item_number
- end_item_text
- handle_pod_and_cut
- handle_text
- handle_whiteline
- hyperlink
- scream
- start_B
- start_C
- start_Data
- start_F
- start_I
- start_L
- start_Para
- start_S
- start_Verbatim
- start_X
- start_fcode
- start_for
- start_head
- start_head1
- start_head2
- start_head3
- start_head4
- start_item_bullet
- start_item_number
- start_item_text
- start_over
- start_over_block
- start_over_bullet
- start_over_empty
- start_over_number
- start_over_text

- whine
- `Pod::Checker->new( %options )`

  Return a reference to a new Pod::Checker object that inherits from Pod::Simple and is used for calling the required methods later. The following options are recognized:

  `-warnings => num` Print warnings if `num` is true. The higher the value of `num`, the more warnings are printed. Currently there are only levels 1 and 2.

  `-quiet => num` If `num` is true, do not print any errors/warnings. This is useful when Pod::Checker is used to munge POD code into plain text from within POD formatters.
- `$checker->poderror( @args )`
- `$checker->poderror( {%opts}, @args )`

  Internal method for printing errors and warnings. If no options are given, simply prints "@_". The following options are recognized and used to form the output:

  ```
  -msg
  ```

  A message to print prior to `@args`.

  ```
  -line
  ```

  The line number the error occurred in.

  ```
  -file
  ```

  The file (name) the error occurred in. Defaults to the name of the current file being processed.

  ```
  -severity
  ```

  The error level, should be 'WARNING' or 'ERROR'.
- `$checker->num_errors()`

  Set (if argument specified) and retrieve the number of errors found.
- `$checker->num_warnings()`

  Set (if argument specified) and retrieve the number of warnings found.
- `$checker->name()`

  Set (if argument specified) and retrieve the canonical name of POD as found in the `=head1 NAME` section.
- `$checker->node()`

  Add (if argument specified) and retrieve the nodes (as defined by `=headX` and `=item`) of the current POD. The nodes are returned in the order of their occurrence. They consist of plain text, each piece of whitespace is collapsed to a single blank.

- `$checker->idx()`

  Add (if argument specified) and retrieve the index entries (as defined by `X<>`) of the current POD. They consist of plain text, each piece of whitespace is collapsed to a single blank.

- `$checker->hyperlinks()`

  Retrieve an array containing the hyperlinks to things outside the current POD (as defined by `L<>`).

  Each is an instance of a class with the following methods:

- line()

  Returns the approximate line number in which the link was encountered

- type()

  Returns the type of the link; one of: `"url"` for things like `http://www.foo`, `"man"` for man pages, or `"pod"`.

- page()

  Returns the linked-to page or url.

- node()

  Returns the anchor or node within the linked-to page, or an empty string (`""`) if none appears in the link.

Pod::Escapes

for resolving Pod E<...> sequences

SYNOPSIS

```
use Pod::Escapes qw(e2char);
...la la la, parsing POD, la la la...
$text = e2char($e_node->label);
unless(defined $text) {
  print "Unknown E sequence \"", $e_node->label, "\"!";
}
...else print/interpolate $text...
```

DESCRIPTION

This module provides things that are useful in decoding Pod E<...> sequences. Presumably, it should be used only by Pod parsers and/or formatters.

By default, Pod::Escapes exports none of its symbols. But you can request any of them to be exported. Either request them individually, as with `use Pod::Escapes qw(symbolname symbolname2...);`, or you can do `use Pod::Escapes qw(:ALL);` to get all exportable symbols.

GOODIES

- e2char($e_content)

  Given a name or number that could appear in a `E<name_or_num>` sequence, this returns the string that it stands for. For example, `e2char('sol')`, `e2char('47')`, `e2char('0x2F')`, and `e2char('057')` all return "/", because `E<sol>`, `E<47>`, `E<0x2f>`, and `E<057>`, all mean "/". If the name has no known value (as with a name of "qacute") or is syntactically invalid (as with a name of "1/4"), this returns undef.

- e2charnum($e_content)

  Given a name or number that could appear in a `E<name_or_num>` sequence, this returns the number of the Unicode character that this stands for. For example, `e2char('sol')`, `e2char('47')`, `e2char('0x2F')`, and `e2char('057')` all return 47, because `E<sol>`, `E<47>`, `E<0x2f>`, and `E<057>`, all mean "/", whose Unicode number is 47. If the name has no known value (as with a name of "qacute") or is syntactically invalid (as with a name of "1/4"), this returns undef.

- $Name2character{*name*}

  Maps from names (as in `E<_name_>`) like "eacute" or "sol" to the string that each stands for. Note that this does not include numerics (like "64" or "x981c"). Under old Perl versions (before 5.7) you get a "?" in place of characters whose Unicode value is over 255.

- $Name2character_number{*name*}

  Maps from names (as in `E<_name_>`) like "eacute" or "sol" to the Unicode value that each stands for. For example, `$Name2character_number{'eacute'}` is 201, and `$Name2character_number{'eacute'}` is 8364. You get the correct Unicode value, regardless of the version of Perl you're using – which differs from `%Name2character`'s behavior under pre-5.7 Perls.

  Note that this hash does not include numerics (like "64" or "x981c").

- $Latin1Code_to_fallback{*integer*}

  For numbers in the range 160 (0x00A0) to 255 (0x00FF), this maps from the character code for a Latin-1 character (like 233 for lowercase e-acute) to the US-ASCII character that best aproximates it (like "e"). You may find this useful if you are rendering POD in a format that you think deals well only with US-ASCII characters.

- $Latin1Char_to_fallback{*character*}

  Just as above, but maps from characters (like "\xE9", lowercase e-acute) to characters (like "e").

- $Code2USASCII{*integer*}

  This maps from US-ASCII codes (like 32) to the corresponding character (like space, for 32). Only characters 32 to 126 are defined. This is meant for use by `e2char($x)` when it senses that it's running on a non-ASCII platform (where chr(32) doesn't get you a space – but $Code2USASCII{32} will). It's documented here just in case you might find it useful.

CAVEATS

On Perl versions before 5.7, Unicode characters with a value over 255 (like lambda or emdash) can't be conveyed. This module does work under such early Perl versions, but in the place of each such character, you get a "?". Latin-1 characters (characters 160-255) are unaffected.

Under EBCDIC platforms, `e2char($n)` may not always be the same as `chr(e2charnum($n))`, and ditto for `$Name2character{$name}` and `chr($Name2character_number{$name})`, because the strings are returned as native, and the numbers are returned as Unicode. However, for Perls starting with v5.8, `e2char($n)` is the same as `chr(utf8::unicode_to_native(e2charnum($n)))`, and ditto for `$Name2character{$name}` and `chr(utf8::unicode_to_native($Name2character_number{$name}))`.

Pod::Functions

Group Perl's functions a la perlfunc.pod

SYNOPSIS

```
use Pod::Functions;

my @misc_ops = @{ $Kinds{ 'Misc' } };
my $misc_dsc = $Type_Description{ 'Misc' };
```

or

```
perl /path/to/lib/Pod/Functions.pm
```

This will print a grouped list of Perl's functions, like the *"Perl Functions by Category" in perlfunc* section.

DESCRIPTION

It exports the following variables:

- This holds a hash-of-lists. Each list contains the functions in the category the key denotes.
- In this hash each key represents a function and the value is the category. The category can be a comma separated list.
- In this hash each key represents a function and the value is a short description of that function.
- In this hash each key represents a category of functions and the value is a short description of that category.
- @Type_Order

  This list of categories is used to produce the same order as the *"Perl Functions by Category" in perlfunc* section.

Pod::Html

module to convert pod files to HTML

SYNOPSIS

```
use Pod::Html;
pod2html([options]);
```

DESCRIPTION

Converts files from pod format (see perlpod) to HTML format. It can automatically generate indexes and cross-references, and it keeps a cache of things it knows how to cross-reference.

FUNCTIONS

pod2html

```
pod2html("pod2html",
         "--podpath=lib:ext:pod:vms",
         "--podroot=/usr/src/perl",
         "--htmlroot=/perl/nmanual",
         "--recurse",
         "--infile=foo.pod",
         "--outfile=/perl/nmanual/foo.html");
```

pod2html takes the following arguments:

- backlink

  ```
  --backlink
  ```

  Turns every head1 heading into a link back to the top of the page. By default, no backlinks are generated.

- cachedir

  ```
  --cachedir=name
  ```

  Creates the directory cache in the given directory.

- css

  ```
  --css=stylesheet
  ```

  Specify the URL of a cascading style sheet. Also disables all HTML/CSS `style` attributes that are output by default (to avoid conflicts).

- flush

  ```
  --flush
  ```

Flushes the directory cache.

- header

```
--header
--noheader
```

Creates header and footer blocks containing the text of the NAME section. By default, no headers are generated.

- help

```
--help
```

Displays the usage message.

- htmldir

```
--htmldir=name
```

Sets the directory to which all cross references in the resulting html file will be relative. Not passing this causes all links to be absolute since this is the value that tells Pod::Html the root of the documentation tree.

Do not use this and –htmlroot in the same call to pod2html; they are mutually exclusive.

- htmlroot

```
--htmlroot=name
```

Sets the base URL for the HTML files. When cross-references are made, the HTML root is prepended to the URL.

Do not use this if relative links are desired: use –htmldir instead.

Do not pass both this and –htmldir to pod2html; they are mutually exclusive.

- index

```
--index
--noindex
```

Generate an index at the top of the HTML file. This is the default behaviour.

- infile

```
--infile=name
```

Specify the pod file to convert. Input is taken from STDIN if no infile is specified.

- outfile

```
--outfile=name
```

Specify the HTML file to create. Output goes to STDOUT if no outfile is specified.

- poderrors

```
--poderrors
--nopoderrors
```

Include a “POD ERRORS” section in the outfile if there were any POD errors in the infile. This section is included by default.

- podpath

```
--podpath=name:...:name
```

Specify which subdirectories of the podroot contain pod files whose HTML converted forms can be linked to in cross references.

- podroot

```
--podroot=name
```

Specify the base directory for finding library pods. Default is the current working directory.

- quiet

```
--quiet
--noquiet
```

Don’t display *mostly harmless* warning messages. These messages will be displayed by default. But this is not the same as `verbose` mode.

- recurse

```
--recurse
--norecurse
```

Recurse into subdirectories specified in podpath (default behaviour).

- title

```
--title=title
```

Specify the title of the resulting HTML file.

- verbose

```
--verbose
--noverbose
```

Display progress messages. By default, they won’t be displayed.

Formerly Exported Auxiliary Functions

Prior to perl-5.36, the following three functions were exported by `Pod::Html`, either by default or on request:

- `htmlify()` (by default)
- `anchorify()` (upon request)

- `relativize_url()` (upon request)

The definition and documentation of these functions have been moved to `Pod::Html::Util`, viewable via `perldoc Pod::Html::Util`.

Beginning with perl-5.38 these functions must be explicitly imported from `Pod::Html::Util`. Please modify your code as needed.

ENVIRONMENT

Uses `$Config{pod2html}` to setup default options.

Modules

- `Pod::Html::Util` - helper functions for Pod-Html

Pod::Html::Util

helper functions for Pod-Html

SUBROUTINES

Note: While these functions are importable on request from `Pod::Html::Util`, they are specifically intended for use within (a) the `Pod-Html` distribution (modules and test programs) shipped as part of the Perl 5 core and (b) other parts of the core such as the `installhtml` program. These functions may be modified or relocated within the core distribution – or removed entirely therefrom – as the core's needs evolve. Hence, you should not rely on these functions in situations other than those just described.

`process_command_line()`

Process command-line switches (options). Returns a reference to a hash. Will provide usage message if `--help` switch is present or if parameters are invalid.

Calling this subroutine may modify `@ARGV`.

usage()

Display customary Pod::Html usage information on STDERR.

unixify()

Ensure that Pod::Html's internals and tests handle paths consistently across Unix, Windows and VMS.

relativize_url()

Convert an absolute URL to one relative to a base URL. Assumes both end in a filename.

html_escape()

Make text safe for HTML.

htmlify()

```
htmlify($heading);
```

Converts a pod section specification to a suitable section specification for HTML. Note that we keep spaces and special characters except " , ? (Netscape problem) and the hyphen (writer's problem...).

anchorify()

```
anchorify(@heading);
```

Similar to `htmlify()`, but turns non-alphanumerics into underscores. Note that `anchorify()` is not exported by default.

trim_leading_whitespace()

Remove any level of indentation (spaces or tabs) from each code block consistently. Adapted from: https://metacpan.org/source/HAARG/MetaCPAN-Pod-XHTML-0.002001/lib/Pod/Simple/Role/StripVerbatimIndent.pm

Pod::Man

Convert POD data to formatted *roff input

SYNOPSIS

```
use Pod::Man;
my $parser = Pod::Man->new (release => $VERSION, section => 8);

# Read POD from STDIN and write to STDOUT.
```

(continues on next page)

(continued from previous page)

```
$parser->parse_file (\*STDIN);

# Read POD from file.pod and write to file.1.
$parser->parse_from_file ('file.pod', 'file.1');
```

DESCRIPTION

Pod::Man is a module to convert documentation in the POD format (the preferred language for documenting Perl) into *roff input using the man macro set. The resulting *roff code is suitable for display on a terminal using nroff(1), normally via man(1), or printing using troff(1). It is conventionally invoked using the driver script **pod2man**, but it can also be used directly.

By default (on non-EBCDIC systems), Pod::Man outputs UTF-8. Its output should work with the **man** program on systems that use **groff** (most Linux distributions) or **mandoc** (most BSD variants), but may result in mangled output on older UNIX systems. To choose a different, possibly more backward-compatible output mangling on such systems, set the `encoding` option to `roff` (the default in earlier Pod::Man versions). See the `encoding` option and "ENCODING" for more details.

See "COMPATIBILITY" for the versions of Pod::Man with significant backward-incompatible changes (other than constructor options, whose versions are documented below), and the versions of Perl that included them.

CLASS METHODS

- new(ARGS)

  Create a new Pod::Man object. ARGS should be a list of key/value pairs, where the keys are chosen from the following. Each option is annotated with the version of Pod::Man in which that option was added with its current meaning.

  - center

    [1.00] Sets the centered page header for the `.TH` macro. The default, if this option is not specified, is `User Contributed Perl Documentation`.

  - date

    [4.00] Sets the centered page footer for the `.TH` macro. If this option is not set, the contents of the environment variable POD_MAN_DATE, if set, will be used. Failing that, the value of SOURCE_DATE_EPOCH, the modification date of the input file, or the current time if stat() can't find that file (which will be the case if the input is from `STDIN`) will be used. If taken from any source other than POD_MAN_DATE (which is used verbatim), the date will be formatted as `YYYY-MM-DD` and will be based on UTC (so that the output will be reproducible regardless of local time zone).

    Note that some system an macro sets assume that the centered footer will be a modification date and will prepend something like `Last modified: `.

  - encoding

[5.00] Specifies the encoding of the output. The value must be an encoding recognized by the *Encode* module (see Encode::Supported), or the special values `roff` or `groff`. The default on non-EBCDIC systems is UTF-8.

If the output contains characters that cannot be represented in this encoding, that is an error that will be reported as configured by the `errors` option. If error handling is other than `die`, the unrepresentable character will be replaced with the Encode substitution character (normally `?`).

If the `encoding` option is set to the special value `groff` (the default on EBCDIC systems), or if the Encode module is not available and the encoding is set to anything other than `roff`, Pod::Man will translate all non-ASCII characters to `\[uNNNN]` Unicode escapes. These are not traditionally part of the *roff language, but are supported by **groff** and **mandoc** and thus by the majority of manual page processors in use today.

If the `encoding` option is set to the special value `roff`, Pod::Man will do its historic transformation of (some) ISO 8859-1 characters into *roff escapes that may be adequate in troff and may be readable (if ugly) in nroff. This was the default behavior of versions of Pod::Man before 5.00. With this encoding, all other non-ASCII characters will be replaced with `X`. It may be required for very old troff and nroff implementations that do not support UTF-8, but its representation of any non-ASCII character is very poor and often specific to European languages.

If the output file handle has a PerlIO encoding layer set, setting `encoding` to anything other than `groff` or `roff` will be ignored and no encoding will be done by Pod::Man. It will instead rely on the encoding layer to make whatever output encoding transformations are desired.

WARNING: The input encoding of the POD source is independent from the output encoding, and setting this option does not affect the interpretation of the POD input. Unless your POD source is US-ASCII, its encoding should be declared with the `=encoding` command in the source. If this is not done, Pod::Simple will will attempt to guess the encoding and may be successful if it's Latin-1 or UTF-8, but it will produce warnings. See perlpod(1) for more information.

– errors

[2.27] How to report errors. `die` says to throw an exception on any POD formatting error. `stderr` says to report errors on standard error, but not to throw an exception. pod says to include a POD ERRORS section in the resulting documentation summarizing the errors. none ignores POD errors entirely, as much as possible.

The default is pod.

– fixed

[6.1.0] The fixed-width font to use for verbatim text and code. Defaults to `CR`. Solaris systems historically preferred `CW` instead. Only matters for **troff** output.

– fixedbold

[1.00] Bold version of the fixed-width font. Defaults to CB. Only matters for **troff** output.

– fixeditalic

[1.00] Italic version of the fixed-width font (something of a misnomer, since most fixed-width fonts only have an oblique version, not an italic version). Defaults to CI. Only matters for **troff** output.

– fixedbolditalic

[1.00] Bold italic (in theory, probably oblique in practice) version of the fixed-width font. Pod::Man doesn't assume you have this, and defaults to CB. Some systems (such as Solaris) have this font available as CX. Only matters for **troff** output.

– guesswork

[5.00] By default, Pod::Man applies some default formatting rules based on guesswork and regular expressions that are intended to make writing Perl documentation easier and require less explicit markup. These rules may not always be appropriate, particularly for documentation that isn't about Perl. This option allows turning all or some of it off.

The special value `all` enables all guesswork. This is also the default for backward compatibility reasons. The special value none disables all guesswork. Otherwise, the value of this option should be a comma-separated list of one or more of the following keywords:

* functions

  Convert function references like `foo()` to bold even if they have no markup. The function name accepts valid Perl characters for function names (including :), and the trailing parentheses must be present and empty.

* manref

  Make the first part (before the parentheses) of manual page references like `foo(1)` bold even if they have no markup. The section must be a single number optionally followed by lowercase letters.

* quoting

  If no guesswork is enabled, any text enclosed in C<> is surrounded by double quotes in nroff (terminal) output unless the contents are already quoted. When this guesswork is enabled, quote marks will also be suppressed for Perl variables, function names, function calls, numbers, and hex constants.

* variables

  Convert Perl variable names to a fixed-width font even if they have no markup. This transformation will only be apparent in troff output, or some other output format (unlike nroff terminal output) that supports fixed-width fonts.

Any unknown guesswork name is silently ignored (for potential future compatibility), so be careful about spelling.

– language

[5.00] Add commands telling **groff** that the input file is in the given language. The value of this setting must be a language abbreviation for which **groff** provides supplemental configuration, such as `ja` (for Japanese) or `zh` (for Chinese).

Specifically, this adds:

```
.mso <language>.tmac
.hla <language>
```

to the start of the file, which configure correct line breaking for the specified language. Without these commands, groff may not know how to add proper line breaks for Chinese and Japanese text if the manual page is installed into the normal manual page directory, such as `/usr/share/man`.

On many systems, this will be done automatically if the manual page is installed into a language-specific manual page directory, such as `/usr/share/man/zh_CN`. In that case, this option is not required.

Unfortunately, the commands added with this option are specific to **groff** and will not work with other **troff** and **nroff** implementations.

– lquote

– rquote

[4.08] Sets the quote marks used to surround C<> text. `lquote` sets the left quote mark and `rquote` sets the right quote mark. Either may also be set to the special value none, in which case no quote mark is added on that side of C<> text (but the font is still changed for troff output).

Also see the `quotes` option, which can be used to set both quotes at once. If both `quotes` and one of the other options is set, `lquote` or `rquote` overrides `quotes`.

– name

[4.08] Set the name of the manual page for the `.TH` macro. Without this option, the manual name is set to the uppercased base name of the file being converted unless the manual section is 3, in which case the path is parsed to see if it is a Perl module path. If it is, a path like `.../lib/Pod/Man.pm` is converted into a name like `Pod::Man`. This option, if given, overrides any automatic determination of the name.

If generating a manual page from standard input, the name will be set to `STDIN` if this option is not provided. In this case, providing this option is strongly recommended to set a meaningful manual page name.

– nourls

[2.27] Normally, L<> formatting codes with a URL but anchor text are formatted to show both the anchor text and the URL. In other words:

```
L<foo|http://example.com/>
```

is formatted as:

```
foo <http://example.com/>
```

This option, if set to a true value, suppresses the URL when anchor text is given, so this example would be formatted as just `foo`. This can produce less cluttered output in cases where the URLs are not particularly important.

– quotes

[4.00] Sets the quote marks used to surround C<> text. If the value is a single character, it is used as both the left and right quote. Otherwise, it is split in half, and the first half of the string is used as the left quote and the second is used as the right quote.

This may also be set to the special value none, in which case no quote marks are added around C<> text (but the font is still changed for troff output).

Also see the `lquote` and `rquote` options, which can be used to set the left and right quotes independently. If both `quotes` and one of the other options is set, `lquote` or `rquote` overrides `quotes`.

– release

[1.12] Set the left-hand page footer for the `.TH` macro. By default, this is set to the version of Perl you run Pod::Man under. Setting this to the empty string will cause some *roff implementations to use the system default value.

– section

[1.00] Set the section for the `.TH` macro. The standard section numbering convention is to use 1 for user commands, 2 for system calls, 3 for functions, 4 for devices, 5 for file formats, 6 for games, 7 for miscellaneous information, and 8 for administrator commands. There is a lot of variation here, however; some systems (like Solaris) use 4 for file formats, 5 for miscellaneous information, and 7 for devices. Still others use 1m instead of 8, or some mix of both. About the only section numbers that are reliably consistent are 1, 2, and 3.

By default, section 1 will be used unless the file ends in `.pm` in which case section 3 will be selected.

– stderr

[2.19] If set to a true value, send error messages about invalid POD to standard error instead of appending a POD ERRORS section to the generated *roff output. This is equivalent to setting `errors` to `stderr` if `errors` is not already set.

This option is for backward compatibility with Pod::Man versions that did not support `errors`. Normally, the `errors` option should be used instead.

– utf8

[2.21] This option used to set the output encoding to UTF-8. Since this is now the default, it is ignored and does nothing.

INSTANCE METHODS

As a derived class from Pod::Simple, Pod::Man supports the same methods and interfaces. See *Pod::Simple* for all the details. This section summarizes the most-frequently-used methods and the ones added by Pod::Man.

- output_fh(FH)

  Direct the output from parse_file(), parse_lines(), or parse_string_document() to the file handle FH instead of STDOUT.

- output_string(REF)

  Direct the output from parse_file(), parse_lines(), or parse_string_document() to the scalar variable pointed to by REF, rather than STDOUT. For example:

```
my $man = Pod::Man->new();
my $output;
$man->output_string(\$output);
$man->parse_file('/some/input/file');
```

  Be aware that the output in that variable will already be encoded in UTF-8.

- parse_file(PATH)

  Read the POD source from PATH and format it. By default, the output is sent to STDOUT, but this can be changed with the output_fh() or output_string() methods.

- parse_from_file(INPUT, OUTPUT)

- parse_from_filehandle(FH, OUTPUT)

  Read the POD source from INPUT, format it, and output the results to OUTPUT.

  parse_from_filehandle() is provided for backward compatibility with older versions of Pod::Man. parse_from_file() should be used instead.

- parse_lines(LINES[, ...[, undef]])

  Parse the provided lines as POD source, writing the output to either STDOUT or the file handle set with the output_fh() or output_string() methods. This method can be called repeatedly to provide more input lines. An explicit `undef` should be passed to indicate the end of input.

  This method expects raw bytes, not decoded characters.

- parse_string_document(INPUT)

  Parse the provided scalar variable as POD source, writing the output to either STDOUT or the file handle set with the output_fh() or output_string() methods.

  This method expects raw bytes, not decoded characters.

ENCODING

As of Pod::Man 5.00, the default output encoding for Pod::Man is UTF-8. This should work correctly on any modern system that uses either **groff** (most Linux distributions) or **mandoc** (Alpine Linux and most BSD variants, including macOS).

The user will probably have to use a UTF-8 locale to see correct output. This may be done by default; if not, set the LANG or LC_CTYPE environment variables to an appropriate local. The locale `C.UTF-8` is available on most systems if one wants correct output without changing the other things locales affect, such as collation.

The backward-compatible output format used in Pod::Man versions before 5.00 is available by setting the `encoding` option to `roff`. This may produce marginally nicer results on older UNIX versions that do not use **groff** or **mandoc**, but none of the available options will correctly render Unicode characters on those systems.

Below are some additional details about how this choice was made and some discussion of alternatives.

History

The default output encoding for Pod::Man has been a long-standing problem. **troff** and **nroff** predate Unicode by a significant margin, and their implementations for many UNIX systems reflect that legacy. It's common for Unicode to not be supported in any form.

Because of this, versions of Pod::Man prior to 5.00 maintained the highly conservative output of the original pod2man, which output pure ASCII with complex macros to simulate common western European accented characters when processed with troff. The nroff output was awkward and sometimes incorrect, and characters not used in western European scripts were replaced with X. This choice maximized backwards compatibility with **man** and **nroff**/**troff** implementations at the cost of incorrect rendering of many POD documents, particularly those containing people's names.

The modern implementations, **groff** (used in most Linux distributions) and **mandoc** (used by most BSD variants), do now support Unicode. Other UNIX systems often do not, but they're now a tiny minority of the systems people use on a daily basis. It's increasingly common (for very good reasons) to use Unicode characters for POD documents rather than using ASCII conversions of people's names or avoiding non-English text, making the limitations in the old output format more apparent.

Four options have been proposed to fix this:

- Optionally support UTF-8 output but don't change the default. This is the approach taken since Pod::Man 2.1.0, which added the `utf8` option. Some Pod::Man users use this option for better output on platforms known to support Unicode, but since the defaults have not changed, people continued to encounter (and file bug reports about) the poor default rendering.
- Convert characters to troff `\(xx` escapes. This requires maintaining a large translation table and addresses only a tiny part of the problem, since many Unicode characters have no standard troff name. **groff** has the largest list, but if one is willing to assume **groff** is the formatter, the next option is better.
- Convert characters to groff `\[uNNNN]` escapes. This is implemented as the `groff` encoding for those who want to use it, and is supported by both **groff** and **mandoc**. However, it is no better than UTF-8 output for portability to other implementations. See "Testing results" for more details.
- Change the default output format to UTF-8 and ask those who want maximum backward compatibility to explicitly select the old encoding. This fixes the issue for most users at the cost of backwards compatibility. While the rendering of non-ASCII

characters is different on older systems that don't support UTF-8, it's not always worse than the old output.

Pod::Man 5.00 and later makes the last choice. This arguably produces worse output when manual pages are formatted with **troff** into PostScript or PDF, but doing this is rare and normally manual, so the encoding can be changed in those cases. The older output encoding is available by setting `encoding` to `roff`.

Testing results

Here is the results of testing `encoding` values of `utf-8` and `groff` on various operating systems. The testing methodology was to create `man/man1` in the current directory, copy `encoding.utf8` or `encoding.groff` from the podlators 5.00 distribution to `man/man1/encoding.1`, and then run:

```
LANG=C.UTF-8 MANPATH=$(pwd)/man man 1 encoding
```

If the locale is not explicitly set to one that includes UTF-8, the Unicode characters were usually converted to ASCII (by, for example, dropping an accent) or deleted or replaced with <?> if there was no conversion.

Tested on 2022-09-25. Many thanks to the GCC Compile Farm project for access to testing hosts.

```
OS                  UTF-8      groff
------------------  -------    -------
AIX 7.1             no [1]     no [2]
Alpine 3.15.0       yes        yes
CentOS 7.9          yes        yes
Debian 7            yes        yes
FreeBSD 13.0        yes        yes
NetBSD 9.2          yes        yes
OpenBSD 7.1         yes        yes
openSUSE Leap 15.4  yes        yes
Solaris 10          yes        no [2]
Solaris 11          no [3]     no [3]
```

I did not have access to a macOS system for testing, but since it uses **mandoc**, it's behavior is probably the same as the BSD hosts.

Notes:

- [1]

  Unicode characters were converted to one or two random ASCII characters unrelated to the original character.

- [2]

  Unicode characters were shown as the body of the groff escape rather than the indicated character (in other words, text like `[u00EF]`).

- [3]

  Unicode characters were deleted entirely, as if they weren't there. Using `nroff -man` instead of **man** to format the page showed the same results as Solaris 10.

Using `groff -k -man -Tutf8` to format the page produced the correct output.

PostScript and PDF output using groff on a Debian 12 system do not support combining accent marks or SMP characters due to a lack of support in the default output font.

Testing on additional platforms is welcome. Please let the author know if you have additional results.

DIAGNOSTICS

- roff font should be 1 or 2 chars, not "%s"

  (F) You specified a *roff font (using `fixed`, `fixedbold`, etc.) that wasn't either one or two characters. Pod::Man doesn't support *roff fonts longer than two characters, although some *roff extensions do (the canonical versions of **nroff** and **troff** don't either).

- Invalid errors setting "%s"

  (F) The `errors` parameter to the constructor was set to an unknown value.

- Invalid quote specification "%s"

  (F) The quote specification given (the `quotes` option to the constructor) was invalid. A quote specification must be either one character long or an even number (greater than one) characters long.

- POD document had syntax errors

  (F) The POD document being formatted had syntax errors and the `errors` option was set to `die`.

ENVIRONMENT

- PERL_CORE

  If set and Encode is not available, silently fall back to an encoding of `groff` without complaining to standard error. This environment variable is set during Perl core builds, which build Encode after podlators. Encode is expected to not (yet) be available in that case.

- POD_MAN_DATE

  If set, this will be used as the value of the left-hand footer unless the `date` option is explicitly set, overriding the timestamp of the input file or the current time. This is primarily useful to ensure reproducible builds of the same output file given the same source and Pod::Man version, even when file timestamps may not be consistent.

- SOURCE_DATE_EPOCH

  If set, and POD_MAN_DATE and the `date` options are not set, this will be used as the modification time of the source file, overriding the timestamp of the input file or the current time. It should be set to the desired time in seconds since UNIX epoch. This is primarily useful to ensure reproducible builds of the same output file given the same source and Pod::Man version, even when file timestamps may not be consistent. See https://reproducible-builds.org/specs/source-date-epoch/ for the full specification.

(Arguably, according to the specification, this variable should be used only if the timestamp of the input file is not available and Pod::Man uses the current time. However, for reproducible builds in Debian, results were more reliable if this variable overrode the timestamp of the input file.)

COMPATIBILITY

Pod::Man 1.02 (based on Pod::Parser) was the first version included with Perl, in Perl 5.6.0.

The current API based on *Pod::Simple* was added in Pod::Man 2.00. Pod::Man 2.04 was included in Perl 5.9.3, the first version of Perl to incorporate those changes. This is the first version that correctly supports all modern POD syntax. The parse_from_filehandle() method was re-added for backward compatibility in Pod::Man 2.09, included in Perl 5.9.4.

Support for anchor text in L<> links of type URL was added in Pod::Man 2.23, included in Perl 5.11.5.

parse_lines(), parse_string_document(), and parse_file() set a default output file handle of STDOUT if one was not already set as of Pod::Man 2.28, included in Perl 5.19.5.

Support for SOURCE_DATE_EPOCH and POD_MAN_DATE was added in Pod::Man 4.00, included in Perl 5.23.7, and generated dates were changed to use UTC instead of the local time zone. This is also the first release that aligned the module version and the version of the podlators distribution. All modules included in podlators, and the podlators distribution itself, share the same version number from this point forward.

Pod::Man 4.10, included in Perl 5.27.8, changed the formatting for manual page references and function names to bold instead of italic, following the current Linux manual page standard.

Pod::Man 5.00, included in Perl 5.37.7, changed the default output encoding to UTF-8, overridable with the new `encoding` option. It also fixed problems with bold or italic extending too far when used with C<> escapes, and began converting Unicode zero-width spaces (U+200B) to the `\:` *roff escape. It also dropped attempts to add subtle formatting corrections in the output that would only be visible when typeset with **troff**, which had previously been a significant source of bugs.

Pod::Man v6.0.0 and later, included in Perl 5.41.2, unconditionally convert `-` to the `\-` *roff escape, representing an ASCII hyphen-minus. Earlier versions attempted to use heuristics to decide when a given `-` character should translate to a hyphen-minus or a true hyphen, but these heuristics were buggy and fragile. v6.0.0 and later also unconditionally convert `` ` `` and `'` to ASCII grave accent and apostrophe marks instead of the default *roff behavior of interpreting them as paired quotes.

Pod::Man v6.1.0 and later use `CR` as the default fixed-width font instead of `CW`, as was used in previous versions. This should only matter for **troff** output.

BUGS

There are numerous bugs and language-specific assumptions in the nroff fallbacks for accented characters in the `roff` encoding. Since the point of this encoding is backward compatibility with the output from earlier versions of Pod::Man, and it is deprecated except when necessary to support old systems, those bugs are unlikely to ever be fixed.

Pod::Man doesn't handle font names longer than two characters. Neither do most **troff** implementations, but groff does as an extension. It would be nice to support as an option for those who want to use it.

CAVEATS

Sentence spacing

It is difficult to write POD documents such that the resulting *roff output has consistent intersentence spacing. For most documents, writing the POD using whatever conventions you prefer and letting the *roff output be inconsistent is probably the best trade-off to make. But if you want to dive into the details, read on.

Pod::Man copies the input spacing verbatim to the output *roff document. This means your output will be affected by how *roff handles sentence spacing.

*roff dates from an era in which it was standard to use two spaces after sentences, and will always add two spaces after a line-ending period (or similar punctuation) when reflowing text, with one exception mentioned below. For example, the following input:

```
=pod

One sentence.
Another sentence.
```

will result in two spaces after the period in **nroff** output when the text is reflowed.

One significant exception, however, is that different versions of groff vary in their interpretation of `."` (a sentence ending with an ASCII double quote). Versions of groff prior to 1.24.0 treat this as the end of a sentence if there are two spaces after the closing quote, or if it comes at the end of a line. Later versions will never treat this as the end of a sentence and will collapse any following spaces down to a single space. For consistent behavior for documents written in POD, you must use Unicode double quotes (“”, U+201C and U+201D) and declare UTF-8 encoding (or some other Unicode encoding). The Unicode closing double-quote, when preceded by a period and followed by two spaces or the end of the line, will always be interpreted as the end of a sentence in modern versions of groff.

Therefore, if you want two spaces after sentences in the **nroff** output, you can achieve this by using Unicode double quotes and using two spaces after periods that end a sentence. You will have to be careful to not end a line with an abbreviation such as `e.g.` or `Ms.`. Alternately, you can use the *roff style guide (and XKCD 1285) recommendation of putting a line break after each sentence, but you will still need to use Unicode double quotes.

If you prefer one space after sentences (which is the more modern style), your best option is to configure your local *roff installation to always format man pages that way, rather than attempt to force this result via your POD source. For example, for groff, groff_man_style(7) documents putting:

```
.\" Put only one space after the end of a sentence.
.ss 12 0 \" See groff(7).
```

in `/usr/share/groff/site-tmac/man.local` (on Debian-derived systems, `/etc/`

`groff/man.local` is used instead). This will affect all man pages formatted with groff on that system, regardless of how their source is formatted.

Hyphens and quotes

The *roff language distinguishes between two types of hyphens: `-`, which is a true typesetting hyphen (roughly equivalent to the Unicode U+2010 code point), and `\-`, which is the ASCII hyphen-minus (U+002D) that is used for UNIX command options and most filenames. Hyphens, where appropriate, produce better typesetting, but incorrectly using them for command names and options can cause problems with searching and cut-and-paste.

POD does not draw this distinction. Before podlators v6.0.0, Pod::Man attempted to translate `-` in the input into either a hyphen or a hyphen-minus, depending on context. However, this distinction proved impossible to do correctly with heuristics. Pod::Man therefore translates all `-` characters in the input to `\-` in the output, ensuring that command names and options are correct at the cost of somewhat inferior typesetting and line breaking issues with long hyphenated phrases.

To use true hyphens in the Pod::Man output, declare an input character set of UTF-8 (or some other Unicode encoding) and use Unicode hyphens. Pod::Man and *roff should handle those correctly with the default output format and most modern *roff implementations.

Similarly, Pod::Man disables the default *roff behavior of turning `` ` `` and `'` characters into matched quotes, and pairs of those characters into matched double quotes, because there is no good way to tell from the POD input whether this interpretation is desired or whether the intent is to use a literal grave accent or neutral apostrophe. If you want paired quotes in the output, use Unicode and its paired quote characters.

AUTHOR

Written by Russ Allbery rra@cpan.org, based on the original **pod2man** by Tom Christiansen tchrist@mox.perl.com.

The modifications to work with Pod::Simple instead of Pod::Parser were contributed by Sean Burke sburke@cpan.org, but I've since hacked them beyond recognition and all bugs are mine.

The manual page documenting the man macro set may be man(5) instead of man(7) on your system.

See perlpodstyle(1) for documentation on writing manual pages in POD if you've not done it before and aren't familiar with the conventions.

The current version of this module is always available from its web site at https://www.eyrie.org/~eagle/software/podlators/. It is also part of the Perl core distribution as of 5.6.0.

Pod::ParseLink

Parse an L<> formatting code in POD text

SYNOPSIS

```
use Pod::ParseLink;
my $link = get_link();
my ($text, $inferred, $name, $section, $type) = parselink($link);
```

DESCRIPTION

This module only provides a single function, parselink(), which takes the text of an L<> formatting code and parses it. It returns the anchor text for the link (if any was given), the anchor text possibly inferred from the name and section, the name or URL, the section if any, and the type of link. The type will be one of `url`, pod, or `man`, indicating a URL, a link to a POD page, or a link to a Unix manual page.

Parsing is implemented per perlpodspec. For backward compatibility, links where there is no section and name contains spaces, or links where the entirety of the link (except for the anchor text if given) is enclosed in double-quotes are interpreted as links to a section (L</section>).

The inferred anchor text is implemented per perlpodspec:

```
L<name>         =>  L<name|name>
L</section>     =>  L<"section"|/section>
L<name/section> =>  L<"section" in name|name/section>
```

The name may contain embedded E<> and Z<> formatting codes, and the section, anchor text, and inferred anchor text may contain any formatting codes. Any double quotes around the section are removed as part of the parsing, as is any leading or trailing whitespace.

If the text of the L<> escape is entirely enclosed in double quotes, it's interpreted as a link to a section for backward compatibility.

No attempt is made to resolve formatting codes. This must be done after calling parselink() (since E<> formatting codes can be used to escape characters that would oth-

erwise be significant to the parser and resolving them before parsing would result in an incorrect parse of a formatting code like:

```
L<verticalE<verbar>barE<sol>slash>
```

which should be interpreted as a link to the `vertical|bar/slash` POD page and not as a link to the `slash` section of the `bar` POD page with an anchor text of `vertical`. Note that not only the anchor text will need to have formatting codes expanded, but so will the target of the link (to deal with E<> and Z<> formatting codes), and special handling of the section may be necessary depending on whether the translator wants to consider markup in sections to be significant when resolving links. See perlpodspec for more information.

Modules

- Pod::Perldoc::BaseTo - Base for Pod::Perldoc formatters
- Pod::Perldoc::GetOptsOO - Customized option parser for Pod::Perldoc
- Pod::Perldoc::ToANSI - render Pod with ANSI color escapes
- Pod::Perldoc::ToChecker - let Perldoc check Pod for errors
- Pod::Perldoc::ToMan - let Perldoc render Pod as man pages
- Pod::Perldoc::ToNroff - let Perldoc convert Pod to nroff
- Pod::Perldoc::ToPod - let Perldoc render Pod as ...
- Pod::Perldoc::ToRtf - let Perldoc render Pod as RTF
- Pod::Perldoc::ToTerm - render Pod with terminal escapes
- Pod::Perldoc::ToText - let Perldoc render Pod as plaintext
- Pod::Perldoc::ToTk - let Perldoc use Tk::Pod to render Pod
- Pod::Perldoc::ToXml - let Perldoc render Pod as XML

Pod::Perldoc::BaseTo

Base for Pod::Perldoc formatters

SYNOPSIS

```
package Pod::Perldoc::ToMyFormat;

use parent qw( Pod::Perldoc::BaseTo );
...
```

DESCRIPTION

This package is meant as a base of Pod::Perldoc formatters, like *Pod::Perldoc::ToText*, *Pod::Perldoc::ToMan*, etc.

It provides default implementations for the methods

```
is_pageable
write_with_binmode
output_extension
_perldoc_elem
```

The concrete formatter must implement

```
new
parse_from_file
```

Pod::Perldoc::GetOptsOO

Customized option parser for Pod::Perldoc

SYNOPSIS

```
use Pod::Perldoc::GetOptsOO ();

Pod::Perldoc::GetOptsOO::getopts( $obj, \@args, $truth )
   or die "wrong usage";
```

DESCRIPTION

Implements a customized option parser used for *Pod::Perldoc*.

Rather like Getopt::Std's getopts:

- Call Pod::Perldoc::GetOptsOO::getopts($object, \@ARGV, $truth)
- Given -n, if there's a opt_n_with, it'll call $object->opt_n_with(ARGUMENT) (e.g., "-n foo" => $object->opt_n_with('foo'). Ditto "-nfoo")
- Otherwise (given -n) if there's an opt_n, we'll call it $object->opt_n($truth) (Truth defaults to 1)
- Otherwise we try calling $object->handle_unknown_option('n') (and we increment the error count by the return value of it)
- If there's no handle_unknown_option, then we just warn, and then increment the error counter

The return value of Pod::Perldoc::GetOptsOO::getopts is true if no errors, otherwise it's false.

Pod::Perldoc::ToANSI

render Pod with ANSI color escapes

SYNOPSIS

```
perldoc -o ansi Some::Modulename
```

DESCRIPTION

This is a “plug-in” class that allows Perldoc to use Pod::Text as a formatter class.

It supports the following options, which are explained in *Pod::Text*: alt, indent, loose, quotes, sentence, width

For example:

```
perldoc -o term -w indent:5 Some::Modulename
```

CAVEAT

This module may change to use a different text formatter class in the future, and this may change what options are supported.

Pod::Perldoc::ToChecker

let Perldoc check Pod for errors

SYNOPSIS

```
% perldoc -o checker SomeFile.pod
No Pod errors in SomeFile.pod
(or an error report)
```

DESCRIPTION

This is a "plug-in" class that allows Perldoc to use Pod::Simple::Checker as a "formatter" class (or if that is not available, then Pod::Checker), to check for errors in a given Pod file.

This is actually a Pod::Simple::Checker (or Pod::Checker) subclass, and inherits all its options.

SEE ALSO

Pod::Perldoc::ToMan

let Perldoc render Pod as man pages

SYNOPSIS

```
perldoc -o man Some::Modulename
```

DESCRIPTION

This is a "plug-in" class that allows Perldoc to use Pod::Man and `groff` for reading Pod pages.

The following options are supported: center, date, fixed, fixedbold, fixeditalic, fixedbolditalic, quotes, release, section

(Those options are explained in *Pod::Man*.)

For example:

```
perldoc -o man -w center:Pod Some::Modulename
```

CAVEAT

This module may change to use a different pod-to-nroff formatter class in the future, and this may change what options are supported.

SEE ALSO

Pod::Man, *Pod::Perldoc*, *Pod::Perldoc::ToNroff*

Pod::Perldoc::ToNroff

let Perldoc convert Pod to nroff

SYNOPSIS

```
perldoc -o nroff -d something.3 Some::Modulename
```

DESCRIPTION

This is a “plug-in” class that allows Perldoc to use Pod::Man as a formatter class.

The following options are supported: center, date, fixed, fixedbold, fixeditalic, fixedbolditalic, quotes, release, section

Those options are explained in *Pod::Man*.

For example:

```
perldoc -o nroff -w center:Pod -d something.3 Some::Modulename
```

CAVEAT

This module may change to use a different pod-to-nroff formatter class in the future, and this may change what options are supported.

Pod::Perldoc::ToPod

let Perldoc render Pod as ... Pod!

SYNOPSIS

```
perldoc -opod Some::Modulename
```

(That's currently the same as the following:)

```
perldoc -u Some::Modulename
```

DESCRIPTION

This is a "plug-in" class that allows Perldoc to display Pod source as itself! Pretty Zen, huh?

Currently this class works by just filtering out the non-Pod stuff from a given input file.

SEE ALSO

Pod::Perldoc

COPYRIGHT AND DISCLAIMERS

Pod::Perldoc::ToRtf

let Perldoc render Pod as RTF

SYNOPSIS

```
perldoc -o rtf Some::Modulename
```

DESCRIPTION

This is a “plug-in” class that allows Perldoc to use Pod::Simple::RTF as a formatter class.

This is actually a Pod::Simple::RTF subclass, and inherits all its options.

You have to have Pod::Simple::RTF installed (from the Pod::Simple dist), or this module won’t work.

If Perldoc is running under MSWin and uses this class as a formatter, the output will be opened with `write.exe` or whatever program is specified in the environment variable `RTFREADER`. For example, to specify that RTF files should be opened the same as they are when you double-click them, you would do `set RTFREADER=start.exe` in your `autoexec.bat`.

Handy tip: put `set PERLDOC=-ortf` in your `autoexec.bat` and that will set this class as the default formatter to run when you do `perldoc whatever`.

Pod::Perldoc::ToTerm

render Pod with terminal escapes

SYNOPSIS

```
perldoc -o term Some::Modulename
```

DESCRIPTION

This is a "plug-in" class that allows Perldoc to use Pod::Text as a formatter class.

It supports the following options, which are explained in *Pod::Text*: alt, indent, loose, quotes, sentence, width

For example:

```
perldoc -o term -w indent:5 Some::Modulename
```

PAGER FORMATTING

Depending on the platform, and because this class emits terminal escapes it will attempt to set the `-R` flag on your pager by injecting the flag into your environment variable for `less` or `more`.

On Windows and DOS, this class will not modify any environment variables.

CAVEAT

This module may change to use a different text formatter class in the future, and this may change what options are supported.

Pod::Simple

framework for parsing Pod

SYNOPSIS

```
# using an existing formatter
use Pod::Simple::XHTML;
my $parser = Pod::Simple::XHTML->new;
$parser->parse_file('path/to/file.pod');

# creating a new formatter
package Pod::Simple::SomeFormatter;
use parent qw(Pod::Simple);
sub _handle_element_start {
    my ($parser, $element_name, $attr_hash_r) = @_;
    ...
}
...
```

DESCRIPTION

Pod::Simple is a Perl library for parsing text in the Pod ("plain old documentation") markup language that is typically used for writing documentation for Perl and for Perl modules. The Pod format is explained in perlpod; the most common formatter is called `perldoc`.

Be sure to read "ENCODING" if your Pod contains non-ASCII characters.

Pod formatters can use Pod::Simple to parse Pod documents and render them into plain text, HTML, or any number of other formats. Typically, such formatters will be subclasses of Pod::Simple, and so they will inherit its methods, like `parse_file`. But note that Pod::Simple doesn't understand and properly parse Perl itself, so if you have a file which contains a Perl program that has a multi-line quoted string which has lines that look like pod, Pod::Simple will treat them as pod. This can be avoided if the file makes these into indented here documents instead.

If you're reading this document just because you have a Pod-processing subclass that you want to use, this document (plus the documentation for the subclass) is probably all you need to read.

If you're reading this document because you want to write a formatter subclass, continue reading it and then read Pod::Simple::Subclassing, and then possibly even read perlpodspec (some of which is for parser-writers, but much of which is notes to formatter-writers).

MAIN METHODS

- `$parser = _SomeClass_->new();`

  This returns a new parser object, where `SomeClass` is a subclass of Pod::Simple.

- `$parser->output_fh( *OUT );`

  This sets the filehandle that `$parser`'s output will be written to. You can pass `*STDOUT` or `*STDERR`, otherwise you should probably do something like this:

```
my $outfile = "output.txt";
open TXTOUT, ">$outfile" or die "Can't write to $outfile: $!";
$parser->output_fh(*TXTOUT);
```

  ...before you call one of the `$parser->parse__whatever_` methods.

- `$parser->output_string( \$somestring );`

  This sets the string that `$parser`'s output will be sent to, instead of any filehandle.

- `$parser->parse_file( _$some_filename_ );`

- `$parser->parse_file( *INPUT_FH );`

  This reads the Pod content of the file (or filehandle) that you specify, and processes it with that `$parser` object, according to however `$parser`'s class works, and according to whatever parser options you have set up for this `$parser` object.

- `$parser->parse_string_document( _$all_content_ );`

  This works just like `parse_file` except that it reads the Pod content not from a file, but from a string that you have already in memory.

- `$parser->parse_lines( _...@lines..._, undef );`

  This processes the lines in `@lines` (where each list item must be a defined value, and must contain exactly one line of content – so no items like `"foo\nbar"` are allowed). The final `undef` is used to indicate the end of document being parsed.

  The other `parser__whatever_` methods are meant to be called only once per `$parser` object; but `parse_lines` can be called as many times per `$parser` ob-

ject as you want, as long as the last call (and only the last call) ends with an undef value.

- `$parser->content_seen`

  This returns true only if there has been any real content seen for this document. Returns false in cases where the document contains content, but does not make use of any Pod markup.

- `_SomeClass_->filter( _$filename_ );`
- `_SomeClass_->filter( _*INPUT_FH_ );`
- `_SomeClass_->filter( _\$document_content_ );`

  This is a shortcut method for creating a new parser object, setting the output handle to STDOUT, and then processing the specified file (or filehandle, or in-memory document). This is handy for one-liners like this:

```
perl -MPod::Simple::Text -e "Pod::Simple::Text->filter('thingy.
↪pod')"
```

SECONDARY METHODS

Some of these methods might be of interest to general users, as well as of interest to formatter-writers.

Note that the general pattern here is that the accessor-methods read the attribute's value with `$value = $parser->_attribute_` and set the attribute's value with `$parser->_attribute_(_newvalue_)`. For each accessor, I typically only mention one syntax or another, based on which I think you are actually most likely to use.

- `$parser->parse_characters( _SOMEVALUE_ )`

  The Pod parser normally expects to read octets and to convert those octets to characters based on the `=encoding` declaration in the Pod source. Set this option to a true value to indicate that the Pod source is already a Perl character stream. This tells the parser to ignore any `=encoding` command and to skip all the code paths involving decoding octets.

- `$parser->no_whining( _SOMEVALUE_ )`

  If you set this attribute to a true value, you will suppress the parser's complaints about irregularities in the Pod coding. By default, this attribute's value is false, meaning that irregularities will be reported.

  Note that turning this attribute to true won't suppress one or two kinds of complaints about rarely occurring unrecoverable errors.

- `$parser->no_errata_section( _SOMEVALUE_ )`

  If you set this attribute to a true value, you will stop the parser from generating a "POD ERRORS" section at the end of the document. By default, this attribute's value is false, meaning that an errata section will be generated, as necessary.

- `$parser->complain_stderr( _SOMEVALUE_ )`

If you set this attribute to a true value, it will send reports of parsing errors to STDERR. By default, this attribute's value is false, meaning that no output is sent to STDERR.

Setting `complain_stderr` also sets `no_errata_section`.

- `$parser->source_filename`

  This returns the filename that this parser object was set to read from.

- `$parser->doc_has_started`

  This returns true if `$parser` has read from a source, and has seen Pod content in it.

- `$parser->source_dead`

  This returns true if `$parser` has read from a source, and come to the end of that source.

- `$parser->strip_verbatim_indent( _SOMEVALUE_ )`

  The perlpod spec for a Verbatim paragraph is "It should be reproduced exactly...", which means that the whitespace you've used to indent your verbatim blocks will be preserved in the output. This can be annoying for outputs such as HTML, where that whitespace will remain in front of every line. It's an unfortunate case where syntax is turned into semantics.

  If the POD you're parsing adheres to a consistent indentation policy, you can have such indentation stripped from the beginning of every line of your verbatim blocks. This method tells Pod::Simple what to strip. For two-space indents, you'd use:

```
$parser->strip_verbatim_indent('  ');
```

  For tab indents, you'd use a tab character:

```
$parser->strip_verbatim_indent("\t");
```

  If the POD is inconsistent about the indentation of verbatim blocks, but you have figured out a heuristic to determine how much a particular verbatim block is indented, you can pass a code reference instead. The code reference will be executed with one argument, an array reference of all the lines in the verbatim block, and should return the value to be stripped from each line. For example, if you decide that you're fine to use the first line of the verbatim block to set the standard for indentation of the rest of the block, you can look at the first line and return the appropriate value, like so:

```
$new->strip_verbatim_indent(sub {
    my $lines = shift;
    (my $indent = $lines->[0]) =~ s/\S.*//;
    return $indent;
});
```

  If you'd rather treat each line individually, you can do that, too, by just transforming them in-place in the code reference and returning `undef`. Say that you don't want *any* lines indented. You can do something like this:

```
$new->strip_verbatim_indent(sub {
    my $lines = shift;
    sub { s/^\s+// for @{ $lines },
    return undef;
});
```

- `$parser->expand_verbatim_tabs( _n_ )`

  Default: 8

  If after any stripping of indentation in verbatim blocks, there remain tabs, this method call indicates what to do with them. `0` means leave them as tabs, any other number indicates that each tab is to be translated so as to have tab stops every n columns.

  This is independent of other methods (except that it operates after any verbatim input stripping is done).

  Like the other methods, the input parameter is not checked for validity. `undef` or containing non-digits has the same effect as 8.

TERTIARY METHODS

- `$parser->abandon_output_fh()`

  Cancel output to the file handle. Any POD read by the `$parser` is not effected.

- `$parser->abandon_output_string()`

  Cancel output to the output string. Any POD read by the `$parser` is not effected.

- `$parser->accept_code( @codes )`

  Alias for accept_codes.

- `$parser->accept_codes( @codes )`

  Allows `$parser` to accept a list of "Formatting Codes" in perlpod. This can be used to implement user-defined codes.

- `$parser->accept_directive_as_data( @directives )`

  Allows `$parser` to accept a list of directives for data paragraphs. A directive is the label of a "Command Paragraph" in perlpod. A data paragraph is one delimited by `=begin/=for/=end` directives. This can be used to implement user-defined directives.

- `$parser->accept_directive_as_processed( @directives )`

  Allows `$parser` to accept a list of directives for processed paragraphs. A directive is the label of a "Command Paragraph" in perlpod. A processed paragraph is also known as "Ordinary Paragraph" in perlpod. This can be used to implement user-defined directives.

- `$parser->accept_directive_as_verbatim( @directives )`

  Allows `$parser` to accept a list of directives for "Verbatim Paragraph" in perlpod. A directive is the label of a "Command Paragraph" in perlpod. This can be used to implement user-defined directives.

- `$parser->accept_target( @targets )`

  Alias for accept_targets.

- `$parser->accept_target_as_text( @targets )`

  Alias for accept_targets_as_text.

- `$parser->accept_targets( @targets )`

  Accepts targets for `=begin/=for/=end` sections of the POD.

- `$parser->accept_targets_as_text( @targets )`

  Accepts targets for `=begin/=for/=end` sections that should be parsed as POD. For details, see "About Data Paragraphs" in perlpodspec.

- `$parser->any_errata_seen()`

  Used to check if any errata was seen.

  Example:

```
die "too many errors\n" if $parser->any_errata_seen();
```

- `$parser->errata_seen()`

  Returns a hash reference of all errata seen, both whines and screams. The hash reference's keys are the line number and the value is an array reference of the errors for that line.

  Example:

```
if ( $parser->any_errata_seen() ) {
   $logger->log( $parser->errata_seen() );
}
```

- `$parser->detected_encoding()`

  Return the encoding corresponding to `=encoding`, but only if the encoding was recognized and handled.

- `$parser->encoding()`

  Return encoding of the document, even if the encoding is not correctly handled.

- `$parser->parse_from_file( $source, $to )`

  Parses from `$source` file to `$to` file. Similar to "parse_from_file" in Pod::Parser.

- `$parser->scream( @error_messages )`

  Log an error that can't be ignored.

- `$parser->unaccept_code( @codes )`

  Alias for unaccept_codes.

- `$parser->unaccept_codes( @codes )`

  Removes `@codes` as valid codes for the parse.

- `$parser->unaccept_directive( @directives )`

  Alias for unaccept_directives.

- `$parser->unaccept_directives( @directives )`

  Removes `@directives` as valid directives for the parse.

- `$parser->unaccept_target( @targets )`

  Alias for unaccept_targets.

- `$parser->unaccept_targets( @targets )`

  Removes `@targets` as valid targets for the parse.

- `$parser->version_report()`

  Returns a string describing the version.

- `$parser->whine( @error_messages )`

  Log an error unless `$parser->no_whining( TRUE );`.

ENCODING

The Pod::Simple parser expects to read **octets**. The parser will decode the octets into Perl's internal character string representation using the value of the `=encoding` declaration in the POD source.

If the POD source does not include an `=encoding` declaration, the parser will attempt to guess the encoding (selecting one of UTF-8 or CP 1252) by examining the first non-ASCII bytes and applying the heuristic described in perlpodspec. (If the POD source contains only ASCII bytes, the encoding is assumed to be ASCII.)

If you set the `parse_characters` option to a true value the parser will expect characters rather than octets; will ignore any `=encoding`; and will make no attempt to decode the input.

Modules

- `Pod::Simple::Checker` - check the Pod syntax of a document
- `Pod::Simple::Debug` - put Pod::Simple into trace/debug mode
- `Pod::Simple::DumpAsText` - dump Pod-parsing events as text
- `Pod::Simple::DumpAsXML` - turn Pod into XML
- `Pod::Simple::HTML` - convert Pod to HTML
- `Pod::Simple::HTMLBatch` - convert several Pod files to several HTML files
- `Pod::Simple::JustPod` - just the Pod, the whole Pod, and nothing but the Pod
- `Pod::Simple::LinkSection` - represent "section" attributes of L codes
- `Pod::Simple::Methody` - turn Pod::Simple events into method calls
- `Pod::Simple::PullParser` - a pull-parser interface to parsing Pod
- `Pod::Simple::PullParserEndToken` - end-tokens from Pod::Simple::PullParser
- `Pod::Simple::PullParserStartToken` - start-tokens from Pod::Simple::PullParser

- `Pod::Simple::PullParserTextToken` - text-tokens from Pod::Simple::PullParser
- `Pod::Simple::PullParserToken` - tokens from Pod::Simple::PullParser
- `Pod::Simple::RTF` - format Pod as RTF
- `Pod::Simple::Search` - find POD documents in directory trees
- `Pod::Simple::SimpleTree` - parse Pod into a simple parse tree
- `Pod::Simple::Text` - format Pod as plaintext
- `Pod::Simple::TextContent` - get the text content of Pod
- `Pod::Simple::XHTML` - format Pod as validating XHTML
- `Pod::Simple::XMLOutStream` - turn Pod into XML

Pod::Simple::Checker

check the Pod syntax of a document

SYNOPSIS

```
perl -MPod::Simple::Checker -e \
 "exit Pod::Simple::Checker->filter(shift)->any_errata_seen" \
 thingy.pod
```

DESCRIPTION

This class is for checking the syntactic validity of Pod. It works by basically acting like a simple-minded version of *Pod::Simple::Text* that formats only the "Pod Errors" section (if Pod::Simple even generates one for the given document).

This is a subclass of *Pod::Simple* and inherits all its methods.

SEE ALSO

Pod::Simple, *Pod::Simple::Text*, *Pod::Checker*

```
use Pod::Simple::Debug (5);  # or some integer
```

Or:

```
my $debuglevel;
use Pod::Simple::Debug (\$debuglevel, 0);
...some stuff that uses Pod::Simple to do stuff, but which
 you don't want debug output from...

$debug_level = 4;
...some stuff that uses Pod::Simple to do stuff, but which
 you DO want debug output from...

$debug_level = 0;
```

DESCRIPTION

This is an internal module for controlling the debug level (a.k.a. trace level) of Pod::Simple. This is of interest only to Pod::Simple developers.

CAVEATS

Note that you should load this module *before* loading Pod::Simple (or any Pod::Simple-based class). If you try loading Pod::Simple::Debug after &Pod::Simple::DEBUG is already defined, Pod::Simple::Debug will throw a fatal error to the effect that "It's too late to call Pod::Simple::Debug".

Note that the `use Pod::Simple::Debug (\$x, _somenum_)` mode will make Pod::Simple (et al) run rather slower, since &Pod::Simple::DEBUG won't be a constant sub anymore, and so Pod::Simple (et al) won't compile with constant-folding.

GUTS

Doing this:

```
use Pod::Simple::Debug (5);  # or some integer
```

is basically equivalent to:

```
BEGIN { sub Pod::Simple::DEBUG () {5} }  # or some integer
use Pod::Simple ();
```

And this:

```
use Pod::Simple::Debug (\$debug_level,0);  # or some integer
```

is basically equivalent to this:

```
my $debug_level;
BEGIN { $debug_level = 0 }
BEGIN { sub Pod::Simple::DEBUG () { $debug_level }
use Pod::Simple ();
```

Pod::Simple::DumpAsText

dump Pod-parsing events as text

SYNOPSIS

```
perl -MPod::Simple::DumpAsText -e \
 "exit Pod::Simple::DumpAsText->filter(shift)->any_errata_seen" \
 thingy.pod
```

DESCRIPTION

This class is for dumping, as text, the events gotten from parsing a Pod document. This class is of interest to people writing Pod formatters based on Pod::Simple. It is useful for seeing exactly what events you get out of some Pod that you feed in.

This is a subclass of *Pod::Simple* and inherits all its methods.

Pod::Simple::DumpAsXML

turn Pod into XML

SYNOPSIS

```
perl -MPod::Simple::DumpAsXML -e \
 "exit Pod::Simple::DumpAsXML->filter(shift)->any_errata_seen" \
 thingy.pod
```

DESCRIPTION

Pod::Simple::DumpAsXML is a subclass of *Pod::Simple* that parses Pod and turns it into indented and wrapped XML. This class is of interest to people writing Pod formatters based on Pod::Simple.

Pod::Simple::DumpAsXML inherits methods from *Pod::Simple*.

SEE ALSO

Pod::Simple::XMLOutStream is rather like this class. Pod::Simple::XMLOutStream's output is space-padded in a way that's better for sending to an XML processor (that is, it has no ignorable whitespace). But Pod::Simple::DumpAsXML's output is much more human-readable, being (more-or-less) one token per line, with line-wrapping.

Pod::Simple::DumpAsText is rather like this class, except that it doesn't dump with XML syntax. Try them and see which one you like best!

Pod::Simple, *Pod::Simple::DumpAsXML*

The older libraries Pod::PXML, Pod::XML, Pod::SAX

Pod::Simple::HTML

convert Pod to HTML

SYNOPSIS

```
perl -MPod::Simple::HTML -e Pod::Simple::HTML::go thingy.pod
```

DESCRIPTION

This class is for making an HTML rendering of a Pod document.

This is a subclass of *Pod::Simple::PullParser* and inherits all its methods (and options).

Note that if you want to do a batch conversion of a lot of Pod documents to HTML, you should see the module *Pod::Simple::HTMLBatch*.

CALLING FROM THE COMMAND LINE

TODO

```
perl -MPod::Simple::HTML -e Pod::Simple::HTML::go Thing.pod Thing.
 ↪html
```

CALLING FROM PERL

Minimal code

```
use Pod::Simple::HTML;
my $p = Pod::Simple::HTML->new;
$p->output_string(\my $html);
$p->parse_file('path/to/Module/Name.pm');
open my $out, '>', 'out.html' or die "Cannot open 'out.html': $!\n";
print $out $html;
```

More detailed example

```
use Pod::Simple::HTML;
```

Set the content type:

```
$Pod::Simple::HTML::Content_decl =  q{<meta http-equiv="Content-Type
 ↪" content="text/html; charset=UTF-8" >};

my $p = Pod::Simple::HTML->new;
```

Include a single javascript source:

```
$p->html_javascript('http://abc.com/a.js');
```

Or insert multiple javascript source in the header (or for that matter include anything, thought this is not recommended)

```
$p->html_javascript('
    <script type="text/javascript" src="http://abc.com/b.js"></
↪script>
    <script type="text/javascript" src="http://abc.com/c.js"></
↪script>');
```

Include a single css source in the header:

```
$p->html_css('/style.css');
```

or insert multiple css sources:

```
$p->html_css('
    <link rel="stylesheet" type="text/css" title="pod_stylesheet"␣
↪href="http://remote.server.com/jquery.css">
    <link rel="stylesheet" type="text/css" title="pod_stylesheet"␣
↪href="/style.css">');
```

Tell the parser where should the output go. In this case it will be placed in the $html variable:

```
my $html;
$p->output_string(\$html);
```

Parse and process a file with pod in it:

```
$p->parse_file('path/to/Module/Name.pm');
```

METHODS

TODO all (most?) accessorized methods

The following variables need to be set **before** the call to the ->new constructor.

Set the string that is included before the opening <html> tag:

```
$Pod::Simple::HTML::Doctype_decl = qq{<!DOCTYPE HTML PUBLIC "-//W3C/
↪/DTD HTML 4.01 Transitional//EN"
  "http://www.w3.org/TR/html4/loose.dtd">\n};
```

Set the content-type in the HTML head: (defaults to ISO-8859-1)

```
$Pod::Simple::HTML::Content_decl =  q{<meta http-equiv="Content-Type
↪" content="text/html; charset=UTF-8" >};
```

Set the value that will be embedded in the opening tags of F, C tags and verbatim text. F maps to , C maps to <code>, Verbatim text maps to <pre> (Computerese defaults to “”)

```
$Pod::Simple::HTML::Computerese =  ' class="some_class_name'';
```

html_css

html_javascript

title_prefix

title_postfix

html_header_before_title

This includes everything before the <title> opening tag including the Document type and including the opening <title> tag. The following call will set it to be a simple HTML file:

```
$p->html_header_before_title('<html><head><title>');
```

top_anchor

By default Pod::Simple::HTML adds a dummy anchor at the top of the HTML. You can change it by calling

```
$p->top_anchor('<a name="zz" >');
```

html_h_level

Normally =head1 will become <h1>, =head2 will become <h2> etc. Using the html_h_level method will change these levels setting the h level of =head1 tags:

```
$p->html_h_level(3);
```

Will make sure that =head1 will become <h3> and =head2 will become <h4> etc...

index

Set it to some true value if you want to have an index (in reality a table of contents) to be added at the top of the generated HTML.

```
$p->index(1);
```

html_header_after_title

Includes the closing tag of </title> and through the rest of the head till the opening of the body

```
$p->html_header_after_title('</title>...</head><body id="my_id">');
```

html_footer

The very end of the document:

```
$p->html_footer( qq[\n<!-- end doc -->\n\n</body></html>\n] );
```

SUBCLASSING

Can use any of the methods described above but for further customization one needs to override some of the methods:

```
package My::Pod;
use strict;
use warnings;

use base 'Pod::Simple::HTML';

# needs to return a URL string such
# http://some.other.com/page.html
# #anchor_in_the_same_file
# /internal/ref.html
sub do_pod_link {
  # My::Pod object and Pod::Simple::PullParserStartToken object
  my ($self, $link) = @_;

  say $link->tagname;          # will be L for links
  say $link->attr('to');       #
  say $link->attr('type');     # will be 'pod' always
  say $link->attr('section');

  # Links local to our web site
  if ($link->tagname eq 'L' and $link->attr('type') eq 'pod') {
    my $to = $link->attr('to');
    if ($to =~ /^Padre::/) {
        $to =~ s{::}{/}g;
        return "/docs/Padre/$to.html";
    }
  }

  # all other links are generated by the parent class
  my $ret = $self->SUPER::do_pod_link($link);
  return $ret;
}

1;
```

Meanwhile in script.pl:

```
use My::Pod;

my $p = My::Pod->new;

my $html;
$p->output_string(\$html);
```

(continues on next page)

(continued from previous page)

```
$p->parse_file('path/to/Module/Name.pm');
open my $out, '>', 'out.html' or die;
print $out $html;
```

TODO

maybe override do_beginning do_end

Pod::Simple::HTMLBatch

convert several Pod files to several HTML files

SYNOPSIS

```
perl -MPod::Simple::HTMLBatch -e 'Pod::Simple::HTMLBatch::go' in out
```

DESCRIPTION

This module is used for running batch-conversions of a lot of HTML documents

This class is NOT a subclass of Pod::Simple::HTML (nor of bad old Pod::Html) – although it uses Pod::Simple::HTML for doing the conversion of each document.

The normal use of this class is like so:

```
use Pod::Simple::HTMLBatch;
my $batchconv = Pod::Simple::HTMLBatch->new;
$batchconv->some_option( some_value );
$batchconv->some_other_option( some_other_value );
$batchconv->batch_convert( \@search_dirs, $output_dir );
```

FROM THE COMMAND LINE

Note that this class also provides (but does not export) the function Pod::Simple::HTMLBatch::go. This is basically just a shortcut for `Pod::Simple::HTMLBatch->batch_convert(@ARGV)`. It's meant to be handy for calling from the command line.

However, the shortcut requires that you specify exactly two command-line arguments, `indirs` and `outdir`.

Example:

```
% mkdir out_html
% perl -MPod::Simple::HTMLBatch -e Pod::Simple::HTMLBatch::go @INC␣
↪out_html
    (to convert the pod from Perl's @INC
     files under the directory ./out_html)
```

(Note that the command line there contains a literal atsign-I-N-C. This is handled as a special case by batch_convert, in order to save you having to enter the odd-looking "" as the first command-line parameter when you mean "just use whatever's in @INC".)

Example:

```
% mkdir ../seekrut
% chmod og-rx ../seekrut
% perl -MPod::Simple::HTMLBatch -e Pod::Simple::HTMLBatch::go . ../
↪seekrut
    (to convert the pod under the current dir into HTML
     files under the directory ./seekrut)
```

Example:

```
% perl -MPod::Simple::HTMLBatch -e Pod::Simple::HTMLBatch::go␣
↪happydocs .
    (to convert all pod from happydocs into the current directory)
```

MAIN METHODS

- $batchconv = Pod::Simple::HTMLBatch->new;

  This creates a new batch converter. The method doesn't take parameters. To change the converter's attributes, use the "ACCESSOR METHODS" below.

- $batchconv->batch_convert(*indirs*, *outdir*);

  This searches the directories given in *indirs* and writes HTML files for each of these to a corresponding directory in *outdir*. The directory *outdir* must exist.

- $batchconv->batch_convert(undef , ...);

- $batchconv->batch_convert(q{@INC}, ...);

  These two values for *indirs* specify that the normal Perl @INC

- $batchconv->batch_convert(\@dirs , ...);

  This specifies that the input directories are the items in the arrayref `\@dirs`.

- $batchconv->batch_convert("somedir" , ...);

  This specifies that the director "somedir" is the input. (This can be an absolute or relative path, it doesn't matter.)

  A common value you might want would be just "." for the current directory:

  ```
  $batchconv->batch_convert( "." , ...);
  ```

- $batchconv->batch_convert('somedir:someother:also' , ...);

  This specifies that you want the dirs "somedir", "someother", and "also" scanned, just as if you'd passed the arrayref `[qw( somedir someother also)]`. Note that a ":"-separator is normal under Unix, but Under MSWin, you'll need `'somedir;someother;also'` instead, since the pathsep on MSWin is ";" instead of ":". (And *that* is because ":" often comes up in paths, like `"c:/perl/lib"`.)

  (Exactly what separator character should be used, is gotten from `$Config::Config{'path_sep'}`, via the *Config* module.)

- $batchconv->batch_convert(... , undef);

  This specifies that you want the HTML output to go into the current directory.

  (Note that a missing or undefined value means a different thing in the first slot than in the second. That's so that `batch_convert()` with no arguments (or undef arguments) means "go from @INC, into the current directory.)

- $batchconv->batch_convert(... , 'somedir');

  This specifies that you want the HTML output to go into the directory 'somedir'. (This can be an absolute or relative path, it doesn't matter.)

Note that you can also call `batch_convert` as a class method, like so:

```
Pod::Simple::HTMLBatch->batch_convert( ... );
```

That is just short for this:

```
Pod::Simple::HTMLBatch-> new-> batch_convert(...);
```

That is, it runs a conversion with default options, for whatever inputdirs and output dir you specify.

ACCESSOR METHODS

The following are all accessor methods – that is, they don't do anything on their own, but just alter the contents of the conversion object, which comprises the options for this particular batch conversion.

We show the "put" form of the accessors below (i.e., the syntax you use for setting the accessor to a specific value). But you can also call each method with no parameters to get its current value. For example, `$self->contents_file()` returns the current value of the contents_file attribute.

- $batchconv->verbose(*nonnegative_integer*);

  This controls how verbose to be during batch conversion, as far as notes to STDOUT (or whatever is `select`'d) about how the conversion is going. If 0, no progress information is printed. If 1 (the default value), some progress information is printed. Higher values print more information.

- $batchconv->index(*true-or-false*);

  This controls whether or not each HTML page is liable to have a little table of contents at the top (which we call an "index" for historical reasons). This is true by default.

- $batchconv->contents_file(*filename*);

  If set, should be the name of a file (in the output directory) to write the HTML index to. The default value is "index.html". If you set this to a false value, no contents file will be written.

- $batchconv->contents_page_start(*HTML_string*);

  This specifies what string should be put at the beginning of the contents page. The default is a string more or less like this:

  ```
  <html>
  <head><title>Perl Documentation</title></head>
  <body class='contentspage'>
  <h1>Perl Documentation</h1>
  ```

- $batchconv->contents_page_end(*HTML_string*);

  This specifies what string should be put at the end of the contents page. The default is a string more or less like this:

```
<p class='contentsfooty'>Generated by
Pod::Simple::HTMLBatch v3.01 under Perl v5.008
<br >At Fri May 14 22:26:42 2004 GMT,
which is Fri May 14 14:26:42 2004 local time.</p>
```

- $batchconv->add_css($url);

  TODO

- $batchconv->add_javascript($url);

  TODO

- $batchconv->css_flurry(*true-or-false*);

  If true (the default value), we autogenerate some CSS files in the output directory, and set our HTML files to use those. TODO: continue

- $batchconv->javascript_flurry(*true-or-false*);

  If true (the default value), we autogenerate a JavaScript in the output directory, and set our HTML files to use it. Currently, the JavaScript is used only to get the browser to remember what stylesheet it prefers. TODO: continue

- $batchconv->no_contents_links(*true-or-false*);

  TODO

- $batchconv->html_render_class(*classname*);

  This sets what class is used for rendering the files. The default is "Pod::Simple::HTML". If you set it to something else, it should probably be a subclass of Pod::Simple::HTML, and you should `require` or `use` that class so that's it's loaded before Pod::Simple::HTMLBatch tries loading it.

- $batchconv->search_class(*classname*);

  This sets what class is used for searching for the files. The default is "Pod::Simple::Search". If you set it to something else, it should probably be a subclass of Pod::Simple::Search, and you should `require` or `use` that class so that's it's loaded before Pod::Simple::HTMLBatch tries loading it.

NOTES ON CUSTOMIZATION

TODO

```
call add_css($someurl) to add stylesheet as alternate
call add_css($someurl,1) to add as primary stylesheet

call add_javascript

subclass Pod::Simple::HTML and set $batchconv->html_render_class to
  that classname
and maybe override
  $page->batch_mode_page_object_init($self, $module, $infile,
↪$outfile, $depth)
```

(continues on next page)

(continued from previous page)

```
or maybe override
  $batchconv->batch_mode_page_object_init($page, $module, $infile,
↪$outfile, $depth)
subclass Pod::Simple::Search and set $batchconv->search_class to
  that classname
```

Pod::Simple::JustPod

just the Pod, the whole Pod, and nothing but the Pod

SYNOPSIS

```
my $infile  = "mixed_code_and_pod.pm";
my $outfile = "just_the_pod.pod";
open my $fh, ">$outfile" or die "Can't write to $outfile: $!";

my $parser = Pod::Simple::JustPod->new();
$parser->output_fh($fh);
$parser->parse_file($infile);
close $fh or die "Can't close $outfile: $!";
```

DESCRIPTION

This class returns a copy of its input, translated into Perl's internal encoding (UTF-8), and with all the non-Pod lines removed.

This is a subclass of *Pod::Simple::Methody* and inherits all its methods. And since, that in turn is a subclass of *Pod::Simple*, you can use any of its methods. This means you can output to a string instead of a file, or you can parse from an array.

This class strives to return the Pod lines of the input completely unchanged, except for any necessary translation into Perl's internal encoding, and it makes no effort to return trailing spaces on lines; these likely will be stripped. If the input pod is well-formed with no warnings nor errors generated, the extracted pod should generate the same documentation when formatted by a Pod formatter as the original file does.

By default, warnings are output to STDERR

Pod::Simple::JustPod was developed by John SJ Anderson `genehack@genehack.org`, with contributions from Karl Williamson `khw@cpan.org`.

Pod::Simple::LinkSection

represent "section" attributes of L codes

SYNOPSIS

```
# a long story
```

DESCRIPTION

This class is not of interest to general users.

Pod::Simple uses this class for representing the value of the "section" attribute of "L" start-element events. Most applications can just use the normal stringification of objects of this class; they stringify to just the text content of the section, such as "foo" for `L<Stuff/foo>`, and "bar" for `L<Stuff/bI<ar>>`.

However, anyone particularly interested in getting the full value of the treelet, can just traverse the content of the treeleet @$treelet_object. To wit:

```
  % perl -MData::Dumper -e
    "use base qw(Pod::Simple::Methody);
     sub start_L { print Dumper($_[1]{'section'} ) }
     __PACKAGE__->new->parse_string_document('=head1 L<Foo/bI<ar>
↪baz>>')
    "
Output:
  $VAR1 = bless( [
                   '',
                   {},
                   'b',
                   bless( [
                            'I',
```

(continues on next page)

(continued from previous page)

```
                                {},
                                'ar'
                              ], 'Pod::Simple::LinkSection' ),
                    'baz'
                  ], 'Pod::Simple::LinkSection' );
```

But stringify it and you get just the text content:

```
  % perl -MData::Dumper -e
    "use base qw(Pod::Simple::Methody);
     sub start_L { print Dumper( '' . $_[1]{'section'} ) }
     __PACKAGE__->new->parse_string_document('=head1 L<Foo/bI<ar>
↪baz>>')
    "
Output:
  $VAR1 = 'barbaz';
```

Pod::Simple::Methody

turn Pod::Simple events into method calls

SYNOPSIS

```
require 5;
use strict;
package SomePodFormatter;
use base qw(Pod::Simple::Methody);

sub handle_text {
  my($self, $text) = @_;
  ...
}

sub start_head1 {
  my($self, $attrs) = @_;
  ...
}
sub end_head1 {
  my($self) = @_;
  ...
}
```

...and start_/end_ methods for whatever other events you want to catch.

DESCRIPTION

This class is of interest to people writing Pod formatters based on Pod::Simple.

This class (which is very small – read the source) overrides Pod::Simple's _handle_element_start, _handle_text, and _handle_element_end methods so that parser events are turned into method calls. (Otherwise, this is a subclass of *Pod::Simple* and inherits all its methods.)

You can use this class as the base class for a Pod formatter/processor.

METHOD CALLING

When Pod::Simple sees a "=head1 Hi there", for example, it basically does this:

```
$parser->_handle_element_start( "head1", \%attributes );
$parser->_handle_text( "Hi there" );
$parser->_handle_element_end( "head1" );
```

But if you subclass Pod::Simple::Methody, it will instead do this when it sees a "=head1 Hi there":

```
$parser->start_head1( \%attributes ) if $parser->can('start_head1');
$parser->handle_text( "Hi there" )   if $parser->can('handle_text');
$parser->end_head1()                 if $parser->can('end_head1');
```

If Pod::Simple sends an event where the element name has a dash, period, or colon, the corresponding method name will have a underscore in its place. For example, "foo.bar:baz" becomes start_foo_bar_baz and end_foo_bar_baz.

See the source for Pod::Simple::Text for an example of using this class.

Pod::Simple::PullParser

a pull-parser interface to parsing Pod

SYNOPSIS

```
my $parser = SomePodProcessor->new;
$parser->set_source( "whatever.pod" );
$parser->run;
```

Or:

```
my $parser = SomePodProcessor->new;
$parser->set_source( $some_filehandle_object );
$parser->run;
```

Or:

```
my $parser = SomePodProcessor->new;
$parser->set_source( \$document_source );
$parser->run;
```

Or:

```
my $parser = SomePodProcessor->new;
$parser->set_source( \@document_lines );
$parser->run;
```

And elsewhere:

```
require 5;
package SomePodProcessor;
use strict;
use base qw(Pod::Simple::PullParser);

sub run {
  my $self = shift;
 Token:
  while(my $token = $self->get_token) {
    ...process each token...
  }
}
```

DESCRIPTION

This class is for using Pod::Simple to build a Pod processor – but one that uses an interface based on a stream of token objects, instead of based on events.

This is a subclass of *Pod::Simple* and inherits all its methods.

A subclass of Pod::Simple::PullParser should define a `run` method that calls `$token = $parser->get_token` to pull tokens.

See the source for Pod::Simple::RTF for an example of a formatter that uses Pod::Simple::PullParser.

METHODS

- my $token = $parser->get_token

  This returns the next token object (which will be of a subclass of *Pod::Simple::PullParserToken*), or undef if the parser-stream has hit the end of the document.

- $parser->unget_token($token)
- $parser->unget_token($token1, $token2, ...)

  This restores the token object(s) to the front of the parser stream.

The source has to be set before you can parse anything. The lowest-level way is to call `set_source`:

- $parser->set_source($filename)
- $parser->set_source($filehandle_object)
- $parser->set_source(\$document_source)
- $parser->set_source(\@document_lines)

Or you can call these methods, which Pod::Simple::PullParser has defined to work just like Pod::Simple's same-named methods:

- $parser->parse_file(...)
- $parser->parse_string_document(...)
- $parser->filter(...)
- $parser->parse_from_file(...)

For those to work, the Pod-processing subclass of Pod::Simple::PullParser has to have defined a $parser->run method – so it is advised that all Pod::Simple::PullParser subclasses do so. See the Synopsis above, or the source for Pod::Simple::RTF.

Authors of formatter subclasses might find these methods useful to call on a parser object that you haven't started pulling tokens from yet:

- my $title_string = $parser->get_title

  This tries to get the title string out of $parser, by getting some tokens, and scanning them for the title, and then ungetting them so that you can process the token-stream from the beginning.

  For example, suppose you have a document that starts out:

```
=head1 NAME

Hoo::Boy::Wowza -- Stuff B<wow> yeah!
```

  $parser->get_title on that document will return "Hoo::Boy::Wowza – Stuff wow yeah!". If the document starts with:

```
=head1 Name

Hoo::Boy::W00t -- Stuff B<w00t> yeah!
```

Then you'll need to pass the nocase option in order to recognize "Name":

```
$parser->get_title(nocase => 1);
```

In cases where get_title can't find the title, it will return empty-string ("").

- my $title_string = $parser->get_short_title

  This is just like get_title, except that it returns just the modulename, if the title seems to be of the form "SomeModuleName – description".

  For example, suppose you have a document that starts out:

```
=head1 NAME

Hoo::Boy::Wowza -- Stuff B<wow> yeah!
```

  then $parser->get_short_title on that document will return "Hoo::Boy::Wowza".

  But if the document starts out:

```
=head1 NAME

Hooboy, stuff B<wow> yeah!
```

  then $parser->get_short_title on that document will return "Hooboy, stuff wow yeah!". If the document starts with:

```
=head1 Name

Hoo::Boy::W00t -- Stuff B<w00t> yeah!
```

  Then you'll need to pass the nocase option in order to recognize "Name":

```
$parser->get_short_title(nocase => 1);
```

  If the title can't be found, then get_short_title returns empty-string ("").

- $author_name = $parser->get_author

  This works like get_title except that it returns the contents of the "=head1 AUTHOR\n\nParagraph...\n" section, assuming that that section isn't terribly long. To recognize a "=head1 Author\n\nParagraph\n" section, pass the nocase option:

```
$parser->get_author(nocase => 1);
```

  (This method tolerates "AUTHORS" instead of "AUTHOR" too.)

- $description_name = $parser->get_description

  This works like get_title except that it returns the contents of the "=head1 DESCRIPTION\n\nParagraph...\n" section, assuming that that section isn't terribly long. To

recognize a "=head1 Description\n\nParagraph\n" section, pass the `nocase` option:

```
$parser->get_description(nocase => 1);
```

- $version_block = $parser->get_version

  This works like get_title except that it returns the contents of the "=head1 VERSION\n\n[BIG BLOCK]\n" block. Note that this does NOT return the module's `$VERSION`!! To recognize a "=head1 Version\n\n[BIG BLOCK]\n" section, pass the `nocase` option:

```
$parser->get_version(nocase => 1);
```

NOTE

You don't actually *have* to define a `run` method. If you're writing a Pod-formatter class, you should define a `run` just so that users can call `parse_file` etc, but you don't *have* to.

And if you're not writing a formatter class, but are instead just writing a program that does something simple with a Pod::PullParser object (and not an object of a subclass), then there's no reason to bother subclassing to add a `run` method.

Pod::Simple::PullParserEndToken

end-tokens from Pod::Simple::PullParser

SYNOPSIS

(See *Pod::Simple::PullParser*)

DESCRIPTION

When you do $parser->get_token on a *Pod::Simple::PullParser*, you might get an object of this class.

This is a subclass of *Pod::Simple::PullParserToken* and inherits all its methods, and adds these methods:

- $token->tagname

  This returns the tagname for this end-token object. For example, parsing a "=head1 ..." line will give you a start-token with the tagname of "head1", token(s) for its content, and then an end-token with the tagname of "head1".

- $token->tagname(*somestring*)

  This changes the tagname for this end-token object. You probably won't need to do this.

- $token->tag(...)

  A shortcut for $token->tagname(...)

- $token->is_tag(*somestring*) or $token->is_tagname(*somestring*)

  These are shortcuts for `$token->tag() eq _somestring_`

You're unlikely to ever need to construct an object of this class for yourself, but if you want to, call `Pod::Simple::PullParserEndToken->new( _tagname_ )`

Pod::Simple::PullParserStartToken

start-tokens from Pod::Simple::PullParser

SYNOPSIS

(See *Pod::Simple::PullParser*)

DESCRIPTION

When you do $parser->get_token on a *Pod::Simple::PullParser* object, you might get an object of this class.

This is a subclass of *Pod::Simple::PullParserToken* and inherits all its methods, and adds these methods:

- $token->tagname

This returns the tagname for this start-token object. For example, parsing a "=head1 ..." line will give you a start-token with the tagname of "head1", token(s) for its content, and then an end-token with the tagname of "head1".

- $token->tagname(*somestring*)

  This changes the tagname for this start-token object. You probably won't need to do this.

- $token->tag(...)

  A shortcut for $token->tagname(...)

- $token->is_tag(*somestring*) or $token->is_tagname(*somestring*)

  These are shortcuts for `$token->tag() eq _somestring_`

- $token->attr(*attrname*)

  This returns the value of the *attrname* attribute for this start-token object, or undef.

  For example, parsing a L<Foo/"Bar"> link will produce a start-token with a "to" attribute with the value "Foo", a "type" attribute with the value "pod", and a "section" attribute with the value "Bar".

- $token->attr(*attrname*, *newvalue*)

  This sets the *attrname* attribute for this start-token object to *newvalue*. You probably won't need to do this.

- $token->attr_hash

  This returns the hashref that is the attribute set for this start-token. This is useful if (for example) you want to ask what all the attributes are – you can just do `keys %{$token->attr_hash}`

You're unlikely to ever need to construct an object of this class for yourself, but if you want to, call `Pod::Simple::PullParserStartToken->new( _tagname_, _attrhash_ )`

Pod::Simple::PullParserTextToken

text-tokens from Pod::Simple::PullParser

SYNOPSIS

(See *Pod::Simple::PullParser*)

DESCRIPTION

When you do $parser->get_token on a *Pod::Simple::PullParser*, you might get an object of this class.

This is a subclass of *Pod::Simple::PullParserToken* and inherits all its methods, and adds these methods:

- $token->text

  This returns the text that this token holds. For example, parsing C<foo> will return a C start-token, a text-token, and a C end-token. And if you want to get the "foo" out of the text-token, call `$token->text`

- $token->text(*somestring*)

  This changes the string that this token holds. You probably won't need to do this.

- $token->text_r()

This returns a scalar reference to the string that this token holds. This can be useful if you don't want to memory-copy the potentially large text value (well, as large as a paragraph or a verbatim block) as calling $token->text would do.

Or, if you want to alter the value, you can even do things like this:

```
for ( ${  $token->text_r  } ) {  # Aliases it with $_ !!

  s/ The / the /g; # just for example

  if( 'A' eq chr(65) ) {  # (if in an ASCII world)
    tr/\xA0/ /;
    tr/\xAD//d;
  }

  ...or however you want to alter the value...
  (Note that starting with Perl v5.8, you can use, e.g.,

      my $nbsp = chr utf8::unicode_to_native(0xA0);
      s/$nbsp/ /g;

  to handle the above regardless if it's an ASCII world or not)
}
```

You're unlikely to ever need to construct an object of this class for yourself, but if you want to, call `Pod::Simple::PullParserTextToken->new( _text_ )`

Pod::Simple::PullParserToken

tokens from Pod::Simple::PullParser

SYNOPSIS

Given a $parser that's an object of class Pod::Simple::PullParser (or a subclass)...

```
while(my $token = $parser->get_token) {
  $DEBUG and print STDERR "Token: ", $token->dump, "\n";
  if($token->is_start) {
    ...access $token->tagname, $token->attr, etc...

  } elsif($token->is_text) {
    ...access $token->text, $token->text_r, etc...

  } elsif($token->is_end) {
    ...access $token->tagname...

  }
}
```

(Also see *Pod::Simple::PullParser*)

DESCRIPTION

When you do $parser->get_token on a *Pod::Simple::PullParser*, you should get an object of a subclass of Pod::Simple::PullParserToken.

Subclasses will add methods, and will also inherit these methods:

- $token->type

  This returns the type of the token. This will be either the string "start", the string "text", or the string "end".

  Once you know what the type of an object is, you then know what subclass it belongs to, and therefore what methods it supports.

  Yes, you could probably do the same thing with code like $token->isa('Pod::Simple::PullParserEndToken'), but that's not so pretty as using just $token->type, or even the following shortcuts:

- $token->is_start

  This is a shortcut for `$token->type() eq "start"`

- $token->is_text

  This is a shortcut for `$token->type() eq "text"`

- $token->is_end

  This is a shortcut for `$token->type() eq "end"`

- $token->dump

  This returns a handy stringified value of this object. This is useful for debugging, as in:

```
while(my $token = $parser->get_token) {
  $DEBUG and print STDERR "Token: ", $token->dump, "\n";
  ...
}
```

SEE ALSO

My subclasses: *Pod::Simple::PullParserStartToken*, *Pod::Simple::PullParserTextToken*, and *Pod::Simple::PullParserEndToken*.

Pod::Simple::RTF

format Pod as RTF

SYNOPSIS

```
perl -MPod::Simple::RTF -e \
 "exit Pod::Simple::RTF->filter(shift)->any_errata_seen" \
 thingy.pod > thingy.rtf
```

DESCRIPTION

This class is a formatter that takes Pod and renders it as RTF, good for viewing/printing in MSWord, WordPad/write.exe, TextEdit, etc.

This is a subclass of *Pod::Simple* and inherits all its methods.

FORMAT CONTROL ATTRIBUTES

You can set these attributes on the parser object before you call `parse_file` (or a similar method) on it:

- $parser->head1_halfpoint_size(*halfpoint_integer*);
- $parser->head2_halfpoint_size(*halfpoint_integer*);
- $parser->head3_halfpoint_size(*halfpoint_integer*);
- $parser->head4_halfpoint_size(*halfpoint_integer*);

  These methods set the size (in half-points, like 52 for 26-point) that these heading levels will appear as.

- $parser->codeblock_halfpoint_size(*halfpoint_integer*);

  This method sets the size (in half-points, like 21 for 10.5-point) that codeblocks ("verbatim sections") will appear as.

- $parser->header_halfpoint_size(*halfpoint_integer*);

  This method sets the size (in half-points, like 15 for 7.5-point) that the header on each page will appear in. The header is usually just "*modulename* p. *pagenumber*".

- $parser->normal_halfpoint_size(*halfpoint_integer*);

  This method sets the size (in half-points, like 26 for 13-point) that normal paragraphic text will appear in.

- $parser->no_proofing_exemptions(*true_or_false*);

  Set this value to true if you don't want the formatter to try putting a hidden code on all Perl symbols (as best as it can notice them) that labels them as being not in English, and so not worth spellchecking.

- $parser->doc_lang(*microsoft_decimal_language_code*)

  This sets the language code to tag this document as being in. By default, it is currently the value of the environment variable `RTFDEFLANG`, or if that's not set, then the value 1033 (for US English).

  Setting this appropriately is useful if you want to use the RTF to spellcheck, and/or if you want it to hyphenate right.

  Here are some notable values:

```
1033  US English
2057  UK English
3081  Australia English
4105  Canada English
1034  Spain Spanish
2058  Mexico Spanish
1031  Germany German
1036  France French
3084  Canada French
1035  Finnish
1044  Norwegian (Bokmal)
2068  Norwegian (Nynorsk)
```

If you are particularly interested in customizing this module's output even more, see the source and/or write to me.

Pod::Simple::Search

find POD documents in directory trees

SYNOPSIS

```
use Pod::Simple::Search;
my $name2path = Pod::Simple::Search->new->limit_glob('LWP::*')->
 ↪survey;
print "Looky see what I found: ",
  join(' ', sort keys %$name2path), "\n";

print "LWPUA docs = ",
  Pod::Simple::Search->new->find('LWP::UserAgent') || "?",
  "\n";
```

DESCRIPTION

Pod::Simple::Search is a class that you use for running searches for Pod files. An object of this class has several attributes (mostly options for controlling search options), and some methods for searching based on those attributes.

The way to use this class is to make a new object of this class, set any options, and then call one of the search options (probably `survey` or `find`). The sections below discuss the syntaxes for doing all that.

CONSTRUCTOR

This class provides the one constructor, called new. It takes no parameters:

```
use Pod::Simple::Search;
my $search = Pod::Simple::Search->new;
```

ACCESSORS

This class defines several methods for setting (and, occasionally, reading) the contents of an object. With two exceptions (discussed at the end of this section), these attributes are just for controlling the way searches are carried out.

Note that each of these return `$self` when you call them as `$self->_whatever(value)_`. That's so that you can chain together set-attribute calls like this:

```
my $name2path =
  Pod::Simple::Search->new
  -> inc(0) -> verbose(1) -> callback(\&blab)
  ->survey(@there);
```

...which works exactly as if you'd done this:

```
my $search = Pod::Simple::Search->new;
$search->inc(0);
$search->verbose(1);
$search->callback(\&blab);
my $name2path = $search->survey(@there);
```

- $search->inc(*true-or-false*);

  This attribute, if set to a true value, means that searches should implicitly add perl's *@INC* paths. This automatically considers paths specified in the `PERL5LIB` environment as this is prepended to *@INC* by the Perl interpreter itself. This attribute's default value is **TRUE**. If you want to search only specific directories, set $self->inc(0) before calling $inc->survey or $inc->find.

- $search->verbose(*nonnegative-number*);

  This attribute, if set to a nonzero positive value, will make searches output (via `warn`) notes about what they're doing as they do it. This option may be useful for debugging a pod-related module. This attribute's default value is zero, meaning that no `warn` messages are produced. (Setting verbose to 1 turns on some messages, and setting it to 2 turns on even more messages, i.e., makes the following search(es) even more verbose than 1 would make them.)

- $search->limit_glob(*some-glob-string*);

  This option means that you want to limit the results just to items whose podnames match the given glob/wildcard expression. For example, you might limit your search to just "LWP::*", to search only for modules starting with "LWP::*" (but not including the module "LWP" itself); or you might limit your search to "LW*" to see only modules whose (full) names begin with "LW"; or you might search for "*Find*"

to search for all modules with "Find" somewhere in their full name. (You can also use "?" in a glob expression; so "DB?" will match "DBI" and "DBD".)

- $search->callback(\&*some_routine*);

  This attribute means that every time this search sees a matching Pod file, it should call this callback routine. The routine is called with two parameters: the current file's filespec, and its pod name. (For example: `("/etc/perljunk/File/Crunk.pm", "File::Crunk")` would be in `@_`.)

  The callback routine's return value is not used for anything.

  This attribute's default value is false, meaning that no callback is called.

- $search->laborious(*true-or-false*);

  Unless you set this attribute to a true value, Pod::Search will apply Perl-specific heuristics to find the correct module PODs quickly. This attribute's default value is false. You won't normally need to set this to true.

  Specifically: Turning on this option will disable the heuristics for seeing only files with Perl-like extensions, omitting subdirectories that are numeric but do *not* match the current Perl interpreter's version ID, suppressing `site_perl` as a module hierarchy name, etc.

- $search->recurse(*true-or-false*);

  Unless you set this attribute to a false value, Pod::Search will recurse into subdirectories of the search directories.

- $search->shadows(*true-or-false*);

  Unless you set this attribute to a true value, Pod::Simple::Search will consider only the first file of a given modulename as it looks thru the specified directories; that is, with this option off, if Pod::Simple::Search has seen a `somepathdir/Foo/Bar.pm` already in this search, then it won't bother looking at a `somelaterpathdir/Foo/Bar.pm` later on in that search, because that file is merely a "shadow". But if you turn on `$self->shadows(1)`, then these "shadow" files are inspected too, and are noted in the pathname2podname return hash.

  This attribute's default value is false; and normally you won't need to turn it on.

- $search->is_case_insensitive(*true-or-false*);

  Pod::Simple::Search will by default internally make an assumption based on the underlying filesystem where the class file is found whether it is case insensitive or not.

  If it is determined to be case insensitive, during survey() it may skip pod files/modules that happen to be equal to names it's already seen, ignoring case.

  However, it's possible to have distinct files in different directories that intentionally has the same name, just differing in case, that should be reported. Hence, you may force the behavior by setting this to true or false.

- $search->limit_re(*some-regxp*);

  Setting this attribute (to a value that's a regexp) means that you want to limit the results just to items whose podnames match the given regexp. Normally this option is not needed, and the more efficient `limit_glob` attribute is used instead.

- $search->dir_prefix(*some-string-value*);

  Setting this attribute to a string value means that the searches should begin in the specified subdirectory name (like "Pod" or "File::Find", also expressible as "File/Find"). For example, the search option `$search->limit_glob("File::Find::R*")` is the same as the combination of the search options `$search->limit_re("^File::Find::R") -> dir_prefix("File::Find")`.

  Normally you don't need to know about the `dir_prefix` option, but I include it in case it might prove useful for someone somewhere.

  (Implementationally, searching with limit_glob ends up setting limit_re and usually dir_prefix.)

- $search->progress(*some-progress-object*);

  If you set a value for this attribute, the value is expected to be an object (probably of a class that you define) that has a `reach` method and a done method. This is meant for reporting progress during the search, if you don't want to use a simple callback.

  Normally you don't need to know about the `progress` option, but I include it in case it might prove useful for someone somewhere.

  While a search is in progress, the progress object's `reach` and done methods are called like this:

```
# Every time a file is being scanned for pod:
$progress->reach($count, "Scanning $file");   ++$count;

# And then at the end of the search:
$progress->done("Noted $count Pod files total");
```

  Internally, we often set this to an object of class Pod::Simple::Progress. That class is probably undocumented, but you may wish to look at its source.

- $name2path = $self->name2path;

  This attribute is not a search parameter, but is used to report the result of `survey` method, as discussed in the next section.

- $path2name = $self->path2name;

  This attribute is not a search parameter, but is used to report the result of `survey` method, as discussed in the next section.

MAIN SEARCH METHODS

Once you've actually set any options you want (if any), you can go ahead and use the following methods to search for Pod files in particular ways.

`$search->survey( @directories )`

The method `survey` searches for POD documents in a given set of files and/or directories. This runs the search according to the various options set by the accessors above. (For example, if the `inc` attribute is on, as it is by default, then the perl @INC directories are implicitly added to the list of directories (if any) that you specify.)

The return value of `survey` is two hashes:

- `name2path`

  A hash that maps from each pod-name to the filespec (like "Stuff::Thing" => "/whatever/plib/Stuff/Thing.pm")

- `path2name`

  A hash that maps from each Pod filespec to its pod-name (like "/whatever/plib/Stuff/Thing.pm" => "Stuff::Thing")

Besides saving these hashes as the hashref attributes `name2path` and `path2name`, calling this function also returns these hashrefs. In list context, the return value of `$search->survey` is the list `(\%name2path, \%path2name)`. In scalar context, the return value is `\%name2path`. Or you can just call this in void context.

Regardless of calling context, calling `survey` saves its results in its `name2path` and `path2name` attributes.

E.g., when searching in `$HOME/perl5lib`, the file `$HOME/perl5lib/MyModule.pm` would get the POD name *MyModule*, whereas `$HOME/perl5lib/Myclass/Subclass.pm` would be *Myclass::Subclass*. The name information can be used for POD translators.

Only text files containing at least one valid POD command are found.

In verbose mode, a warning is printed if shadows are found (i.e., more than one POD file with the same POD name is found, e.g. `CPAN.pm` in different directories). This usually indicates duplicate occurrences of modules in the *@INC* search path, which is occasionally inadvertent (but is often simply a case of a user's path dir having a more recent version than the system's general path dirs in general.)

The options to this argument is a list of either directories that are searched recursively, or files. (Usually you wouldn't specify files, but just dirs.) Or you can just specify an empty-list, as in $name2path; with the `inc` option on, as it is by default.

The POD names of files are the plain basenames with any Perl-like extension (.pm, .pl, .pod) stripped, and path separators replaced by `::`'s.

Calling Pod::Simple::Search->search(...) is short for Pod::Simple::Search->new->search(...). That is, a throwaway object with default attribute values is used.

`$search->simplify_name( $str )`

The method **simplify_name** is equivalent to **basename**, but also strips Perl-like extensions (.pm, .pl, .pod) and extensions like `.bat`, `.cmd` on Win32 and OS/2, or `.com` on VMS, respectively.

`$search->find( $pod )`

`$search->find( $pod, @search_dirs )`

Returns the location of a Pod file, given a Pod/module/script name (like "Foo::Bar" or "perlvar" or "perldoc"), and an idea of what files/directories to look in. It searches according to the various options set by the accessors above. (For example, if the `inc` attribute is on, as it is by default, then the perl @INC directories are implicitly added to the list of directories (if any) that you specify.)

This returns the full path of the first occurrence to the file. Package names (eg 'A::B') are automatically converted to directory names in the selected directory. Additionally, '.pm', '.pl' and '.pod' are automatically appended to the search as required. (So, for example, under Unix, "A::B" is converted to "somedir/A/B.pm", "somedir/A/B.pod", or "somedir/A/B.pl", as appropriate.)

If no such Pod file is found, this method returns undef.

If any of the given search directories contains a `pod/` subdirectory, then it is searched. (That's how we manage to find `perlfunc`, for example, which is usually in `pod/perlfunc` in most Perl dists.)

The `verbose` and `inc` attributes influence the behavior of this search; notably, `inc`, if true, adds @INC *and also $Config::Config{'scriptdir'}* to the list of directories to search.

It is common to simply say `$filename = Pod::Simple::Search-> new \ ->find("perlvar")` so that just the @INC (well, and scriptdir) directories are searched. (This happens because the `inc` attribute is true by default.)

Calling Pod::Simple::Search->find(...) is short for Pod::Simple::Search->new->find(...). That is, a throwaway object with default attribute values is used.

`$self->contains_pod( $file )`

Returns true if the supplied filename (not POD module) contains some Pod documentation.

SUPPORT

Pod::Simple::SimpleTree

parse Pod into a simple parse tree

SYNOPSIS

```
% cat ptest.pod

=head1 PIE

I like B<pie>!

% perl -MPod::Simple::SimpleTree -MData::Dumper -e \
   "print Dumper(Pod::Simple::SimpleTree->new->parse_file(shift)->
↪root)" \
   ptest.pod

$VAR1 = [
          'Document',
          { 'start_line' => 1 },
          [
            'head1',
            { 'start_line' => 1 },
            'PIE'
          ],
          [
```

(continues on next page)

(continued from previous page)

```
            'Para',
            { 'start_line' => 3 },
            'I like ',
            [
              'B',
              {},
              'pie'
            ],
            '!'
          ]
        ];
```

DESCRIPTION

This class is of interest to people writing a Pod processor/formatter.

This class takes Pod and parses it, returning a parse tree made just of arrayrefs, and hashrefs, and strings.

This is a subclass of *Pod::Simple* and inherits all its methods.

This class is inspired by XML::Parser's "Tree" parsing-style, although it doesn't use exactly the same LoL format.

METHODS

At the end of the parse, call `$parser->root` to get the tree's top node.

Tree Contents

Every element node in the parse tree is represented by an arrayref of the form: `[ _elementname_, \%attributes, _...subnodes..._ ]`. See the example tree dump in the Synopsis, above.

Every text node in the tree is represented by a simple (non-ref) string scalar. So you can test `ref($node)` to see whether you have an element node or just a text node.

The top node in the tree is `[ 'Document', \%attributes, _...subnodes..._ ]`

Pod::Simple::Text

format Pod as plaintext

SYNOPSIS

```
perl -MPod::Simple::Text -e \
 "exit Pod::Simple::Text->filter(shift)->any_errata_seen" \
 thingy.pod
```

DESCRIPTION

This class is a formatter that takes Pod and renders it as wrapped plaintext.

Its wrapping is done by *Text::Wrap*, so you can change `$Text::Wrap::columns` as you like.

This is a subclass of *Pod::Simple* and inherits all its methods.

Pod::Simple::TextContent

get the text content of Pod

SYNOPSIS

```
TODO

 perl -MPod::Simple::TextContent -e \
  "exit Pod::Simple::TextContent->filter(shift)->any_errata_seen" \
  thingy.pod
```

DESCRIPTION

This class is that parses Pod and dumps just the text content. It is mainly meant for use by the Pod::Simple test suite, but you may find some other use for it.

This is a subclass of *Pod::Simple* and inherits all its methods.

SEE ALSO

Pod::Simple::XHTML

format Pod as validating XHTML

SYNOPSIS

```
use Pod::Simple::XHTML;

my $parser = Pod::Simple::XHTML->new();

...

$parser->parse_file('path/to/file.pod');
```

DESCRIPTION

This class is a formatter that takes Pod and renders it as XHTML validating HTML.

This is a subclass of *Pod::Simple::Methody* and inherits all its methods. The implementation is entirely different than *Pod::Simple::HTML*, but it largely preserves the same interface.

Minimal code

```
use Pod::Simple::XHTML;
my $psx = Pod::Simple::XHTML->new;
$psx->output_string(\my $html);
$psx->parse_file('path/to/Module/Name.pm');
open my $out, '>', 'out.html' or die "Cannot open 'out.html': $!\n";
print $out $html;
```

You can also control the character encoding and entities. For example, if you're sure that the POD is properly encoded (using the `=encoding` command), you can prevent high-bit characters from being encoded as HTML entities and declare the output character set as UTF-8 before parsing, like so:

```
  $psx->html_charset('UTF-8');
use warnings;
  $psx->html_encode_chars(q{&<>'"});
```

METHODS

Pod::Simple::XHTML offers a number of methods that modify the format of the HTML output. Call these after creating the parser object, but before the call to `parse_file`:

```
my $parser = Pod::PseudoPod::HTML->new();
$parser->set_optional_param("value");
$parser->parse_file($file);
```

perldoc_url_prefix

In turning LFoo::Bar into http://whatever/Foo%3a%3aBar, what to put before the "Foo%3a%3aBar". The default value is "https://metacpan.org/pod/".

perldoc_url_postfix

What to put after "Foo%3a%3aBar" in the URL. This option is not set by default.

man_url_prefix

In turning `L<crontab(5)>` into http://whatever/man/1/crontab.1, what to put before the "1/crontab.1". The default value is "https://man7.org/linux/man-pages/man".

man_url_postfix

What to put after "1/crontab.1" in the URL. This option is set to ".html" by default.

title_prefix, title_postfix

What to put before and after the title in the head. The values should already be &-escaped.

html_css

```
$parser->html_css('path/to/style.css');
```

The URL or relative path of a CSS file to include. This option is not set by default.

html_javascript

The URL or relative path of a JavaScript file to pull in. This option is not set by default.

html_doctype

A document type tag for the file. This option is not set by default.

html_charset

The character set to declare in the Content-Type meta tag created by default for `html_header_tags`. Note that this option will be ignored if the value of `html_header_tags` is changed. Defaults to "ISO-8859-1".

html_header_tags

Additional arbitrary HTML tags for the header of the document. The default value is just a content type header tag:

```
<meta http-equiv="Content-Type" content="text/html; charset=ISO-
↪8859-1">
```

Add additional meta tags here, or blocks of inline CSS or JavaScript (wrapped in the appropriate tags).

html_encode_chars

A string containing all characters that should be encoded as HTML entities, specified using the regular expression character class syntax (what you find within brackets in regular expressions). This value will be passed as the second argument to the `encode_entities` function of *HTML::Entities*. If *HTML::Entities* is not installed, then any characters other than &<"> will be encoded numerically.

html_h_level

This is the level of HTML "Hn" element to which a Pod "head1" corresponds. For example, if `html_h_level` is set to 2, a head1 will produce an H2, a head2 will produce an H3, and so on.

default_title

Set a default title for the page if no title can be determined from the content. The value of this string should already be &-escaped.

force_title

Force a title for the page (don't try to determine it from the content). The value of this string should already be &-escaped.

html_header, html_footer

Set the HTML output at the beginning and end of each file. The default header includes a title, a doctype tag (if `html_doctype` is set), a content tag (customized by `html_header_tags`), a tag for a CSS file (if `html_css` is set), and a tag for a Javascript file (if `html_javascript` is set). The default footer simply closes the `html` and body tags.

The options listed above customize parts of the default header, but setting `html_header` or `html_footer` completely overrides the built-in header or footer. These may be useful if you want to use template tags instead of literal HTML headers and footers or are integrating converted POD pages in a larger website.

If you want no headers or footers output in the HTML, set these options to the empty string.

index

Whether to add a table-of-contents at the top of each page (called an index for the sake of tradition).

anchor_items

Whether to anchor every definition `=item` directive. This needs to be enabled if you want to be able to link to specific `=item` directives, which are output as `<dt>` elements. Disabled by default.

backlink

Whether to turn every =head1 directive into a link pointing to the top of the page (specifically, the opening body tag).

SUBCLASSING

If the standard options aren't enough, you may want to subclass Pod::Simple::XHMTL. These are the most likely candidates for methods you'll want to override when subclassing.

handle_text

This method handles the body of text within any element: it's the body of a paragraph, or everything between a "=begin" tag and the corresponding "=end" tag, or the text within an L entity, etc. You would want to override this if you are adding a custom element type that does more than just display formatted text. Perhaps adding a way to generate HTML tables from an extended version of POD.

So, let's say you want to add a custom element called 'foo'. In your subclass's `new` method, after calling `SUPER::new` you'd call:

```
$new->accept_targets_as_text( 'foo' );
```

Then override the `start_for` method in the subclass to check for when "$flags->{'target'}" is equal to 'foo' and set a flag that marks that you're in a foo block (maybe "$self->{'in_foo'} = 1"). Then override the `handle_text` method to check for the flag, and pass $text to your custom subroutine to construct the HTML output for 'foo' elements, something like:

```
sub handle_text {
    my ($self, $text) = @_;
    if ($self->{'in_foo'}) {
        $self->{'scratch'} .= build_foo_html($text);
        return;
    }
    $self->SUPER::handle_text($text);
}
```

handle_code

This method handles the body of text that is marked up to be code. You might for instance override this to plug in a syntax highlighter. The base implementation just escapes the text.

The callback methods `start_code` and `end_code` emits the `code` tags before and after `handle_code` is invoked, so you might want to override these together with `handle_code` if this wrapping isn't suitable.

Note that the code might be broken into multiple segments if there are nested formatting codes inside a `C<...>` sequence. In between the calls to `handle_code` other markup tags might have been emitted in that case. The same is true for verbatim sections if the `codes_in_verbatim` option is turned on.

accept_targets_as_html

This method behaves like `accept_targets_as_text`, but also marks the region as one whose content should be emitted literally, without HTML entity escaping or wrapping in a `div` element.

resolve_pod_page_link

```
my $url = $pod->resolve_pod_page_link('Net::Ping', 'INSTALL');
my $url = $pod->resolve_pod_page_link('perlpodspec');
my $url = $pod->resolve_pod_page_link(undef, 'SYNOPSIS');
```

Resolves a POD link target (typically a module or POD file name) and section name to a URL. The resulting link will be returned for the above examples as:

```
https://metacpan.org/pod/Net::Ping#INSTALL
https://metacpan.org/pod/perlpodspec
#SYNOPSIS
```

Note that when there is only a section argument the URL will simply be a link to a section in the current document.

resolve_man_page_link

```
my $url = $pod->resolve_man_page_link('crontab(5)', 'EXAMPLE CRON␣
↪FILE');
my $url = $pod->resolve_man_page_link('crontab');
```

Resolves a man page link target and numeric section to a URL. The resulting link will be returned for the above examples as:

```
https://man7.org/linux/man-pages/man5/crontab.5.html
https://man7.org/linux/man-pages/man1/crontab.1.html
```

Note that the first argument is required. The section number will be parsed from it, and if it's missing will default to 1. The second argument is currently ignored. Subclass to link to a different man page HTTP server.

idify

```
my $id   = $pod->idify($text);
my $hash = $pod->idify($text, 1);
```

This method turns an arbitrary string into a valid XHTML ID attribute value. The rules enforced, following http://webdesign.about.com/od/htmltags/a/aa031707.htm, are:

- The id must start with a letter (a-z or A-Z)
- All subsequent characters can be letters, numbers (0-9), hyphens (-), underscores (_), colons (:), and periods (.).
- The final character can't be a hyphen, colon, or period. URLs ending with these characters, while allowed by XHTML, can be awkward to extract from plain text.
- Each id must be unique within the document.

In addition, the returned value will be unique within the context of the Pod::Simple::XHTML object unless a second argument is passed a true value. ID attributes should always be unique within a single XHTML document, but pass the true value if you are creating not an ID but a URL hash to point to an ID (i.e., if you need to put the "#foo" in `<a href="#foo">foo</a>`.

batch_mode_page_object_init

```
$pod->batch_mode_page_object_init($batchconvobj, $module, $infile,
 ↪$outfile, $depth);
```

Called by *Pod::Simple::HTMLBatch* so that the class has a chance to initialize the converter. Internally it sets the `batch_mode` property to true and sets `batch_mode_current_level()`, but Pod::Simple::XHTML does not currently use those features. Subclasses might, though.

Pod::Simple::XMLOutStream

turn Pod into XML

SYNOPSIS

```
perl -MPod::Simple::XMLOutStream -e \
 "exit Pod::Simple::XMLOutStream->filter(shift)->any_errata_seen" \
 thingy.pod
```

DESCRIPTION

Pod::Simple::XMLOutStream is a subclass of *Pod::Simple* that parses Pod and turns it into XML.

Pod::Simple::XMLOutStream inherits methods from *Pod::Simple*.

SEE ALSO

Pod::Simple::DumpAsXML is rather like this class; see its documentation for a discussion of the differences.

Pod::Text

Convert POD data to formatted text

SYNOPSIS

```
use Pod::Text;
my $parser = Pod::Text->new (sentence => 1, width => 78);

# Read POD from STDIN and write to STDOUT.
$parser->parse_from_filehandle;

# Read POD from file.pod and write to file.txt.
$parser->parse_from_file ('file.pod', 'file.txt');
```

DESCRIPTION

Pod::Text is a module that can convert documentation in the POD format (the preferred language for documenting Perl) into formatted text. It uses no special formatting controls or codes, and its output is therefore suitable for nearly any device.

Encoding

Pod::Text uses the following logic to choose an output encoding, in order:

1. If a PerlIO encoding layer is set on the output file handle, do not do any output encoding and will instead rely on the PerlIO encoding layer.
2. If the `encoding` or `utf8` options are set, use the output encoding specified by those options.
3. If the input encoding of the POD source file was explicitly specified (using `=encoding`) or automatically detected by Pod::Simple, use that as the output encoding as well.
4. Otherwise, if running on a non-EBCDIC system, use UTF-8 as the output encoding. Since this is a superset of ASCII, this will result in ASCII output unless the POD input contains non-ASCII characters without declaring or autodetecting an encoding (usually via E<> escapes).
5. Otherwise, for EBCDIC systems, output without doing any encoding and hope this works.

One caveat: Pod::Text has to commit to an output encoding the first time it outputs a non-ASCII character, and then has to stick with it for consistency. However, `=encoding` commands don't have to be at the beginning of a POD document. If someone uses a non-ASCII character early in a document with an escape, such as E<0xEF>, and then puts `=encoding iso-8859-1` later, ideally Pod::Text would follow rule 3 and output the entire document as ISO 8859-1. Instead, it will commit to UTF-8 following rule 4 as soon as it sees that escape, and then stick with that encoding for the rest of the document.

Unfortunately, there's no universally good choice for an output encoding. Each choice will be incorrect in some circumstances. This approach was chosen primarily for backwards compatibility. Callers should consider forcing the output encoding via `encoding` if they have any knowledge about what encoding the user may expect.

In particular, consider importing the Encode::Locale module, if available, and setting `encoding` to `locale` to use an output encoding appropriate to the user's locale. But be aware that if the user is not using locales or is using a locale of C, Encode::Locale will set the output encoding to US-ASCII. This will cause all non-ASCII characters will be replaced

with ? and produce a flurry of warnings about unsupported characters, which may or may not be what you want.

CLASS METHODS

- new(ARGS)

  Create a new Pod::Text object. ARGS should be a list of key/value pairs, where the keys are chosen from the following. Each option is annotated with the version of Pod::Text in which that option was added with its current meaning.

  - alt

    [2.00] If set to a true value, selects an alternate output format that, among other things, uses a different heading style and marks `=item` entries with a colon in the left margin. Defaults to false.

  - code

    [2.13] If set to a true value, the non-POD parts of the input file will be included in the output. Useful for viewing code documented with POD blocks with the POD rendered and the code left intact.

  - encoding

    [6.1.0] Specifies the encoding of the output. The value must be an encoding recognized by the *Encode* module (see Encode::Supported) or the special value none. If the output contains characters that cannot be represented in this encoding, that is an error that will be reported as configured by the `errors` option. If error handling is other than `die`, the unrepresentable character will be replaced with the Encode substitution character (normally ?).

    If the output file handle has a PerlIO encoding layer set, this parameter will be ignored and no encoding will be done by Pod::Man. It will instead rely on the encoding layer to make whatever output encoding transformations are desired.

    As a special case, if the encoding is set to none, no encoding will be done and characters will be output in Perl's internal representation. This option only makes sense in combination with output_string(). It is intended for special cases when the results of formatting are kept in memory and will be encoded for output at some later step.

    WARNING: The input encoding of the POD source is independent from the output encoding, and setting this option does not affect the interpretation of the POD input. Unless your POD source is US-ASCII, its encoding should be declared with the `=encoding` command in the source, as near to the top of the file as possible. If this is not done, Pod::Simple will will attempt to guess the encoding and may be successful if it's Latin-1 or UTF-8, but it will produce warnings. See perlpod(1) for more information.

  - errors

    [3.17] How to report errors. `die` says to throw an exception on any POD formatting error. `stderr` says to report errors on standard error, but not to throw an exception. pod says to include a POD ERRORS section in the resulting docu-

mentation summarizing the errors. none ignores POD errors entirely, as much as possible.

The default is pod.

– guesswork

[5.01] By default, Pod::Text applies some default formatting rules based on guesswork and regular expressions that are intended to make writing Perl documentation easier and require less explicit markup. These rules may not always be appropriate, particularly for documentation that isn't about Perl. This option allows turning all or some of it off.

The special value `all` enables all guesswork. This is also the default for backward compatibility reasons. The special value none disables all guesswork. Otherwise, the value of this option should be a comma-separated list of one or more of the following keywords:

* quoting

  If no guesswork is enabled, any text enclosed in C<> is surrounded by double quotes in nroff (terminal) output unless the contents are already quoted. When this guesswork is enabled, quote marks will also be suppressed for Perl variables, function names, function calls, numbers, and hex constants.

Any unknown guesswork name is silently ignored (for potential future compatibility), so be careful about spelling.

– indent

[2.00] The number of spaces to indent regular text, and the default indentation for `=over` blocks. Defaults to 4.

– loose

[2.00] If set to a true value, a blank line is printed after a `=head1` heading. If set to false (the default), no blank line is printed after `=head1`, although one is still printed after `=head2`. This is the default because it's the expected formatting for manual pages; if you're formatting arbitrary text documents, setting this to true may result in more pleasing output.

– margin

[2.21] The width of the left margin in spaces. Defaults to 0. This is the margin for all text, including headings, not the amount by which regular text is indented; for the latter, see the *indent* option. To set the right margin, see the *width* option.

– nourls

[3.17] Normally, L<> formatting codes with a URL but anchor text are formatted to show both the anchor text and the URL. In other words:

```
L<foo|http://example.com/>
```

is formatted as:

```
foo <http://example.com/>
```

This option, if set to a true value, suppresses the URL when anchor text is given, so this example would be formatted as just `foo`. This can produce less cluttered output in cases where the URLs are not particularly important.

– quotes

[4.00] Sets the quote marks used to surround C<> text. If the value is a single character, it is used as both the left and right quote. Otherwise, it is split in half, and the first half of the string is used as the left quote and the second is used as the right quote.

This may also be set to the special value none, in which case no quote marks are added around C<> text.

– sentence

[3.00] If set to a true value, Pod::Text will assume that each sentence ends in two spaces, and will try to preserve that spacing. If set to false, all consecutive whitespace in non-verbatim paragraphs is compressed into a single space. Defaults to false.

– stderr

[3.10] Send error messages about invalid POD to standard error instead of appending a POD ERRORS section to the generated output. This is equivalent to setting `errors` to `stderr` if `errors` is not already set. It is supported for backward compatibility.

– utf8

[3.12] If this option is set to a true value, the output encoding is set to UTF-8. This is equivalent to setting `encoding` to `UTF-8` if `encoding` is not already set. It is supported for backward compatibility.

– width

[2.00] The column at which to wrap text on the right-hand side. Defaults to 76.

INSTANCE METHODS

As a derived class from Pod::Simple, Pod::Text supports the same methods and interfaces. See *Pod::Simple* for all the details. This section summarizes the most-frequently-used methods and the ones added by Pod::Text.

- output_fh(FH)

  Direct the output from parse_file(), parse_lines(), or parse_string_document() to the file handle FH instead of `STDOUT`.

- output_string(REF)

  Direct the output from parse_file(), parse_lines(), or parse_string_document() to the scalar variable pointed to by REF, rather than `STDOUT`. For example:

```
my $man = Pod::Man->new();
my $output;
$man->output_string(\$output);
$man->parse_file('/some/input/file');
```

Be aware that the output in that variable will already be encoded (see "Encoding") unless the `encoding` option to Pod::Text is set to none.

- parse_file(PATH)

  Read the POD source from PATH and format it. By default, the output is sent to `STDOUT`, but this can be changed with the output_fh() or output_string() methods.

- parse_from_file(INPUT, OUTPUT)

- parse_from_filehandle(FH, OUTPUT)

  Read the POD source from INPUT, format it, and output the results to OUTPUT.

  parse_from_filehandle() is provided for backward compatibility with older versions of Pod::Man. parse_from_file() should be used instead.

- parse_lines(LINES[, ...[, undef]])

  Parse the provided lines as POD source, writing the output to either `STDOUT` or the file handle set with the output_fh() or output_string() methods. This method can be called repeatedly to provide more input lines. An explicit `undef` should be passed to indicate the end of input.

  This method expects raw bytes, not decoded characters.

- parse_string_document(INPUT)

  Parse the provided scalar variable as POD source, writing the output to either `STDOUT` or the file handle set with the output_fh() or output_string() methods.

  This method expects raw bytes, not decoded characters.

FUNCTIONS

Pod::Text exports one function for backward compatibility with older versions. This function is deprecated; instead, use the object-oriented interface described above.

- pod2text([[-a,] [-NNN,]] INPUT[, OUTPUT])

  Convert the POD source from INPUT to text and write it to OUTPUT. If OUTPUT is not given, defaults to `STDOUT`. INPUT can be any expression supported as the second argument to two-argument open().

  If `-a` is given as an initial argument, pass the `alt` option to the Pod::Text constructor. This enables alternative formatting.

  If `-NNN` is given as an initial argument, pass the `width` option to the Pod::Text constructor with the number `NNN` as its argument. This sets the wrap line width to NNN.

DIAGNOSTICS

- Bizarre space in item
- Item called without tag

  (W) Something has gone wrong in internal `=item` processing. These messages indicate a bug in Pod::Text; you should never see them.

- Can't open %s for reading: %s

  (F) Pod::Text was invoked via the compatibility mode pod2text() interface and the input file it was given could not be opened.

- Invalid errors setting "%s"

  (F) The `errors` parameter to the constructor was set to an unknown value.

- Invalid quote specification "%s"

  (F) The quote specification given (the `quotes` option to the constructor) was invalid. A quote specification must be either one character long or an even number (greater than one) characters long.

- Margin is wider than the output width

  (W) The requested margin width, determined from the sum of indentations requested by `=over` and the baseline indentation for text, is equal to or wider than the desired output width specified with `width`. The text will be formatted as if the margin was set to zero.

- POD document had syntax errors

  (F) The POD document being formatted had syntax errors and the `errors` option was set to `die`.

COMPATIBILITY

Pod::Text 2.03 (based on Pod::Parser) was the first version of this module included with Perl, in Perl 5.6.0. Earlier versions of Perl had a different Pod::Text module, with a different API.

The current API based on *Pod::Simple* was added in Pod::Text 3.00. Pod::Text 3.01 was included in Perl 5.9.3, the first version of Perl to incorporate those changes. This is the first version that correctly supports all modern POD syntax. The parse_from_filehandle() method was re-added for backward compatibility in Pod::Text 3.07, included in Perl 5.9.4.

Pod::Text 3.12, included in Perl 5.10.1, first implemented the current practice of attempting to match the default output encoding with the input encoding of the POD source, unless overridden by the `utf8` option or (added later) the `encoding` option.

Support for anchor text in L<> links of type URL was added in Pod::Text 3.14, included in Perl 5.11.5.

parse_lines(), parse_string_document(), and parse_file() set a default output file handle of STDOUT if one was not already set as of Pod::Text 3.18, included in Perl 5.19.5.

Pod::Text 4.00, included in Perl 5.23.7, aligned the module version and the version of the podlators distribution. All modules included in podlators, and the podlators distribution itself, share the same version number from this point forward.

Pod::Text 4.09, included in Perl 5.25.7, fixed a serious bug on EBCDIC systems, present in all versions back to 3.00, that would cause opening brackets to disappear.

Pod::Text 5.00 and later, included in Perl 5.37.7, default, on non-EBCDIC systems, to UTF-8 encoding if it sees a non-ASCII character in the input and the input encoding is not specified. They also commit to an encoding with the first non-ASCII character and does not change the output encoding if the input encoding changes. The *Encode* module is now used for all output encoding rather than PerlIO layers, which fixes earlier problems with output to scalars.

Pod::Text 6.1.0 added support for the none option to `encoding`.

CAVEATS

Line wrapping is done only at ASCII spaces and tabs, rather than using a correct Unicode-aware line wrapping algorithm.

AUTHOR

Russ Allbery rra@cpan.org, based *very* heavily on the original Pod::Text by Tom Christiansen tchrist@mox.perl.com and its conversion to Pod::Parser by Brad Appleton bradapp@enteract.com. Sean Burke's initial conversion of Pod::Man to use Pod::Simple provided much-needed guidance on how to use Pod::Simple.

Modules

- `Pod::Text::Color` - Convert POD data to formatted color ASCII text
- `Pod::Text::Overstrike` - Convert POD data to formatted overstrike text
- `Pod::Text::Termcap` - Convert POD data to ASCII text with format escapes

Pod::Text::Color

Convert POD data to formatted color ASCII text

SYNOPSIS

```
use Pod::Text::Color;
my $parser = Pod::Text::Color->new (sentence => 0, width => 78);

# Read POD from STDIN and write to STDOUT.
$parser->parse_from_filehandle;

# Read POD from file.pod and write to file.txt.
$parser->parse_from_file ('file.pod', 'file.txt');
```

DESCRIPTION

Pod::Text::Color is a simple subclass of Pod::Text that highlights output text using ANSI color escape sequences. Apart from the color, it in all ways functions like Pod::Text. See *Pod::Text* for details and available options.

Term::ANSIColor is used to get colors and therefore must be installed to use this module.

COMPATIBILITY

Pod::Text::Color 0.05 (based on Pod::Parser) was the first version of this module included with Perl, in Perl 5.6.0.

The current API based on *Pod::Simple* was added in Pod::Text::Color 2.00. Pod::Text::Color 2.01 was included in Perl 5.9.3, the first version of Perl to incorporate those changes.

Several problems with wrapping and line length were fixed as recently as Pod::Text::Color 6.0.0.

This module inherits its API and most behavior from Pod::Text, so the details in *"COMPATIBILITY" in Pod::Text* also apply. Pod::Text and Pod::Text::Color have had the same module version since 4.00, included in Perl 5.23.7. (They unfortunately diverge in confusing ways prior to that.)

CAVEATS

Line wrapping is done only at ASCII spaces and tabs, rather than using a correct Unicode-aware line wrapping algorithm.

AUTHOR

Russ Allbery rra@cpan.org.

COPYRIGHT AND LICENSE

Copyright 1999, 2001, 2004, 2006, 2008, 2009, 2018-2019, 2022, 2024, 2026 Russ Allbery rra@cpan.org

This program is free software; you may redistribute it and/or modify it under the same terms as Perl itself.

SEE ALSO

Pod::Text, *Pod::Simple*

The current version of this module is always available from its web site at https://www.eyrie.org/~eagle/software/podlators/. It is also part of the Perl core distribution as of 5.6.0.

Pod::Text::Overstrike

Convert POD data to formatted overstrike text

SYNOPSIS

```
use Pod::Text::Overstrike;
my $parser = Pod::Text::Overstrike->new (sentence => 0, width =>␣
↪78);

# Read POD from STDIN and write to STDOUT.
$parser->parse_from_filehandle;

# Read POD from file.pod and write to file.txt.
$parser->parse_from_file ('file.pod', 'file.txt');
```

DESCRIPTION

Pod::Text::Overstrike is a simple subclass of Pod::Text that highlights output text using overstrike sequences, in a manner similar to nroff. Characters in bold text are overstruck (character, backspace, character) and characters in underlined text are converted to overstruck underscores (underscore, backspace, character). This format was originally designed for hard-copy terminals and/or line printers, yet is readable on soft-copy (CRT) terminals.

Overstruck text is best viewed by page-at-a-time programs that take advantage of the terminal's **stand-out** and *underline* capabilities, such as the less program on Unix.

Apart from the overstrike, it in all ways functions like Pod::Text. See *Pod::Text* for details and available options.

BUGS

Currently, the outermost formatting instruction wins, so for example underlined text inside a region of bold text is displayed as simply bold. There may be some better approach possible.

COMPATIBILITY

Pod::Text::Overstrike 1.01 (based on Pod::Parser) was the first version of this module included with Perl, in Perl 5.6.1.

The current API based on *Pod::Simple* was added in Pod::Text::Overstrike 2.00, included in Perl 5.9.3.

Several problems with wrapping and line length were fixed as recently as Pod::Text::Overstrike 6.0.0.

This module inherits its API and most behavior from Pod::Text, so the details in *"COMPATIBILITY" in Pod::Text* also apply. Pod::Text and Pod::Text::Overstrike have had the same module version since 4.00, included in Perl 5.23.7. (They unfortunately diverge in confusing ways prior to that.)

CAVEATS

Line wrapping is done only at ASCII spaces and tabs, rather than using a correct Unicode-aware line wrapping algorithm.

Pod::Text::Termcap

Convert POD data to ASCII text with format escapes

SYNOPSIS

```
use Pod::Text::Termcap;
my $parser = Pod::Text::Termcap->new (sentence => 0, width => 78);

# Read POD from STDIN and write to STDOUT.
$parser->parse_from_filehandle;

# Read POD from file.pod and write to file.txt.
$parser->parse_from_file ('file.pod', 'file.txt');
```

DESCRIPTION

Pod::Text::Termcap is a simple subclass of Pod::Text that highlights output text using the correct termcap escape sequences for the current terminal. Apart from the format codes, it in all ways functions like Pod::Text. See *Pod::Text* for details and available options.

This module uses *Term::Cap* to find the correct terminal settings. See the documentation of that module for how it finds terminal database information and how to override that behavior if necessary. If unable to find control strings for bold and underscore formatting, that formatting is skipped, resulting in the same output as Pod::Text.

COMPATIBILITY

Pod::Text::Termcap 0.04 (based on Pod::Parser) was the first version of this module included with Perl, in Perl 5.6.0.

The current API based on *Pod::Simple* was added in Pod::Text::Termcap 2.00. Pod::Text::Termcap 2.01 was included in Perl 5.9.3, the first version of Perl to incorporate those changes.

Pod::Text::Termcap 4.13 stopped setting the TERMPATH environment variable during module load. It also stopped falling back on VT100 escape sequences if Term::Cap was not able to find usable escape sequences, instead producing unformatted output for better results on dumb terminals. The next version to be incorporated into Perl, 4.14, was included in Perl 5.31.8.

Several problems with wrapping and line length were fixed as recently as Pod::Text::Termcap 6.0.0.

This module inherits its API and most behavior from Pod::Text, so the details in *"COMPATIBILITY" in Pod::Text* also apply. Pod::Text and Pod::Text::Termcap have had the same module version since 4.00, included in Perl 5.23.7. (They unfortunately diverge in confusing ways prior to that.)

CAVEATS

Line wrapping is done only at ASCII spaces and tabs, rather than using a correct Unicode-aware line wrapping algorithm.

Pod::Usage

extracts POD documentation and shows usage information

SYNOPSIS

```
use Pod::Usage;

my $message_text  = "This text precedes the usage message.";
my $exit_status   = 2;          ## The exit status to use
my $verbose_level = 0;          ## The verbose level to use
my $filehandle    = \*STDERR;   ## The filehandle to write to

pod2usage($message_text);

pod2usage($exit_status);

pod2usage( { -message => $message_text ,
             -exitval => $exit_status  ,
             -verbose => $verbose_level,
             -output  => $filehandle } );

pod2usage(   -msg     => $message_text ,
             -exitval => $exit_status  ,
             -verbose => $verbose_level,
             -output  => $filehandle );
```

(continues on next page)

(continued from previous page)

```
pod2usage(    -verbose => 2,
              -noperldoc => 1  );

pod2usage(    -verbose => 2,
              -perlcmd => $path_to_perl,
              -perldoc => $path_to_perldoc,
              -perldocopt => $perldoc_options );
```

ARGUMENTS

pod2usage should be given either a single argument, or a list of arguments corresponding to an associative array (a "hash"). When a single argument is given, it should correspond to exactly one of the following:

- A string containing the text of a message to print *before* printing the usage message
- A numeric value corresponding to the desired exit status
- A reference to a hash

If more than one argument is given then the entire argument list is assumed to be a hash. If a hash is supplied (either as a reference or as a list) it should contain one or more elements with the following keys:

- `-message` *string*
- `-msg` *string*

  The text of a message to print immediately prior to printing the program's usage message.

- `-exitval` *value*

  The desired exit status to pass to the **exit()** function. This should be an integer, or else the string `NOEXIT` to indicate that control should simply be returned without terminating the invoking process.

- `-verbose` *value*

  The desired level of "verboseness" to use when printing the usage message. If the value is 0, then only the "SYNOPSIS" and/or "USAGE" sections of the pod documentation are printed. If the value is 1, then the "SYNOPSIS" and/or "USAGE" sections, along with any section entitled "OPTIONS", "ARGUMENTS", or "OPTIONS AND ARGUMENTS" is printed. If the corresponding value is 2 or more then the entire manpage is printed, using perldoc if available; otherwise *Pod::Text* is used for the formatting. For better readability, the all-capital headings are downcased, e.g. `SYNOPSIS` => `Synopsis`.

  The special verbosity level 99 requires to also specify the -sections parameter; then these sections are extracted and printed.

- `-sections` *spec*

  There are two ways to specify the selection. Either a string (scalar) representing a selection regexp for sections to be printed when -verbose is set to 99, e.g.

```
"NAME|SYNOPSIS|DESCRIPTION|VERSION"
```

With the above regexp all content following (and including) any of the given =head1 headings will be shown. It is possible to restrict the output to particular subsections only, e.g.:

```
"DESCRIPTION/Algorithm"
```

This will output only the =head2 Algorithm heading and content within the =head1 DESCRIPTION section. The regexp binding is stronger than the section separator, such that e.g.:

```
"DESCRIPTION|OPTIONS|ENVIRONMENT/Caveats"
```

will print any =head2 Caveats section (only) within any of the three =head1 sections.

Alternatively, an array reference of section specifications can be used:

```
pod2usage(-verbose => 99, -sections => [
  qw(DESCRIPTION DESCRIPTION/Introduction) ] );
```

This will print only the content of =head1 DESCRIPTION and the =head2 Introduction sections, but no other =head2, and no other =head1 either.

- `-output` *handle*

  A reference to a filehandle, or the pathname of a file to which the usage message should be written. The default is *STDERR unless the exit value is less than 2 (in which case the default is *STDOUT).

- `-input` *handle*

  A reference to a filehandle, or the pathname of a file from which the invoking script's pod documentation should be read. It defaults to the file indicated by $0 ($PROGRAM_NAME for users of English.pm).

  If you are calling **pod2usage()** from a module and want to display that module's POD, you can use this:

```
use Pod::Find qw(pod_where);
pod2usage( -input => pod_where({-inc => 1}, __PACKAGE__) );
```

- `-pathlist` *string*

  A list of directory paths. If the input file does not exist, then it will be searched for in the given directory list (in the order the directories appear in the list). It defaults to the list of directories implied by $ENV{PATH}. The list may be specified either by a reference to an array, or by a string of directory paths which use the same path separator as $ENV{PATH} on your system (e.g., : for Unix, ; for MSWin32 and DOS).

- `-noperldoc`

  By default, Pod::Usage will call perldoc when -verbose >= 2 is specified. This does not work well e.g. if the script was packed with PAR. This option suppresses the

external call to perldoc and uses the simple text formatter (*Pod::Text*) to output the POD.

- `-perlcmd`

  By default, Pod::Usage will call perldoc when -verbose >= 2 is specified. In case of special or unusual Perl installations, this option may be used to supply the path to a perl executable which should run perldoc.

- `-perldoc` *path-to-perldoc*

  By default, Pod::Usage will call perldoc when -verbose >= 2 is specified. In case perldoc is not installed where the perl interpreter thinks it is (see *Config*), the -perldoc option may be used to supply the correct path to perldoc.

- `-perldocopt` *string*

  By default, Pod::Usage will call perldoc when -verbose >= 2 is specified. This option may be used to supply options to perldoc. The string may contain several, space-separated options.

Formatting base class

The default text formatter is *Pod::Text*. The base class for Pod::Usage can be defined by pre-setting `$Pod::Usage::Formatter` *before* loading Pod::Usage, e.g.:

```
BEGIN { $Pod::Usage::Formatter = 'Pod::Text::Termcap'; }
use Pod::Usage qw(pod2usage);
```

Pod::Usage uses *Pod::Simple*'s _handle_element_end() method to implement the section selection, and in case of verbosity < 2 it down-cases the all-caps headings to first capital letter and rest lowercase, and adds a colon/newline at the end of the headings, for better readability. Same for verbosity = 99.

Pass-through options

The following options are passed through to the underlying text formatter. See the manual pages of these modules for more information.

```
alt code indent loose margin quotes sentence stderr utf8 width
```

DESCRIPTION

pod2usage will print a usage message for the invoking script (using its embedded pod documentation) and then exit the script with the desired exit status. The usage message printed may have any one of three levels of "verboseness": If the verbose level is 0, then only a synopsis is printed. If the verbose level is 1, then the synopsis is printed along with a description (if present) of the command line options and arguments. If the verbose level is 2, then the entire manual page is printed.

Unless they are explicitly specified, the default values for the exit status, verbose level, and output stream to use are determined as follows:

- If neither the exit status nor the verbose level is specified, then the default is to use an exit status of 2 with a verbose level of 0.

- If an exit status *is* specified but the verbose level is *not*, then the verbose level will default to 1 if the exit status is less than 2 and will default to 0 otherwise.
- If an exit status is *not* specified but verbose level *is* given, then the exit status will default to 2 if the verbose level is 0 and will default to 1 otherwise.
- If the exit status used is less than 2, then output is printed on STDOUT. Otherwise output is printed on STDERR.

Although the above may seem a bit confusing at first, it generally does "the right thing" in most situations. This determination of the default values to use is based upon the following typical Unix conventions:

- An exit status of 0 implies "success". For example, **diff(1)** exits with a status of 0 if the two files have the same contents.
- An exit status of 1 implies possibly abnormal, but non-defective, program termination. For example, **grep(1)** exits with a status of 1 if it did *not* find a matching line for the given regular expression.
- An exit status of 2 or more implies a fatal error. For example, **ls(1)** exits with a status of 2 if you specify an illegal (unknown) option on the command line.
- Usage messages issued as a result of bad command-line syntax should go to STDERR. However, usage messages issued due to an explicit request to print usage (like specifying **-help** on the command line) should go to STDOUT, just in case the user wants to pipe the output to a pager (such as **more(1)**).
- If program usage has been explicitly requested by the user, it is often desirable to exit with a status of 1 (as opposed to 0) after issuing the user-requested usage message. It is also desirable to give a more verbose description of program usage in this case.

pod2usage does not force the above conventions upon you, but it will use them by default if you don't expressly tell it to do otherwise. The ability of **pod2usage()** to accept a single number or a string makes it convenient to use as an innocent looking error message handling function:

```
use strict;
use Pod::Usage;
use Getopt::Long;

## Parse options
my %opt;
GetOptions(\%opt, "help|?", "man", "flag1")  ||  pod2usage(2);
pod2usage(1)  if ($opt{help});
pod2usage(-exitval => 0, -verbose => 2)  if ($opt{man});

## Check for too many filenames
pod2usage("$0: Too many files given.\n")  if (@ARGV > 1);
```

Some user's however may feel that the above "economy of expression" is not particularly readable nor consistent and may instead choose to do something more like the following:

```
use strict;
use Pod::Usage qw(pod2usage);
use Getopt::Long qw(GetOptions);

## Parse options
my %opt;
GetOptions(\%opt, "help|?", "man", "flag1")  ||
  pod2usage(-verbose => 0);

pod2usage(-verbose => 1)  if ($opt{help});
pod2usage(-verbose => 2)  if ($opt{man});

## Check for too many filenames
pod2usage(-verbose => 2, -message => "$0: Too many files given.\n")
  if (@ARGV > 1);
```

As with all things in Perl, *there's more than one way to do it*, and **pod2usage()** adheres to this philosophy. If you are interested in seeing a number of different ways to invoke **pod2usage** (although by no means exhaustive), please refer to "EXAMPLES".

Scripts

The Pod::Usage distribution comes with a script pod2usage which offers a command line interface to the functionality of Pod::Usage. See pod2usage.

EXAMPLES

Each of the following invocations of `pod2usage()` will print just the "SYNOPSIS" section to STDERR and will exit with a status of 2:

```
pod2usage();

pod2usage(2);

pod2usage(-verbose => 0);

pod2usage(-exitval => 2);

pod2usage({-exitval => 2, -output => \*STDERR});

pod2usage({-verbose => 0, -output  => \*STDERR});

pod2usage(-exitval => 2, -verbose => 0);

pod2usage(-exitval => 2, -verbose => 0, -output => \*STDERR);
```

Each of the following invocations of `pod2usage()` will print a message of "Syntax error." (followed by a newline) to STDERR, immediately followed by just the "SYNOPSIS" section (also printed to STDERR) and will exit with a status of 2:

```
pod2usage("Syntax error.");

pod2usage(-message => "Syntax error.", -verbose => 0);

pod2usage(-msg  => "Syntax error.", -exitval => 2);

pod2usage({-msg => "Syntax error.", -exitval => 2, -output => \
 ↪*STDERR});

pod2usage({-msg => "Syntax error.", -verbose => 0, -output => \
 ↪*STDERR});

pod2usage(-msg  => "Syntax error.", -exitval => 2, -verbose => 0);

pod2usage(-message => "Syntax error.",
          -exitval => 2,
          -verbose => 0,
          -output  => \*STDERR);
```

Each of the following invocations of pod2usage() will print the "SYNOPSIS" section and any "OPTIONS" and/or "ARGUMENTS" sections to STDOUT and will exit with a status of 1:

```
pod2usage(1);

pod2usage(-verbose => 1);

pod2usage(-exitval => 1);

pod2usage({-exitval => 1, -output => \*STDOUT});

pod2usage({-verbose => 1, -output => \*STDOUT});

pod2usage(-exitval => 1, -verbose => 1);

pod2usage(-exitval => 1, -verbose => 1, -output => \*STDOUT});
```

Each of the following invocations of pod2usage() will print the entire manual page to STDOUT and will exit with a status of 1:

```
pod2usage(-verbose  => 2);

pod2usage({-verbose => 2, -output => \*STDOUT});

pod2usage(-exitval  => 1, -verbose => 2);

pod2usage({-exitval => 1, -verbose => 2, -output => \*STDOUT});
```

Recommended Use

Most scripts should print some type of usage message to STDERR when a command line syntax error is detected. They should also provide an option (usually -H or -help) to print a (possibly more verbose) usage message to STDOUT. Some scripts may even wish to go so far as to provide a means of printing their complete documentation to STDOUT (perhaps by allowing a -man option). The following complete example uses **Pod::Usage** in combination with **Getopt::Long** to do all of these things:

```
use strict;
use Getopt::Long qw(GetOptions);
use Pod::Usage qw(pod2usage);

my $man = 0;
my $help = 0;
## Parse options and print usage if there is a syntax error,
## or if usage was explicitly requested.
GetOptions('help|?' => \$help, man => \$man) or pod2usage(2);
pod2usage(1) if $help;
pod2usage(-verbose => 2) if $man;

## If no arguments were given, then allow STDIN to be used only
## if it's not connected to a terminal (otherwise print usage)
pod2usage("$0: No files given.")  if ((@ARGV == 0) && (-t STDIN));

__END__

=head1 NAME

sample - Using GetOpt::Long and Pod::Usage

=head1 SYNOPSIS

sample [options] [file ...]

 Options:
   -help            brief help message
   -man             full documentation

=head1 OPTIONS

=over 4

=item B<-help>

Prints a brief help message and exits.

=item B<-man>

Prints the manual page and exits.
```

(continues on next page)

(continued from previous page)

```
=back

=head1 DESCRIPTION

B<This program> will read the given input file(s) and do something
useful with the contents thereof.

=cut
```

CAVEATS

By default, **pod2usage()** will use `$0` as the path to the pod input file. Unfortunately, not all systems on which Perl runs will set `$0` properly (although if `$0` is not found, **pod2usage()** will search `$ENV{PATH}` or else the list specified by the `-pathlist` option). If this is the case for your system, you may need to explicitly specify the path to the pod docs for the invoking script using something similar to the following:

```
pod2usage(-exitval => 2, -input => "/path/to/your/pod/docs");
```

In the pathological case that a script is called via a relative path *and* the script itself changes the current working directory (see *"chdir" in perlfunc*) *before* calling pod2usage, Pod::Usage will fail even on robust platforms. Don't do that. Or use *FindBin* to locate the script:

```
use FindBin;
pod2usage(-input => $FindBin::Bin . "/" . $FindBin::Script);
```

SUPPORT

This module is managed in a GitHub repository, https://github.com/Dual-Life/Pod-Usage Feel free to fork and contribute, or to clone and send patches!

Please use https://github.com/Dual-Life/Pod-Usage/issues/new to file a bug report. The previous ticketing system, https://rt.cpan.org/Dist/Display.html?Queue=Pod-Usage, is deprecated for this package.

More general questions or discussion about POD should be sent to the `pod-people@perl.org` mail list. Send an empty email to `pod-people-subscribe@perl.org` to subscribe.

5.2.85 SDBM_File

Tie a Perl hash to an on-disk SDBM database so keys and values persist between runs.

SDBM_File is a **tied-hash interface**: you never call `FETCH`, `STORE`, `DELETE`, or `EXISTS` directly. You bind a hash to a database file with `tie`, and from then on any ordinary hash syntax - `$h{key}`, `delete $h{key}`, `exists $h{key}`, `keys %h`, `each %h` - is routed by Perl's tie machinery to the uppercase hook methods defined here.

The database itself lives in two files alongside each other, `NAME.dir` and `NAME.pag`, that persist between program runs. Neither `untie` nor program exit removes them - clean-up is the caller's responsibility.

Synopsis

```
use Fcntl;
use SDBM_File;

tie my %h, 'SDBM_File', 'mydb', O_RDWR | O_CREAT, 0666
    or die "tie failed: $!";
$h{greeting} = 'hello';
print $h{greeting};        # hello
untie %h;
```

Persistence

Tying creates (or opens) two files named after the `$basename` argument: `$basename.dir` and `$basename.pag`. Values written through the tied hash land in these files immediately and survive the process. `untie` closes the handle but leaves the files in place for the next run. Use `unlink` if you want them gone.

The six-argument form of `tie` lets you name the two files independently when the `.dir` / `.pag` naming convention does not fit - typically with `File::Temp` handles.

Size limits

SDBM is a fixed-page format. The combined length of a key and its value must not exceed **1008 bytes** (the `PAIRMAX` constant). A `STORE` for a too-large pair croaks with `sdbm store returned -1, errno 22, key "..."` and the pair is not written. The two filename-extension constants `PAGFEXT` and `DIRFEXT` are exported for code that needs to locate the backing files.

Security

Do not open SDBM files from untrusted sources. The on-disk layout was designed for speed, not integrity, and a maliciously crafted file can drive the reader into undefined behavior.

This is a native implementation of SDBM_File 1.17, its sdbm library included; `SDBM_File.pm` is used unchanged. The files it writes are byte for byte those perl5's SDBM_File writes, and each reads the other's.

Differences from upstream

None.

Functions

Tie hooks

`error`

Report whether the database has a sticky I/O-error flag set. Called as a method on the tied object: `(tied %h)->error`.

`sdbm_clearerr`

Clear the sticky I/O-error flag on the database. Called as a method on the tied object: `(tied %h)->sdbm_clearerr`.

Filters

`filter_fetch_key`

Install a callback that rewrites keys on the way out of the database. Called as a method on the tied object: `(tied %h)->filter_fetch_key(sub { ... })`.

`filter_store_key`

Install a callback that rewrites keys on the way into the database. Called as a method on the tied object: `(tied %h)->filter_store_key(sub { ... })`.

`filter_fetch_value`

Install a callback that rewrites values on the way out of the database. Called as a method on the tied object: `(tied %h)->filter_fetch_value(sub { ... })`.

`filter_store_value`

Install a callback that rewrites values on the way into the database. Called as a method on the tied object: `(tied %h)->filter_store_value(sub { ... })`.

5.2.86 SDL2

Perl bindings for SDL2 - windows, input, timers and hardware-accelerated 2D drawing.

SDL2 is the library behind a large share of the cross-platform games and media applications written in the last decade. This module makes it available to Perl with no compiled binding to build: drawing and input go to the `libSDL2-2.0.so.0` installed on the machine, which is located the first time the module is used. If that library is absent, the first SDL call dies with a message naming the distribution package to install.

Two layers

There are two ways to use this module, and they interoperate freely.

The **direct layer** mirrors SDL2's C API one-for-one - same function names, same argument order, same return values. Every prototype in SDL2's own documentation applies unchanged, which is what you want when you are following an SDL tutorial or porting C:

```
use SDL2 qw(:all);

SDL_Init(SDL_INIT_VIDEO);
my $win = SDL_CreateWindow('hello', 100, 100, 640, 480, SDL_WINDOW_
 ↪SHOWN);
```

The **object layer** wraps the same calls as Perl objects that free themselves, which is what you want when writing Perl rather than transcribing C:

```
use SDL2;

my $win = SDL2::Window->new(title => 'hello', w => 640, h => 480);
my $ren = $win->renderer;
```

Handles pass between the layers in both directions: a direct-layer function accepts an object wherever it expects a handle, and `SDL2::Window->from_handle($h)` adopts a raw handle.

Lifetime

An object frees its SDL resource when the last Perl reference to it goes away, so nothing has to be destroyed by hand. Raw handles from the direct layer are yours to destroy, exactly as in C. Destroying a resource through the direct layer while an object also holds it is safe: the object is emptied at the same time, so it will not free it a second time.

Errors

The two layers report failure differently, each following its own convention. A direct-layer function returns what C returns - a negative integer or an undefined handle - and leaves the reason in `SDL_GetError()`. An object-layer method croaks with that text instead, so an error is an exception you can trap with `eval`.

Because a failed object-layer call is an exception, a successful one returns the object itself. That means calls chain:

```
$ren->set_draw_color(30, 30, 40, 255)->clear;
$ren->fill_rect([10, 10, 40, 20]);
$ren->present;
```

and it means **`or die` is for the object layer only**. On a direct-layer call it is always wrong, because C reports success with zero:

```
$ren->clear or die;              # correct: clear croaks, so this
                                 # never fires
SDL_RenderClear($ren) or die;    # WRONG: 0 IS success
SDL_RenderClear($ren) == 0 or die "clear: " . SDL_GetError();   #␣
↪right
```

The one object-layer method that returns nothing is `destroy`. It is the explicit finalizer, so there is nothing left to chain from.

Exports and constants

`use SDL2` exports nothing. Every direct-layer `SDL_*` function and every constant can be asked for by name, or by tag: `:init` (`SDL_INIT_*`), `:window` (`SDL_WINDOW_*`, `SDL_WINDOWPOS_*`), `:gl` (`SDL_GL_*` attributes), `:render` (renderer, flip, texture-access and blend-mode flags), `:events` (event types such as `SDL_QUIT` and `SDL_KEYDOWN`, window events, mouse buttons), `:keycode` (`SDLK_*`, `KMOD_*`), `:scancode` (`SDL_SCANCODE_*`), `:pixels` (`SDL_PIXELFORMAT_*`), `:syswm` (`SDL_SYSWM_*`), `:misc` (`IMG_INIT_*`, for `SDL2::Image`), and `:all` for everything. The values are those of SDL 2's own headers. The object-layer methods are reached through their objects and are never exported.

Modules

- `SDL2::Events` - Keyboard, mouse and window events.
- `SDL2::Image` - loading and saving image files
- `SDL2::Render` - Hardware-accelerated 2D drawing: renderers and textures.
- `SDL2::Surface` - Surfaces - images in ordinary memory.
- `SDL2::Video` - Windows and OpenGL contexts.

Functions

Lifecycle

SDL_Init

Initialise the SDL subsystems named by the OR of `SDL_INIT_*` flags.

SDL_InitSubSystem

Initialise one further subsystem after `SDL_Init` has run.

SDL_Quit

Shut SDL down and release everything it holds.

SDL_QuitSubSystem

Shut down just the subsystems named by the flags.

SDL_WasInit

Which of the subsystems named by the flags are currently initialised, as the OR of their `SDL_INIT_*` bits. Pass 0 to ask about all of them.

have_sdl

True when libSDL2 was found on this machine.

Errors and version

SDL_GetError

The message describing the last SDL call that failed, or the empty string if none has. The direct layer leaves failures here rather than dying, so this is how you find out what went wrong.

SDL_ClearError

Forget the last error message.

SDL_GetVersion

The version of the SDL2 library actually loaded, as the list `($major, $minor, $patch)`.

version

The loaded SDL2 library's version as a string, `"2.30.1"`.

SDL_GetPlatform

The name SDL gives this platform, such as `"Linux"`.

Timing

SDL_GetTicks

Milliseconds since SDL was initialised.

SDL_Delay

Sleep for the given number of milliseconds.

Renderers

SDL_CreateRenderer

Creates a renderer for a window and returns its handle, or undef.

SDL_DestroyRenderer

Frees a renderer. Accepts a raw handle or an `SDL2::Renderer`, emptying the object so it will not free the renderer again.

SDL_RenderPresent

Shows everything drawn since the last present. The last call of every frame; nothing appears on screen until you make it.

SDL_RenderSetLogicalSize

Fixes the coordinate system the renderer draws in, letting SDL scale to whatever size the window actually is. Draw against 320x240 and it stays correct when the user resizes. Returns 0 on success.

SDL_GetRendererOutputSize

The renderer's drawable size in pixels, as the list `($w, $h)`.

SDL_RenderReadPixels

Reads pixels back from the rendering target as a byte string, four bytes per pixel in RGBA order, row by row with no padding.

SDL_SetRenderTarget

Directs subsequent drawing into a texture instead of the window. Pass undef to go back to the window. The texture must have been created with `SDL_TEXTUREACCESS_TARGET`. Returns 0 on success.

Drawing

SDL_RenderClear

Fills the whole rendering target with the current draw color. The first call of every frame. Returns 0 on success.

SDL_SetRenderDrawColor

Sets the color used by the drawing calls and by `SDL_RenderClear`. Components are 0 to 255; alpha defaults to 255 (opaque) and only has an effect when the blend mode is not `SDL_BLENDMODE_NONE`.

SDL_GetRenderDrawColor

The current draw color, as the list `($r, $g, $b, $a)`.

SDL_SetRenderDrawBlendMode

Chooses how drawing combines with what is already there. `SDL_BLENDMODE_NONE` overwrites; `SDL_BLENDMODE_BLEND` composites using the alpha channel, which is what you want for anything translucent. Returns 0 on success.

SDL_RenderDrawPoint

Draws one pixel in the current draw color. Returns 0 on success.

SDL_RenderDrawLine

Draws a line between two points in the current draw color. Returns 0 on success.

SDL_RenderDrawRect

Draws the outline of a rectangle. Pass undef for the whole target. Returns 0 on success.

SDL_RenderFillRect

Fills a rectangle with the current draw color. Pass undef for the whole target. Returns 0 on success.

SDL_RenderCopy

Draws a texture. `$src` selects part of the texture and `$dst` says where on the target it goes; undef means the whole of either. Returns 0 on success.

SDL_RenderCopyEx

Draws a texture rotated and/or mirrored. `$angle` is in degrees clockwise, `$center` is the pivot as `[x, y]` relative to `$dst` (undef for its middle), and `$flip` is the OR of `SDL_FLIP_*`. Returns 0 on success.

Textures

SDL_CreateTexture

Creates an empty texture. `$access` is one of `SDL_TEXTUREACCESS_STATIC`, `STREAMING` or `TARGET`. Returns the handle, or undef on failure.

SDL_CreateTextureFromSurface

Uploads a surface to the GPU as a texture. Returns the handle, or undef.

SDL_DestroyTexture

Frees a texture. Accepts a raw handle or an `SDL2::Texture`.

SDL_QueryTexture

A texture's properties as the list `($format, $access, $w, $h)`.

SDL_SetTextureAlphaMod

Scales the texture's alpha when it is drawn, 0 to 255. Returns 0 on success.

SDL_SetTextureColorMod

Tints the texture when it is drawn: each channel is multiplied by the value you give divided by 255. Returns 0 on success.

SDL_SetTextureBlendMode

Chooses how the texture combines with what is under it. Returns 0 on success.

Event queue

SDL_PollEvent

Takes the next event off the queue and returns it as a hash reference, or undef when there is nothing waiting.

SDL_PushEvent

Puts an event on the queue, so a later `SDL_PollEvent` returns it.

SDL_WaitEvent

Waits for the next event and returns it as a hash reference, blocking until one arrives. Returns undef if the wait fails.

SDL_WaitEventTimeout

Waits up to `$ms` milliseconds for an event. Returns the event as a hash reference, or undef if the timeout passed with nothing to report.

SDL_PumpEvents

Collects pending input from the operating system into SDL's queue.

SDL_FlushEvents

Discards queued events whose type falls between `$min` and `$max` inclusive. Called with no arguments it discards everything.

SDL_HasEvents

True when the queue holds an event whose type is between `$min` and `$max` inclusive.

Keyboard

SDL_GetKeyboardState

The whole keyboard as a string of bytes, one per scancode, each 1 when that key is down. Index it with a `SDL_SCANCODE_*` constant:

key_pressed

True when the physical key named by a `SDL_SCANCODE_*` constant is held down right now.

SDL_GetModState

The modifier keys held down right now, as the OR of the `KMOD_*` constants.

SDL_GetKeyName

The printable name of a key symbol, such as `"Left"` or `"A"`. The empty string if there is no such key.

SDL_GetScancodeName

The printable name of a physical key position, such as `"Left"`.

SDL_GetKeyFromName

The key symbol with the given name - the inverse of `SDL_GetKeyName`. Returns `SDLK_UNKNOWN` if the name is not one SDL knows.

SDL_GetKeyFromScancode

The key symbol a physical key currently produces, which depends on the user's keyboard layout.

SDL_GetScancodeFromKey

The physical key that currently produces a key symbol.

Mouse

SDL_GetMouseState

The mouse as the list `($buttons, $x, $y)`. `$buttons` is a bitmask - test it against `SDL_BUTTON_LMASK` and its siblings - and the position is relative to the focused window.

Surfaces

SDL_SaveBMP

Writes a surface as a BMP file. Returns 0 on success.

SDL_FreeSurface

Frees a surface. Accepts a raw handle or an `SDL2::Surface`.

Windows

SDL_CreateWindow

Creates a window and returns its handle, or undef on failure.

SDL_DestroyWindow

Closes a window and frees it. Safe to pass either a raw handle or an `SDL2::Window`; passing the object also empties it, so its own cleanup will not free the window a second time.

SDL_SetWindowTitle

Sets the window's caption.

SDL_GetWindowTitle

The window's caption.

SDL_SetWindowSize

Resizes the window's client area to `$w` by `$h` pixels.

SDL_GetWindowSize

The window's client area as the list `($w, $h)`.

SDL_SetWindowPosition

Moves the window so its top-left corner is at `($x, $y)`.

SDL_GetWindowPosition

The window's top-left corner as the list `($x, $y)`.

SDL_ShowWindow

Makes a hidden window visible.

SDL_HideWindow

Hides the window without destroying it.

SDL_RaiseWindow

Brings the window to the front and gives it the input focus.

SDL_MaximizeWindow

Makes the window as large as the window manager allows.

SDL_MinimizeWindow

Iconifies the window.

SDL_RestoreWindow

Returns the window to its size and position from before it was minimized or maximized.

SDL_SetWindowFullscreen

Switches the window between windowed and full screen. Pass 0 for windowed, `SDL_WINDOW_FULLSCREEN` for a real video-mode change, or `SDL_WINDOW_FULLSCREEN_DESKTOP` for a borderless window filling the display - which is what most programs want. Returns 0 on success.

SDL_SetWindowResizable

Allows or forbids the user resizing the window.

SDL_SetWindowBordered

Shows or hides the window's border and title bar.

SDL_GetWindowFlags

The OR of the `SDL_WINDOW_*` bits describing the window's current state.

SDL_GetWindowID

The window's numeric id - what an event's `window_id` field holds, so this is how you tell which of several windows an event came from.

SDL_GetWindowFromID

The window handle for a numeric window id, or undef if there is no such window. This is how an event's `window_id` becomes the window it happened in, when a program has more than one.

SDL_UpdateWindowSurface

Copies the window's surface to the screen. Only for windows drawn through `SDL_GetWindowSurface`; a window with a renderer uses `SDL_RenderPresent` instead. Returns 0 on success.

SDL_GetCurrentVideoDriver

The name of the video driver SDL initialised, or undef when the video subsystem is not up.

SDL_GetWindowWMInfo

The window manager's own handles for this window, as a hash reference, or undef when SDL will not say.

OpenGL

SDL_GL_SetAttribute

Requests an OpenGL context attribute BEFORE the window is created. Setting `SDL_GL_CONTEXT_MAJOR_VERSION`, `SDL_GL_CONTEXT_MINOR_VERSION` and `SDL_GL_CONTEXT_PROFILE_MASK` is how you ask for a specific OpenGL version. Returns 0 on success.

SDL_GL_GetAttribute

The value an OpenGL context attribute actually has - which can differ from what you asked for, since the driver may give you more than you requested. Returns the list `($result, $value)`, `$result` being 0 on success.

SDL_GL_CreateContext

Creates an OpenGL context for a window created with `SDL_WINDOW_OPENGL`, and makes it current. Returns the handle, or undef on failure. Free it with `SDL_GL_DeleteContext`.

SDL_GL_DeleteContext

Frees an OpenGL context.

SDL_GL_MakeCurrent

Makes a context current on a window, which is what you call when rendering to more than one window. Returns 0 on success.

SDL_GL_SwapWindow

Shows the frame OpenGL has just drawn - the OpenGL counterpart of `SDL_RenderPresent`.

SDL_GL_SetSwapInterval

Chooses how `SDL_GL_SwapWindow` waits: 0 for no wait, 1 to sync with the display's refresh, -1 for adaptive sync. Returns 0 on success, and -1 if the request is not supported.

SDL_GL_GetSwapInterval

The swap interval currently in effect.

SDL_GL_GetProcAddress

The address of an OpenGL function, as an integer, or undef if this driver does not have it.

SDL_GL_GetDrawableSize

The drawable size in pixels as the list `($w, $h)`. On a high-DPI display this is larger than the window size, which is in screen coordinates - use this one for `glViewport`.

SDL2::Events

Keyboard, mouse and window events.

`SDL_PollEvent` takes the next event off the queue and returns it as a plain hash reference, or `undef` when the queue is empty. Draining the queue each frame is the shape of every SDL program:

```
while (my $ev = SDL_PollEvent()) {
    last if $ev->{type} == SDL_QUIT;
    if ($ev->{type} == SDL_KEYDOWN) {
        $paddle_x -= 25 if $ev->{sym} == SDLK_LEFT;
        $paddle_x += 25 if $ev->{sym} == SDLK_RIGHT;
    }
}
```

Every event has `type` and `timestamp`. What else it carries depends on the type, and only the relevant keys are present:

Event	Keys
SDL_QUIT	-
SDL_KEYDOWN, SDL_KEYUP	window_id, state, repeat, scancode, sym, mod, key_name
SDL_TEXTINPUT	window_id, text
SDL_MOUSEMOTION	window_id, which, state, x, y, xrel, yrel
SDL_MOUSEBUTTONDOWN, SDL_MOUSEBUTTONUP	window_id, which, button, state, clicks, x, y
SDL_MOUSEWHEEL	window_id, which, x, y, direction, precise_x, precise_y
SDL_WINDOWEVENT	window_id, event, data1, data2

`sym` is the key as a layout-dependent symbol - compare it against the `SDLK_*` constants, which is what you want for "the user pressed left". `scancode` is the physical key position, layout-independent, and compares against `SDL_SCANCODE_*`; that is what you want for WASD, which should stay in the same place on an AZERTY keyboard.

Held keys

Events tell you when a key changed. For "is it held down right now", which is what smooth movement needs, ask the keyboard state instead:

```
SDL_PumpEvents();
$x -= 4 if SDL2::key_pressed(SDL_SCANCODE_LEFT);
$x += 4 if SDL2::key_pressed(SDL_SCANCODE_RIGHT);
```

`key_pressed` reads SDL's live key array directly and allocates nothing, so it is safe to call several times per frame.

SDL2::Image

`SDL2::Image` - loading and saving image files.

Core SDL2 reads and writes exactly one image format, BMP. This module adds the rest through `libSDL2_image`: PNG and JPEG both ways, and reading for everything else that library was built with - GIF, WEBP, TIFF, AVIF, QOI, XPM and more.

```
use SDL2;
use SDL2::Image;

my $tex = SDL2::Image::load_texture($ren, 'sprite.png');
$ren->copy($tex, undef, [10, 10, 64, 64]);

$ren->save_png('screenshot.png');     # the frame just drawn
```

Saving what you drew

`$ren->save_png($path)`, `$ren->save_jpg($path, $quality)` and `$ren->save_bmp($path)` write the renderer's current target to a file. They exist because doing it by hand has two traps that produce a wrong-looking image rather than an error:

- the bytes come back **RGBA**, and most image libraries want a different channel order, so they have to be swizzled;
- a row of pixels is not always `width * 4` bytes - libraries pad rows to an alignment, and the padding has to be skipped.

These methods do neither by hand: the pixels go straight into a surface that already agrees with them, and SDL2_image writes it.

What this build can do

`SDL2::Image::have_image()` says whether libSDL2_image was found at all, and `SDL2::Image::init($flags)` asks it to load the codecs you need, returning the ones it got. A format its build lacks fails on use rather than at load.

Functions

Loading

load

Reads an image file into an `SDL2::Surface`, guessing the format from the file's own contents rather than its name. Croaks if the file cannot be read or its format is not one this build has.

`load_texture`

Reads an image file straight into an `SDL2::Texture` for a renderer, which is what you want for a sprite: it skips the surface entirely.

Saving

`save_png`

Writes a surface as a PNG. Returns 0 on success.

`save_jpg`

Writes a surface as a JPEG at the given quality, 0 to 100. Returns 0 on success.

Library information

`have_image`

True when libSDL2_image was found on this machine.

`init`

Loads the codecs named by the OR of `IMG_INIT_*` flags, returning the OR of those it actually got - which may be fewer than you asked for.

`quit`

Releases the codecs `init` loaded.

SDL2::Render

Hardware-accelerated 2D drawing: renderers and textures.

A renderer draws into a window, using the GPU when one is available and falling back to software when it is not. It is the fast path for 2D work: clear the target, draw shapes and textures, then present the finished frame.

Rectangles

Anywhere a rectangle is wanted you may pass an array reference `[$x, $y, $w, $h]`, a hash reference `{x => .., y => .., w => .., h => ..}`, or `undef` to mean "the whole target". The array form is the short one and is what the examples use.

The `SDL2::Renderer` object

Usually obtained from a window rather than constructed directly:

```
my $ren = $win->renderer;                    # accelerated, vsync␣
↪off
my $ren = $win->renderer(vsync => 1);        # wait for the refresh
my $ren = $win->renderer(software => 1);     # force software␣
↪rendering
```

Its methods:

- `$ren->clear` - fill the whole target with the draw color.
- `$ren->present` - show the frame just drawn.
- `$ren->set_draw_color($r, $g, $b, $a)` - alpha defaults to 255.
- `$ren->draw_color` - the list `($r, $g, $b, $a)`.
- `$ren->set_blend_mode($mode)` - one of the `SDL_BLENDMODE_*` constants.
- `$ren->draw_point($x, $y)`, `$ren->draw_line($x1, $y1, $x2, $y2)`.
- `$ren->draw_rect($rect)` - outline; `$ren->fill_rect($rect)` - solid.
- `$ren->copy($texture, $src, $dst)` - blit a texture.
- `$ren->copy_ex($texture, $src, $dst, $angle, $center, $flip)` - blit rotated and/or flipped.
- `$ren->output_size` - the list `($w, $h)` of the drawable area.
- `$ren->set_logical_size($w, $h)` - draw in fixed coordinates and let SDL scale to the real window size.
- `$ren->read_pixels($rect)` - the raw RGBA bytes of the target, four bytes per pixel, row by row. Useful for saving a frame or checking in a test what was actually drawn.
- `$ren->handle`, `$ren->destroy`.

The SDL2::Texture object

A texture is an image living in the renderer's memory, which is what makes drawing it fast.

- `SDL2::Texture->new($renderer, %opts)` - `w`, `h`, `access`, `format`.
- `$tex->size` - the list `($w, $h)`.
- `$tex->set_alpha_mod($a)`, `$tex->set_color_mod($r, $g, $b)`, `$tex->set_blend_mode($mode)` - modulation applied when it is drawn.
- `$tex->handle`, `$tex->destroy`.

SDL2::Surface

Surfaces - images in ordinary memory.

A surface is a block of pixels the CPU can read and write, as opposed to a texture, which lives in the renderer's memory and is fast to draw but awkward to inspect. Loading an

image file gives you a surface; `$ren->read_pixels` gives you the bytes to make one from; and saving a frame goes through one.

The SDL2::Surface object

```
# wrap pixels you already have - four bytes per pixel, RGBA order
my $surf = SDL2::Surface->from_pixels($bytes, $w, $h);

$surf->save_bmp('frame.bmp');            # core SDL2, always␣
↪available
my $tex = $ren->texture_from_surface($surf);
```

Its methods:

- `SDL2::Surface->from_pixels($bytes, $w, $h, [$format])` - a surface over a copy of `$bytes`. The default format is RGBA, four bytes per pixel, which is what `read_pixels` returns.
- `$surf->size` - the list `($w, $h)`.
- `$surf->pitch` - the bytes per row, which is not always `$w * 4`.
- `$surf->pixels` - the raw bytes back again.
- `$surf->save_bmp($path)` - write it out. BMP needs no extra library, so it works everywhere; for PNG or JPEG see `SDL2::Image`.
- `$surf->handle`, `$surf->destroy`, and `SDL2::Surface->from_handle($h)` to adopt a raw handle from the direct layer.

SDL2::Video

Windows and OpenGL contexts.

This is the part of SDL2 that puts something on the screen: it opens a window, moves and resizes it, and - when you ask for one - gives it an OpenGL context to render into.

The SDL2::Window object

`SDL2::Window->new` takes named arguments, all optional except that a window with no size is not much use:

```
my $win = SDL2::Window->new(
    title => 'my program',   # window caption
    x     => undef,          # position; undef means "let the system␣
↪choose"
    y     => undef,
    w     => 640,            # size in pixels (default 640 x 480)
    h     => 480,
    flags => 0,              # OR of SDL_WINDOW_* constants
    shown => 1,              # false opens the window hidden
    opengl => 0,             # true adds SDL_WINDOW_OPENGL
    resizable => 0,          # true adds SDL_WINDOW_RESIZABLE
);
```

It calls `SDL_Init(SDL_INIT_VIDEO)` for you if the video subsystem is not up yet, and croaks if the window cannot be created. The window closes and is freed when the last reference to `$win` goes away.

Its methods:

- `$win->title` / `$win->set_title($text)` - the caption.
- `$win->size` - the list `($w, $h)`; `$win->set_size($w, $h)` to change it.
- `$win->position` - the list `($x, $y)`; `$win->set_position($x, $y)`.
- `$win->show` / `$win->hide` / `$win->raise` - visibility.
- `$win->minimize` / `$win->maximize` / `$win->restore`.
- `$win->set_fullscreen($flags)` - 0 for windowed, `SDL_WINDOW_FULLSCREEN_DESKTOP` for borderless full screen.
- `$win->id` - the numeric id events carry in their `window_id` field.
- `$win->flags` - the OR of the `SDL_WINDOW_*` bits currently set.
- `$win->wm_info` - the window manager's own handles for this window, as a hash reference. What a graphics API other than OpenGL needs in order to draw here; see below.
- `$win->renderer(%opts)` - a `SDL2::Renderer` drawing into this window.
- `$win->gl_context` - an `SDL2::GLContext`, made current immediately.
- `$win->gl_swap` - show the frame just drawn by OpenGL.
- `$win->destroy` - close it now rather than at scope exit.
- `$win->handle` - the raw pointer, for passing to the direct layer.

The `SDL2::GLContext` object

`$win->gl_context` returns one, already current. Ask for the OpenGL version you need BEFORE creating the window, with `SDL_GL_SetAttribute`:

```
SDL_GL_SetAttribute(SDL_GL_CONTEXT_MAJOR_VERSION, 3);
SDL_GL_SetAttribute(SDL_GL_CONTEXT_MINOR_VERSION, 3);
SDL_GL_SetAttribute(SDL_GL_CONTEXT_PROFILE_MASK, SDL_GL_CONTEXT_
 ↪PROFILE_CORE);

my $win = SDL2::Window->new(w => 800, h => 600, opengl => 1);
my $ctx = $win->gl_context;
```

Its methods are `$ctx->make_current($win)`, `$ctx->handle` and `$ctx->destroy`. `SDL_GL_GetProcAddress($name)` resolves an OpenGL entry point through the context, which is how a Perl OpenGL binding finds the modern functions without GLEW.

Drawing on the window with something other than OpenGL

A GPU API that is not OpenGL does not take a context from SDL; it takes the window manager's own handles and builds its own surface on them. `$win->wm_info` is where those come from:

```
my $wm = $win->wm_info;
# { subsystem => 2, driver => 'x11', display => ..., window => ... }
```

`driver` is the same lowercase name `SDL_GetCurrentVideoDriver` returns, and it decides which other keys are there: `display` and `window` under X11, `display` and `surface` under Wayland. They are plain integers - a C pointer and an X11 XID - meant to be handed straight back to whatever asked for them, not followed from Perl.

`Peta::WebGPU::Device->new(window => $win)` is the one consumer in the runtime today; it reads exactly these keys.

SDL_CreateRenderer

Creates a renderer for a window and returns its handle, or undef.

```
my $ren = SDL_CreateRenderer($win, -1, SDL_RENDERER_ACCELERATED);
```

`-1` asks SDL to choose the driver, which is what you almost always want. `$flags` is the OR of `SDL_RENDERER_*`: `ACCELERATED` for the GPU, `PRESENTVSYNC` to sync presentation with the display's refresh, `SOFTWARE` to force CPU rendering, `TARGETTEXTURE` to allow rendering into a texture. Free it with `SDL_DestroyRenderer`.

SDL_PushEvent

Puts an event on the queue, so a later `SDL_PollEvent` returns it.

Takes the same hash reference shape `SDL_PollEvent` hands back, so an event can be captured, altered and replayed. Give at least `type`; any field that type carries may be set and the rest default to zero.

```
SDL_PushEvent({ type => SDL_KEYDOWN, sym => SDLK_LEFT });
SDL_PushEvent({ type => SDL_QUIT });
```

Returns 1 if the event was queued, 0 if a filter dropped it, and a negative number on error. Synthesising input this way is how a test drives a program that normally waits for a person.

SDL_GetKeyboardState

The whole keyboard as a string of bytes, one per scancode, each 1 when that key is down. Index it with a `SDL_SCANCODE_*` constant:

```
my $keys = SDL_GetKeyboardState();
my $left = ord substr $keys, SDL_SCANCODE_LEFT, 1;
```

`SDL2::key_pressed($scancode)` is the same question without building the string, and is what a per-frame check should use.

SDL_CreateWindow

Creates a window and returns its handle, or undef on failure.

```
my $win = SDL_CreateWindow($title, $x, $y, $w, $h, $flags);
```

`$x` and `$y` are pixel positions, or `SDL_WINDOWPOS_CENTERED` / `SDL_WINDOWPOS_UNDEFINED`. `$flags` is the OR of `SDL_WINDOW_*` constants - `SDL_WINDOW_SHOWN` to make it visible immediately, `SDL_WINDOW_OPENGL` if it will carry an OpenGL context, `SDL_WINDOW_RESIZABLE` to let the user resize it.

The window must be freed with `SDL_DestroyWindow`. `SDL2::Window->new` is the same call with a Perl object that frees itself.

SDL_GetWindowWMInfo

The window manager's own handles for this window, as a hash reference, or undef when SDL will not say.

```
my $wm = SDL_GetWindowWMInfo($win) or die SDL_GetError();
printf "%s display=%#x window=%#x\n", $wm->{driver}, $wm->{display},
 ↪$wm->{window};
```

`subsystem` is the numeric `SDL_SYSWM_*` value and `driver` is the same lowercase name `SDL_GetCurrentVideoDriver` uses. The remaining keys are the ones that windowing system has: `display` and `window` under X11, `display` and `surface` under Wayland - as plain integers, because they are C pointers and XIDs, not anything Perl can follow.

This is what a graphics API that is not OpenGL needs in order to draw on an SDL window: `Peta::WebGPU` creates its surface from exactly these two handles.

5.2.87 Safe

Compile and execute code in restricted compartments

SYNOPSIS

```
use Safe;

$compartment = new Safe;

$compartment->permit(qw(time sort :browse));

$result = $compartment->reval($unsafe_code);
```

DESCRIPTION

The Safe extension module allows the creation of compartments in which perl code can be evaluated. Each compartment has

- a new namespace

The "root" of the namespace (i.e. "main::") is changed to a different package and code evaluated in the compartment cannot refer to variables outside this namespace, even with run-time glob lookups and other tricks.

Code which is compiled outside the compartment can choose to place variables into (or *share* variables with) the compartment's namespace and only that data will be visible to code evaluated in the compartment.

By default, the only variables shared with compartments are the "underscore" variables $_ and @_ (and, technically, the less frequently used %_, the _ filehandle and so on). This is because otherwise perl operators which default to $_ will not work and neither will the assignment of arguments to @_ on subroutine entry.

- an operator mask

  Each compartment has an associated "operator mask". Recall that perl code is compiled into an internal format before execution. Evaluating perl code (e.g. via "eval" or "do 'file'") causes the code to be compiled into an internal format and then, provided there was no error in the compilation, executed. Code evaluated in a compartment compiles subject to the compartment's operator mask. Attempting to evaluate code in a compartment which contains a masked operator will cause the compilation to fail with an error. The code will not be executed.

  The default operator mask for a newly created compartment is the ':default' optag.

  It is important that you read the *Opcode* module documentation for more information, especially for detailed definitions of opnames, optags and opsets.

  Since it is only at the compilation stage that the operator mask applies, controlled access to potentially unsafe operations can be achieved by having a handle to a wrapper subroutine (written outside the compartment) placed into the compartment. For example,

```
$cpt = new Safe;
sub wrapper {
  # vet arguments and perform potentially unsafe operations
}
$cpt->share('&wrapper');
```

WARNING

The Safe module does not implement an effective sandbox for evaluating untrusted code with the perl interpreter.

Bugs in the perl interpreter that could be abused to bypass Safe restrictions are not treated as vulnerabilities. See perlsecpolicy for additional information.

The authors make **no warranty**, implied or otherwise, about the suitability of this software for safety or security purposes.

The authors shall not in any case be liable for special, incidental, consequential, indirect or other similar damages arising from the use of this software.

Your mileage will vary. If in any doubt **do not use it**.

METHODS

To create a new compartment, use

```
$cpt = new Safe;
```

Optional argument is (NAMESPACE), where NAMESPACE is the root namespace to use for the compartment (defaults to "Safe::Root0", incremented for each new compartment).

Note that version 1.00 of the Safe module supported a second optional parameter, MASK. That functionality has been withdrawn pending deeper consideration. Use the permit and deny methods described below.

The following methods can then be used on the compartment object returned by the above constructor. The object argument is implicit in each case.

permit (OP, ...)

Permit the listed operators to be used when compiling code in the compartment (in *addition* to any operators already permitted).

You can list opcodes by names, or use a tag name; see *"Predefined Opcode Tags" in Opcode*.

permit_only (OP, ...)

Permit *only* the listed operators to be used when compiling code in the compartment (*no* other operators are permitted).

deny (OP, ...)

Deny the listed operators from being used when compiling code in the compartment (other operators may still be permitted).

deny_only (OP, ...)

Deny *only* the listed operators from being used when compiling code in the compartment (*all* other operators will be permitted, so you probably don't want to use this method).

trap (OP, ...), untrap (OP, ...)

The trap and untrap methods are synonyms for deny and permit respectfully.

share (NAME, ...)

This shares the variable(s) in the argument list with the compartment. This is almost identical to exporting variables using the *Exporter* module.

Each NAME must be the **name** of a non-lexical variable, typically with the leading type identifier included. A bareword is treated as a function name.

Examples of legal names are '$foo' for a scalar, '@foo' for an array, '%foo' for a hash, '&foo' or 'foo' for a subroutine and '*foo' for a glob (i.e. all symbol table entries associated with "foo", including scalar, array, hash, sub and filehandle).

Each NAME is assumed to be in the calling package. See share_from for an alternative method (which `share` uses).

share_from (PACKAGE, ARRAYREF)

This method is similar to share() but allows you to explicitly name the package that symbols should be shared from. The symbol names (including type characters) are supplied as an array reference.

```
$safe->share_from('main', [ '$foo', '%bar', 'func' ]);
```

Names can include package names, which are relative to the specified PACKAGE. So these two calls have the same effect:

```
$safe->share_from('Scalar::Util', [ 'reftype' ]);
$safe->share_from('main', [ 'Scalar::Util::reftype' ]);
```

varglob (VARNAME)

This returns a glob reference for the symbol table entry of VARNAME in the package of the compartment. VARNAME must be the **name** of a variable without any leading type marker. For example:

```
${$cpt->varglob('foo')} = "Hello world";
```

has the same effect as:

```
$cpt = new Safe 'Root';
$Root::foo = "Hello world";
```

but avoids the need to know $cpt's package name.

reval (STRING, STRICT)

This evaluates STRING as perl code inside the compartment.

The code can only see the compartment's namespace (as returned by the **root** method). The compartment's root package appears to be the `main::` package to the code inside the compartment.

Any attempt by the code in STRING to use an operator which is not permitted by the compartment will cause an error (at run-time of the main program but at compile-time for the code in STRING). The error is of the form "'%s' trapped by operation mask...".

If an operation is trapped in this way, then the code in STRING will not be executed. If such a trapped operation occurs or any other compile-time or return error, then $@ is set to the error message, just as with an eval().

If there is no error, then the method returns the value of the last expression evaluated, or a return statement may be used, just as with subroutines and **eval()**. The context (list or scalar) is determined by the caller as usual.

If the return value of reval() is (or contains) any code reference, those code references are wrapped to be themselves executed always in the compartment. See "wrap_code_refs_within".

The formerly undocumented STRICT argument sets strictness: if true 'use strict;' is used, otherwise it uses 'no strict;'. **Note**: if STRICT is omitted 'no strict;' is the default.

Some points to note:

If the entereval op is permitted then the code can use eval "..." to 'hide' code which might use denied ops. This is not a major problem since when the code tries to execute the eval it will fail because the opmask is still in effect. However this technique would allow clever, and possibly harmful, code to 'probe' the boundaries of what is possible.

Any string eval which is executed by code executing in a compartment, or by code called from code executing in a compartment, will be eval'd in the namespace of the compartment. This is potentially a serious problem.

Consider a function foo() in package pkg compiled outside a compartment but shared with it. Assume the compartment has a root package called 'Root'. If foo() contains an eval statement like eval '$foo = 1' then, normally, $pkg::foo will be set to 1. If foo() is called from the compartment (by whatever means) then instead of setting $pkg::foo, the eval will actually set $Root::pkg::foo.

This can easily be demonstrated by using a module, such as the Socket module, which uses eval "..." as part of an AUTOLOAD function. You can 'use' the module outside the compartment and share an (autoloaded) function with the compartment. If an autoload is triggered by code in the compartment, or by any code anywhere that is called by any means from the compartment, then the eval in the Socket module's AUTOLOAD function happens in the namespace of the compartment. Any variables created or used by the eval'd code are now under the control of the code in the compartment.

A similar effect applies to *all* runtime symbol lookups in code called from a compartment but not compiled within it.

rdo (FILENAME)

This evaluates the contents of file FILENAME inside the compartment. It uses the same rules as perl's built-in do to locate the file, poossibly using `@INC`.

See above documentation on the **reval** method for further details.

root (NAMESPACE)

This method returns the name of the package that is the root of the compartment's namespace.

Note that this behaviour differs from version 1.00 of the Safe module where the root module could be used to change the namespace. That functionality has been withdrawn pending deeper consideration.

mask (MASK)

This is a get-or-set method for the compartment's operator mask.

With no MASK argument present, it returns the current operator mask of the compartment.

With the MASK argument present, it sets the operator mask for the compartment (equivalent to calling the deny_only method).

wrap_code_ref (CODEREF)

Returns a reference to an anonymous subroutine that, when executed, will call CODEREF with the Safe compartment 'in effect'. In other words, with the package namespace adjusted and the opmask enabled.

Note that the opmask doesn't affect the already compiled code, it only affects any *further* compilation that the already compiled code may try to perform.

This is particularly useful when applied to code references returned from reval().

(It also provides a kind of workaround for RT#60374: "Safe.pm sort {} bug with -Dusethreads". See https://rt.perl.org/rt3//Public/Bug/Display.html?id=60374 for *much* more detail.)

wrap_code_refs_within (...)

Wraps any CODE references found within the arguments by replacing each with the result of calling "wrap_code_ref" on the CODE reference. Any ARRAY or HASH references in the arguments are inspected recursively.

Returns nothing.

RISKS

This section is just an outline of some of the things code in a compartment might do (intentionally or unintentionally) which can have an effect outside the compartment.

- Memory

  Consuming all (or nearly all) available memory.

- CPU

  Causing infinite loops etc.

- Snooping

  Copying private information out of your system. Even something as simple as your user name is of value to others. Much useful information could be gleaned from your environment variables for example.

- Signals

  Causing signals (especially SIGFPE and SIGALARM) to affect your process.

  Setting up a signal handler will need to be carefully considered and controlled. What mask is in effect when a signal handler gets called? If a user can get an imported function to get an exception and call the user's signal handler, does that

user's restricted mask get re-instated before the handler is called? Does an imported handler get called with its original mask or the user's one?

- State Changes

  Ops such as chdir obviously effect the process as a whole and not just the code in the compartment. Ops such as rand and srand have a similar but more subtle effect.

AUTHOR

Originally designed and implemented by Malcolm Beattie.

Reworked to use the Opcode module and other changes added by Tim Bunce.

5.2.88 Scalar

Namespace containing the following modules:

- `Scalar::List`
- `Scalar::Util` - General-utility subroutines for inspecting and tagging scalar values.

Scalar::List

Namespace containing the following modules:

- `Scalar::List::Utils` - A distribution of general-utility subroutines

Scalar::List::Utils

A distribution of general-utility subroutines

SYNOPSIS

```
use Scalar::Util qw(blessed);
use List::Util qw(any);
```

DESCRIPTION

`Scalar::List::Utils` does nothing on its own. It is packaged with several useful modules.

MODULES

List::Util

List::Util contains a selection of useful subroutines for operating on lists of values.

Scalar::Util

Scalar::Util contains a selection of useful subroutines for interrogating or manipulating scalar values.

Sub::Util

Sub::Util contains a selection of useful subroutines for interrogating or manipulating subroutine references.

Scalar::Util

General-utility subroutines for inspecting and tagging scalar values.

What kind of thing a value is - an object of which class (`blessed`), which basic type underneath (`reftype`), which address (`refaddr`), a number in disguise (`looks_like_number`), a v-string (`isvstring`), read-only (`readonly`), tainted (`tainted`), an open filehandle (`openhandle`) - and two ways of making one: a value with separate number and string sides (`dualvar`), and a reference that does not keep its target alive (`weaken`). Nothing is exported by default; name what you need.

This is Scalar::Util from Scalar-List-Utils 1.70; `Scalar/Util.pm` is upstream's. On perl 5.40 and later it makes `blessed`, `refaddr`, `reftype`, `weaken`, `unweaken` and `isweak` the `builtin::` functions of the same names (`isweak` is `builtin::is_weak`), as upstream does; the others are ListUtil.xs's XS functions.

Synopsis

```
use Scalar::Util qw(blessed reftype refaddr looks_like_number
↪dualvar
                    isdual readonly weaken isweak openhandle);

my $obj = bless {}, 'My::Class';
print blessed($obj), ' ', reftype($obj), "\n";        # My::Class
↪HASH
print defined(blessed({})) ? "blessed\n" : "plain\n";  # plain

print join(',', map { looks_like_number($_) ? 1 : 0 }
                    42, '4.2e1', ' 42 ', 'abc', undef), "\n";  # 1,
↪1,1,0,0

my $v = dualvar(5, 'five');
print $v + 1, ' ', "$v", "\n";                         # 6 five

my $ref = { name => 'x' };
my %cache = (x => $ref);
weaken($cache{x});                  # the cache does not keep it
↪alive
undef $ref;
print defined $cache{x} ? "kept\n" : "gone\n";         # gone
```

(continues on next page)

(continued from previous page)

```
print openhandle(\*STDIN) ? "open\n" : "closed\n";     # open
```

The builtin functions

- `blessed($ref)` - the class name of an object, undef for anything else (an unblessed reference, a plain scalar).
- `reftype($ref)` - the type a reference points to - HASH, ARRAY, SCALAR, CODE, GLOB, REGEXP, ... - ignoring any blessing; undef for a non-reference.
- `refaddr($ref)` - the address a reference points to, as a number; the same for every reference to the same thing, whatever its class or overloading.
- `weaken($ref)` - make this copy of a reference weak: it does not count towards keeping the target alive, and becomes undef when the target is freed. Copying it gives a strong reference again.
- `unweaken($ref)` - make a weak reference strong again.
- `isweak($ref)` - true if the reference is weak.

Differences from upstream

None: every function is checked against perl 5.44 by t/81-xs-native/Scalar-Util, and upstream's own tests pass unchanged (t/81-xs-native/List-Util, the `upstream` files).

Modules

- `Scalar::Util::Numeric` - Numeric tests for scalars: is a value a number, and what kind.

Functions

Inspection

`looks_like_number`

True if perl would use the value as a number without a "not numeric" warning: a number, or a string of digits with an optional sign, decimal point and exponent, surrounding whitespace allowed (`"42"`, `"-.5"`, `" 4.2e1 "`), or `"Inf"`, `"Infinity"`, `"NaN"`. False for undef, the empty string, `"abc"`, `"1e"`, and for the notations only literals have (`"0x10"`, `"1_000"`). An object that overloads `0+` counts by the value it converts to.

`tainted`

`tainted($var)` - returns true if `$var` is tainted.

readonly

`readonly($var)` - returns true if `$var` is read-only.

openhandle

The argument itself if it is an open filehandle - a glob, a reference to one, or an IO object, opened (or tied) - and undef otherwise: for a handle never opened, one already closed, or anything that is no handle.

isdual

True if the value currently has both a string and a numeric side - a `dualvar`, `$!`, but also an ordinary string once it has been used as a number (`my $n = "10"; $n + 0;` makes `isdual($n)` true), as perl caches the conversion.

isvstring

True if the value is a v-string - written as `v1.2.3`, or as a bare number with two or more dots (`1.2.3`) - and false for the string `"1.2.3"`.

Construction

dualvar

`dualvar($num, $str)`: a value that is `$num` where a number is used and `$str` where a string is - as `$!` is both an error number and its message.

Other Functions

reftype

`reftype($ref)` - returns type string without blessing.

set_prototype

`set_prototype($code, $prototype)` - sets the prototype of the subroutine given by the `$code` reference, or deletes it if `$prototype` is `undef`.

Scalar::Util::Numeric

Numeric tests for scalars: is a value a number, and what kind.

Each function asks perl's own number parser (`grok_number`, the one `looks_like_number` uses) about the string form of its argument, so a string and a number answer alike: `isint("42")` and `isint(42)` are both true.

Synopsis

```
use Scalar::Util::Numeric qw(isnum isint isfloat isneg);

print isnum("3.5e2") ? "number\n" : "not\n";   # number
print isint(" 7 "), "\n";                      # 1
print isint("-7"), "\n";                       # -1
print isfloat("1e3"), "\n";                    # 1
print isnum("abc"), "\n";                      # 0
```

Functions

`isnum($v)` is `grok_number`'s answer: 0 for a non-number, otherwise a set of flags - 0x01 the value fits a UV, 0x02 it is larger, 0x04 it has a fraction or an exponent, 0x08 it is negative, 0x10 infinity, 0x20 NaN. `isint` is 1 for a non-negative integer, -1 for a negative one and 0 otherwise; `isuv`, `isbig`, `isfloat`, `isneg`, `isinf` and `isnan` each test one flag and return 1 or 0. `uvmax()` is the largest UV. `undef` is not a number. Nothing is exported by default; `:all` exports the eight tests.

This is a native implementation of Scalar::Util::Numeric 0.40's `Numeric.xs`; its `Scalar/Util/Numeric.pm` is used unchanged.

Differences from upstream

None.

Functions

Numeric tests

uvmax

The largest unsigned integer perl holds natively.

Synopsis

```
my $max = Scalar::Util::Numeric::uvmax();   # 18446744073709551615
```

isnum

Whether a value is a number, and which kind.

isint

Whether a value is an integer, and its sign.

isuv

Whether a value is a number that fits an unsigned integer.

isbig

Whether a value is a number larger than the unsigned range.

isfloat

Whether a value is a number with a fraction or an exponent.

isneg

Whether a value is a negative number.

Synopsis

```
use Scalar::Util::Numeric qw(isneg);
isneg("-3");   # 1
```

What you get back

1 when the number has a leading minus sign, else 0.

isinf

Whether a value is infinity.

isnan

Whether a value is NaN.

Synopsis

```
use Scalar::Util::Numeric qw(isnan);
isnan("NaN");   # 1
```

What you get back

1 for a NaN, in any spelling perl reads as NaN, else 0.

isnum

Whether a value is a number, and which kind.

Synopsis

```
use Scalar::Util::Numeric qw(isnum);
my $flags = isnum($v);
```

What you get back

0 when $v is not a number or is undef; otherwise the flags of perl's number parser: 0x01 fits an unsigned integer, 0x02 is larger, 0x04 has a fraction or exponent, 0x08 is negative, 0x10 is infinity, 0x20 is NaN. Leading and trailing whitespace is allowed, as perl allows it when it converts a string.

isint

Whether a value is an integer, and its sign.

Synopsis

```
use Scalar::Util::Numeric qw(isint);
isint(42);       # 1
isint("-42");    # -1
isint(4.2);      # 0
```

What you get back

1 for a non-negative integer within the unsigned range, -1 for a negative integer within it, 0 for anything else - fractions, exponents, numbers beyond the range, and non-numbers.

isuv

Whether a value is a number that fits an unsigned integer.

Synopsis

```
use Scalar::Util::Numeric qw(isuv);
isuv("1.5");     # 1 - the integer part fits
```

What you get back

1 when the number's integer part is within the unsigned range, whatever its sign or fraction, else 0.

isbig

Whether a value is a number larger than the unsigned range.

Synopsis

```
use Scalar::Util::Numeric qw(isbig);
isbig("18446744073709551616");   # 1
```

What you get back

1 when the number's integer part exceeds the largest unsigned integer, else 0.

isfloat

Whether a value is a number with a fraction or an exponent.

Synopsis

```
use Scalar::Util::Numeric qw(isfloat);
isfloat("1.0");   # 1
isfloat("1e3");   # 1
isfloat(10);      # 0
```

What you get back

1 when the number is written with a decimal point or an exponent, or is infinity or NaN, else 0.

isinf

Whether a value is infinity.

Synopsis

```
use Scalar::Util::Numeric qw(isinf);
isinf("Inf");     # 1
isinf(9**9**9);   # 1
```

What you get back

1 for positive or negative infinity, in any spelling perl reads as infinity, else 0.

tainted

`tainted($var)` - returns true if `$var` is tainted.

Under taint mode (`-T`) everything that comes from outside the program is tainted: `%ENV`, `@ARGV`, `$0`, data read from files, and any value derived from them. Constants and values computed only from constants are not. Outside taint mode nothing is tainted, so this always returns false. Takes exactly one argument.

```
$taint = tainted("constant");       # false
$taint = tainted($ENV{PWD});        # true if running under -T
```

readonly

`readonly($var)` - returns true if `$var` is read-only.

The true value is not 1. Exactly as in perl5, it is the raw internal flag word, so a read-only scalar yields a number such as 134283264. Test it for truth; never compare it against 1. Takes exactly one argument.

```
sub foo { readonly($_[0]) }
$ro = foo($bar);                    # false
$ro = foo(0);                       # true
```

set_prototype

`set_prototype($code, $prototype)` - sets the prototype of the subroutine given by the `$code` reference, or deletes it if `$prototype` is `undef`.

Returns the `$code` reference itself, so calls can be chained. The code reference comes FIRST and the prototype second; `Sub::Util` spells the same operation with the arguments the other way round.

```
set_prototype \&foo, '$$';
```

The `&$` prototype makes the first argument a `\&name` or `sub {...}` and a call with fewer than two arguments a compile-time error. Called with `&` to bypass the prototype, a missing prototype argument deletes the prototype, and a first argument that is not a reference to a subroutine croaks with `set_prototype: not a subroutine reference` (`set_prototype: not a reference` when it is no reference at all).

5.2.89 Search

Namespace containing the following modules:

- `Search::Dict` - look - search for key in dictionary file

Search::Dict

look - search for key in dictionary file

SYNOPSIS

```
use Search::Dict;
look *FILEHANDLE, $key, $dict, $fold;

use Search::Dict;
look *FILEHANDLE, $key, $params;
```

DESCRIPTION

Sets file position in FILEHANDLE to be first line greater than or equal (stringwise) to *$key*. Returns the new file position, or -1 if an error occurs.

The flags specify dictionary order and case folding:

If *$dict* is true, search by dictionary order (ignore anything but word characters and whitespace). The default is honour all characters.

If *$fold* is true, ignore case. The default is to honour case.

If there are only three arguments and the third argument is a hash reference, the keys of that hash can have values `dict`, `fold`, and `comp` or `xfrm` (see below), and their corresponding values will be used as the parameters.

If a comparison subroutine (comp) is defined, it must return less than zero, zero, or greater than zero, if the first comparand is less than, equal, or greater than the second comparand.

If a transformation subroutine (xfrm) is defined, its value is used to transform the lines read from the filehandle before their comparison.

5.2.90 SelectSaver

save and restore selected file handle

SYNOPSIS

```
use SelectSaver;

{
   my $saver = SelectSaver->new(FILEHANDLE);
   # FILEHANDLE is selected
}
# previous handle is selected

{
   my $saver = SelectSaver->new;
   # new handle may be selected, or not
}
# previous handle is selected
```

DESCRIPTION

A `SelectSaver` object contains a reference to the file handle that was selected when it was created. If its new method gets an extra parameter, then that parameter is selected; otherwise, the selected file handle remains unchanged.

When a `SelectSaver` is destroyed, it re-selects the file handle that was selected when it was created.

5.2.91 SelfLoader

load functions only on demand

SYNOPSIS

```
package FOOBAR;
use SelfLoader;

... (initializing code)

__DATA__
sub {....
```

DESCRIPTION

This module tells its users that functions in the FOOBAR package are to be autoloaded from after the __DATA__ token. See also *"Autoloading" in perlsub*.

The __DATA__ token

The __DATA__ token tells the perl compiler that the perl code for compilation is finished. Everything after the __DATA__ token is available for reading via the filehandle FOOBAR::DATA, where FOOBAR is the name of the current package when the __DATA__ token is reached. This works just the same as __END__ does in package 'main', but for other modules data after __END__ is not automatically retrievable, whereas data after __DATA__ is. The __DATA__ token is not recognized in versions of perl prior to 5.001m.

Note that it is possible to have __DATA__ tokens in the same package in multiple files, and that the last __DATA__ token in a given package that is encountered by the compiler is the one accessible by the filehandle. This also applies to __END__ and main, i.e. if the 'main' program has an __END__, but a module 'require'd (_not_ 'use'd) by that program has a 'package main;' declaration followed by an '__DATA__', then the DATA filehandle is set to access the data after the __DATA__ in the module, _not_ the data after the __END__ token in the 'main' program, since the compiler encounters the 'require'd file later.

SelfLoader autoloading

The **SelfLoader** works by the user placing the __DATA__ token *after* perl code which needs to be compiled and run at 'require' time, but *before* subroutine declarations that can be loaded in later - usually because they may never be called.

The **SelfLoader** will read from the FOOBAR::DATA filehandle to load in the data after __DATA__, and load in any subroutine when it is called. The costs are the one-time parsing of the data after __DATA__, and a load delay for the _first_ call of any autoloaded function. The benefits (hopefully) are a speeded up compilation phase, with no need to load functions which are never used.

The **SelfLoader** will stop reading from __DATA__ if it encounters the __END__ token - just as you would expect. If the __END__ token is present, and is followed by the token DATA, then the **SelfLoader** leaves the FOOBAR::DATA filehandle open on the line after that token.

The **SelfLoader** exports the AUTOLOAD subroutine to the package using the **SelfLoader**, and this loads the called subroutine when it is first called.

There is no advantage to putting subroutines which will _always_ be called after the __DATA__ token.

Autoloading and package lexicals

A 'my $pack_lexical' statement makes the variable $pack_lexical local _only_ to the file up to the __DATA__ token. Subroutines declared elsewhere _cannot_ see these types of variables, just as if you declared subroutines in the package but in another file, they cannot see these variables.

So specifically, autoloaded functions cannot see package lexicals (this applies to both the **SelfLoader** and the Autoloader). The `vars` pragma provides an alternative to defining package-level globals that will be visible to autoloaded routines. See the documentation on **vars** in the pragma section of perlmod.

SelfLoader and AutoLoader

The **SelfLoader** can replace the AutoLoader - just change 'use AutoLoader' to 'use SelfLoader' (though note that the **SelfLoader** exports the AUTOLOAD function - but if you have your own AUTOLOAD and are using the AutoLoader too, you probably know what you're doing), and the __END__ token to __DATA__. You will need perl version 5.001m or later to use this (version 5.001 with all patches up to patch m).

There is no need to inherit from the **SelfLoader**.

The **SelfLoader** works similarly to the AutoLoader, but picks up the subs from after the __DATA__ instead of in the 'lib/auto' directory. There is a maintenance gain in not needing to run AutoSplit on the module at installation, and a runtime gain in not needing to keep opening and closing files to load subs. There is a runtime loss in needing to parse the code after the __DATA__. Details of the **AutoLoader** and another view of these distinctions can be found in that module's documentation.

__DATA__, __END__, and the FOOBAR::DATA filehandle

This section is only relevant if you want to use the FOOBAR::DATA together with the **SelfLoader**.

Data after the __DATA__ token in a module is read using the FOOBAR::DATA filehandle. __END__ can still be used to denote the end of the __DATA__ section if followed by the token DATA - this is supported by the **SelfLoader**. The FOOBAR::DATA filehandle is left open if an __END__ followed by a DATA is found, with the filehandle positioned at the start of the line after the __END__ token. If no __END__ token is present, or an __END__ token with no DATA token on the same line, then the filehandle is closed.

The **SelfLoader** reads from wherever the current position of the FOOBAR::DATA filehandle is, until the EOF or __END__. This means that if you want to use that filehandle (and ONLY if you want to), you should either

1. Put all your subroutine declarations immediately after the __DATA__ token and put your own data after those declarations, using the __END__ token to mark the end of

subroutine declarations. You must also ensure that the **SelfLoader** reads first by calling 'SelfLoader->load_stubs();', or by using a function which is selfloaded;

or

2. You should read the `FOOBAR::DATA` filehandle first, leaving the handle open and positioned at the first line of subroutine declarations.

You could conceivably do both.

Classes and inherited methods

For modules which are not classes, this section is not relevant. This section is only relevant if you have methods which could be inherited.

A subroutine stub (or forward declaration) looks like

```
sub stub;
```

i.e. it is a subroutine declaration without the body of the subroutine. For modules which are not classes, there is no real need for stubs as far as autoloading is concerned.

For modules which ARE classes, and need to handle inherited methods, stubs are needed to ensure that the method inheritance mechanism works properly. You can load the stubs into the module at 'require' time, by adding the statement 'SelfLoader->load_stubs();' to the module to do this.

The alternative is to put the stubs in before the `__DATA__` token BEFORE releasing the module, and for this purpose the `Devel::SelfStubber` module is available. However this does require the extra step of ensuring that the stubs are in the module. If this is done I strongly recommend that this is done BEFORE releasing the module - it should NOT be done at install time in general.

Multiple packages and fully qualified subroutine names

Subroutines in multiple packages within the same file are supported - but you should note that this requires exporting the `SelfLoader::AUTOLOAD` to every package which requires it. This is done automatically by the **SelfLoader** when it first loads the subs into the cache, but you should really specify it in the initialization before the `__DATA__` by putting a 'use SelfLoader' statement in each package.

Fully qualified subroutine names are also supported. For example,

```
__DATA__
sub foo::bar {23}
package baz;
sub dob {32}
```

will all be loaded correctly by the **SelfLoader**, and the **SelfLoader** will ensure that the packages 'foo' and 'baz' correctly have the **SelfLoader** `AUTOLOAD` method when the data after `__DATA__` is first parsed.

AUTHOR

`SelfLoader` is maintained by the perl5-porters. Please direct any questions to the canonical mailing list. Anything that is applicable to the CPAN release can be sent to its maintainer, though.

You should have received a copy of the Artistic License with this Kit, in the file named “Artistic”. If not, I’ll be glad to provide one.

You should also have received a copy of the GNU General Public License along with this program in the file named “Copying”. If not, see <https://www.gnu.org/licenses/>.

For those of you that choose to use the GNU General Public License, my interpretation of the GNU General Public License is that no Perl script falls under the terms of the GPL unless you explicitly put said script under the terms of the GPL yourself. Furthermore, any object code linked with perl does not automatically fall under the terms of the GPL, provided such object code only adds definitions of subroutines and variables, and does not otherwise impair the resulting interpreter from executing any standard Perl script. I consider linking in C subroutines in this manner to be the moral equivalent of defining subroutines in the Perl language itself. You may sell such an object file as proprietary provided that you provide or offer to provide the Perl source, as specified by the GNU General Public License. (This is merely an alternate way of specifying input to the program.) You may also sell a binary produced by the dumping of a running Perl script that belongs to you, provided that you provide or offer to provide the Perl source as specified by the GPL. (The fact that a Perl interpreter and your code are in the same binary file is, in this case, a form of mere aggregation.) This is my interpretation of the GPL. If you

still have concerns or difficulties understanding my intent, feel free to contact me. Of course, the Artistic License spells all this out for your protection, so you may prefer to use that.

5.2.92 Socket

BSD socket constants and address pack/unpack helpers that feed Perl's built-in `socket`, `bind`, `connect`, `accept`, `send`, `recv`, `setsockopt`, and `shutdown`.

Typical flow: import a constant, pack it into a sockaddr, hand the result to the built-in.

```
use Socket;
socket(my $sock, PF_INET, SOCK_STREAM, IPPROTO_TCP) or die $!;
my $addr = pack_sockaddr_in(80, inet_aton("127.0.0.1"));
connect($sock, $addr) or die $!;
```

What lives here

- **Address families**: `AF_INET`, `AF_INET6`, `AF_UNIX`, `AF_LOCAL`, `AF_UNSPEC`, plus the matching `PF_*` protocol families.
- **Socket types**: `SOCK_STREAM`, `SOCK_DGRAM`, `SOCK_RAW`, `SOCK_SEQPACKET`.
- **Well-known addresses**: `INADDR_ANY`, `INADDR_LOOPBACK`, `INADDR_BROADCAST`, `INADDR_NONE`, `IN6ADDR_ANY`, `IN6ADDR_LOOPBACK` (packed binary, ready for `pack_sockaddr_in` / `pack_sockaddr_in6`).
- **Protocol numbers**: `IPPROTO_IP`, `IPPROTO_TCP`, `IPPROTO_UDP`, `IPPROTO_IPV6`, `IPPROTO_ICMP`, `IPPROTO_RAW`.
- **Socket-option levels and names**: `SOL_SOCKET`, `SO_REUSEADDR`, `SO_KEEPALIVE`, `SO_BROADCAST`, `SO_LINGER`, `SO_SNDBUF`, `SO_RCVBUF`, `SO_ERROR`, `SO_TYPE`, and the rest of the `SO_*` family.
- **TCP options**: `TCP_NODELAY`.
- **IP options**: `IP_TOS`, `IP_TTL`, `IP_MULTICAST_TTL`, `IP_MULTICAST_LOOP`, `IP_ADD_MEMBERSHIP`, `IP_DROP_MEMBERSHIP`, plus the `IPV6_*` counterparts.
- **Message flags**: `MSG_OOB`, `MSG_PEEK`, `MSG_DONTWAIT`, `MSG_WAITALL`, `MSG_NOSIGNAL`.
- **Shutdown modes**: `SHUT_RD`, `SHUT_WR`, `SHUT_RDWR`.
- **Address packing**: `pack_sockaddr_in`, `unpack_sockaddr_in`, `pack_sockaddr_in6`, `unpack_sockaddr_in6`, `pack_sockaddr_un`, `unpack_sockaddr_un`, plus the dual-mode `sockaddr_in` / `sockaddr_in6` shortcuts and the `sockaddr_family` extractor.
- **Address parsing**: `inet_aton`, `inet_ntoa`, `inet_pton`, `inet_ntop`.
- **Name resolution**: `getaddrinfo`, `getnameinfo`, plus the `AI_*`, `NI_*`, and `EAI_*` flag and error constants.

The dual-mode shortcuts

`sockaddr_in`, `sockaddr_in6` and `sockaddr_un` pack in scalar context and unpack in list context:

```
my $sin           = sockaddr_in(80, inet_aton("127.0.0.1"));
my ($port, $addr) = sockaddr_in(getpeername($sock));
```

A wrong argument count for the chosen direction croaks with a usage message. The old six-argument `sockaddr_in($af, $port, @quad)` still packs, and warns "6-ARG sockaddr_in call is deprecated" under `use warnings 'Socket'`.

A constant this system does not have dies when called: a name Socket knows but the platform lacks (`AF_802`, `SO_STATE`) with "Your vendor has not defined Socket macro AF_802, used at FILE line N", any other name with "FOO is not a valid Socket macro at FILE line N".

Differences from upstream

One, where perl 5.44 with Socket.xs fails: `unpack_sockaddr_un` of an abstract address (a `sun_path` starting with a NUL byte) that is longer than `sun_path` returns the 108 bytes `sun_path` holds. Socket.xs trusts the given length and returns bytes read from past the end of its copy of the structure (t/81-xs-native/Socket/190-or-better.t).

Address packing

pack_ip_mreq

Pack an IPv4 multicast group membership request, the value the `IP_ADD_MEMBERSHIP` and `IP_DROP_MEMBERSHIP` socket options take.

unpack_ip_mreq

Split a packed IPv4 multicast group membership request back into its two addresses.

pack_ip_mreq_source

Pack a source-specific IPv4 multicast group membership request, the value the `IP_ADD_SOURCE_MEMBERSHIP` family of socket options takes.

unpack_ip_mreq_source

Split a packed source-specific IPv4 multicast group membership request back into its three addresses.

pack_ipv6_mreq

Pack an IPv6 multicast group membership request, the value the `IPV6_ADD_MEMBERSHIP` and `IPV6_DROP_MEMBERSHIP` socket options take.

unpack_ipv6_mreq

Split a packed IPv6 multicast group membership request back into its address and interface index.

pack_sockaddr_in

Build a packed `sockaddr_in` from a port number and a 4-byte IPv4 address, ready to hand to `bind` or `connect`.

unpack_sockaddr_in

Split a packed `sockaddr_in` back into its port and 4-byte address.

pack_sockaddr_in6

Build a packed `sockaddr_in6` from a port, a 16-byte IPv6 address, and optional scope and flow-info fields.

unpack_sockaddr_in6

Split a packed `sockaddr_in6` into port, 16-byte address, scope id, and flow-info.

pack_sockaddr_un

Build a packed `sockaddr_un` from a filesystem path, for use with Unix-domain sockets.

unpack_sockaddr_un

Extract the filesystem path from a packed `sockaddr_un`.

sockaddr_family

Read the address-family byte from any packed sockaddr without committing to one unpacking shape.

sockaddr_in

Dual-mode shortcut: in scalar context it behaves like `pack_sockaddr_in`; in list context it behaves like `unpack_sockaddr_in`.

sockaddr_in6

Dual-mode IPv6 shortcut: in scalar context it behaves like `pack_sockaddr_in6`; in list context it behaves like `unpack_sockaddr_in6`.

Address parsing

inet_aton

Turn a dotted-quad string or a hostname into a 4-byte packed IPv4 address, or undef if the name cannot be resolved.

inet_ntoa

Turn a 4-byte packed IPv4 address back into a dotted-quad string.

inet_pton

Parse an address string into its packed binary form for either IPv4 or IPv6, selected by the first argument.

inet_ntop

Turn a packed IPv4 or IPv6 address back into its printable string form, selected by the first argument.

Name resolution

getaddrinfo

Resolve a host name and/or service name into a list of ready-to-use address records, honouring IPv4/IPv6 and protocol preferences carried through a hints hash.

getnameinfo

Turn a packed sockaddr into a host name and service name, with optional flags to force numeric output or demand a successful DNS lookup.

inet_aton

Turn a dotted-quad string or a hostname into a 4-byte packed IPv4 address, or undef if the name cannot be resolved.

Synopsis

```
my $packed = inet_aton("127.0.0.1");
my $packed = inet_aton("localhost");
```

What you get back

A 4-byte string in network byte order suitable as the second argument to pack_sockaddr_in, or undef on failure. To see the bytes as a human-readable address, pass the result through inet_ntoa.

Examples

```
my $loop = inet_aton("127.0.0.1");        # 4-byte string
print join(".", unpack("C4", $loop));     # 127.0.0.1
```

```
my $sin = pack_sockaddr_in(80, inet_aton("example.com"));
# pass $sin to connect()
```

Edge cases

- A literal IPv4 address is parsed directly - no DNS lookup.
- A non-resolvable name returns `undef`.
- IPv6 addresses are rejected here; use `inet_pton(AF_INET6, ...)`.

Differences from upstream

Fully compatible with upstream Socket.

See also

- `inet_ntoa` - reverse direction, packed bytes to dotted-quad string.
- `inet_pton` - same idea but parameterised by address family.
- `pack_sockaddr_in` - the immediate consumer of the packed address.
- `getaddrinfo` - richer resolver when you also need a port or IPv6.

inet_ntoa

Turn a 4-byte packed IPv4 address back into a dotted-quad string.

Synopsis

```
my $str = inet_ntoa($packed_ipv4);
```

What you get back

A string like `"192.0.2.1"`.

Examples

```
print inet_ntoa(INADDR_LOOPBACK);    # 127.0.0.1
```

```
my ($port, $ip) = unpack_sockaddr_in($peer);
printf "%s:%d\n", inet_ntoa($ip), $port;
```

Edge cases

- Input of any length but 4 croaks “Bad arg length for Socket::inet_ntoa, length is N, should be 4”.
- A character above 255 croaks “Wide character in Socket::inet_ntoa”.

Differences from upstream

Fully compatible with upstream Socket.

See also

- `inet_aton` - reverse direction, string to packed bytes.
- `inet_ntop` - same idea for IPv4 or IPv6, parameterised by family.
- `unpack_sockaddr_in` - usually the producer of the packed address.

inet_pton

Parse an address string into its packed binary form for either IPv4 or IPv6, selected by the first argument.

Synopsis

```
my $v4 = inet_pton(AF_INET,  "192.0.2.1");
my $v6 = inet_pton(AF_INET6, "2001:db8::1");
```

What you get back

A 4-byte string for `AF_INET` or a 16-byte string for `AF_INET6`, in network byte order. Returns `undef` when the string is not a valid address for the requested family.

Examples

```
my $addr = inet_pton(AF_INET6, "::1");
my $sin6 = pack_sockaddr_in6(443, $addr);
```

```
defined(inet_pton(AF_INET, $input))
    or die "not a valid IPv4 address: $input\n";
```

Edge cases

- A family other than `AF_INET` or `AF_INET6` croaks “Bad address family for Socket::inet_pton”.
- Unlike `inet_aton`, there is no DNS fallback - hostnames are rejected.
- Scoped IPv6 literals like `"fe80::1%eth0"` are not accepted; use `getaddrinfo` to carry the zone index through.

Differences from upstream

Fully compatible with upstream Socket.

See also

- `inet_ntop` - reverse direction, packed bytes to string.
- `inet_aton` - IPv4-only convenience with DNS fallback.
- `pack_sockaddr_in6` - the usual consumer of an IPv6 packed address.

inet_ntop

Turn a packed IPv4 or IPv6 address back into its printable string form, selected by the first argument.

Synopsis

```
my $s = inet_ntop(AF_INET,  $packed4);
my $s = inet_ntop(AF_INET6, $packed6);
```

What you get back

A dotted-quad string for `AF_INET`, a canonical colon-hex string (with `::` compression) for `AF_INET6`.

Examples

```
print inet_ntop(AF_INET6, IN6ADDR_LOOPBACK);   # ::1
```

```
my ($port, $addr, $scope, $flow) = unpack_sockaddr_in6($peer);
printf "[%s]:%d\n", inet_ntop(AF_INET6, $addr), $port;
```

Edge cases

- Input that is not exactly the family's address length (4 or 16) croaks "Bad address length for Socket::inet_ntop".
- Any family other than `AF_INET` or `AF_INET6` croaks "Bad address family for Socket::inet_ntop".
- A character above 255 croaks "Wide character in Socket::inet_ntop".

Differences from upstream

Fully compatible with upstream Socket.

See also

- `inet_pton` - reverse direction, string to packed bytes.
- `inet_ntoa` - IPv4-only shortcut with no family argument.

pack_sockaddr_in

Build a packed `sockaddr_in` from a port number and a 4-byte IPv4 address, ready to hand to `bind` or `connect`.

Synopsis

```
my $sin = pack_sockaddr_in($port, $packed_ipv4);
```

What you get back

A fixed-size byte string whose layout matches the platform's `struct sockaddr_in`: address family (`AF_INET`), port in network byte order, the raw 4 address bytes, and trailing padding. The result is opaque from Perl's perspective - treat it as a cookie for the socket built-ins.

Examples

```
my $addr = pack_sockaddr_in(80, inet_aton("example.com"));
connect($sock, $addr) or die $!;
```

```
# Bind to every local interface on a chosen port.
bind($sock, pack_sockaddr_in(8080, INADDR_ANY)) or die $!;
```

Edge cases

- Port is truncated to 16 bits; a value above 65535 warns "Port number above 0xFFFF, will be truncated to N". An `undef` port is 0.
- An address of any length but 4 croaks "Bad arg length"; an `undef` address croaks "Undefined address".
- The address argument is a **packed** 4-byte string, not a dotted-quad literal. Pass `inet_aton(...)` or `INADDR_*`.

See also

- `unpack_sockaddr_in` - reverse direction.
- `sockaddr_in` - dual-mode shortcut: packs in scalar context, unpacks in list context (a Perl sub in Socket.pm).
- `pack_sockaddr_in6` - IPv6 counterpart.
- `inet_aton` - usual source of the address argument.

unpack_sockaddr_in

Split a packed `sockaddr_in` back into its port and 4-byte address.

Synopsis

```
my ($port, $packed_ipv4) = unpack_sockaddr_in($sockaddr);
```

What you get back

A two-element list: the port as an integer, the address as a 4-byte packed string. Feed the second through `inet_ntoa` to see it as dotted-quad. In scalar context only the address comes back.

Examples

```
my $peer = getpeername($sock);
my ($port, $ip) = unpack_sockaddr_in($peer);
printf "connected from %s:%d\n", inet_ntoa($ip), $port;
```

Edge cases

- Input that is not exactly a `sockaddr_in` croaks “Bad arg length”; `undef` croaks “Undefined address”.
- A family other than `AF_INET` croaks “Bad address family”.

See also

- `pack_sockaddr_in` - reverse direction.
- `sockaddr_family` - read just the family byte without unpacking.
- `unpack_sockaddr_in6` - IPv6 counterpart.
- `inet_ntoa` - turn the returned packed address into a string.

pack_sockaddr_in6

Build a packed `sockaddr_in6` from a port, a 16-byte IPv6 address, and optional scope and flow-info fields.

Synopsis

```
my $sin6 = pack_sockaddr_in6($port, $packed_ipv6);
my $sin6 = pack_sockaddr_in6($port, $packed_ipv6, $scope_id,
 ↪$flowinfo);
```

What you get back

A fixed-size byte string matching the platform's `struct sockaddr_in6`, ready for `bind` or `connect`.

Examples

```
my $addr = inet_pton(AF_INET6, "::1");
my $sin6 = pack_sockaddr_in6(443, $addr);
connect($sock, $sin6) or die $!;
```

```
# Link-local address with scope index for eth0.
my $scope = scalar getsockopt(...);   # or from if_nametoindex
my $sin6  = pack_sockaddr_in6(5353, inet_pton(AF_INET6, "fe80::1"),
 ↪$scope);
```

Edge cases

- `$scope_id` and `$flowinfo` default to 0 when omitted.
- An address of any length but 16 croaks "Bad arg length"; `undef` croaks "Undefined address".
- Port and flow-info are truncated to 16 and 32 bits respectively; a port above 65535 warns "Port number above 0xFFFF".

See also

- `unpack_sockaddr_in6` - reverse direction.
- `sockaddr_in6` - dual-mode shortcut: packs in scalar context, unpacks in list context (a Perl sub in Socket.pm).
- `pack_sockaddr_in` - IPv4 counterpart.
- `inet_pton` - usual source of the address argument.

unpack_sockaddr_in6

Split a packed `sockaddr_in6` into port, 16-byte address, scope id, and flow-info.

Synopsis

```
my ($port, $addr, $scope_id, $flowinfo) = unpack_sockaddr_in6(
 ↪$sockaddr);
```

What you get back

A four-element list in list context; the address alone in scalar context.

Examples

```
my ($port, $addr, $scope, $flow) = unpack_sockaddr_in6(getpeername(
 ↪$sock));
printf "[%s%%%d]:%d\n", inet_ntop(AF_INET6, $addr), $scope, $port;
```

Edge cases

- Scope id and flow-info are often 0 for non-link-local traffic.
- Input that is not exactly a `sockaddr_in6` croaks “Bad arg length”; `undef` croaks “Undefined address”.
- A family other than `AF_INET6` croaks “Bad address family”.

See also

- `pack_sockaddr_in6` - reverse direction.
- `unpack_sockaddr_in` - IPv4 counterpart.
- `inet_ntop` - turn the returned packed address into a string.

pack_sockaddr_un

Build a packed `sockaddr_un` from a filesystem path, for use with Unix-domain sockets.

Synopsis

```
my $sun = pack_sockaddr_un($path);
```

What you get back

A fixed-size byte string matching the platform’s `struct sockaddr_un`, ready for `bind` or `connect` against an `AF_UNIX` / `AF_LOCAL` socket.

Examples

```
socket(my $sock, AF_UNIX, SOCK_STREAM, 0) or die $!;
connect($sock, pack_sockaddr_un("/tmp/app.sock")) or die $!;
```

```
# Abstract Linux namespace: first byte is NUL.
my $sun = pack_sockaddr_un("\0app.mysvc");
```

Edge cases

- A path longer than `sun_path` (108 bytes) warns “Path length (N) is longer than maximum supported length (108) and will be truncated” and is cut to fit.
- An `undef` path croaks “Undefined path for Socket::pack_sockaddr_un”.

- An abstract name (leading NUL, more than one byte) gives a structure that ends where the name ends, since such a name may itself contain NULs; any other path gives the full structure.

See also

- `unpack_sockaddr_un` - reverse direction.
- `sockaddr_family` - read the family byte from an unknown sockaddr.

unpack_sockaddr_un

Extract the filesystem path from a packed `sockaddr_un`.

Synopsis

```
my ($path) = unpack_sockaddr_un($sockaddr);
```

What you get back

The `sun_path` field as a string, trimmed at the first NUL byte.

Examples

```
my ($path) = unpack_sockaddr_un(getsockname($sock));
print "listening on $path\n";
```

Edge cases

- An abstract Linux-namespace name (leading NUL) comes back whole, NULs included: its length is the structure's length less the family field.
- A structure shorter than `struct sockaddr_un` is accepted, as the kernel returns from `accept`, `recvfrom`, `getpeername` and `getsockname`.
- `undef` croaks "Undefined address for Socket::unpack_sockaddr_un"; a family other than `AF_UNIX` croaks "Bad address family".

See also

- `pack_sockaddr_un` - reverse direction.

sockaddr_family

Read the address-family byte from any packed sockaddr without committing to one unpacking shape.

Synopsis

```
my $family = sockaddr_family($sockaddr);
```

What you get back

An integer equal to one of `AF_INET`, `AF_INET6`, `AF_UNIX`, etc.

Examples

```
my $sa = getpeername($sock);
if (sockaddr_family($sa) == AF_INET6) {
    my ($port, $addr) = unpack_sockaddr_in6($sa);
    ...
} else {
    my ($port, $addr) = unpack_sockaddr_in($sa);
    ...
}
```

Edge cases

- The family byte is read in native byte order - this matches how every `pack_sockaddr_*` writes it.
- Input shorter than 2 bytes croaks “Bad arg length for Socket::sockaddr_family, length is N, should be at least 2”.

See also

- `unpack_sockaddr_in`, `unpack_sockaddr_in6`, `unpack_sockaddr_un`: the right unpacker depends on the family returned here.

getaddrinfo

Resolve a host name and/or service name into a list of ready-to-use address records, honouring IPv4/IPv6 and protocol preferences carried through a hints hash.

Synopsis

```
my ($err, @res) = getaddrinfo($host, $service);
my ($err, @res) = getaddrinfo($host, $service, { family => AF_INET6␣
↪});
```

What you get back

A list whose first element is the error, a dualvar: as a string it is empty on success, otherwise the message from `gai_strerror`; as a number it is 0 or the `EAI_*` code, so `$err == EAI_NONAME` works. Every subsequent element is a hash reference describing one resolved endpoint, with keys:

- `family` - integer address family (`AF_INET`, `AF_INET6`, ...).
- `socktype` - integer socket type (`SOCK_STREAM`, `SOCK_DGRAM`, ...).
- `protocol` - integer protocol number.
- `addr` - packed sockaddr ready for `bind` or `connect`.
- `canonname` - canonical hostname (only populated when the hints hash requests it with `flags => AI_CANONNAME`).

The hints hash accepts `family`, `socktype`, `protocol`, and `flags`, each an integer; unknown keys are ignored.

Examples

```
my ($err, @res) = getaddrinfo("example.com", "https",
    { socktype => SOCK_STREAM });
die "resolve: $err\n" if $err;
for my $r (@res) {
    socket(my $s, $r->{family}, $r->{socktype}, $r->{protocol}) or␣
 ↪next;
    connect($s, $r->{addr}) and last;
    close $s;
}
```

```
# Numeric-only, no DNS lookup, no service lookup.
my ($err, @res) = getaddrinfo("2001:db8::1", "443",
    { flags => AI_NUMERICHOST | AI_NUMERICSERV });
```

```
# Listening side: ask for a wildcard bind address.
my ($err, @res) = getaddrinfo(undef, "8080",
    { flags => AI_PASSIVE, family => AF_INET6 });
```

Edge cases

- On error the result list is exactly one element, the message, so `scalar @res` is 1 and the first hashref is absent.
- Pass `undef` for `$host` to resolve a service with no specific host (typically combined with `AI_PASSIVE`).
- Pass `undef` for `$service` to resolve a host with no port.
- Hints that are defined but not a hash reference croak “hints is not a HASH reference”.

See also

- `getnameinfo` - reverse direction, sockaddr to host and service.
- `inet_pton` - parse a single address string without a full resolver.
- `pack_sockaddr_in`, `pack_sockaddr_in6` - when you already have the address bytes and just need the struct.

getnameinfo

Turn a packed sockaddr into a host name and service name, with optional flags to force numeric output or demand a successful DNS lookup.

Synopsis

```
my ($err, $host, $service) = getnameinfo($sockaddr);
my ($err, $host, $service) = getnameinfo($sockaddr, $flags);
my ($err, $host, $service) = getnameinfo($sockaddr, $flags,
 ↪$xflags);
```

What you get back

`($err, $host, $service)`; on error, `$err` alone. `$err` is the same dualvar `getaddrinfo` returns. `$xflags` takes `NIx_NOHOST` and `NIx_NOSERV`, which skip that half of the lookup and return it as `undef`.

Useful flag bits:

- `NI_NUMERICHOST` - skip DNS, return a printable address.
- `NI_NUMERICSERV` - return the port number as a decimal string.
- `NI_NAMEREQD` - fail instead of falling back to numeric host.
- `NI_NOFQDN` - local hosts keep their short name.
- `NI_DGRAM` - look up the service as UDP rather than TCP.

Examples

```
my ($err, $host, $svc) = getnameinfo(getpeername($sock));
die "reverse lookup: $err\n" if $err;
print "peer: $host:$svc\n";
```

```
# Numeric formatting only - no DNS, no /etc/services.
my ($err, $host, $svc) = getnameinfo($sockaddr,
    NI_NUMERICHOST | NI_NUMERICSERV);
```

Edge cases

- A sockaddr that is not a string croaks “addr is not a string”.
- A malformed sockaddr is reported through `$err` (`EAI_FAMILY`).

See also

- `getaddrinfo` - reverse direction, name to sockaddr.
- `inet_ntop` - format a raw address without a resolver.

- `unpack_sockaddr_in`, `unpack_sockaddr_in6` - when you need the numeric port and address without any lookup.

sockaddr_in

Dual-mode shortcut: in scalar context it behaves like `pack_sockaddr_in`; in list context it behaves like `unpack_sockaddr_in`.

Synopsis

```
my $sin             = sockaddr_in($port, $packed_ipv4);
my ($port, $addr)   = sockaddr_in($sockaddr);
```

What you get back

The same values as the underlying `pack_sockaddr_in` or `unpack_sockaddr_in`, depending on calling context.

Examples

```
# Packing
connect($sock, sockaddr_in(80, inet_aton("127.0.0.1"))) or die $!;
```

```
# Unpacking
my ($port, $ip) = sockaddr_in(getpeername($sock));
```

Edge cases

- The dispatch is on calling context, not argument count. In list context exactly one argument is required, in scalar context exactly two (or the deprecated six-argument form); any other count croaks with a usage message, so `my ($p, $a) = sockaddr_in($port, $ip)` dies.
- Prefer the explicit `pack_sockaddr_in` / `unpack_sockaddr_in` in new code; this name exists for compatibility with older Perl idioms.

Differences from upstream

Fully compatible with upstream Socket.

See also

- `pack_sockaddr_in`, `unpack_sockaddr_in` - the explicit forms.
- `sockaddr_in6` - IPv6 counterpart with the same dual behaviour.

sockaddr_in6

Dual-mode IPv6 shortcut: in scalar context it behaves like `pack_sockaddr_in6`; in list context it behaves like `unpack_sockaddr_in6`.

Synopsis

```
my $sin6                              = sockaddr_in6($port, $addr);
my $sin6                              = sockaddr_in6($port, $addr,
 ↪$scope, $flow);
my ($port, $addr, $scope, $flow)  = sockaddr_in6($sockaddr);
```

What you get back

The same values as the underlying `pack_sockaddr_in6` or `unpack_sockaddr_in6`, depending on calling context.

Examples

```
my $sin6 = sockaddr_in6(443, inet_pton(AF_INET6, "::1"));
```

```
my ($port, $addr) = sockaddr_in6(getpeername($sock));
```

Edge cases

- The dispatch is on calling context - list context requires exactly one argument, scalar context two to four; any other count croaks with a usage message.
- Prefer the explicit pack/unpack forms in new code.

Differences from upstream

Fully compatible with upstream Socket.

See also

- `pack_sockaddr_in6`, `unpack_sockaddr_in6` - the explicit forms.
- `sockaddr_in` - IPv4 counterpart.

5.2.93 Storable

Serialise arbitrary Perl data structures to bytes, reconstruct them later, or deep-clone them in memory.

`Storable` turns a reference - to a scalar, array, hash, blessed object, or any tree built from them - into an opaque byte string that can be written to disk, sent over a socket, or fed back into the module to reproduce the original structure. The round trip preserves shared references, circular references, weak references, tied variables, regexp objects, and blessed classes (with `STORABLE_freeze` / `STORABLE_thaw` hooks honoured).

Two axes of choice cover every use:

- **Where the bytes go.** `freeze` returns them as a string, `store` writes them to a named file, `store_fd` writes them to an open filehandle. `thaw`, `retrieve`, and `fd_retrieve` are the matching readers.
- **Byte order on the wire.** `freeze` / `store` / `store_fd` use the host's native byte order - fastest, but only portable between machines of the same endianness and integer size. The n-prefixed variants `nfreeze`, `nstore`, `nstore_fd` use network (big-endian) order and are portable across architectures. The reader side auto-detects which was used.

`dclone` is the in-memory shortcut for "I want a structurally independent copy of this data." It serialises and immediately deserialises, so every element is freshly allocated and every `STORABLE_freeze` / `STORABLE_thaw` hook runs - which is the only safe way to clone objects that wrap non-SV resources (a PDL's engine pointer, a tied variable's backing state, a file handle).

`file_magic` and `read_magic` inspect a frozen payload without thawing it, returning a hash describing byte order, header size, and version metadata. Use them to validate untrusted input or to pick a reader before committing to a thaw.

This is Storable 3.41; `Storable.pm` is upstream's, its engine native. An image written by perl5's Storable reads here and the other way round.

Synopsis

```
use Storable qw(nstore retrieve nfreeze thaw dclone);

my %config = (name => 'demo', ports => [80, 443], nested => { on =>␣
↪1 });
nstore(\%config, 'config.sto');             # portable byte order
my $back = retrieve('config.sto');
print "$back->{name} @{ $back->{ports} }\n"; # demo 80 443

my $bytes = nfreeze([1, { two => 2 }]);      # a string, e.g. for a␣
↪socket
print thaw($bytes)->[1]{two}, "\n";          # 2

my $deep = dclone(\%config);                 # an independent copy
$deep->{ports}[0] = 8080;                    # %config keeps 80

package Counter;                             # what an object stores
sub STORABLE_freeze { my ($self, $cloning) = @_; return $self->{n} }
sub STORABLE_thaw   { my ($self, $cloning, $n) = @_; $self->{n} = $n␣
↪}
```

The functions, written in Perl

`store` and `retrieve` are exported by default, the rest on request.

- `store($ref, $file)`, `nstore($ref, $file)` - write to a file; `lock_store`, `lock_nstore` take an exclusive `flock` first.

- `retrieve($file)`, `lock_retrieve($file)` - read one back.
- `store_fd($ref, $fh)`, `nstore_fd($ref, $fh)`, `fd_retrieve($fh)` - the same over an open filehandle.
- `freeze($ref)`, `nfreeze($ref)`, `thaw($string)` - to and from a string.
- `file_magic($file)`, `read_magic($string)` - the header of an image as a hash, without reading it.

A writer dies on what it cannot store ("Can't store CODE items"). A reader returns undef for a truncated image and dies for one that is no Storable image at all ("Magic number checking on storable string failed", or a version it does not know). `$Storable::canonical` sorts hash keys, so equal data gives equal bytes; `$Storable::Deparse` and `$Storable::Eval` store and restore code references.

Differences from upstream

Two, each where perl 5.44 with Storable.xs fails (t/81-xs-native/Storable/980-or-better.t):

- An image whose length field asks for more memory than the process can get is a truncated image: the read returns undef. perl5 dies "Out of memory!", ending the process.
- `Storable::pretrieve` on a handle with nothing to read (opened, then closed) fails the image check; perl5 parses whatever an earlier `freeze` left in its buffer.

Functions

Deep cloning

dclone

A deep copy of what a reference points to: every array, hash and scalar in it newly made, shared and circular references kept as they were, objects re-blessed, and `STORABLE_freeze`/`STORABLE_thaw` hooks run - in one step, without a byte string in between. Dies "Not a reference" for anything else, and "Can't store CODE items" for a structure holding a code reference unless `$Storable::Deparse` and `$Storable::Eval` are set, as for `freeze`.

Inside a hook

last_op_in_netorder

True if the last store or retrieve used network byte order (`nstore`, `nfreeze`, or reading such an image), false after a native one. Not exportable: call it as `Storable::last_op_in_netorder()`.

is_storing

True while a store is running - inside a `STORABLE_freeze` hook, say - and false otherwise. Call it as `Storable::is_storing()`.

is_retrieving

True while a retrieve is running - inside a `STORABLE_thaw` hook, say - and false otherwise. Call it as `Storable::is_retrieving()`.

Recursion limits

stack_depth

How deeply nested arrays a store or retrieve may follow before it dies "Max. recursion depth with nested structures exceeded": `$Storable::recursion_limit`, 512 unless set (-1 for no limit).

stack_depth_hash

The same for nested hashes: `$Storable::recursion_limit_hash`, 256 unless set (-1 for no limit).

5.2.94 String

Namespace containing the following modules:

- `String::CRC32` - Compute the 32-bit CRC of a string or of what a filehandle reads, the CRC-32 of zip, gzip and PNG.

String::CRC32

Compute the 32-bit CRC of a string or of what a filehandle reads, the CRC-32 of zip, gzip and PNG.

`crc32` is exported by default. Its last argument, when it has more than one, is the CRC to continue from, so a large input can be taken in pieces. A filehandle is read from where it stands to its end.

The CRC is computed by the zlib engine of the built-in Compress::Raw::Zlib, so the two modules always agree.

This is a native implementation of String::CRC32 2.100's `CRC32.xs`; its `String/CRC32.pm` is used unchanged.

Synopsis

```
use String::CRC32;

printf "%08x\n", crc32("123456789");          # cbf43926
my $crc = crc32("12345");
printf "%08x\n", crc32("6789", $crc);         # cbf43926, continued

open my $fh, '<:raw', $path or die $!;
my $file_crc = crc32($fh);                    # the rest of the file
```

Differences from upstream

One, where perl 5.44 with CRC32.xs fails (t/81-xs-native/String-CRC32/150-or-better.t): a filehandle whose read fails, a closed one for instance, gives the CRC of no data. perl5 keeps the failed read's -1 as 65535 bytes read, from a buffer of 32768, and dumps core.

Functions

Checksums

`crc32`

`crc32($data)`, `crc32($data, $crc)`: the CRC-32 of a string (its bytes; a character string's UTF-8), or of what a filehandle - a glob, a reference to one, an IO object - reads from where it stands to its end. With more than one argument, the last is the CRC to continue from (0 when there is none), read as a number. The CRC is an unsigned integer.

5.2.95 Sub

Namespace containing the following modules:

- `Sub::Exporter`
- `Sub::Identify` - Ask a code reference for its name, its package and where it was defined.
- `Sub::Name` - Give a sub a name: what `caller`, stack traces and profilers report for it.
- `Sub::Util` - Names and prototypes of code references: read the name a sub was defined under, give an anonymous sub a name that stack traces, `caller` and profilers show, and set a sub's prototype at run time.

Sub::Exporter

Namespace containing the following modules:

- `Sub::Exporter::Progressive` - Only use Sub::Exporter if you need it

Sub::Exporter::Progressive

Only use Sub::Exporter if you need it

VERSION

version 0.001013

SYNOPSIS

```
package Syntax::Keyword::Gather;

use Sub::Exporter::Progressive -setup => {
```

(continues on next page)

(continued from previous page)

```
  exports => [qw( break gather gathered take )],
  groups => {
    default => [qw( break gather gathered take )],
  },
};

# elsewhere

# uses Exporter for speed
use Syntax::Keyword::Gather;

# somewhere else

# uses Sub::Exporter for features
use Syntax::Keyword::Gather 'gather', take => { -as => 'grab' };
```

DESCRIPTION

Sub::Exporter is an incredibly powerful module, but with that power comes great responsibility, er- as well as some runtime penalties. This module is a `Sub::Exporter` wrapper that will let your users just use *Exporter* if all they are doing is picking exports, but use `Sub::Exporter` if your users try to use `Sub::Exporter`'s more advanced features, like renaming exports, if they try to use them.

Note that this module will export `@EXPORT`, `@EXPORT_OK` and `%EXPORT_TAGS` package variables for `Exporter` to work. Additionally, if your package uses advanced `Sub::Exporter` features like currying, this module will only ever use `Sub::Exporter`, so you might as well use it directly.

Sub::Identify

Ask a code reference for its name, its package and where it was defined.

Synopsis

```
use Sub::Identify qw(sub_name stash_name sub_fullname get_code_info
                     get_code_location is_sub_constant);

sub Foo::bar { 1 }
my $code = \&Foo::bar;
print sub_name($code), "\n";        # bar
print stash_name($code), "\n";      # Foo
print sub_fullname($code), "\n";    # Foo::bar
my ($file, $line) = get_code_location($code);
print is_sub_constant(sub () { 42 }) ? "constant\n" : "not\n";
```

Functions

`get_code_info($code)` returns the package and the name of the glob the sub was defined under - `('main', '__ANON__')` for an anonymous sub - or nothing for a sub still being compiled. `sub_name`, `stash_name` and `sub_fullname` are its parts. `get_code_location` returns the file and line of the sub's first statement, or nothing for an XSUB or a sub with no body. `is_sub_constant` is true for a sub perl inlines as a constant (`sub () { 42 }`, `use constant`). A non-reference gives nothing (0 for `is_sub_constant`). Nothing is exported by default; `:all` exports everything.

This is a native implementation of Sub::Identify 0.14's `Identify.xs`; its `Sub/Identify.pm` is used unchanged.

Differences from upstream

None.

Functions

Code introspection

get_code_info

The package and the name a sub was defined under.

get_code_location

The file and line where a sub's body begins.

is_sub_constant

Whether a sub is a constant perl inlines.

get_code_info

The package and the name a sub was defined under.

Synopsis

```
use Sub::Identify qw(get_code_info);
my ($package, $name) = get_code_info(\&Foo::bar);   # ('Foo', 'bar')
```

What you get back

The name of the sub's package and its own name, from the glob it was defined in: an anonymous sub gives `__ANON__`, a sub imported under another name keeps the name it was defined with. Nothing for a non-reference, or for a sub that is still being compiled.

get_code_location

The file and line where a sub's body begins.

Synopsis

```
use Sub::Identify qw(get_code_location);
my ($file, $line) = get_code_location(\&Foo::bar);
```

What you get back

The file the sub was compiled from and the line of its first statement. Nothing for a non-reference, an XSUB, or a sub declared but never defined.

is_sub_constant

Whether a sub is a constant perl inlines.

Synopsis

```
use Sub::Identify qw(is_sub_constant);
use constant PI => 3.14159;
is_sub_constant(\&PI);              # true
is_sub_constant(sub () { $x });     # false: it closes over $x
```

What you get back

True for a sub with an empty prototype that perl has made a constant - `use constant`, or `sub () { LITERAL }` - and false for everything else, including a non-reference.

Sub::Name

Give a sub a name: what `caller`, stack traces and profilers report for it.

Synopsis

```
use Sub::Name;

my $code = subname 'My::Pkg::handler' => sub { die "oops" };
$code->();           # oops at ... line N.  (in My::Pkg::handler)

subname 'helper', $code;   # an unqualified name goes to the caller
↪'s package
```

What you get back

`subname NAME, CODEREF` renames the sub in place and returns the code reference. A NAME with `::` (or the old `'` separator) puts the sub in that package, creating it; without one it goes to the package of the calling code. Only the sub's own name changes: no symbol table entry is created, so the sub is not callable under its new name. CODEREF can also be a glob or, without `strict refs`, the name of a sub. `subname` is exported by default.

This is a native implementation of Sub::Name 0.28's `Name.xs`; its `Sub/Name.pm` is used unchanged.

Differences from upstream

Renaming a sub under the debugger no longer leaks a reference to its `%DB::sub` entry, one per call: `Sub::Util::set_subname`, which perl ships and which was taken from this module, fixed that, and pperl runs that code for both modules (t/81-xs-native/Sub-Name/150-or-better.t).

Functions

Names

subname

Rename a sub in place.

subname

Rename a sub in place.

Synopsis

```
use Sub::Name;
my $named = subname 'Pkg::name', sub { ... };
```

What you get back

The code reference passed in, the sub now named NAME. The name is split at its last `::` or `'` into package and name; the package is created if it does not exist, and an unqualified name goes to the package of the calling code. Dies with `Not a subroutine reference`, `Undefined subroutine NAME`, or, under `strict refs`, `Can't use string ... as a subroutine ref` for a string that is not a code reference.

Sub::Util

Names and prototypes of code references: read the name a sub was defined under, give an anonymous sub a name that stack traces, `caller` and profilers show, and set a sub's prototype at run time.

This is Sub::Util from Scalar-List-Utils 1.70; `Sub/Util.pm` is upstream's, and its three functions are the XS ones of ListUtil.xs.

Synopsis

```
use Sub::Util qw(subname set_subname set_prototype);

my $anon = sub { (caller(0))[3] };
print subname($anon), "\n";                 # main::__ANON__

my $named = set_subname('My::helper', $anon);
print subname($named), "\n";                # My::helper
print $named->(), "\n";                     # caller() sees it:
 ↪My::helper

set_prototype('$$', $named);
print prototype($named), "\n";              # $$
```

Differences from upstream

None: upstream's own tests of the three functions pass unchanged (t/81-xs-native/List-Util/490-upstream-subname.t, 380-upstream-prototype.t).

Functions

Names

subname

Return the fully qualified name of a subroutine reference.

set_subname

Assign a name to a subroutine reference in place.

Prototypes

set_prototype

Set or clear the prototype on a subroutine reference.

subname

Return the fully qualified name of a subroutine reference.

Synopsis

```
use Sub::Util qw(subname);
my $name = subname \&some_sub;         # 'Pkg::some_sub'
my $name = subname sub { 1 };          # 'main::__ANON__'
```

What you get back

A string of the form `"Package::name"`. Anonymous subroutines produce `"Package::__ANON__"`. If the subroutine has been renamed with `set_subname`, the new name is returned. Passing something that is not a code reference croaks with `Not a subroutine reference`.

Examples

```
package My::Pkg;
sub hello { 1 }
print Sub::Util::subname(\&hello);    # 'My::Pkg::hello'
```

Differences from upstream

Fully compatible with upstream.

See also

- `set_subname` - rename a code reference (useful for stack traces).

set_subname

Assign a name to a subroutine reference in place.

Synopsis

```
use Sub::Util qw(set_subname);
my $code = set_subname 'My::Pkg::name', sub { ... };
```

What you get back

The same code reference, now reporting `$name` under `subname`, `caller`, and stack traces. If `$name` contains `::` or a quote-style separator (`'`), the left part becomes the package and the right part the short name. An unqualified name is attached to the current compilation package.

Examples

```
my $sub = set_subname 'My::Thing::handler', sub { process(@_) };
print Sub::Util::subname($sub);         # 'My::Thing::handler'
```

```
# Naming closures so stack traces are readable:
for my $op (qw( add sub mul )) {
    $dispatch{$op} = set_subname "op_$op", sub { ... };
}
```

Edge cases

- Croaks with `Not a subroutine reference` for non-CODE arguments.
- Croaks `Usage: Sub::Util::set_subname(name, sub)` unless given two args.

Differences from upstream

Fully compatible with upstream.

See also

- `subname` - read back the fully qualified name.
- `set_prototype` - adjust the prototype of a code reference.

set_prototype

Set or clear the prototype on a subroutine reference.

Synopsis

```
use Sub::Util qw(set_prototype);
my $code = set_prototype '$$', \&adder;
my $code = set_prototype undef, \&adder;   # clear the prototype
```

What you get back

The same code reference, with its prototype replaced by `$proto` (a string like `'$$'`, `'&@'`, `'\@'`) or cleared when `$proto` is `undef`.

Examples

```
set_prototype '$$', \&my_add;     # force two scalar args
set_prototype '&@',  \&wrapper;    # block followed by a list
set_prototype undef, \&free_form;  # no prototype
```

Edge cases

- Croaks with `set_prototype: not a reference` for scalars.
- Croaks with `set_prototype: not a subroutine reference` for non-CODE refs.
- Croaks `Usage: Sub::Util::set_prototype(proto, code)` unless given two args.

Differences from upstream

Fully compatible with upstream.

See also

- `set_subname` - rename a code reference.
- `prototype` - perl built-in that reads a prototype.

5.2.96 Symbol

manipulate Perl symbols and their names

SYNOPSIS

```
use Symbol;

$sym = gensym;
open($sym, '<', "filename");
$_ = <$sym>;
# etc.

ungensym $sym;      # no effect

# replace *FOO{IO} handle but not $FOO, %FOO, etc.
*FOO = geniosym;

print qualify("x"), "\n";             # "main::x"
print qualify("x", "FOO"), "\n";      # "FOO::x"
print qualify("BAR::x"), "\n";        # "BAR::x"
print qualify("BAR::x", "FOO"), "\n"; # "BAR::x"
print qualify("STDOUT", "FOO"), "\n"; # "main::STDOUT" (global)
print qualify(\*x), "\n";             # returns \*x
print qualify(\*x, "FOO"), "\n";      # returns \*x

use strict refs;
print { qualify_to_ref $fh } "foo!\n";
$ref = qualify_to_ref $name, $pkg;

use Symbol qw(delete_package);
delete_package('Foo::Bar');
print "deleted\n" unless exists $Foo::{'Bar::'};
```

DESCRIPTION

`Symbol::gensym` creates an anonymous glob and returns a reference to it. Such a glob reference can be used as a file or directory handle.

For backward compatibility with older implementations that didn't support anonymous globs, `Symbol::ungensym` is also provided. But it doesn't do anything.

`Symbol::geniosym` creates an anonymous IO handle. This can be assigned into an existing glob without affecting the non-IO portions of the glob.

`Symbol::qualify` turns unqualified symbol names into qualified variable names (e.g. "myvar" -> "MyPackage::myvar"). If it is given a second parameter, `qualify` uses it as the default package; otherwise, it uses the package of its caller. Regardless, global variable names (e.g. "STDOUT", "ENV", "SIG") are always qualified with "main::".

Qualification applies only to symbol names (strings). References are left unchanged under the assumption that they are glob references, which are qualified by their nature.

`Symbol::qualify_to_ref` is just like `Symbol::qualify` except that it returns a glob ref rather than a symbol name, so you can use the result even if `use strict 'refs'` is in effect.

`Symbol::delete_package` wipes out a whole package namespace. Note this routine is not exported by default–you may want to import it explicitly.

BUGS

`Symbol::delete_package` is a bit too powerful. It undefines every symbol that lives in the specified package. Since perl, for performance reasons, does not perform a symbol table lookup each time a function is called or a global variable is accessed, some code that has already been loaded and that makes use of symbols in package Foo may stop working after you delete Foo, even if you reload the Foo module afterwards.

5.2.97 Sys

Namespace containing the following modules:

- `Sys::Hostname` - The name of the machine the program runs on.
- `Sys::Syslog` - Messages to the system log: syslog(3) from Perl.

Sys::Hostname

The name of the machine the program runs on.

`hostname()`, exported by default, returns the system's host name (what gethostname(2) reports, the same as `uname -n`), and dies "Cannot get host name of local machine" if there is none. The first answer is kept in `$Sys::Hostname::host` and returned from then on; `ghname()` asks again every time.

This is Sys::Hostname 1.25; `Sys/Hostname.pm` is upstream's, and its XS half is native.

Synopsis

```
use Sys::Hostname;

my $host = hostname();                  # e.g. "build-01"
my $now  = Sys::Hostname::ghname();     # asked again, not cached
```

Differences from upstream

None: upstream's test passes unchanged (t/81-xs-native/Sys-Hostname/100-upstream-hostname.t), and the rest there checks against perl 5.44.

Functions

Other Functions

ghname

`ghname()` - asks the operating system for the hostname, uncached.

Sys::Syslog

Messages to the system log: syslog(3) from Perl.

This is Sys::Syslog 0.36; `Sys/Syslog.pm` is upstream's and is the interface. It sends a message by the first mechanism that works - the C library's syslog(3) ("native", these XSUBs), a UNIX socket, TCP, UDP, the console - and formats it, `printf`-style.

Synopsis

```
use Sys::Syslog qw(:standard :macros);

openlog('myprog', 'ndelay,pid', LOG_USER);   # ident, options, facility
syslog(LOG_INFO, 'started with %d workers', 4);
syslog('warning', 'disk %s at %d%%', '/var', 91);   # levels by name too
setlogmask(LOG_UPTO(LOG_NOTICE));             # drop info and debug
closelog();
```

The functions, written in Perl

`:standard` exports the first four:

- `openlog($ident, $options, $facility)` - name the program, choose options (`cons`, `ndelay`, `nofatal`, `perror`, `pid`), and the default facility (`LOG_USER`, `LOG_DAEMON`, `LOG_LOCAL0`..`LOG_LOCAL7`, ...). Optional: `syslog` opens with defaults.
- `syslog($priority, $format, @args)` - one message; `$priority` is a level (`LOG_ERR`, `"err"`, ...), optionally with a facility (`"local0|info"`, `LOG_LOCAL0 | LOG_INFO`).
- `setlogmask($mask)` - which levels get through; returns the old mask.
- `closelog()`.
- `setlogsock($type)` (`:extended`) - choose the mechanism: `native`, `unix`, `tcp`, `udp`, `stream`, `pipe`, `console`.

`:macros` exports the levels (`LOG_EMERG` .. `LOG_DEBUG`), the facilities, the option flags (`LOG_PID`, `LOG_NDELAY`, ...), `LOG_MASK` and `LOG_UPTO`.

Differences from upstream

None: upstream's tests pass unchanged (t/81-xs-native/Sys-Syslog, the `upstream` files), and 010-constants.t checks every constant against perl 5.44.

Functions

Masks

LOG_MASK

The `setlogmask` bit of one level: `setlogmask(LOG_MASK(LOG_ERR))` lets only errors through. Exported with `:macros`.

LOG_UPTO

The `setlogmask` bits of a level and every more urgent one: `setlogmask(LOG_UPTO(LOG_WARNING))` drops notices, informational and debug messages. Exported with `:macros`.

Priority values

LOG_FAC

The facility number of a combined priority value: `LOG_FAC(134)` is 16 for `LOG_LOCAL0` (whose value is 16 << 3). Not exported; call it as `Sys::Syslog::LOG_FAC`.

LOG_PRI

The level part of a combined priority value: `LOG_PRI(134)` is 6, `LOG_INFO`. Not exported; call it as `Sys::Syslog::LOG_PRI`.

LOG_MAKEPRI

A combined priority value from a facility and a level: `LOG_MAKEPRI(LOG_LOCAL0, LOG_INFO)` is 134. Not exported; call it as `Sys::Syslog::LOG_MAKEPRI`.

5.2.98 TAP

Namespace containing the following modules:

- `TAP::Base` - Base class that provides common functionality to *TAP::Parser* and *TAP::Harness*
- `TAP::Formatter`
- `TAP::Harness` - Run test scripts with statistics
- `TAP::Object` - Base class that provides common functionality to all `TAP::*` modules
- `TAP::Parser` - Parse TAP output

TAP::Base

Base class that provides common functionality to *TAP::Parser* and *TAP::Harness*

VERSION

Version 3.52

SYNOPSIS

```
package TAP::Whatever;

use base 'TAP::Base';
```

(continues on next page)

(continued from previous page)

```
# ... later ...

my $thing = TAP::Whatever->new();

$thing->callback( event => sub {
    # do something interesting
} );
```

DESCRIPTION

`TAP::Base` provides callback management.

METHODS

Class Methods

`callback`

Install a callback for a named event.

`get_time`

Return the current time using Time::HiRes if available.

`time_is_hires`

Return true if the time returned by get_time is high resolution (i.e. if Time::HiRes is available).

`get_times`

Return array reference of the four-element list of CPU seconds, as with *"times" in perlfunc*.

TAP::Formatter

Namespace containing the following modules:

- `TAP::Formatter::Base` - Base class for harness output delegates
- `TAP::Formatter::Color` - Run Perl test scripts with color
- `TAP::Formatter::Console` - Harness output delegate for default console output
- `TAP::Formatter::File` - Harness output delegate for file output
- `TAP::Formatter::Session` - Abstract base class for harness output delegate

TAP::Formatter::Base

Base class for harness output delegates

VERSION

Version 3.52

DESCRIPTION

This provides console orientated output formatting for TAP::Harness.

SYNOPSIS

```
use TAP::Formatter::Console;
my $harness = TAP::Formatter::Console->new( \%args );
```

METHODS

Class Methods

new

```
my %args = (
   verbose => 1,
)
my $harness = TAP::Formatter::Console->new( \%args );
```

The constructor returns a new `TAP::Formatter::Console` object. If a *TAP::Harness* is created with no `formatter` a `TAP::Formatter::Console` is automatically created. If any of the following options were given to TAP::Harness->new they well be passed to this constructor which accepts an optional hashref whose allowed keys are:

- `verbosity`

  Set the verbosity level.

- `verbose`

  Printing individual test results to STDOUT.

- `timer`

  Append run time for each test to output. Uses *Time::HiRes* if available.

- `failures`

  Show test failures (this is a no-op if `verbose` is selected).

- `comments`

  Show test comments (this is a no-op if `verbose` is selected).

- `quiet`

  Suppressing some test output (mostly failures while tests are running).

- `really_quiet`

  Suppressing everything but the tests summary.

- `silent`

  Suppressing all output.

- `errors`

  If parse errors are found in the TAP output, a note of this will be made in the summary report. To see all of the parse errors, set this argument to true:

  ```
  errors => 1
  ```

- `directives`

  If set to a true value, only test results with directives will be displayed. This overrides other settings such as `verbose`, `failures`, or `comments`.

- `stdout`

  A filehandle for catching standard output.

- `color`

  If defined specifies whether color output is desired. If `color` is not defined it will default to color output if color support is available on the current platform and output is not being redirected.

- `jobs`

  The number of concurrent jobs this formatter will handle.

- `show_count`

  Boolean value. If false, disables the `X/Y` test count which shows up while tests are running.

Any keys for which the value is `undef` will be ignored.

prepare

Called by Test::Harness before any test output is generated.

This is an advisory and may not be called in the case where tests are being supplied to Test::Harness by an iterator.

open_test

Called to create a new test session. A test session looks like this:

```
my $session = $formatter->open_test( $test, $parser );
while ( defined( my $result = $parser->next ) ) {
    $session->result($result);
    exit 1 if $result->is_bailout;
}
$session->close_test;
```

summary

```
$harness->summary( $aggregate );
```

`summary` prints the summary report after all tests are run. The first argument is an aggregate to summarise. An optional second argument may be set to a true value to indicate that the summary is being output as a result of an interrupted test run.

TAP::Formatter::Color

Run Perl test scripts with color

VERSION

Version 3.52

DESCRIPTION

Note that this harness is *experimental*. You may not like the colors I've chosen and I haven't yet provided an easy way to override them.

This test harness is the same as *TAP::Harness*, but test results are output in color. Passing tests are printed in green. Failing tests are in red. Skipped tests are blue on a white background and TODO tests are printed in white.

If *Term::ANSIColor* cannot be found (and Win32::Console::ANSI if running under Windows) tests will be run without color.

SYNOPSIS

```
use TAP::Formatter::Color;
my $harness = TAP::Formatter::Color->new( \%args );
$harness->runtests(@tests);
```

METHODS

Class Methods

new

The constructor returns a new `TAP::Formatter::Color` object. If *Term::ANSIColor* is not installed, returns undef.

can_color

```
Test::Formatter::Color->can_color()
```

Returns a boolean indicating whether or not this module can actually generate colored output. This will be false if it could not load the modules needed for the current platform.

set_color

Set the output color.

TAP::Formatter::Console

Harness output delegate for default console output

VERSION

Version 3.52

DESCRIPTION

This provides console orientated output formatting for TAP::Harness.

SYNOPSIS

```
use TAP::Formatter::Console;
my $harness = TAP::Formatter::Console->new( \%args );
```

open_test

See *TAP::Formatter::Base*

Modules

- `TAP::Formatter::Console::ParallelSession` - Harness output delegate for parallel console output
- `TAP::Formatter::Console::Session` - Harness output delegate for default console output

TAP::Formatter::Console::ParallelSession

Harness output delegate for parallel console output

VERSION

Version 3.52

DESCRIPTION

This provides console orientated output formatting for *TAP::Harness* when run with multiple *"jobs" in TAP::Harness*.

SYNOPSIS

METHODS

Class Methods

header

Output test preamble

result

```
Called by the harness for each line of TAP it receives .
```

clear_for_close

close_test

TAP::Formatter::Console::Session

Harness output delegate for default console output

VERSION

Version 3.52

DESCRIPTION

This provides console orientated output formatting for TAP::Harness.

clear_for_close

TAP::Formatter::File

Harness output delegate for file output

VERSION

Version 3.52

DESCRIPTION

This provides file orientated output formatting for TAP::Harness.

SYNOPSIS

```
use TAP::Formatter::File;
my $harness = TAP::Formatter::File->new( \%args );
```

open_test

See *TAP::Formatter::Base*

Modules

- `TAP::Formatter::File::Session` - Harness output delegate for file output

TAP::Formatter::File::Session

Harness output delegate for file output

VERSION

Version 3.52

DESCRIPTION

This provides file orientated output formatting for *TAP::Harness*. It is particularly important when running with parallel tests, as it ensures that test results are not interleaved, even when run verbosely.

METHODS

result

Stores results for later output, all together.

close_test

When the test file finishes, outputs the summary, together.

TAP::Formatter::Session

Abstract base class for harness output delegate

VERSION

Version 3.52

METHODS

Class Methods

new

```
my %args = (
   formatter => $self,
)
my $harness = TAP::Formatter::Console::Session->new( \%args );
```

The constructor returns a new `TAP::Formatter::Console::Session` object.

- `formatter`
- `parser`
- `name`
- `show_count`

header

Output test preamble

result

Called by the harness for each line of TAP it receives.

close_test

Called to close a test session.

clear_for_close

Called by `close_test` to clear the line showing test progress, or the parallel test ruler, prior to printing the final test result.

time_report

Return a formatted string about the elapsed (wall-clock) time and about the consumed CPU time.

TAP::Harness

Run test scripts with statistics

VERSION

Version 3.52

DESCRIPTION

This is a simple test harness which allows tests to be run and results automatically aggregated and output to STDOUT.

SYNOPSIS

```
use TAP::Harness;
my $harness = TAP::Harness->new( \%args );
$harness->runtests(@tests);
```

METHODS

Class Methods

new

```
my %args = (
   verbosity => 1,
   lib     => [ 'lib', 'blib/lib', 'blib/arch' ],
)
my $harness = TAP::Harness->new( \%args );
```

The constructor returns a new `TAP::Harness` object. It accepts an optional hashref whose allowed keys are:

- `verbosity`

  Set the verbosity level:

  ```
   1   verbose        Print individual test results to STDOUT.
   0   normal
  -1   quiet          Suppress some test output (mostly failures
                      while tests are running).
  -2   really quiet   Suppress everything but the tests summary.
  -3   silent         Suppress everything.
  ```

- `timer`

  Append run time for each test to output. Uses *Time::HiRes* if available.

- `failures`

  Show test failures (this is a no-op if `verbose` is selected).

- `comments`

  Show test comments (this is a no-op if `verbose` is selected).

- `show_count`

  Update the running test count during testing.

- `normalize`

  Set to a true value to normalize the TAP that is emitted in verbose modes.

- `lib`

  Accepts a scalar value or array ref of scalar values indicating which paths to allowed libraries should be included if Perl tests are executed. Naturally, this only makes sense in the context of tests written in Perl.

- `switches`

  Accepts a scalar value or array ref of scalar values indicating which switches should be included if Perl tests are executed. Naturally, this only makes sense in the context of tests written in Perl.

- `test_args`

  A reference to an `@INC` style array of arguments to be passed to each test program.

```
test_args => ['foo', 'bar'],
```

  if you want to pass different arguments to each test then you should pass a hash of arrays, keyed by the alias for each test:

```
test_args => {
  my_test    => ['foo', 'bar'],
  other_test => ['baz'],
}
```

- `color`

  Attempt to produce color output.

- `exec`

  Typically, Perl tests are run through this. However, anything which spits out TAP is fine. You can use this argument to specify the name of the program (and optional switches) to run your tests with:

```
exec => ['/usr/bin/ruby', '-w']
```

  You can also pass a subroutine reference in order to determine and return the proper program to run based on a given test script. The subroutine reference should expect the TAP::Harness object itself as the first argument, and the file name as the second argument. It should return an array reference containing the command to be run and including the test file name. It can also simply return `undef`, in which case TAP::Harness will fall back on executing the test script in Perl:

```
exec => sub {
    my ( $harness, $test_file ) = @_;

    # Let Perl tests run.
    return undef if $test_file =~ /[.]t$/;
    return [ qw( /usr/bin/ruby -w ), $test_file ]
      if $test_file =~ /[.]rb$/;
  }
```

  If the subroutine returns a scalar with a newline or a filehandle, it will be interpreted as raw TAP or as a TAP stream, respectively.

- `merge`

  If `merge` is true the harness will create parsers that merge STDOUT and STDERR together for any processes they start.

- `sources`

  NEW to 3.18.

  If set, `sources` must be a hashref containing the names of the *TAP::Parser::SourceHandler*s to load and/or configure. The values are a hash of configuration that will be accessible to the source handlers via *"config_for" in TAP::Parser::Source*.

  For example:

```
sources => {
  Perl => { exec => '/path/to/custom/perl' },
  File => { extensions => [ '.tap', '.txt' ] },
  MyCustom => { some => 'config' },
}
```

  The `sources` parameter affects how `source`, `tap` and `exec` parameters are handled.

  For more details, see the `sources` parameter in *"new" in TAP::Parser*, *TAP::Parser::Source*, and *TAP::Parser::IteratorFactory*.

- `aggregator_class`

  The name of the class to use to aggregate test results. The default is *TAP::Parser::Aggregator*.

- `version`

  NEW to 3.22.

  Assume this TAP version for *TAP::Parser* instead of default TAP version 12.

- `formatter_class`

  The name of the class to use to format output. The default is *TAP::Formatter::Console*, or *TAP::Formatter::File* if the output isn't a TTY.

- `multiplexer_class`

  The name of the class to use to multiplex tests during parallel testing. The default is *TAP::Parser::Multiplexer*.

- `parser_class`

  The name of the class to use to parse TAP. The default is *TAP::Parser*.

- `scheduler_class`

  The name of the class to use to schedule test execution. The default is *TAP::Parser::Scheduler*.

- `formatter`

  If set `formatter` must be an object that is capable of formatting the TAP output. See *TAP::Formatter::Console* for an example.

- `errors`

  If parse errors are found in the TAP output, a note of this will be made in the summary report. To see all of the parse errors, set this argument to true:

```
errors => 1
```

- `directives`

  If set to a true value, only test results with directives will be displayed. This overrides other settings such as `verbose` or `failures`.

- `ignore_exit`

  If set to a true value instruct `TAP::Parser` to ignore exit and wait status from test scripts.

- `jobs`

  The maximum number of parallel tests to run at any time. Which tests can be run in parallel is controlled by `rules`. The default is to run only one test at a time.

- `rules`

  A reference to a hash of rules that control which tests may be executed in parallel. If no rules are declared and *CPAN::Meta::YAML* is available, `TAP::Harness` attempts to load rules from a YAML file specified by the `rulesfile` parameter. If no rules file exists, the default is for all tests to be eligible to be run in parallel.

  Here some simple examples. For the full details of the data structure and the related glob-style pattern matching, see *"Rules data structure" in TAP::Parser::Scheduler*.

```
# Run all tests in sequence, except those starting with "p"
$harness->rules({
    par => 't/p*.t'
});

# Equivalent YAML file
---
par: t/p*.t

# Run all tests in parallel, except those starting with "p"
$harness->rules({
    seq => [
              { seq => 't/p*.t' },
              { par => '**'     },
          ],
});

# Equivalent YAML file
---
seq:
    - seq: t/p*.t
    - par: **
```

(continues on next page)

(continued from previous page)

```
# Run some  startup tests in sequence, then some parallel tests␣
↪than some
# teardown tests in sequence.
$harness->rules({
    seq => [
        { seq => 't/startup/*.t' },
        { par => ['t/a/*.t','t/b/*.t','t/c/*.t'], }
        { seq => 't/shutdown/*.t' },
    ],

});

# Equivalent YAML file
---
seq:
    - seq: t/startup/*.t
    - par:
        - t/a/*.t
        - t/b/*.t
        - t/c/*.t
    - seq: t/shutdown/*.t
```

This is an experimental feature and the interface may change.

- `rulesfiles`

  This specifies where to find a YAML file of test scheduling rules. If not provided, it looks for a default file to use. It first checks for a file given in the `HARNESS_RULESFILE` environment variable, then it checks for `testrules.yml` and then `t/testrules.yml`.

- `stdout`

  A filehandle for catching standard output.

- `trap`

  Attempt to print summary information if run is interrupted by SIGINT (Ctrl-C).

Any keys for which the value is `undef` will be ignored.

Instance Methods

`runtests`

```
$harness->runtests(@tests);
```

Accepts an array of `@tests` to be run. This should generally be the names of test files, but this is not required. Each element in `@tests` will be passed to `TAP::Parser::new()` as a `source`. See *TAP::Parser* for more information.

It is possible to provide aliases that will be displayed in place of the test name by supplying the test as a reference to an array containing `[ $test, $alias ]`:

```
$harness->runtests( [ 't/foo.t', 'Foo Once' ],
                    [ 't/foo.t', 'Foo Twice' ] );
```

Normally it is an error to attempt to run the same test twice. Aliases allow you to overcome this limitation by giving each run of the test a unique name.

Tests will be run in the order found.

If the environment variable `PERL_TEST_HARNESS_DUMP_TAP` is defined it should name a directory into which a copy of the raw TAP for each test will be written. TAP is written to files named for each test. Subdirectories will be created as needed.

Returns a *TAP::Parser::Aggregator* containing the test results.

summary

```
$harness->summary( $aggregator );
```

Output the summary for a *TAP::Parser::Aggregator*.

aggregate_tests

```
$harness->aggregate_tests( $aggregate, @tests );
```

Run the named tests and display a summary of result. Tests will be run in the order found.

Test results will be added to the supplied *TAP::Parser::Aggregator*. `aggregate_tests` may be called multiple times to run several sets of tests. Multiple `Test::Harness` instances may be used to pass results to a single aggregator so that different parts of a complex test suite may be run using different `TAP::Harness` settings. This is useful, for example, in the case where some tests should run in parallel but others are unsuitable for parallel execution.

```
my $formatter   = TAP::Formatter::Console->new;
my $ser_harness = TAP::Harness->new( { formatter => $formatter } );
my $par_harness = TAP::Harness->new(
    {   formatter => $formatter,
        jobs      => 9
    }
);
my $aggregator = TAP::Parser::Aggregator->new;

$aggregator->start();
$ser_harness->aggregate_tests( $aggregator, @ser_tests );
$par_harness->aggregate_tests( $aggregator, @par_tests );
$aggregator->stop();
$formatter->summary($aggregator);
```

Note that for simpler testing requirements it will often be possible to replace the above code with a single call to `runtests`.

Each element of the `@tests` array is either:

- the source name of a test to run
- a reference to a [source name, display name] array

In the case of a perl test suite, typically *source names* are simply the file names of the test scripts to run.

When you supply a separate display name it becomes possible to run a test more than once; the display name is effectively the alias by which the test is known inside the harness. The harness doesn't care if it runs the same test more than once when each invocation uses a different name.

make_scheduler

Called by the harness when it needs to create a *TAP::Parser::Scheduler*. Override in a subclass to provide an alternative scheduler. `make_scheduler` is passed the list of tests that was passed to `aggregate_tests`.

jobs

Gets or sets the number of concurrent test runs the harness is handling. By default, this value is 1 – for parallel testing, this should be set higher.

make_parser

Make a new parser and display formatter session. Typically used and/or overridden in subclasses.

```
my ( $parser, $session ) = $harness->make_parser;
```

finish_parser

Terminate use of a parser. Typically used and/or overridden in subclasses. The parser isn't destroyed as a result of this.

CONFIGURING

`TAP::Harness` is designed to be easy to configure.

Plugins

`TAP::Parser` plugins let you change the way TAP is *input* to and *output* from the parser.

*TAP::Parser::SourceHandler*s handle TAP *input*. You can configure them and load custom handlers using the `sources` parameter to "new".

*TAP::Formatter*s handle TAP *output*. You can load custom formatters by using the `formatter_class` parameter to "new". To configure a formatter, you currently need to instantiate it outside of *TAP::Harness* and pass it in with the `formatter` parameter to "new". This *may* be addressed by adding a *formatters* parameter to "new" in the future.

Module::Build

Module::Build version 0.30 supports TAP::Harness.

To load TAP::Harness plugins, you'll need to use the tap_harness_args parameter to new, typically from your Build.PL. For example:

```
Module::Build->new(
    module_name         => 'MyApp',
    test_file_exts      => [qw(.t .tap .txt)],
    use_tap_harness     => 1,
    tap_harness_args    => {
        sources => {
            MyCustom => {},
            File => {
                extensions => ['.tap', '.txt'],
            },
        },
        formatter_class => 'TAP::Formatter::HTML',
    },
    build_requires      => {
        'Module::Build' => '0.30',
        'TAP::Harness'  => '3.18',
    },
)->create_build_script;
```

See "new"

ExtUtils::MakeMaker

ExtUtils::MakeMaker does not support *TAP::Harness* out-of-the-box.

prove

prove supports TAP::Harness plugins, and has a plugin system of its own. See "FORMATTERS" in prove, "SOURCE HANDLERS" in prove and *App::Prove* for more details.

WRITING PLUGINS

If you can't configure TAP::Harness to do what you want, and you can't find an existing plugin, consider writing one.

The two primary use cases supported by *TAP::Harness* for plugins are *input* and *output*:

- Customize how TAP gets into the parser

  To do this, you can either extend an existing *TAP::Parser::SourceHandler*, or write your own. It's a pretty simple API, and they can be loaded and configured using the sources parameter to "new".

- Customize how TAP results are output from the parser

  To do this, you can either extend an existing *TAP::Formatter*, or write your own. Writing formatters are a bit more involved than writing a *SourceHandler*, as you'll

need to understand the *TAP::Parser* API. A good place to start is by understanding how “aggregate_tests” works.

Custom formatters can be loaded configured using the `formatter_class` parameter to “new”.

SUBCLASSING

If you can’t configure `TAP::Harness` to do exactly what you want, and writing a plugin isn’t an option, consider extending it. It is designed to be (mostly) easy to subclass, though the cases when sub-classing is necessary should be few and far between.

Methods

The following methods are ones you may wish to override if you want to subclass `TAP::Harness`.

- “new”
- “runtests”
- “summary”

REPLACING

If you like the `prove` utility and *TAP::Parser* but you want your own harness, all you need to do is write one and provide `new` and `runtests` methods. Then you can use the `prove` utility like so:

```
prove --harness My::Test::Harness
```

Note that while `prove` accepts a list of tests (or things to be tested), `new` has a fairly rich set of arguments. You’ll probably want to read over this code carefully to see how all of them are being used.

SEE ALSO

Test::Harness

Modules

- `TAP::Harness::Env` - Parsing harness related environmental variables where appropriate

TAP::Harness::Env

Parsing harness related environmental variables where appropriate

VERSION

Version 3.52

SYNOPSIS

```
my $harness = TAP::Harness::Env->create(\%extra_args)
```

DESCRIPTION

This module implements the environmental variables that *Test::Harness* uses with TAP::Harness, and instantiates the appropriate class with the appropriate arguments.

METHODS

- create(\%args)

  This function reads the environment and generates an appropriate argument hash from it. If given any arguments in `%extra_args`, these will override the environmental defaults. In accepts `harness_class` (which defaults to `TAP::Harness`), and any argument the harness class accepts.

ENVIRONMENTAL VARIABLES

- `HARNESS_PERL_SWITCHES`

  Setting this adds perl command line switches to each test file run.

  For example, `HARNESS_PERL_SWITCHES=-T` will turn on taint mode. `HARNESS_PERL_SWITCHES=-MDevel::Cover` will run `Devel::Cover` for each test.

- `HARNESS_VERBOSE`

  If true, `TAP::Harness` will output the verbose results of running its tests.

- `HARNESS_SUBCLASS`

  Specifies a TAP::Harness subclass to be used in place of TAP::Harness.

- `HARNESS_OPTIONS`

  Provide additional options to the harness. Currently supported options are:

  - `j<n>`

    Run <n> (default 9) parallel jobs.

  - `c`

    Try to color output. See *"new" in TAP::Formatter::Base*.

  - `a<file.tgz>`

    Will use TAP::Harness::Archive as the harness class, and save the TAP to `file.tgz`

- `fPackage-With-Dashes`

  Set the formatter_class of the harness being run. Since the `HARNESS_OPTIONS` is separated by `:`, we use `-` instead.

Multiple options may be separated by colons:

```
HARNESS_OPTIONS=j9:c make test
```

- `HARNESS_TIMER`

  Setting this to true will make the harness display the number of milliseconds each test took. You can also use `prove`'s `--timer` switch.

- `HARNESS_COLOR`

  Attempt to produce color output.

- `HARNESS_IGNORE_EXIT`

  If set to a true value instruct `TAP::Parser` to ignore exit and wait status from test scripts.

TAP::Object

Base class that provides common functionality to all `TAP::*` modules

VERSION

Version 3.52

SYNOPSIS

```
package TAP::Whatever;

use strict;

use base 'TAP::Object';

# new() implementation by TAP::Object
sub _initialize {
    my ( $self, @args) = @_;
    # initialize your object
    return $self;
}

# ... later ...
my $obj = TAP::Whatever->new(@args);
```

DESCRIPTION

`TAP::Object` provides a default constructor and exception model for all `TAP::*` classes. Exceptions are raised using *Carp*.

METHODS

Class Methods

new

Create a new object. Any arguments passed to `new` will be passed on to the "_initialize" method. Returns a new object.

Instance Methods

_initialize

Initializes a new object. This method is a stub by default, you should override it as appropriate.

Note: "new" expects you to return `$self` or raise an exception. See "_croak", and *Carp*.

_croak

Raise an exception using `croak` from *Carp*, eg:

```
$self->_croak( 'why me?', 'aaarrgh!' );
```

May also be called as a *class* method.

```
$class->_croak( 'this works too' );
```

_confess

Raise an exception using `confess` from *Carp*, eg:

```
$self->_confess( 'why me?', 'aaarrgh!' );
```

May also be called as a *class* method.

```
$class->_confess( 'this works too' );
```

_construct

Create a new instance of the specified class.

mk_methods

Create simple getter/setters.

```
__PACKAGE__->mk_methods(@method_names);
```

TAP::Parser

Parse TAP output

VERSION

Version 3.52

SYNOPSIS

```
use TAP::Parser;

my $parser = TAP::Parser->new( { source => $source } );

while ( my $result = $parser->next ) {
    print $result->as_string;
}
```

DESCRIPTION

`TAP::Parser` is designed to produce a proper parse of TAP output. For an example of how to run tests through this module, see the simple harnesses `examples/`.

There's a wiki dedicated to the Test Anything Protocol:

http://testanything.org

It includes the TAP::Parser Cookbook:

http://testanything.org/testing-with-tap/perl/tap::parser-cookbook.html

METHODS

Class Methods

new

```
my $parser = TAP::Parser->new(\%args);
```

Returns a new `TAP::Parser` object.

The arguments should be a hashref with *one* of the following keys:

- `source`

  CHANGED in 3.18

  This is the preferred method of passing input to the constructor.

The `source` is used to create a *TAP::Parser::Source* that is passed to the "iterator_factory_class" which in turn figures out how to handle the source and creates a TAP::Parser::Iterator for it. The iterator is used by the parser to read in the TAP stream.

To configure the *IteratorFactory* use the `sources` parameter below.

Note that `source`, `tap` and `exec` are *mutually exclusive*.

- `tap`

  CHANGED in 3.18

  The value should be the complete TAP output.

  The *tap* is used to create a *TAP::Parser::Source* that is passed to the "iterator_factory_class" which in turn figures out how to handle the source and creates a TAP::Parser::Iterator for it. The iterator is used by the parser to read in the TAP stream.

  To configure the *IteratorFactory* use the `sources` parameter below.

  Note that `source`, `tap` and `exec` are *mutually exclusive*.

- `exec`

  Must be passed an array reference.

  The *exec* array ref is used to create a *TAP::Parser::Source* that is passed to the "iterator_factory_class" which in turn figures out how to handle the source and creates a TAP::Parser::Iterator for it. The iterator is used by the parser to read in the TAP stream.

  By default the *TAP::Parser::SourceHandler::Executable* class will create a *TAP::Parser::Iterator::Process* object to handle the source. This passes the array reference strings as command arguments to *IPC::Open3::open3*:

  ```
  exec => [ '/usr/bin/ruby', 't/my_test.rb' ]
  ```

  If any `test_args` are given they will be appended to the end of the command argument list.

  To configure the *IteratorFactory* use the `sources` parameter below.

  Note that `source`, `tap` and `exec` are *mutually exclusive*.

The following keys are optional.

- `sources`

  NEW to 3.18.

  If set, `sources` must be a hashref containing the names of the *TAP::Parser::SourceHandler*s to load and/or configure. The values are a hash of configuration that will be accessible to the source handlers via *"config_for" in TAP::Parser::Source*.

  For example:

  ```
  sources => {
    Perl => { exec => '/path/to/custom/perl' },
  ```

(continues on next page)

(continued from previous page)

```
  File => { extensions => [ '.tap', '.txt' ] },
  MyCustom => { some => 'config' },
}
```

This will cause `TAP::Parser` to pass custom configuration to two of the built-in source handlers - *TAP::Parser::SourceHandler::Perl*, *TAP::Parser::SourceHandler::File* - and attempt to load the `MyCustom` class. See *"load_handlers" in TAP::Parser::IteratorFactory* for more detail.

The `sources` parameter affects how `source`, `tap` and `exec` parameters are handled.

See *TAP::Parser::IteratorFactory*, *TAP::Parser::SourceHandler* and subclasses for more details.

- `callback`

  If present, each callback corresponding to a given result type will be called with the result as the argument if the `run` method is used:

```
my %callbacks = (
    test    => \&test_callback,
    plan    => \&plan_callback,
    comment => \&comment_callback,
    bailout => \&bailout_callback,
    unknown => \&unknown_callback,
);

my $aggregator = TAP::Parser::Aggregator->new;
for my $file ( @test_files ) {
    my $parser = TAP::Parser->new(
        {
            source    => $file,
            callbacks => \%callbacks,
        }
    );
    $parser->run;
    $aggregator->add( $file, $parser );
}
```

- `switches`

  If using a Perl file as a source, optional switches may be passed which will be used when invoking the perl executable.

```
my $parser = TAP::Parser->new( {
    source   => $test_file,
    switches => [ '-Ilib' ],
} );
```

- `test_args`

  Used in conjunction with the `source` and `exec` option to supply a reference to an `@ARGV` style array of arguments to pass to the test program.

- `spool`

  If passed a filehandle will write a copy of all parsed TAP to that handle.

- `merge`

  If false, STDERR is not captured (though it is 'relayed' to keep it somewhat synchronized with STDOUT.)

  If true, STDERR and STDOUT are the same filehandle. This may cause breakage if STDERR contains anything resembling TAP format, but does allow exact synchronization.

  Subtleties of this behavior may be platform-dependent and may change in the future.

- `grammar_class`

  This option was introduced to let you easily customize which *grammar* class the parser should use. It defaults to *TAP::Parser::Grammar*.

  See also "make_grammar".

- `result_factory_class`

  This option was introduced to let you easily customize which *result* factory class the parser should use. It defaults to *TAP::Parser::ResultFactory*.

  See also "make_result".

- `iterator_factory_class`

  CHANGED in 3.18

  This option was introduced to let you easily customize which *iterator* factory class the parser should use. It defaults to *TAP::Parser::IteratorFactory*.

Instance Methods

next

```
my $parser = TAP::Parser->new( { source => $file } );
while ( my $result = $parser->next ) {
    print $result->as_string, "\n";
}
```

This method returns the results of the parsing, one result at a time. Note that it is destructive. You can't rewind and examine previous results.

If callbacks are used, they will be issued before this call returns.

Each result returned is a subclass of *TAP::Parser::Result*. See that module and related classes for more information on how to use them.

run

```
$parser->run;
```

This method merely runs the parser and parses all of the TAP.

make_grammar

Make a new *TAP::Parser::Grammar* object and return it. Passes through any arguments given.

The `grammar_class` can be customized, as described in "new".

make_result

Make a new *TAP::Parser::Result* object using the parser's *TAP::Parser::ResultFactory*, and return it. Passes through any arguments given.

The `result_factory_class` can be customized, as described in "new".

make_iterator_factory

NEW to 3.18.

Make a new *TAP::Parser::IteratorFactory* object and return it. Passes through any arguments given.

`iterator_factory_class` can be customized, as described in "new".

INDIVIDUAL RESULTS

If you've read this far in the docs, you've seen this:

```
while ( my $result = $parser->next ) {
    print $result->as_string;
}
```

Each result returned is a *TAP::Parser::Result* subclass, referred to as *result types*.

Result types

Basically, you fetch individual results from the TAP. The six types, with examples of each, are as follows:

- Version

  ```
  TAP version 12
  ```

- Plan

  ```
  1..42
  ```

- Pragma

```
pragma +strict
```

- Test

```
ok 3 - We should start with some foobar!
```

- Comment

```
# Hope we don't use up the foobar.
```

- Bailout

```
Bail out!  We ran out of foobar!
```

- Unknown

```
... yo, this ain't TAP! ...
```

Each result fetched is a result object of a different type. There are common methods to each result object and different types may have methods unique to their type. Sometimes a type method may be overridden in a subclass, but its use is guaranteed to be identical.

Common type methods

type

Returns the type of result, such as `comment` or `test`.

as_string

Prints a string representation of the token. This might not be the exact output, however. Tests will have test numbers added if not present, TODO and SKIP directives will be capitalized and, in general, things will be cleaned up. If you need the original text for the token, see the `raw` method.

raw

Returns the original line of text which was parsed.

is_plan

Indicates whether or not this is the test plan line.

is_test

Indicates whether or not this is a test line.

is_comment

Indicates whether or not this is a comment. Comments will generally only appear in the TAP stream if STDERR is merged to STDOUT. See the `merge` option.

is_bailout

Indicates whether or not this is bailout line.

is_yaml

Indicates whether or not the current item is a YAML block.

is_unknown

Indicates whether or not the current line could be parsed.

is_ok

```
if ( $result->is_ok ) { ... }
```

Reports whether or not a given result has passed. Anything which is **not** a test result returns true. This is merely provided as a convenient shortcut which allows you to do this:

```
my $parser = TAP::Parser->new( { source => $source } );
while ( my $result = $parser->next ) {
    # only print failing results
    print $result->as_string unless $result->is_ok;
}
```

plan methods

```
if ( $result->is_plan ) { ... }
```

If the above evaluates as true, the following methods will be available on the `$result` object.

plan

```
if ( $result->is_plan ) {
   print $result->plan;
}
```

This is merely a synonym for `as_string`.

directive

```
my $directive = $result->directive;
```

If a SKIP directive is included with the plan, this method will return it.

```
1..0 # SKIP: why bother?
```

explanation

```
my $explanation = $result->explanation;
```

If a SKIP directive was included with the plan, this method will return the explanation, if any.

pragma methods

```
if ( $result->is_pragma ) { ... }
```

If the above evaluates as true, the following methods will be available on the `$result` object.

pragmas

Returns a list of pragmas each of which is a + or - followed by the pragma name.

comment methods

```
if ( $result->is_comment ) { ... }
```

If the above evaluates as true, the following methods will be available on the `$result` object.

comment

```
if ( $result->is_comment ) {
    my $comment = $result->comment;
    print "I have something to say:  $comment";
}
```

bailout methods

```
if ( $result->is_bailout ) { ... }
```

If the above evaluates as true, the following methods will be available on the `$result` object.

explanation

```
if ( $result->is_bailout ) {
    my $explanation = $result->explanation;
    print "We bailed out because ($explanation)";
}
```

If, and only if, a token is a bailout token, you can get an "explanation" via this method. The explanation is the text after the mystical "Bail out!" words which appear in the tap output.

unknown methods

```
if ( $result->is_unknown ) { ... }
```

There are no unique methods for unknown results.

test methods

```
if ( $result->is_test ) { ... }
```

If the above evaluates as true, the following methods will be available on the `$result` object.

ok

```
my $ok = $result->ok;
```

Returns the literal text of the ok or not ok status.

number

```
my $test_number = $result->number;
```

Returns the number of the test, even if the original TAP output did not supply that number.

description

```
my $description = $result->description;
```

Returns the description of the test, if any. This is the portion after the test number but before the directive.

directive

```
my $directive = $result->directive;
```

Returns either `TODO` or `SKIP` if either directive was present for a test line.

explanation

```
my $explanation = $result->explanation;
```

If a test had either a `TODO` or `SKIP` directive, this method will return the accompanying explanation, if present.

```
not ok 17 - 'Pigs can fly' # TODO not enough acid
```

For the above line, the explanation is *not enough acid*.

is_ok

```
if ( $result->is_ok ) { ... }
```

Returns a boolean value indicating whether or not the test passed. Remember that for TODO tests, the test always passes.

Note: this was formerly `passed`. The latter method is deprecated and will issue a warning.

is_actual_ok

```
if ( $result->is_actual_ok ) { ... }
```

Returns a boolean value indicating whether or not the test passed, regardless of its TODO status.

Note: this was formerly `actual_passed`. The latter method is deprecated and will issue a warning.

is_unplanned

```
if ( $test->is_unplanned ) { ... }
```

If a test number is greater than the number of planned tests, this method will return true. Unplanned tests will *always* return false for `is_ok`, regardless of whether or not the test `has_todo` (see *TAP::Parser::Result::Test* for more information about this).

has_skip

```
if ( $result->has_skip ) { ... }
```

Returns a boolean value indicating whether or not this test had a SKIP directive.

has_todo

```
if ( $result->has_todo ) { ... }
```

Returns a boolean value indicating whether or not this test had a TODO directive.

Note that TODO tests *always* pass. If you need to know whether or not they really passed, check the `is_actual_ok` method.

in_todo

```
if ( $parser->in_todo ) { ... }
```

True while the most recent result was a TODO. Becomes true before the TODO result is returned and stays true until just before the next non- TODO test is returned.

TOTAL RESULTS

After parsing the TAP, there are many methods available to let you dig through the results and determine what is meaningful to you.

Individual Results

These results refer to individual tests which are run.

passed

```
my @passed = $parser->passed; # the test numbers which passed
my $passed = $parser->passed; # the number of tests which passed
```

This method lets you know which (or how many) tests passed. If a test failed but had a TODO directive, it will be counted as a passed test.

failed

```
my @failed = $parser->failed; # the test numbers which failed
my $failed = $parser->failed; # the number of tests which failed
```

This method lets you know which (or how many) tests failed. If a test passed but had a TODO directive, it will **NOT** be counted as a failed test.

actual_passed

```
# the test numbers which actually passed
my @actual_passed = $parser->actual_passed;

# the number of tests which actually passed
my $actual_passed = $parser->actual_passed;
```

This method lets you know which (or how many) tests actually passed, regardless of whether or not a TODO directive was found.

actual_ok

This method is a synonym for `actual_passed`.

actual_failed

```
# the test numbers which actually failed
my @actual_failed = $parser->actual_failed;

# the number of tests which actually failed
my $actual_failed = $parser->actual_failed;
```

This method lets you know which (or how many) tests actually failed, regardless of whether or not a TODO directive was found.

todo

```
my @todo = $parser->todo; # the test numbers with todo directives
my $todo = $parser->todo; # the number of tests with todo directives
```

This method lets you know which (or how many) tests had TODO directives.

todo_passed

```
# the test numbers which unexpectedly succeeded
my @todo_passed = $parser->todo_passed;

# the number of tests which unexpectedly succeeded
my $todo_passed = $parser->todo_passed;
```

This method lets you know which (or how many) tests actually passed but were declared as “TODO” tests.

todo_failed

```
# deprecated in favor of 'todo_passed'.  This method was horribly␣
 ↪misnamed.
```

This was a badly misnamed method. It indicates which TODO tests unexpectedly succeeded. Will now issue a warning and call `todo_passed`.

skipped

```
my @skipped = $parser->skipped; # the test numbers with SKIP␣
 ↪directives
my $skipped = $parser->skipped; # the number of tests with SKIP␣
 ↪directives
```

This method lets you know which (or how many) tests had SKIP directives.

Pragmas

pragma

Get or set a pragma. To get the state of a pragma:

```
if ( $p->pragma('strict') ) {
    # be strict
}
```

To set the state of a pragma:

```
$p->pragma('strict', 1); # enable strict mode
```

pragmas

Get a list of all the currently enabled pragmas:

```
my @pragmas_enabled = $p->pragmas;
```

Summary Results

These results are "meta" information about the total results of an individual test program.

plan

```
my $plan = $parser->plan;
```

Returns the test plan, if found.

good_plan

Deprecated. Use `is_good_plan` instead.

is_good_plan

```
if ( $parser->is_good_plan ) { ... }
```

Returns a boolean value indicating whether or not the number of tests planned matches the number of tests run.

Note: this was formerly `good_plan`. The latter method is deprecated and will issue a warning.

And since we're on that subject ...

tests_planned

```
print $parser->tests_planned;
```

Returns the number of tests planned, according to the plan. For example, a plan of '1..17' will mean that 17 tests were planned.

tests_run

```
print $parser->tests_run;
```

Returns the number of tests which actually were run. Hopefully this will match the number of `$parser->tests_planned`.

skip_all

Returns a true value (actually the reason for skipping) if all tests were skipped.

start_time

Returns the wall-clock time when the Parser was created.

end_time

Returns the wall-clock time when the end of TAP input was seen.

start_times

Returns the CPU times (like *"times" in perlfunc* when the Parser was created.

end_times

Returns the CPU times (like *"times" in perlfunc* when the end of TAP input was seen.

has_problems

```
if ( $parser->has_problems ) {
    ...
}
```

This is a 'catch-all' method which returns true if any tests have currently failed, any TODO tests unexpectedly succeeded, or any parse errors occurred.

version

```
$parser->version;
```

Once the parser is done, this will return the version number for the parsed TAP. Version numbers were introduced with TAP version 13 so if no version number is found version 12 is assumed.

exit

```
$parser->exit;
```

Once the parser is done, this will return the exit status. If the parser ran an executable, it returns the exit status of the executable.

wait

```
$parser->wait;
```

Once the parser is done, this will return the wait status. If the parser ran an executable, it returns the wait status of the executable. Otherwise, this merely returns the `exit` status.

ignore_exit

```
$parser->ignore_exit(1);
```

Tell the parser to ignore the exit status from the test when determining whether the test passed. Normally tests with non-zero exit status are considered to have failed even if all individual tests passed. In cases where it is not possible to control the exit value of the test script use this option to ignore it.

parse_errors

```
my @errors = $parser->parse_errors; # the parser errors
my $errors = $parser->parse_errors; # the number of parser_errors
```

Fortunately, all TAP output is perfect. In the event that it is not, this method will return parser errors. Note that a junk line which the parser does not recognize is `not` an error. This allows this parser to handle future versions of TAP. The following are all TAP errors reported by the parser:

- Misplaced plan

  The plan (for example, '1..5'), must only come at the beginning or end of the TAP output.

- No plan

  Gotta have a plan!

- More than one plan

  ```
  1..3
  ok 1 - input file opened
  not ok 2 - first line of the input valid # todo some data
  ok 3 read the rest of the file
  1..3
  ```

  Right. Very funny. Don't do that.

- Test numbers out of sequence

```
1..3
ok 1 - input file opened
not ok 2 - first line of the input valid # todo some data
ok 2 read the rest of the file
```

That last test line above should have the number '3' instead of '2'.

Note that it's perfectly acceptable for some lines to have test numbers and others to not have them. However, when a test number is found, it must be in sequence. The following is also an error:

```
1..3
ok 1 - input file opened
not ok - first line of the input valid # todo some data
ok 2 read the rest of the file
```

But this is not:

```
1..3
ok  - input file opened
not ok - first line of the input valid # todo some data
ok 3 read the rest of the file
```

get_select_handles

Get an a list of file handles which can be passed to `select` to determine the readiness of this parser.

delete_spool

Delete and return the spool.

```
my $fh = $parser->delete_spool;
```

CALLBACKS

As mentioned earlier, a "callback" key may be added to the `TAP::Parser` constructor. If present, each callback corresponding to a given result type will be called with the result as the argument if the `run` method is used. The callback is expected to be a subroutine reference (or anonymous subroutine) which is invoked with the parser result as its argument.

```
my %callbacks = (
    test    => \&test_callback,
    plan    => \&plan_callback,
    comment => \&comment_callback,
    bailout => \&bailout_callback,
    unknown => \&unknown_callback,
);
```

(continues on next page)

(continued from previous page)

```
my $aggregator = TAP::Parser::Aggregator->new;
for my $file ( @test_files ) {
    my $parser = TAP::Parser->new(
        {
            source    => $file,
            callbacks => \%callbacks,
        }
    );
    $parser->run;
    $aggregator->add( $file, $parser );
}
```

Callbacks may also be added like this:

```
$parser->callback( test => \&test_callback );
$parser->callback( plan => \&plan_callback );
```

The following keys allowed for callbacks. These keys are case-sensitive.

- `test`

  Invoked if `$result->is_test` returns true.

- `version`

  Invoked if `$result->is_version` returns true.

- `plan`

  Invoked if `$result->is_plan` returns true.

- `comment`

  Invoked if `$result->is_comment` returns true.

- `bailout`

  Invoked if `$result->is_unknown` returns true.

- `yaml`

  Invoked if `$result->is_yaml` returns true.

- `unknown`

  Invoked if `$result->is_unknown` returns true.

- `ELSE`

  If a result does not have a callback defined for it, this callback will be invoked. Thus, if all of the previous result types are specified as callbacks, this callback will *never* be invoked.

- `ALL`

  This callback will always be invoked and this will happen for each result after one of the above callbacks is invoked. For example, if *Term::ANSIColor* is loaded, you could use the following to color your test output:

```
my %callbacks = (
    test => sub {
        my $test = shift;
        if ( $test->is_ok && not $test->directive ) {
            # normal passing test
            print color 'green';
        }
        elsif ( !$test->is_ok ) {    # even if it's TODO
            print color 'white on_red';
        }
        elsif ( $test->has_skip ) {
            print color 'white on_blue';

        }
        elsif ( $test->has_todo ) {
            print color 'white';
        }
    },
    ELSE => sub {
        # plan, comment, and so on (anything which isn't a test
↪line)
        print color 'black on_white';
    },
    ALL => sub {
        # now print them
        print shift->as_string;
        print color 'reset';
        print "\n";
    },
);
```

- EOF

  Invoked when there are no more lines to be parsed. Since there is no accompanying *TAP::Parser::Result* object the `TAP::Parser` object is passed instead.

TAP GRAMMAR

If you're looking for an EBNF grammar, see *TAP::Parser::Grammar*.

BACKWARDS COMPATIBILITY

The Perl-QA list attempted to ensure backwards compatibility with *Test::Harness*. However, there are some minor differences.

Differences

- TODO plans

  A little-known feature of *Test::Harness* is that it supported TODO lists in the plan:

```
1..2 todo 2
ok 1 - We have liftoff
not ok 2 - Anti-gravity device activated
```

Under *Test::Harness*, test number 2 would *pass* because it was listed as a TODO test on the plan line. However, we are not aware of anyone actually using this feature and hard-coding test numbers is discouraged because it's very easy to add a test and break the test number sequence. This makes test suites very fragile. Instead, the following should be used:

```
1..2
ok 1 - We have liftoff
not ok 2 - Anti-gravity device activated # TODO
```

- 'Missing' tests

  It rarely happens, but sometimes a harness might encounter 'missing tests:

```
ok 1
ok 2
ok 15
ok 16
ok 17
```

  Test::Harness would report tests 3-14 as having failed. For the `TAP::Parser`, these tests are not considered failed because they've never run. They're reported as parse failures (tests out of sequence).

SUBCLASSING

If you find you need to provide custom functionality (as you would have using Test::Harness::Straps), you're in luck: `TAP::Parser` and friends are designed to be easily plugged-into and/or subclassed.

Before you start, it's important to know a few things:

1. All `TAP::*` objects inherit from *TAP::Object*.
2. Many `TAP::*` classes have a *SUBCLASSING* section to guide you.
3. Note that `TAP::Parser` is designed to be the central "maker" - ie: it is responsible for creating most new objects in the `TAP::Parser::*` namespace.

   This makes it possible for you to have a single point of configuring what subclasses should be used, which means that in many cases you'll find you only need to sub-class one of the parser's components.

   The exception to this rule are *SourceHandlers* & *Iterators*, but those are both created with customizable *IteratorFactory*.
4. By subclassing, you may end up overriding undocumented methods. That's not a bad thing per se, but be forewarned that undocumented methods may change without warning from one release to the next - we cannot guarantee backwards compatibility. If any *documented* method needs changing, it will be deprecated first, and changed in a later release.

Parser Components

Sources

A TAP parser consumes input from a single *raw source* of TAP, which could come from anywhere (a file, an executable, a database, an IO handle, a URI, etc..). The source gets bundled up in a *TAP::Parser::Source* object which gathers some meta data about it. The parser then uses a *TAP::Parser::IteratorFactory* to determine which *TAP::Parser::SourceHandler* to use to turn the raw source into a stream of TAP by way of "Iterators".

If you simply want `TAP::Parser` to handle a new source of TAP you probably don't need to subclass `TAP::Parser` itself. Rather, you'll need to create a new *TAP::Parser::SourceHandler* class, and just plug it into the parser using the *sources* param to "new". Before you start writing one, read through *TAP::Parser::IteratorFactory* to get a feel for how the system works first.

If you find you really need to use your own iterator factory you can still do so without sub-classing `TAP::Parser` by setting "iterator_factory_class".

If you just need to customize the objects on creation, subclass *TAP::Parser* and override "make_iterator_factory".

Note that `make_source` & `make_perl_source` have been *DEPRECATED* and are now removed.

Iterators

A TAP parser uses *iterators* to loop through the *stream* of TAP read in from the *source* it was given. There are a few types of Iterators available by default, all sub-classes of *TAP::Parser::Iterator*. Choosing which iterator to use is the responsibility of the *iterator factory*, though it simply delegates to the *Source Handler* it uses.

If you're writing your own *TAP::Parser::SourceHandler*, you may need to create your own iterators too. If so you'll need to subclass *TAP::Parser::Iterator*.

Note that "make_iterator" has been *DEPRECATED* and is now removed.

Results

A TAP parser creates *TAP::Parser::Result*s as it iterates through the input *stream*. There are quite a few result types available; choosing which class to use is the responsibility of the *result factory*.

To create your own result types you have two options:

- option 1

  Subclass *TAP::Parser::Result* and register your new result type/class with the default *TAP::Parser::ResultFactory*.

- option 2

  Subclass *TAP::Parser::ResultFactory* itself and implement your own *TAP::Parser::Result* creation logic. Then you'll need to customize the class used by your parser by setting the `result_factory_class` parameter. See "new" for more details.

If you need to customize the objects on creation, subclass *TAP::Parser* and override "make_result".

Grammar

TAP::Parser::Grammar is the heart of the parser. It tokenizes the TAP input *stream* and produces results. If you need to customize its behaviour you should probably familiarize yourself with the source first. Enough lecturing.

Subclass *TAP::Parser::Grammar* and customize your parser by setting the `grammar_class` parameter. See "new" for more details.

If you need to customize the objects on creation, subclass *TAP::Parser* and override "make_grammar"

ACKNOWLEDGMENTS

All of the following have helped. Bug reports, patches, (im)moral support, or just words of encouragement have all been forthcoming.

BUGS

Please report any bugs or feature requests to `bug-test-harness@rt.cpan.org`, or through the web interface at http://rt.cpan.org/NoAuth/ReportBug.html?Queue=Test-Harness. We will be notified, and then you’ll automatically be notified of progress on your bug as we make changes.

Obviously, bugs which include patches are best. If you prefer, you can patch against bleed by via anonymous checkout of the latest version:

```
git clone git://github.com/Perl-Toolchain-Gang/Test-Harness.git
```

Modules

- `TAP::Parser::Aggregator` - Aggregate TAP::Parser results
- `TAP::Parser::Grammar` - A grammar for the Test Anything Protocol.
- `TAP::Parser::Iterator` - Base class for TAP source iterators
- `TAP::Parser::IteratorFactory` - Figures out which SourceHandler objects to use for a given Source
- `TAP::Parser::Multiplexer` - Multiplex multiple TAP::Parsers
- `TAP::Parser::Result` - Base class for TAP::Parser output objects
- `TAP::Parser::ResultFactory` - Factory for creating TAP::Parser output objects
- `TAP::Parser::Scheduler` - Schedule tests during parallel testing
- `TAP::Parser::Source` - a TAP source & meta data about it

- `TAP::Parser::SourceHandler` - Base class for different TAP source handlers
- `TAP::Parser::YAMLish`

TAP::Parser::Aggregator

Aggregate TAP::Parser results

VERSION

Version 3.52

SYNOPSIS

```
use TAP::Parser::Aggregator;

my $aggregate = TAP::Parser::Aggregator->new;
$aggregate->add( 't/00-load.t', $load_parser );
$aggregate->add( 't/10-lex.t',  $lex_parser  );

my $summary = <<'END_SUMMARY';
Passed:  %s
Failed:  %s
Unexpectedly succeeded: %s
END_SUMMARY
printf $summary,
       scalar $aggregate->passed,
       scalar $aggregate->failed,
       scalar $aggregate->todo_passed;
```

DESCRIPTION

`TAP::Parser::Aggregator` collects parser objects and allows reporting/querying their aggregate results.

METHODS

Class Methods

new

```
my $aggregate = TAP::Parser::Aggregator->new;
```

Returns a new `TAP::Parser::Aggregator` object.

Instance Methods

add

```
$aggregate->add( $description => $parser );
```

The `$description` is usually a test file name (but only by convention.) It is used as a unique identifier (see e.g. "parsers".) Reusing a description is a fatal error.

The `$parser` is a *TAP::Parser* object.

parsers

```
my $count   = $aggregate->parsers;
my @parsers = $aggregate->parsers;
my @parsers = $aggregate->parsers(@descriptions);
```

In scalar context without arguments, this method returns the number of parsers aggregated. In list context without arguments, returns the parsers in the order they were added.

If `@descriptions` is given, these correspond to the keys used in each call to the add() method. Returns an array of the requested parsers (in the requested order) in list context or an array reference in scalar context.

Requesting an unknown identifier is a fatal error.

descriptions

Get an array of descriptions in the order in which they were added to the aggregator.

start

Call `start` immediately before adding any results to the aggregator. Among other times it records the start time for the test run.

stop

Call `stop` immediately after adding all test results to the aggregator.

elapsed

Elapsed returns a *Benchmark* object that represents the running time of the aggregated tests. In order for `elapsed` to be valid you must call `start` before running the tests and `stop` immediately afterwards.

elapsed_timestr

Returns a formatted string representing the runtime returned by `elapsed()`. This lets the caller not worry about Benchmark.

all_passed

Return true if all the tests passed and no parse errors were detected.

get_status

Get a single word describing the status of the aggregated tests. Depending on the outcome of the tests returns 'PASS', 'FAIL' or 'NOTESTS'. This token is understood by CPAN::Reporter.

Summary methods

Each of the following methods will return the total number of corresponding tests if called in scalar context. If called in list context, returns the descriptions of the parsers which contain the corresponding tests (see add for an explanation of description.

- failed
- parse_errors
- passed
- planned
- skipped
- todo
- todo_passed
- wait
- exit

For example, to find out how many tests unexpectedly succeeded (TODO tests which passed when they shouldn't):

```
my $count        = $aggregate->todo_passed;
my @descriptions = $aggregate->todo_passed;
```

Note that `wait` and `exit` are the totals of the wait and exit statuses of each of the tests. These values are totalled only to provide a true value if any of them are non-zero.

total

```
my $tests_run = $aggregate->total;
```

Returns the total number of tests run.

has_problems

```
if ( $parser->has_problems ) {
    ...
}
```

Identical to `has_errors`, but also returns true if any TODO tests unexpectedly succeeded. This is more akin to "warnings".

has_errors

```
if ( $parser->has_errors ) {
    ...
}
```

Returns true if *any* of the parsers failed. This includes:

- Failed tests
- Parse errors
- Bad exit or wait status

todo_failed

```
# deprecated in favor of 'todo_passed'.  This method was horribly␣
 ↪misnamed.
```

This was a badly misnamed method. It indicates which TODO tests unexpectedly succeeded. Will now issue a warning and call `todo_passed`.

TAP::Parser

TAP::Harness

TAP::Parser::Grammar

A grammar for the Test Anything Protocol.

VERSION

Version 3.52

SYNOPSIS

```
use TAP::Parser::Grammar;
my $grammar = $self->make_grammar({
  iterator => $tap_parser_iterator,
  parser   => $tap_parser,
  version  => 12,
});

my $result = $grammar->tokenize;
```

DESCRIPTION

`TAP::Parser::Grammar` tokenizes lines from a *TAP::Parser::Iterator* and constructs *TAP::Parser::Result* subclasses to represent the tokens.

Do not attempt to use this class directly. It won't make sense. It's mainly here to ensure that we will be able to have pluggable grammars when TAP is expanded at some future date (plus, this stuff was really cluttering the parser).

METHODS

Class Methods

new

```
my $grammar = TAP::Parser::Grammar->new({
    iterator => $iterator,
    parser   => $parser,
    version  => $version,
});
```

Returns *TAP::Parser* grammar object that will parse the TAP stream from the specified iterator. Both `iterator` and `parser` are required arguments. If `version` is not set it defaults to 12 (see "set_version" for more details).

Instance Methods

set_version

```
$grammar->set_version(13);
```

Tell the grammar which TAP syntax version to support. The lowest supported version is 12. Although 'TAP version' isn't valid version 12 syntax it is accepted so that higher version numbers may be parsed.

tokenize

```
my $token = $grammar->tokenize;
```

This method will return a *TAP::Parser::Result* object representing the current line of TAP.

token_types

```
my @types = $grammar->token_types;
```

Returns the different types of tokens which this grammar can parse.

syntax_for

```
my $syntax = $grammar->syntax_for($token_type);
```

Returns a pre-compiled regular expression which will match a chunk of TAP corresponding to the token type. For example (not that you should really pay attention to this, `$grammar->syntax_for('comment')` will return `qr/^#(.*)/`.

handler_for

```
my $handler = $grammar->handler_for($token_type);
```

Returns a code reference which, when passed an appropriate line of TAP, returns the lexed token corresponding to that line. As a result, the basic TAP parsing loop looks similar to the following:

```
my @tokens;
my $grammar = TAP::Grammar->new;
LINE: while ( defined( my $line = $parser->_next_chunk_of_tap ) ) {
    for my $type ( $grammar->token_types ) {
        my $syntax  = $grammar->syntax_for($type);
        if ( $line =~ $syntax ) {
            my $handler = $grammar->handler_for($type);
            push @tokens => $grammar->$handler($line);
            next LINE;
        }
    }
    push @tokens => $grammar->_make_unknown_token($line);
}
```

TAP GRAMMAR

NOTE: This grammar is slightly out of date. There's still some discussion about it and a new one will be provided when we have things better defined.

The *TAP::Parser* does not use a formal grammar because TAP is essentially a stream-based protocol. In fact, it's quite legal to have an infinite stream. For the same reason that we don't apply regexes to streams, we're not using a formal grammar here. Instead, we parse the TAP in lines.

For purposes for forward compatibility, any result which does not match the following grammar is currently referred to as *TAP::Parser::Result::Unknown*. It is *not* a parse error.

A formal grammar would look similar to the following:

```
(*
    For the time being, I'm cheating on the EBNF by allowing
    certain terms to be defined by POSIX character classes by
    using the following syntax:

      digit ::= [:digit:]
```

(continues on next page)

(continued from previous page)

```
    As far as I am aware, that's not valid EBNF.  Sue me.  I
    didn't know how to write "char" otherwise (Unicode issues).
    Suggestions welcome.
*)

tap            ::= version? { comment | unknown } leading_plan lines
                   |
                   lines trailing_plan {comment}

version        ::= 'TAP version ' positiveInteger {positiveInteger}
 ↪"\n"

leading_plan   ::= plan skip_directive? "\n"

trailing_plan  ::= plan "\n"

plan           ::= '1..' nonNegativeInteger

lines          ::= line {line}

line           ::= (comment | test | unknown | bailout ) "\n"

test           ::= status positiveInteger? description? directive?

status         ::= 'not '? 'ok '

description    ::= (character - (digit | '#')) {character - '#'}

directive      ::= todo_directive | skip_directive

todo_directive ::= hash_mark 'TODO' ' ' {character}

skip_directive ::= hash_mark 'SKIP' ' ' {character}

comment        ::= hash_mark {character}

hash_mark      ::= '#' {' '}

bailout        ::= 'Bail out!' {character}

unknown        ::= { (character - "\n") }

(* POSIX character classes and other terminals *)

digit              ::= [:digit:]
character          ::= ([:print:] - "\n")
positiveInteger    ::= ( digit - '0' ) {digit}
nonNegativeInteger ::= digit {digit}
```

SUBCLASSING

Please see *"SUBCLASSING" in TAP::Parser* for a subclassing overview.

If you *really* want to subclass *TAP::Parser*'s grammar the best thing to do is read through the code. There's no easy way of summarizing it here.

SEE ALSO

TAP::Object, *TAP::Parser*, *TAP::Parser::Iterator*, *TAP::Parser::Result*,

TAP::Parser::Iterator

Base class for TAP source iterators

VERSION

Version 3.52

SYNOPSIS

```
# to subclass:
use TAP::Parser::Iterator ();
use base 'TAP::Parser::Iterator';
sub _initialize {
  # see TAP::Object...
}

sub next_raw { ... }
sub wait     { ... }
sub exit     { ... }
```

DESCRIPTION

This is a simple iterator base class that defines *TAP::Parser*'s iterator API. Iterators are typically created from *TAP::Parser::SourceHandler*s.

METHODS

Class Methods

new

Create an iterator. Provided by *TAP::Object*.

Instance Methods

next

```
while ( my $item = $iter->next ) { ... }
```

Iterate through it, of course.

next_raw

Note: this method is abstract and should be overridden.

```
while ( my $item = $iter->next_raw ) { ... }
```

Iterate raw input without applying any fixes for quirky input syntax.

handle_unicode

If necessary switch the input stream to handle unicode. This only has any effect for I/O handle based streams.

The default implementation does nothing.

get_select_handles

Return a list of filehandles that may be used upstream in a select() call to signal that this Iterator is ready. Iterators that are not handle-based should return an empty list.

The default implementation does nothing.

wait

Note: this method is abstract and should be overridden.

```
my $wait_status = $iter->wait;
```

Return the `wait` status for this iterator.

exit

Note: this method is abstract and should be overridden.

```
my $wait_status = $iter->exit;
```

Return the `exit` status for this iterator.

SUBCLASSING

Please see *"SUBCLASSING" in TAP::Parser* for a subclassing overview.

You must override the abstract methods as noted above.

Example

TAP::Parser::Iterator::Array is probably the easiest example to follow. There's not much point repeating it here.

SEE ALSO

TAP::Object, *TAP::Parser*, *TAP::Parser::Iterator::Array*, *TAP::Parser::Iterator::Stream*, *TAP::Parser::Iterator::Process*,

Modules

- `TAP::Parser::Iterator::Array` - Iterator for array-based TAP sources
- `TAP::Parser::Iterator::Process` - Iterator for process-based TAP sources
- `TAP::Parser::Iterator::Stream` - Iterator for filehandle-based TAP sources

TAP::Parser::Iterator::Array

Iterator for array-based TAP sources

VERSION

Version 3.52

SYNOPSIS

```
use TAP::Parser::Iterator::Array;
my @data = ('foo', 'bar', baz');
my $it   = TAP::Parser::Iterator::Array->new(\@data);
my $line = $it->next;
```

DESCRIPTION

This is a simple iterator wrapper for arrays of scalar content, used by *TAP::Parser*. Unless you're writing a plugin or subclassing, you probably won't need to use this module directly.

METHODS

Class Methods

new

Create an iterator. Takes one argument: an `$array_ref`

Instance Methods

next

Iterate through it, of course.

next_raw

Iterate raw input without applying any fixes for quirky input syntax.

wait

Get the wait status for this iterator. For an array iterator this will always be zero.

exit

Get the exit status for this iterator. For an array iterator this will always be zero.

ATTRIBUTION

Originally ripped off from *Test::Harness*.

SEE ALSO

TAP::Object, *TAP::Parser*, *TAP::Parser::Iterator*,

TAP::Parser::Iterator::Process

Iterator for process-based TAP sources

VERSION

Version 3.52

SYNOPSIS

```
use TAP::Parser::Iterator::Process;
my %args = (
 command  => ['python', 'setup.py', 'test'],
 merge    => 1,
 setup    => sub { ... },
 teardown => sub { ... },
);
my $it   = TAP::Parser::Iterator::Process->new(\%args);
my $line = $it->next;
```

DESCRIPTION

This is a simple iterator wrapper for executing external processes, used by *TAP::Parser*. Unless you're writing a plugin or subclassing, you probably won't need to use this module directly.

METHODS

Class Methods

new

Create an iterator. Expects one argument containing a hashref of the form:

```
command  => \@command_to_execute
merge    => $attempt_merge_stderr_and_stdout?
setup    => $callback_to_setup_command
teardown => $callback_to_teardown_command
```

Tries to uses *IPC::Open3* & *IO::Select* to communicate with the spawned process if they are available. Falls back onto `open()`.

Instance Methods

next

Iterate through the process output, of course.

next_raw

Iterate raw input without applying any fixes for quirky input syntax.

wait

Get the wait status for this iterator's process.

exit

Get the exit status for this iterator's process.

handle_unicode

Upgrade the input stream to handle UTF8.

get_select_handles

Return a list of filehandles that may be used upstream in a select() call to signal that this Iterator is ready. Iterators that are not handle based should return an empty list.

ATTRIBUTION

Originally ripped off from *Test::Harness*.

SEE ALSO

TAP::Object, *TAP::Parser*, *TAP::Parser::Iterator*,

TAP::Parser::Iterator::Stream

Iterator for filehandle-based TAP sources

VERSION

Version 3.52

SYNOPSIS

```
use TAP::Parser::Iterator::Stream;
open( TEST, 'test.tap' );
my $it   = TAP::Parser::Iterator::Stream->new(\*TEST);
my $line = $it->next;
```

DESCRIPTION

This is a simple iterator wrapper for reading from filehandles, used by *TAP::Parser*. Unless you're writing a plugin or subclassing, you probably won't need to use this module directly.

METHODS

Class Methods

new

Create an iterator. Expects one argument containing a filehandle.

Instance Methods

next

Iterate through it, of course.

next_raw

Iterate raw input without applying any fixes for quirky input syntax.

wait

Get the wait status for this iterator. Always returns zero.

exit

Get the exit status for this iterator. Always returns zero.

ATTRIBUTION

Originally ripped off from *Test::Harness*.

TAP::Object, *TAP::Parser*, *TAP::Parser::Iterator*,

TAP::Parser::IteratorFactory

Figures out which SourceHandler objects to use for a given Source

VERSION

Version 3.52

SYNOPSIS

```
use TAP::Parser::IteratorFactory;
my $factory = TAP::Parser::IteratorFactory->new({ %config });
my $iterator  = $factory->make_iterator( $filename );
```

DESCRIPTION

This is a factory class that takes a *TAP::Parser::Source* and runs it through all the registered *TAP::Parser::SourceHandler*s to see which one should handle the source.

If you're a plugin author, you'll be interested in how to "register_handler"s, how "detect_source" works.

METHODS

Class Methods

new

Creates a new factory class:

```
my $sf = TAP::Parser::IteratorFactory->new( $config );
```

`$config` is optional. If given, sets "config" and calls "load_handlers".

register_handler

Registers a new *TAP::Parser::SourceHandler* with this factory.

```
__PACKAGE__->register_handler( $handler_class );
```

handlers

List of handlers that have been registered.

Instance Methods

config

```
my $cfg = $sf->config;
$sf->config({ Perl => { %config } });
```

Chaining getter/setter for the configuration of the available source handlers. This is a hashref keyed on handler class whose values contain config to be passed onto the handlers during detection & creation. Class names may be fully qualified or abbreviated, eg:

```
# these are equivalent
$sf->config({ 'TAP::Parser::SourceHandler::Perl' => { %config } });
$sf->config({ 'Perl' => { %config } });
```

load_handlers

```
$sf->load_handlers;
```

Loads the handler classes defined in "config". For example, given a config:

```
$sf->config({
  MySourceHandler => { some => 'config' },
});
```

`load_handlers` will attempt to load the `MySourceHandler` class by looking in `@INC` for it in this order:

```
TAP::Parser::SourceHandler::MySourceHandler
MySourceHandler
```

`croaks` on error.

make_iterator

```
my $iterator = $src_factory->make_iterator( $source );
```

Given a *TAP::Parser::Source*, finds the most suitable *TAP::Parser::SourceHandler* to use to create a *TAP::Parser::Iterator* (see "detect_source"). Dies on error.

detect_source

Given a *TAP::Parser::Source*, detects what kind of source it is and returns *one TAP::Parser::SourceHandler* (the most confident one). Dies on error.

The detection algorithm works something like this:

```
for (@registered_handlers) {
  # ask them how confident they are about handling this source
  $confidence{$handler} = $handler->can_handle( $source )
}
# choose the most confident handler
```

Ties are handled by choosing the first handler.

SUBCLASSING

Please see *"SUBCLASSING" in TAP::Parser* for a subclassing overview.

Example

If we've done things right, you'll probably want to write a new source, rather than sub-classing this (see *TAP::Parser::SourceHandler* for that).

But in case you find the need to...

```
package MyIteratorFactory;

use strict;

use base 'TAP::Parser::IteratorFactory';

# override source detection algorithm
sub detect_source {
  my ($self, $raw_source_ref, $meta) = @_;
  # do detective work, using $meta and whatever else...
}

1;
```

AUTHORS

Steve Purkis

ATTRIBUTION

Originally ripped off from *Test::Harness*.

Moved out of *TAP::Parser* & converted to a factory class to support extensible TAP source detective work by Steve Purkis.

SEE ALSO

TAP::Object, *TAP::Parser*, *TAP::Parser::SourceHandler*, *TAP::Parser::SourceHandler::File*, *TAP::Parser::SourceHandler::Perl*, *TAP::Parser::SourceHandler::RawTAP*, *TAP::Parser::SourceHandler::Handle*, *TAP::Parser::SourceHandler::Executable*

TAP::Parser::Multiplexer

Multiplex multiple TAP::Parsers

VERSION

Version 3.52

SYNOPSIS

```
use TAP::Parser::Multiplexer;

my $mux = TAP::Parser::Multiplexer->new;
$mux->add( $parser1, $stash1 );
$mux->add( $parser2, $stash2 );
while ( my ( $parser, $stash, $result ) = $mux->next ) {
    # do stuff
}
```

DESCRIPTION

`TAP::Parser::Multiplexer` gathers input from multiple TAP::Parsers. Internally it calls select on the input file handles for those parsers to wait for one or more of them to have input available.

See *TAP::Harness* for an example of its use.

METHODS

Class Methods

new

```
my $mux = TAP::Parser::Multiplexer->new;
```

Returns a new `TAP::Parser::Multiplexer` object.

Instance Methods

add

```
$mux->add( $parser, $stash );
```

Add a TAP::Parser to the multiplexer. `$stash` is an optional opaque reference that will be returned from `next` along with the parser and the next result.

parsers

```
my $count   = $mux->parsers;
```

Returns the number of parsers. Parsers are removed from the multiplexer when their input is exhausted.

next

Return a result from the next available parser. Returns a list containing the parser from which the result came, the stash that corresponds with that parser and the result.

```
my ( $parser, $stash, $result ) = $mux->next;
```

If `$result` is undefined the corresponding parser has reached the end of its input (and will automatically be removed from the multiplexer).

When all parsers are exhausted an empty list will be returned.

```
if ( my ( $parser, $stash, $result ) = $mux->next ) {
    if ( ! defined $result ) {
        # End of this parser
    }
    else {
        # Process result
    }
}
else {
    # All parsers finished
}
```

TAP::Parser

TAP::Harness

TAP::Parser::Result

Base class for TAP::Parser output objects

VERSION

Version 3.52

SYNOPSIS

```
# abstract class - not meant to be used directly
# see TAP::Parser::ResultFactory for preferred usage
```

(continues on next page)

(continued from previous page)

```
# directly:
use TAP::Parser::Result;
my $token  = {...};
my $result = TAP::Parser::Result->new( $token );
```

DESCRIPTION

This is a simple base class used by *TAP::Parser* to store objects that represent the current bit of test output data from TAP (usually a single line). Unless you're subclassing, you probably won't need to use this module directly.

METHODS

new

```
# see TAP::Parser::ResultFactory for preferred usage

# to use directly:
my $result = TAP::Parser::Result->new($token);
```

Returns an instance the appropriate class for the test token passed in.

Boolean methods

The following methods all return a boolean value and are to be overridden in the appropriate subclass.

- `is_plan`

  Indicates whether or not this is the test plan line.

  ```
  1..3
  ```

- `is_pragma`

  Indicates whether or not this is a pragma line.

  ```
  pragma +strict
  ```

- `is_test`

  Indicates whether or not this is a test line.

  ```
  ok 1 Is OK!
  ```

- `is_comment`

  Indicates whether or not this is a comment.

  ```
  # this is a comment
  ```

- `is_bailout`

  Indicates whether or not this is bailout line.

  ```
  Bail out! We're out of dilithium crystals.
  ```

- `is_version`

  Indicates whether or not this is a TAP version line.

  ```
  TAP version 4
  ```

- `is_unknown`

  Indicates whether or not the current line could be parsed.

  ```
  ... this line is junk ...
  ```

- `is_yaml`

  Indicates whether or not this is a YAML chunk.

raw

```
print $result->raw;
```

Returns the original line of text which was parsed.

type

```
my $type = $result->type;
```

Returns the "type" of a token, such as `comment` or `test`.

as_string

```
print $result->as_string;
```

Prints a string representation of the token. This might not be the exact output, however. Tests will have test numbers added if not present, TODO and SKIP directives will be capitalized and, in general, things will be cleaned up. If you need the original text for the token, see the `raw` method.

is_ok

```
if ( $result->is_ok ) { ... }
```

Reports whether or not a given result has passed. Anything which is **not** a test result returns true. This is merely provided as a convenient shortcut.

passed

Deprecated. Please use `is_ok` instead.

has_directive

```
if ( $result->has_directive ) {
    ...
}
```

Indicates whether or not the given result has a TODO or SKIP directive.

has_todo

```
if ( $result->has_todo ) {
    ...
}
```

Indicates whether or not the given result has a TODO directive.

has_skip

```
if ( $result->has_skip ) {
    ...
}
```

Indicates whether or not the given result has a SKIP directive.

set_directive

Set the directive associated with this token. Used internally to fake TODO tests.

SUBCLASSING

Please see *"SUBCLASSING" in TAP::Parser* for a subclassing overview.

Remember: if you want your subclass to be automatically used by the parser, you'll have to register it with *"register_type" in TAP::Parser::ResultFactory*.

If you're creating a completely new result *type*, you'll probably need to subclass *TAP::Parser::Grammar* too, or else it'll never get used.

Example

```
package MyResult;

use strict;

use base 'TAP::Parser::Result';
```

(continues on next page)

(continued from previous page)

```
# register with the factory:
TAP::Parser::ResultFactory->register_type( 'my_type' => __PACKAGE__
↪);

sub as_string { 'My results all look the same' }
```

SEE ALSO

TAP::Object, *TAP::Parser*, *TAP::Parser::ResultFactory*, *TAP::Parser::Result::Bailout*, *TAP::Parser::Result::Comment*, *TAP::Parser::Result::Plan*, *TAP::Parser::Result::Pragma*, *TAP::Parser::Result::Test*, *TAP::Parser::Result::Unknown*, *TAP::Parser::Result::Version*, *TAP::Parser::Result::YAML*,

Modules

- `TAP::Parser::Result::Bailout` - Bailout result token.
- `TAP::Parser::Result::Comment` - Comment result token.
- `TAP::Parser::Result::Plan` - Plan result token.
- `TAP::Parser::Result::Pragma` - TAP pragma token.
- `TAP::Parser::Result::Test` - Test result token.
- `TAP::Parser::Result::Unknown` - Unknown result token.
- `TAP::Parser::Result::Version` - TAP syntax version token.
- `TAP::Parser::Result::YAML` - YAML result token.

TAP::Parser::Result::Bailout

Bailout result token.

VERSION

Version 3.52

DESCRIPTION

This is a subclass of *TAP::Parser::Result*. A token of this class will be returned if a bail out line is encountered.

```
1..5
ok 1 - woo hooo!
Bail out! Well, so much for "woo hooo!"
```

OVERRIDDEN METHODS

Mainly listed here to shut up the pitiful screams of the pod coverage tests. They keep me awake at night.

- `as_string`

Instance Methods

explanation

```
if ( $result->is_bailout ) {
    my $explanation = $result->explanation;
    print "We bailed out because ($explanation)";
}
```

If, and only if, a token is a bailout token, you can get an "explanation" via this method. The explanation is the text after the mystical "Bail out!" words which appear in the tap output.

TAP::Parser::Result::Comment

Comment result token.

VERSION

Version 3.52

DESCRIPTION

This is a subclass of *TAP::Parser::Result*. A token of this class will be returned if a comment line is encountered.

```
1..1
ok 1 - woo hooo!
# this is a comment
```

OVERRIDDEN METHODS

Mainly listed here to shut up the pitiful screams of the pod coverage tests. They keep me awake at night.

- `as_string`

  Note that this method merely returns the comment preceded by a '# '.

Instance Methods

comment

```
if ( $result->is_comment ) {
    my $comment = $result->comment;
    print "I have something to say:  $comment";
}
```

TAP::Parser::Result::Plan

Plan result token.

VERSION

Version 3.52

DESCRIPTION

This is a subclass of *TAP::Parser::Result*. A token of this class will be returned if a plan line is encountered.

```
1..1
ok 1 - woo hooo!
```

1..1 is the plan. Gotta have a plan.

OVERRIDDEN METHODS

Mainly listed here to shut up the pitiful screams of the pod coverage tests. They keep me awake at night.

- as_string
- raw

Instance Methods

plan

```
if ( $result->is_plan ) {
   print $result->plan;
}
```

This is merely a synonym for as_string.

tests_planned

```
my $planned = $result->tests_planned;
```

Returns the number of tests planned. For example, a plan of 1..17 will cause this method to return '17'.

directive

```
my $directive = $plan->directive;
```

If a SKIP directive is included with the plan, this method will return it.

```
1..0 # SKIP: why bother?
```

has_skip

```
if ( $result->has_skip ) { ... }
```

Returns a boolean value indicating whether or not this test has a SKIP directive.

explanation

```
my $explanation = $plan->explanation;
```

If a SKIP directive was included with the plan, this method will return the explanation, if any.

todo_list

```
my $todo = $result->todo_list;
for ( @$todo ) {
    ...
}
```

TAP::Parser::Result::Pragma

TAP pragma token.

VERSION

Version 3.52

DESCRIPTION

This is a subclass of *TAP::Parser::Result*. A token of this class will be returned if a pragma is encountered.

```
TAP version 13
pragma +strict, -foo
```

Pragmas are only supported from TAP version 13 onwards.

OVERRIDDEN METHODS

Mainly listed here to shut up the pitiful screams of the pod coverage tests. They keep me awake at night.

- `as_string`
- `raw`

Instance Methods

`pragmas`

if ($result->is_pragma) { @pragmas = $result->pragmas; }

TAP::Parser::Result::Test

Test result token.

VERSION

Version 3.52

DESCRIPTION

This is a subclass of *TAP::Parser::Result*. A token of this class will be returned if a test line is encountered.

```
1..1
ok 1 - woo hooo!
```

OVERRIDDEN METHODS

This class is the workhorse of the *TAP::Parser* system. Most TAP lines will be test lines and if `$result->is_test`, then you have a bunch of methods at your disposal.

Instance Methods

`ok`

```
my $ok = $result->ok;
```

Returns the literal text of the ok or `not ` ok status.

`number`

```
my $test_number = $result->number;
```

Returns the number of the test, even if the original TAP output did not supply that number.

description

```
my $description = $result->description;
```

Returns the description of the test, if any. This is the portion after the test number but before the directive.

directive

```
my $directive = $result->directive;
```

Returns either `TODO` or `SKIP` if either directive was present for a test line.

explanation

```
my $explanation = $result->explanation;
```

If a test had either a `TODO` or `SKIP` directive, this method will return the accompanying explanation, if present.

```
not ok 17 - 'Pigs can fly' # TODO not enough acid
```

For the above line, the explanation is *not enough acid*.

is_ok

```
if ( $result->is_ok ) { ... }
```

Returns a boolean value indicating whether or not the test passed. Remember that for TODO tests, the test always passes.

If the test is unplanned, this method will always return false. See `is_unplanned`.

is_actual_ok

```
if ( $result->is_actual_ok ) { ... }
```

Returns a boolean value indicating whether or not the test passed, regardless of its TODO status.

actual_passed

Deprecated. Please use `is_actual_ok` instead.

todo_passed

```
if ( $test->todo_passed ) {
   # test unexpectedly succeeded
}
```

If this is a TODO test and an 'ok' line, this method returns true. Otherwise, it will always return false (regardless of passing status on non-todo tests).

This is used to track which tests unexpectedly succeeded.

todo_failed

```
# deprecated in favor of 'todo_passed'.  This method was horribly␣
↪misnamed.
```

This was a badly misnamed method. It indicates which TODO tests unexpectedly succeeded. Will now issue a warning and call `todo_passed`.

has_skip

```
if ( $result->has_skip ) { ... }
```

Returns a boolean value indicating whether or not this test has a SKIP directive.

has_todo

```
if ( $result->has_todo ) { ... }
```

Returns a boolean value indicating whether or not this test has a TODO directive.

as_string

```
print $result->as_string;
```

This method prints the test as a string. It will probably be similar, but not necessarily identical, to the original test line. Directives are capitalized, some whitespace may be trimmed and a test number will be added if it was not present in the original line. If you need the original text of the test line, use the `raw` method.

is_unplanned

```
if ( $test->is_unplanned ) { ... }
$test->is_unplanned(1);
```

If a test number is greater than the number of planned tests, this method will return true. Unplanned tests will *always* return false for `is_ok`, regardless of whether or not the test `has_todo`.

Note that if tests have a trailing plan, it is not possible to set this property for unplanned tests as we do not know it's unplanned until the plan is reached:

```
print <<'END';
ok 1
ok 2
```

(continues on next page)

(continued from previous page)

```
1..1
END
```

TAP::Parser::Result::Unknown

Unknown result token.

VERSION

Version 3.52

DESCRIPTION

This is a subclass of *TAP::Parser::Result*. A token of this class will be returned if the parser does not recognize the token line. For example:

```
1..5
VERSION 7
ok 1 - woo hooo!
... woo hooo! is cool!
```

In the above "TAP", the second and fourth lines will generate "Unknown" tokens.

OVERRIDDEN METHODS

Mainly listed here to shut up the pitiful screams of the pod coverage tests. They keep me awake at night.

- `as_string`
- `raw`

TAP::Parser::Result::Version

TAP syntax version token.

VERSION

Version 3.52

DESCRIPTION

This is a subclass of *TAP::Parser::Result*. A token of this class will be returned if a version line is encountered.

```
TAP version 13
ok 1
not ok 2
```

The first version of TAP to include an explicit version number is 13.

OVERRIDDEN METHODS

Mainly listed here to shut up the pitiful screams of the pod coverage tests. They keep me awake at night.

- `as_string`
- `raw`

Instance Methods

version

```
if ( $result->is_version ) {
   print $result->version;
}
```

This is merely a synonym for `as_string`.

TAP::Parser::Result::YAML

YAML result token.

VERSION

Version 3.52

DESCRIPTION

This is a subclass of *TAP::Parser::Result*. A token of this class will be returned if a YAML block is encountered.

```
1..1
ok 1 - woo hooo!
```

`1..1` is the plan. Gotta have a plan.

OVERRIDDEN METHODS

Mainly listed here to shut up the pitiful screams of the pod coverage tests. They keep me awake at night.

- `as_string`
- `raw`

Instance Methods

data

```
if ( $result->is_yaml ) {
   print $result->data;
}
```

Return the parsed YAML data for this result

TAP::Parser::ResultFactory

Factory for creating TAP::Parser output objects

SYNOPSIS

```
use TAP::Parser::ResultFactory;
my $token   = {...};
my $factory = TAP::Parser::ResultFactory->new;
my $result  = $factory->make_result( $token );
```

VERSION

Version 3.52

DESCRIPTION

This is a simple factory class which returns a *TAP::Parser::Result* subclass representing the current bit of test data from TAP (usually a single line). It is used primarily by *TAP::Parser::Grammar*. Unless you're subclassing, you probably won't need to use this module directly.

METHODS

Class Methods

new

Creates a new factory class. *Note:* You currently don't need to instantiate a factory in order to use it.

make_result

Returns an instance the appropriate class for the test token passed in.

```
my $result = TAP::Parser::ResultFactory->make_result($token);
```

Can also be called as an instance method.

class_for

Takes one argument: `$type`. Returns the class for this $type, or `croaks` with an error.

register_type

Takes two arguments: `$type`, `$class`

This lets you override an existing type with your own custom type, or register a completely new type, eg:

```
# create a custom result type:
package MyResult;
use strict;
use base 'TAP::Parser::Result';

# register with the factory:
TAP::Parser::ResultFactory->register_type( 'my_type' => __PACKAGE__
 ↪);

# use it:
my $r = TAP::Parser::ResultFactory->( { type => 'my_type' } );
```

Your custom type should then be picked up automatically by the *TAP::Parser*.

SUBCLASSING

Please see *"SUBCLASSING" in TAP::Parser* for a subclassing overview.

There are a few things to bear in mind when creating your own `ResultFactory`:

1. The factory itself is never instantiated (this *may* change in the future). This means that `_initialize` is never called.
2. `TAP::Parser::Result->new` is never called, $tokens are reblessed. This *will* change in a future version!
3. *TAP::Parser::Result* subclasses will register themselves with *TAP::Parser::ResultFactory* directly:

   ```
   package MyFooResult;
   TAP::Parser::ResultFactory->register_type( foo => __PACKAGE__ );
   ```

   Of course, it's up to you to decide whether or not to ignore them.

Example

```
package MyResultFactory;

use strict;

use MyResult;
```

(continues on next page)

(continued from previous page)

```
use base 'TAP::Parser::ResultFactory';

# force all results to be 'MyResult'
sub class_for {
  return 'MyResult';
}

1;
```

TAP::Parser::Scheduler

Schedule tests during parallel testing

VERSION

Version 3.52

SYNOPSIS

```
use TAP::Parser::Scheduler;
```

DESCRIPTION

METHODS

Class Methods

new

```
my $sched = TAP::Parser::Scheduler->new(tests => \@tests);
my $sched = TAP::Parser::Scheduler->new(
    tests => [ ['t/test_name.t','Test Description'], ... ],
    rules => \%rules,
);
```

Given 'tests' and optional 'rules' as input, returns a new `TAP::Parser::Scheduler` object. Each member of `@tests` should be either a a test file name, or a two element arrayref, where the first element is a test file name, and the second element is a test description. By default, we'll use the test name as the description.

The optional `rules` attribute provides direction on which tests should be run in parallel and which should be run sequentially. If no rule data structure is provided, a default data structure is used which makes every test eligible to be run in parallel:

```
{ par => '**' },
```

The rules data structure is documented more in the next section.

Rules data structure

The "rules" data structure is the the heart of the scheduler. It allows you to express simple rules like "run all tests in sequence" or "run all tests in parallel except these five tests.". However, the rules structure also supports glob-style pattern matching and recursive definitions, so you can also express arbitrarily complicated patterns.

The rule must only have one top level key: either 'par' for "parallel" or 'seq' for "sequence".

Values must be either strings with possible glob-style matching, or arrayrefs of strings or hashrefs which follow this pattern recursively.

Every element in an arrayref directly below a 'par' key is eligible to be run in parallel, while values directly below a 'seq' key must be run in sequence.

Rules examples

Here are some examples:

```
# All tests be run in parallel (the default rule)
{ par => '**' },

# Run all tests in sequence, except those starting with "p"
{ par => 't/p*.t' },

# Run all tests in parallel, except those starting with "p"
{
    seq => [
              { seq => 't/p*.t' },
              { par => '**'     },
           ],
}

# Run some  startup tests in sequence, then some parallel tests then
 ↪some
# teardown tests in sequence.
{
    seq => [
        { seq => 't/startup/*.t' },
        { par => ['t/a/*.t','t/b/*.t','t/c/*.t'], }
        { seq => 't/shutdown/*.t' },
    ],
},
```

Rules resolution

- By default, all tests are eligible to be run in parallel. Specifying any of your own rules removes this one.
- "First match wins". The first rule that matches a test will be the one that applies.
- Any test which does not match a rule will be run in sequence at the end of the run.
- The existence of a rule does not imply selecting a test. You must still specify the tests to run.
- Specifying a rule to allow tests to run in parallel does not make the run in parallel. You still need specify the number of parallel `jobs` in your Harness object.

Glob-style pattern matching for rules

We implement our own glob-style pattern matching. Here are the patterns it supports:

```
** is any number of characters, including /, within a pathname
* is zero or more characters within a filename/directory name
? is exactly one character within a filename/directory name
{foo,bar,baz} is any of foo, bar or baz.
\ is an escape character
```

Instance Methods

get_all

Get a list of all remaining tests.

get_job

Return the next available job as *TAP::Parser::Scheduler::Job* object or `undef` if none are available. Returns a *TAP::Parser::Scheduler::Spinner* if the scheduler still has pending jobs but none are available to run right now.

as_string

Return a human readable representation of the scheduling tree. For example:

```
my @tests = (qw{
    t/startup/foo.t
    t/shutdown/foo.t

    t/a/foo.t t/b/foo.t t/c/foo.t t/d/foo.t
});
my $sched = TAP::Parser::Scheduler->new(
    tests => \@tests,
    rules => {
        seq => [
            { seq => 't/startup/*.t' },
```

(continues on next page)

(continued from previous page)

```
            { par => ['t/a/*.t','t/b/*.t','t/c/*.t'] },
            { seq => 't/shutdown/*.t' },
        ],
    },
);
```

Produces:

```
par:
  seq:
    par:
      seq:
        par:
          seq:
            't/startup/foo.t'
        par:
          seq:
            't/a/foo.t'
          seq:
            't/b/foo.t'
          seq:
            't/c/foo.t'
        par:
          seq:
            't/shutdown/foo.t'
    't/d/foo.t'
```

Modules

- `TAP::Parser::Scheduler::Job` - A single testing job.
- `TAP::Parser::Scheduler::Spinner` - A no-op job.

TAP::Parser::Scheduler::Job

A single testing job.

VERSION

Version 3.52

SYNOPSIS

```
use TAP::Parser::Scheduler::Job;
```

DESCRIPTION

Represents a single test 'job'.

METHODS

Class Methods

new

```
my $job = TAP::Parser::Scheduler::Job->new(
    $filename, $description
);
```

Given the filename and description of a test as scalars, returns a new *TAP::Parser::Scheduler::Job* object.

Instance Methods

on_finish

```
$self->on_finish(\&method).
```

Register a closure to be called when this job is destroyed. The callback will be passed the `TAP::Parser::Scheduler::Job` object as it's only argument.

finish

```
$self->finish;
```

Called when a job is complete to unlock it. If a callback has been registered with `on_finish`, it calls it. Otherwise, it does nothing.

Attributes

```
$self->filename;
$self->description;
$self->context;
```

These are all "getters" which return the data set for these attributes during object construction.

filename

description

context

as_array_ref

For backwards compatibility in callbacks.

is_spinner

```
$self->is_spinner;
```

Returns false indicating that this is a real job rather than a 'spinner'. Spinners are returned when the scheduler still has pending jobs but can't (because of locking) return one right now.

TAP::Parser::Scheduler::Spinner

A no-op job.

VERSION

Version 3.52

SYNOPSIS

```
use TAP::Parser::Scheduler::Spinner;
```

DESCRIPTION

A no-op job. Returned by `TAP::Parser::Scheduler` as an instruction to the harness to spin (keep executing tests) while the scheduler can't return a real job.

METHODS

Class Methods

new

```
my $job = TAP::Parser::Scheduler::Spinner->new;
```

Ignores any arguments and returns a new `TAP::Parser::Scheduler::Spinner` object.

Instance Methods

is_spinner

Returns true indicating that is a 'spinner' job. Spinners are returned when the scheduler still has pending jobs but can't (because of locking) return one right now.

SEE ALSO

TAP::Parser::Scheduler, *TAP::Parser::Scheduler::Job*

TAP::Parser::Source

a TAP source & meta data about it

VERSION

Version 3.52

SYNOPSIS

```
use TAP::Parser::Source;
my $source = TAP::Parser::Source->new;
$source->raw( \'reference to raw TAP source' )
       ->config( \%config )
       ->merge( $boolean )
       ->switches( \@switches )
       ->test_args( \@args )
       ->assemble_meta;

do { ... } if $source->meta->{is_file};
# see assemble_meta for a full list of data available
```

DESCRIPTION

A TAP *source* is something that produces a stream of TAP for the parser to consume, such as an executable file, a text file, an archive, an IO handle, a database, etc. `TAP::Parser::Sources` encapsulate these *raw* sources, and provide some useful meta data about them. They are used by *TAP::Parser::SourceHandler*s, which do whatever is required to produce & capture a stream of TAP from the *raw* source, and package it up in a *TAP::Parser::Iterator* for the parser to consume.

Unless you're writing a new *TAP::Parser::SourceHandler*, a plugin or subclassing *TAP::Parser*, you probably won't need to use this module directly.

METHODS

Class Methods

new

```
my $source = TAP::Parser::Source->new;
```

Returns a new `TAP::Parser::Source` object.

Instance Methods

raw

```
my $raw = $source->raw;
$source->raw( $some_value );
```

Chaining getter/setter for the raw TAP source. This is a reference, as it may contain large amounts of data (eg: raw TAP).

meta

```
my $meta = $source->meta;
$source->meta({ %some_value });
```

Chaining getter/setter for meta data about the source. This defaults to an empty hashref. See “assemble_meta” for more info.

has_meta

True if the source has meta data.

config

```
my $config = $source->config;
$source->config({ %some_value });
```

Chaining getter/setter for the source’s configuration, if any has been provided by the user. How it’s used is up to you. This defaults to an empty hashref. See “config_for” for more info.

merge

```
my $merge = $source->merge;
$source->config( $bool );
```

Chaining getter/setter for the flag that dictates whether STDOUT and STDERR should be merged (where appropriate). Defaults to undef.

switches

```
my $switches = $source->switches;
$source->config([ @switches ]);
```

Chaining getter/setter for the list of command-line switches that should be passed to the source (where appropriate). Defaults to undef.

test_args

```
my $test_args = $source->test_args;
$source->config([ @test_args ]);
```

Chaining getter/setter for the list of command-line arguments that should be passed to the source (where appropriate). Defaults to undef.

assemble_meta

```
my $meta = $source->assemble_meta;
```

Gathers meta data about the “raw” source, stashes it in “meta” and returns it as a hashref. This is done so that the *TAP::Parser::SourceHandler*s don’t have to repeat common checks. Currently this includes:

```
  is_scalar => $bool,
  is_hash   => $bool,
  is_array  => $bool,

  # for scalars:
  length => $n
  has_newlines => $bool

  # only done if the scalar looks like a filename
  is_file => $bool,
  is_dir  => $bool,
  is_symlink => $bool,
  file => {
      # only done if the scalar looks like a filename
      basename => $string, # including ext
      dir      => $string,
      ext      => $string,
      lc_ext   => $string,
      # system checks
      exists  => $bool,
      stat    => [ ... ], # perldoc -f stat
      empty   => $bool,
      size    => $n,
      text    => $bool,
      binary  => $bool,
      read    => $bool,
      write   => $bool,
      execute => $bool,
      setuid  => $bool,
      setgid  => $bool,
      sticky  => $bool,
      is_file => $bool,
      is_dir  => $bool,
      is_symlink => $bool,
      # only done if the file's a symlink
      lstat      => [ ... ], # perldoc -f lstat
      # only done if the file's a readable text file
      shebang => $first_line,
  }

# for arrays:
size => $n,
```

shebang

Get the shebang line for a script file.

```
my $shebang = TAP::Parser::Source->shebang( $some_script );
```

May be called as a class method

config_for

```
my $config = $source->config_for( $class );
```

Returns "config" for the $class given. Class names may be fully qualified or abbreviated, eg:

```
# these are equivalent
$source->config_for( 'Perl' );
$source->config_for( 'TAP::Parser::SourceHandler::Perl' );
```

If a fully qualified $class is given, its abbreviated version is checked first.

TAP::Parser::SourceHandler

Base class for different TAP source handlers

VERSION

Version 3.52

SYNOPSIS

```
# abstract class - don't use directly!
# see TAP::Parser::IteratorFactory for general usage

# must be sub-classed for use
package MySourceHandler;
use base 'TAP::Parser::SourceHandler';
sub can_handle    { return $confidence_level }
sub make_iterator { return $iterator }

# see example below for more details
```

DESCRIPTION

This is an abstract base class for *TAP::Parser::Source* handlers / handlers.

A `TAP::Parser::SourceHandler` does whatever is necessary to produce & capture a stream of TAP from the *raw* source, and package it up in a *TAP::Parser::Iterator* for the parser to consume.

`SourceHandlers` must implement the *source detection & handling* interface used by *TAP::Parser::IteratorFactory*. At 2 methods, the interface is pretty simple: "can_handle" and "make_source".

Unless you're writing a new *TAP::Parser::SourceHandler*, a plugin, or subclassing *TAP::Parser*, you probably won't need to use this module directly.

METHODS

Class Methods

`can_handle`

Abstract method.

```
my $vote = $class->can_handle( $source );
```

`$source` is a *TAP::Parser::Source*.

Returns a number between `0` & `1` reflecting how confidently the raw source can be handled. For example, `0` means the source cannot handle it, `0.5` means it may be able to, and `1` means it definitely can. See *"detect_source" in TAP::Parser::IteratorFactory* for details on how this is used.

`make_iterator`

Abstract method.

```
my $iterator = $class->make_iterator( $source );
```

`$source` is a *TAP::Parser::Source*.

Returns a new *TAP::Parser::Iterator* object for use by the *TAP::Parser*. `croaks` on error.

SUBCLASSING

Please see *"SUBCLASSING" in TAP::Parser* for a subclassing overview, and any of the subclasses that ship with this module as an example. What follows is a quick overview.

Start by familiarizing yourself with *TAP::Parser::Source* and *TAP::Parser::IteratorFactory*. *TAP::Parser::SourceHandler::RawTAP* is the easiest sub-class to use as an example.

It's important to point out that if you want your subclass to be automatically used by *TAP::Parser* you'll have to and make sure it gets loaded somehow. If you're using prove you can write an *App::Prove* plugin. If you're using *TAP::Parser* or *TAP::Harness* directly (e.g. through a custom script, *ExtUtils::MakeMaker*, or Module::Build) you can use the

`config` option which will cause *"load_sources" in TAP::Parser::IteratorFactory* to load your subclass).

Don't forget to register your class with *"register_handler" in TAP::Parser::IteratorFactory*.

Example

```
package MySourceHandler;

use strict;

use MySourceHandler; # see TAP::Parser::SourceHandler
use TAP::Parser::IteratorFactory;

use base 'TAP::Parser::SourceHandler';

TAP::Parser::IteratorFactory->register_handler( __PACKAGE__ );

sub can_handle {
    my ( $class, $src ) = @_;
    my $meta   = $src->meta;
    my $config = $src->config_for( $class );

    if ($config->{accept_all}) {
        return 1.0;
    } elsif (my $file = $meta->{file}) {
        return 0.0 unless $file->{exists};
        return 1.0 if $file->{lc_ext} eq '.tap';
        return 0.9 if $file->{shebang} && $file->{shebang} =~ /^#!.
↪+tap/;
        return 0.5 if $file->{text};
        return 0.1 if $file->{binary};
    } elsif ($meta->{scalar}) {
        return 0.8 if $$raw_source_ref =~ /\d\.\.\d/;
        return 0.6 if $meta->{has_newlines};
    } elsif ($meta->{array}) {
        return 0.8 if $meta->{size} < 5;
        return 0.6 if $raw_source_ref->[0] =~ /foo/;
        return 0.5;
    } elsif ($meta->{hash}) {
        return 0.6 if $raw_source_ref->{foo};
        return 0.2;
    }

    return 0;
}

sub make_iterator {
    my ($class, $source) = @_;
    # this is where you manipulate the source and
    # capture the stream of TAP in an iterator
```

(continues on next page)

(continued from previous page)

```
    # either pick a TAP::Parser::Iterator::* or write your own...
    my $iterator = TAP::Parser::Iterator::Array->new([ 'foo', 'bar'␣
↪]);
    return $iterator;
}

1;
```

Modules

- `TAP::Parser::SourceHandler::Executable` - Stream output from an executable TAP source
- `TAP::Parser::SourceHandler::File` - Stream TAP from a text file.
- `TAP::Parser::SourceHandler::Handle` - Stream TAP from an IO::Handle or a GLOB.
- `TAP::Parser::SourceHandler::Perl` - Stream TAP from a Perl executable
- `TAP::Parser::SourceHandler::RawTAP` - Stream output from raw TAP in a scalar/array ref.

TAP::Parser::SourceHandler::Executable

Stream output from an executable TAP source

VERSION

Version 3.52

SYNOPSIS

```
use TAP::Parser::Source;
use TAP::Parser::SourceHandler::Executable;

my $source = TAP::Parser::Source->new->raw(['/usr/bin/ruby',
```

(continues on next page)

(continued from previous page)

```
 ↪'mytest.rb']);
$source->assemble_meta;

my $class = 'TAP::Parser::SourceHandler::Executable';
my $vote  = $class->can_handle( $source );
my $iter  = $class->make_iterator( $source );
```

DESCRIPTION

This is an *executable* *TAP::Parser::SourceHandler* - it has 2 jobs:

1. Figure out if the *TAP::Parser::Source* it's given is an executable command ("can_handle").

2. Creates an iterator for executable commands ("make_iterator").

Unless you're writing a plugin or subclassing *TAP::Parser*, you probably won't need to use this module directly.

METHODS

Class Methods

`can_handle`

```
my $vote = $class->can_handle( $source );
```

Only votes if $source looks like an executable file. Casts the following votes:

```
0.9  if it's a hash with an 'exec' key
0.8  if it's a .bat file
0.75 if it's got an execute bit set
```

`make_iterator`

```
my $iterator = $class->make_iterator( $source );
```

Returns a new *TAP::Parser::Iterator::Process* for the source. `$source->raw` must be in one of the following forms:

```
{ exec => [ @exec ] }

[ @exec ]

$file
```

`croaks` on error.

iterator_class

The class of iterator to use, override if you're sub-classing. Defaults to *TAP::Parser::Iterator::Process*.

SUBCLASSING

Please see *"SUBCLASSING" in TAP::Parser* for a subclassing overview.

Example

```
package MyRubySourceHandler;

use strict;

use Carp qw( croak );
use TAP::Parser::SourceHandler::Executable;

use base 'TAP::Parser::SourceHandler::Executable';

# expect $handler->(['mytest.rb', 'cmdline', 'args']);
sub make_iterator {
  my ($self, $source) = @_;
  my @test_args = @{ $source->test_args };
  my $rb_file   = $test_args[0];
  croak("error: Ruby file '$rb_file' not found!") unless (-f $rb_
↪file);
  return $self->SUPER::raw_source(['/usr/bin/ruby', @test_args]);
}
```

TAP::Parser::SourceHandler::File

Stream TAP from a text file.

VERSION

Version 3.52

SYNOPSIS

```
use TAP::Parser::Source;
use TAP::Parser::SourceHandler::File;
```

(continues on next page)

(continued from previous page)

```
my $source = TAP::Parser::Source->new->raw( \'file.tap' );
$source->assemble_meta;

my $class = 'TAP::Parser::SourceHandler::File';
my $vote  = $class->can_handle( $source );
my $iter  = $class->make_iterator( $source );
```

DESCRIPTION

This is a *raw TAP stored in a file* *TAP::Parser::SourceHandler* - it has 2 jobs:

1. Figure out if the *raw* source it's given is a file containing raw TAP output. See *TAP::Parser::IteratorFactory* for more details.

2. Takes raw TAP from the text file given, and converts into an iterator.

Unless you're writing a plugin or subclassing *TAP::Parser*, you probably won't need to use this module directly.

METHODS

Class Methods

can_handle

```
my $vote = $class->can_handle( $source );
```

Only votes if $source looks like a regular file. Casts the following votes:

```
0.9 if it's a .tap file
0.9 if it has an extension matching any given in user config.
```

make_iterator

```
my $iterator = $class->make_iterator( $source );
```

Returns a new *TAP::Parser::Iterator::Stream* for the source. `croaks` on error.

iterator_class

The class of iterator to use, override if you're sub-classing. Defaults to *TAP::Parser::Iterator::Stream*.

CONFIGURATION

```
{
 extensions => [ @case_insensitive_exts_to_match ]
}
```

SUBCLASSING

Please see *"SUBCLASSING" in TAP::Parser* for a subclassing overview.

SEE ALSO

TAP::Parser::SourceHandler::Handle

Stream TAP from an IO::Handle or a GLOB.

VERSION

Version 3.52

SYNOPSIS

```
use TAP::Parser::Source;
use TAP::Parser::SourceHandler::Executable;

my $source = TAP::Parser::Source->new->raw( \*TAP_FILE );
$source->assemble_meta;

my $class = 'TAP::Parser::SourceHandler::Handle';
my $vote  = $class->can_handle( $source );
my $iter  = $class->make_iterator( $source );
```

DESCRIPTION

This is a *raw TAP stored in an IO Handle* *TAP::Parser::SourceHandler* class. It has 2 jobs:

1. Figure out if the *TAP::Parser::Source* it's given is an *IO::Handle* or GLOB containing raw TAP output ("can_handle").

2. Creates an iterator for IO::Handle's & globs ("make_iterator").

Unless you're writing a plugin or subclassing *TAP::Parser*, you probably won't need to use this module directly.

METHODS

Class Methods

can_handle

```
my $vote = $class->can_handle( $source );
```

Casts the following votes:

```
0.9 if $source is an IO::Handle
0.8 if $source is a glob
```

make_iterator

```
my $iterator = $class->make_iterator( $source );
```

Returns a new *TAP::Parser::Iterator::Stream* for the source.

iterator_class

The class of iterator to use, override if you're sub-classing. Defaults to *TAP::Parser::Iterator::Stream*.

SUBCLASSING

Please see *"SUBCLASSING" in TAP::Parser* for a subclassing overview.

SEE ALSO

TAP::Object, *TAP::Parser*, *TAP::Parser::Iterator*, *TAP::Parser::Iterator::Stream*, *TAP::Parser::IteratorFactory*, *TAP::Parser::SourceHandler*, *TAP::Parser::SourceHandler::Executable*, *TAP::Parser::SourceHandler::Perl*, *TAP::Parser::SourceHandler::File*, *TAP::Parser::SourceHandler::RawTAP*

TAP::Parser::SourceHandler::Perl

Stream TAP from a Perl executable

VERSION

Version 3.52

SYNOPSIS

```
use TAP::Parser::Source;
use TAP::Parser::SourceHandler::Perl;

my $source = TAP::Parser::Source->new->raw( \'script.pl' );
$source->assemble_meta;

my $class = 'TAP::Parser::SourceHandler::Perl';
my $vote  = $class->can_handle( $source );
my $iter  = $class->make_iterator( $source );
```

DESCRIPTION

This is a *Perl* *TAP::Parser::SourceHandler* - it has 2 jobs:

1. Figure out if the *TAP::Parser::Source* it's given is actually a Perl script ("can_handle").

2. Creates an iterator for Perl sources ("make_iterator").

Unless you're writing a plugin or subclassing *TAP::Parser*, you probably won't need to use this module directly.

METHODS

Class Methods

can_handle

```
my $vote = $class->can_handle( $source );
```

Only votes if $source looks like a file. Casts the following votes:

```
0.9  if it has a shebang ala "#!...perl"
0.3  if it has any shebang
0.8  if it's a .t file
0.9  if it's a .pl file
0.75 if it's in a 't' directory
0.25 by default (backwards compat)
```

make_iterator

```
my $iterator = $class->make_iterator( $source );
```

Constructs & returns a new *TAP::Parser::Iterator::Process* for the source. Assumes `$source->raw` contains a reference to the perl script. `croaks` if the file could not be found.

The command to run is built as follows:

```
$perl @switches $perl_script @test_args
```

The perl command to use is determined by "get_perl". The command generated is guaranteed to preserve:

```
PERL5LIB
PERL5OPT
Taint Mode, if set in the script's shebang
```

Note: the command generated will *not* respect any shebang line defined in your Perl script. This is only a problem if you have compiled a custom version of Perl or if you want to use a specific version of Perl for one test and a different version for another, for example:

```
#!/path/to/a/custom_perl --some --args
#!/usr/local/perl-5.6/bin/perl -w
```

Currently you need to write a plugin to get around this.

get_taint

Decode any taint switches from a Perl shebang line.

```
# $taint will be 't'
my $taint = TAP::Parser::SourceHandler::Perl->get_taint( '#!/usr/
 ↪bin/perl -t' );

# $untaint will be undefined
my $untaint = TAP::Parser::SourceHandler::Perl->get_taint( '#!/usr/
 ↪bin/perl' );
```

get_perl

Gets the version of Perl currently running the test suite.

SUBCLASSING

Please see *"SUBCLASSING" in TAP::Parser* for a subclassing overview.

Example

```
package MyPerlSourceHandler;

use strict;

use TAP::Parser::SourceHandler::Perl;

use base 'TAP::Parser::SourceHandler::Perl';

# use the version of perl from the shebang line in the test file
sub get_perl {
    my $self = shift;
    if (my $shebang = $self->shebang( $self->{file} )) {
        $shebang =~ /^#!(.*\bperl.*?)(?:(?:\s)|(?:$))/;
        return $1 if $1;
    }
    return $self->SUPER::get_perl(@_);
}
```

SEE ALSO

TAP::Object, *TAP::Parser*, *TAP::Parser::IteratorFactory*, *TAP::Parser::SourceHandler*, *TAP::Parser::SourceHandler::Executable*, *TAP::Parser::SourceHandler::File*, *TAP::Parser::SourceHandler::Handle*, *TAP::Parser::SourceHandler::RawTAP*

TAP::Parser::SourceHandler::RawTAP

Stream output from raw TAP in a scalar/array ref.

VERSION

Version 3.52

SYNOPSIS

```
use TAP::Parser::Source;
use TAP::Parser::SourceHandler::RawTAP;

my $source = TAP::Parser::Source->new->raw( \"1..1\nok 1\n" );
$source->assemble_meta;

my $class = 'TAP::Parser::SourceHandler::RawTAP';
my $vote  = $class->can_handle( $source );
my $iter  = $class->make_iterator( $source );
```

DESCRIPTION

This is a *raw TAP output* *TAP::Parser::SourceHandler* - it has 2 jobs:

1. Figure out if the *TAP::Parser::Source* it's given is raw TAP output ("can_handle").

2. Creates an iterator for raw TAP output ("make_iterator").

Unless you're writing a plugin or subclassing *TAP::Parser*, you probably won't need to use this module directly.

METHODS

Class Methods

can_handle

```
my $vote = $class->can_handle( $source );
```

Only votes if $source is an array, or a scalar with newlines. Casts the following votes:

```
0.9  if it's a scalar with '..' in it
0.7  if it's a scalar with 'ok' in it
0.3  if it's just a scalar with newlines
0.5  if it's an array
```

make_iterator

```
my $iterator = $class->make_iterator( $source );
```

Returns a new *TAP::Parser::Iterator::Array* for the source. `$source->raw` must be an array ref, or a scalar ref.

`croaks` on error.

SUBCLASSING

Please see *"SUBCLASSING" in TAP::Parser* for a subclassing overview.

SEE ALSO

TAP::Object, *TAP::Parser*, *TAP::Parser::IteratorFactory*, *TAP::Parser::SourceHandler*, *TAP::Parser::SourceHandler::Executable*, *TAP::Parser::SourceHandler::Perl*, *TAP::Parser::SourceHandler::File*, *TAP::Parser::SourceHandler::Handle*

TAP::Parser::YAMLish

Namespace containing the following modules:

- `TAP::Parser::YAMLish::Reader` - Read YAMLish data from iterator
- `TAP::Parser::YAMLish::Writer` - Write YAMLish data

TAP::Parser::YAMLish::Reader

Read YAMLish data from iterator

VERSION

Version 3.52

SYNOPSIS

DESCRIPTION

Note that parts of this code were derived from YAML::Tiny with the permission of Adam Kennedy.

METHODS

Class Methods

new

The constructor `new` creates and returns an empty `TAP::Parser::YAMLish::Reader` object.

```
my $reader = TAP::Parser::YAMLish::Reader->new;
```

Instance Methods

read

```
my $got = $reader->read($iterator);
```

Read YAMLish from a *TAP::Parser::Iterator* and return the data structure it represents.

get_raw

```
my $source = $reader->get_source;
```

Return the raw YAMLish source from the most recent `read`.

AUTHOR

Andy Armstrong, andy@hexten.net

Adam Kennedy wrote YAML::Tiny which provided the template and many of the YAML matching regular expressions for this module.

TAP::Parser::YAMLish::Writer

Write YAMLish data

VERSION

Version 3.52

SYNOPSIS

```
use TAP::Parser::YAMLish::Writer;

my $data = {
    one => 1,
    two => 2,
    three => [ 1, 2, 3 ],
};

my $yw = TAP::Parser::YAMLish::Writer->new;

# Write to an array...
$yw->write( $data, \@some_array );

# ...an open file handle...
$yw->write( $data, $some_file_handle );

# ...a string ...
$yw->write( $data, \$some_string );

# ...or a closure
$yw->write( $data, sub {
    my $line = shift;
    print "$line\n";
} );
```

DESCRIPTION

Encodes a scalar, hash reference or array reference as YAMLish.

METHODS

Class Methods

new

```
my $writer = TAP::Parser::YAMLish::Writer->new;
```

The constructor new creates and returns an empty `TAP::Parser::YAMLish::Writer` object.

Instance Methods

write

```
$writer->write($obj, $output );
```

Encode a scalar, hash reference or array reference as YAML.

```
my $writer = sub {
    my $line = shift;
    print SOMEFILE "$line\n";
};

my $data = {
    one => 1,
    two => 2,
    three => [ 1, 2, 3 ],
};

my $yw = TAP::Parser::YAMLish::Writer->new;
$yw->write( $data, $writer );
```

The `$output` argument may be:

- a reference to a scalar to append YAML to
- the handle of an open file
- a reference to an array into which YAML will be pushed
- a code reference

If you supply a code reference the subroutine will be called once for each line of output with the line as its only argument. Passed lines will have no trailing newline.

5.2.99 Template

Namespace containing the following modules:

- `Template::Stash`

Template::Stash

Namespace containing the following modules:

- `Template::Stash::XS` - The compiled stash of the Template Toolkit: `get` and `set`, which resolve a template variable such as `user.name` or `list.0.size` against the stash's data.

Template::Stash::XS

The compiled stash of the Template Toolkit: `get` and `set`, which resolve a template variable such as `user.name` or `list.0.size` against the stash's data.

A dotted variable is walked one element at a time: a hash key, a list index, an object method, a code reference called with its arguments, or a virtual method. `size`, `max`, `reverse` and `join` on a list, `keys`, `values` and `each` on a hash, and `length` and `defined` on a scalar are compiled; every other virtual method comes from `Template::Stash`'s `%LIST_OPS`, `%HASH_OPS` and `%SCALAR_OPS`.

This is a native implementation of the `Stash.xs` of Template Toolkit 3.106; its `Template/Stash/XS.pm` is used unchanged, and the Template Toolkit itself comes from CPAN. It is the stash the Template Toolkit uses by default.

Synopsis

```
use Template;
use Template::Stash::XS;

my $stash = Template::Stash::XS->new({ user => { name => 'Ann' } });
print $stash->get('user.name'), "\n";          # Ann
$stash->set('user.mail', 'ann@example.org');

my $tt = Template->new({ STASH => $stash });
```

Differences from upstream

- An object method that dies "Can't locate object method" no longer removes a value from the caller's argument list: after the third such method in one dotted variable, perl overwrites the caller's arguments, so `f('A', 'B', 'C', 'D', $stash->get('x.k.k.k.v'))` passes the error text in place of `'D'`.
- `set` called with a root that is not a reference dies "don't know how to assign to [ ].key"; perl reads the root as if it were a reference and crashes for undef, a number or a long string.

Functions

Template Toolkit

get

The value of a template variable: `$ident` is a name, a dotted name such as `'user.name'` (arguments in parentheses are dropped), or a list `[ name => \@args, name =>`

`\@args, ... ]`; `\@args` as a third argument is passed to a plain name that is a code ref or method.

set

Assign `$value` to a template variable named as for `get`, creating the hashes on the way; with a true fourth argument, only when the variable is not already true. Returns the value assigned, or an empty string when nothing was.

get

The value of a template variable: `$ident` is a name, a dotted name such as `'user.name'` (arguments in parentheses are dropped), or a list `[ name => \@args, name => \@args, ... ]`; `\@args` as a third argument is passed to a plain name that is a code ref or method.

Synopsis

```
$stash->get('title');
$stash->get('user.name');
$stash->get([ 'user', 0, 'greet', [ 'Hello' ] ]);
```

Edge cases

- A variable that is not defined is passed to `$stash->undefined`, whose value is returned (Template::Stash's returns an empty string, or dies under `STRICT`).
- A reference other than a list ref as `$ident` dies "Template::Stash::XS: get (arg 2) must be a scalar or listref".
- A true `_DEBUG` in the stash makes a missing variable die "NAME is undefined".

set

Assign `$value` to a template variable named as for `get`, creating the hashes on the way; with a true fourth argument, only when the variable is not already true. Returns the value assigned, or an empty string when nothing was.

Synopsis

```
$stash->set('title', 'Home');
$stash->set('user.mail', 'ann@example.org');   # creates user if␣
↪needed
$stash->set('title', 'Default', 1);            # only if not already␣
↪true
```

Edge cases

- A reference other than a list ref as `$ident` dies "Template::Stash::XS: set (arg 2) must be a scalar or listref".
- Names starting with `_` or `.` are private and are not assigned while `$Template::Stash::PRIVATE` is true.
- The last element on an object calls its method with `$value` as the last argument.

5.2.100 Term

Namespace containing the following modules:

- `Term::ANSIColor` - Color screen output using ANSI escape sequences
- `Term::Cap` - Perl termcap interface
- `Term::Complete` - Perl word completion module
- `Term::ReadKey` - Terminal modes (cooked, no-echo, cbreak, raw), reads that time out or do not block, and the terminal's size, speed and control characters.
- `Term::ReadLine` - Perl interface to various `readline` packages.
- `Term::Table` - Format a header and rows into a table

Term::ANSIColor

Color screen output using ANSI escape sequences

SYNOPSIS

```
use Term::ANSIColor;
print color('bold blue');
print "This text is bold blue.\n";
print color('reset');
print "This text is normal.\n";
print colored("Yellow on magenta.", 'yellow on_magenta'), "\n";
print "This text is normal.\n";
print colored(['yellow on_magenta'], 'Yellow on magenta.', "\n");
print colored(['red on_bright_yellow'], 'Red on bright yellow.', "\n
 ↪");
print colored(['bright_red on_black'], 'Bright red on black.', "\n
 ↪");
print "\n";

# Map escape sequences back to color names.
use Term::ANSIColor 1.04 qw(uncolor);
my @names = uncolor('01;31');
print join(q{ }, @names), "\n";

# Strip all color escape sequences.
use Term::ANSIColor 2.01 qw(colorstrip);
```

(continues on next page)

(continued from previous page)

```
print colorstrip("\e1mThis is bold\e[0m"), "\n";

# Determine whether a color is valid.
use Term::ANSIColor 2.02 qw(colorvalid);
my $valid = colorvalid('blue bold', 'on_magenta');
print "Color string is ", $valid ? "valid\n" : "invalid\n";

# Create new aliases for colors.
use Term::ANSIColor 4.00 qw(coloralias);
coloralias('alert', 'red');
print "Alert is ", coloralias('alert'), "\n";
print colored("This is in red.", 'alert'), "\n";

use Term::ANSIColor qw(:constants);
print BOLD, BLUE, "This text is in bold blue.\n", RESET;

use Term::ANSIColor qw(:constants);
{
    local $Term::ANSIColor::AUTORESET = 1;
    print BOLD BLUE "This text is in bold blue.\n";
    print "This text is normal.\n";
}

use Term::ANSIColor 2.00 qw(:pushpop);
print PUSHCOLOR RED ON_GREEN "This text is red on green.\n";
print PUSHCOLOR BRIGHT_BLUE "This text is bright blue on green.\n";
print RESET BRIGHT_BLUE "This text is just bright blue.\n";
print POPCOLOR "Back to red on green.\n";
print LOCALCOLOR GREEN ON_BLUE "This text is green on blue.\n";
print "This text is red on green.\n";
{
    local $Term::ANSIColor::AUTOLOCAL = 1;
    print ON_BLUE "This text is red on blue.\n";
    print "This text is red on green.\n";
}
print POPCOLOR "Back to whatever we started as.\n";
```

DESCRIPTION

This module has two interfaces, one through color() and colored() and the other through constants. It also offers the utility functions uncolor(), colorstrip(), colorvalid(), and coloralias(), which have to be explicitly imported to be used (see [“SYNOPSIS”).

If you are using Term::ANSIColor in a console command, consider supporting the CLICOLOR standard. See “Supporting CLICOLOR” for more information.

See “COMPATIBILITY” for the versions of Term::ANSIColor that introduced particular features and the versions of Perl that included them.

Supported Colors

Terminal emulators that support color divide into four types: ones that support only eight colors, ones that support sixteen, ones that support 256, and ones that support 24-bit color. This module provides the ANSI escape codes for all of them. These colors are referred to as ANSI colors 0 through 7 (normal), 8 through 15 (16-color), 16 through 255 (256-color), and true color (called direct-color by **xterm**).

Unfortunately, interpretation of colors 0 through 7 often depends on whether the emulator supports eight colors or sixteen colors. Emulators that only support eight colors (such as the Linux console) will display colors 0 through 7 with normal brightness and ignore colors 8 through 15, treating them the same as white. Emulators that support 16 colors, such as gnome-terminal, normally display colors 0 through 7 as dim or darker versions and colors 8 through 15 as normal brightness. On such emulators, the "normal" white (color 7) usually is shown as pale grey, requiring bright white (15) to be used to get a real white color. Bright black usually is a dark grey color, although some terminals display it as pure black. Some sixteen-color terminal emulators also treat normal yellow (color 3) as orange or brown, and bright yellow (color 11) as yellow.

Following the normal convention of sixteen-color emulators, this module provides a pair of attributes for each color. For every normal color (0 through 7), the corresponding bright color (8 through 15) is obtained by prepending the string `bright_` to the normal color name. For example, `red` is color 1 and `bright_red` is color 9. The same applies for background colors: `on_red` is the normal color and `on_bright_red` is the bright color. Capitalize these strings for the constant interface.

There is unfortunately no way to know whether the current emulator supports more than eight colors, which makes the choice of colors difficult. The most conservative choice is to use only the regular colors, which are at least displayed on all emulators. However, they will appear dark in sixteen-color terminal emulators, including most common emulators in UNIX X environments. If you know the display is one of those emulators, you may wish to use the bright variants instead. Even better, offer the user a way to configure the colors for a given application to fit their terminal emulator.

For 256-color emulators, this module additionally provides `ansi0` through `ansi15`, which are the same as colors 0 through 15 in sixteen-color emulators but use the 256-color escape syntax, `grey0` through `grey23` ranging from nearly black to nearly white, and a set of RGB colors. The RGB colors are of the form `rgb_RGB_` where *R*, *G*, and *B* are numbers from 0 to 5 giving the intensity of red, green, and blue. The grey and RGB colors are also available as `ansi16` through `ansi255` if you want simple names for all 256 colors. `on_` variants of all of these colors are also provided. These colors may be ignored completely on non-256-color terminals or may be misinterpreted and produce random behavior. Additional attributes such as blink, italic, or bold may not work with the 256-color palette.

For true color emulators, this module supports attributes of the form `r_NNN_g_NNN_b_NNN_` and `on_r_NNN_g_NNN_b_NNN_` for all values of *NNN* between 0 and 255. These represent foreground and background colors, respectively, with the RGB values given by the *NNN* numbers. These colors may be ignored completely on non-true-color terminals or may be misinterpreted and produce random behavior.

Function Interface

The function interface uses attribute strings to describe the colors and text attributes to assign to text. The recognized non-color attributes are clear, reset, bold, dark, faint, italic, underline, underscore, blink, reverse, and concealed. Clear and reset (reset to default attributes), dark and faint (dim and saturated), and underline and underscore are equivalent, so use whichever is the most intuitive to you.

Note that not all attributes are supported by all terminal types, and some terminals may not support any of these sequences. Dark and faint, italic, blink, and concealed in particular are frequently not implemented.

The recognized normal foreground color attributes (colors 0 to 7) are:

```
black  red  green  yellow  blue  magenta  cyan  white
```

The corresponding bright foreground color attributes (colors 8 to 15) are:

```
bright_black  bright_red      bright_green  bright_yellow
bright_blue   bright_magenta  bright_cyan   bright_white
```

The recognized normal background color attributes (colors 0 to 7) are:

```
on_black  on_red      on_green  on yellow
on_blue   on_magenta  on_cyan   on_white
```

The recognized bright background color attributes (colors 8 to 15) are:

```
on_bright_black  on_bright_red      on_bright_green  on_bright_
 ↪yellow
on_bright_blue   on_bright_magenta  on_bright_cyan   on_bright_white
```

For 256-color terminals, the recognized foreground colors are:

```
ansi0 .. ansi255
grey0 .. grey23
```

plus `rgb_RGB_` for *R*, *G*, and *B* values from 0 to 5, such as `rgb000` or `rgb515`. Similarly, the recognized background colors are:

```
on_ansi0 .. on_ansi255
on_grey0 .. on_grey23
```

plus `on_rgb_RGB_` for *R*, *G*, and *B* values from 0 to 5.

For true color terminals, the recognized foreground colors are `r_RRR_g_GGG_b_BBB_` for *RRR*, *GGG*, and *BBB* values between 0 and 255. Similarly, the recognized background colors are `on_r_RRR_g_GGG_b_BBB_` for *RRR*, *GGG*, and *BBB* values between 0 and 255.

For any of the above listed attributes, case is not significant.

Attributes, once set, last until they are unset (by printing the attribute `clear` or `reset`). Be careful to do this, or otherwise your attribute will last after your script is done running, and people get very annoyed at having their prompt and typing changed to weird colors.

- color(ATTR[, ATTR ...])

  color() takes any number of strings as arguments and considers them to be space-separated lists of attributes. It then forms and returns the escape sequence to set those attributes. It doesn't print it out, just returns it, so you'll have to print it yourself if you want to. This is so that you can save it as a string, pass it to something else, send it to a file handle, or do anything else with it that you might care to. color() throws an exception if given an invalid attribute.

- colored(STRING, ATTR[, ATTR ...])

- colored(ATTR-REF, STRING[, STRING...])

  As an aid in resetting colors, colored() takes a scalar as the first argument and any number of attribute strings as the second argument and returns the scalar wrapped in escape codes so that the attributes will be set as requested before the string and reset to normal after the string. Alternately, you can pass a reference to an array as the first argument, and then the contents of that array will be taken as attributes and color codes and the remainder of the arguments as text to colorize.

  Normally, colored() just puts attribute codes at the beginning and end of the string, but if you set $Term::ANSIColor::EACHLINE to some string, that string will be considered the line delimiter and the attribute will be set at the beginning of each line of the passed string and reset at the end of each line. This is often desirable if the output contains newlines and you're using background colors, since a background color that persists across a newline is often interpreted by the terminal as providing the default background color for the next line. Programs like pagers can also be confused by attributes that span lines. Normally you'll want to set $Term::ANSIColor::EACHLINE to `"\n"` to use this feature.

  Particularly consider setting $Term::ANSIColor::EACHLINE if you are interleaving output to standard output and standard error and you aren't flushing standard output (via autoflush() or setting `$|`). If you don't, the code to reset the color may unexpectedly sit in the standard output buffer rather than going to the display, causing standard error output to appear in the wrong color.

- uncolor(ESCAPE)

  uncolor() performs the opposite translation as color(), turning escape sequences into a list of strings corresponding to the attributes being set by those sequences. uncolor() will never return `ansi16` through `ansi255`, instead preferring the `grey` and `rgb` names (and likewise for `on_ansi16` through `on_ansi255`).

- colorstrip(STRING[, STRING ...])

  colorstrip() removes all color escape sequences from the provided strings, returning the modified strings separately in array context or joined together in scalar context. Its arguments are not modified.

- colorvalid(ATTR[, ATTR ...])

  colorvalid() takes attribute strings the same as color() and returns true if all attributes are known and false otherwise.

- coloralias(ALIAS[, ATTR ...])

  If ATTR is specified, it is interpreted as a list of space-separated strings naming attributes or existing aliases. In this case, coloralias() sets up an alias of ALIAS

for the set of attributes given by ATTR. From that point forward, ALIAS can be passed into color(), colored(), and colorvalid() and will have the same meaning as the sequence of attributes given in ATTR. One possible use of this facility is to give more meaningful names to the 256-color RGB colors. Only ASCII alphanumerics, ., _, and - are allowed in alias names.

If ATTR includes aliases, those aliases will be expanded at definition time and their values will be used to define the new alias. This means that if you define an alias A in terms of another alias B, and then later redefine alias B, the value of alias A will not change.

If ATTR is not specified, coloralias() returns the standard attribute or attributes to which ALIAS is aliased, if any, or undef if ALIAS does not exist. If it is aliased to multiple attributes, the return value will be a single string and the attributes will be separated by spaces.

This is the same facility used by the ANSI_COLORS_ALIASES environment variable (see "ENVIRONMENT" below) but can be used at runtime, not just when the module is loaded.

Later invocations of coloralias() with the same ALIAS will override earlier aliases. There is no way to remove an alias.

Aliases have no effect on the return value of uncolor().

WARNING: Aliases are global and affect all callers in the same process. There is no way to set an alias limited to a particular block of code or a particular object.

Constant Interface

Alternately, if you import `:constants`, you can use the following constants directly:

```
CLEAR           RESET             BOLD            DARK
FAINT           ITALIC            UNDERLINE       UNDERSCORE
BLINK           REVERSE           CONCEALED

BLACK           RED               GREEN           YELLOW
BLUE            MAGENTA           CYAN            WHITE
BRIGHT_BLACK    BRIGHT_RED        BRIGHT_GREEN    BRIGHT_YELLOW
BRIGHT_BLUE     BRIGHT_MAGENTA    BRIGHT_CYAN     BRIGHT_WHITE

ON_BLACK        ON_RED            ON_GREEN        ON_YELLOW
ON_BLUE         ON_MAGENTA        ON_CYAN         ON_WHITE
ON_BRIGHT_BLACK ON_BRIGHT_RED     ON_BRIGHT_GREEN ON_BRIGHT_YELLOW
ON_BRIGHT_BLUE  ON_BRIGHT_MAGENTA ON_BRIGHT_CYAN  ON_BRIGHT_WHITE
```

These are the same as color('attribute') and can be used if you prefer typing:

```
print BOLD BLUE ON_WHITE "Text", RESET, "\n";
```

to

```
print colored ("Text", 'bold blue on_white'), "\n";
```

(Note that the newline is kept separate to avoid confusing the terminal as described above since a background color is being used.)

If you import `:constants256`, you can use the following constants directly:

```
ANSI0 .. ANSI255
GREY0 .. GREY23

RGBXYZ (for X, Y, and Z values from 0 to 5, like RGB000 or RGB515)

ON_ANSI0 .. ON_ANSI255
ON_GREY0 .. ON_GREY23

ON_RGBXYZ (for X, Y, and Z values from 0 to 5)
```

Note that `:constants256` does not include the other constants, so if you want to mix both, you need to include `:constants` as well. You may want to explicitly import at least `RESET`, as in:

```
use Term::ANSIColor 4.00 qw(RESET :constants256);
```

True color and aliases are not supported by the constant interface.

When using the constants, if you don't want to have to remember to add the `, RESET` at the end of each print line, you can set $Term::ANSIColor::AUTORESET to a true value. Then, the display mode will automatically be reset if there is no comma after the constant. In other words, with that variable set:

```
print BOLD BLUE "Text\n";
```

will reset the display mode afterward, whereas:

```
print BOLD, BLUE, "Text\n";
```

will not. If you are using background colors, you will probably want to either use say() (in newer versions of Perl) or print the newline with a separate print statement to avoid confusing the terminal.

If $Term::ANSIColor::AUTOLOCAL is set (see below), it takes precedence over $Term::ANSIColor::AUTORESET, and the latter is ignored.

The subroutine interface has the advantage over the constants interface in that only two subroutines are exported into your namespace, versus thirty-eight in the constants interface, and aliases and true color attributes are supported. On the flip side, the constants interface has the advantage of better compile time error checking, since misspelled names of colors or attributes in calls to color() and colored() won't be caught until runtime whereas misspelled names of constants will be caught at compile time. So, pollute your namespace with almost two dozen subroutines that you may not even use that often, or risk a silly bug by mistyping an attribute. Your choice, TMTOWTDI after all.

The Color Stack

You can import :pushpop and maintain a stack of colors using PUSHCOLOR, POPCOLOR, and LOCALCOLOR. PUSHCOLOR takes the attribute string that starts its argument and pushes it onto a stack of attributes. POPCOLOR removes the top of the stack and restores the previous attributes set by the argument of a prior PUSHCOLOR. LOCALCOLOR surrounds its argument in a PUSHCOLOR and POPCOLOR so that the color resets afterward.

If $Term::ANSIColor::AUTOLOCAL is set, each sequence of color constants will be implicitly preceded by LOCALCOLOR. In other words, the following:

```
{
    local $Term::ANSIColor::AUTOLOCAL = 1;
    print BLUE "Text\n";
}
```

is equivalent to:

```
print LOCALCOLOR BLUE "Text\n";
```

If $Term::ANSIColor::AUTOLOCAL is set, it takes precedence over $Term::ANSIColor::AUTORESET, and the latter is ignored.

When using PUSHCOLOR, POPCOLOR, and LOCALCOLOR, it's particularly important to not put commas between the constants.

```
print PUSHCOLOR BLUE "Text\n";
```

will correctly push BLUE onto the top of the stack.

```
print PUSHCOLOR, BLUE, "Text\n";    # wrong!
```

will not, and a subsequent pop won't restore the correct attributes. PUSHCOLOR pushes the attributes set by its argument, which is normally a string of color constants. It can't ask the terminal what the current attributes are.

Supporting CLICOLOR

https://bixense.com/clicolors/ proposes a standard for enabling and disabling color output from console commands using two environment variables, CLICOLOR and CLICOLOR_FORCE. Term::ANSIColor cannot automatically support this standard, since the correct action depends on where the output is going and Term::ANSIColor may be used in a context where colors should always be generated even if CLICOLOR is set in the environment. But you can use the supported environment variable ANSI_COLORS_DISABLED to implement CLICOLOR in your own programs with code like this:

```
if (exists($ENV{CLICOLOR}) && $ENV{CLICOLOR} == 0) {
    if (!$ENV{CLICOLOR_FORCE}) {
        $ENV{ANSI_COLORS_DISABLED} = 1;
    }
}
```

If you are using the constant interface, be sure to include this code before you use any

color constants (such as at the very top of your script), since this environment variable is only honored the first time a color constant is seen.

Be aware that this will export ANSI_COLORS_DISABLED to any child processes of your program as well.

DIAGNOSTICS

- Bad color mapping %s

  (W) The specified color mapping from ANSI_COLORS_ALIASES is not valid and could not be parsed. It was ignored.

- Bad escape sequence %s

  (F) You passed an invalid ANSI escape sequence to uncolor().

- Bareword "%s" not allowed while "strict subs" in use

  (F) You probably mistyped a constant color name such as:

  ```
  $Foobar = FOOBAR . "This line should be blue\n";
  ```

  or:

  ```
  @Foobar = FOOBAR, "This line should be blue\n";
  ```

  This will only show up under use strict (another good reason to run under use strict).

- Cannot alias standard color %s

  (F) The alias name passed to coloralias() matches a standard color name. Standard color names cannot be aliased.

- Cannot alias standard color %s in %s

  (W) The same, but in ANSI_COLORS_ALIASES. The color mapping was ignored.

- Invalid alias name %s

  (F) You passed an invalid alias name to coloralias(). Alias names must consist only of alphanumerics, ., -, and _.

- Invalid alias name %s in %s

  (W) You specified an invalid alias name on the left hand of the equal sign in a color mapping in ANSI_COLORS_ALIASES. The color mapping was ignored.

- Invalid attribute name %s

  (F) You passed an invalid attribute name to color(), colored(), or coloralias().

- Invalid attribute name %s in %s

  (W) You specified an invalid attribute name on the right hand of the equal sign in a color mapping in ANSI_COLORS_ALIASES. The color mapping was ignored.

- Name "%s" used only once: possible typo

  (W) You probably mistyped a constant color name such as:

```
print FOOBAR "This text is color FOOBAR\n";
```

It's probably better to always use commas after constant names in order to force the next error.

- No comma allowed after filehandle

  (F) You probably mistyped a constant color name such as:

```
print FOOBAR, "This text is color FOOBAR\n";
```

  Generating this fatal compile error is one of the main advantages of using the constants interface, since you'll immediately know if you mistype a color name.

- No name for escape sequence %s

  (F) The ANSI escape sequence passed to uncolor() contains escapes which aren't recognized and can't be translated to names.

ENVIRONMENT

- ANSI_COLORS_ALIASES

  This environment variable allows the user to specify custom color aliases that will be understood by color(), colored(), and colorvalid(). None of the other functions will be affected, and no new color constants will be created. The custom colors are aliases for existing color names; no new escape sequences can be introduced. Only alphanumerics, `.`, `_`, and `-` are allowed in alias names.

  The format is:

```
ANSI_COLORS_ALIASES='newcolor1=oldcolor1,newcolor2=oldcolor2'
```

  Whitespace is ignored. The alias value can be a single attribute or a space-separated list of attributes.

  For example the Solarized colors can be mapped with:

```
ANSI_COLORS_ALIASES='\
    base00=bright_yellow, on_base00=on_bright_yellow,\
    base01=bright_green,  on_base01=on_bright_green, \
    base02=black,         on_base02=on_black,        \
    base03=bright_black,  on_base03=on_bright_black, \
    base0=bright_blue,    on_base0=on_bright_blue,   \
    base1=bright_cyan,    on_base1=on_bright_cyan,   \
    base2=white,          on_base2=on_white,         \
    base3=bright_white,   on_base3=on_bright_white,  \
    orange=bright_red,    on_orange=on_bright_red,   \
    violet=bright_magenta,on_violet=on_bright_magenta'
```

  This environment variable is read and applied when the Term::ANSIColor module is loaded and is then subsequently ignored. Changes to ANSI_COLORS_ALIASES after the module is loaded will have no effect. See coloralias() for an equivalent facility that can be used at runtime.

- ANSI_COLORS_DISABLED

  If this environment variable is set to a true value, all of the functions defined by this module (color(), colored(), and all of the constants) will not output any escape sequences and instead will just return the empty string or pass through the original text as appropriate. This is intended to support easy use of scripts using this module on platforms that don't support ANSI escape sequences.

- NO_COLOR

  If this environment variable is set to any value, it suppresses generation of escape sequences the same as if ANSI_COLORS_DISABLED is set to a true value. This implements the https://no-color.org/ informal standard. Programs that want to enable color despite NO_COLOR being set will need to unset that environment variable before any constant or function provided by this module is used.

COMPATIBILITY

Term::ANSIColor was first included with Perl in Perl 5.6.0.

The uncolor() function and support for ANSI_COLORS_DISABLED were added in Term::ANSIColor 1.04, included in Perl 5.8.0.

Support for dark was added in Term::ANSIColor 1.08, included in Perl 5.8.4.

The color stack, including the `:pushpop` import tag, PUSHCOLOR, POPCOLOR, LOCALCOLOR, and the $Term::ANSIColor::AUTOLOCAL variable, was added in Term::ANSIColor 2.00, included in Perl 5.10.1.

colorstrip() was added in Term::ANSIColor 2.01 and colorvalid() was added in Term::ANSIColor 2.02, both included in Perl 5.11.0.

Support for colors 8 through 15 (the `bright_` variants) was added in Term::ANSIColor 3.00, included in Perl 5.13.3.

Support for italic was added in Term::ANSIColor 3.02, included in Perl 5.17.1.

Support for colors 16 through 256 (the `ansi`, `rgb`, and `grey` colors), the `:constants256` import tag, the coloralias() function, and support for the ANSI_COLORS_ALIASES environment variable were added in Term::ANSIColor 4.00, included in Perl 5.17.8.

$Term::ANSIColor::AUTOLOCAL was changed to take precedence over $Term::ANSIColor::AUTORESET, rather than the other way around, in Term::ANSIColor 4.00, included in Perl 5.17.8.

`ansi16` through `ansi255`, as aliases for the `rgb` and `grey` colors, and the corresponding `on_ansi` names and `ANSI` and `ON_ANSI` constants were added in Term::ANSIColor 4.06, included in Perl 5.25.7.

Support for true color (the `rNNNgNNNbNNN` and `on_rNNNgNNNbNNN` attributes), defining aliases in terms of other aliases, and aliases mapping to multiple attributes instead of only a single attribute was added in Term::ANSIColor 5.00.

Support for NO_COLOR was added in Term::ANSIColor 5.01.

RESTRICTIONS

Both colored() and many uses of the color constants will add the reset escape sequence after a newline. If a program mixes colored output to standard output with output to standard error, this can result in the standard error text having the wrong color because the reset escape sequence hasn't yet been flushed to the display (since standard output to a terminal is line-buffered by default). To avoid this, either set autoflush() on STDOUT or set $Term::ANSIColor::EACHLINE to "\n".

It would be nice if one could leave off the commas around the constants entirely and just say:

```
print BOLD BLUE ON_WHITE "Text\n" RESET;
```

but the syntax of Perl doesn't allow this. You need a comma after the string. (Of course, you may consider it a bug that commas between all the constants aren't required, in which case you may feel free to insert commas unless you're using $Term::ANSIColor::AUTORESET or PUSHCOLOR/POPCOLOR.)

For easier debugging, you may prefer to always use the commas when not setting $Term::ANSIColor::AUTORESET or PUSHCOLOR/POPCOLOR so that you'll get a fatal compile error rather than a warning.

It's not possible to use this module to embed formatting and color attributes using Perl formats. They replace the escape character with a space (as documented in perlform(1)), resulting in garbled output from the unrecognized attribute. Even if there were a way around that problem, the format doesn't know that the non-printing escape sequence is zero-length and would incorrectly format the output. For formatted output using color or other attributes, either use sprintf() instead or use formline() and then add the color or other attributes after formatting and before output.

NOTES

The codes generated by this module are standard terminal control codes, complying with ECMA-048 and ISO 6429 (generally referred to as "ANSI color" for the color codes). The non-color control codes (bold, dark, italic, underline, and reverse) are part of the earlier ANSI X3.64 standard for control sequences for video terminals and peripherals.

Note that not all displays are ISO 6429-compliant, or even X3.64-compliant (or are even attempting to be so). This module will not work as expected on displays that do not honor these escape sequences, such as cmd.exe, 4nt.exe, and command.com under either Windows NT or Windows 2000. They may just be ignored, or they may display as an ESC character followed by some apparent garbage.

Jean Delvare provided the following table of different common terminal emulators and their support for the various attributes and others have helped me flesh it out:

```
            clear    bold     faint   under    blink   reverse␣
↪conceal
------------------------------------------------------------------
↪----
xterm         yes      yes      no      yes      yes      yes     ␣
↪yes
```

(continues on next page)

(continued from previous page)

```
linux          yes      yes      yes    bold       yes      yes      ␣
 ↪no
rxvt           yes      yes      no      yes   bold/black   yes      ␣
 ↪no
dtterm         yes      yes      yes     yes     reverse    yes      ␣
 ↪yes
teraterm       yes    reverse    no      yes     rev/red    yes      ␣
 ↪no
aixterm       kinda   normal     no      yes       no       yes      ␣
 ↪yes
PuTTY          yes     color     no      yes       no       yes      ␣
 ↪no
Windows        yes      no       no      no        no       yes      ␣
 ↪no
Cygwin SSH     yes      yes      no     color     color    color     ␣
 ↪yes
Terminal.app   yes      yes      no      yes       yes      yes      ␣
 ↪yes
```

Windows is Windows telnet, Cygwin SSH is the OpenSSH implementation under Cygwin on Windows NT, and Mac Terminal is the Terminal application in Mac OS X. Where the entry is other than yes or no, that emulator displays the given attribute as something else instead. Note that on an aixterm, clear doesn't reset colors; you have to explicitly set the colors back to what you want. More entries in this table are welcome.

Support for code 3 (italic) is rare and therefore not mentioned in that table. It is not believed to be fully supported by any of the terminals listed, although it's displayed as green in the Linux console, but it is reportedly supported by urxvt.

Note that codes 6 (rapid blink) and 9 (strike-through) are specified in ANSI X3.64 and ECMA-048 but are not commonly supported by most displays and emulators and therefore aren't supported by this module. ECMA-048 also specifies a large number of other attributes, including a sequence of attributes for font changes, Fraktur characters, double-underlining, framing, circling, and overlining. As none of these attributes are widely supported or useful, they also aren't currently supported by this module.

Most modern X terminal emulators support 256 colors. Known to not support those colors are aterm, rxvt, Terminal.app, and TTY/VC.

For information on true color support in various terminal emulators, see True Colour support.

AUTHORS

Original idea (using constants) by Zenin, reimplemented using subs by Russ Allbery rra@cpan.org, and then combined with the original idea by Russ with input from Zenin. 256-color support is based on work by Kurt Starsinic. Russ Allbery now maintains this module.

PUSHCOLOR, POPCOLOR, and LOCALCOLOR were contributed by openmethods.com voice solutions.

SEE ALSO

The CPAN module Term::ExtendedColor provides a different and more comprehensive interface for 256-color emulators that may be more convenient. The CPAN module Win32::Console::ANSI provides ANSI color (and other escape sequence) support in the Win32 Console environment. The CPAN module Term::Chrome provides a different interface using objects and operator overloading.

ECMA-048 is available on-line (at least at the time of this writing) at https://www.ecma-international.org/publications/standards/Ecma-048.htm.

ISO 6429 is available from ISO for a charge; the author of this module does not own a copy of it. Since the source material for ISO 6429 was ECMA-048 and the latter is available for free, there seems little reason to obtain the ISO standard.

The 256-color control sequences are documented at https://invisible-island.net/xterm/ctlseqs/ctlseqs.html (search for 256-color).

Information about true color support in various terminal emulators and test programs you can run to check the true color support in your terminal emulator are available at https://gist.github.com/XVilka/8346728.

CLICOLORS and NO_COLOR are useful standards to be aware of, and ideally follow, for any application using color. Term::ANSIColor complies with the latter.

The current version of this module is always available from its web site at https://www.eyrie.org/~eagle/software/ansicolor/. It is also part of the Perl core distribution as of 5.6.0.

Term::Cap

Perl termcap interface

SYNOPSIS

```
require Term::Cap;
$terminal = Term::Cap->Tgetent({ TERM => undef, OSPEED => $ospeed }
 ↪);
$terminal->Trequire(qw/ce ku kd/);
$terminal->Tgoto('cm', $col, $row, $FH);
$terminal->Tputs('dl', $count, $FH);
$terminal->Tpad($string, $count, $FH);
```

DESCRIPTION

These are low-level functions to extract and use capabilities from a terminal capability (termcap) database.

More information on the terminal capabilities will be found in the termcap manpage on most Unix-like systems.

METHODS

The output strings for **Tputs** are cached for counts of 1 for performance. **Tgoto** and **Tpad** do not cache. `$self->{_xx}` is the raw termcap data and `$self->{xx}` is the cached version.

```
print $terminal->Tpad($self->{_xx}, 1);
```

Tgoto, **Tputs**, and **Tpad** return the string and will also output the string to $FH if specified.

- **Tgetent**

  Returns a blessed object reference which the user can then use to send the control strings to the terminal using **Tputs** and **Tgoto**.

  The function extracts the entry of the specified terminal type *TERM* (defaults to the environment variable *TERM*) from the database.

  It will look in the environment for a *TERMCAP* variable. If found, and the value does not begin with a slash, and the terminal type name is the same as the environment string *TERM*, the *TERMCAP* string is used instead of reading a termcap file. If it does begin with a slash, the string is used as a path name of the termcap file to search. If *TERMCAP* does not begin with a slash and name is different from *TERM*, **Tgetent** searches the files `$HOME/.termcap`, `/etc/termcap`, and `/usr/share/misc/termcap`, in that order, unless the environment variable *TERMPATH* exists, in which case it specifies a list of file pathnames (separated by spaces or colons) to be searched **instead**. Whenever multiple files are searched and a tc field occurs in the requested entry, the entry it names must be found in the same file or one of the succeeding files. If there is a `:tc=...:` in the *TERMCAP* environment variable string it will continue the search in the files as above.

  The extracted termcap entry is available in the object as `$self->{TERMCAP}`.

  It takes a hash reference as an argument with two optional keys:

  – OSPEED

    The terminal output bit rate (often mistakenly called the baud rate) for this terminal - if not set a warning will be generated and it will be defaulted to 9600. *OSPEED* can be specified as either a POSIX termios/SYSV termio speeds (where 9600 equals 9600) or an old DSD-style speed (where 13 equals 9600).

  – TERM

    The terminal type whose termcap entry will be used - if not supplied it will default to $ENV{TERM}: if that is not set then **Tgetent** will croak.

  It calls `croak` on failure.

- **Tpad**

  Outputs a literal string with appropriate padding for the current terminal.

  It takes three arguments:

  - **$string**

    The literal string to be output. If it starts with a number and an optional '*' then the padding will be increased by an amount relative to this number, if the '*' is present then this amount will be multiplied by $cnt. This part of $string is removed before output/

  - **$cnt**

    Will be used to modify the padding applied to string as described above.

  - **$FH**

    An optional filehandle (or IO::Handle) that output will be printed to.

  The padded $string is returned.

- **Tputs**

  Output the string for the given capability padded as appropriate without any parameter substitution.

  It takes three arguments:

  - **$cap**

    The capability whose string is to be output.

  - **$cnt**

    A count passed to Tpad to modify the padding applied to the output string. If $cnt is zero or one then the resulting string will be cached.

  - **$FH**

    An optional filehandle (or IO::Handle) that output will be printed to.

  The appropriate string for the capability will be returned.

- **Tgoto**

  Tgoto decodes a cursor addressing string with the given parameters.

  There are four arguments:

  - **$cap**

    The name of the capability to be output.

  - **$col**

    The first value to be substituted in the output string (usually the column in a cursor addressing capability)

  - **$row**

    The second value to be substituted in the output string (usually the row in cursor addressing capabilities)

– **$FH**

An optional filehandle (or IO::Handle) to which the output string will be printed.

Substitutions are made with $col and $row in the output string with the following sprintf() line formats:

```
%%   output `%'
%d   output value as in printf %d
%2   output value as in printf %2d
%3   output value as in printf %3d
%.   output value as in printf %c
%+x  add x to value, then do %.

%>xy if value > x then add y, no output
%r   reverse order of two parameters, no output
%i   increment by one, no output
%B   BCD (16*(value/10)) + (value%10), no output

%n   exclusive-or all parameters with 0140 (Datamedia 2500)
%D   Reverse coding (value - 2*(value%16)), no output (Delta
 ↪Data)
```

The output string will be returned.

- **Trequire**

Takes a list of capabilities as an argument and will croak if one is not found.

EXAMPLES

```
use Term::Cap;

# Get terminal output speed
require POSIX;
my $termios = POSIX::Termios->new;
$termios->getattr;
my $ospeed = $termios->getospeed;

# Old-style ioctl code to get ospeed:
#     require 'ioctl.pl';
#     ioctl(TTY,$TIOCGETP,$sgtty);
#     ($ispeed,$ospeed) = unpack('cc',$sgtty);

# allocate and initialize a terminal structure
my $terminal = Term::Cap->Tgetent({ TERM => undef, OSPEED => $ospeed
 ↪});

# require certain capabilities to be available
$terminal->Trequire(qw/ce ku kd/);
```

(continues on next page)

(continued from previous page)

```
# Output Routines, if $FH is undefined these just return the string

# Tgoto does the % expansion stuff with the given args
$terminal->Tgoto('cm', $col, $row, $FH);

# Tputs doesn't do any % expansion.
$terminal->Tputs('dl', $count = 1, $FH);
```

Term::Complete

Perl word completion module

SYNOPSIS

```
$input = Complete('prompt_string', \@completion_list);
$input = Complete('prompt_string', @completion_list);
```

DESCRIPTION

This routine provides word completion on the list of words in the array (or array ref).

The tty driver is put into raw mode and restored using an operating system specific command, in UNIX-like environments `stty`.

The following command characters are defined:

- <tab>

  Attempts word completion. Cannot be changed.

- ^D

  Prints completion list. Defined by *$Term::Complete::complete*.

- ^U

  Erases the current input. Defined by *$Term::Complete::kill*.

- <del>, <bs>

  Erases one character. Defined by *$Term::Complete::erase1* and *$Term::Complete::erase2*.

DIAGNOSTICS

Bell sounds when word completion fails.

BUGS

The completion character <tab> cannot be changed.

AUTHOR

Wayne Thompson

Term::ReadKey

Terminal modes (cooked, no-echo, cbreak, raw), reads that time out or do not block, and the terminal's size, speed and control characters.

Synopsis

```
use Term::ReadKey;

ReadMode 'cbreak';                  # one key at a time, no echo
my $key = ReadKey(0.5);             # wait half a second at most
ReadMode 'restore';

my ($cols, $rows) = GetTerminalSize();
my %cc = GetControlChars();         # INTERRUPT => "\cC", ...
```

How it works

`ReadMode` changes the handle's termios settings, saving the ones it found on first use; mode 0 (`restore`) puts those back and forgets them. `ReadKey` and `ReadLine` with a positive timeout wait with `select()`, and with a negative one switch the handle to non-blocking for the one read. `GetTerminalSize` asks the terminal (TIOCGWINSZ), then `$COLUMNS`/`$LINES`, then `resize` and `stty size`.

This is a native implementation of TermReadKey 2.38's `ReadKey.xs` and the `cchars.h` its genchars.pl writes, as they build on Linux (termios, `O_NDELAY` and `select()`, no `poll()`); its `Term/ReadKey.pm`, which ReadKey.pm.PL writes, is used unchanged.

Differences from upstream

Three, each where perl 5.44 with ReadKey.xs aborts or returns memory it never wrote (t/81-xs-native/Term-ReadKey/150-or-better.t):

- A timed `ReadKey`/`ReadLine` on a closed handle reads nothing, as an untimed one does; perl5 aborts ("bit out of range 0 - FD_SETSIZE on fd_set"). One on a descriptor of 1024 or above waits as on any other; perl5 aborts the same way.
- `GetSpeed` on a handle that is not a terminal returns (0, 0); perl5 returns two numbers from uninitialised memory, different each time.
- `SetTerminalSize` with a width or height of ten characters or more (1000000000, -100000000) sets `COLUMNS`/`LINES` for child processes as for any other; perl5 aborts ("buffer overflow detected").

Functions

Terminal modes

`selectfile`

Wait until a handle has input, for at most `delay` seconds.

`SetReadMode`

Put a terminal handle into one of the modes 0 to 5.

`setnodelay`

Switch a handle's descriptor to non-blocking reads (`mode` true) or back.

`pollfile`

The `poll()` wait of builds that have it; this one dies "pollfile is not supported on this architecture".

`Win32PeekChar`

The Windows console read; here it dies "Win32PeekChar is not supported on this architecture".

Terminal properties

`blockoptions`

The ways this build can read without blocking, as bits: 1 non-blocking descriptors, 2 `poll()`, 4 `select()`, 8 the Windows console. Here 5.

termoptions

The terminal interface this build drives: 1 termios, 2 termio, 3 sgtty, 4 the `stty` program, 5 the Windows console. Here 1.

termsizeoptions

The ways this build can ask a terminal its size, as bits: 1 OS/2's VIO, 2 TIOCGWINSZ, 4 TIOCGSIZE, 8 the Windows console. Here 2.

GetTermSizeWin32

The Windows console's size; here it dies "TermSizeWin32 is not implemented on this architecture".

GetTermSizeVIO

OS/2's screen size; here it dies "TermSizeVIO is not implemented on this architecture".

GetTermSizeGWINSZ

A terminal's size from the TIOCGWINSZ ioctl.

GetTermSizeGSIZE

The TIOCGSIZE size of systems without TIOCGWINSZ; here it dies "TermSizeGSIZE is not implemented on this architecture".

SetTerminalSize

Tell a terminal its size.

GetSpeed

A terminal's input and output speeds in baud.

GetControlChars

A terminal's control characters, as name/character pairs.

SetControlChars

Change a terminal's control characters.

selectfile

Wait until a handle has input, for at most `delay` seconds.

Synopsis

```
my $ready = Term::ReadKey::selectfile(\*STDIN, 0.25);
```

What you get back

1 when the handle's buffer already holds input, -1 when `select()` says the descriptor is readable (or fails), 0 when the time ran out. `ReadKey` and `ReadLine` call it for a positive timeout.

SetReadMode

Put a terminal handle into one of the modes 0 to 5.

Synopsis

```
Term::ReadKey::SetReadMode(3, \*STDIN);   # ReadMode 'cbreak'
```

How it works

The numeric half of `ReadMode`, which maps the names (`restore`, `normal`, `noecho`, `cbreak`, `raw`, `ultra-raw`) to 0 to 5. The first change of a descriptor saves its settings; mode 0 restores them and forgets them, so the next change saves afresh. Any other number dies "ReadMode N is not implemented on this architecture.".

setnodelay

Switch a handle's descriptor to non-blocking reads (`mode` true) or back.

Synopsis

```
Term::ReadKey::setnodelay(\*STDIN, 1);
my $c = getc STDIN;                    # undef if nothing is waiting
Term::ReadKey::setnodelay(\*STDIN, 0);
```

What you get back

Always 0. `ReadKey` and `ReadLine` call it around a read with a negative timeout.

GetTermSizeGWINSZ

A terminal's size from the TIOCGWINSZ ioctl.

Synopsis

```
my ($cols, $rows, $xpix, $ypix) = Term::ReadKey::GetTermSizeGWINSZ(\
 ↪*STDOUT);
```

What you get back

Width and height in characters and in pixels (0 where the terminal does not say), or an empty list when the handle is not a terminal. `GetTerminalSize` calls it first and falls back from an empty list.

SetTerminalSize

Tell a terminal its size.

Synopsis

```
SetTerminalSize(132, 50, 0, 0, \*STDOUT);
```

What you get back

0. The size is the terminal's record, read by the programs on it (a change sends them SIGWINCH); the window does not change. `COLUMNS` and `LINES` are set for child processes, not in `%ENV`. A handle that is not a terminal dies "TIOCSWINSZ ioctl call to set terminal size failed: " and the system's reason.

GetSpeed

A terminal's input and output speeds in baud.

Synopsis

```
my ($in, $out) = GetSpeed();          # e.g. (38400, 38400)
```

What you get back

Two numbers, decimal: a speed outside the table of 50 to 115200 baud comes back as the system's own code for it. A handle that is not a terminal gives (0, 0).

GetControlChars

A terminal's control characters, as name/character pairs.

Synopsis

```
my %cc = GetControlChars(\*STDIN);
printf "interrupt is ^%c\n", ord($cc{INTERRUPT}) + 64;
```

What you get back

A list for a hash: DISCARD, EOF, EOL, EOL2, ERASE, ERASEWORD, INTERRUPT, KILL, MIN, QUIT, QUOTENEXT, REPRINT, START, STOP, SUSPEND, SWITCH and TIME, each with its character as a one-character string (MIN and TIME are counts, as characters). A handle that is not a terminal dies “Unable to read terminal settings in GetControlChars”.

SetControlChars

Change a terminal’s control characters.

Synopsis

```
SetControlChars(INTERRUPT => "\cX", EOF => 4, \*STDIN);
```

How it works

Takes name/value pairs as `GetControlChars` returns them, and an odd last argument as the handle (STDIN without one). A value that is a number is the character’s code; any other the first character of its string. An unknown name dies “Invalid control character passed to SetControlChars” before any change is made; a handle that is not a terminal dies “Unable to read terminal settings in SetControlChars”.

Term::ReadLine

Perl interface to various `readline` packages. If no real package is found, substitutes stubs instead of basic functions.

SYNOPSIS

```
use Term::ReadLine;
my $term = Term::ReadLine->new('Simple Perl calc');
my $prompt = "Enter your arithmetic expression: ";
my $OUT = $term->OUT || \*STDOUT;
while ( defined ($_ = $term->readline($prompt)) ) {
  my $res = eval($_);
  warn $@ if $@;
  print $OUT $res, "\n" unless $@;
  $term->addhistory($_) if /\S/;
}
```

DESCRIPTION

This package is just a front end to some other packages. It's a stub to set up a common interface to the various ReadLine implementations found on CPAN (under the `Term::ReadLine::*` namespace).

Minimal set of supported functions

All the supported functions should be called as methods, i.e., either as

```
$term = Term::ReadLine->new('name');
```

or as

```
$term->addhistory('row');
```

where $term is a return value of Term::ReadLine->new().

- `ReadLine`

  returns the actual package that executes the commands. Among possible values are `Term::ReadLine::Gnu`, `Term::ReadLine::Perl`, `Term::ReadLine::Stub`.

- `new`

  returns the handle for subsequent calls to following functions. Argument is the name of the application. Optionally can be followed by two arguments for `IN` and `OUT` filehandles. These arguments should be globs.

- `readline`

  gets an input line, *possibly* with actual `readline` support. Trailing newline is removed. Returns `undef` on `EOF`.

- `addhistory`

  adds the line to the history of input, from where it can be used if the actual `readline` is present.

- `IN`, `OUT`

  return the filehandles for input and output or `undef` if `readline` input and output cannot be used for Perl.

- `MinLine`

  If argument is specified, it is an advice on minimal size of line to be included into history. `undef` means do not include anything into history. Returns the old value.

- `findConsole`

  returns an array with two strings that give most appropriate names for files for input and output using conventions `"<$in"`, `">out"`.

  The strings returned may not be useful for 3-argument open().

- Attribs

returns a reference to a hash which describes internal configuration of the package. Names of keys in this hash conform to standard conventions with the leading `rl_` stripped.

- `Features`

  Returns a reference to a hash with keys being features present in current implementation. Several optional features are used in the minimal interface: `appname` should be present if the first argument to `new` is recognized, and `minline` should be present if `MinLine` method is not dummy. `autohistory` should be present if lines are put into history automatically (maybe subject to `MinLine`), and `addhistory` if `addhistory` method is not dummy.

  If `Features` method reports a feature `attribs` as present, the method `Attribs` is not dummy.

Additional supported functions

Actually `Term::ReadLine` can use some other package, that will support a richer set of commands.

All these commands are callable via method interface and have names which conform to standard conventions with the leading `rl_` stripped.

The stub package included with the perl distribution allows some additional methods:

- `tkRunning`

  makes Tk event loop run when waiting for user input (i.e., during `readline` method).

- `event_loop`

  Registers call-backs to wait for user input (i.e., during `readline` method). This supersedes tkRunning.

  The first call-back registered is the call back for waiting. It is expected that the callback will call the current event loop until there is something waiting to get on the input filehandle. The parameter passed in is the return value of the second call back.

  The second call-back registered is the call back for registration. The input filehandle (often STDIN, but not necessarily) will be passed in.

  For example, with AnyEvent:

```
$term->event_loop(sub {
  my $data = shift;
  $data->[1] = AE::cv();
  $data->[1]->recv();
}, sub {
  my $fh = shift;
  my $data = [];
  $data->[0] = AE::io($fh, 0, sub { $data->[1]->send() });
  $data;
});
```

The second call-back is optional if the call back is registered prior to the call to $term->readline.

Deregistration is done in this case by calling event_loop with `undef` as its parameter:

```
$term->event_loop(undef);
```

This will cause the data array ref to be removed, allowing normal garbage collection to clean it up. With AnyEvent, that will cause $data->[0] to be cleaned up, and AnyEvent will automatically cancel the watcher at that time. If another loop requires more than that to clean up a file watcher, that will be up to the caller to handle.

- `ornaments`

  makes the command line stand out by using termcap data. The argument to `ornaments` should be 0, 1, or a string of a form `"aa,bb,cc,dd"`. Four components of this string should be names of *terminal capacities*, first two will be issued to make the prompt standout, last two to make the input line standout.

- `newTTY`

  takes two arguments which are input filehandle and output filehandle. Switches to use these filehandles.

One can check whether the currently loaded ReadLine package supports these methods by checking for corresponding `Features`.

EXPORTS

None

ENVIRONMENT

The environment variable `PERL_RL` governs which ReadLine clone is loaded. If the value is false, a dummy interface is used. If the value is true, it should be tail of the name of the package to use, such as `Perl` or `Gnu`.

As a special case, if the value of this variable is space-separated, the tail might be used to disable the ornaments by setting the tail to be `o=0` or `ornaments=0`. The head should be as described above, say

If the variable is not set, or if the head of space-separated list is empty, the best available package is loaded.

```
export "PERL_RL=Perl o=0" # Use Perl ReadLine sans ornaments
export "PERL_RL= o=0"     # Use best available ReadLine sans␣
↪ornaments
```

(Note that processing of `PERL_RL` for ornaments is in the discretion of the particular used `Term::ReadLine::*` package).

Modules

- `Term::ReadLine::Gnu` - Peta::ReadLine under the name programs know

Term::ReadLine::Gnu

Peta::ReadLine under the name programs know

SYNOPSIS

```
use Term::ReadLine;
my $term = Term::ReadLine->new('demo');
print $term->ReadLine;    # Term::ReadLine::Gnu
```

DESCRIPTION

`Term::ReadLine::Gnu` is an alias of *Peta::ReadLine*: the same methods, the same `Attribs` hash, the same `Term::ReadLine::Gnu::XS` functions, under the name that *Term::ReadLine* loads first and that programs such as CPAN.pm and perl's debugger test for before they install their completers. `$term->ReadLine` answers `Term::ReadLine::Gnu` for an object made through this name and `Peta::ReadLine` for one made through that.

Term::Table

Format a header and rows into a table

DESCRIPTION

This is used by some failing tests to provide diagnostics about what has gone wrong. This module is able to format rows of data into tables.

SYNOPSIS

```
use Term::Table;

my $table = Term::Table->new(
    max_width      => 80,    # Defaults to terminal size
    pad            => 4,     # Extra padding between table and max-
↪width (defaults to 4)
    allow_overflow => 0,     # Default is 0, when off an exception␣
↪will be thrown if the table is too big
    collapse       => 1,     # Do not show empty columns

    header => ['name', 'age', 'hair color'],
    rows   => [
        ['Fred Flintstone',  2000000, 'black'],
        ['Wilma Flintstone', 1999995, 'red'],
        ...
```

(continues on next page)

(continued from previous page)

```
    ],
);

say $_ for $table->render;
```

This prints a table like this:

```
+------------------+---------+------------+
| name             | age     | hair color |
+------------------+---------+------------+
| Fred Flintstone  | 2000000 | black      |
| Wilma Flintstone | 1999995 | red        |
| ...              | ...     | ...        |
+------------------+---------+------------+
```

INTERFACE

```
use Term::Table;
my $table = Term::Table->new(...);
```

OPTIONS

- header => [...]

  If you want a header specify it here. This takes an arrayref with each columns heading.

- rows => [[...], [...], ...]

  This should be an arrayref containing an arrayref per row.

- collapse => $bool

  Use this if you want to hide empty columns, that is any column that has no data in any row. Having a header for the column will not effect collapse.

- max_width => $num

  Set the maximum width of the table, the table may not be this big, but it will be no bigger. If none is specified it will attempt to find the width of your terminal and use that, otherwise it falls back to the terminal width or `80`.

- pad => $num

  Defaults to 4, extra padding for row width calculations. Default is for legacy support. Set this to `0` to turn padding off.

- allow_overflow => $bool

  Defaults to `0`. If this is off then an exception will be thrown if the table cannot be made to fit inside the max-width. If this is set to 1 then the table will be rendered anyway, larger than max-width, if it is not possible to stay within the max-width. In other words this turns max-width from a hard-limit to a soft recommendation.

- sanitize => $bool

  This will sanitize all the data in the table such that newlines, control characters, and all whitespace except for ASCII 20 ' ' are replaced with escape sequences. This prevents newlines, tabs, and similar whitespace from disrupting the table.

  Note: newlines are marked as \n, but a newline is also inserted into the data so that it typically displays in a way that is useful to humans.

  Example:

```
my $field = "foo\nbar\nbaz\n";

print join "\n" => table(
    sanitize => 1,
    rows => [
        [$field,      'col2'     ],
        ['row2 col1', 'row2 col2']
    ]
);
```

  Prints:

```
+-----------------+-----------+
| foo\n           | col2      |
| bar\n           |           |
| baz\n           |           |
|                 |           |
| row2 col1       | row2 col2 |
+-----------------+-----------+
```

  So it marks the newlines by inserting the escape sequence, but it also shows the data across as many lines as it would normally display.

- mark_tail => $bool

  This will replace the last whitespace character of any trailing whitespace with its escape sequence. This makes it easier to notice trailing whitespace when comparing values.

- show_header => $bool

  Set this to false to hide the header. This defaults to true if the header is set, false if no header is provided.

- auto_columns => $bool

  Set this to true to automatically add columns that are not named in the header. This defaults to false if a header is provided, and defaults to true when there is no header.

- no_collapse => [$col_num_a, $col_num_b, ...]
- no_collapse => [$col_name_a, $col_name_b, ...]
- no_collapse => { $col_num_a => 1, $col_num_b => 1, ... }
- no_collapse => { $col_name_a => 1, $col_name_b => 1, ... }

Specify (by number and/or name) columns that should not be removed when empty. The 'name' form only works when a header is specified. There is currently no protection to insure that names you specify are actually in the header, invalid names are ignored, patches to fix this will be happily accepted.

NOTE ON UNICODE/WIDE CHARACTERS

Some unicode characters, such as 婧 (U+5A67) are wider than others. These will render just fine if you `use utf8;` as necessary, and *Unicode::GCString* is installed, however if the module is not installed there will be anomalies in the table:

```
+-----+-----+---+
| a   | b   | c |
+-----+-----+---+
| 婧 | x   | y |
| x   | y   | z |
| x   | 婧 | z |
+-----+-----+---+
```

Term::Table::HashBase

Build hash based classes.

SYNOPSIS

A class:

```
package My::Class;
use strict;
use warnings;

# Generate 3 accessors
use Term::Table::HashBase qw/foo -bar ^baz <bat >ban +boo/;

# Chance to initialize defaults
sub init {
    my $self = shift;    # No other args
    $self->{+FOO} ||= "foo";
    $self->{+BAR} ||= "bar";
    $self->{+BAZ} ||= "baz";
    $self->{+BAT} ||= "bat";
    $self->{+BAN} ||= "ban";
    $self->{+BOO} ||= "boo";
}

sub print {
    print join ", " => map { $self->{$_} } FOO, BAR, BAZ, BAT, BAN,␣
 ↪BOO;
}
```

Subclass it

```
package My::Subclass;
use strict;
use warnings;

# Note, you should subclass before loading HashBase.
use base 'My::Class';
```

(continues on next page)

(continued from previous page)

```
use Term::Table::HashBase qw/bub/;

sub init {
    my $self = shift;

    # We get the constants from the base class for free.
    $self->{+FOO} ||= 'SubFoo';
    $self->{+BUB} ||= 'bub';

    $self->SUPER::init();
}
```

use it:

```
package main;
use strict;
use warnings;
use My::Class;

# These are all functionally identical
my $one   = My::Class->new(foo => 'MyFoo', bar => 'MyBar');
my $two   = My::Class->new({foo => 'MyFoo', bar => 'MyBar'});
my $three = My::Class->new(['MyFoo', 'MyBar']);

# Readers!
my $foo = $one->foo;    # 'MyFoo'
my $bar = $one->bar;    # 'MyBar'
my $baz = $one->baz;    # Defaulted to: 'baz'
my $bat = $one->bat;    # Defaulted to: 'bat'
# '>ban' means setter only, no reader
# '+boo' means no setter or reader, just the BOO constant

# Setters!
$one->set_foo('A Foo');

#'-bar' means read-only, so the setter will throw an exception (but␣
 ↪is defined).
$one->set_bar('A bar');

# '^baz' means deprecated setter, this will warn about the setter␣
 ↪being
# deprecated.
$one->set_baz('A Baz');

# '<bat' means no setter defined at all
# '+boo' means no setter or reader, just the BOO constant

$one->{+FOO} = 'xxx';
```

DESCRIPTION

This package is used to generate classes based on hashrefs. Using this class will give you a `new()` method, as well as generating accessors you request. Generated accessors will be getters, `set_ACCESSOR` setters will also be generated for you. You also get constants for each accessor (all caps) which return the key into the hash for that accessor. Single inheritance is also supported.

THIS IS A BUNDLED COPY OF HASHBASE

This is a bundled copy of Object::HashBase. This file was generated using the `/home/exodist/perl5/perlbrew/perls/main/bin/hashbase_inc.pl` script.

METHODS

PROVIDED BY HASH BASE

- $it = $class->new(%PAIRS)
- $it = $class->new(\%PAIRS)
- $it = $class->new(\@ORDERED_VALUES)

  Create a new instance.

  HashBase will not export `new()` if there is already a `new()` method in your packages inheritance chain.

  If you do not want this method you can define your own you just have to declare it before loading *Term::Table::HashBase*.

```
package My::Package;

# predeclare new() so that HashBase does not give us one.
sub new;

use Term::Table::HashBase qw/foo bar baz/;

# Now we define our own new method.
sub new { ... }
```

  This makes it so that HashBase sees that you have your own `new()` method. Alternatively you can define the method before loading HashBase instead of just declaring it, but that scatters your use statements.

  The most common way to create an object is to pass in key/value pairs where each key is an attribute and each value is what you want assigned to that attribute. No checking is done to verify the attributes or values are valid, you may do that in `init()` if desired.

  If you would like, you can pass in a hashref instead of pairs. When you do so the hashref will be copied, and the copy will be returned blessed as an object. There is no way to ask HashBase to bless a specific hashref.

  In some cases an object may only have 1 or 2 attributes, in which case a hashref may be too verbose for your liking. In these cases you can pass in an arrayref with

only values. The values will be assigned to attributes in the order the attributes were listed. When there is inheritance involved the attributes from parent classes will come before subclasses.

HOOKS

- $self->init()

  This gives you the chance to set some default values to your fields. The only argument is `$self` with its indexes already set from the constructor.

  Note: Term::Table::HashBase checks for an init using `$class->can('init')` during construction. It DOES NOT call `can()` on the created object. Also note that the result of the check is cached, it is only ever checked once, the first time an instance of your class is created. This means that adding an `init()` method AFTER the first construction will result in it being ignored.

ACCESSORS

READ/WRITE

To generate accessors you list them when using the module:

```
use Term::Table::HashBase qw/foo/;
```

This will generate the following subs in your namespace:

- foo()

  Getter, used to get the value of the `foo` field.

- set_foo()

  Setter, used to set the value of the `foo` field.

- FOO()

  Constant, returns the field `foo`'s key into the class hashref. Subclasses will also get this function as a constant, not simply a method, that means it is copied into the subclass namespace.

  The main reason for using these constants is to help avoid spelling mistakes and similar typos. It will not help you if you forget to prefix the '+' though.

READ ONLY

```
use Term::Table::HashBase qw/-foo/;
```

- set_foo()

  Throws an exception telling you the attribute is read-only. This is exported to override any active setters for the attribute in a parent class.

DEPRECATED SETTER

```
use Term::Table::HashBase qw/^foo/;
```

- set_foo()

  This will set the value, but it will also warn you that the method is deprecated.

NO SETTER

```
use Term::Table::HashBase qw/<foo/;
```

Only gives you a reader, no `set_foo` method is defined at all.

NO READER

```
use Term::Table::HashBase qw/>foo/;
```

Only gives you a write (`set_foo`), no `foo` method is defined at all.

CONSTANT ONLY

```
use Term::Table::HashBase qw/+foo/;
```

This does not create any methods for you, it just adds the `FOO` constant.

SUBCLASSING

You can subclass an existing HashBase class.

```
use base 'Another::HashBase::Class';
use Term::Table::HashBase qw/foo bar baz/;
```

The base class is added to `@ISA` for you, and all constants from base classes are added to subclasses automatically.

GETTING A LIST OF ATTRIBUTES FOR A CLASS

Term::Table::HashBase provides a function for retrieving a list of attributes for an Term::Table::HashBase class.

- @list = Term::Table::HashBase::attr_list($class)
- @list = $class->Term::Table::HashBase::attr_list()

  Either form above will work. This will return a list of attributes defined on the object. This list is returned in the attribute definition order, parent class attributes are listed before subclass attributes. Duplicate attributes will be removed before the list is returned.

  Note: This list is used in the `$class->new(\@ARRAY)` constructor to determine the attribute to which each value will be paired.

Term::Table::LineBreak

Break up lines for use in tables.

DESCRIPTION

This is meant for internal use. This package takes long lines of text and splits them so that they fit in table rows.

SYNOPSIS

```
use Term::Table::LineBreak;

my $lb = Term::Table::LineBreak->new(string => $STRING);

$lb->break($SIZE);
while (my $part = $lb->next) {
    ...
}
```

Term::Table::Util

Utilities for Term::Table.

DESCRIPTION

This package exports some tools used by Term::Table.

EXPORTS

CONSTANTS

- $bool = USE_GCS

  True if *Unicode::GCString* is installed.

- $bool = USE_TERM_READKEY

  True if *Term::ReadKey* is installed.

UTILITIES

- $width = term_size()

  Get the width of the terminal.

  If the `$TABLE_TERM_SIZE` environment variable is set then that value will be returned.

  This will default to 80 if there is no good way to get the size, or if the size is unreasonably small.

  If *Term::ReadKey* is installed it will be used.

- $width = uni_length($string)

  Get the width (in columns) of the specified string. When *Unicode::GCString* is installed this will work on unicode strings, otherwise it will just use `length($string)`.

SOURCE

The source code repository for Term-Table can be found at `http://github.com/exodist/Term-Table/`.

5.2.101 Test

provides a simple framework for writing test scripts

SYNOPSIS

```
use strict;
use Test;

# use a BEGIN block so we print our plan before MyModule is loaded
BEGIN { plan tests => 14, todo => [3,4] }

# load your module...
use MyModule;

# Helpful notes.  All note-lines must start with a "#".
print "# I'm testing MyModule version $MyModule::VERSION\n";

ok(0); # failure
ok(1); # success

ok(0); # ok, expected failure (see todo list, above)
ok(1); # surprise success!

ok(0,1);             # failure: '0' ne '1'
ok('broke','fixed'); # failure: 'broke' ne 'fixed'
ok('fixed','fixed'); # success: 'fixed' eq 'fixed'
ok('fixed',qr/x/);   # success: 'fixed' =~ qr/x/
```

(continues on next page)

(continued from previous page)

```
ok(sub { 1+1 }, 2);  # success: '2' eq '2'
ok(sub { 1+1 }, 3);  # failure: '2' ne '3'

my @list = (0,0);
ok @list, 3, "\@list=".join(',',@list);      #extra notes
ok 'segmentation fault', '/(?i)success/';    #regex match

skip(
  $^O =~ m/MSWin/ ? "Skip if MSWin" : 0,  # whether to skip
  $foo, $bar  # arguments just like for ok(...)
);
skip(
  $^O =~ m/MSWin/ ? 0 : "Skip unless MSWin",  # whether to skip
  $foo, $bar  # arguments just like for ok(...)
);
```

DESCRIPTION

This module simplifies the task of writing test files for Perl modules, such that their output is in the format that *Test::Harness* expects to see.

QUICK START GUIDE

To write a test for your new (and probably not even done) module, create a new file called `t/test.t` (in a new `t` directory). If you have multiple test files, to test the "foo", "bar", and "baz" feature sets, then feel free to call your files `t/foo.t`, `t/bar.t`, and `t/baz.t`

Functions

This module defines three public functions, `plan(...)`, `ok(...)`, and `skip(...)`. By default, all three are exported by the `use Test;` statement.

- `plan(...)`

  ```
  BEGIN { plan %theplan; }
  ```

  This should be the first thing you call in your test script. It declares your testing plan, how many there will be, if any of them should be allowed to fail, and so on.

  Typical usage is just:

  ```
  use Test;
  BEGIN { plan tests => 23 }
  ```

  These are the things that you can put in the parameters to plan:

  - `tests => _number_`

    The number of tests in your script. This means all ok() and skip() calls.

  - `todo => [_1,5,14_]`

A reference to a list of tests which are allowed to fail. See "TODO TESTS".

- `onfail => sub { ... }`
- `onfail => \&some_sub`

  A subroutine reference to be run at the end of the test script, if any of the tests fail. See "ONFAIL".

You must call `plan(...)` once and only once. You should call it in a `BEGIN {...}` block, like so:

```
BEGIN { plan tests => 23 }
```

- `ok(...)`

```
ok(1 + 1 == 2);
ok($have, $expect);
ok($have, $expect, $diagnostics);
```

This function is the reason for `Test`'s existence. It's the basic function that handles printing "ok" or "not ok", along with the current test number. (That's what `Test::Harness` wants to see.)

In its most basic usage, `ok(...)` simply takes a single scalar expression. If its value is true, the test passes; if false, the test fails. Examples:

```
# Examples of ok(scalar)

ok( 1 + 1 == 2 );           # ok if 1 + 1 == 2
ok( $foo =~ /bar/ );        # ok if $foo contains 'bar'
ok( baz($x + $y) eq 'Armondo' );    # ok if baz($x + $y) returns
                                    # 'Armondo'
ok( @a == @b );             # ok if @a and @b are the same
                            # length
```

The expression is evaluated in scalar context. So the following will work:

```
ok( @stuff );                       # ok if @stuff has any
                                    # elements
ok( !grep !defined $_, @stuff );    # ok if everything in @stuff
                                    # is defined.
```

A special case is if the expression is a subroutine reference (in either `sub {...}` syntax or `\&foo` syntax). In that case, it is executed and its value (true or false) determines if the test passes or fails. For example,

```
ok( sub {   # See whether sleep works at least passably
  my $start_time = time;
  sleep 5;
  time() - $start_time  >= 4
});
```

In its two-argument form, `ok(_arg1_, _arg2_)` compares the two scalar values to see if they match. They match if both are undefined, or if *arg2* is a regex that

matches *arg1*, or if they compare equal with eq.

```
# Example of ok(scalar, scalar)

ok( "this", "that" );                # not ok, 'this' ne 'that'
ok( "", undef );                     # not ok, "" is defined
```

The second argument is considered a regex if it is either a regex object or a string that looks like a regex. Regex objects are constructed with the qr// operator in recent versions of perl. A string is considered to look like a regex if its first and last characters are "/", or if the first character is "m" and its second and last characters are both the same non-alphanumeric non-whitespace character. These regexp

Regex examples:

```
ok( 'JaffO', '/Jaff/' );    # ok, 'JaffO' =~ /Jaff/
ok( 'JaffO', 'm|Jaff|' );   # ok, 'JaffO' =~ m|Jaff|
ok( 'JaffO', qr/Jaff/ );    # ok, 'JaffO' =~ qr/Jaff/;
ok( 'JaffO', '/(?i)jaff/ ); # ok, 'JaffO' =~ /jaff/i;
```

If either (or both!) is a subroutine reference, it is run and used as the value for comparing. For example:

```
ok sub {
    open(OUT, '>', 'x.dat') || die $!;
    print OUT "\x{e000}";
    close OUT;
    my $bytecount = -s 'x.dat';
    unlink 'x.dat' or warn "Can't unlink : $!";
    return $bytecount;
  },
  4
;
```

The above test passes two values to `ok(arg1, arg2)` – the first a coderef, and the second is the number 4. Before ok compares them, it calls the coderef, and uses its return value as the real value of this parameter. Assuming that `$bytecount` returns 4, ok ends up testing `4 eq 4`. Since that's true, this test passes.

Finally, you can append an optional third argument, in `ok(_arg1_,_arg2_, _note_)`, where *note* is a string value that will be printed if the test fails. This should be some useful information about the test, pertaining to why it failed, and/or a description of the test. For example:

```
ok( grep($_ eq 'something unique', @stuff), 1,
    "Something that should be unique isn't!\n".
    '@stuff = '.join ', ', @stuff
  );
```

Unfortunately, a note cannot be used with the single argument style of `ok()`. That is, if you try `ok(_arg1_, _note_)`, then `Test` will interpret this as `ok(_arg1_, _arg2_)`, and probably end up testing `_arg1_ eq _arg2_` – and that's not what you want!

All of the above special cases can occasionally cause some problems. See "BUGS and CAVEATS".

- `skip(_skip_if_true_, _args..._)`

  This is used for tests that under some conditions can be skipped. It's basically equivalent to:

```
if( $skip_if_true ) {
  ok(1);
} else {
  ok( args... );
}
```

  ...except that the `ok(1)` emits not just "`ok _testnum_`" but actually "`ok _testnum_ # _skip_if_true_value_`".

  The arguments after the *skip_if_true* are what is fed to `ok(...)` if this test isn't skipped.

  Example usage:

```
my $if_MSWin =
  $^O =~ m/MSWin/ ? 'Skip if under MSWin' : '';

# A test to be skipped if under MSWin (i.e., run except under
# MSWin)
skip($if_MSWin, thing($foo), thing($bar) );
```

  Or, going the other way:

```
my $unless_MSWin =
  $^O =~ m/MSWin/ ? '' : 'Skip unless under MSWin';

# A test to be skipped unless under MSWin (i.e., run only under
# MSWin)
skip($unless_MSWin, thing($foo), thing($bar) );
```

  The tricky thing to remember is that the first parameter is true if you want to *skip* the test, not *run* it; and it also doubles as a note about why it's being skipped. So in the first codeblock above, read the code as "skip if MSWin – (otherwise) test whether `thing($foo)` is `thing($bar)`" or for the second case, "skip unless MSWin...".

  Also, when your *skip_if_reason* string is true, it really should (for backwards compatibility with older Test.pm versions) start with the string "Skip", as shown in the above examples.

  Note that in the above cases, `thing($foo)` and `thing($bar)` *are* evaluated – but as long as the `skip_if_true` is true, then we `skip(...)` just tosses out their value (i.e., not bothering to treat them like values to `ok(...)`. But if you need to *not* eval the arguments when skipping the test, use this format:

```
skip( $unless_MSWin,
  sub {
    # This code returns true if the test passes.
    # (But it doesn't even get called if the test is skipped.)
    thing($foo) eq thing($bar)
  }
);
```

or even this, which is basically equivalent:

```
skip( $unless_MSWin,
  sub { thing($foo) }, sub { thing($bar) }
);
```

That is, both are like this:

```
if( $unless_MSWin ) {
  ok(1);  # but it actually appends "# $unless_MSWin"
          #  so that Test::Harness can tell it's a skip
} else {
  # Not skipping, so actually call and evaluate...
  ok( sub { thing($foo) }, sub { thing($bar) } );
}
```

TEST TYPES

- NORMAL TESTS

  These tests are expected to succeed. Usually, most or all of your tests are in this category. If a normal test doesn't succeed, then that means that something is *wrong*.

- SKIPPED TESTS

  The `skip(...)` function is for tests that might or might not be possible to run, depending on the availability of platform-specific features. The first argument should evaluate to true (think "yes, please skip") if the required feature is *not* available. After the first argument, `skip(...)` works exactly the same way as `ok(...)` does.

- TODO TESTS

  TODO tests are designed for maintaining an **executable TODO list**. These tests are *expected to fail.* If a TODO test does succeed, then the feature in question shouldn't be on the TODO list, now should it?

  Packages should NOT be released with succeeding TODO tests. As soon as a TODO test starts working, it should be promoted to a normal test, and the newly working feature should be documented in the release notes or in the change log.

ONFAIL

```
BEGIN { plan test => 4, onfail => sub { warn "CALL 911!" } }
```

Although test failures should be enough, extra diagnostics can be triggered at the end of a test run. `onfail` is passed an array ref of hash refs that describe each test failure. Each hash will contain at least the following fields: `package`, `repetition`, and `result`. (You shouldn't rely on any other fields being present.) If the test had an expected value or a diagnostic (or "note") string, these will also be included.

The *optional* `onfail` hook might be used simply to print out the version of your package and/or how to report problems. It might also be used to generate extremely sophisticated diagnostics for a particularly bizarre test failure. However it's not a panacea. Core dumps or other unrecoverable errors prevent the `onfail` hook from running. (It is run inside an `END` block.) Besides, `onfail` is probably over-kill in most cases. (Your test code should be simpler than the code it is testing, yes?)

BUGS and CAVEATS

- `ok(...)`'s special handing of strings which look like they might be regexes can also cause unexpected behavior. An innocent:

```
ok( $fileglob, '/path/to/some/*stuff/' );
```

  will fail, since Test.pm considers the second argument to be a regex! The best bet is to use the one-argument form:

```
ok( $fileglob eq '/path/to/some/*stuff/' );
```

- `ok(...)`'s use of string `eq` can sometimes cause odd problems when comparing numbers, especially if you're casting a string to a number:

```
$foo = "1.0";
ok( $foo, 1 );      # not ok, "1.0" ne 1
```

  Your best bet is to use the single argument form:

```
ok( $foo == 1 );    # ok "1.0" == 1
```

- As you may have inferred from the above documentation and examples, `ok`'s prototype is `($;$$)` (and, incidentally, `skip`'s is `($;$$$)`). This means, for example, that you can do `ok @foo, @bar` to compare the *size* of the two arrays. But don't be fooled into thinking that `ok @foo, @bar` means a comparison of the contents of two arrays – you're comparing *just* the number of elements of each. It's so easy to make that mistake in reading `ok @foo, @bar` that you might want to be very explicit about it, and instead write `ok scalar(@foo), scalar(@bar)`.

- This almost definitely doesn't do what you expect:

```
ok $thingy->can('some_method');
```

  Why? Because `can` returns a coderef to mean "yes it can (and the method is this...)", and then `ok` sees a coderef and thinks you're passing a function that you want it to call and consider the truth of the result of! I.e., just like:

```
ok $thingy->can('some_method')->();
```

  What you probably want instead is this:

```
ok $thingy->can('some_method') && 1;
```

If the `can` returns false, then that is passed to `ok`. If it returns true, then the larger expression `$thingy->can('some_method') && 1` returns 1, which `ok` sees as a simple signal of success, as you would expect.

- The syntax for `skip` is about the only way it can be, but it's still quite confusing. Just start with the above examples and you'll be okay.

  Moreover, users may expect this:

```
skip $unless_mswin, foo($bar), baz($quux);
```

  to not evaluate `foo($bar)` and `baz($quux)` when the test is being skipped. But in reality, they *are* evaluated, but `skip` just won't bother comparing them if `$unless_mswin` is true.

  You could do this:

```
skip $unless_mswin, sub{foo($bar)}, sub{baz($quux)};
```

  But that's not terribly pretty. You may find it simpler or clearer in the long run to just do things like this:

```
if( $^O =~ m/MSWin/ ) {
  print "# Yay, we're under $^O\n";
  ok foo($bar), baz($quux);
  ok thing($whatever), baz($stuff);
  ok blorp($quux, $whatever);
  ok foo($barzbarz), thang($quux);
} else {
  print "# Feh, we're under $^O.  Watch me skip some tests...\n
 ↪";
  for(1 .. 4) { skip "Skip unless under MSWin" }
}
```

  But be quite sure that `ok` is called exactly as many times in the first block as `skip` is called in the second block.

ENVIRONMENT

If `PERL_TEST_DIFF` environment variable is set, it will be used as a command for comparing unexpected multiline results. If you have GNU diff installed, you might want to set `PERL_TEST_DIFF` to `diff -u`. If you don't have a suitable program, you might install the `Text::Diff` module and then set `PERL_TEST_DIFF` to be `perl \-MText::Diff -e 'print diff(@ARGV)'`. If `PERL_TEST_DIFF` isn't set but the `Algorithm::Diff` module is available, then it will be used to show the differences in multiline results.

NOTE

A past developer of this module once said that it was no longer being actively developed. However, rumors of its demise were greatly exaggerated. Feedback and suggestions are quite welcome.

Be aware that the main value of this module is its simplicity. Note that there are already more ambitious modules out there, such as *Test::More* and Test::Unit.

Some earlier versions of this module had docs with some confusing typos in the description of `skip(...)`.

SEE ALSO

Test::Harness

Test::Simple, *Test::More*, *Devel::Cover*

Test::Builder for building your own testing library.

Test::Unit is an interesting XUnit-style testing library.

Test::Inline lets you embed tests in code.

Modules

- `Test::Builder` - Backend for building test libraries
- `Test::Harness` - Run Perl standard test scripts with statistics
- `Test::LeakTrace` - Find the scalars, arrays, hashes and code a block of Perl leaves behind.
- `Test::More` - yet another framework for writing test scripts
- `Test::Simple` - Basic utilities for writing tests.
- `Test::Tester` - Ease testing test modules built with Test::Builder
- `Test::use`

Test::Builder

Backend for building test libraries

SYNOPSIS

```
package My::Test::Module;
use base 'Test::Builder::Module';

my $CLASS = __PACKAGE__;

sub ok {
    my($test, $name) = @_;
    my $tb = $CLASS->builder;

    $tb->ok($test, $name);
}
```

DESCRIPTION

Test::Simple and *Test::More* have proven to be popular testing modules, but they're not always flexible enough. Test::Builder provides a building block upon which to write your own test libraries *which can work together*.

Construction

- **new**

  ```
  my $Test = Test::Builder->new;
  ```

  Returns a Test::Builder object representing the current state of the test.

  Since you only run one test per program `new` always returns the same Test::Builder object. No matter how many times you call `new()`, you're getting the same object. This is called a singleton. This is done so that multiple modules share such global information as the test counter and where test output is going.

  If you want a completely new Test::Builder object different from the singleton, use `create`.

- **create**

  ```
  my $Test = Test::Builder->create;
  ```

  Ok, so there can be more than one Test::Builder object and this is how you get it. You might use this instead of `new()` if you're testing a Test::Builder based module, but otherwise you probably want `new`.

  NOTE: the implementation is not complete. `level`, for example, is still shared by **all** Test::Builder objects, even ones created using this method. Also, the method name may change in the future.

- **subtest**

  ```
  $builder->subtest($name, \&subtests, @args);
  ```

  See documentation of `subtest` in Test::More.

`subtest` also, and optionally, accepts arguments which will be passed to the subtests reference.

- **name**

```
diag $builder->name;
```

Returns the name of the current builder. Top level builders default to `$0` (the name of the executable). Child builders are named via the `child` method. If no name is supplied, will be named "Child of $parent->name".

- **reset**

```
$Test->reset;
```

Reinitializes the Test::Builder singleton to its original state. Mostly useful for tests run in persistent environments where the same test might be run multiple times in the same process.

Setting up tests

These methods are for setting up tests and declaring how many there are. You usually only want to call one of these methods.

- **plan**

```
$Test->plan('no_plan');
$Test->plan( skip_all => $reason );
$Test->plan( tests => $num_tests );
```

A convenient way to set up your tests. Call this and Test::Builder will print the appropriate headers and take the appropriate actions.

If you call `plan()`, don't call any of the other methods below.

- **expected_tests**

```
my $max = $Test->expected_tests;
$Test->expected_tests($max);
```

Gets/sets the number of tests we expect this test to run and prints out the appropriate headers.

- **no_plan**

```
$Test->no_plan;
```

Declares that this test will run an indeterminate number of tests.

- **done_testing**

```
$Test->done_testing();
$Test->done_testing($num_tests);
```

Declares that you are done testing, no more tests will be run after this point.

If a plan has not yet been output, it will do so.

$num_tests is the number of tests you planned to run. If a numbered plan was already declared, and if this contradicts, a failing test will be run to reflect the planning mistake. If no_plan was declared, this will override.

If done_testing() is called twice, the second call will issue a failing test.

If $num_tests is omitted, the number of tests run will be used, like no_plan.

done_testing() is, in effect, used when you'd want to use no_plan, but safer. You'd use it like so:

```
$Test->ok($a == $b);
$Test->done_testing();
```

Or to plan a variable number of tests:

```
for my $test (@tests) {
    $Test->ok($test);
}
$Test->done_testing(scalar @tests);
```

- **has_plan**

```
$plan = $Test->has_plan
```

Find out whether a plan has been defined. $plan is either undef (no plan has been set), no_plan (indeterminate # of tests) or an integer (the number of expected tests).

- **skip_all**

```
$Test->skip_all;
$Test->skip_all($reason);
```

Skips all the tests, using the given $reason. Exits immediately with 0.

- **exported_to**

```
my $pack = $Test->exported_to;
$Test->exported_to($pack);
```

Tells Test::Builder what package you exported your functions to.

This method isn't terribly useful since modules which share the same Test::Builder object might get exported to different packages and only the last one will be honored.

Running tests

These actually run the tests, analogous to the functions in Test::More.

They all return true if the test passed, false if the test failed.

$name is always optional.

- **ok**

```
$Test->ok($test, $name);
```

Your basic test. Pass if `$test` is true, fail if $test is false. Just like Test::Simple's `ok()`.

- **is_eq**

```
$Test->is_eq($got, $expected, $name);
```

Like Test::More's `is()`. Checks if `$got eq $expected`. This is the string version.

`undef` only ever matches another `undef`.

- **is_num**

```
$Test->is_num($got, $expected, $name);
```

Like Test::More's `is()`. Checks if `$got == $expected`. This is the numeric version.

`undef` only ever matches another `undef`.

- **isnt_eq**

```
$Test->isnt_eq($got, $dont_expect, $name);
```

Like *Test::More*'s `isnt()`. Checks if `$got ne $dont_expect`. This is the string version.

- **isnt_num**

```
$Test->isnt_num($got, $dont_expect, $name);
```

Like *Test::More*'s `isnt()`. Checks if `$got ne $dont_expect`. This is the numeric version.

- **like**

```
$Test->like($thing, qr/$regex/, $name);
$Test->like($thing, '/$regex/', $name);
```

Like *Test::More*'s `like()`. Checks if $thing matches the given `$regex`.

- **unlike**

```
$Test->unlike($thing, qr/$regex/, $name);
$Test->unlike($thing, '/$regex/', $name);
```

Like *Test::More*'s `unlike()`. Checks if $thing **does not match** the given `$regex`.

- **cmp_ok**

```
$Test->cmp_ok($thing, $type, $that, $name);
```

Works just like *Test::More*'s `cmp_ok()`.

```
$Test->cmp_ok($big_num, '!=', $other_big_num);
```

Other Testing Methods

These are methods which are used in the course of writing a test but are not themselves tests.

- **BAIL_OUT**

```
$Test->BAIL_OUT($reason);
```

  Indicates to the *Test::Harness* that things are going so badly all testing should terminate. This includes running any additional test scripts.

  It will exit with 255.

- **skip**

```
$Test->skip;
$Test->skip($why);
```

  Skips the current test, reporting `$why`.

- **todo_skip**

```
$Test->todo_skip;
$Test->todo_skip($why);
```

  Like `skip()`, only it will declare the test as failing and TODO. Similar to

```
print "not ok $tnum # TODO $why\n";
```

Test building utility methods

These methods are useful when writing your own test methods.

- **maybe_regex**

```
$Test->maybe_regex(qr/$regex/);
$Test->maybe_regex('/$regex/');
```

  This method used to be useful back when Test::Builder worked on Perls before 5.6 which didn't have qr//. Now its pretty useless.

  Convenience method for building testing functions that take regular expressions as arguments.

  Takes a quoted regular expression produced by `qr//`, or a string representing a regular expression.

  Returns a Perl value which may be used instead of the corresponding regular expression, or `undef` if its argument is not recognized.

  For example, a version of `like()`, sans the useful diagnostic messages, could be written as:

```
sub laconic_like {
    my ($self, $thing, $regex, $name) = @_;
    my $usable_regex = $self->maybe_regex($regex);
    die "expecting regex, found '$regex'\n"
        unless $usable_regex;
    $self->ok($thing =~ m/$usable_regex/, $name);
}
```

- **is_fh**

```
my $is_fh = $Test->is_fh($thing);
```

Determines if the given `$thing` can be used as a filehandle.

Test style

- **level**

```
$Test->level($how_high);
```

How far up the call stack should `$Test` look when reporting where the test failed.

Defaults to 1.

Setting `$Test::Builder::Level` overrides. This is typically useful localized:

```
sub my_ok {
    my $test = shift;

    local $Test::Builder::Level = $Test::Builder::Level + 1;
    $TB->ok($test);
}
```

To be polite to other functions wrapping your own you usually want to increment `$Level` rather than set it to a constant.

- **use_numbers**

```
$Test->use_numbers($on_or_off);
```

Whether or not the test should output numbers. That is, this if true:

```
ok 1
ok 2
ok 3
```

or this if false

```
ok
ok
ok
```

Most useful when you can't depend on the test output order, such as when threads or forking is involved.

Defaults to on.

- **no_diag**

```
$Test->no_diag($no_diag);
```

If set true no diagnostics will be printed. This includes calls to `diag()`.

- **no_ending**

```
$Test->no_ending($no_ending);
```

Normally, Test::Builder does some extra diagnostics when the test ends. It also changes the exit code as described below.

If this is true, none of that will be done.

- **no_header**

```
$Test->no_header($no_header);
```

If set to true, no "1..N" header will be printed.

Output

Controlling where the test output goes.

It's ok for your test to change where STDOUT and STDERR point to, Test::Builder's default output settings will not be affected.

- **diag**

```
$Test->diag(@msgs);
```

Prints out the given `@msgs`. Like `print`, arguments are simply appended together.

Normally, it uses the `failure_output()` handle, but if this is for a TODO test, the `todo_output()` handle is used.

Output will be indented and marked with a # so as not to interfere with test output. A newline will be put on the end if there isn't one already.

We encourage using this rather than calling print directly.

Returns false. Why? Because `diag()` is often used in conjunction with a failing test (`ok() || diag()`) it "passes through" the failure.

```
return ok(...) || diag(...);
```

- **note**

```
$Test->note(@msgs);
```

Like `diag()`, but it prints to the `output()` handle so it will not normally be seen by the user except in verbose mode.

- **explain**

```
my @dump = $Test->explain(@msgs);
```

Will dump the contents of any references in a human readable format. Handy for things like...

```
is_deeply($have, $want) || diag explain $have;
```

or

```
is_deeply($have, $want) || note explain $have;
```

- **output**
- **failure_output**
- **todo_output**

```
my $filehandle = $Test->output;
$Test->output($filehandle);
$Test->output($filename);
$Test->output(\$scalar);
```

These methods control where Test::Builder will print its output. They take either an open `$filehandle`, a `$filename` to open and write to or a `$scalar` reference to append to. It will always return a `$filehandle`.

output is where normal "ok/not ok" test output goes.

Defaults to STDOUT.

failure_output is where diagnostic output on test failures and `diag()` goes. It is normally not read by Test::Harness and instead is displayed to the user.

Defaults to STDERR.

`todo_output` is used instead of `failure_output()` for the diagnostics of a failing TODO test. These will not be seen by the user.

Defaults to STDOUT.

- reset_outputs

```
$tb->reset_outputs;
```

Resets all the output filehandles back to their defaults.

- carp

```
$tb->carp(@message);
```

Warns with `@message` but the message will appear to come from the point where the original test function was called (`$tb->caller`).

- croak

```
$tb->croak(@message);
```

Dies with `@message` but the message will appear to come from the point where the original test function was called (`$tb->caller`).

Test Status and Info

- **no_log_results**

  This will turn off result long-term storage. Calling this method will make `details` and `summary` useless. You may want to use this if you are running enough tests to fill up all available memory.

```
Test::Builder->new->no_log_results();
```

  There is no way to turn it back on.

- **current_test**

```
my $curr_test = $Test->current_test;
$Test->current_test($num);
```

  Gets/sets the current test number we're on. You usually shouldn't have to set this.

  If set forward, the details of the missing tests are filled in as 'unknown'. if set backward, the details of the intervening tests are deleted. You can erase history if you really want to.

- **is_passing**

```
my $ok = $builder->is_passing;
```

  Indicates if the test suite is currently passing.

  More formally, it will be false if anything has happened which makes it impossible for the test suite to pass. True otherwise.

  For example, if no tests have run `is_passing()` will be true because even though a suite with no tests is a failure you can add a passing test to it and start passing.

  Don't think about it too much.

- **summary**

```
my @tests = $Test->summary;
```

  A simple summary of the tests so far. True for pass, false for fail. This is a logical pass/fail, so todos are passes.

  Of course, test #1 is $tests[0], etc...

- **details**

```
my @tests = $Test->details;
```

  Like `summary()`, but with a lot more detail.

```
$tests[$test_num - 1] =
        { 'ok'       => is the test considered a pass?
          actual_ok  => did it literally say 'ok'?
          name       => name of the test (if any)
          type       => type of test (if any, see below).
          reason     => reason for the above (if any)
        };
```

'ok' is true if Test::Harness will consider the test to be a pass.

'actual_ok' is a reflection of whether or not the test literally printed 'ok' or 'not ok'. This is for examining the result of 'todo' tests.

'name' is the name of the test.

'type' indicates if it was a special test. Normal tests have a type of ''. Type can be one of the following:

```
skip        see skip()
todo        see todo()
todo_skip   see todo_skip()
unknown     see below
```

Sometimes the Test::Builder test counter is incremented without it printing any test output, for example, when `current_test()` is changed. In these cases, Test::Builder doesn't know the result of the test, so its type is 'unknown'. These details for these tests are filled in. They are considered ok, but the name and actual_ok is left `undef`.

For example "not ok 23 - hole count # TODO insufficient donuts" would result in this structure:

```
$tests[22] =    # 23 - 1, since arrays start from 0.
  { ok        => 1,   # logically, the test passed since its
↪todo
    actual_ok => 0,   # in absolute terms, it failed
    name      => 'hole count',
    type      => 'todo',
    reason    => 'insufficient donuts'
  };
```

- **todo**

```
my $todo_reason = $Test->todo;
my $todo_reason = $Test->todo($pack);
```

If the current tests are considered "TODO" it will return the reason, if any. This reason can come from a `$TODO` variable or the last call to `todo_start()`.

Since a TODO test does not need a reason, this function can return an empty string even when inside a TODO block. Use `$Test->in_todo` to determine if you are currently inside a TODO block.

`todo()` is about finding the right package to look for `$TODO` in. It's pretty good at guessing the right package to look at. It first looks for the caller based on `$Level`

+ 1, since `todo()` is usually called inside a test function. As a last resort it will use `exported_to()`.

Sometimes there is some confusion about where `todo()` should be looking for the `$TODO` variable. If you want to be sure, tell it explicitly what $pack to use.

- **find_TODO**

```
my $todo_reason = $Test->find_TODO();
my $todo_reason = $Test->find_TODO($pack);
```

Like `todo()` but only returns the value of `$TODO` ignoring `todo_start()`.

Can also be used to set `$TODO` to a new value while returning the old value:

```
my $old_reason = $Test->find_TODO($pack, 1, $new_reason);
```

- **in_todo**

```
my $in_todo = $Test->in_todo;
```

Returns true if the test is currently inside a TODO block.

- **todo_start**

```
$Test->todo_start();
$Test->todo_start($message);
```

This method allows you declare all subsequent tests as TODO tests, up until the `todo_end` method has been called.

The `TODO:` and `$TODO` syntax is generally pretty good about figuring out whether or not we're in a TODO test. However, often we find that this is not possible to determine (such as when we want to use `$TODO` but the tests are being executed in other packages which can't be inferred beforehand).

Note that you can use this to nest "todo" tests

```
$Test->todo_start('working on this');
# lots of code
$Test->todo_start('working on that');
# more code
$Test->todo_end;
$Test->todo_end;
```

This is generally not recommended, but large testing systems often have weird internal needs.

We've tried to make this also work with the TODO: syntax, but it's not guaranteed and its use is also discouraged:

```
TODO: {
    local $TODO = 'We have work to do!';
    $Test->todo_start('working on this');
    # lots of code
```

(continues on next page)

(continued from previous page)

```
    $Test->todo_start('working on that');
    # more code
    $Test->todo_end;
    $Test->todo_end;
}
```

Pick one style or another of "TODO" to be on the safe side.

- `todo_end`

```
$Test->todo_end;
```

Stops running tests as "TODO" tests. This method is fatal if called without a preceding `todo_start` method call.

- **caller**

```
my $package = $Test->caller;
my($pack, $file, $line) = $Test->caller;
my($pack, $file, $line) = $Test->caller($height);
```

Like the normal `caller()`, except it reports according to your `level()`.

`$height` will be added to the `level()`.

If `caller()` winds up off the top of the stack it report the highest context.

EXIT CODES

If all your tests passed, Test::Builder will exit with zero (which is normal). If anything failed it will exit with how many failed. If you run less (or more) tests than you planned, the missing (or extras) will be considered failures. If no tests were ever run Test::Builder will throw a warning and exit with 255. If the test died, even after having successfully completed all its tests, it will still be considered a failure and will exit with 255.

So the exit codes are...

```
0                   all tests successful
255                 test died or all passed but wrong # of tests run
any other number    how many failed (including missing or extras)
```

If you fail more than 254 tests, it will be reported as 254.

THREADS

In perl 5.8.1 and later, Test::Builder is thread-safe. The test number is shared by all threads. This means if one thread sets the test number using `current_test()` they will all be affected.

While versions earlier than 5.8.1 had threads they contain too many bugs to support.

Test::Builder is only thread-aware if threads.pm is loaded *before* Test::Builder.

You can directly disable thread support with one of the following:

```
$ENV{T2_NO_IPC} = 1
```

or

```
no Test2::IPC;
```

or

```
Test2::API::test2_ipc_disable()
```

MEMORY

An informative hash, accessible via `details()`, is stored for each test you perform. So memory usage will scale linearly with each test run. Although this is not a problem for most test suites, it can become an issue if you do large (hundred thousands to million) combinatorics tests in the same run.

In such cases, you are advised to either split the test file into smaller ones, or use a reverse approach, doing "normal" (code) compares and triggering `fail()` should anything go unexpected.

Future versions of Test::Builder will have a way to turn history off.

EXAMPLES

CPAN can provide the best examples. *Test::Simple*, *Test::More*, Test::Exception and Test::Differences all use Test::Builder.

Test::Builder::Formatter

Test::Builder subclass of Test2::Formatter::TAP

DESCRIPTION

This is what takes events and turns them into TAP.

SYNOPSIS

```
use Test::Builder; # Loads Test::Builder::Formatter for you
```

SOURCE

Test::Builder::Module

Base class for test modules

SYNOPSIS

```
# Emulates Test::Simple
package Your::Module;

my $CLASS = __PACKAGE__;

use parent 'Test::Builder::Module';
@EXPORT = qw(ok);

sub ok ($;$) {
    my $tb = $CLASS->builder;
    return $tb->ok(@_);
}

1;
```

DESCRIPTION

This is a superclass for *Test::Builder*-based modules. It provides a handful of common functionality and a method of getting at the underlying *Test::Builder* object.

Importing

Test::Builder::Module is a subclass of *Exporter* which means your module is also a subclass of Exporter. @EXPORT, @EXPORT_OK, etc... all act normally.

A few methods are provided to do the `use Your::Module tests => 23` part for you.

import

Test::Builder::Module provides an `import()` method which acts in the same basic way as *Test::More*'s, setting the plan and controlling exporting of functions and variables. This allows your module to set the plan independent of *Test::More*.

All arguments passed to `import()` are passed onto `Your::Module->builder->plan()` with the exception of `import =>[qw(things to import)]`.

```
use Your::Module import => [qw(this that)], tests => 23;
```

says to import the functions `this()` and `that()` as well as set the plan to be 23 tests.

`import()` also sets the `exported_to()` attribute of your builder to be the caller of the `import()` function.

Additional behaviors can be added to your `import()` method by overriding `import_extra()`.

import_extra

```
Your::Module->import_extra(\@import_args);
```

`import_extra()` is called by `import()`. It provides an opportunity for you to add behaviors to your module based on its import list.

Any extra arguments which shouldn't be passed on to `plan()` should be stripped off by this method.

See *Test::More* for an example of its use.

NOTE This mechanism is *VERY ALPHA AND LIKELY TO CHANGE* as it feels like a bit of an ugly hack in its current form.

Builder

Test::Builder::Module provides some methods of getting at the underlying Test::Builder object.

builder

```
my $builder = Your::Class->builder;
```

This method returns the *Test::Builder* object associated with Your::Class. It is not a constructor so you can call it as often as you like.

This is the preferred way to get the *Test::Builder* object. You should *not* get it via `Test::Builder->new` as was previously recommended.

The object returned by `builder()` may change at runtime so you should call `builder()` inside each function rather than store it in a global.

```
sub ok {
    my $builder = Your::Class->builder;

    return $builder->ok(@_);
}
```

SEE ALSO

Test2::Manual::Tooling::TestBuilder describes the improved options for writing testing modules provided by *Test2*.

Test::Builder::Tester

test testsuites that have been built with Test::Builder

SYNOPSIS

```
use Test::Builder::Tester tests => 1;
use Test::More;

test_out("not ok 1 - foo");
test_fail(+1);
fail("foo");
test_test("fail works");
```

DESCRIPTION

A module that helps you test testing modules that are built with *Test::Builder*.

The testing system is designed to be used by performing a three step process for each test you wish to test. This process starts with using `test_out` and `test_err` in advance to declare what the testsuite you are testing will output with *Test::Builder* to stdout and stderr.

You then can run the test(s) from your test suite that call *Test::Builder*. At this point the output of *Test::Builder* is safely captured by *Test::Builder::Tester* rather than being interpreted as real test output.

The final stage is to call `test_test` that will simply compare what you predeclared to what *Test::Builder* actually outputted, and report the results back with a "ok" or "not ok" (with debugging) to the normal output.

Functions

These are the six methods that are exported as default.

- test_out
- test_err

  Procedures for predeclaring the output that your test suite is expected to produce until `test_test` is called. These procedures automatically assume that each line terminates with "\n". So

  ```
  test_out("ok 1","ok 2");
  ```

  is the same as

```
test_out("ok 1\nok 2");
```

which is even the same as

```
test_out("ok 1");
test_out("ok 2");
```

Once `test_out` or `test_err` (or `test_fail` or `test_diag`) have been called, all further output from *Test::Builder* will be captured by *Test::Builder::Tester*. This means that you will not be able perform further tests to the normal output in the normal way until you call `test_test` (well, unless you manually meddle with the output filehandles)

- test_fail

  Because the standard failure message that *Test::Builder* produces whenever a test fails will be a common occurrence in your test error output, and because it has changed between Test::Builder versions, rather than forcing you to call `test_err` with the string all the time like so

  ```
  test_err("# Failed test ($0 at line ".line_num(+1).")");
  ```

  `test_fail` exists as a convenience function that can be called instead. It takes one argument, the offset from the current line that the line that causes the fail is on.

  ```
  test_fail(+1);
  ```

  This means that the example in the synopsis could be rewritten more simply as:

  ```
  test_out("not ok 1 - foo");
  test_fail(+1);
  fail("foo");
  test_test("fail works");
  ```

- test_diag

  As most of the remaining expected output to the error stream will be created by *Test::Builder*'s `diag` function, *Test::Builder::Tester* provides a convenience function `test_diag` that you can use instead of `test_err`.

  The `test_diag` function prepends comment hashes and spacing to the start and newlines to the end of the expected output passed to it and adds it to the list of expected error output. So, instead of writing

  ```
  test_err("# Couldn't open file");
  ```

  you can write

  ```
  test_diag("Couldn't open file");
  ```

  Remember that *Test::Builder*'s diag function will not add newlines to the end of output and test_diag will. So to check

```
Test::Builder->new->diag("foo\n","bar\n");
```

You would do

```
test_diag("foo","bar")
```

without the newlines.

- test_test

  Actually performs the output check testing the tests, comparing the data (with eq) that we have captured from *Test::Builder* against what was declared with `test_out` and `test_err`.

  This takes name/value pairs that affect how the test is run.

  - title (synonym 'name', 'label')

    The name of the test that will be displayed after the ok or `not ok`.

  - skip_out

    Setting this to a true value will cause the test to ignore if the output sent by the test to the output stream does not match that declared with `test_out`.

  - skip_err

    Setting this to a true value will cause the test to ignore if the output sent by the test to the error stream does not match that declared with `test_err`.

  As a convenience, if only one argument is passed then this argument is assumed to be the name of the test (as in the above examples.)

  Once `test_test` has been run test output will be redirected back to the original filehandles that *Test::Builder* was connected to (probably STDOUT and STDERR,) meaning any further tests you run will function normally and cause success/errors for *Test::Harness*.

- line_num

  A utility function that returns the line number that the function was called on. You can pass it an offset which will be added to the result. This is very useful for working out the correct text of diagnostic functions that contain line numbers.

  Essentially this is the same as the `__LINE__` macro, but the `line_num(+3)` idiom is arguably nicer.

In addition to the six exported functions there exists one function that can only be accessed with a fully qualified function call.

- color

  When `test_test` is called and the output that your tests generate does not match that which you declared, `test_test` will print out debug information showing the two conflicting versions. As this output itself is debug information it can be confusing which part of the output is from `test_test` and which was the original output from your original tests. Also, it may be hard to spot things like extraneous whitespace at the end of lines that may cause your test to fail even though the output looks similar.

To assist you `test_test` can colour the background of the debug information to disambiguate the different types of output. The debug output will have its background coloured green and red. The green part represents the text which is the same between the executed and actual output, the red shows which part differs.

The `color` function determines if colouring should occur or not. Passing it a true or false value will enable or disable colouring respectively, and the function called with no argument will return the current setting.

To enable colouring from the command line, you can use the Text::Builder::Tester::Color module like so:

```
perl -Mlib=Text::Builder::Tester::Color test.t
```

Or by including the *Test::Builder::Tester::Color* module directly in the PERL5LIB.

BUGS

Test::Builder::Tester does not handle plans well. It has never done anything special with plans. This means that plans from outside Test::Builder::Tester will affect Test::Builder::Tester, worse plans when using Test::Builder::Tester will affect overall testing. At this point there are no plans to fix this bug as people have come to depend on it, and Test::Builder::Tester is now discouraged in favor of `Test2::API::intercept()`. See https://github.com/Test-More/test-more/issues/667

Calls `Test::Builder->no_ending` turning off the ending tests. This is needed as otherwise it will trip out because we've run more tests than we strictly should have and it'll register any failures we had that we were testing for as real failures.

The color function doesn't work unless *Term::ANSIColor* is compatible with your terminal. Additionally, Win32::Console::ANSI must be installed on windows platforms for color output.

Bugs (and requests for new features) can be reported to the author though GitHub: https://github.com/Test-More/test-more/issues

Modules

- `Test::Builder::Tester::Color` - turn on colour in Test::Builder::Tester

Test::Builder::Tester::Color

turn on colour in Test::Builder::Tester

SYNOPSIS

```
When running a test script

  perl -MTest::Builder::Tester::Color test.t
```

DESCRIPTION

Importing this module causes the subroutine color in Test::Builder::Tester to be called with a true value causing colour highlighting to be turned on in debug output.

The sole purpose of this module is to enable colour highlighting from the command line.

Test::Harness

Run Perl standard test scripts with statistics

VERSION

Version 3.52

SYNOPSIS

```
use Test::Harness;

runtests(@test_files);
```

DESCRIPTION

Although, for historical reasons, the *Test::Harness* distribution takes its name from this module it now exists only to provide *TAP::Harness* with an interface that is somewhat backwards compatible with *Test::Harness* 2.xx. If you're writing new code consider using *TAP::Harness* directly instead.

Emulation is provided for `runtests` and `execute_tests` but the pluggable 'Straps' interface that previous versions of *Test::Harness* supported is not reproduced here. Straps is now available as a stand alone module: Test::Harness::Straps.

See *TAP::Parser*, *TAP::Harness* for the main documentation for this distribution.

FUNCTIONS

The following functions are available.

runtests(@test_files)

This runs all the given *@test_files* and divines whether they passed or failed based on their output to STDOUT (details above). It prints out each individual test which failed along with a summary report and a how long it all took.

It returns true if everything was ok. Otherwise it will `die()` with one of the messages in the DIAGNOSTICS section.

execute_tests(tests => \@test_files, out => *FH)

Runs all the given `@test_files` (just like `runtests()`) but doesn't generate the final report. During testing, progress information will be written to the currently selected output filehandle (usually `STDOUT`), or to the filehandle given by the `out` parameter. The *out* is optional.

Returns a list of two values, `$total` and `$failed`, describing the results. `$total` is a hash ref summary of all the tests run. Its keys and values are this:

```
bonus           Number of individual todo tests unexpectedly passed
max             Number of individual tests ran
ok              Number of individual tests passed
sub_skipped     Number of individual tests skipped
todo            Number of individual todo tests

files           Number of test files ran
good            Number of test files passed
bad             Number of test files failed
tests           Number of test files originally given
skipped         Number of test files skipped
```

If `$total->{bad} == 0` and `$total->{max} > 0`, you've got a successful test.

`$failed` is a hash ref of all the test scripts that failed. Each key is the name of a test script, each value is another hash representing how that script failed. Its keys are these:

```
name        Name of the test which failed
estat       Script's exit value
wstat       Script's wait status
max         Number of individual tests
failed      Number which failed
canon       List of tests which failed (as string).
```

`$failed` should be empty if everything passed.

EXPORT

`&runtests` is exported by `Test::Harness` by default.

`&execute_tests`, `$verbose`, `$switches` and `$debug` are exported upon request.

ENVIRONMENT VARIABLES THAT TAP::HARNESS::COMPATIBLE SETS

`Test::Harness` sets these before executing the individual tests.

- `HARNESS_ACTIVE`

  This is set to a true value. It allows the tests to determine if they are being executed through the harness or by any other means.

- `HARNESS_VERSION`

  This is the version of `Test::Harness`.

ENVIRONMENT VARIABLES THAT AFFECT TEST::HARNESS

- `HARNESS_PERL_SWITCHES`

  Setting this adds perl command line switches to each test file run.

  For example, `HARNESS_PERL_SWITCHES=-T` will turn on taint mode. `HARNESS_PERL_SWITCHES=-MDevel::Cover` will run `Devel::Cover` for each test.

  `-w` is always set. You can turn this off in the test with `BEGIN { $^W = 0 }`.

- `HARNESS_TIMER`

  Setting this to true will make the harness display the number of milliseconds each test took. You can also use `prove`'s `--timer` switch.

- `HARNESS_VERBOSE`

  If true, `Test::Harness` will output the verbose results of running its tests. Setting `$Test::Harness::verbose` will override this, or you can use the `-v` switch in the `prove` utility.

- `HARNESS_OPTIONS`

  Provide additional options to the harness. Currently supported options are:

  – `j<n>`

    Run <n> (default 9) parallel jobs.

  – `c`

    Try to color output. See *"new" in TAP::Formatter::Base*.

  – `a<file.tgz>`

    Will use TAP::Harness::Archive as the harness class, and save the TAP to `file.tgz`

- `fPackage-With-Dashes`

  Set the formatter_class of the harness being run. Since the `HARNESS_OPTIONS` is separated by `:`, we use `-` instead.

Multiple options may be separated by colons:

```
HARNESS_OPTIONS=j9:c make test
```

- `HARNESS_SUBCLASS`

  Specifies a TAP::Harness subclass to be used in place of TAP::Harness.

- `HARNESS_SUMMARY_COLOR_SUCCESS`

  Determines the *Term::ANSIColor* for the summary in case it is successful. This color defaults to `'green'`.

- `HARNESS_SUMMARY_COLOR_FAIL`

  Determines the *Term::ANSIColor* for the failure in case it is successful. This color defaults to `'red'`.

Taint Mode

Normally when a Perl program is run in taint mode the contents of the `PERL5LIB` environment variable do not appear in `@INC`.

Because `PERL5LIB` is often used during testing to add build directories to `@INC` `Test::Harness` passes the names of any directories found in `PERL5LIB` as -I switches. The net effect of this is that `PERL5LIB` is honoured even in taint mode.

Test::LeakTrace

Find the scalars, arrays, hashes and code a block of Perl leaves behind.

Each of the functions runs a block and reports what it allocated and did not free: the values themselves, a count, or a report naming the file and line that created each one. The test functions turn that into a test, so a leak becomes a failing test.

Synopsis

```
use Test::More;
use Test::LeakTrace;

no_leaks_ok { my @a = (1 .. 10); my %h = (a => 1) } 'no leaks';

leaks_cmp_ok { my $x; $x = \$x } '<', 2, 'one cycle at most';

my $count = leaked_count { my $x; $x = \$x };      # 1
my @refs  = leaked_refs  { my $x; $x = \$x };      # (\$x)
my @info  = leaked_info  { my $x; $x = \$x };      # ([\$x, $file,
 ↪$line])

leaktrace { my $x; $x = \$x } -verbose;            # report on␣
 ↪STDERR
done_testing;
```

Reporting modes

`leaktrace BLOCK MODE` reports each leaked value on STDERR. `-simple`, the default, prints its type, address and the line that created it; `-lines` adds the source lines around that line; `-sv_dump` dumps the value as `Devel::Peek` does; `-verbose` is `-lines` and `-sv_dump` together; `-silent` prints nothing. A code reference as MODE is called once per leaked value with a reference to it, the file and the line.

`Test::LeakTrace::Script` runs the whole program under a trace: `perl -MTest::LeakTrace::Script=-verbose script.pl`, or the mode in `TEST_LEAKTRACE`.

This is a native implementation of the XS half of Test::LeakTrace 0.17; its `Test/LeakTrace.pm` and `Test/LeakTrace/Script.pm` are used unchanged. Everything

listed above is exported by default.

Differences from upstream

None.

Modules

- `Test::LeakTrace::Script` - A LeakTrace interface for whole scripts

Test::LeakTrace::Script

A LeakTrace interface for whole scripts

SYNOPSIS

```
#!perl -w
use Test::LeakTrace::Script sub{
        my($svref, $file, $line) = @_;

        warn "leaked $svref from $file line $line.\n";
};
```

DESCRIPTION

This is a interface to `Test::LeakTrace` for whole scripts.

INTERFACE

Command line interface

```
$ perl -MTest::LeakTrace::Script script.pl

$ perl -MTest::LeakTrace::Script=-verbose script.pl

$ TEST_LEAKTRACE=-lines script.pl
```

ENVIRONMENT VARIABLES

TEST_LEAKTRACE=mode

-simple (DEFAULT)

-sv_dump

-lines

-verbose

SEE ALSO

Test::LeakTrace.

Test::More

yet another framework for writing test scripts

SYNOPSIS

```
use Test::More tests => 23;
# or
use Test::More skip_all => $reason;
# or
use Test::More;   # see done_testing()

require_ok( 'Some::Module' );

# Various ways to say "ok"
ok($got eq $expected, $test_name);

is  ($got, $expected, $test_name);
isnt($got, $expected, $test_name);

# Rather than print STDERR "# here's what went wrong\n"
diag("here's what went wrong");

like  ($got, qr/expected/, $test_name);
unlike($got, qr/expected/, $test_name);

cmp_ok($got, '==', $expected, $test_name);

is_deeply($got_complex_structure, $expected_complex_structure,
 ↪$test_name);

SKIP: {
    skip $why, $how_many unless $have_some_feature;

    ok( foo(),       $test_name );
    is( foo(42), 23, $test_name );
};

TODO: {
    local $TODO = $why;

    ok( foo(),       $test_name );
    is( foo(42), 23, $test_name );
};

can_ok($module, @methods);
```

(continues on next page)

(continued from previous page)

```
isa_ok($object, $class);

pass($test_name);
fail($test_name);

BAIL_OUT($why);

# UNIMPLEMENTED!!!
my @status = Test::More::status;
```

DESCRIPTION

STOP! If you're just getting started writing tests, have a look at *Test2::Suite* first.

This is a drop in replacement for Test::Simple which you can switch to once you get the hang of basic testing.

The purpose of this module is to provide a wide range of testing utilities. Various ways to say "ok" with better diagnostics, facilities to skip tests, test future features and compare complicated data structures. While you can do almost anything with a simple ok() function, it doesn't provide good diagnostic output.

I love it when a plan comes together

Before anything else, you need a testing plan. This basically declares how many tests your script is going to run to protect against premature failure.

The preferred way to do this is to declare a plan when you `use Test::More`.

```
use Test::More tests => 23;
```

There are cases when you will not know beforehand how many tests your script is going to run. In this case, you can declare your tests at the end.

```
use Test::More;

... run your tests ...

done_testing( $number_of_tests_run );
```

NOTE `done_testing()` should never be called in an `END { ... }` block.

Sometimes you really don't know how many tests were run, or it's too difficult to calculate. In which case you can leave off $number_of_tests_run.

In some cases, you'll want to completely skip an entire testing script.

```
use Test::More skip_all => $skip_reason;
```

Your script will declare a skip with the reason why you skipped and exit immediately with a zero (success). See *Test::Harness* for details.

If you want to control what functions Test::More will export, you have to use the 'import' option. For example, to import everything but 'fail', you'd do:

```
use Test::More tests => 23, import => ['!fail'];
```

Alternatively, you can use the `plan()` function. Useful for when you have to calculate the number of tests.

```
use Test::More;
plan tests => keys %Stuff * 3;
```

or for deciding between running the tests at all:

```
use Test::More;
if( $^O eq 'MacOS' ) {
    plan skip_all => 'Test irrelevant on MacOS';
}
else {
    plan tests => 42;
}
```

- **done_testing**

  ```
  done_testing();
  done_testing($number_of_tests);
  ```

  If you don't know how many tests you're going to run, you can issue the plan when you're done running tests.

  $number_of_tests is the same as `plan()`, it's the number of tests you expected to run. You can omit this, in which case the number of tests you ran doesn't matter, just the fact that your tests ran to conclusion.

  This is safer than and replaces the "no_plan" plan.

  Note: You must never put `done_testing()` inside an `END { ... }` block. The plan is there to ensure your test does not exit before testing has completed. If you use an END block you completely bypass this protection.

Test names

By convention, each test is assigned a number in order. This is largely done automatically for you. However, it's often very useful to assign a name to each test. Which would you rather see:

```
ok 4
not ok 5
ok 6
```

or

```
ok 4 - basic multi-variable
not ok 5 - simple exponential
ok 6 - force == mass * acceleration
```

The later gives you some idea of what failed. It also makes it easier to find the test in your script, simply search for "simple exponential".

All test functions take a name argument. It's optional, but highly suggested that you use it.

I'm ok, you're not ok.

The basic purpose of this module is to print out either "ok #" or "not ok #" depending on if a given test succeeded or failed. Everything else is just gravy.

All of the following print "ok" or "not ok" depending on if the test succeeded or failed. They all also return true or false, respectively.

- **ok**

```
ok($got eq $expected, $test_name);
```

  This simply evaluates any expression (`$got eq $expected` is just a simple example) and uses that to determine if the test succeeded or failed. A true expression passes, a false one fails. Very simple.

  For example:

```
ok( $exp{9} == 81,                   'simple exponential' );
ok( Film->can('db_Main'),            'set_db()' );
ok( $p->tests == 4,                  'saw tests' );
ok( !grep(!defined $_, @items),      'all items defined' );
```

  (Mnemonic: "This is ok.")

  $test_name is a very short description of the test that will be printed out. It makes it very easy to find a test in your script when it fails and gives others an idea of your intentions. $test_name is optional, but we **very** strongly encourage its use.

  Should an `ok()` fail, it will produce some diagnostics:

```
not ok 18 - sufficient mucus
#   Failed test 'sufficient mucus'
#   in foo.t at line 42.
```

  This is the same as *Test::Simple*'s `ok()` routine.

- **is**
- **isnt**

```
is  ( $got, $expected, $test_name );
isnt( $got, $expected, $test_name );
```

  Similar to `ok()`, `is()` and `isnt()` compare their two arguments with `eq` and `ne` respectively and use the result of that to determine if the test succeeded or failed. So these:

```
# Is the ultimate answer 42?
is( ultimate_answer(), 42,          "Meaning of Life" );

# $foo isn't empty
isnt( $foo, '',     "Got some foo" );
```

are similar to these:

```
ok( ultimate_answer() eq 42,        "Meaning of Life" );
ok( $foo ne '',     "Got some foo" );
```

undef will only ever match undef. So you can test a value against undef like this:

```
is($not_defined, undef, "undefined as expected");
```

(Mnemonic: "This is that." "This isn't that.")

So why use these? They produce better diagnostics on failure. ok() cannot know what you are testing for (beyond the name), but is() and isnt() know what the test was and why it failed. For example this test:

```
my $foo = 'waffle';  my $bar = 'yarblokos';
is( $foo, $bar,   'Is foo the same as bar?' );
```

Will produce something like this:

```
not ok 17 - Is foo the same as bar?
#   Failed test 'Is foo the same as bar?'
#   in foo.t at line 139.
#          got: 'waffle'
#     expected: 'yarblokos'
```

So you can figure out what went wrong without rerunning the test.

You are encouraged to use is() and isnt() over ok() where possible, however do not be tempted to use them to find out if something is true or false!

```
# XXX BAD!
is( exists $brooklyn{tree}, 1, 'A tree grows in Brooklyn' );
```

This does not check if exists $brooklyn{tree} is true, it checks if it returns 1. Very different. Similar caveats exist for false and 0. In these cases, use ok().

```
ok( exists $brooklyn{tree},    'A tree grows in Brooklyn' );
```

A simple call to isnt() usually does not provide a strong test but there are cases when you cannot say much more about a value than that it is different from some other value:

```
new_ok $obj, "Foo";

my $clone = $obj->clone;
isa_ok $obj, "Foo", "Foo->clone";
```

(continues on next page)

(continued from previous page)

```
isnt $obj, $clone, "clone() produces a different object";
```

Historically we supported an `isn't()` function as an alias of `isnt()`, however in Perl 5.37.9 support for the use of apostrophe as a package separator was deprecated and by Perl 5.42.0 support for it will have been removed completely. Accordingly use of `isn't()` is also deprecated, and will produce warnings when used unless 'deprecated' warnings are specifically disabled in the scope where it is used. You are strongly advised to migrate to using `isnt()` instead.

- **like**

```
like( $got, qr/expected/, $test_name );
```

Similar to `ok()`, `like()` matches $got against the regex `qr/expected/`.

So this:

```
like($got, qr/expected/, 'this is like that');
```

is similar to:

```
ok( $got =~ m/expected/, 'this is like that');
```

(Mnemonic "This is like that".)

The second argument is a regular expression. It may be given as a regex reference (i.e. `qr//`) or (for better compatibility with older perls) as a string that looks like a regex (alternative delimiters are currently not supported):

```
like( $got, '/expected/', 'this is like that' );
```

Regex options may be placed on the end (`'/expected/i'`).

Its advantages over `ok()` are similar to that of `is()` and `isnt()`. Better diagnostics on failure.

- **unlike**

```
unlike( $got, qr/expected/, $test_name );
```

Works exactly as `like()`, only it checks if $got **does not** match the given pattern.

- **cmp_ok**

```
cmp_ok( $got, $op, $expected, $test_name );
```

Halfway between `ok()` and `is()` lies `cmp_ok()`. This allows you to compare two arguments using any binary perl operator. The test passes if the comparison is true and fails otherwise.

```
# ok( $got eq $expected );
cmp_ok( $got, 'eq', $expected, 'this eq that' );
```

(continues on next page)

(continued from previous page)

```
# ok( $got == $expected );
cmp_ok( $got, '==', $expected, 'this == that' );

# ok( $got && $expected );
cmp_ok( $got, '&&', $expected, 'this && that' );
...etc...
```

Its advantage over `ok()` is when the test fails you'll know what $got and $expected were:

```
not ok 1
#   Failed test in foo.t at line 12.
#     '23'
#         &&
#     undef
```

It's also useful in those cases where you are comparing numbers and `is()`'s use of eq will interfere:

```
cmp_ok( $big_hairy_number, '==', $another_big_hairy_number );
```

It's especially useful when comparing greater-than or smaller-than relation between values:

```
cmp_ok( $some_value, '<=', $upper_limit );
```

- **can_ok**

```
can_ok($module, @methods);
can_ok($object, @methods);
```

Checks to make sure the $module or $object can do these @methods (works with functions, too).

```
can_ok('Foo', qw(this that whatever));
```

is almost exactly like saying:

```
ok( Foo->can('this') &&
    Foo->can('that') &&
    Foo->can('whatever')
  );
```

only without all the typing and with a better interface. Handy for quickly testing an interface.

No matter how many @methods you check, a single `can_ok()` call counts as one test. If you desire otherwise, use:

```
foreach my $meth (@methods) {
    can_ok('Foo', $meth);
}
```

- **isa_ok**

```
isa_ok($object,   $class, $object_name);
isa_ok($subclass, $class, $object_name);
isa_ok($ref,      $type,  $ref_name);
```

Checks to see if the given `$object->isa($class)`. Also checks to make sure the object was defined in the first place. Handy for this sort of thing:

```
my $obj = Some::Module->new;
isa_ok( $obj, 'Some::Module' );
```

where you'd otherwise have to write

```
my $obj = Some::Module->new;
ok( defined $obj && $obj->isa('Some::Module') );
```

to safeguard against your test script blowing up.

You can also test a class, to make sure that it has the right ancestor:

```
isa_ok( 'Vole', 'Rodent' );
```

It works on references, too:

```
isa_ok( $array_ref, 'ARRAY' );
```

The diagnostics of this test normally just refer to 'the object'. If you'd like them to be more specific, you can supply an $object_name (for example 'Test customer').

- **new_ok**

```
my $obj = new_ok( $class );
my $obj = new_ok( $class => \@args );
my $obj = new_ok( $class => \@args, $object_name );
```

A convenience function which combines creating an object and calling `isa_ok()` on that object.

It is basically equivalent to:

```
my $obj = $class->new(@args);
isa_ok $obj, $class, $object_name;
```

If @args is not given, an empty list will be used.

This function only works on `new()` and it assumes `new()` will return just a single object which isa `$class`.

- **subtest**

```
subtest $name => \&code, @args;
```

`subtest()` runs the &code as its own little test with its own plan and its own result. The main test counts this as a single test using the result of the whole subtest to determine if its ok or not ok.

For example...

```
use Test::More tests => 3;

pass("First test");

subtest 'An example subtest' => sub {
    plan tests => 2;

    pass("This is a subtest");
    pass("So is this");
};

pass("Third test");
```

This would produce.

```
1..3
ok 1 - First test
    # Subtest: An example subtest
    1..2
    ok 1 - This is a subtest
    ok 2 - So is this
ok 2 - An example subtest
ok 3 - Third test
```

A subtest may call `skip_all`. No tests will be run, but the subtest is considered a skip.

```
subtest 'skippy' => sub {
    plan skip_all => 'cuz I said so';
    pass('this test will never be run');
};
```

Returns true if the subtest passed, false otherwise.

Due to how subtests work, you may omit a plan if you desire. This adds an implicit `done_testing()` to the end of your subtest. The following two subtests are equivalent:

```
subtest 'subtest with implicit done_testing()', sub {
    ok 1, 'subtests with an implicit done testing should work';
    ok 1, '... and support more than one test';
    ok 1, '... no matter how many tests are run';
};

subtest 'subtest with explicit done_testing()', sub {
    ok 1, 'subtests with an explicit done testing should work';
    ok 1, '... and support more than one test';
    ok 1, '... no matter how many tests are run';
    done_testing();
};
```

Extra arguments given to `subtest` are passed to the callback. For example:

```
sub my_subtest {
    my $range = shift;
    ...
}

for my $range (1, 10, 100, 1000) {
    subtest "testing range $range", \&my_subtest, $range;
}
```

- **pass**
- **fail**

```
pass($test_name);
fail($test_name);
```

Sometimes you just want to say that the tests have passed. Usually the case is you've got some complicated condition that is difficult to wedge into an `ok()`. In this case, you can simply use `pass()` (to declare the test ok) or fail (for not ok). They are synonyms for `ok(1)` and `ok(0)`.

Use these very, very, very sparingly.

Module tests

Sometimes you want to test if a module, or a list of modules, can successfully load. For example, you'll often want a first test which simply loads all the modules in the distribution to make sure they work before going on to do more complicated testing.

For such purposes we have `use_ok` and `require_ok`.

- **require_ok**

```
require_ok($module);
require_ok($file);
```

Tries to `require` the given $module or $file. If it loads successfully, the test will pass. Otherwise it fails and displays the load error.

`require_ok` will guess whether the input is a module name or a filename.

No exception will be thrown if the load fails.

```
# require Some::Module
require_ok "Some::Module";

# require "Some/File.pl";
require_ok "Some/File.pl";

# stop testing if any of your modules will not load
for my $module (@module) {
    require_ok $module or BAIL_OUT "Can't load $module";
}
```

- **use_ok**

```
BEGIN { use_ok($module); }
BEGIN { use_ok($module, @imports); }
```

Like `require_ok`, but it will `use` the $module in question and only loads modules, not files.

If you just want to test a module can be loaded, use `require_ok`.

If you just want to load a module in a test, we recommend simply using `use` directly. It will cause the test to stop.

It's recommended that you run `use_ok()` inside a BEGIN block so its functions are exported at compile-time and prototypes are properly honored.

If @imports are given, they are passed through to the use. So this:

```
BEGIN { use_ok('Some::Module', qw(foo bar)) }
```

is like doing this:

```
use Some::Module qw(foo bar);
```

Version numbers can be checked like so:

```
# Just like "use Some::Module 1.02"
BEGIN { use_ok('Some::Module', 1.02) }
```

Don't try to do this:

```
BEGIN {
    use_ok('Some::Module');

    ...some code that depends on the use...
    ...happening at compile time...
}
```

because the notion of "compile-time" is relative. Instead, you want:

```
BEGIN { use_ok('Some::Module') }
BEGIN { ...some code that depends on the use... }
```

If you want the equivalent of `use Foo ()`, use a module but not import anything, use `require_ok`.

```
BEGIN { require_ok "Foo" }
```

Complex data structures

Not everything is a simple eq check or regex. There are times you need to see if two data structures are equivalent. For these instances Test::More provides a handful of useful functions.

NOTE I'm not quite sure what will happen with filehandles.

- **is_deeply**

```
is_deeply( $got, $expected, $test_name );
```

Similar to `is()`, except that if $got and $expected are references, it does a deep comparison walking each data structure to see if they are equivalent. If the two structures are different, it will display the place where they start differing.

`is_deeply()` compares the dereferenced values of references, the references themselves (except for their type) are ignored. This means aspects such as blessing and ties are not considered "different".

`is_deeply()` currently has very limited handling of function reference and globs. It merely checks if they have the same referent. This may improve in the future.

Test::Differences and Test::Deep provide more in-depth functionality along these lines.

NOTE is_deeply() has limitations when it comes to comparing strings and refs:

```
my $path = path('.');
my $hash = {};
is_deeply( $path, "$path" ); # ok
is_deeply( $hash, "$hash" ); # fail
```

This happens because is_deeply will unoverload all arguments unconditionally. It is probably best not to use is_deeply with overloading. For legacy reasons this is not likely to ever be fixed. If you would like a much better tool for this you should see *Test2::Suite* Specifically *Test2::Tools::Compare* has an `is()` function that works like `is_deeply` with many improvements.

Diagnostics

If you pick the right test function, you'll usually get a good idea of what went wrong when it failed. But sometimes it doesn't work out that way. So here we have ways for you to write your own diagnostic messages which are safer than just `print STDERR`.

- **diag**

```
diag(@diagnostic_message);
```

Prints a diagnostic message which is guaranteed not to interfere with test output. Like `print` @diagnostic_message is simply concatenated together.

Returns false, so as to preserve failure.

Handy for this sort of thing:

```
ok( grep(/foo/, @users), "There's a foo user" ) or
    diag("Since there's no foo, check that /etc/bar is set up␣
↪right");
```

which would produce:

```
not ok 42 - There's a foo user
#   Failed test 'There's a foo user'
#   in foo.t at line 52.
# Since there's no foo, check that /etc/bar is set up right.
```

You might remember `ok() or diag()` with the mnemonic `open() or die()`.

NOTE The exact formatting of the diagnostic output is still changing, but it is guaranteed that whatever you throw at it won't interfere with the test.

- **note**

```
note(@diagnostic_message);
```

Like `diag()`, except the message will not be seen when the test is run in a harness. It will only be visible in the verbose TAP stream.

Handy for putting in notes which might be useful for debugging, but don't indicate a problem.

```
note("Tempfile is $tempfile");
```

- **explain**

```
my @dump = explain @diagnostic_message;
```

Will dump the contents of any references in a human readable format. Usually you want to pass this into `note` or `diag`.

Handy for things like...

```
is_deeply($have, $want) || diag explain $have;
```

or

```
note explain \%args;
Some::Class->method(%args);
```

Conditional tests

Sometimes running a test under certain conditions will cause the test script to die. A certain function or method isn't implemented (such as `fork()` on MacOS), some resource isn't available (like a net connection) or a module isn't available. In these cases it's necessary to skip tests, or declare that they are supposed to fail but will work in the future (a todo test).

For more details on the mechanics of skip and todo tests see *Test::Harness*.

The way Test::More handles this is with a named block. Basically, a block of tests which can be skipped over or made todo. It's best if I just show you...

- **SKIP: BLOCK**

```
SKIP: {
    skip $why, $how_many if $condition;

    ...normal testing code goes here...
}
```

This declares a block of tests that might be skipped, $how_many tests there are, $why and under what $condition to skip them. An example is the easiest way to illustrate:

```
SKIP: {
    eval { require HTML::Lint };

    skip "HTML::Lint not installed", 2 if $@;

    my $lint = new HTML::Lint;
    isa_ok( $lint, "HTML::Lint" );

    $lint->parse( $html );
    is( $lint->errors, 0, "No errors found in HTML" );
}
```

If the user does not have HTML::Lint installed, the whole block of code *won't be run at all.* Test::More will output special ok's which Test::Harness interprets as skipped, but passing, tests.

It's important that $how_many accurately reflects the number of tests in the SKIP block so the # of tests run will match up with your plan. If your plan is `no_plan` $how_many is optional and will default to 1.

It's perfectly safe to nest SKIP blocks. Each SKIP block must have the label `SKIP`, or Test::More can't work its magic.

You don't skip tests which are failing because there's a bug in your program, or for which you don't yet have code written. For that you use TODO. Read on.

- **TODO: BLOCK**

```
TODO: {
    local $TODO = $why if $condition;

    ...normal testing code goes here...
}
```

Declares a block of tests you expect to fail and $why. Perhaps it's because you haven't fixed a bug or haven't finished a new feature:

```
TODO: {
    local $TODO = "URI::Geller not finished";

    my $card = "Eight of clubs";
    is( URI::Geller->your_card, $card, 'Is THIS your card?' );
```

(continues on next page)

(continued from previous page)

```
    my $spoon;
    URI::Geller->bend_spoon;
    is( $spoon, 'bent',    "Spoon bending, that's original" );
}
```

With a todo block, the tests inside are expected to fail. Test::More will run the tests normally, but print out special flags indicating they are "todo". *Test::Harness* will interpret failures as being ok. Should anything succeed, it will report it as an unexpected success. You then know the thing you had todo is done and can remove the TODO flag.

The nice part about todo tests, as opposed to simply commenting out a block of tests, is that it is like having a programmatic todo list. You know how much work is left to be done, you're aware of what bugs there are, and you'll know immediately when they're fixed.

Once a todo test starts succeeding, simply move it outside the block. When the block is empty, delete it.

Note that, if you leave $TODO unset or undef, Test::More reports failures as normal. This can be useful to mark the tests as expected to fail only in certain conditions, e.g.:

```
TODO: {
    local $TODO = "$^O doesn't work yet. :(" if !_os_is_
↪supported($^O);

    ...
}
```

- **todo_skip**

```
TODO: {
    todo_skip $why, $how_many if $condition;

    ...normal testing code...
}
```

With todo tests, it's best to have the tests actually run. That way you'll know when they start passing. Sometimes this isn't possible. Often a failing test will cause the whole program to die or hang, even inside an `eval BLOCK` with and using `alarm`. In these extreme cases you have no choice but to skip over the broken tests entirely.

The syntax and behavior is similar to a `SKIP: BLOCK` except the tests will be marked as failing but todo. *Test::Harness* will interpret them as passing.

- When do I use SKIP vs. TODO?

  If it's something the user might not be able to do, use SKIP. This includes optional modules that aren't installed, running under an OS that doesn't have some feature (like `fork()` or symlinks), or maybe you need an Internet connection and one isn't available.

  If it's something the programmer hasn't done yet, use TODO. This is for any code

you haven't written yet, or bugs you have yet to fix, but want to put tests in your testing script (always a good idea).

Test control

- **BAIL_OUT**

```
BAIL_OUT($reason);
```

Indicates to the harness that things are going so badly all testing should terminate. This includes the running of any additional test scripts.

This is typically used when testing cannot continue such as a critical module failing to compile or a necessary external utility not being available such as a database connection failing.

The test will exit with 255.

For even better control look at Test::Most.

Discouraged comparison functions

The use of the following functions is discouraged as they are not actually testing functions and produce no diagnostics to help figure out what went wrong. They were written before `is_deeply()` existed because I couldn't figure out how to display a useful diff of two arbitrary data structures.

These functions are usually used inside an `ok()`.

```
ok( eq_array(\@got, \@expected) );
```

`is_deeply()` can do that better and with diagnostics.

```
is_deeply( \@got, \@expected );
```

They may be deprecated in future versions.

- **eq_array**

```
my $is_eq = eq_array(\@got, \@expected);
```

Checks if two arrays are equivalent. This is a deep check, so multi-level structures are handled correctly.

- **eq_hash**

```
my $is_eq = eq_hash(\%got, \%expected);
```

Determines if the two hashes contain the same keys and values. This is a deep check.

- **eq_set**

```
my $is_eq = eq_set(\@got, \@expected);
```

Similar to `eq_array()`, except the order of the elements is **not** important. This is a deep check, but the irrelevancy of order only applies to the top level.

```
ok( eq_set(\@got, \@expected) );
```

Is better written:

```
is_deeply( [sort @got], [sort @expected] );
```

NOTE By historical accident, this is not a true set comparison. While the order of elements does not matter, duplicate elements do.

NOTE `eq_set()` does not know how to deal with references at the top level. The following is an example of a comparison which might not work:

```
eq_set([\1, \2], [\2, \1]);
```

Test::Deep contains much better set comparison functions.

Extending and Embedding Test::More

Sometimes the Test::More interface isn't quite enough. Fortunately, Test::More is built on top of *Test::Builder* which provides a single, unified backend for any test library to use. This means two test libraries which both use *Test::Builder* **can** be used together in the same program.

If you simply want to do a little tweaking of how the tests behave, you can access the underlying *Test::Builder* object like so:

- **builder**

```
my $test_builder = Test::More->builder;
```

Returns the *Test::Builder* object underlying Test::More for you to play with.

EXIT CODES

If all your tests passed, *Test::Builder* will exit with zero (which is normal). If anything failed it will exit with how many failed. If you run less (or more) tests than you planned, the missing (or extras) will be considered failures. If no tests were ever run *Test::Builder* will throw a warning and exit with 255. If the test died, even after having successfully completed all its tests, it will still be considered a failure and will exit with 255.

So the exit codes are...

```
0                   all tests successful
255                 test died or all passed but wrong # of tests run
any other number    how many failed (including missing or extras)
```

If you fail more than 254 tests, it will be reported as 254.

NOTE This behavior may go away in future versions.

COMPATIBILITY

Test::More works with Perls as old as 5.8.1.

Thread support is not very reliable before 5.10.1, but that's because threads are not very reliable before 5.10.1.

Although Test::More has been a core module in versions of Perl since 5.6.2, Test::More has evolved since then, and not all of the features you're used to will be present in the shipped version of Test::More. If you are writing a module, don't forget to indicate in your package metadata the minimum version of Test::More that you require. For instance, if you want to use `done_testing()` but want your test script to run on Perl 5.10.0, you will need to explicitly require Test::More > 0.88.

Key feature milestones include:

- subtests

  Subtests were released in Test::More 0.94, which came with Perl 5.12.0. Subtests did not implicitly call `done_testing()` until 0.96; the first Perl with that fix was Perl 5.14.0 with 0.98.

- `done_testing()`

  This was released in Test::More 0.88 and first shipped with Perl in 5.10.1 as part of Test::More 0.92.

- `cmp_ok()`

  Although `cmp_ok()` was introduced in 0.40, 0.86 fixed an important bug to make it safe for overloaded objects; the fixed first shipped with Perl in 5.10.1 as part of Test::More 0.92.

- `new_ok()` `note()` and `explain()`

  These were was released in Test::More 0.82, and first shipped with Perl in 5.10.1 as part of Test::More 0.92.

There is a full version history in the Changes file, and the Test::More versions included as core can be found using *Module::CoreList*:

```
$ corelist -a Test::More
```

CAVEATS and NOTES

- UTF-8 / "Wide character in print"

  If you use UTF-8 or other non-ASCII characters with Test::More you might get a "Wide character in print" warning. Using `binmode STDOUT, ":utf8"` will not fix it. *Test::Builder* (which powers Test::More) duplicates STDOUT and STDERR. So any changes to them, including changing their output disciplines, will not be seen by Test::More.

  One work around is to apply encodings to STDOUT and STDERR as early as possible and before Test::More (or any other Test module) loads.

  ```
  use open ':std', ':encoding(UTF-8)';
  use Test::More;
  ```

A more direct work around is to change the filehandles used by *Test::Builder*.

```
my $builder = Test::More->builder;
binmode $builder->output,         ":encoding(UTF-8)";
binmode $builder->failure_output, ":encoding(UTF-8)";
binmode $builder->todo_output,    ":encoding(UTF-8)";
```

- Overloaded objects

  String overloaded objects are compared **as strings** (or in `cmp_ok()`'s case, strings or numbers as appropriate to the comparison op). This prevents Test::More from piercing an object's interface allowing better blackbox testing. So if a function starts returning overloaded objects instead of bare strings your tests won't notice the difference. This is good.

  However, it does mean that functions like `is_deeply()` cannot be used to test the internals of string overloaded objects. In this case I would suggest Test::Deep which contains more flexible testing functions for complex data structures.

- Threads

  Test::More will only be aware of threads if `use threads` has been done *before* Test::More is loaded. This is ok:

  ```
  use threads;
  use Test::More;
  ```

  This may cause problems:

  ```
  use Test::More
  use threads;
  ```

  5.8.1 and above are supported. Anything below that has too many bugs.

HISTORY

This is a case of convergent evolution with Joshua Pritikin's *Test* module. I was largely unaware of its existence when I'd first written my own `ok()` routines. This module exists because I can't figure out how to easily wedge test names into Test's interface (along with a few other problems).

The goal here is to have a testing utility that's simple to learn, quick to use and difficult to trip yourself up with while still providing more flexibility than the existing Test.pm. As such, the names of the most common routines are kept tiny, special cases and magic side-effects are kept to a minimum. WYSIWYG.

SEE ALSO

ALTERNATIVES

Test2::Suite is the most recent and modern set of tools for testing.

Test::Simple if all this confuses you and you just want to write some tests. You can upgrade to Test::More later (it's forward compatible).

Test::Legacy tests written with Test.pm, the original testing module, do not play well with other testing libraries. Test::Legacy emulates the Test.pm interface and does play well with others.

ADDITIONAL LIBRARIES

Test::Differences for more ways to test complex data structures. And it plays well with Test::More.

Test::Class is like xUnit but more perlish.

Test::Deep gives you more powerful complex data structure testing.

Test::Inline shows the idea of embedded testing.

Mock::Quick The ultimate mocking library. Easily spawn objects defined on the fly. Can also override, block, or reimplement packages as needed.

Test::FixtureBuilder Quickly define fixture data for unit tests.

OTHER COMPONENTS

Test::Harness is the test runner and output interpreter for Perl. It's the thing that powers `make test` and where the `prove` utility comes from.

BUNDLES

Test::Most Most commonly needed test functions and features.

ENVIRONMENT VARIABLES

See *Test2::Env* for a list of meaningful environment variables.

Test::Simple

Basic utilities for writing tests.

SYNOPSIS

```
use Test::Simple tests => 1;

ok( $foo eq $bar, 'foo is bar' );
```

DESCRIPTION

** If you are unfamiliar with testing **read Test::Tutorial first!** **

This is an extremely simple, extremely basic module for writing tests suitable for CPAN modules and other pursuits. If you wish to do more complicated testing, use the Test::More module (a drop-in replacement for this one).

The basic unit of Perl testing is the ok. For each thing you want to test your program will print out an "ok" or "not ok" to indicate pass or fail. You do this with the `ok()` function (see below).

The only other constraint is you must pre-declare how many tests you plan to run. This is in case something goes horribly wrong during the test and your test program aborts, or skips a test or whatever. You do this like so:

```
use Test::Simple tests => 23;
```

You must have a plan.

- **ok**

  ```
  ok( $foo eq $bar, $name );
  ok( $foo eq $bar );
  ```

  `ok()` is given an expression (in this case `$foo eq $bar`). If it's true, the test passed. If it's false, it didn't. That's about it.

  `ok()` prints out either "ok" or "not ok" along with a test number (it keeps track of that for you).

  ```
  # This produces "ok 1 - Hell not yet frozen over" (or not ok)
  ok( get_temperature($hell) > 0, 'Hell not yet frozen over' );
  ```

If you provide a $name, that will be printed along with the "ok/not ok" to make it easier to find your test when if fails (just search for the name). It also makes it easier for the next guy to understand what your test is for. It's highly recommended you use test names.

All tests are run in scalar context. So this:

```
ok( @stuff, 'I have some stuff' );
```

will do what you mean (fail if stuff is empty)

Test::Simple will start by printing number of tests run in the form "1..M" (so "1..5" means you're going to run 5 tests). This strange format lets *Test::Harness* know how many tests you plan on running in case something goes horribly wrong.

If all your tests passed, Test::Simple will exit with zero (which is normal). If anything failed it will exit with how many failed. If you run less (or more) tests than you planned, the missing (or extras) will be considered failures. If no tests were ever run Test::Simple will throw a warning and exit with 255. If the test died, even after having successfully completed all its tests, it will still be considered a failure and will exit with 255.

So the exit codes are...

```
0                   all tests successful
255                 test died or all passed but wrong # of tests run
any other number    how many failed (including missing or extras)
```

If you fail more than 254 tests, it will be reported as 254.

This module is by no means trying to be a complete testing system. It's just to get you started. Once you're off the ground its recommended you look at *Test::More*.

EXAMPLE

Here's an example of a simple .t file for the fictional Film module.

```
use Test::Simple tests => 5;

use Film;  # What you're testing.

my $btaste = Film->new({ Title    => 'Bad Taste',
                         Director => 'Peter Jackson',
                         Rating   => 'R',
                         NumExplodingSheep => 1
                       });
ok( defined($btaste) && ref $btaste eq 'Film',     'new() works' );

ok( $btaste->Title      eq 'Bad Taste',     'Title() get'    );
ok( $btaste->Director   eq 'Peter Jackson', 'Director() get' );
ok( $btaste->Rating     eq 'R',             'Rating() get'   );
ok( $btaste->NumExplodingSheep == 1,        'NumExplodingSheep() get
↪' );
```

It will produce output like this:

```
1..5
ok 1 - new() works
ok 2 - Title() get
ok 3 - Director() get
not ok 4 - Rating() get
#   Failed test 'Rating() get'
#   in t/film.t at line 14.
ok 5 - NumExplodingSheep() get
# Looks like you failed 1 tests of 5
```

Indicating the Film::Rating() method is broken.

CAVEATS

Test::Simple will only report a maximum of 254 failures in its exit code. If this is a problem, you probably have a huge test script. Split it into multiple files. (Otherwise blame the Unix folks for using an unsigned short integer as the exit status).

Because VMS's exit codes are much, much different than the rest of the universe, and perl does horrible mangling to them that gets in my way, it works like this on VMS.

```
0      SS$_NORMAL        all tests successful
4      SS$_ABORT         something went wrong
```

Unfortunately, I can't differentiate any further.

NOTES

Test::Simple is **explicitly** tested all the way back to perl 5.6.0.

Test::Simple is thread-safe in perl 5.8.1 and up.

HISTORY

This module was conceived while talking with Tony Bowden in his kitchen one night about the problems I was having writing some really complicated feature into the new Testing module. He observed that the main problem is not dealing with these edge cases but that people hate to write tests **at all**. What was needed was a dead simple module that took all the hard work out of testing and was really, really easy to learn. Paul Johnson simultaneously had this idea (unfortunately, he wasn't in Tony's kitchen). This is it.

SEE ALSO

- *Test::More*

  More testing functions! Once you outgrow Test::Simple, look at *Test::More*. Test::Simple is 100% forward compatible with *Test::More* (i.e. you can just use *Test::More* instead of Test::Simple in your programs and things will still work).

Look in *Test::More*'s SEE ALSO for more testing modules.

Test::Tester

Ease testing test modules built with Test::Builder

SYNOPSIS

```
use Test::Tester tests => 6;

use Test::MyStyle;

check_test(
  sub {
    is_mystyle_eq("this", "that", "not eq");
  },
  {
    ok => 0, # expect this to fail
    name => "not eq",
    diag => "Expected: 'this'\nGot: 'that'",
  }
);
```

or

```
use Test::Tester tests => 6;

use Test::MyStyle;

check_test(
  sub {
    is_mystyle_qr("this", "that", "not matching");
  },
  {
    ok => 0, # expect this to fail
```

(continues on next page)

(continued from previous page)

```
    name => "not matching",
    diag => qr/Expected: 'this'\s+Got: 'that'/,
  }
);
```

or

```
use Test::Tester;

use Test::More tests => 3;
use Test::MyStyle;

my ($premature, @results) = run_tests(
  sub {
    is_database_alive("dbname");
  }
);

# now use Test::More::like to check the diagnostic output

like($results[0]->{diag}, "/^Database ping took \\d+ seconds$"/,
 ↪"diag");
```

DESCRIPTION

If you have written a test module based on Test::Builder then Test::Tester allows you to test it with the minimum of effort.

HOW TO USE (THE EASY WAY)

From version 0.08 Test::Tester no longer requires you to included anything special in your test modules. All you need to do is

```
use Test::Tester;
```

in your test script **before** any other Test::Builder based modules and away you go.

Other modules based on Test::Builder can be used to help with the testing. In fact you can even use functions from your module to test other functions from the same module (while this is possible it is probably not a good idea, if your module has bugs, then using it to test itself may give the wrong answers).

The easiest way to test is to do something like

```
check_test(
  sub { is_mystyle_eq("this", "that", "not eq") },
  {
    ok => 0, # we expect the test to fail
    name => "not eq",
    diag => "Expected: 'this'\nGot: 'that'",
```

(continues on next page)

(continued from previous page)

```
  }
);
```

this will execute the is_mystyle_eq test, capturing its results and checking that they are what was expected.

You may need to examine the test results in a more flexible way, for example, the diagnostic output may be quite long or complex or it may involve something that you cannot predict in advance like a timestamp. In this case you can get direct access to the test results:

```
my ($premature, @results) = run_tests(
  sub {
    is_database_alive("dbname");
  }
);

like($result[0]->{diag}, "/^Database ping took \\d+ seconds$"/,
 ↪"diag");
```

or

```
check_test(
  sub { is_mystyle_qr("this", "that", "not matching") },
  {
    ok => 0, # we expect the test to fail
    name => "not matching",
    diag => qr/Expected: 'this'\s+Got: 'that'/,
  }
);
```

We cannot predict how long the database ping will take so we use Test::More's like() test to check that the diagnostic string is of the right form.

HOW TO USE (THE HARD WAY)

This is here for backwards compatibility only

Make your module use the Test::Tester::Capture object instead of the Test::Builder one. How to do this depends on your module but assuming that your module holds the Test::Builder object in $Test and that all your test routines access it through $Test then providing a function something like this

```
sub set_builder
{
  $Test = shift;
}
```

should allow your test scripts to do

```
Test::YourModule::set_builder(Test::Tester->capture);
```

and after that any tests inside your module will captured.

TEST RESULTS

The result of each test is captured in a hash. These hashes are the same as the hashes returned by Test::Builder->details but with a couple of extra fields.

These fields are documented in *Test::Builder* in the details() function

- ok

  Did the test pass?

- actual_ok

  Did the test really pass? That is, did the pass come from Test::Builder->ok() or did it pass because it was a TODO test?

- name

  The name supplied for the test.

- type

  What kind of test? Possibilities include, skip, todo etc. See *Test::Builder* for more details.

- reason

  The reason for the skip, todo etc. See *Test::Builder* for more details.

These fields are exclusive to Test::Tester.

- diag

  Any diagnostics that were output for the test. This only includes diagnostics output **after** the test result is declared.

  Note that Test::Builder ensures that any diagnostics end in a \n and it in earlier versions of Test::Tester it was essential that you have the final \n in your expected diagnostics. From version 0.10 onward, Test::Tester will add the \n if you forgot it. It will not add a \n if you are expecting no diagnostics. See below for help tracking down hard to find space and tab related problems.

- depth

  This allows you to check that your test module is setting the correct value for $Test::Builder::Level and thus giving the correct file and line number when a test fails. It is calculated by looking at caller() and $Test::Builder::Level. It should count how many subroutines there are before jumping into the function you are testing. So for example in

  ```
  run_tests( sub { my_test_function("a", "b") } );
  ```

  the depth should be 1 and in

  ```
  sub deeper { my_test_function("a", "b") }

  run_tests(sub { deeper() });
  ```

depth should be 2, that is 1 for the sub {} and one for deeper(). This might seem a little complex but if your tests look like the simple examples in this doc then you don't need to worry as the depth will always be 1 and that's what Test::Tester expects by default.

Note: if you do not specify a value for depth in check_test() then it automatically compares it against 1, if you really want to skip the depth test then pass in undef.

Note: depth will not be correctly calculated for tests that run from a signal handler or an END block or anywhere else that hides the call stack.

Some of Test::Tester's functions return arrays of these hashes, just like Test::Builder->details. That is, the hash for the first test will be array element 1 (not 0). Element 0 will not be a hash it will be a string which contains any diagnostic output that came before the first test. This should usually be empty, if it's not, it means something output diagnostics before any test results showed up.

SPACES AND TABS

Appearances can be deceptive, especially when it comes to emptiness. If you are scratching your head trying to work out why Test::Tester is saying that your diagnostics are wrong when they look perfectly right then the answer is probably whitespace. From version 0.10 on, Test::Tester surrounds the expected and got diag values with single quotes to make it easier to spot trailing whitespace. So in this example

```
# Got diag (5 bytes):
# 'abcd '
# Expected diag (4 bytes):
# 'abcd'
```

it is quite clear that there is a space at the end of the first string. Another way to solve this problem is to use colour and inverse video on an ANSI terminal, see below COLOUR below if you want this.

Unfortunately this is sometimes not enough, neither colour nor quotes will help you with problems involving tabs, other non-printing characters and certain kinds of problems inherent in Unicode. To deal with this, you can switch Test::Tester into a mode whereby all "tricky" characters are shown as \{xx}. Tricky characters are those with ASCII code less than 33 or higher than 126. This makes the output more difficult to read but much easier to find subtle differences between strings. To turn on this mode either call `show_space()` in your test script or set the `TESTTESTERSPACE` environment variable to be a true value. The example above would then look like

```
# Got diag (5 bytes):
# abcd\x{20}
# Expected diag (4 bytes):
# abcd
```

COLOUR

If you prefer to use colour as a means of finding tricky whitespace characters then you can set the TESTTESTCOLOUR environment variable to a comma separated pair of colours, the first for the foreground, the second for the background. For example "white,red" will print white text on a red background. This requires the Term::ANSIColor module. You can specify any colour that would be acceptable to the Term::ANSIColor::color function.

If you spell colour differently, that's no problem. The TESTTESTERCOLOR variable also works (if both are set then the British spelling wins out).

EXPORTED FUNCTIONS

($premature, @results) = run_tests(\&test_sub)

\&test_sub is a reference to a subroutine.

run_tests runs the subroutine in $test_sub and captures the results of any tests inside it. You can run more than 1 test inside this subroutine if you like.

$premature is a string containing any diagnostic output from before the first test.

@results is an array of test result hashes.

cmp_result(\%result, \%expect, $name)

\%result is a ref to a test result hash.

\%expect is a ref to a hash of expected values for the test result.

cmp_result compares the result with the expected values. If any differences are found it outputs diagnostics. You may leave out any field from the expected result and cmp_result will not do the comparison of that field.

cmp_results(\@results, \@expects, $name)

\@results is a ref to an array of test results.

\@expects is a ref to an array of hash refs.

cmp_results checks that the results match the expected results and if any differences are found it outputs diagnostics. It first checks that the number of elements in \@results and \@expects is the same. Then it goes through each result checking it against the expected result as in cmp_result() above.

($premature, @results) = check_tests(\&test_sub, \@expects, $name)

\&test_sub is a reference to a subroutine.

\@expect is a ref to an array of hash refs which are expected test results.

check_tests combines run_tests and cmp_tests into a single call. It also checks if the tests died at any stage.

It returns the same values as run_tests, so you can further examine the test results if you need to.

($premature, @results) = check_test(\&test_sub, \%expect, $name)

\&test_sub is a reference to a subroutine.

\%expect is a ref to an hash of expected values for the test result.

check_test is a wrapper around check_tests. It combines run_tests and cmp_tests into a single call, checking if the test died. It assumes that only a single test is run inside \&test_sub and include a test to make sure this is true.

It returns the same values as run_tests, so you can further examine the test results if you need to.

show_space()

Turn on the escaping of characters as described in the SPACES AND TABS section.

HOW IT WORKS

Normally, a test module (let's call it Test:MyStyle) calls Test::Builder->new to get the Test::Builder object. Test::MyStyle calls methods on this object to record information about test results. When Test::Tester is loaded, it replaces Test::Builder's new() method with one which returns a Test::Tester::Delegate object. Most of the time this object behaves as the real Test::Builder object. Any methods that are called are delegated to the real Test::Builder object so everything works perfectly. However once we go into test mode, the method calls are no longer passed to the real Test::Builder object, instead they go to the Test::Tester::Capture object. This object seems exactly like the real Test::Builder object, except, instead of outputting test results and diagnostics, it just records all the information for later analysis.

CAVEATS

Support for calling Test::Builder->note is minimal. It's implemented as an empty stub, so modules that use it will not crash but the calls are not recorded for testing purposes like the others. Patches welcome.

SEE ALSO

Test::Builder the source of testing goodness. *Test::Builder::Tester* for an alternative approach to the problem tackled by Test::Tester - captures the strings output by Test::Builder. This means you cannot get separate access to the individual pieces of information and you must predict **exactly** what your test will output.

Test::Tester::Capture

Help testing test modules built with Test::Builder

DESCRIPTION

This is a subclass of Test::Builder that overrides many of the methods so that they don't output anything. It also keeps track of its own set of test results so that you can use Test::Builder based modules to perform tests on other Test::Builder based modules.

AUTHOR

Most of the code here was lifted straight from Test::Builder and then had chunks removed by Fergal Daly fergal@esatclear.ie.

Test::use

Namespace containing the following modules:

- `Test::use::ok` - Alternative to Test::More::use_ok

Test::use::ok

Alternative to Test::More::use_ok

SYNOPSIS

```
use ok 'Some::Module';
```

DESCRIPTION

According to the **Test::More** documentation, it is recommended to run `use_ok()` inside a `BEGIN` block, so functions are exported at compile-time and prototypes are properly honored.

That is, instead of writing this:

```
use_ok( 'Some::Module' );
use_ok( 'Other::Module' );
```

One should write this:

```
BEGIN { use_ok( 'Some::Module' ); }
BEGIN { use_ok( 'Other::Module' ); }
```

However, people often either forget to add `BEGIN`, or mistakenly group `use_ok` with other tests in a single `BEGIN` block, which can create subtle differences in execution order.

With this module, simply change all `use_ok` in test scripts to `use ok`, and they will be executed at `BEGIN` time. The explicit space after `use` makes it clear that this is a single compile-time action.

5.2.102 Test2

Framework for writing test tools that all work together.

DESCRIPTION

Test2 is a new testing framework produced by forking *Test::Builder*, completely refactoring it, adding many new features and capabilities.

WHAT IS NEW?

- Easier to test new testing tools.

  From the beginning Test2 was built with introspection capabilities. With Test::Builder it was difficult at best to capture test tool output for verification. Test2 Makes it easy with `Test2::API::intercept()`.

- Better diagnostics capabilities.

  Test2 uses an *Test2::API::Context* object to track filename, line number, and tool details. This object greatly simplifies tracking for where errors should be reported.

- Event driven.

  Test2 based tools produce events which get passed through a processing system before being output by a formatter. This event system allows for rich plugin and extension support.

- More complete API.

  Test::Builder only provided a handful of methods for generating lines of TAP. Test2 took inventory of everything people were doing with Test::Builder that required hacking it up. Test2 made public API functions for nearly all the desired functionality people didn't previously have.

- Support for output other than TAP.

  Test::Builder assumed everything would end up as TAP. Test2 makes no such assumption. Test2 provides ways for you to specify alternative and custom formatters.

- Subtest implementation is more sane.

  The Test::Builder implementation of subtests was certifiably insane. Test2 uses a stacked event hub system that greatly improves how subtests are implemented.

- Support for threading/forking.

  Test2 support for forking and threading can be turned on using *Test2::IPC*. Once turned on threading and forking operate sanely and work as one would expect.

GETTING STARTED

If you are interested in writing tests using new tools then you should look at *Test2::Suite*. *Test2::Suite* is a separate cpan distribution that contains many tools implemented on Test2.

If you are interested in writing new tools you should take a look at *Test2::API* first.

NAMESPACE LAYOUT

This describes the namespace layout for the Test2 ecosystem. Not all the namespaces listed here are part of the Test2 distribution, some are implemented in *Test2::Suite*.

Test2::Tools::

This namespace is for sets of tools. Modules in this namespace should export tools like `ok()` and `is()`. Most things written for Test2 should go here. Modules in this namespace **MUST NOT** export subs from other tools. See the "Test2::Bundle::" namespace if you want to do that.

Test2::Plugin::

This namespace is for plugins. Plugins are modules that change or enhance the behavior of Test2. An example of a plugin is a module that sets the encoding to utf8 globally. Another example is a module that causes a bail-out event after the first test failure.

Test2::Bundle::

This namespace is for bundles of tools and plugins. Loading one of these may load multiple tools and plugins. Modules in this namespace should not implement tools directly. In general modules in this namespace should load tools and plugins, then re-export things into the consumers namespace.

Test2::Require::

This namespace is for modules that cause a test to be skipped when conditions do not allow it to run. Examples would be modules that skip the test on older perls, or when non-essential modules have not been installed.

Test2::Formatter::

Formatters live under this namespace. *Test2::Formatter::TAP* is the only formatter currently. It is acceptable for third party distributions to create new formatters under this namespace.

Test2::Event::

Events live under this namespace. It is considered acceptable for third party distributions to add new event types in this namespace.

Test2::Hub::

Hub subclasses (and some hub utility objects) live under this namespace. It is perfectly reasonable for third party distributions to add new hub subclasses in this namespace.

Test2::IPC::

The IPC subsystem lives in this namespace. There are not many good reasons to add anything to this namespace, with exception of IPC drivers.

Test2::IPC::Driver::

IPC drivers live in this namespace. It is fine to create new IPC drivers and to put them in this namespace.

Test2::Util::

This namespace is for general utilities used by testing tools. Please be considerate when adding new modules to this namespace.

Test2::API::

This is for Test2 API and related packages.

Test2::

The Test2:: namespace is intended for extensions and frameworks. Tools, Plugins, etc should not go directly into this namespace. However extensions that are used to build tools and plugins may go here.

In short: If the module exports anything that should be run directly by a test script it should probably NOT go directly into `Test2::XXX`.

SEE ALSO

Test2::API - Primary API functions.

Test2::API::Context - Detailed documentation of the context object.

Test2::IPC - The IPC system used for threading/fork support.

Test2::Formatter - Formatters such as TAP live here.

Test2::Event - Events live in this namespace.

Test2::Hub - All events eventually funnel through a hub. Custom hubs are how `intercept()` and `run_subtest()` are implemented.

CONTACTING US

Many Test2 developers and users lurk on irc://irc.perl.org/#perl-qa and irc://irc.perl.org/#toolchain. We also have a slack team that can be joined by anyone with an `@cpan.org` email address https://perl-test2.slack.com/ If you do not have an `@cpan.org` email you can ask for a slack invite by emailing Chad Granum exodist@cpan.org.
